Subject headings pit cells; hepatic natural killer cells; large granular lymphocytes

INTRODUCTION

Natural killer (NK) cells are functionally defined by their ability to kill certain tumor cells and virus-infected cells without prior sensitization^[1]. NK cells comprise about 10% to 15% of lymphocytes in the peripheral blood and most of these cells in human and rat have the morphology of large granular lymphocytes (LGL)^[2]. However, recent studies have demonstrated that small agranular lymphocytes, lacking CD3 expression, have cytolytic activity comparable to NK cells^[3]. These variations may be related to the stage of NK cell differentiation or heterogeneity^[4]. Moreover, some cytotoxic T lymphocytes (CTL) also display LGL characteristics^[4]. Besides NK cells in peripheral blood, NK cells are also found in tissue compartments, such as the spleen, lung, intestine, lymph nodes, bone marrow and liver^[4]. NK cells in the liver, also called pit cells^[5], constitute a unique, resident NK population in the liver sinusoids. Their immunophenotypical, morphological and functional characteristics are different from blood NK cells^[6]. Presently, several

names, such as pit cells, hepatic NK cells and LGL are used to describe pit cells, referring to different aspects of their morphology or function^[6]. We prefer to use the first-given name of pit cells for these cells in the liver, because it is not related to the ever varying levels of function and morphology or a person (like Kupffer cells)^[7]. In addition, liver-associated lymphocytes (LAL), in some instances, are used to describe the total population of lymphoid cells in the liver^[8,9]. However, LAL contain about 30% T lymphocytes, 3% B lymphocytes besides 43% pit cells in a human liver washout^[9]. Rat liver washouts contain 43% T lymphocytes, 16% of B lymphocytes, 3.3% of monocytes and 26% pit cells^[10].

The present review will discuss the biological relevance of pit cells with emphasis on rat liver.

IDENTIFICATION, STRUCTURE AND TISSUE DISTRIBUTION OF PIT CELLS

Pit cells were firstly described in 1976 by Wisse *et al*^[5]. The name pit cell was introduced because of the characteristic cytoplasmic granules, which in Dutch language are called pit, resembling the pits in a grape^[5]. The hypothesis that pit cells might possess NK activity was suggested by Kaneda *et al*^[11], because of their morphologic resemblance to LGL. The development of a method for the isolation and purification of pit cells from rat liver and the evidence of pit cells possessing spontaneous cytotoxicity against NK sensitive YAC-1 lymphoma cells confirmed these cells to be hepatic NK cells^[12,13].

Pit cells exist in the liver sinusoids and often adhere to endothelial cells (Ec), although they incidentally contact Kupffer cells (Kc) (Figure 1). They face the blood directly. Pseudopodia of pit cells can penetrate the fenestrae of the Ec, and enter the space of Disse and can directly contact the microvilli of hepatocytes^[5,14]. Their appearance in the space of Disse is not a common feature^[15]. By morphological investigation, the frequency of pit cells in liver tissue is about an average of 1 pit cell per 10 Kupffer cells. The number of pit cells, in untreated rats, is therefore estimated to be $(1.4-2) \times 10^6$ cells per gram liver weight^[12]. By immunohistochemistry, using mAb 3.2.3 against NKR-P1A (a specific marker of NK cells), the

number of pit cells in frozen sections of rat liver is about 13.7 per mm² [16]. After intravenous injection of biological response modifiers (BRM), the number of pit cells increases 4-fold to 6-fold in rat liver treated with zymosan^[17] and 43-fold with interleukin-2 (IL-2)^[18]. The surplus of pit cells is considered to originate from local proliferation and from the bone marrow^[17,18]. Pit cells were found to be more numerous in the periportal than in the pericentral region of the liver lobule^[11,16].

Pit cells have essentially the same morphology as NK cells from blood and other organs, *i.e.* LGL (Figure 1). LGL morphology is characterized by a relatively large size, the presence of granules in the cytoplasm, a pronounced asymmetry of the cell and an indented or kidney shaped nucleus of high density^[10]. Pit cells in the rat are about 7µm in diameter and vary in shape, while possessing well developed pseudopodia. They show a pronounced polarity with an eccentric nucleus and most organelles lying at one side of the nucleus.

The most conspicuous organelles are the electron-dense granules. These granules have several characteristics. They are azurophilic, therefore, Giemsa staining of a cell smear or cytopspin preparation reveals the presence of the granules in pit cells with light microscopic examination. As measured by electron microscopy, the granules differ in size between different pit cell subpopulations (LD and HD pit cells, see next page), but within one cell type the granules are very homogeneous with respect to size, shape and electronic density^[19]. The granules are membrane bound and range in size between 0.2µm in LD pit cells and 0.5µm in LAK cells. These granules contain a number of lysosomal enzymes, such as acid phosphatase^[12,20]. Although perforin and granzymes, which have been isolated from NK cell granules^[21,22], are not yet been identified in pit cell granules, it is believed by analogy that these molecules are present in the granules of pit cells.

Rod-cored vesicles are small inclusions, ranging in diameter from 0.17 µm to 0.2 µm, and are exclusively found in LGL^[11]. They contain a straight rod structure which is 30 nm-50 nm in length, that bridges the entire diameter of the vesicle^[11,20]. Rod-cored vesicles derive from and distribute preferentially around the Golgi apparatus. Possibly rod-cored vesicles may also contain cytotoxic factors functioning in natural cytotoxicity^[15].

Pit cells also exist in human and mouse liver, but the identification of pit cells in human and mouse liver is more difficult than in rat because they contain a lower number and smaller size of the typical dense granules and very few rod-cored vesicles^[9,23,24]. On the other hand, 5% to 25% of human pit cells contain 'parallel tubular arrays' (PTA), that were also reported in human blood NK

cells and considered as a characteristic of these cells^[6,23].

SURFACE PHENOTYPE OF PIT CELLS

Extensive phenotypic analysis has shown that no unique NK cell marker has been identified yet, but expression of a set of differentiation antigens in the absence of antigen-specific receptors of T and B lymphocytes serves to identify NK cells. NKR-P1 was first identified in the rat^[25] and has now been shown to be expressed also by mouse and human NK cells^[26,27]. NKR-P1 is a type II membrane glycoprotein of the C-type lectin superfamily^[28]. The NKR-P1 genes are located on mouse chromosome 6^[29], human chromosome 12 p 12-p13^[27], and rat chromosome 4 in a region designated as the 'NK gene complex' (NKC)^[28]. NKR-P1 antigen is present on 94% of rat LGL and serves as a triggering structure on these cells^[25]. NKR-P1 is considered to be a useful marker for NK cell identification^[25]. However, a subset of T lymphocytes and polymorphonuclear leukocytes also express NKR-P1^[25,27]. CD56 and CD16 are expressed, either alone or in combination, on the majority of human NK cells and are most extensively used as human NK cell 'markers' for clinical and basic research purposes^[2]. Other surface antigens expressed on NK cells are: CD2, CD8, CD11a-c, CD18, CD45, CD54, CD56, CD58 and CD69^[2,4,30,31].

Most surface antigens found on rat pit cells are similar to that found on spleen or peripheral blood NK cells (Table 1)^[13,16,32]. All LGLs from a rat liver washout, in preparations for light and electron microscopy, were found to express NKR-P1^[16] (Figure 2) as recognized by using the monoclonal antibody (mAb) 3.2.3^[25]. CD11a is present on 90% of rat pit cells, which is different from rat peripheral blood NK cells (54%)^[32]. Approximately 90% of rat pit cells express CD18, 35% express CD54 and 80% express CD2^[32]. Asialo-GM1, which is expressed by all rat blood NK cells^[19], is present on 36% of LD pit cells and 70% of HD pit cells^[13]. CD8, a marker of NK cells and cytotoxic T lymphocytes^[2], is present on all rat pit cells^[13]. However, the composition of CD8 in NK cells and T lymphocytes is different. Most CD8⁺ NK cells express CD8α/CD8α homodimers rather than the CD8α/CD8β heterodimers prevalent on cytotoxic T cells^[3,31]. In addition, rat pit cells do not express T cell receptor and CD5 antigen (a pan T cell marker)^[13,15].

LAL from human liver contain about 35% CD56⁺ cells, in which three subsets are found: ① CD3⁺/CD16⁻, ② CD3⁻/CD16⁻, ③ CD3⁻/CD16⁺^[8]. Moreover, all the CD56⁺ LAL express CD11a and CD18, and partly express CD2, CD11b, CD11c, CD54 and CD58^[8,34,35].

Table 1 Characteristics of LD, HD pit cells and peripheral blood NK cells

Item	LD pit cell	HD pit cell	Blood NK cell
Morphology*			
Size(μm^2)	27.7	24.5	24.8
Rod-cored vesicles per cell	1.0	0.8	0.5
Microvilli per cell	5.2	5.9	7.1
Size of granules (μm^2)	Smaller(0.09)	Intermediate(0.1)	Larger(0.14)
Number of granules per cell	Higher(50)	Intermediate(20)	Lower(10)
Surface antigens [†]			
CD2	80	80	80
CD8	100	100	40
CD11a	90	90	54
CD18	90	90	90
CD54	35	35	35
Asialo-GM1	36	70	100
NKR-P1	95	95	94
Functional features			
NK activity	High	Intermediate	Low
P815 cell killing	Yes	No	No

*Data from reference 19.

[†]Approximate % of cells that express antigen; data summarized from references 2, 13, 16, 19, 25, and 32.

Figure 1 Transmission electron micrograph of a pit cell in a rat hepatic sinusoidal lumen (L). The pit cell shows polarity with an eccentric nucleus. The cytoplasm is abundant and contains characteristic electron-dense granules and other organelles lying mainly on one side of the nucleus. The cell contacts an endothelial cell (E) and a portion of a Kupffer cell (K) with a positive peroxidase reaction product in the rough endoplasmic reticulum. Bar = 1 μm . (from *Hepatology*, 1988;8: 46-52, with permission)

Figure 2 Immuno-transmission electron micrograph showing a 3.2.3 positive LGL (pit cell) (arrowhead) and a 3.2.3 negative agranular cell. The 3.2.3⁺ pit cell shows characteristic electron-dense granules in the cytoplasm and immunoperoxidase reaction product on the surface. Bar = 1 μm . (from *Hepatology*, 1995;21: 1690-1694, with permission)

ISOLATION AND PURIFICATION OF PIT CELLS

Our isolation method for rat pit cells is based on a washout technique^[12] followed by purification, based on the magnetic negative-selection of cells using mAbs against surface antigens and receptors found on T and B cells^[6,36]. Since pit cells are apparently not heavily anchored in the liver sinusoids, the cells could be washed out by this non-enzymatic, high-pressure (50cm water) perfusion of the liver via the portal vein with phosphate-buffered saline supplemented with 0.1% EDTA^[12]. The washout was collected from the vena cava. The erythrocytes, granulocytes and cell debris in the washout were removed by Ficoll-Paque gradient centrifugation. The mononuclear cells recovered from the interface of Ficoll-Paque gradient contained T cells, pit cells, B cells, monocytes, and a few Ec and Kc. Adherent monocytes and B cells in this population could be selectively removed in a nylon wool column^[12]. Pit cells were further purified by magnetic cell sorting^[36]. With this system, a highly purified population of pit cells was obtained by negative selection, *i.e.* by elimination of remaining monocytes, T and B cells using specific antibodies and immunomagnetic beads. By this method, we obtained pit cells with a purity of more than 90% and a viability of more than 95% (Figure 3). Moreover, this non-enzymatic method does not destroy cell surface molecules.

Alternatively, pit cells could be isolated by enzymatic methods^[5]. However, this method is time consuming, labor-intensive and only provides pit cells with 30% purity and 90% viability^[6,12].

HETEROGENEITY AND ORIGIN OF PIT CELLS

A considerable set of data indicates that rat pit cells constitute a heterogeneous population. Based on the cell density, pit cells can be separated into a low density (LD) and high density (HD) fraction by 45% iso-osmotic Percoll gradient centrifugation^[19]. These two cell populations have been shown to differ immunophenotypically, morphologically and functionally from each other and from blood LGL (Table 1)^[19,37]. LD pit cells (Figure 4A) contain more rod-cored vesicles and more, but smaller granules than blood NK cells (Figure 4B)^[19,37]. The number of rod-cored vesicles and granule composition (number and size) of HD pit cells are intermediate between LD pit cells and blood NK cells^[19,37]. Immunophenotypically, almost all blood NK cells are asialo-GM1 positive, and 70% of HD pit cells are strongly positive, whereas only 36% of LD pit cells are weakly positive^[19]. Furthermore, functional differences have been observed among these three populations. The LD pit cells are five to eight times more cytotoxic against YAC-1 cells and

colon carcinoma cells than blood NK cells^[37]. The HD pit cells have intermediate cytotoxic activity between LD pit cells and blood NK cells^[37]. In addition, LD pit cells are able to lyse LAK-sensitive P815 mastocytoma targets, which are resistant to normal blood NK cells and hepatic HD pit cells^[37].

Pit cells are considered to originate from blood NK cells^[38,39]. Several evidences support the concept that blood NK cells immigrate into the hepatic sinusoids to become HD pit cells, which further differentiate into LD pit cells. Importantly, the characteristics and functions of HD pit cells are intermediate between blood NK cells and LD pit cells^[19]. Kinetic experiments with sublethal total body irradiation (700cGy) showed that blood NK cells and HD pit cells were depleted in about one week after irradiation, whereas LD pit cells totally disappeared at two weeks after irradiation^[39]. Shielding of the liver gave similar results and splenectomy did not affect pit cell number^[39]. By using intravenous anti-asialo-GM1 antiserum injection, blood NK and HD pit cells totally disappeared within one week of treatment, whereas LD pit cells disappeared from the liver one week later^[39]. The direct evidence for LD pit cells originating from asialo-GM1 positive precursors (blood NK and HD pit cells) was given by the adoptive transfer of fluorescent-labeled HD pit cells into syngeneic rats^[39]. After three days, 5% of labeled cells were recovered in the LD fraction and these cells displayed typical LD pit cell morphology^[39]. These observations also indicate that the life span of pit cells in the liver is about two weeks^[6,39].

The mechanism behind the migration of blood NK cells to the liver sinusoids is not fully understood. Several adhesion molecules were found to be involved in the process^[32]. Rat blood NK and pit cells express LFA-1 (CD11a/CD18) and CD2 (LFA-2) adhesion molecules^[32]. Their ligands, CD54 (ICAM-1) and CD58 (LFA-3) were found to be present on liver Ec^[40]. After intravenous injection of antibodies against CD2, CD11a and CD18 into rats, the number of pit cells in the liver decreased significantly, indicating that the interactions of LFA-1/CD54 and CD2/CD58 are involved in the recruitment of pit cells in the liver^[32].

Once marginated in the liver sinusoids, blood NK precursors further differentiate into HD pit cells, then into LD pit cells. The microenvironment of the liver sinusoid is believed to be responsible for this differentiation process^[41]. Vanderkerken *et al* found that Kc were selectively eliminated 3 days after intravenous injection of liposomes containing the cytotoxic drug dichloromethylene

diphosphonate^[41]. The number of HD pit cells declined 3 days after the injection. Conversely, the LD pit cell population showed no change in number after 3 days, but a decline of about 80% was seen 7 days after the injection^[41]. These data indicate that pit cells constitute a Kupffer cell-dependent population and that Kc play an essential role in the differentiation of pit cells in the liver. However, it remains unclear what factor(s) secreted by Kc is responsible for this differentiation. On the other hand, other conditions present in the liver microenvironment, *i.e.* Ec and their secreted factors, may work synergically with Kc to contribute to pit cell differentiation, since cocultivation of HD pit cells with Kc failed to induce the full differentiation of HD into LD pit cells^[41].

FUNCTIONS OF PIT CELLS

NK cells were initially defined as lymphoid cells capable of mediating spontaneous killing of target cells, including tumor and virus-infected cells^[1]. Such NK cytotoxic activity is mediated without prior sensitization and any obvious stimulation or activation^[1]. In addition to this natural spontaneous pathway of tumor killing, NK cells can mediate antibody-dependent cellular cytotoxicity (ADCC) by a mechanism involving CD16, an IgG Fc receptor^[42]. Most human and mouse NK cells express CD16^[2]. Rat NK cells contain genes with a high level of homology to human and murine Fc receptors^[43] and are able to display ADCC^[44]. Unfortunately, no antibodies against rat CD16 are available yet.

Although the cytotoxic function of NK cells is spontaneous, it can be significantly augmented by several cytokines^[2]. One of these, IL-2, has been shown to play a central role in the regulation of NK cells, including augmenting NK cell cytotoxicity, expanding NK cell antitumor spectrum and inducing NK cell proliferation^[4].

NK cytotoxic (*i.e.* cytolytic) activity is usually determined by measuring the release of radiolabeled chromium from target cells after been exposed to effector cells^[2]. A new assay using flow cytometry to assess NK cell activity, in which various dyes are used to differentiate viable from dead target cells, has recently been described^[45]. Initial studies have shown that this method is quick, reliable, and correlates well with the standard ⁵¹Cr release assay^[45].

Besides the cytotoxic function, NK cells can produce various cytokines^[46], regulate the growth of hemopoietic tissues and bone marrow transplants^[47], and participate in the resistance to microbial pathogens^[2].

Figure 3 Light micrograph of an isolated and purified pit cell population in a May-Grünwald-Giemsa-stained cytospin. The cells contain cytoplasmic granules, which can be used to recognize and count the number of pit cells in freshly isolated liver-associated lymphocyte population. Bar = 5 μ m.

Figure 4 Transmission electron micrographs of a typical LD pit cell and a blood NK cell (B).

(A) The main morphological characteristic of LD pit cells, compared to HD cells and blood NK cells, is the presence of numerous small cytoplasmic granules.

(B) Note the few, but large granules in blood NK cell. Bar = 1 μ m. (from *Hepatology*, 1990;12:70-75, with permission)

Most investigations on pit cell functions focus on cytotoxic activity. Rat pit cells have high spontaneous cytotoxic activity against various tumor cell lines, such as YAC-1, P815, CC531s, DHD-K12, L929, 3LL, and 3LL-R^[10]. Compared with blood NK cells, pit cells are four to eight times more cytotoxic against YAC-1 and CC531s cells, and are able to kill the NK-resistant but lymphokine activated killer (LAK)-sensitive P815 cells (Figure 5)^[19,48]. This evidence seems to support the idea that pit cells become activated once they become liver residents. However, it is not understood yet what kind(s) of factor(s) is (are) responsible for the activation of pit cells in the liver, although it has been shown that pit cells are dependent on the presence of a healthy Kc population^[41]. Furthermore, NK activity in the liver could be augmented by BRM, like *Propionibacterium acnes* or maleic anhydride divinyl ether^[24]. Interestingly, an increase in function seems to coincide with a large increase in the number of LGL^[17,24]. IL-2 treatment results in a dramatic accumulation of pit cells in the hepatic sinusoids *in vivo*^[18], induces HD cell proliferation and augments liver HD pit cell cytotoxic activity *in vitro*^[49]. In contrast, IL-2 treatment does not induce liver LD pit cell proliferation^[49].

MOLECULAR MECHANISMS IN NK CELL-MEDIATED CYTOTOXICITY

It is believed that the cytotoxic function of NK cells is mediated by multiple pathways, and each pathway, in principle, encompasses a cascade of events, including recognition of target cells, binding of effector cells to target cells (conjugation), activation of effector cells, delivery of the lethal signal to target cells, and effector cell detachment and recycling^[2,4,50]. Although the precise mechanisms of individual steps in this process have not been fully elucidated, significant progress has been made recently in identifying a number of molecules participating in NK cell-mediated cytotoxicity.

CONJUGATION

The prerequisite of NK cell killing is the binding of one or more effector cells to a target cell, that is, conjugation^[6]. Several adhesion molecules on the NK cell, such as CD2, CD28 and LFA-1, and on the target cell, such as CD58, B7 and CD54, participate in this process, and some of them may also possess co-stimulatory or even triggering capacity in the cytotoxic cascade^[28,50-52].

CD2 is an adhesion molecule of the immunoglobulin (Ig) superfamily expressed on T cells and NK cells^[53]. Approximately 80% of rat pit

cells express CD2^[32]. Although CD2 is a well-known activation structure on T cells^[53], mAbs against CD2, depending on experimental conditions, either induce^[54,55] or inhibit NK activity^[31,56]. Anti-CD2 mAb had no effect on the binding of pit cells to rat colon carcinoma cells (CC531s), or on the cytotoxicity against CC531s^[57]. However, the anti-CD2 mAb enhanced the cytolytic function in rat pit cells against FcγR⁺ P815 target cells^[57]. The ligand of CD2 is another adhesion molecule, CD58 (LFA-3) that is widely expressed on various cell types^[53]. Transfection of CD58 into murine cell lines increased the lysis of these targets by some human CD2⁺ NK cell clones^[58]. However, expression of CD58 alone is insufficient to confer cells sensitive to NK cell-mediated lysis, indicating that CD2 may serve as a costimulatory receptor that augments, but not initiates, the primary activation of NK cells^[58].

The interaction between β2 integrins (CD11a-c/CD18) and ICAMs (in tercellular adhesion molecules) has been found to be important in the binding of NK cells to their targets^[31,51,56]. β2 integrins are heterodimers containing a common β-chain (CD18) and one of three different β-chains (CD11a, CD11b, CD11c). β2 Integrins are expressed only in leukocytes, including NK^[56] and pit cells^[32]. Besides the effect on the binding to target cells, LFA-1 (CD11a/CD18) also participates in signal transduction in NK cells required for NK cell activation^[59]. Cross-linking of LFA-1 on NK cells with its antibody is known to induce a calcium influx, phosphoinositide turnover, tumor necrosis factor-α (TNF-α) production^[59], and to inhibit the target cell killing by NK cells^[60]. LFA-1 was also found to be involved in pit cell-mediated cytotoxicity. The antibody against LFA-1 inhibits not only the binding of pit cells to target cells, but also the killing of target cells by pit cells^[57]. Taken together, this information suggests that LFA-1 on effector cells may have a dual function of binding to target cells and of triggering cytolysis.

Studies have shown that conjugation between NK cells and target cells is essential but not sufficient for NK activity^[50]. After conjugation, further recognition events mediated by triggering and inhibitory receptors on NK cells are required to trigger NK cell cytotoxic activity^[2,51].

NK CELL RECEPTORS INVOLVED IN MHC CLASS I RECOGNITION

NK cell-mediated cytotoxicity was originally thought to be spontaneous and major histocompatibility complex (MHC) class I-unrestricted. However, increasing evidence indicates that NK cells preferentially kill cells

lacking MHC class I. Expression of MHC class I on a number of target cells is correlated with target cell resistance to natural killing^[61-65]. Masking of MHC class I by a n mAb, enhances pit cell-mediated cytotoxicity against CC531s cells, indicating that MHC class I on CC531s cells protects these cells from being killed by rat pit cells^[66].

An explanation for these observations is, that the cytotoxic activity of NK cells is regulated by positive and negative signals from triggering and inhibitory membrane receptors. The final outcome, *i.e.* triggering of cytotoxic activity or inhibition of cytotoxicity, appears to depend on the balance between the positive and negative signals^[51,67]. An increasing number of triggering and inhibitory receptors have been described in recent years^[28,68,69]. In hibitory receptors on NK cells recognize MHC class I, and these generally inhibit the lysis of MHC class I⁺ cells^[28,67-71]. Three receptor families, Ly49, CD94/NKG2 and Killer-cell inhibitory receptors (KIRs), are reported to be involved in the recognition of MHC class I molecules on target cells^[28]. The Ly49 family is the product of at least nine highly related genes (Ly 49A-Ly49I) present on mouse chromosome 6 in the NKC^[72]. Ly-49 homologies have been identified on rat chromosome 4 in the 'NKC'^[73], but have not been found in human. The Ly-49 molecules are type II membrane glycoproteins and belong to the C-type lectin superfamily^[72]. Ly-49 receptors recognize a trimeric MHC class I complex composed of the H-2D or H-2K heavy chain, β2-microglobulin, and a bound peptide. However, the composition of the bound peptide does not appear to influence the interaction to a large extent^[68]. Most, but not all, Ly-49 receptors contain an immunoreceptor tyrosine-based inhibitory motif (ITIM) in their cytoplasmic domains^[28,67]. Ly-49 receptors containing the ITIM sequence inhibit NK cell effector function^[28,67], whereas Ly-49 lacking ITIM, such as Ly-49D and Ly-49H, can activate NK cell-mediated cytotoxicity when the receptor is ligated by anti-Ly49D mAb^[74].

KIRs, the inhibitory receptors recognizing MHC class I in human NK cells, are monomeric type I glycoproteins that contain Ig domains^[67]. They are encoded by genes located on human chromosome 19q13.4^[28]. Two subfamilies of KIRs can be identified by the number of Ig-like domains in the extracellular regions of the molecules^[28]. The KIR3D subfamily contains three Ig-like domains, whereas the KIR2D contains two Ig-like domains^[28]. A remarkable feature of both KIR2D and KIR3D is the heterogeneity in the length of the cytoplasmic domains. KIRs with long cytoplasmic

domains, *i.e.* KIR2DL (p58) and KIR3DL (p70), contain two ITIM sequences that are responsible for the inhibitory function of these molecules^[67,75]. KIRs containing short cytoplasmic domains, *i.e.* KIR2DS (p50) and KIR3DS, lack ITIM and potentially activate NK activity^[76,77]. Both KIR2D and KIR3D molecules bind to HLA class I trimers, composed of a class I heavy chain, β^2 microglobulin, and a bound peptide^[28].

In addition to KIRs, human NK cells also express another type of receptor capable of recognizing MHC class I, namely CD94/NKG2^[78-80]. This receptor is a heterodimer and is composed of CD94 glycoprotein that is disulfide-bonded to either a NKG2A or a NKG2C subunit^[58]. CD94 and NKG2 genes are present on human chromosome 12p12.3 - p13.1 in the 'NKC'^[81]. Both CD94 and NKG2 molecules belong to the C-type lectin superfamily^[81]. CD94 lacks a cytoplasmic domain, thus lacking intrinsic signal transduction capacity^[81]. However, CD94 is required for the transport and membrane expression of the NKG2A or NKG2C glycoproteins^[78,80]. Since NKG2A possesses an ITIM sequence in the cytoplasmic domain and NKG2C lacks an ITIM, the CD94/NKG2A complex acts as inhibitory receptor, whereas CD94/NKG2C complex acts as a noninhibitory receptor for MHC class I on NK cells^[28,68].

Triggering NK cell receptors

Several membrane molecules are described to serve as triggering receptors on NK cells, including CD16, NKR-P1, NK-TR1, 2B4, P38 and Lag3^[28,51,69]. Only CD16 and NKR-P1 can be regarded as 'established' triggering receptors, while the role of the others is still undefined or controversial^[51]. However, CD16 is responsible and necessary for ADCC and is not involved in natural killing activity^[28].

NKR-P1, a marker of NK cells^[25], is expressed by rat^[25], mouse^[82] and human NK cells^[27], including pit cells^[16]. There are three homologous NKR-P1 genes, NKR-P1A, NKR-P1B and NKR-P1C, in mice and rats^[26,82,83], while only one human NKR-P1 gene has been found^[27]. MAbs against mouse and rat NKR-P1 were found to trigger NK cell-mediated lysis of FcR⁺ target cells, termed re-directed ADCC^[25]. This action also involves a rise in intracellular Ca²⁺ levels^[84] and cytokine production^[85]. Furthermore, mAbs to NKR-P1 stimulate phosphoinositide turnover^[84], arachidonic acid generation^[86] and granule exocytosis^[25]. NKR-P1 on pit cells is involved in pit cell-mediated cytotoxicity against FcR⁺ P815 target, but not in

FcR⁺ CC531s target killing^[66]. However, the function of NKR-P1 on human NK cells appears more complex. Treatment of human NK cells with anti-NKR-P1 mAb gives controversial results, such as activation, inhibition or no effect, depending on the NK cell population studied^[27,87]. The conditions determining the outcome of the engagement of NKR-P1 in human NK cells are not known. When human NKR-P1 is compared with the corresponding rat and mouse proteins, it was found that all rodent NKR-P1 has the C \times CP motif that interacts with phosphorylated P56^{lck}^[88], whereas human NKR-P1 lacks this motif^[28].

THE TWO MAJOR PATHWAYS OF NK CELL-MEDIATED CYTOTOXICITY

CTL and NK cells, including rat pit cells, kill target cells by one of two distinct mechanisms or both: necrosis and apoptosis^[19,48,50,89]. Necrosis or cytolysis is characterized by swelling of the cell and organelles, and results in disruption and leakage of the cell membrane and in lysis^[6]. Cell membrane damage is a key event in cytolysis and release of the cytoplasmic contents possibly leads to an inflammatory response *in vivo*^[6]. The ⁵¹Cr-release assay is thought to reflect this type of damage^[6].

Apoptosis or programmed cell death is morphologically recognizable by membrane blebbing, chromatin condensation, nuclear fragmentation, shrinking, condensation of cells and their organelles, and fragmentation of the cells into apoptotic bodies (Figure 6). The cellular remains are phagocytosed by neighboring cells or macrophages. When phagocytosing cells are absent, apoptotic bodies progress to secondary necrosis^[6,90].

Recent studies have demonstrated that NK cell-mediated apoptosis can mainly be implemented by two pathways, *i.e.* the perforin/granzyme (granule exocytosis) pathway and the Fas/FasL (Fas ligand) pathway^[91,92]. NK cell-mediated lysis is believed to be mainly based on granule exocytosis^[91], whereas Fas-mediated necrosis has been recently reported when caspases are blocked^[93].

The Fas pathway of apoptosis is mediated by the interaction of CD95 ligand (CD95 L, FasL) with the apoptosis-inducer CD95 (Fas/APO-1) molecule expressed on target cells^[91,94,95]. CD95 is a member of the tumor necrosis factor (TNF) and nerve growth factor (NGF) receptor family^[95,96]. CD95 is widely expressed on lymphoid and nonlymphoid tissues, and some tumor cells^[89,95]. The expression of CD95 can be up-regulated by interferon γ (IFN- γ) in various cell lines^[96,97]. The cytoplasmic tail of CD95 contains a motif called 'death domain', that is essential for transmitting the apoptotic signal^[98].

CD95L is a type II transmembrane protein of the TNF family^[95]. CD95L is expressed by activated T cells, NK cells and pit cells^[89,95,99,100]. The binding of CD95L to its receptor CD95 induces apoptosis of CD95-bearing cells^[94]. It is demonstrated that CD95/CD95L plays an important role in the killing of virus-infected cells and tumor cells by CTL and NK cells^[98]. Although CD95 is expressed on CC531s cells and CD95L is expressed on rat pit cells, pit cell-mediated CC531s apoptosis was found to be exclusively implemented by the perforin/granzyme exocytosis pathway^[89].

The perforin/granzyme pathway is a Ca^{2+} -dependent pathway and is mediated by the pore-forming protein perforin and granzymes, especially granzyme B, both of which are stored in NK cell granules^[92]. After the contact between effector and target cells, perforin and granzymes are released in a directed manner into the intercellular space between these cells. Perforin alone induces lysis without inducing apoptosis, *i.e.* fragmentation of target cell DNA. Granzymes play a critical role in the rapid induction of DNA fragmentation by CTL, NK cells and pit cells (Figure 7)^[89,101]. Entrance of granzymes into target cells is postulated to occur through pores produced in the target cell membrane by perforin. Recent studies have shown that granzyme B is endocytosed by target cells independently of perforin, possibly through saturable high affinity cell surface binding sites. In the absence of perforin, granzyme B shows a cytoplasmic localization. When perforin is added, granzyme B relocates to a nuclear position, rapidly inducing apoptosis^[102,103]. These data indicate that the cooperation of the two molecules is necessary to induce apoptosis including DNA fragmentation.

Figure 5 Comparison of cytotoxicity between rat blood NK, HD and LD pit cells. The ratio of freshly isolated effector cells to target cells was 20:1. The cytotoxicity was measured in a 4 hour ⁵¹Cr-release assay for YAC-1 and P815 cells and a 16 hour ⁵¹Cr-release assay for CC531s cells. The data show that LD pit cells are more cytotoxic against YAC-1, P815 and CC531s than HD cells and blood NK cells. Values were means \pm SD of three to five independent experiments. (Hepatology, 1990;12:70-75, with permission)

Figure 6 Transmission electron micrograph of an apoptotic CC531s cell (T) coincubated with pit cells (E) for 3 hours. The apoptotic CC531s cell (T) shows vacuolization (large arrowhead), blebbing of the cell surface (small arrowhead), chromatin condensation (thin arrow), and fragmentation of the nucleus (thick arrow). Bar: 2 μ m. (Hepatology, 1999;29:51-56, with permission)

Figure 7 The involvement of the perforin/granzyme pathway in pit cell-induced CC531s apoptosis. The ratio of freshly isolated pit cells to CC531s cells was 10:1. Apoptosis was measured in a 3 hour DNA-fragmentation assay. EGTA is a Ca^{2+} chelator that blocks granule exocytosis and the action of perforin. DCI is a granzyme inhibitor. Z-DEVD-FMK is an inhibitor of caspase 3. These treatments completely inhibit pit cell-induced CC531s apoptosis. Values were mean \pm SD of three independent experiments. (Hepatology, 1999;29:51-56, with permission)

SUMMARY

There is growing evidence that pit cells are highly active, liver-specific NK cells. Pit cells are located in the liver sinusoids and can be easily isolated and purified by liver sinusoidal lavage and a magnetic separation method. Furthermore, pit cells can be separated into a LD and HD fraction by 45% isosmotic Percoll gradient centrifugation. These two populations are shown to differ morphologically, phenotypically and functionally from each other and from blood NK cells. LD pit cells contain more rod-cored vesicles and more, but smaller granules than blood NK cells although both of them share LGL morphology. Phenotypically, LD cells have a higher expression of LFA-1 and a lower expression of asialo-GM1 molecules compared to blood or spleen NK cells. Functionally, pit cells are more cytotoxic against several tumor cell lines as

compared to blood NK cells, and are able to kill-NK-resistant but LAK-sensitive P815 cells. These data indicate that pit cells are a kind of naturally activated NK cells and their cytotoxic function is comparable to IL-2 *in vitro* activated NK cells. The characteristics of HD cells are intermediate between LD pit cells and blood NK cells. Pit cells most probably originate from blood NK cells, although they show mitosis in the liver after certain stimuli. The recruitment of pit cells in the liver is mediated by adhesion molecules. A major challenge is to achieve a better understanding of the mechanisms of pit cell cytotoxicity and the cooperation between pit cells and other cells in the liver, *i.e.* Kc, Ec and LAL. Moreover, since pit cells are located in a strategic position in the hepatic sinusoids, they represent a first line of cellular defense against metastasizing colon cancer cells. The role of pit cells in a number of liver pathologies deserves more attention.

ACKNOWLEDGEMENTS We thank Carine Seynaeve and Marijke Baekeland for their excellent technical support and Chris Derom for her photographic support.

Dynamic and ultrastructural study of sphincter of Oddi in early-stage cholelithiasis in rabbits with hypercholesterolemia

Wei JG, Wang YC, Du F and Yu HJ

Subject headings hypercholesterolemia; cholelithiasis; sphincter of Oddi/ultrastructure

Abstract

AIM To study the relationship between pre-formation of gallstone and the kinetics and ultra-structure of sphincter of Oddi.

METHODS Adult female rabbits were used and divided into 3 groups, and fed with either normal or high cholesterol diet for four or eight weeks. Each group contained eight rabbits. The manometry of sphincter of Oddi, biliary cineradiography, gallbladder volume measurement and ultrastructure observation under electron microscope were performed.

RESULTS In groups I and II, the basal pressure in low-pressure ampulla or high pressure zone of sphincter of Oddi was elevated, the amplitude of phasic contraction was decreased and the volume of gallbladder were increased, with a significant difference ($P < 0.01$, from those of control). Gallstones were found in group II rabbits (7/8). Under cineradiography, low-pressure ampulla showed a spasmodic status without apparent peristaltic contraction. Under electron microscope, inside the muscular cells of sphincter of Oddi, loosening of microfilament and swelling of plasmosomes which congregated at the top were observed. The amount showed no obvious change under nitric oxide synthase (NOS) stain.

CONCLUSION Twisting of the microfilament and disarrangement of kink macula densa inside the muscular cells suggested that the sphincter of Oddi was under spasmodic status. The impaired diastolic function caused and aggravated the stasis of cystic bile. The swelling plasmosome could be one of the important factors in elevating the tonic pressure of sphincter of Oddi.

INTRODUCTION

Gallstone formation results from many complex factors working together. Among them the bile stasis caused by impaired gallbladder emptying is thought to be the fundamental kinetic factor. Because the sphincter of Oddi (SO) is the only gate through which bile discharged into the duodenum, the bile filling and excretion of the gallbladder are closely related with the motility state of SO. Hypercholesterolemia is a crucial factor of lithogenesis. But up to date, there has been no report on the effect of hypercholesterolemia on SO and the causal relationship between abnormality of SO and gallstone formation. The aim of this study is to investigate the relationship between SO motility and its ultra-morphology, and gallstone formation under the influence of hypercholesterolemia.

MATERIAL AND METHODS

Animal experiment

Twenty-four adult female rabbits weighing between 2.0 kg and 2.5 kg were provided by the Laboratory Animal Center of the Fourth Military Medical University. They were divided randomly into three groups ($n = 8$ each). Control group, fed with standard diet; Group I, standard diet plus cholesterol 1 g/d, 6 times/week, sacrificed after 4 weeks; and Group II standard diet plus cholesterol with 1 g/d, 6 times/week, sacrificed after 8 weeks.

The cholesterol (98% purification, 0.1% phosphatide) was purchased from Changsha Biochemical Pharmaceutical Factory, China. Before the study, the serum cholesterol was tested and only animals with a concentration lower than 3 mmol/L were included in the study. After feeding, a concentration higher than 10 mmol/L was evaluated as hypercholesterolemia. During laparotomy, if crude cholesterol crystal was observed in naked eye in the bile and the surface of gallbladder mucosa, it was interpreted as gallstone formed^[1].

Manometry and equipment

Manometry catheter was modified from Cook's 5F (outer-diameter 1.6 mm) angiographic catheter. The tip hole was blocked, and a side-hole (0.4 mm diameter) was made from 10 mm of the tip. During

manometry, the catheter lumen was infused with 9 g/L saline at 0.25 mL/min using a miniature complaint hydraulic infusion pump^[2]. The baseline resistance for duodenum pressure was set to zero during infusion. Recordings were obtained using a 4-channel RM-6200C polygraphic recorder (Chengdu Instrument Inc., Chengdu, China) with a PT-14M transducer (Gaolian Transducer Science Inc., Shanghai, China). Following an overnight fast (except water), the animals were anesthetized with ketamine (30 mg/kg) (Shaanxi Medical Research Institute) and maintained with 15 mg/kg per 30 min. After anesthesia the animals were tied supine on a board and underwent laparotomy. The extra-hepatic bile duct system was readily visible. The duodenum was cut open, and the catheter was cannulated into common bile duct through the duodenal papilla of billiary duct. The catheter was withdrawn at 1 mm-2 mm increments, and measurement was started after 5 min pause until the tip of the catheter dropped out into the duodenum.

After manometry, 300 g/L meglucamine diatrizoate was injected into biliary tract of controls and group I animals. The cineradiographic recording of biliary tract was obtained at a frame rate of 25/s when the tract was full of contrast.

Nitric oxide synthetase histochemistry and imaging analysis

SO specimens from three rabbits of each group were subjected to histochemistry and image examinations after manometry. Each specimen was fixed in 40 g/L paraformal dehyde PBS solution at 4 °C for 16-18 hours, then put into 100 g/L sourose solution and preserved at low temperature according to the method of Thune A^[2]. After NPDPH stain, the total number of NADPH, mean string length and spacing were measured with MPIAS 500 Multimedia Color Pathologic Image Pattern Analysis System (Qing Ping Imaging Corp.).

Statistical analyses

All results were expressed as $\bar{x} \pm s$. Differences were tested for sign ificance by Student's *t* test, and $P < 0.05$ was considered as significant difference.

RESULTS

Serum cholesterol

Before the cholesterol-feeding, the total serum cholesterol had no difference between control and groups I and II (< 3 mmol/L), while the concentration was elevated significantly (> 10 mmol/L) after four or eight weeks of cholesterol feeding, reaching the standard of hypercholesterolemia. There was significant difference between control and experimental groups ($P < 0.01$), but no difference was observed between

groups I and II ($P > 0.05$), (Table 1).

Table 1 Serum cholesterol concentration (mmol/L)

Group	Pre-feeding	Post-feeding
Control	1.43±0.61	1.36±0.42
Group I	1.57±0.56 ^a	30.61±6.32 ^a
Group II	1.40±0.68 ^b	29.03±2.59 ^b

Post ^a $P < 0.01$, $t = 13.06$, ^b $P < 0.01$, $t = 32.17$ vs control.

Gallbladder volume and bile characteristics

Gallbladder volume of control, group I and II was 2.0 mL \pm 1.0 mL, 3.4 mL \pm 1.0 mL, 3.9 mL \pm 0.9 mL respectively, and volume of gallbladder of group I and II increased more significantly than control group (^a $P < 0.01$, $t = 2.8$ vs control. ^b $P < 0.01$, $t = 3.96$ vs control), and there was no difference between group I and II (^b $P > 0.05$, $t = 1.04$ vs group I).

Cineradiography

The calibra of low-pressure ampulla segment in control animals was uneven, and enlarged significantly at the site where contrast media concentrated, while in group I it was smaller than that of the controls and the changes of caliber were not prominent during excretion of contrast (Figures 1, 2).

Manometry

In the control, manometry showed a constant high-pressure zone (HPZ) at the terminal of SO segment. It featured a high basal pressure and inconspicuous amplitude fluctuation. A low-pressure zone existed beyond the HPZ (proximal to the SO), with a lower basal pressure but relatively more prominent rhythmic peristalsis. These results coordinated with Toouli's report^[3].

The results obtained in groups I and II are compared and listed in Table 2. The basal pressure in proximal segment of groups I and II was higher than that of controls ($P < 0.01$), but there was no difference between the two groups II ($P > 0.05$). The amplitude of peristalsis in these segments were lower than the controls ($P < 0.01$), with no difference between groups I and II.

The basal pressure in HPZ of groups I and II was higher than the controls, but the amplitudes were lower than the control. There was no difference in basal pressures between groups I and II ($P > 0.05$), (Figures 3-5).

NADPH stain imaging analysis

As shown in Table 3, there was no difference in the total number, total area, area density, area percentage, mean string length and mean spacing among the groups ($P > 0.05$).

Figure 1 The cineradiographic recording of same biliary tract of one control. The contrast clustering the proximal segment (low-pressure ampulla) which enlarged significantly during excretion of contrast indicated that part was distended. ($\uparrow \rightarrow \uparrow$: External segment of SO)

Figure 2 Biliary tract cineradiographic image of group I rabbit. The caliber of proximal segment decreased, retained a fixed spasm state. ($\uparrow \rightarrow \uparrow$: External segment of SO)

Figure 4 Pressure curve of SO segment of group I rabbit.

Figure 5 Pressure curve of SO segment of group II rabbit.

Figure 6 Electron-microscopic scanning of a control rabbit's SO segment smooth muscle. The myofilaments were regularly arranged, kink macula densa clear and dense, plasmosome was normal.

Figure 7 Electron-microscopic scanning of a group I rabbit's SO segment smooth muscle. Image showed the swelling of plasmosome and disappearance of intercrystal space, decrease of kink macula densa and twisting of myofilaments.

Figure 8 Electron-microscopic scanning of a group II rabbit's SO segment smooth muscle. It shows the swelling of plasmosome, irregular arranged or fragmented intercrystal space, some vacuolized, congregated at one end of nuclear, and disarrangement of kink macula densa.

Table 2 Manometry of rabbits SO (mmHg)

	Proximal segment		HPZ	
	Basal pressure	Amplitude	Basal pressure	Amplitude
Controls	11.7±2.8	18.1±5.9	69.3±9.8	8.7±3.6
Group I	20.9±6.1	6.4±4.5 ^a	138.4±45.5	4.2±2.2 ^a
Group II	25.6±9.1	6.7±4.8 ^b	144.5±40.5	3.4±2.2 ^b

Proximal: Basal pressure ^a $P < 0.01$, $t = 4.20$, ^b $P < 0.01$, $t = 5.11$ vs controls; Amplitude ^a $P < 0.01$, $t = 4.47$, ^b $P < 0.01$, $t = 4.24$ vs control.

HPZ: Basal pressure ^a $P < 0.01$, $t = 4.20$, ^b $P < 0.01$, $t = 5.11$ vs control; Amplitude ^a $P < 0.01$, $t = 3.15$, ^b $P < 0.01$, $t = 3.17$ vs control.

Table 3 Rabbit's smooth muscle of SO NADPH stain imaging analysis (μm)

	Total (number)	Total (area)	Area (density)	Area (percentage)	Mean (string)	Mean (spatial range)
Controls	107.6±64.4	330.5±133.4	0.0079±0.0048	2.4±1.0	1.6±0.4	77.2±67.7
Group I	117.6±43.4	319.5±126.5	0.0087±0.0032	2.4±0.9	1.5±0.3	69.7±26.2
Group II	109.6±45.4	360.4±190.4	0.0081±0.0033	2.7±1.4	1.6±0.4	79.9±61.7

Reference area is 13550.6μm.

Pathologic examination

Two SO specimens of each group were examined histologically. Each specimen was fixed in formalin and then HE stained. Under light microscope, the smooth muscle arranged regularly. There was no increase of inflammatory cell and collagenous or elastic fibers.

Three SO smooth muscle specimens of each group were collected randomly. They were cut into 1mm small specimens, soaked in 30 g/L glutaraldehyde promptly and pre-fixed for 2-4 hours under 4 °C, then post-fixed, dehydrated, embedded, ultra-thin sliced, lead/uranium double stained and observed under JEM-200EX transmission electronic microscope. It was found that SO smooth muscle cells' microfilament was loose and irregularly arranged, kink macula densa reduction, swelling and intercrystal space disappeared or vacuolized and congregated at the top of the nuclear of plasmosome in groups I and II, but no such changes in the controls (Figures 6-8).

DISCUSSION

The biliary tract system can be treated as a half-opened and low-flow system according to its anatomic features, and SO is the only excreting gate to the duo denum. According to Dodd WJ *et al*^[4], at fasting state only 50%-75% of hepatic bile enters the gallbladder while the remainder flows directly into the duodenum. Obviously, SO plays an important role in the participating in hepatic bile flow and remaining the pressure gradient of biliary system, consequently the regulating gallbladder filling and emptying.

The pathologic agents that related to the gallstone formation were still the hot spot of research. Most researchers hold that hypotonus of gallbladder and bile stasis are the main factors of cholelithiasis while the dyskinesia may be the result of gallbladder pathologic lesion itself^[5]. However, Lange K *et al*^[6] found that the tension of gallbladder was not decreased, but increased during the early stage of cholelithiasis formation. Pitt A *et al*^[7] and Li YF *et al*^[8] had shown that sphincterectomy may prevent the formation of gallbladder stone and improve the contractility of gallbladder partially, but has no effect on the cholesterol crystal genesis. All these suggested that the dysfunction of the SO may result in the abnormal motility of gallbladder.

Toouli J *et al*^[3] and Wei JG *et al*^[9] reported their findings on SO dynamics anatomy, which indicated that choledochus sphincter's physiological anatomy consisted of a high pressure distal segment and a low-pressure proximal ampulla segment. The low-pressure ampulla segment's rhythmic contractile and diastole activity are the primary kinetic sources during fasting. Our results showed that there was no difference in basal pressure of low-pressure segment and total pressure (basal+phasic amplitude) of HPZ between experimental groups and the control. It suggested that hypercholesterolemia did not impair the construction foundation of the contractile activity of SO. But the contractile amplitude of functional ampulla in the experimental rabbits was decreased to those of the controls. The amplitude of low-pressure ampulla/ total (basal + amplitude) was 60.7% in the control rabbits, but was only 23.4% and 25.5% in groups I and II. Obviously that

elevated basal pressure of low-pressure ampulla of SO significantly decreased the phasic amplitude in the experimental animals. The cineradiography showed that the low-pressure ampulla retained a fixed spasm state, thus, the diastolic and peristaltic functions were impaired. According to the hydrodynamic laws, $Q_{out} = -dv/dt$, i.e. excretion volume of liquid is equal to the shrunken volume of the elastic vessel. This suggested that the effective excretion of each pumping (peristaltic wave) per unit time of low-pressure ampulla was impaired in groups I and II.

Additionally, all experimental animals characterized by a more distinctly elevated basal pressure in HPZ than SO proximal segment, and the manometric curve appeared almost like a plateau, on this basis, the phasic amplitude significantly decreased. The HPZ is not merely a passive "valve", but also an intrinsic conducting tube of bile, so that the increased basal pressure may enhance the excreting resistance of the bile significantly. This study demonstrated that the volume of gallbladder increased in experiment animals, suggesting that the tonus alteration in ampulla and HPZ of experimental rabbits may play an important role in the bladder bile stasis, subsequently that may be the pathologic motility function of cholelithiasis formation.

There were many reports about nitric oxide (NO) regulation of SO smooth muscle. Some authors confirmed that NO may be the terminal neuron transmitter of SO smooth muscle^[2]. Several studies showed that there were abundant NO synthetase (NOS) in SO, which had tissue-specific characteristics. The results may demonstrate that relaxation of SO is related to the quality and quantity of NOS directly. But our data showed no difference in quantities of NOS between the experimental and control animals, indicating that the decreased diastolic activity of the sphincter may not be the result of reduced quantities of NOS in sphincter tissues.

Gaasch WH *et al*^[10] reported that diastolic deficiency is the early change of heart dysfunction.

This may be related to malfunctioning energy metabolism of the heart muscle cell. This study showed that the cell of SO underwent changes of plasmosome swelling which may affect the energy metabolism of sphincter cell, while the swelling of myofilament may indicate the intracellular edema of sphincter. Zhang JS *et al*^[11] reported that during sphincter cell culture *in vitro* in high cholesterol solution, the cell underwent similar alteration. The sensitivity of cell membrane to digestive synthetase was increased. According to these data, the changes of sphincter cells of experimental animals may relate to the alteration of cell membrane biological characteristics due to hypercholesterolemia. Since the sphincter functional ampulla (low pressure segment) acts like kinetic heart pump during bile excretion, we conclude that diastole of functional ampulla may be an active movement and energy consumption process, the swelling of plasmosome may result in decrease of energy supply during diastole, leading to diastole deficiency eventually.

The relation between HLA-DQA1 genes and genetic susceptibility to duodenal ulcer in Wuhan Hans

Du YP, Deng CS, Lu DY, Huang MF, Guo SF and Hou W

Subject headings duodenal ulcer; HLA-DQA1 gene; polymerase chain reaction; restricted fragment length polymorphism; genetic susceptibility

Abstract

AIM To study the genetic susceptibility of HLA-DQA1 alleles to duodenal ulcer in Wuhan Hans. **METHODS** Seventy patients with duodenal ulcer and fifty healthy controls were examined for HLA-DQA1 genotypes. HLA-DQA1 typing was carried out by digesting the locus specific polymerase chain reaction amplified products with alleles specific restriction enzymes (PCR-RFLP), i.e. *Apal*-I, *Bsaj*-I, *Hph*-I, *Fok*-I, *Mbo*-II and *Mnl*-I.

RESULTS The allele frequencies of DQA1*0301 and DQA1*0102 in patients with duodenal ulcer were significantly higher and lower respectively than those in healthy controls (0.40 vs 0.20, $P = 0.003$, $P_{\text{correct}} = 0.024$) and (0.05 vs 0.14, $P = 0.012$, but $P_{\text{correct}} > 0.05$), respectively.

CONCLUSION DQA1*0301 is a susceptible gene for duodenal ulcer in Wuhan Hans, and there are immunogenetic differences in HLA-DQA1 locus between duodenal ulcer patients and healthy controls.

INTRODUCTION

Duodenal ulcer is a set of extensive heterogeneous hereditary diseases with varied pathogeny and pathogenesis^[1], there were some immunological changes in some patients with duodenal ulcer^[2-4]. Immunopathogenesis may play a role in the pathogenesis of duodenal ulcer. Human leukocyte antigen (HLA-DQA1 gene) contributes to the pathogenesis of some diseases. Investigating the correlation between HLA-DQA1 gene and duodenal ulcer may afford important clues to reveal duodenal ulcer pathogenesis. HLA-DQA1 genotypes are highly polymorphism and can not be determined by ordinary serological methods. We applied polymerase chain reaction-restricted fragment length polymorphism (PCR-RFLP) nucleotide typing technique to study the genetic susceptibility of HLA-DQA1 alleles to duodenal ulcer in Wuhan Hans.

MATERIALS AND METHODS

Subjects

We examined 70 patients with duodenal ulcer (53 male, 17 female; mean age 38 years) and 50 healthy controls (38 male, 12 female; mean age 36 years) for HLA-DQA1 genotypes. All these subjects were from the Digestive Department, Second Hospital of Hubei Medical University. Duodenal ulcer was diagnosed endoscopically. The ulcerogenic drugs, such as aspirin, indomethacin or corticosteroids were ruled out as the etiological factors in all of the duodenal ulcer patients. Patients with combined duodenal and gastric ulcers were excluded from this study. All patients and controls were Chinese Hans living in Wuhan.

Primer synthesis and reagents

HLA-DQA1 locus specific PCR primers were designed by Ota M^[5]. Primer GH26: 5'-GTGCTGCAGGTGTAACTTGTACCAG-3', primer GH27: 5'-CACGGATCCGGTAGCAGCGGTAGAGTTG-3', they were synthesized by Shanghai Branch, Canadian Sangon Company. Alleles specific restriction enzymes (*Apal*-I, *Bsaj*-I, *Hph*-I, *Fok*-I, *Mbo*-II and *Mnl*-I) were all purchased from New England Biolabs Company. Taq DNA polymerase and DNA dNTP were purchased from Canadian Sangon Company. Proteinase K and pBR322/*Hae*-III Mark were provided by Huamei Bioengineer Company.

Methods

DNA extraction Leukocytes from anticoagulated whole blood were isolated with hypo-osmotic haemolytic method. DNA was extracted by phenol-chloroform extraction method from leukocytes.

PCR amplification A total amount of 100 μ L reaction solution contained 1 μ g DNA sample, 200 μ mol/L dNTP and 50 pmol each of primers 1 and 2. The amplification of HLA-DQA1 exon 2 was carried out in one reaction system and PCR procedure was as follows: predenaturation at 94 $^{\circ}$ C for 5 min, addition of 2.5 μ g Taq DNA polymerase, denaturation at 94 $^{\circ}$ C for 1 min, annealing at 62 $^{\circ}$ C for 2 min and extension at 72 $^{\circ}$ C for 2 min repeated 30 cycles and finally extension at 72 $^{\circ}$ C for 5 min to terminate the reaction. Because some alleles of HLA-DQA1 locus had a 3 bp deletion in the PCR-amplification the size of the amplified region of the DQA1 exon 2 was 239 bp or 242 bp as indicated (Figure 1).

Digestion with restriction endonucleases After amplification, aliquots (7 μ L) of the reaction mixture were digested with restriction endonucleases (Apa-I, Hph-I, Fok-I and Mbo-II: 5 units) at 37 $^{\circ}$ C for 1 h after addition of appropriate incubation buffer. When digested by Bsa-I, the reaction mixture was incubated at 60 $^{\circ}$ C for 1 h.

Acrylamide gel electrophoresis Samples of the restriction enzyme cleaved product amplified DNA were usually subjected to electrophoresis in 12 % polyacrylamide gel in a horizontal minigel apparatus. They were expected to allow discrimination of seven alleles among the eight DQA1 alleles because the DQA1*0101 and DQA1*0102 alleles gave the same restriction map. However, when digested with Mnl-I enzyme, DQA1*0101 and DQA1*0102 can be discriminated with 15% polyacrylamide gel. Cleavage or no cleavage of amplified fragments was detected by staining with ethidium bromide. Eight alleles of HLA-DQA1 locus were determined by this method^[5]. The restriction map of the DQA1 alleles concerning these enzymes is shown in Figure 2.

Statistical analysis

Chi-square test or Yate's correction Allele detection frequencies (f) were made by the direct count. According to Hardy-Weinberg theorem, gene frequencies (AF) were calculated by $AF = 1 - f$. Comparisons of allele frequencies were made by the exact probabilities in 2 \times 2 table *P* test. Relative risk frequencies (RR) were made by Wolf formula. The corrected *P* value was *P* times the number of alleles in comparison^[6].

Figure 1 The size of the amplified region of the HLA-DQA1 exon 2 is 242 bp as indicated (12% PAGE). M: pBR322/Hae-III Mark

Figure 2 Cleavage patterns of polymorphic restriction fragments in the PCR-amplified DQA1 genes obtained with restriction enzymes (12% PAGE). M: pBR322 / Hae-III Mark; 1: Apa-I; 2: Hph-I; 3: Bsa-I; 4: Fok-I; 5: Mbo-II; a: 0301 / 0501; b: 0103 / 0501; c: 0102 / 0601

RESULTS

The distribution of HLA-DQA1 alleles is shown in Table 1. DQA1*0301 is the allele commonly seen in healthy controls. The detect frequency and the allele frequency of DQA1*0301 was 0.36 and 0.20 in healthy controls, and 0.64 and 0.40 in patients with duodenal ulcer, respectively. The increased allele frequency of DQA1*0301 in patients with duodenal ulcer (0.40) was statistically significant ($RR = 3.20$, $P = 0.003$, $P_{correct} = 0.024$) compared with healthy controls (0.20). In contrast, the detect frequency and the allele frequency of DQA1*0102 was 0.26 and 0.14 in healthy controls, and 0.09 and 0.05 in patients with duodenal ulcer, respectively. The decreased frequency of DQA1*0102 in patients with duodenal ulcer (0.05) controls (0.14) was statistically significant compared with healthy ($RR = 0.27$, $P = 0.012$, but $P_{correct} > 0.05$). There were no significant differences in other allele frequencies between duodenal ulcer patients and healthy controls.

Table 1 Distribution of DQA1 allele frequency in duodenal ulcer patients and healthy controls from Wuhan Hans

HLA-DQA1 alleles	Controls (n = 50)			DU (n = 70)		
	PN	PF	AF	PN	PF	AF
0101	10	0.20	0.11	9	0.13	0.07
0102	13	0.26	0.14	6	0.09 ^a	0.05
0103	8	0.16	0.08	12	0.17	0.09
0201	7	0.14	0.07	10	0.14	0.07
0301	18	0.36	0.20	45	0.64 ^b	0.40
0401	2	0.04	0.02	1	0.01	0.01
0501	12	0.24	0.13	22	0.31	0.17
0601	7	0.14	0.07	12	0.17	0.09

PN: positive number; PF: phenotype frequency; AF: allele frequency. Compared with controls: ^a $P = 0.012$, $RR = 0.27$, $P_{correct} > 0.05$; ^b $P = 0.003$, $RR = 3.2$, $P_{correct} < 0.05$.

DISCUSSION

Various factors are accepted as the causes of duodenal ulcer disease. Not only inherited factor, but also immuno-dysfunction is associated with duodenal ulcer. Since the discovery of *Helicobacter pylori* (*H. pylori*)-its infection has been widely accepted as the predominant cause of duodenal ulcer disease. The pathogenic mechanisms that *H. pylori* causes human disease remain poorly understood. The human leukocyte antigen (HLA) DQA1 gene contributes to the host response against *H. pylori*. Many immune responses are controlled by genes of the major histocompatibility complex which encode HLA. Individuals with different HLA types may differ in susceptibility or resistance to particular infectious pathogens, and associations between HLA polymorphism and susceptibility or resistance to infectious or autoimmune diseases have been

identified^[7,8]. The polymorphic HLA-DQA1 genes encode polypeptides which fold together to form a receptor that specifies T-lymphocyte recognition of self and foreign peptides^[9]. Therefore we examined the HLA DQA1 locus in patients with duodenal ulcer in an attempt to investigate immunogenetic differences in the host.

Researches in the correlation between HLA and peptic ulcer disease were started sixty years ago. The finding showed that HLA-B5 antigen was associated with peptic ulcer^[10-13]. However, traditional serological method was used in some investigations, but it was obsolete and inaccurate. The individual genetic difference of HLA at the level of DNA was produced by encoded gene^[14]. To understand the disease essence, correlation between peptic ulcer and HLA should be further studied with nucleotide typing technique.

DQA1 gene is the most polymorphism in HLA Class II gene and is strongly associated with some diseases. We analysed nucleotide sequences of PCR-amplified regions in the DQA1 genes for allele specific restriction sites to study DQA1 genes involved in the genetic susceptibility to duodenal ulcer in Wuhan Hans. The result of the present study indicated a significant difference in the frequencies of HLA-DQA1 alleles between duodenal ulcer patients and healthy controls. The allele frequency of DQA1*0301 was significantly higher ($RR = 3.20$, $P = 0.003$, $P_{correct} = 0.024$) in duodenal ulcer patients (0.40) than in healthy controls (0.20). In contrast, the allele frequency of DQA1*0102 was significantly lower ($RR = 0.27$, $P = 0.012$) in duodenal ulcer patients (0.05) than in healthy controls (0.14), but $P_{correct} > 0.05$. These results suggest that the HLA-DQA1*0301 may contribute to the susceptibility to duodenal ulcer.

DQA1 chain is not on isolated entity and is tightly linked with DR and DQB locus genes in the all genes region of the major histocompatibility complex. The result of the present study may provide a clue that HLAII genes are more strongly associated with duodenal ulcer than HLAI genes. The clue could not affirm which locus gene of HLAII Class genes is more important. Further genetic analysis of DRB1 and DQB1 genes, using various DNA markers to clarify the host genetic factors of susceptibility or resistance to duodenal ulcer, is required.

The relationship of *Imp2* and DR3 genes with susceptibility to type I diabetes mellitus in south China Han population

Ding HL, Cheng H, Fu ZZ, Deng QL, Yan L and Yan T

Subject headings diabetes mellitus; *Imp2* genes; DR3 genes; polymerase chain reaction; restriction fragment length polymorphism; genetic susceptibility

Abstract

AIM To study the relationship of *Imp2* and DR3 genes with type I diabetes mellitus.

METHODS *Imp2* genotypes and DR3 were identified in 68 patients with type I diabetes mellitus (I-DM) and 71 healthy controls. Then, I-DM patients and controls were respectively allocated into DR3-positive and DR3-negative groups. The frequencies of *Imp2* and DR3 gene in random subjects, and *Imp2* genotypes in DR3-matched subjects were compared between I-DM patients and controls. At the same time, I-DM patients were divided into 3 groups based on the onset age of diabetics: group A ≤ 14 years, group B 15-30 years and group C ≥ 31 years.

RESULTS The frequency of DR3 in I-DM patients was significantly higher than that in controls (47% vs 21%, $P < 0.005$), and it was significantly higher in group A than that in group B+C (70% vs 36%, $\chi^2 = 7.07$, $P < 0.01$). There was a significant difference among groups with different onset age of diabetics ($\chi^2 = 8.19$, $rp = 0.33$, $P < 0.05$). In random subjects, the frequency of *Imp2* R/R in I-DM patients was lower (43% vs 61%, $P < 0.05$) and *Imp2*-R/H higher (53% vs 28%, $P < 0.05$) than that in controls, and there was no significant difference among groups with different onset age of diabetics. In DR3-positive subjects, the frequency of *Imp2*-R/R in I-DM patients was lower (47% vs 87%, $P < 0.05$) and *Imp2*-R/H

higher (47% vs 13%, $P < 0.05$) than that in controls. In DR3-negative subjects, the frequency of *Imp2*-R/H in I-DM patients was higher than that in controls (58% vs 32%, $P < 0.01$), but the frequency of *Imp2*-R/R and *Imp2*-H/H was not significantly different between these two groups.

CONCLUSION DR3 gene may be one of the susceptible genes of I-DM, and significantly related to the onset age of diabetics, and the persons with DR3 may have a younger onset age of diabetes. The *Imp2*-R/R may be the protective genotype of I-DM, and *Imp2*-R/H the susceptible genotype. These were not affected by DR3 gene. *Imp2* genotypes were not related with the onset age of diabetics.

INTRODUCTION

Type I diabetes mellitus (I-DM) is an autoimmune disease due to insufficient insulin secretion resulting from immunologically mediated destruction of pancreatic beta cells. Previous studies suggested that some genes (including DR3 gene) within Major Histocompatibility Complex (MHC) class II region determined the susceptibility to I-DM in other populations^[1-4]. We investigated the relationship of DQA1 and DQB1 with I-DM^[5,6], in south China Han population. However, the relationship between DR3 and I-DM has not yet been studied. *Imp2* is another gene locus within MHC class II region, its polymorphism site is at R/H-60. When the amino acid at position 60 is arginine (R) or histidine (H), the allele will be *Imp2*-R or *Imp2*-H. *Imp2* has 3 genotypes, i.e., *Imp2*-R/R, *Imp2*-R/H and *Imp2*-H/H. The relationship between *Imp2* and I-DM is still controversial. This study aims at investigating the relationship of *Imp2* and DR3 gene with I-DM in south China Han population.

MATERIALS AND METHODS

Subjects

Sixty-eight I-DM patients and 71 healthy persons (as controls) were included in this study. All the subjects were Han population without relatives from southern China. The controls were the healthy

persons having no family history of autoimmune or hereditary diseases. The diagnosis of I-DM was based on 1985 WHO criteria. Both IDDM patients and controls were subdivided into DR3 positive and DR3-negative groups. The I-DM patients were divided based on the onset age of diabetics into 3 groups: group A ≤ 14 years, group B 15-30 years and group C ≥ 31 years.

DNA extraction

Genomic DNA was extracted from peripheral blood leukocytes treated with protease-K, saturated phenol/chloroform extraction and collected by cold ethanol precipitation.

Identification of DR3 gene

DR3 gene was identified by the nested-PCR^[7]. First, the exon2 of DRB1 was amplified from genomic DNA, and the PCR primers were exon2.1, 5'-CCGGATC CTTCGTGTCCCCACAGCAC-3' and exon 2.2, 5'-TCGCCGCTGCACTGTGAAG-3'. Then, DR3 gene was amplified from exon2, the PCR primers were DR3.1, 5'-TACTTCCATAACCA G G A G G A G A - 3', DR3.2, 5'-TGCAGTAGTTGTCCACCCG-3'. The primer amplifying DR3 was used to amplify all the alleles (except for DR10) within exon2 of DRB1 to justify its specificity.

Genotyping of *Imp2*

Imp2 was genotyped by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP)^[21].

PCR amplification The PCR primers were *Imp2*-1, 5'-GCCAGCA AGAGCGGAAACAAG-3' and *Imp2*-2, 5'-GTGAACCGAGTGTGTTGAGAAGC-3'. The PCR product was a DNA fragment of 252bp containing the *Imp2* polymorphism site R/H-60. PCR was performed in 50 μ L of reactive volume containing 100 ng of genomic DNA, 0.8 μ mol/L primer, 0.2 μ mol/L dNTP, 5 μ L 10 \times PCR buffer and 1.5 u Taq DNA polymerase. The samples were subjected to 35 thermal cycles of 50 s at 94 $^{\circ}$ C for denaturing, 60 s at 52 $^{\circ}$ C for annealing, and 60 s at 72 $^{\circ}$ C for extension, 7 min at 94 $^{\circ}$ C for denaturing before the first cycle, and 5 min at 72 $^{\circ}$ C for extension after the last cycle.

Hha-I digestion of PCR production The reactive volume 20 μ L contained 10 μ L of PCR product, and 10 u of Hha-I (Gibco). The samples were incubated in warm water bath at 37 $^{\circ}$ C overnight. The allele *Imp2*-R contained the Hha-I site, however, the *Imp2*-H did not. Therefore, the polymorphism of *Imp2* can be revealed by Hha-I. When Hha-I digestion was performed, the PCR

products with known *Imp2* genotype were used as controls.

Statistical analysis

The χ^2 test in the 2 \times 2 table was used to compare the frequencies of *Imp2* genotypes and DR3 gene between I-DM patients and controls, and if the results were significant, the odds ratio (Ψ) would be calculated. The frequencies of *Imp2* genotypes and DR3 gene were compared among groups with different onset age of diabetics by the χ^2 test in the R \times C table, and if the results were significant, the Pearson's *rp* would be calculated.

RESULTS

Genotyping of *Imp2* and identification of DR3 gene Figure 1 shows the DR3 gene by nested-PCR. Figure 2 shows the various genotypes of *Imp2* and the product of PCR. The identification of DR3 was made twice in 90 samples, getting 99% (89/90) precision. Genotyping of *Imp2* was performed twice in 70 samples with 100% coincidence. The primer amplifying DR3 and Hha-I digestion had excellent specificity.

Distribution of DR3 and *Imp2* in random subjects

The frequency of *Imp2*-R/R in I-DM patients was significantly lower, but the frequency of *Imp2*-R/H and DR3 was significantly higher than that in controls. And *Imp2*-H/H showed no significant difference between these two groups (Table 1).

Table 1 Comparison of frequencies of *Imp2* genotypes and DR3 gene between I-DM patients and controls in random subjects

	<i>n</i>	DR3	<i>Imp2</i>		
			R/R	R/H	H/H
I-DM	68	32(0.47) ^a	29(0.43) ^b	36(0.53) ^c	3(0.04)
Controls	71	15(0.21)	43(0.61)	20(0.28)	8(0.11)

Compared with controls: ^a $\chi^2 = 10.44$, $\psi = 3.32$, $P < 0.005$; ^b $\chi^2 = 4.47$, $\psi = 0.48$, $P < 0.05$; ^c $\chi^2 = 8.86$, $\psi = 2.87$, $P < 0.005$.

Distribution of *Imp2* in DR3-matched subjects
In DR3-positive subjects The frequency of *Imp2*-R/R and *Imp2*-R/H in I-DM patients was respectively lower and higher respectively than that in controls with significant difference, but *Imp2*-H/H had no significant difference between these 2 groups (Table 2).

In DR3-negative subjects The frequency of *Imp2*-R/H in I-DM patients was significantly higher than that in controls, while *Imp2*-R/R and *Imp2*-H/H had no significant differences between these two groups (Table 2).

Table 2 Frequencies of *Imp2* genotypes compared between I-DM patients and controls in DR3-matched subjects

	Positive DR3		Negative DR3	
	I-DM (<i>n</i> = 32)	Controls (<i>n</i> = 15)	I-DM (<i>n</i> = 36)	Controls (<i>n</i> = 56)
R/R	15(0.47) ^a	13(0.87)	14(0.39)	30(0.54)
R/H	15(0.47) ^b	2(0.13)	21(0.58) ^c	18(0.32)
H/H	2(0.06)	0(0.00)	1(0.03)	8(0.14)

Compared with controls: ^a $\chi^2 = 7.50$, $\psi = 0.14$, $P < 0.01$; ^b $\chi^2 = 4.98$, $\psi = 5.74$, $P < 0.05$; ^c $\chi^2 = 6.15$, $\psi = 2.96$, $P < 0.01$.

Distribution of *Imp2* and DR3 in groups with different diabetic onset age

There was a significant difference in DR3 frequency among different groups of diabetic onset age. The frequency of DR3 in group B was not significantly different from that in group C, thus, groups B and C were merged into group B+C, and its frequency of DR3 was 36% (16/45). When group A was compared with group B + C, the χ^2 was 7.07, and $P < 0.01$, indicating that, the younger the age of diabetic onset, the higher the DR3 frequency (Table 3).

There were no significant differences in *Imp2* frequencies among different groups of diabetic onset age (Table 3).

Table 3 Frequencies of *Imp2* genotypes and DR3 gene compared among different age groups of diabetic onset

	<i>n</i>	DR3		<i>Imp2</i>		
		Positive	Negative	R/R	R/H	H/H
Group A	23	16(70%)	7(30%)	11(48%)	10(43%)	2(9%)
Group B	26	11(42%)	15(58%)	8(31%)	17(65%)	1(4%)
Group C	19	5(26%)	14(74%)	10(53%)	9(47%)	0

Difference of DR3 frequency among different age groups of diabetic onset was $\chi^2 = 8.19$, $rp = 0.33$, $P < 0.05$, *Imp2* was $\chi^2 = 4.53$, $P > 0.05$.

DISCUSSION

The relation between DR3 and I-DM Previous studies showed that DR3 is one of the susceptible genes of I-DM in some populations^[1]. We studied the Han population in south China, and found that the frequency of DR3 in I-DM patients was significantly higher than that in controls. It suggests that DR3 may be one of the susceptible genes of I-DM, and the persons with DR3 have a higher risk of suffering from I-DM.

Relation between *Imp2* and I-DM The *Imp2* encoded product is LMP protease, which is responsible for processing antigen, and may play an important role in antigen presentation^[8]. Therefore, *Imp2* may be an attractive candidate as a gene related with susceptibility to I-DM. Studies on the relation between *Imp2* and I-DM were still controversial. A recent study by Deng *et al.*^[9] suggested that *Imp2*-HR may be the protective genotype, and *Imp2*-R/H the susceptible genotype of I-DM, and they may have no linkage disequilibrium to HLA-DR/DQ. Undlien *et al.*^[10] divided the subjects into many subgroups according to HLA-DRB1-DQA1-DQB1, and found that *Imp2* genotypes had no association with I-DM, but, the sample size was too small after divided into subgroups. The studies by Van Endert *et al.*^[11], Kawaguchi *et al.*^[12] and Chauffert *et al.*^[13] yielded the similar results.

Our data indicated that, in random subjects, the frequencies of *Imp2*-R/R and *Imp2*-R/H in I-DM patients were significantly lower, and higher than those in controls respectively (Table 1). Therefore, *Imp2*-R/R may be the protective genotype, and *Imp2*-R/H the susceptible genotype of I-DM. In order to make sure that the effect of *Imp2* on I-DM will be affected by DR3, we investigated the frequency of *Imp2* genotypes in DR3-matched subjects. We divided the subjects into DR3 positive and DR3 negative groups and compared the frequencies of *Imp2* genotypes between I-DM and controls respectively in these groups, and obtained nearly the same results as

those in random subjects (Table 2). Therefore, our data suggested that the relationship between *Imp2* and I-DM may not be affected by DR3 gene. However, we have not study the relationship between *Imp2* and other protective and susceptible genes of I -DM within MHC class II region, so we can not confirm whether *Imp2* genotype s have independent effects on I-DM or not. Nevertheless, our data show that *Imp2* genotypes can predict the risk of I-DM occurrence. The persons with *Imp2*-R/R have a decreased risk, and those with *Imp2*-R/H a increase d risk of suffering from I-DM.

Relation among *Imp2* genotype, DR3 gene and the onset age of diabetics Recently, many studies have shown that I-DM is a heterogeneous disease. The study by Caillat-Zucman *et al*^[8] showed that DRB1, DQA1 and DQB1 were not only associated with the predisposition to I-DM, but also with the onset age of diabetics, and the younger the onset age of diabetics, the higher the frequencies of these genes. Some recent studies by my colleagues showed the same results in DQA1 and DQB1^[9,10]. This study also indicated that DR3 was associated with the age of onset in I-DM and the frequency of DR3 in patients with I-DM developed in childhood (≤ 14 years) was significantly higher than that in adulthood (≥ 15 years), suggesting that the persons with DR3 may have an earlier diabetic onset.

However, our data did not show any differences in frequencies of *Imp2* genotypes among various age groups of diabetic onset, suggesting that the *Imp2* genotypes may not have any association with the age of diabetic onset, and the distribution of *Imp2* genotypes may not be the same as that of DR3, D QA1 and DQB1 in I-DM patients.

Experimental study of "Tong Xia" purgative method in ameliorating lung injury in acute necrotizing pancreatitis

Xia Q, Jiang JM, Gong X, Chen GY, Li L and Huang ZW

Subject headings pancreatitis/ therapy; lung disease; tumor necrosis factor; Tong Xia method

Abstract

AIM To investigate the role of tumor necrosis factor (TNF) in lung injury during acute necrotizing pancreatitis (ANP), and the therapeutic effect of "Tong Xia" purgative method in minimizing the severity of lung injury. **METHODS** Fourteen canines were randomly divided into 3 groups: the "Tong Xia" treatment group ($n = 5$) using Dachengqitang; saline control group ($n = 5$), and the sham operation group ($n = 4$). TNF activity in serum and in bronchoalveolar lavage fluid (BALF), the serum endotoxin levels were measured, and the severity of lung injury evaluated.

RESULTS Elevation of TNF activity was more prominent in BALF than in serum. TNF activity in serum at 6 and 12 hours and in BALF was significantly decreased in the "Tong Xia" treatment group than in the saline control one ($q = 21.11$, $q = 12.07$, $q = 9.03$, respectively, $P < 0.01$) and the lung injury was significantly alleviated at 12 hours as compared with that in the saline group, manifested as amelioration of the lung wet/dry weight ratio, decrease in protein concentration and neutrophils count in BALF, and improvement of pulmonary inflammatory changes. A positive correlation was demonstrated between serum TNF activity

and endotoxin level.

CONCLUSION Hypersecretion of TNF is shown to be one of the major causes of lung injury during ANP; "Tong Xia" purgative method could alleviate the degree of lung injury mediated by TNF.

INTRODUCTION

In the process of the multiple organ dysfunction syndrome (MODS) caused by severe acute pancreatitis, acute lung injury (ALI) occurs most frequently. A number of cytokines are involved in ALI caused by severe acute pancreatitis due to excessive stimulation of monocyte macrophages provoked by endotoxin. Dachengqitang can inhibit the absorption of enterogenous endotoxin and relieve endotoxemia so as to prevent and ameliorate the MODS including the lungs. The purpose of this study is to investigate the effects of TNF on ALI in acute necrotizing pancreatitis (ANP) and to determine whether the herb mixture could relieve the ALI, and investigate its mechanism of action.

MATERIALS AND METHODS

Grouping of experimental animals

Fourteen healthy adult canines, male and female, weighing 7.7 kg-9.9 kg (8.8 ± 1.1), were used. The ANP model canines were divided randomly into 3 groups, *i.e.* saline control group ($n = 5$), Dachengqitang treatment group ($n = 5$), and sham operation group ($n = 4$).

Preparation of animal models

ANP models were made by the retrograde injection of 5% sodium taurocholate into the pancreatic duct. The canines were only accessible to drinking water, 24 hours later were anesthetized with 3% pentobarbital sodium (1 mL/kg) intraperitoneally

in normal saline ($10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) dripping continuously. A median incision was made in the upper abdomen to expose the duodenum, then a transverse incision (2 cm) was made at the level of the orifice of the main pancreatic duct. A catheter was inserted and 5% sodium taurocholate (1 mL/kg) was injected into the pancreatic duct at a pressure of 16 kPa, then pulled out, the duodenal dwelling catheter was placed, and Chinese herbal medicine or normal saline could be given via the duodenum. In sham operation group, the catheter was pulled out and no medicine or saline was given.

Preparation of Chinese herbal medicine

Dachengqitang consisted of -Radix at Rhizoma Rhei 30 g, Natrii Sulfas 20 g, Cortex Magnoliae Officinalis 30 g, and Fructus Aurantii Immaturus 15 g. The latter two were decocted for 25 minutes with 500 mL water, then added with Radix at Rhizoma Rhei, decocted for another 3 minutes, and then filtered to yield 150 mL medicinal fluid. Finally, the Natrii Sulfas was added. In treatment group, 50 mL of the medicinal fluid and saline were given through the duodenal fistula tube at 0.5, 4 and 8 hours, respectively.

Observation indices

Serum amylase It was measured before the model was made and at 2, 6 and 12 hours after.

Serum endotoxin It was measured with the of azo coloration before the model preparation and at 2, 6 and 12 hours after, 2 mL blood was drawn from the femoral vein, and the serum was isolated for measurement. The standard curve correlation coefficient was $r = 0.999$.

Serum TNF activity It was measured with the method of the mouse fibroblast L_{929} biological activity quantitative analysis, the same procedure was carried out before and after.

Broncho-alveolar lavage fluid (BALF) The canines were exsanguinated to death 12 hours after the model preparation. After thoracotomy, the whole lungs together with the trachea were taken out, the left bronchus was ligated and the left lung was removed and weighed; the right lung together with the trachea was used for lavage purpose. The surface blood was washed away with normal saline. A total of 100 mL of normal saline was repeatedly lavaged for 5 times, and 80 mL of the lavage fluid was collected. Ten mL was centrifuged, and 2 mL of supernatant was obtained for protein content measurement; another 2 mL was used for the TNF

activity measurement. The sediment was stained for the counting of all kinds of nucleated cells.

Pathological examination The lung and the pancreatic tissues were sectioned and preserved in 10% formalin fluid.

The lung wet/dry weight ratio The wet left lung was weighed and placed in the oven for 24 hours at 60°C , and weighed when it was dry. The wet/dry weight ratio was calculated.

Statistical analysis

All data were placed in the computer for the statistical analysis with the STATA statistics software.

RESULTS

Autopsy findings

Abdominal cavity In both saline control group and treatment group, as much as 300 mL-500 mL of bloody ascitic fluid were present. There was no statistical significance between them. In sham operation group, only a small amount of clear ascitic fluid was noted. In saline control group and treatment group, the pancreas appeared violet black and enlarged, subserous hemorrhage and a little saponification were observed.

The lungs In saline control group, there were various degrees of pulmonary edema and extensive patchy or petechial hemorrhage. In treatment group, the pulmonary edema was less severe without any patchy hemorrhage. In sham operation group, the lung tissue was normal.

		Negative	Mild	Moderate	Severe	0	I	II	III
Saline	5			2	3		1	3	1
"Tong Xia"	5			3	2		4	1	
Sham operation	4	4				4			

DISCUSSION

MODS is frequently seen in severe acute pancreatitis. It is probably due to the cytokines produced by excessive activation of the monocyte-macrophage system, and the influx and infiltration of polymorphonuclear leukocyte cytokines as TNF, IL, inflammatory mediators, phospholipase A₂, oxygen free radicals, cathepsin may all contribute^[4]. Among them TNF plays an important role in the processes. Many authors reported that TNF activity was increased in the serum and BALF from the patients with severe acute pancreatitis and adult respiratory distress syndrome^[5]. Majority of the authors believed that the increase in TNF activity was due to excessive stimulation of mononuclear-macrophage by endotoxin. In this study, serum TNF activity was remarkably increased, which indicated and was involved in the pathophysiological processes of ANP. TNF activity was also increased more markedly in the BALF than that in the serum, which suggested that TNF also came from pulmonary alveolar macrophages. There was a positive correlation between serum TNF activity and endotoxin level, which indicated that

the increase in TNF activity was caused by the stimulation of endotoxin. In BALF, polymorphonuclears and macrophages were both increased more remarkably than those in sham operation group, indicating the involvement of polymorphonuclears in the lung injury. In treatment group, at 6 and 12 hours after the model preparation, TNF activities in both serum and BALF were lower than those in saline control group, and the lung injury was also much milder, indicating that Dachengqitang could ameliorate the lung injury mediated by TNF.

“Tong Xia” therapeutic method, is an important part of traditional Chinese medicine in treating acute pancreatitis, and has been studied extensively by Chinese scholars. As regards to the therapeutic mechanism, the herb mixture by purgation could decrease the absorption of the gut endotoxin, ameliorate the endotoxemia and translocation of gut bacteria, and protect the gut barrier function. In this study, at 6 hours after

ANP, the serum endotoxin level was a little lower in the treatment group than that in saline control one, and the serum TNF activity was lowered very much, suggesting that Dachengqitang inhibited TNF activity via inhibiting the absorption of endotoxin.

Prevalence of primary *Helicobacter pylori* resistance to metronidazole and clarithromycin in Singapore

Hua JS, Bow H, Zheng PY and Khay-Guan Y

Subject headings *Helicobacter pylori*; triple therapy; metronidazole; clarithromycin

INTRODUCTION

Eradication of *Helicobacter pylori*, a bacterium residing in stomach and causing peptic ulcer disease, can be achieved by using combination therapies consisting of one or two antibiotics with a proton pump inhibitor (PPI). The major antibiotics widely used in the regimens to eradicate *H. pylori* are metronidazole and clarithromycin^[1-3]. However, resistance to these antibiotics by *H. pylori* affects the effectiveness of treatment. Treatment failure is often associated with resistance to metronidazole and clarithromycin^[4-7]. In the United States, the frequency of resistance to metronidazole is about 25% with range from about 20% to more than 50%^[8]. In the Netherlands and Germany, the incidence of metronidazole resistance is 17%^[9] and 32%^[10], respectively. In contrast, the prevalence of metronidazole resistance in developing countries was reported to be as high as 70%-90%^[4].

Compared to metronidazole resistance, clarithromycin resistance is low with a range of 7%-14% in the United States^[8], 1% in the Netherlands^[9] and 3% in Germany^[10]. Data on clarithromycin resistance in developing countries are rare.

The rise in antibiotic resistance emphasizes the need for surveillance of *H. pylori* sensitivity to antibiotics as in other infectious diseases. These data will allow clinicians to choose suitable therapy

for their patients. The present study provides recent data on the prevalence of primary metronidazole and clarithromycin resistance of *H. pylori* in Singapore.

MATERIALS AND METHODS

H. pylori strains isolated from 282 consecutive of *H. pylori* positive patients (108 females and 174 males) undergoing routine endoscopy with informed consent for dyspepsia at the Singapore National University Hospital were included in this study. None of the 282 patients had been previously treated for *H. pylori* or had known exposure to antibiotics, bismuth compound or proton pump inhibitor in the past four weeks. Methods for isolation and culture of *H. pylori* were described previously^[11,12]. Briefly, 2 gastric biopsies were obtained from the gastric antrum within 2cm of the pylorus from each patient. The biopsies were transported in 0.85% sterile saline to the laboratory for processing within 24h. The two biopsies were smeared onto a chocolate blood agar plate (blood agar base No.2 supplemented with 5% horse blood) without antibiotics followed by smearing onto a chocolate blood agar plate supplemented with antibiotics (vancomycin 3mg/L, colistin methane sulphate 7.5mg/L, nystatin 12500U/L and trimethoprim 5mg/L). The plates were incubated at 37°C in a humidified incubator (Forma Scientific) with 5% CO₂. Identification of *H. pylori* isolates was based on the results of Gram staining, cell morphology and positive reaction for catalase, oxidase and urease activity. These isolates were further confirmed by API ZYM Kit (BioMérieux)^[13], a semiquantitative micromethod for the rapid detection of the presence of 19 preformed enzymes.

The disk diffusion test was used for the testing of bacterial sensitivity to antimicrobial agents. An inoculum of 0.2 mL of *H. pylori* suspension equivalent to McFarland 3 turbidity standard was spread onto the chocolate blood agar plate. The plates were dried completely for 5 min - 10 min before a metronidazole disk (5µg, Oxoid) or clarithromycin disk (15 µg, Oxoid) was placed on the surface of each dried agar plate. These plates were incubated at 37°C in 5% CO₂ atmosphere for

Received 1999-09-22 **Accepted** 1999-11-15

2-4 days. The inhibitory zone around each antibiotic disk was recorded accordingly. Inhibitory zones of less than 15mm for metronidazole^[14,15] and 30mm for clarithromycin^[16] were considered resistance.

Fisher's exact test was used for statistical analysis. *P* value of less than 0.05 was considered to be statistically significant.

RESULTS

In a total of 282 *H. pylori* isolates, resistance to metronidazole was found in 130 isolates (46%; 95% confidence interval, 40.3% - 51.9%) and clarithromycin in 18 isolates (6%; 95% confidence interval, 3.2%-8.8%), respectively. Eight of 18 isolates (3%; 95% confidence interval, 1.92% - 3.68%) resistant to clarithromycin were also resistant to metronidazole.

Of the 20 isolates obtained in 1995, 4 (20%; 95% confidence interval, 2.5% - 37.5%) isolates were resistant to metronidazole. Of the 36 isolates obtained in 1996, 19(53%; 95% confidence interval, 36.7%-69.3%) isolates were resistant to metronidazole. In 1997 and 1998, 40/83 (48%; 95% confidence interval, 37.8%-58.7%) and 67/143 (47%; 95% confidence interval, 39.9%-54.1%) isolates were found to be resistant to metronidazole, respectively (Table 1).

Of 282 isolates, 50/108(47%; 95% confidence interval, 37.5%-56.4%) and 80/174 (46%; 95% confidence interval, 38.6%-53.4%) isolates from females and males, respectively, were found to be resistant to metronidazole. No statistical difference was found between two genders (*P*>0.05).

Table 1 Prevalence of metronidazole resistance to *H. pylori*

Year	No.	Resistant isolate	Resistance %
1995	20	4	20
1996	36	19	53
1997	83	40	48
1998	143	67	47
Total	282	130	46

DISCUSSION

This study showed that during the 4 years period of investigation the metronidazole resistant rate increased from 20% in 1995 to 47% in 1998 with an average of 46% in 282 *H. pylori* isolates from Singapore. Our previous investigation in 1994 revealed 13% metronidazole resistant rate in 43 isolates^[17]. It is, therefore, believed that resistance to metronidazole in Singapore rose to reach a platform of about 50%. On the other hand, clarithromycin resistance was 6% in the total of 282 isolates from Singapore in this study.

Since metronidazole attains high concentration in the stomach and is not influenced by pH, it is among the most antibiotics to be used to eradicate *H. pylori*. However, the effectiveness of treatment was compromised by emergence of metronidazole resistance^[4-7]. Thus, it is of great importance to monitor the resistance. The prevalence of metronidazole resistance varies widely from country to country. A study of multicentre in Europe showed that metronidazole resistance is 28% with large variation from 7% in Spain to 49% in Greece^[18]. Recent studies from Germany^[10] and the Netherlands^[9] reported the prevalences of metronidazole resistance are 32% and 17%, respectively. The finding of 46% of metronidazole resistance in Singapore in this study is relatively higher than those of developed countries, but the 6% of clarithromycin resistance in Singapore is similar to those in developed countries, such as 10% in France^[19], 5% in Ireland^[16], 1% the Netherlands^[9], 3% in German^[10] and 7%-14% in the United States^[8]. This may be due to the fact that the history of metronidazole application in treating infectious diseases other than *H. pylori* in Singapore is much longer than that of clarithromycin. However, if the use of clarithromycin increases, the clarithromycin resistance could pose a serious problem in eradication of *H. pylori* in the future.

In 8 of 18 clarithromycin resistant isolates, metronidazole resistance was also found. The combination of resistance to 2 antibiotics has been reported elsewhere^[9,10,18]. The data remind gastroenterologists to be cautious in the use of triple therapy comprising both clarithromycin and metronidazole when they treat patients with peptic ulcer disease. Such therapy if administered to patients infected with *H. pylori* which is resistant to both clarithromycin and metronidazole may result in treatment failure. On the other hand, the treatment may overcome the problem if the isolate is resistant only to one of these two antibiotics.

It is interesting to note that there is no discrimination of metronidazole resistance in terms of gender distribution. This is in contrast to the reports from Europe which state that women are more likely to harbour resistance metronidazole than men^[8-10]. This difference possibly reflects equal exposure of metronidazole to males and females in Singapore.

In conclusion, in Singapore the prevalence of resistance to metronidazole is high (46%) as compared to developed countries. However, the prevalence of clarithromycin resistance is comparatively low (6%). The surveillance of *H. pylori* susceptibility to antibiotics is critical in guiding the clinicians on the effectiveness of

treatment regimens. If antibiotic susceptibility testing of *H. pylori* is not available, it is suggested that the clarithromycin-contained triple regimen be preferred to metronidazole-contained triple regimen in local population.

Schistosomiasis: progress and problems

Wu GY and Halim MH

Subject schistosomiasis;
development; immune response; diagnosis;
treatment

INTRODUCTION

Schistosomiasis, also commonly known as bilharziasis, is one of the most significant parasitic diseases of humans. A report of World Health Organization in 1996 estimated that over 200 million people were infested worldwide, mainly in rural agricultural and periurban areas. Of these, 20 million suffer severe consequences from the disease and 120 million are symptomatic. Symptoms range from fever, headache and lethargy, to severe sequelae including ascites, hepatosplenomegaly and even death^[1]. More than 600 million people in the tropics are at risk for developing schistosomiasis. Schistosomiasis is the major public health problem in rural Egypt, with almost six million Egyptians are infested^[2].

Schistosomiasis is caused by digenetic trematodes belong to phylum platyhelminthes, super family schistosmatoida, genus schistosoma. It is usually attributed to three species, subdivided into intestinal *Schistosoma mansoni* and *Schistosoma japonicum* or urinary *Schistosoma hematobium* types, according to the site preferred by the adult worms. In Egypt, the two species of bilharziasis are *Schistosoma mansoni* and *hematobium* whose intermediate hosts are fresh water snails, *Biomphalaria alexandra*, and *Bulinus truncatus* respectively^[3].

In humans, these blood flukes reside in the mesenteric and vesical venules. They have a life span of many years and daily produce large numbers of eggs, which must traverse the gut and bladder tissues on their way to the lumens of the excretory organs. Many of the eggs remain in the host tissues, inducing immunologically mediated granulomatous inflammation and fibrosis. Heavy worm burdens may produce hepatosplenic disease in schistosomiasis

mansoni and *japonica* and urinary tract disease in schistosomiasis hematobia. Because both the schistosomes and the eggs utilize host metabolites, and because the host responses to the parasite are affected by its nutritional status, malnutrition may strongly affect both the parasite and the complex host-parasite relationship^[4].

HISTORICAL REVIEW

Egyptians have had a long history of symptoms caused by schistosomiasis, notably hematuria, which appeared classically in young boys and was once deemed to be a sign of puberty. It was in Egypt in 1851 that Theodore Bilharz discovered, in autopsy material that the causative agent of hematuria was *schistosoma*^[2].

In 1903, Manson^[5] observed lateral spined eggs in the feces of a patient who had no hematuria. He suggested that more than one species of the worm was involved in the vesical and intestinal forms of the disease on grounds of dissimilar geographical distribution of both types of infestation.

In 1907, Sambon^[6] verified Manson's suggestion and named the worm that produced lateral spined eggs and caused intestinal infestation as *Schistosoma mansoni*.

In 1915, Leiper^[7] discovered the two genera of snails in Egypt (*Bulinus* and *Biomphalaria*) that transmitted the two species *S. hematobium* and *S. mansoni*, respectively.

In 1937, Scott^[8] reported on the prevalence of schistosomiasis in 100 Egyptian Villages. At that time, *S. hematobium* infestations were common, while *S. mansoni* infestations were rare in the Nile delta. Since 1977 this pattern of schistosomiasis in Egypt changed as the prevalence of *S. mansoni* infestation increased and of *S. hematobium* decreased. This change has important public health implications, because the hepatosplenic schistosomiasis caused by *S. mansoni* is more difficult to trace and is associated with more morbidity and mortality than the urinary schistosomiasis caused by *S. hematobium*^[9].

LIFE CYCLE OF-SCHISTOSOMA-PARASITE

The three species of schistosomes that commonly affect human (*S. hematobium*, *S. mansoni* and *S. japonicum*) have similar life cycles and develop by a succession of stages: the egg, miracidium, first stage sporocyst, second stage sporocyst, cercariae, schistosomule and adult.

All the species of schistosomes are contracted in the same way: by direct contact with infested surface water containing free-living forms of the parasite known as cercariae, which can penetrate the skin. Schistosome cercariae consist of a tail, used for motility in the water, and a head region, which is used for attachment to host skin, and glands containing proteolytic enzymes to facilitate penetration of the skin.

During penetration of the skin, the tail is shed and several other major changes accompany transformation into a new form called the schistosomulum. After penetrating the wall of a nearby vein, schistosomes are carried in the host blood flow, eventually reaching the liver where they grow and reach sexual maturity. The mature male and female worms pair, and then, depending on species, migrate to the vessels of the bowel or bladder where egg production occurs. Many eggs pass through the intestinal or bladder wall and are excreted in the feces or urine. The schistosome life-cycle is completed when the eggs hatch, releasing free-swimming miracidia, which in turn, reinfect freshwater snails.

Rather than being excreted, however, some of the eggs may lodge in the tissues of the host. It is the presence of these retained eggs, rather than the worms themselves, that causes the pathology of schistosomiasis. In intestinal schistosomiasis, eggs lodged in the mucosa or submucosa of the gut cause granulomatous reactions, which may extend into the gut lumen as pseudopapillomas, resulting in colonic obstruction and blood loss. Eggs lodged in the liver result in portal fibrosis, leading to portal hypertension, splenomegaly, ascites, esophageal and gastric varices. Exsanguination from bleeding esophageal varices is the major cause of death^[10].

DEVELOPMENT OF SCHISTOSOMA

In vitro cultivation methods can provide useful insights into the biology, nutrition and immunology of schistosomes. Among the key issues in parasite cultivation is the degree to which cultured organisms resemble their counterparts reared in normal hosts^[11].

Trials to cultivate *S. mansoni* from cercariae have led to production of nonviable eggs by worm pairs grown entirely *in vitro*^[11].

In 1974, Tiba *et al*^[12] showed that artificially prepared schistosomes can develop to maturity when injected into mice shortly after preparation. Basch *et al*^[13] demonstrated that 2 hour and 13 day old schistosomes grown *in vitro* from *S. mansoni* cercariae can complete normal development successfully after implantation into mouse mesenteric veins.

Clemens *et al*^[14] also studied the rate

development of *S. mansoni* schistosomes *in vitro*, as determined by developmental milestones and thymidine incorporation into DNA.

An alternative approach, the study of egg production by pairs of mature worms maintained *in vitro*, has not been productive. In general, egg laying has been observed for only a few days after adult worms were transferred from the host to cultures and ceased after the 10th day^[15].

In 1986, Wu *et al*^[16] demonstrated that the portal serum from various mammalian sources have components that stimulated *S. mansoni* oviposition *in vitro*.

In 1993, Hobbs *et al*^[17] established protocols for the initiation and maintenance of cultures from juvenile worms of *S. mansoni*. These cultures exhibited properties characteristic of the organism from which they originated and could be maintained for as long as 6 months *in vitro*.

The work of Taylor *et al*^[18] and Taylor^[19] showed that in single-sex infestations, schistosomes migrated to the portal-mesenteric venous system, indicating that each sex is capable of locating the preferred site independent of the other sex. Blood draining to the portal vein is derived from the gastrointestinal tract. Therefore, it is different from the peripheral blood in many respects^[20]. The site preference of *S. mansoni* could be dependent on a constituent of portal blood that is not present in the periphery. This might take the form of a substance that the parasite recognizes or requires to develop.

It has been shown that egg production can be stimulated by portal serum components added to culture media, but not by serum from peripheral blood^[21]. This occurred regardless of whether the host is a natural or not. More recently, immature schistosomes in culture have been shown to have enhanced cellular proliferation when portal serum was added to the medium. This effect could not be reproduced by serum obtained from the vena cava. Furthermore, when the serum was fractionated, the size of the stimulatory substances was estimated to be larger than would be expected for simple nutrients absorbed from the gut^[22].

In experimental animals, granuloma formation has been shown to be induced and elicited by soluble egg antigens (SEA) secreted by the miracidia within eggs^[23]. Over the years, several laboratories have isolated antigenic fractions from crude egg homogenates. A number of partially purified glycoproteins have been shown to possess serological, dermal, lymphocyte-stimulating, hepatotoxic, and granuloma inductive properties^[24]. However, the relative importance of the various fractions as granulomatogenic agents remains unexplored. More recently, the differential

responsiveness of acute-versus chronic-infestation murine lymphocytes to a panel of SEA-derived fractions has been demonstrated. A 38-kDa fraction was found to be egg stage specific, to elicit strong lymphokine production *in vitro*, and to induce granuloma formation *in vivo* during the acute stage of murine schistosomiasis^[25].

THE IMMUNE RESPONSE IN SCHISTOSOMIASIS

The immunology of schistosomiasis is largely dependent on the biological characteristics of the parasite itself. After skin penetration, schistosome undergo a complex migratory life cycle in the vertebrate host before they settle, in the case of *S. mansoni*, in the blood vessels of the portal and mesenteric system. In this intravascular situation, the adult worms release a large amount of excretory or secretory material, which elicits a strong antibody response. Antigens may be found in the serum and various body fluids in the form of free antigens, and more generally as immune complexes^[1]. This continuous release of soluble antigens has important implications in the regulation of the immune response, both in terms of antigenic competition and as direct factors of immunosuppression or tolerance. The major role of antibodies in protective immunity is to induce cytotoxic destruction of schistosome targets, and antibody-cell mediated cytotoxicity appears to be the main mechanism for destruction of parasites both in rat and human schistosomiasis^[26].

The persistence of the trematodes in an immunologically hostile environment has been attributed to their ability to acquire or synthesize, during their maturation, surface antigenic determinants (host antigens) to which the animal is unresponsive^[27]. The worm tegument, which undergoes a continuous and rapid turnover, acquires numerous host molecules ranging from various serum proteins or glycolipid to major histocompatibility antigens. This phenomenon has been considered as an essential escape mechanism^[28-30].

It has been assumed from epidemiological studies in endemic areas that age-dependent immunity may develop against infestation, or against reinfestation after treatment, with *S. mansoni*^[31] or *S. hematobium* infestation^[32]. Using a mathematical model, it has also been shown that predicted patterns of variation in age-related changes in the intensity and prevalence of *S. hematobium* infestation are consistent with the epidemiological effects of acquired immunity^[33]. At present, however, there is no effective vaccine against schistosomiasis or any other human parasitic disease. In order to develop such vaccines, it is obviously important to elucidate mechanisms involved in protective immunity at the cellular and

molecular levels because of the complex life cycle and stages of parasites which occur in the human body.

CLINICAL MANIFESTATIONS

Clinical manifestations reflect developmental stages of the parasites and host responses to toxic or antigenic substances derived from the parasite and eggs.

During the early stage of infestation, the patient may present with signs caused by cercarial penetration of the skin (cercarial dermatitis), followed by bronchopulmonary manifestations attributed to the passage of schistosomes through the lungs. Approximately five weeks after infestation, more dramatic symptoms, often known as Katayama Disease consist of malaise, weight loss, gastrointestinal symptoms, eosinophilia and fever. They are caused by the initial deposition of eggs by female worms^[34].

In the case of *S. japonicum* and *S. mansoni*, female worms lay eggs in the mesenteric branches of the portal vein along the intestinal wall and although a relatively large part of the eggs are carried into the liver and other organs by the blood flow, the remainder of them may stay in the small venules until the embryo they contain develop in to miracidia within 10 days. Antigenic substances excreted from miracidia diffuse out through submicroscopic pores in the egg shell, and elicit an acute inflammation in the surrounding tissues, resulting in the rupture of the vascular wall and escape of the eggs from the venules through the intestinal submucosa and mucosa into the intestinal lumen. The inflammation causes recurrent daily fever, abdominal pain and enlarged tender liver and spleen, and discharge of eggs into the intestinal canal is accompanied by dysentery or diarrhea^[35]. Blood chemistry may reveal a transient elevation of glutamic pyruvic transaminase, glutamic oxaloacetic transaminase and alkaline phosphatase 5-6 weeks after infestation. Eosinophilia may be observed in most of the patients with or without increase of leukocyte counts. Serum level of IgE may increase as observed in other helminth infestations^[36].

Chronic schistosomiasis is characterized by a series of chronic inflammatory lesions produced in and around blood vessels by the eggs or their product^[37]. The chronic manifestations in *S. japonicum* and *S. mansoni* infestations is characterized by hepatosplenomegaly, although development of polyps or mucosal proliferation of the intestine may also be observed in most cases. Egg granulomas are replaced by fibrotic tissues, which are prominent in the periportal areas and lead to the development of pipestem fibrosis^[38].

Hepatosplenic schistosomiasis refers to the

major complication of chronic infestation with *S. mansoni* and *S. japonicum*. Hepatosplenic schistosomiasis is usually, but not invariably, associated with enlargement of the liver and spleen, and reversible hepatosplenomegaly may occur in early infestations not complicated by the development of portal hypertension^[39].

The liver is invariably involved in intestinal schistosomiasis, but the extent of such involvement depends on many factors including intensity of infestation and duration of infestation which are mainly responsible for the changes produced. The liver gradually decreases in size, but increases in hardness as fibrosis is gradually extended into the parenchyma, resulting eventually in liver cirrhosis in severe cases. The enlarged spleen may reach the level of the umbilicus or even at times expand to fill most of the abdomen^[35].

End stage hepatosplenic schistosomiasis may be complicated by features of hepato cellular failure, ascites often being the most obvious clinical sign. While this may all result from severe schistosomiasis, the possibility of other coexistent liver disease must be considered. In Nairobi, two of 25 patients considered to have schistosomal portal hypertension also had histological evidence of cirrhosis^[39].

The portal hypertension of schistosomiasis is presinusoidal and presumably related to the portal zone reaction^[40]. In advanced schistosomiasis, hepatic arterial hypertension contributes to increased sinusoidal pressure^[41]. Retrograde flow develops in the portal vein. Hepatic blood flow is not significantly reduced.

At the stage when hemorrhage occurs from varices, the granulomatous reaction may have subsided and the picture is predominantly that of fibrosis^[42]. Portal hypertension is considered present when the portal vein pressure is raised to 5 mmHg above inferior vena caval pressure, when the intrasplenic pressure is above 15 mmHg, or when the portal vein pressure measured directly at surgery is above 30 mmHg^[43]. While portal hypertension is a prerequisite for the development of a collateral circulation, in cirrhosis the risk of bleeding cannot be directly correlated with the exact portal vein pressure, although hemorrhage is unlikely in cases where the portal vein pressure is less than 10 mm Hg above inferior venal caval pressure^[44].

Cirrhosis is defined anatomically as a diffuse process with fibrosis and nodule formation^[45]. It has followed hepato-cellular necrosis. Although the causes are many, the end result is the same.

Fibrosis is not synonymous with cirrhosis. Fibrosis may be in zone 3 in heart failure, or in zone 1 in bile duct obstruction and congenital hepatic

fibrosis or interlobular in granulomatous liver disease, but without a true cirrhosis^[42].

Urinary schistosomiasis is caused by *S. hematobium* and affects the genito-urinary system. The stage of oviposition is manifested by genito-urinary trouble such as cystitis, dysuria with terminal hematuria, dull suprapubic pain, spermatorrhea and hemospermia. Spontaneous recovery is rare and the condition may be complicated by the bladder ulcer, calculi, polyps, fistulae, hydronephrosis or carcinomatous changes of the bladder^[46].

The association of bladder cancer with *S. hematobium* has been discussed in the context of the involvement of urinary tract infestations by species of nitrate-reducing bacteria. The urine of patients infected with *S. hematobium* contained higher levels of nitrosamines, in association with nitrate-reducing bacteria, than the urine of either Egyptian or German controls, and this may result in the endogenous formation of carcinogenic N-nitrosocompounds in the urine^[47].

The involvement of gynecological organs may be observed in *S. hematobium* infestation. As a disease entity, female genital schistosomiasis has been neglected, despite the fact that vaginal schistosomiasis was reported from Egypt as early as in 1899. It has generally been considered that the presence of *S. hematobium* eggs is not as common in female genital organs as in male genital organs, although in the female lesions are found in the vulva, vagina, cervix and less commonly the ovaries, fallopian tubes or uterus^[48]. However, *S. hematobium* may migrate through the network of female pelvic vasculature during puberty and especially during pregnancy make ectopic localization of the parasites possible^[49]. Because sexually transmitted disease increase the probability of HIV transmission, presumably through lesions in the genital mucosa, female genital schistosomiasis may be an important risk factor for transmission of HIV^[50].

PATHOGENESIS AND PATHOLOGY

The pathological changes in schistosome infestations are caused mainly by the deposition of the eggs into various tissues and organs where granulomas or pseudo tubercles are formed around them. In primary infestations, the granuloma is composed of aggregations of mononuclear phagocytes, neutrophils, lymphocytes, plasma cells and fibroblasts. Giant cells are also frequently observed in the granulomas. Granulomas may vary in size and cellular components with the immune status of the host in experimental infestations in immunized animals, a dominant cellular infiltration of eosinophils and lymphocytes is observed around the

eggs and the egg granuloma is smaller^[35].

Granuloma formation around schistosome eggs has been considered to be the result of delayed-type hypersensitivity reactions mediated through a T cell mediated immune response to soluble egg antigens^[51]. However, recent studies have demonstrated that there exist at least 2 subsets of T helper cells with a CD4 phenotype, termed Th1 and Th2 cells, which can be distinguished from each other by their cytokine production^[52]. The cytokines derived from Th1 cells, such as IL (IL)-2, interferon or tumor necrosis factor (TNF), may be responsible for activation of macrophages and cell-mediated immunity, whereas IL-4 or IL-5, the cytokine produced by Th2 cells, stimulates IgE production or eosinophilia, respectively^[53].

DIAGNOSTIC TESTS

Decisions on individual and community treatment, estimations on prognosis and assessment of morbidity, evaluation of chemotherapy and control measures all depend on the results from diagnostic tests. Selection and application of methods should, therefore, correspond to the type of information sought by the clinician or the epidemiologist^[54].

Specific diagnosis of schistosomiasis can be made by detection of the characteristic eggs in the stools or urine under microscopic examination.

In *S. mansoni*, where eggs are excreted in feces, simple concentration and sedimentation of fecal specimens are reliable. Many concentration techniques have been described^[55]. These involve removal of fat, fecal debris and mucus and require more sophisticated laboratory facilities. They find their optimum use in the detection of "light" infestations where few eggs are excreted or, in some cases, eggs are excreted intermittently.

Currently, the cellophane thick fecal smear, the Kato technique^[56], or one of its numerous modifications^[57,58] have become standard diagnostic tools in epidemiological studies. They are simple microscopic methods which examine about 50 mg of stool and are quantitative thus permitting comparison of data.

Infestation with all human schistosome species are efficiently diagnosed through microscopic examination of minute biopsies of the rectal mucous. Snips are taken from suspicious lesions or if absent, from the plica transversalis recti. Even in infestation with *S. hematobium*, eggs are frequently detectable in rectal snips^[59,60]. Since rectoscopy is an invasive technique, its application is limited to the hospital or the experienced gastroenterologist^[61] has, therefore, advocated rectal swabs with for patients in areas that lack these resources.

It is rarely necessary to resort to liver biopsy

for diagnosing infestation with intestinal schistosomes, but where this has been done, the examination of hepatic tissue in crush preparations is more efficient than sectioning of the material. The probability of aspirating tissue that contains egg granulomas is rather low in conventional and even ultrasound-guided fine needle liver puncture^[62].

Moreover, diagnosis of peripheral fibrosis is made with similar efficiency by means of ultrasonography and, therefore, does not require biopsies with histological sectioning^[63]. Except when carcinoma of the bladder is considered as differential diagnosis, cystoscopy and bladder biopsy seem wholly unjustified. In contrast, filtration of several 24 h urine samples is commonly available in hospital and frequently leads to the detection of ova in urine^[64]. Furthermore, Burki *et al*^[65] have demonstrated that ultrasonography compares favorably with cystoscopy and pyelography to detect specific pathology.

Indirect methods for the diagnosis depend on clinical symptoms and signs, and biochemical or immunological analyses. Especially for urinary schistosomiasis, hematuria is a suggestive sign and microhematuria or proteinuria may correlate well with the intensity of infestation in endemic areas^[66]. In intestinal schistosomiasis, the repeated presence of blood in stool is indicative of high intensity of infestation^[67].

Immunodiagnosis may be useful for demonstration of active or chronic schistosome infestation. A unique immunological method for the diagnosis of schistosomiasis is the circumoval precipitin (COP) test in which precipitate is formed around the eggs containing live miracidia after incubation in the serum of infected individuals^[68].

The enzyme linked immunosorbent assays (ELISA) is also widely used in diagnosis. Furthermore, ELISAs for the detection of circulating anodic antigen (CAA) and circulating cathodic antigen (CCA) in serum and urine have been developed and applied as an epidemiologic tool in a recent, intense focus of *S. mansoni* in Senegal^[69]. CAA and CCA in serum and CCA in urine were found in 94%, 83% and 95%, respectively, of the population of which 91% were positive on stool examination. Circulating antigens were also detectable in sera and urine of most egg-negative individuals. The sensitivities of the urine CCA and serum CAA ELISA were substantially higher than that of a single egg count and increased with egg output. The CAA and CCA levels correlated well with egg counts and with each other. The age related evolution of antigen levels followed a similar pattern to egg counts, providing supplementary evidence for a genuine reduction of worm burden in adults in spite of the supposed

absence of acquired immunity in this recently exposed community^[70].

TREATMENT OF SCHISTOSOMIASIS

There have been great advances in chemotherapy of schistosomiasis during the past 2 decades. Compared to antimonials, which were the only available chemotherapeutic agents for schistosomiasis from the 1920s to the 1960s, new drugs are more consistently effective, less toxic and applicable to oral rather than parenteral administration, thereby making field trials of mass chemotherapy feasible^[35]. The major antischistosomal drugs that have been or still are in use against infestation with schistosomes are metrifonate, oxamniquine and praziquantel and all three are included in the World Health Organization list of essential drugs^[70].

The classification of antischistosomal drugs can now be simplified into two categories^[71]:

1-The one drug effective against all species of schistosomes infecting man (praziquantel).

2-The other drugs effective against one species of schistosomes *i.e.* the monospecific drugs: oxamniquine, effective only against *S. mansoni* and metrifonate, used in *S. hematobium* infestations.

Praziquantel is the newest and most effective drug for treating schistosomiasis occurring in man^[72]. It is effective orally in a single dose (40 mg·kg⁻¹) yielding 70% to 95% cure rates against all species of schistosomes infecting man. With few significant side effects and no adverse reactions on liver, renal, hematopoietic or other body functions, praziquantel is undoubtedly the most advanced in antihelminthic chemotherapy of recent decades.

The exact mode of action of praziquantel is unknown. Most evidence implicates the susceptibility of muscle and tegumental systems as important sites of action. Praziquantel's effect on worms is very dramatic. Worms exposed to 1μM praziquantel *in vitro* show almost an instantaneous and sustained contraction with a half-maximal effect time of 12 sec. This contraction results in paralysis of the parasite leading to the hepatic shift observed *in vivo* which is 95% complete within 5min after a single oral dose for infested mice^[73].

The effect of praziquantel on worm muscle tension seems to result from the ability of the drug to increase the permeability of the worm muscle cells to calcium ions. Praziquantel also, causes severe destruction of the worm's tegument^[74].

Recently, however, the possible existence of an *S. mansoni* isolate tolerance to praziquantel has been reported from Senegal where the parasitologic cure rate 12 weeks after treatment was as low as 18%^[75]. The tolerance of the Senegalese isolate to praziquantel may be defined as tolerance, indicating

an innate insusceptibility of a parasite to a drug to which it has never been previously exposed^[76]. In contrast, a genetically transmitted loss of susceptibility in a parasite population that was previously susceptible to a given schistosomicidal drug has been termed resistance^[70]. Indeed, in recent work carried out in Egypt, where praziquantel has been extensively used, it has been demonstrated that a small percentage (1%-2.4%) of villagers may harbor parasites which cannot be killed even after repeated administration of high doses of praziquantel^[77]. When isolates obtained from these uncured individuals were examined in the mouse model, the ED₅₀ values of the isolates were found to be 3 times higher than that of one reference control isolate^[76]. The reduced susceptibility of *S. mansoni* to praziquantel in infected human populations has important implications for current schistosomiasis control programs.

Oxamniquine is widely used in the treatment of infestation due to *S. mansoni*. It is a well known, highly useful drug for the treatment of all forms of *S. mansoni* infestation including many complicated syndromes^[78].

Recent studies showed that oxamniquine irreversibly inhibits nucleic acids and protein synthesis in adult worms. Male were more susceptible than females to the drug and showed a higher degree of inhibition of protein synthesis^[79].

Metrifonate, an organophosphorus cholinesterase inhibitor, is used for the treatment of urinary schistosomiasis. Metrifonate, like other organophosphorus compounds, inactivates the enzyme that destroys acetylcholine. Because this action allows the chemical neurotransmitter to persist, cholinergic symptoms might be expected during treatment. These include fatigue, muscular weakness, abdominal colic, nausea, diarrhea and vomiting. All of these symptoms are a reflection of stimulation of cholinergic synapses in the autonomic nervous system, ganglionic sites in both parasympathetic and sympathetic divisions, the neuromuscular junction and several sites in the cardiovascular system^[71].

CONCLUSION

In conclusion, control of schistosomiasis is not an easy task. Even after successful treatment, reinfestation easily takes place in most of endemic areas, unless transmission is cut off somewhere between the intermediate hosts and the final hosts in the life cycle of the parasites.

Much work has concerned the immunopathology of the disease, particularly granuloma formation. Although the granulomas contribute significantly to the pathology, they do

seem to protect the host liver from the toxic secretion of the egg. Reduction in granuloma size, without affecting its protective function, would seem to be a desirable aim. A number of approaches are currently under investigation, including the use of live cercariae and schistosomules, and the use of more or less purified antigens.

A wide range of approaches are being taken towards the development of an effective vaccine for schistosomiasis. These range from basic research into schistosome biology through to human epidemiological and immunogenetic studies, construction of a variety of different types of vaccine including native or recombinant proteins, peptide constructs and nucleic acid vaccines, as well as vaccination trials utilizing these in experimental animals ranging from mice to water buffalo. Taken together, the breadth of research into schistosomiasis vaccine development is substantial. Hopefully, these efforts will result in a successful outcome.

Schistosomiasis can be treated with relative ease today since a number of good drugs, several of which are taken orally, have become available. The response to some of the drugs may differ markedly according to geographic location. The emergence of poorly susceptible (tolerant) strains is an area of concern, and that deserves further research to develop new agents for control of the disease.

Expression of the CagA gene of *H. pylori* and application of its product

Han FC, Yan XJ and Su CZ

Subject headings *Helicobacter* infection; *Helicobacter pylori*; CagA; gene expression; polymerase chain reaction; immunogold

INTRODUCTION

Helicobacter pylori (Hp) plays an important role in the upper digestive tract diseases. It can be divided into two main groups (toxic and non-toxic Hp) according to the production of vacuolating cytotoxin (VacA). The toxic bacteria also produce cytotoxin associated protein A (CagA) which might have something to do with the transcription, folding, transportation or the function of VacA. Studies showed that CagA positive Hp (CagA⁺Hp) accounted for more than 50% of all kinds of Hp, and peptic ulcer and gastric cancer were closely related to their infection^[1-7]. Therefore, detection of the infection of CagA⁺Hp is of great significance. This study was carried out to express CagA gene in *E.coli* and develop an immuno-assay for the rapid detection of CagA⁺Hp.

MATERIAL AND METHODS

Material

pMC3, plasmid that contains most parts of the 5'-end of CagA was kindly given by Dr. Tummuru (Vanderbilt University, USA); pBV220 (preserved in our institute); superdex HR75 (Pharmacia, USA); Wizard plus milipres DNA purification kits (Pr omega, USA); ELISA detecting kits for anti-CagA antibody (Jing Ying Biotech Company, Shanghai); thermolyse PCR Amplitron (USA); Hermle Z323K refrigerated high speed centrifuge (Germany); DU-640-nucleic acid protein analyser (Bechman, USA); 373 Auto-DNA sequencer, (Bechman Company, USA); bio-Rad mini-protein II electrophoresis (Joss Bio-Lab Company); sera from patients and healthy people (Xijing Hospital, Xi'an).

Methods

CagA gene cloning The oligonucleotide primers were designed and synthesized to amplify a 2544bp fragment at the 5'-end of CagA according to its sequence^[8]. The primers were CagAp1 (5'-TCGCCC-GGGATGACTAACGAACTATTGACC-3') and CagAp2 (5'-CAGGTCGACTTAGACTAGGG-TTCCGTTACAC-3'). At the 5'-end of each primer, there was a restriction endo-nuclease site (*SmaI* or *SalI*), which was favorable for the cloning of PCR products. Fifty microlitre polymerase chain reaction mixture contained 0.4 μmol/L primers, 0.2 mmol/L dNTPs, 2 units Taq-DNA polymerase, 1 ng pMC3, 100 mmol/L Tris-HCl, 50 mmol/L KCl, and 15 mmol/L MgCl₂. The CagA was amplified by denaturing at 94 °C for 1 min, annealing at 55 °C for 1 min, and extending at 72 °C for 3 min, and the procedures were repeated 30 times. The PCR product was analyzed by 15g/L agarose gel containing 0.5mg/L ethidium bromide (EB). The bands were examined under ultraviolet light and recovered by low melt point agarose gel. By preparing the pUC19 with alkaline dissolving method, we cloned the CagA gene fragment into it for sequencing.

CagA gene expression First, we digested pUC19/CagA with *SmaI* and *SalI* separately, and cloned the 2544 bp fragment into pBV220, but this gene fragment failed to express in DH5α. We then digested the pUC19/CagA with Eco-RI and Bam-HI, and recovered the 5'-end fragment of CagA (FCagA, 854 bp), which was then subcloned into vector pBV220 to form pBV220/FCagA. After transforming the competent DH5α with the pBV220/FCagA, the clones that could grow in Luria-Bertani (LB) plate containing ampicillinum (100 mg/L) were selected and cultured in LB solution at 30 °C overnight. We diluted (1:100) the cultured mixture of a positive clone in LB and let it grow at 30 °C till the late stage of logarithmic. Then we immediately raised the temperature to 42 °C and kept for 4 h. The heat induced fragment of CagA (FCagA) was analyzed by 12% sodiumdodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE).

Purification of FCagA Differential test showed that most of the FCagA existed in inclusion body, of which only 2% was in the supernatant after the

lysate was centrifuged at $12000\times g$ for 10 min. The soluble protein was precipitated by 50% saturated ammonium sulphate and resuspended in phosphate buffered saline (PBS) containing 1.3 mmol/L NaH_2PO_4 , 11 mmol/L Na_2HPO_4 and 140 mmol/L NaCl. Three millilitre mixture was applied to Superdex HR75 column (100 mL volume bed), and eluted with PBS in a HPLC protein purification system. The active peak was collected after being tested by dot immunogold filtration assay (DIGFA), with staphylococci protein A as the second antibody and colloidgold as the marker^[9]. The solution was then lyophilized and dialysed against PBS to eliminate extra salt.

Rapid detection anti-CagA antibody by DIGFA The colloidgold and immunogold were prepared according to the published articles^[10,11]. The purified FCagA was immobilized on the nitrocellulose membrane. To block non-specific conjugate sites, the membrane was immersed in 5% bovine serum albumin in (BSA) for 2 h, then washed with PBS three times and laid to dry automatically. Later, we assembled the DIGFA detecting kits. After a drop of serum was added to the membrane and passed through it, the immunogold was added. If the serum contained anti-CagA antibody, there would be a red dot on the membrane, otherwise, there would be no dot.

RESULTS

Cloning and sequencing of CagA

With pMC3 used as template, CagAp1 and CagAp2 as the primers, the 5'-end of CagA was amplified by polymerase chain reaction. The PCR products were analyzed under ultraviolet light after 1.5% agarose gel electrophoresis (Figure 1). We then cloned the 2544 bp CagA fragment into pUC19 for sequencing. The results showed that the PCR product was indeed a portion sequence of CagA, from which the 854 bp upstream fragment of CagA was achieved when digested with Bam-HI (Figure 2).

Expression of CagA and purification of its products

Subcloning FCagA into vector pBV220 and transforming DH5 α with pBV220/FCagA permitted the expression of FCagA with a MW of 38 kDa when the culture temperature reached 42 °C (Figure 3). The new protein mainly existed in inclusion body with only 2% soluble. When the supernatant of the bacterium lysate was precipitated with ammonium sulphate and the FCagA was purified by Superdex HR75 column, only one protein band of 38 kDa could be seen when the collected fraction correspondent to the active peak was analyzed by 12% SDS PAGE (Figure 4).

Figure 4 Determination of the purified FCagA by 12% SDS-PAGE.

1: Protein markers; 2: FCagA.

The antigenicity of FcagA

To identify the antigenicity of FCagA, DIGFA was performed with FCagA acting as antigen. The results showed that FCagA had the same antigenicity as CagA when 20 samples of anti-antibody positive serum were tested.

Specifications of the DIGFA kits

① Tests of specificity and sensitivity. Using the DIGFA kits, we detected the anti-CagA IgG in 262 cases. Comparing with ELISA, the specificity of DIGFA was 98.5%, the sensitivity was 96.8%, and the coincident rate was 97.7% (Table 1). ② Duplicate tests. From the 262 serum samples, we randomly selected 100 sera for the detection of anti-CagA IgG. The experiment was repeated 5 times and the same result was got: 42 serum positive, 58 serum negative. ③ Blocking tests. When 20 anti-CagA IgG positive sera were randomly chosen, a mixture of 10 μ L serum and excess amount of FCagA (10 μ g) would make the result negative, and a mixture of serum and BSA did not change the positive result, indicating that FCagA can specifically bind anti-CagA IgG. ④ Stability. The stability tests showed that the specifications of the kits were stable for at least 6 months at 4 °C.

Table 1 Results of anti-CagA IgG in sera detected by DIGFA and ELISA

		ELISA		Total
		Positive	Negative	
DIGFA	Positive	123	2	125
	Negative	4	133	137
Total		127	135	262

DISCUSSION

Hp CagA is a bacterium surface protein with a MW of 120 kDa-128 kDa. A dominant characteristic of this protein is its high antigenicity^[1]. The infection of CagA positive *Hp* results in local and systemic humoral immuno-reaction, and there is high concentration of anti-CagA in the patient's blood and gastric juice^[3,6]. This is the base of immuno-detection of anti-CagA antibody. Most recombinants of CagA previously expressed were at its carbonic end and the antigenicity of its amino end has not been reported. Since the 5'-end of CagA had no usable restriction endonuclease sites, we used PCR to amplify the 5'-end fragment of CagA, and cloned it into pBV220^[12]. Subsequently the DH5 α was transformed by pBV220/FCagA, and a 38 kDa recombinant was induced by heat when temperature reached 42 °C. The new protein accounted for 33% of the total bacterium proteins and could combine with anti-CagA IgG, indicating that the recombinant had the antigenicity of CagA. Purification of the soluble part of the recombinant

protein made it possible to develop immuno-detecting method for CagA⁺Hp.

At present, the detecting methods of *Hp* infection can be divided into two categories: injury and non-injury. Since the injury methods are based on the gastrointestinal endoscope, the non-injury methods are preferred, among which the rapid urease test has low specificity, and the ELISA takes too much time. The same problems exist in the detection of CagA⁺Hp. Since the infection rate of CagA⁺Hp is high and its harmful effects on human being are great, it is necessary to develop rapid, simple, and non-injury approaches to detect the infection of CagA⁺Hp.

DIGFA is an immuno-method developed in recent years. In this method, the red immunogold is used as the marker and nitrocellulose as the substrate, which has the function of absorption, filtration, concentration, and capillary, and can let the antigen-antibody reaction take place rapidly. In this study, we established an anti-CagA assay and developed the test kits which have great applicable value and high sensitivity and specificity. This may contribute to the epidemic study of the infection of CagA⁺Hp in a large scale.

The expression and clinical significance of CD44v in human gastric cancers

Chen GY and Wang DR

Subject headings CD44v gene; stomach neoplasms; neoplasm metastasis; gene expression

INTRODUCTION

CD44 was originally implicated as a "homing" receptor directing the migration of recirculating lymphocytes^[1]. CD44 expression has been confirmed not only in lymphocytes but also in a wide variety of epithelial tissues. It is considered as an important cell adhesion molecule for cell to cell interactions^[2]. Molecular cloning and analysis of the genetic structure have revealed that the CD44 gene has at least 19 exons, of which 12 can be alternatively spliced to make up a wide variety of CD44 splice variants which have been found in various types of human malignancies and have been considered as a marker in tumor progression and metastasis^[3]. We analysed the expression of aberrant CD44 transcripts with RT-PCR method in gastric carcinomas, and discussed the clinical significance of metastasis-related CD44v gene.

MATERIALS AND METHODS

Materials

Fresh tissue specimens including normal gastric mucosa, gastric tumor and mucosa adjacent to tumor were tissues taken from 20 patients with gastric cancers who underwent surgical treatment in the Department of General Surgery in our hospital from November 1997 to February 1998. The diagnosis was confirmed before operation, by endoscopic and pathological examinations. The normal mucosae were taken from mucosae 10 cm away from carcinomas, and the adjacent tissues 2 cm away from the carcinomas. The specimens were derived in 30 minutes after surgical resection, and were frozen in liquid nitrogen prior to store below -70 °C.

Received 1999-07-21 **Accepted** 1999-10-11

There were 15 males and 5 females, aged 30-79 years, with an average of 58. Pathological examination showed two types of tumors according to *Laureu's* classification division of Finland: intestinal type (well-differentiated) and diffuse type (poorly-differentiated). All the gastric mucosae, gastric cancers and their adjacent tissues expressed CD44s: 16 of 20 gastric cancer cases including 14 cases of diffuse type and 2 cases of well-differentiated type had positive expression of CD44v; 5 of 10 adjacent tissues had positive expression of CD44v. In contrast, there was no positive expression of CD44v in all 10 normal gastric mucosae.

RT-PCR method

Primers sp1 and sp2 were taken from the cDNA sequence described by Matsumura^[4]. sp1: 5'-GACA-CATATTGCTTCAATGCTTCAGC3', sp2: GAT-GCCAAGATGATCAGCCATTCTGGAAT3', pointing to part of exons of standard CD44s, the amplified product was CD44s; primer p1 and p2 were taken from No.1 and No.5 exons in human cDNA sequence described by Hofmann^[5], p1: 5'-GACAGACACCTCAGTTTTTCTGGA3', p2: 5'-TTCCTTCGTGTGTGGGTAATGAGA3', pointing to the abnormal splice variants of CD44 gene containing v7 exon, the amplified product was CD44v. The two couples of primers were both synthesized by SAGON Co, Canada, kits and TaqDNA polymerase were purchased from PE Co. USA.

Total RNA extraction was prepared according to AGPC single-step method^[6]. RT-PCR: model RNA 3 µL, down primers (sp1, p1) 2 µL (25 pmol) and 2 µL AMV-RTase were put into 20 µL reaction system to synthesize cDNA. Putting 10 µL cDNA into a reaction tube, the primers sp2, p2 and 2 µL TaqDNA polymerase were added, then the amplification happened in 50 µL reaction system. The conditions of PCR reaction was 94 °C for 50", 52 °C for 50" and 72 °C for 1'33" undergoing 35 cycles. For negative controls, template cDNA was not added to the reaction mix. The amplified product was electrophoresed in a 2% agarose gel, observed and photographed with ultraviolet radiography.

Statistical analysis

Data were analyzed for Fisher exact examination by

running statistical software SPSS for Win95. *P* value was set at 0.05 for statistical significance.

RESULTS

Amplified with sp1 and sp2 as primers, the CD44s specific 482 bp product was obtained from all the gastric cancers, the adjacent tissues and normal gastric mucosas (Figure 1).

With p1, p2 as primers, 10 normal gastric mucosas showed no RT-PCR fragment; 5 of 10 adjacent tissues showed specifically the 740 bp CD44v product of RT-PCR fragment, these 5 cases with positive CD44v expression were diffuse-type gastric cancers with distant lymph node metastasis; 16 of 20 gastric cancers expressed specific 740 bp band, of which, 14 of 15 were diffuse cancers, only 2 of 5 cases were well-differentiated cancers; 15 of 16 cases with lymph node metastasis had CD44v expression, only 1 case had CD44v expression in all 4 cases without lymph node metastasis. All the cases with CD44v expression in adjacent tissues were diffuse-type gastric cancer with distant lymph node metastasis (Figure 2).

The relationship between the biological behaviors of gastric cancer and CD44v mRNA expression is presented in Table 1.

Figure 1 Electrophoretic pattern of RT-PCR product for CD44s in gastric tissues.

DISCUSSION

As an adhesive molecule, CD44 exists on the surface of cells. The NH₂-terminal function area of CD44 can join the hyaluronate in the basement membrane to extracellular matrix, thus to regulate the movement and function of cells. By this mechanism, neoplastic cells can adhere itself to the extracellular matrix and basement membrane of the host cell, resulting in invasion and metastasis of malignancy. On the other hand, the degraded products of hyaluronic acid can motivate the growth of local vessels providing the basis for invasion and metastasis. This varied CD44v is a promising marker in diagnosing gastric cancer clinically^[4,7].

Yokozaki^[8]'s research suggests that the rate of abnormal expression of CD44 gene whether in well or poorly-differentiated gastric cancer may approach to 100%. In gastric cancer cells, CD44 gene generates abnormal splice variant CD44v during transcription, whereas in normal gastric mucosa cells, CD44 gene only expresses CD44s protein. In metastatic cells of gastric cancer the abnormal expression of CD44v is strengthened more than those in primary cancer cells. Therefore, CD44 gene's abnormal expression may not only serve as a good marker for identifying gastric cancer in normal mucosa, but also predict cancer metastasis.

We have got similar result to Yokozaki's. The expression rate of CD44v in gastric tissue is up to 80% with difference between two types of gastric cancer, but not high in the adjacent tissue and normal mucosa. It shows that the variant expression of CD44v is related to the phenotype of gastric malignancy, and may serve as a useful indicator in tumor metastasis, and have potential significance in diagnosing gastric cancer.

The formation and metastasis of gastric cancer are related to the abnormal expression of onco-gene (c-erb2, c-myc, ras) and suppressor onco-gene (p53). CD44's abnormal expression may be an earlier event than that of ras, p53 and other genes, and may be related to the activation of ras gene. The mechanism in promoting the formation of cancer cell and metastasis may probably be related to the function of CD44. The cancer cell with CD44v expression may get lymphocyte's guise so as to escape the recognition and execution from human immune system and easily invades lymph node, resulting in metastasis^[9].

Our results show that 16 of 20 gastric cancer specimens and 5 of 10 adjacent tissue specimens had positive CD44v expression, and none of the normal mucosa had CD44v expression (Chi-square $\chi^2 = 17.160$, $P < 0.05$). There was no statistical significance as comparing the former two with the normal mucosa. The CD44v expression rates in two types of gastric cancer were different significantly ($P < 0.05$), the rates were also markedly different ($P < 0.05$) in cases with or without lymph node metastasis. Expression of CD44v mRNA was related to the genesis and prognosis of gastric cancer, and is one of the biological markers indicating metastasis and poor prognosis. However the expression of CD44v had nothing to do with clinical stage or size of the cancer. Considering the limited data available, further investigations are needed.

No specific strand was discovered in the 20 cases of normal gastric mucosal tissues, Northern blot-hybridization method has also been used for CD44 variant gene expression product in different tumors, *i.e.* gastric cancer, lung adenocarcinoma, colon cancer and esophagus cancer tissues.

However, the method is less sensitive than RT-PCR method, it is also time-consuming and needs large quantities of RNA and tissues. RT-PCR technique can be used to detect CD44 gene's variant expression product rapidly with a tiny amount of tissues in batches, so it is highly valuable in clinical practice. False negative result is possible if only RT-PCR is used for detecting CD44, thus further researches are needed to improve the detecting sensitivity, when RT-PCR with Southern blot-hybridization technique or semiquantitative density technique are used in combination.

Study of primary leiomyosarcoma induced by MNNG in BALB/C nude mice

Zhu JS, Su Q, Zhou JG, Hu PL and Xu JH

Subject headings leiomyosarcoma; stomach neoplasms; MNNG; BALB/C nude mice

INTRODUCTION

It has been well known that MNNG is one of the strong and multipotential carcinogens that have been frequently reported inducing malignant peptic tumors. We have successfully induced rat and dog gastric adenocarcinomas, squamous cell carcinomas of rat forestomach and gastric leiomyosarcoma of rats since 1979. In order to replicate the model of human gastric carcinoma in rats, large doses of MNNG was administered to BALB/C nude mice, to which human embryonic mucosa had been transplanted. During the experiment, the primary leiomyosarcoma (PLS) of the nude mouse was unexpectedly obtained.

MATERIALS AND METHODS

Experimental animals and human embryonic gastric mucosa Twenty-two ZZ BALB/C nude mice (offered by the Center of Experimental Animals of Chinese Academy of Medical Sciences), 6-8 weeks of age and 16 g-20 g in weight, half and half female and male, were raised in the "SPF" environment (constant temperature and humidity, and sterilized water, food and padding).

Human embryonic gastric mucosa was obtained from 3-8 month old 31 fetuses (12 males, 19 females) of induced labor and the mucosa was cut into lumps of 0.5 cm³ and sewed in a bag-like shape for transplantation.

Reagent MNNG (product of Sigma Chemical Co.) was dissolved in DW to form 10 µg/L solution which was then filtered with 0.25 µ filter-membrane. Vimetin, desmin, actin and cytokeratin were products of Maixin Co.

Mucosa transplantation The nude mouse was anesthetized and its peritoneal cavity was opened on a superclean working table. Human embryonic gastric mucosa was transplanted into nude mice's peritoneum by sewing it with surgical threads. The cut healed in 5-7 days. When human embryonic gastric mucosa was wrapped by peritoneum into a tumor, each mouse was injected with 0.1 mL of MNNG at an interval of 15 days. The injection was repeated four times in all. In the meantime, immunosuppressant was administered. Those experimental nude mice were killed at different intervals 5 weeks later.

Pathological observation and general staining

Autopsy was made on the killed animals, and the transplants and adjacent organs were observed. The transplants and adjacent organs were fixed in 10% neutral-buffered formalin, dehydrated according to the routine and embedded in paraffin wax and sectioned. Finally, the sections were stained with H. E. and observed microscopically.

Special staining "Tumor-like" tissues were sectioned and then stained with AB/PAS, Argyrophil, VG, Masson's and PTAH.

Immunohistochemical method SP method has been applied in this research.

Electron microscopy The tumor tissues were cut into small pieces (0.5 mm in diameter) and first fixed with 2.5% glutaraldehyde and then postfixed with 1% osmic acid and dehydrated in a graded series of acetone and embedded in epoxy resin 812. The ultra thin sections were stained with lead acetate followed by lead nitric acid. The grids were observed under a EM109 electron microscopy and photographed.

Test of DNA repetitive sequence DNA was extracted from the tumor and NIH/3T3 cells were then hybridized by A/u probe.

RESULTS

PLS induction and gross inspection Except that four nude mice which died in the early stage of the experiment, the rest of 18 nude mice were kept under observation for 9 months. Three (16.7%) cases of PLS were induced successfully. The

duration for forming a tumor was 3-9 months, averaging 6 months. Exploratory laparotomy was performed and the tumors localized in the right abdominal wall were partly connected with tissues of the right ilium. The surface of the tumor was nodal-like, smooth and dark-red. The size of the three tumors was 2.5 cm × 2.0 cm × 2.0 cm, 3.0 cm × 2.5 cm × 2.0 cm and 3.0 cm × 2.5 cm × 2.5 cm, respectively. The tumor looked like sarcoma.

Light microscope There was a large number of tumor cells characterized by their interlaced cell

arrangement (Figure 1), their irregular cell shape such as fusiform or oval forms and their various sizes in the neoplastic tissues. The rich cytoplasm was stained red, part of that was in the form of granules or vacuoles. The nucleuses were seen to exist in polymorphic shapes such as oval or stab form with unusually thick nuclear membrane.

Hyperchromasia, nucleolus, giant nucleus, multinucleus tumor giant cells, karyokinesis (0-3/HPF) and pathological karyokinesis could be seen (Figure 2). Necrosis could be seen also. Besides, surrounding tissues were invaded by tumor cells.

Figure 1 Interlaced arrangement of leiomyosarcoma cells stained with HE. ×20

Figure 2 Karyokinesis of leiomyosarcoma cells stained with HE. ×40

Figure 3 Reticular fibers of leiomyosarcoma cells stained with silver. ×40

Figure 4 Leiomyosarcoma cells stained red by Masson's method. ×40

Figure 5 Micrograph of positively stained desmin of cytoplasm of leiomyosarcoma cells by immunohistochemical method. ×20

Figure 6 Micrograph of positively stained actin of cytoplasm of leiomyosarcoma cells by immunohistochemical method. ×20

Figure 7 Electron micrograph of dense bodies and myofilaments of leiomyosarcoma. E.M.×20000

Special staining Tumor cells stained with AB/PAS were negative. Argyrophil staining showed that reticular fiber surrounded the tumor cells (Figure 3). The tumor cells were stained in yellow by VG and were red by Masson's staining (Figure 4). Cross striation was seen in the tumor cells by PTAH staining.

Immunohistochemistry Cytokeratin of the tumor cells was negative. Vimetin, desmin (Figure 5) and actin (Figure 6) of the tumor cells were positive.

Electronic microscope The tumor cells had thick membrane, dense patches, dense bodies and myofilaments, with oval nucleuses. Concave nuclear membrane was very thick and the heterochromosome under the membrane was very large. The entosthoblast was quite clear (Figure 7).

Tests of human DNA repetitive sequence A/u test showed that the DNA of both tumor cells and NIH/3T3 cells had no human A/u repetitive sequence, suggesting that the gene of the tumor cells belonged to nude mice and not human being.

DISCUSSION

MNNG is a very powerful carcinogen, which can not only induce tumor of mouse, cancer of dog's gland stomach, squamous cell cancer of non-gland stomach of mouse, but also PLS of mouse, nevertheless, it has not been reported that MNNG can induce PLS of nude mice.

Our research aims at inducing PLS of nude mice to duplicate human stomach tumor model after

human embryonic gastric mucosa was transplanted into BALB/C nude mice which were then injected MNNG. The pathoanatomy of PLS of nude mice looked like that of PLS of mouse cervix or PLS of human soft tissue^[1-3]. It was unexpected that the tumor originated from soft tissue of abdominal wall. The special staining of AB/PAS, VG, Argyrophil, Masson's and PTAH and the results of immunohistochemistry indicate that tumor tissues originate from the smooth muscle cells^[2,3], but A/u test shows that the tumor cells do not originate from human being. We, therefore, conclude that it is PLS of nude mice.

The mechanism of MNNG inducing PLS in nude mice is still unclear, but it can be inferred that a large amount of MNNG that has affinity to smooth muscle cells continues to act on smooth muscle cells and damages the DNA of these cells, and then activates oncogene or inactivates suppressive gene and finally results in formation of sarcoma. In addition, the lack of T cells and the use of immunosuppressant amplify the effect of carcinogen. It was recently reported that MNNG inducing PLS was a very complicated process of multistage and multigene variation. A researcher found that MNNG damaged DNA and the damaged DNA was not repaired on time and then ras oncogene produced point mutation to activate ras oncogene^[4]. Wang B *et al*^[5] reported that MNNG induced gastric epithelium cells strain of GES₁ with point mutation at codon 12 of C-Ha-ras oncogene, rearrangement of C-met oncogen and increase of C-erbB-2 oncogene.

In brief, further study of MNNG inducing PLS in nude mice is significant so that we can learn more about the mechanism of the molecular pathology of oncogene and suppressive gene.

The value of postoperative hepatic regional chemotherapy in prevention of recurrence after radical resection of primary liver cancer

Wu ZQ, Fan J, Qiu SJ, Zhou J and Tang ZY

Subject headings liver neoplasms/drug therapy; neoplasm recurrence/prevention and control; regional chemotherapy

INTRODUCTION

In China, primary liver cancer (PLC) ranks second in cancer mortality since the 1990s. In the field of PLC treatment, surgical resection remains the best, which includes large PLC resection, small PLC resection, re-resection of subclinical recurrence, as well as cytoreduction and sequential resection for unresectable PLC. However, recurrence and metastasis have become the major obstacles for further prolonging survival after resection. In authors' institute, as reported in 1984, the 1-, 3-, and 5-year recurrence rates after curative resection were 17.1%, 32.5% and 61.5%, respectively^[1]. Similar results were reported in 1993, being 15.0%, 45.5% and 55.3%^[2]. Even after curative resection of small hepatocellular carcinoma (HCC), the recurrence rate remained high being 6.5%, 25.7% and 43.5% (Tang *et al*, 1989). Therefore, recurrence and metastasis might be the next important targets to be studied. New strategies for the prevention of recurrence after curative resection become a key point to further improving the results of operation for PLC patients. In the literature, the opinion was preoperative transcatheter arterial chemoembolization (TACE) for resectable PLC could result in intrahepatic spreading and lung metastasis and could not improve the survival. Herein, the efficacy of postoperative hepatic regional chemotherapy in prevention of recurrence after radical resection for PLC was evaluated.

MATERIALS AND METHODS

The criteria for the curative resection were listed as follows: a. No distance metastasis was found in patients preoperatively. b. The tumor should be completely removed with the surgical margin from the tumor edge to the cut surface for over 0.5cm. c. The α -fetoprotein (AFP) level should return to normal within 2 months after resection for AFP positive patients and no residual tumors were detected by B-model ultrasonography and/or lipiodol-computed tomography (L-CT) at 2 months after resection for AFP-negative patients.

A total implantable port system was used for chemoembolization. The top of the system was inserted into hepatic artery proper via gastroduodenal artery without hepatic artery ligated during operation. Another system should be put into the main trunk of portal vein for patients with tumor embolus in portal vein or hepatic vein system. A four-day course of chemoembolization with 5 fluorouracil 750 mg-1000 mg, mitomycin C 8 mg-12 mg, cisplatin 80 mg and Ultralipiodol 5 mL was performed at 4-6 weeks postoperatively. For patients with tumor embolus in the portal vein or hepatic vein system, the drugs were equally injected via the two catheters, while the lipiodol was given via the hepatic artery only. The regional hepatic chemotherapy will be repeated at regular interval of 2-4 months thereafter.

After discharge from the hospital, all the patients were closely followed up: every 2 - 3 months during the first 2 postoperative years and 6-months intervals thereafter. Follow-up comprised a clinical examination, conventional liver function tests, serum AFP level assay, ultrasonography and chest X-ray. Lipiodol-CT were done at 2-3 weeks after each time of chemoembolization. When recurrence and/or metastasis were suspected, more detailed examinations including CT, MRI and bone scan were taken. The diagnosis of recurrence or metastasis were decided according to the positive imaging examinations.

A total of 105 patients having a histologically verified PLC met all the above-mentioned criteria from January 1995 to December 1997 at Shanghai Liver Cancer Institute. The median age of the entire series was 52 years (range, 30-73 years) and the median diameter of the tumor was 6.8 cm (range,

1cm - 18.8 cm). The male to female ratio was 5.5:1. Among these patients, ninety two patients (87.6%) combined with posthepatic cirrhosis and seventy patients had positive AFP level. As to the number of tumor, it was found 76 patients with single nodule, 19 with two nodules and 10 with three to six nodules. Five patients had visible tumor embolus in the second branch of portal vein and one patient had tumor embolus in the right hepatic vein. The average time of chemoembolization given to patients was 3.4 times (range, 1-7 times).

Statistical analysis: the difference between different groups were tested by χ^2 test.

RESULTS

All patients were followed up for 4 - 40 ($\bar{x} \pm s = 22.7 \pm 9.7$) months. Two patients without recurrence died of severe hepatitis at 12 or 13 months, respectively. In the remaining 103 patients, recurrence in the remnant liver was found in 11 patients, metastasis to the lung in 1 patient and implantation in the abdominal cavity also in one. The recurrence rates of 1-, 2-, 3- years were 1%, 15% and 18%, respectively. The interval between recurrence and operation varied from 10 to 20 ($\bar{x} \pm s = 15.2 \pm 2.9$) months. Another two patients had a second primary tumor in the breast and lung. For the treatments of the 13 recurrent patients, a second resection was done in 9 patients, hepatic regional chemoembolization plus percutaneous intratumor ethanol injection was done in the other four patients, who could not tolerate the second operation. Neither recurrence nor metastasis was found in six patients with tumor embolus in portal vein or hepatic vein.

The recurrence rates of different groups are shown in Table 1.

Table 1 The recurrence rates of different groups of PLC

Items	No.	Recurrence rate (%)
AFP	Positive	70
	Negative	35
Tumor	>5cm	45
	<5cm	60
Nodules	Single	74
	Multiple	31

DISCUSSION

The following causes might be involved for the recurrence after curative resection for PLC: a: There existed undetectable intrahepatic spreading or long distance metastasis. b: A metachronous and unrecognized synchronous multifocal primary tumor may be responsible for recurrence. c: The procedure of operation can make tumor cell

detached and spread in the liver. So, curative resection doesn't mean all the tumor cells being totally removed. The depressed immune system's function of PLC patient can not guarantee that all the residual tumor will be killed even under the condition of combining with oral or one shot of hepatic chemotherapy via the hepatic artery^[3,4]. Systemic chemotherapy is abandoned in prevention of recurrence for it can not only damage the immune function of the patient but also can not guarantee the effective drug concentration at the target organs. Contrast to the systemic chemotherapy, hepatic regional chemotherapy given via hepatic artery and/or portal vein can result in a high drug concentration in the target organ without severe damage to the immunologic function.

No significance difference was found between AFP-positive patients and AFP-negative patients and between large PLC and small one and between patients with single or multiple tumor nodules (Table 1). Take into consideration that the short time recurrence rates of large PLC, multiple PLC and PLC with tumor embolus in the portal vein or hepatic vein were not higher than those of small PLC, PLC with single nodule and PLC without tumor embolus, our results indicated that postoperative hepatic regional chemotherapy can significantly decrease the short time recurrence rate after curative resection for these patients.

The peak recurrence time for PLC was within two years after curative operation. The resection for PLC and depress the patients' immune function and stimulate secretion of some regeneration related factors^[5]. These changes can make residual tumor cells and precancerous cell fast dividing and more sensitive to chemotherapy. So, it is a good chance for patients to receive postoperative hepatic regional therapy once the liver function and immune function return to normal level. It should be emphasized that if the liver function and immune function have not returned to normal, too early chemotherapy could result in further damage to patients. In general, the first time chemoembolization should be taken at 4-6 weeks after curative resection and repeated at regular interval of 2-4 months thereafter until the patients survive over the peak recurrence time. The interval of chemoembolization can be prolonged under the closing of follow up and without positive signs which indicating recurrence.

Our results indicate that auxiliary hepatic regional chemotherapy after curative resection can significant decrease the recurrence rate during the peak recurrent time. Considering that chemotherapy can neither kill tumor cell completely

nor can permanently prevent new tumor foci occurring in the remnant liver. It is no doubt that hepatic regional chemotherapy can't effectively prevent recurrence of PLC permanently. Repeated chemotherapy via hepatic artery can occlude the hepatic artery and damage the liver function. Most patients' port system can maintain in good condition for only about one year, this may contribute to the higher recurrence rates in the later two years as compared to that of the first year. Other multimodality treatment, such as immunotherapy, should be used in combination to further reduce the recurrence rate after curative resection.

Overexpression of P-glycoprotein in hepatocellular carcinoma and its clinical implication

Kong XB, Yang ZK, Liang LJ, Huang JF and Lin HL

Subject headings liver neoplasms; carcinoma, hepatocellular; P-glycoprotein; multidrug resistance-1 gene; immunohistochemistry

INTRODUCTION

Most advanced hepatocellular carcinoma (HCC) is insensitive to most anticancer drugs which might be related to the high frequency of expression of the multidrug resistance-1 (MDR1) gene^[1] and its product, P-glycoprotein (P-gp)^[2]. P-gp expression may also be concerned with tumor progression and differentiation^[3]. In the present study, we investigated P-gp expression and assessed the relationship between expression level of P-gp and the clinico-pathological parameters of HCC by immunohistochemistry in combination with computer-imaging analysis.

MATERIALS AND METHODS

Patients and specimens

The data were from 47 HCC resected specimens, from June 1996 to July 1997, including 47 tumor tissues and 33 adjacent tissues, 39 men and 8 women, age 25-74 years (mean 49 years). No one received preoperative chemotherapy. Of the 47 tumors, 72% were >5 cm, and 28% were ≤5 cm, 40% and 26% were accompanied by involvement of portal veins with presence of satellite nodules and intrahepatic metastasis, respectively. The HCC consisted of well and poorly differentiated types and 11 normal liver tissues were obtained at surgery from patients without chronic liver disease as control.

Immunohistochemical stainings for P-gp

Serial sections of 4μm in thickness were prepared and immunohistochemical examination was performed by the streptavidin-biotin-complex (SABC) method using monoclonal antibody JSB1 (Boehringer Mannheim). The negative control was processed by substituting PBS for the primary antibody. The positive control was a breast cancer sample shown to express P-gp by SABC method.

Quantitative analysis

Immunoprecipitates were analyzed using an Axiotron microscope (Zeiss, Germany) and a 3CCD camera (JVC, Japan), and then processed by an image analysis system (IBAS, Kontron, Germany). According to Shen's method^[4], only the gray level and the area of defined area A and the phase α of positive products in A need to be tested. Positive unit (PU) was tested and calculated with the formula in A: $PU = 100 \times |G_{\alpha} - G_A| / (1 - A_{A\alpha}) \times G_{max}$. G_{α} and G_A denote respectively the mean gray level of the studied structure α and the test area A. $A_{A\alpha}$ means the area density of phase α in A. G_{max} is the maximum gray level of the instrument. PU that reflected intensity and area of the phase α of positive products in A represented P-gp expression level. Five times were performed at random in a section to obtain the mean PU.

Statistical analysis

PU of P-gp was expressed as mean±SD. The data were analyzed statistically by means of Student's *t* test. Statistical significance was defined as a two-sided *P* value of *P*<0.05.

RESULTS

Positive expression of P-gp in HCC, adjacent to tumor and normal liver tissues

P-gp positive cells were not uniformly distributed, the intensity of immunoreactivity was also variable, staining was mainly on the cellular membrane. In normal liver, P-gp was present on the bile canalicular surface of hepatocytes and the luminal surface of bile duct epithelial cells. In P-gp-positive HCC, the staining was observed on the contact surface between tumor cells resembling the canalicular staining pattern (Figure 1). P-gp expression was found in 70% (33/47) of HCC tissues and 66% (22/33) of adjacent tissues. The staining was mild in three normal liver tissues

specimens. A significant increase in *P*-gp expression level was observed in HCC tissues ($P < 0.01$) and those adjacent to the tumor ($P < 0.01$) but without significant difference ($P > 0.05$).

P-gp expression level in relation to clinico-pathological parameters in HCC

The expression level of *P*-gp in HCC with local invasion was significantly higher than that in HCC without ($P < 0.05$). Moreover, it was significantly higher in HCC of the well differentiated type than that of poorly differentiated ($P < 0.01$). Recurrence of HCC also had a significantly higher *P*-gp expression than that without ($P < 0.01$). On the other hand, there were no relationships between *P*-gp expression level and the tumor size ($P > 0.05$).

DISCUSSION

Hepatocytes exclusively express *P*-gp on the bile canalicular surface, it is a $M_r 170\,000$ membrane protein responsible for pumping lipophilic anticancer drugs such as doxorubicine and vincristine out of tumor cells^[5], resulting in chemotherapeutic effect poor. Recent reports showed increased expression of *P*-gp in HCC was significantly associated with non-responders^[6]. Our results indicated more than two thirds of the samples were positive for *P*-gp in HCC and adjacent tissues, this suggested that *P*-gp overexpression be probably responsible for the so-called innate drug resistance of HCC or non responder.

The fact that *P*-gp expression level was significantly higher in well differentiated than poorly differentiated HCC ($P < 0.01$), suggested the well differentiated HCC have a stronger potential of *P*-gp expression and a tendency to produce resistance to anticancer drugs more easily. It is worth trial to treat with anticancer drugs in

combination with a reverse agents of MDR1 gene or *P*-gp modulator as verapamil, preferably supported by data on *P*-gp expression.

The intrahepatic spreading, metastasis and postoperative recurrence were closely related to the biologic behavior of tumor cells, etc, about 43.5% of patients with small HCC recurred within 5 years after surgical resection^[7]. Recently, *P*-gp overexpression had been demonstrated in cancer with recurrence^[8]. So far there have been no reports on *P*-gp expression in HCC recurrence. In this study, hepatic recurrence had a significantly higher *P*-gp expression level than that without ($P < 0.01$). These results revealed that recurrence of hepatoma probably more easily to acquire multidrug resistance, thereby, the response to chemotherapy was likely unsatisfactory.

Our study further showed *P*-gp expression level of invasive HCC was significantly higher than that of non-invasive HCC ($P < 0.05$), suggesting that a high *P*-gp expression level was well associated with the invasiveness of HCC, and not related to the size of the tumor whether large or small.

Localization of HCV RNA and capsid protein in human hepatocellular carcinoma

Dai YM, Shou ZP, Ni CR, Wang NJ and Zhang SP

Subject headings hepatitis C virus, liver neoplasms; carcinoma, hepatocellular; in situ hybridization; immunohistochemistry

INTRODUCTION

The relation of HCV to hepatocytic carcinoma (HCC) has been emphasized recently in low HBV infection countries and regions. The distribution patterns of HCV in liver tissues are not well understood although studies on HCV infection in blood and hepatocytes have been conducted by PCR. In this study, 42 liver cancers and surrounding liver tissues were detected for HCV RNA and HCAg using photosensitive biotin-labeled HCV cDNA probe and Immuno-gold-silver stain (IGSS) method.

MATERIALS AND METHODS

Human HCC and paratumor tissues

Fourty-two samples including cancers and their surrounding tissues were collected and processed into formalin-fixed, paraffin-embedded blocks.

Probe preparation

NS5 cDNA probe PCR product from NS₅ region was inserted into charomid 9-42. This resulted in recombinant HCV plasmid which could be spliced into specific cDNA fragment with DNA length 534 bp^[1].

HCV cDNA probe HCVC cDNA probe was the PCR product of C region.

The preparation of photosensitive biotin-labelled probe was as described in literature^[2].

In situ hybridization

Five μ m sections were dewaxed, rehydrated in buffered solutions, then digested in proteinase K,

and fixed in polyformaldehyde. After dehydration, prehybridization was performed and then the sections were denatured (steaming bath at 100 °C, 10 min, then rapidly cooling down in ice bath), and hybridized again (42 °C, overnight). After rinse, the sections were conjugated with gold-labeled strepto-biotin, stained with AgNO₃ buffered solution, then restained in hemoxyl and eosin or eosin. Positive stain should be present as intracytoplasmic or intranuclear black granules.

Immunohistochemical detection of HCAg PAP method was used. The specific human anti-HCV antibody was from Laboratory of Immunology at Tongji Medical University.

Negative control Sections were treated with RNase (0.1 g/L), 1 hour, at 37 °C.

RESULTS

HCV RNA in liver tissues

HCV RNA positivity was detected in 8 cancers and their surrounding tissues including 2 positivity in cancers, 1 in both cancer and their surrounding tissue, 5 in surrounding liver tissues. Positive cells appeared diffuse, clustered, or discrete in cancer and its surrounding tissues. Three types of positive granules were noted: ① cytoplasmic, diffuse granules in cytoplasm with prominent perinuclear staining (Figure 1); ② nuclear, evenly diffuse granules in nucleus; ③ nuclear-cytoplasmic, positive granules present in both cytoplasm and nucleus. Detection by NS₅ cDNA probe revealed that 7 out of 42 were positive; detection by C cDNA probe showed one nuclear positive in 2 cases.

HCAg expression in liver tissues

Ten out of 42 stained positive for HCAg and positive cells were distributed in cancers and its surrounding tissues. HCAg positive cells appeared diffuse, clustered or discrete. Two distributing patterns of intracellular positive granules: ① cytoplasmic type: diffuse positive granules in cytoplasm; ② inclusion type: positive granules present as inclusions in cytoplasm (Figure 2).

DISCUSSION

HCV is a single-stranded RNA virus which reproduces itself on the template of negative strand and its copies are rarely present in tissues. It has been established that replication of HCV RNA occurs mainly in liver tissues. How it infects liver cells and at which point it starts duplication remains unknown.

Since 1992, there have been some reports on detection of HCV RNA in hepatic tissues using ISH, and HCV RNA was present in cytoplasm or nucleus^[3-8]. However, it is still unclear whether HCV RNA is present in hepatocytic carcinoma. Using ISH, we found that HCV RNA did infect cancers and their surrounding tissues, which was in good agreement with other authors' reports. HCV infected cells appeared diffuse, clustered or discrete in cancers and their surrounding tissues.

There is a viewpoint that the reverse transcriptase form of HCV RNA does not exist at all during its replication. Therefore, it is disputable on the significance of its presence in nucleus. Kayhan^[8] reported that HCV RNA was present in nucleus and nucleoli, and suggested that HCV duplication might use its host's genes or intranuclear apparatus, or HCV granules accumulated in infected cells like HBV. Our results were in accordance with the above findings. The studies on yellow fever virus also supported the above viewpoints: NS5 protein could be detected in nucleus and nucleoli, indicating that viral replication could occur in nucleus^[9].

In 42 liver cancers, 10 were positive for HCAg, while only 8 expressed HCV RNA by ISH, indicating that positivity of viral genes was lower than that of viral antigen. It is suggested that this phenomenon could be accounted by the variations of viral genes, and the fixing time by formalin. HCV is a variable virus, it may differ individually and

may vary at different stages of infection. Therefore, the variation of gene sequence may result in less sensitivity of ISH detection. In addition, longer fixation may cause loss of viral genes or false negativity. The above defects could be overcome by using probes of different fragments of the same gene. Two cases with HCAg(+), NS5 cDNA(-) were hybridized again and revealed positive signals of NS5 cDNA in one case. This agreed well with Haruna's^[7] findings. Although ISH is not as sensitive as PCR, it is a promising technique in the study of relation of HCV RNA and infected cells^[10-12].

The significance and mechanism of continual variation of HCV gene *in vitro* remain to be resolved in recent years. It was reported that HCVs continual variation *in vivo* may be related to virus escape from host immune deletion and virus configurative change brought about by immune injury introduced by the host^[13-15].

Expression of IGF-II, p53, p21 and HBxAg in precancerous events of hepatocarcinogenesis induced by AFB1 and/or HBV in tree shrews

Qin LL, Su JJ, Li Y, Yang C, Ban KC and Yian RQ

Subject heading liver neoplasms; carcinoma, hepatocellular; hepatitis B virus; IGF-II; p53 gene; p21 gene; HBxAg; aflatoxin B1

INTRODUCTION

In order to study the relationship between oncogene expression and HCC generation, we observed the precancerous hepatic GGT foci, IGF-II, p53 and p21 expression during hepatocarcinogenesis of tree shrew induced by hepatitis B virus (HBV) and/or aflatoxin B1 (AFB1).

MATERIALS AND METHODS

Materials

One hundred and twenty tree shrews (Tupaia Belangeri Chinese) were purchased from Yunnan Province of China. Their body weight was 100g-159g.

HBV infected serum was got from the patients with hepatitis B, positive for HBsAg and HBeAg. Monoclonal antibodies (MoAb) to HBsAg, p21 (MAB-0143), p53 D0.7 (MAB-0142) and S-P Kit were purchased from Maxim Technic Co. Anti-HBxAg MoAb was presented by Professor Wu GH in Liver Disease Institute, General Hospital of PLA Beijing Military Area Command. IGF-II (Lot 12850) RbAb was from Upstate Co. HBV DNA-Bio probe and *in situ* hybridization kit were provided by Liver Disease Institute of Beijing Medical University.

Methods

HBV infection marks were negative in serum of the animals before inoculation. Liver biopsy (LB) was taken from each animal which was negative for

HBV-infected marks in serum before inoculation. It was used as self-control. Each of the 80 tree shrews was inoculated with HBV-infected serum, injected through the femoral vein. Blood was taken from the animals were from wk2 to wk8 after inoculation. The animals positive for HBsAg, HBeAg and anti-HBcAg were divided randomly into group A and group B. The remaining 40 animals that did not receive inoculation of HBV were divided into group C and group D. Group A was HBV positive and fed with AFB1; group B was HBV infected; group C was fed with AFB1 and group D was as control. AFB1 mixed in the milk was freely lapped by animals, 6 d/w at a dose of 150 $\mu\text{g}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$. LB was taken from all animals anaesthetized by ketamine. The size of the tissue was about 0.8 cm \times 0.4 cm \times 0.4 cm, and they were fixed immediately. LB was taken repeatedly in every other 15wk after fed with AFB1.

HBsAg, HBxAg, IGF-II, p53 and p21 were detected by immunohistochemistry. Microwave citrate buffer strengthened HBxAg and p53. After testing suitable concentration of antibodies, slides were stained according to the S-P kit instructions. Positive and negative controls were set in each test to differentiate false reaction. GGT was stained by the method of Rutenberg. *In situ* hybridization of HBV-DNA was made according to the kit information.

The data was statistically evaluated by using *t* and χ^2 tests.

RESULTS

HCC was not found after 75 wk of observation. The average amount of AFB1 taken by each animal in groups A and C was 9.9 mg and 10.4 mg respectively ($P>0.05$).

The number of GGT positive foci was larger in group A than in groups B and C ($P<0.05$). GGT positive foci in groups A, B and C were more and bigger than in group D ($P<0.01$) (Table 1).

Table 1 GGT positive foci at wk75

Group	HBV	AFB1	Animal No	GGT positive foci ($\bar{x}\pm s$)		
				No/cm ²	mm ² /cm ²	mm ² /focus
A	+	+	15	143.3 \pm 96.4	7.12 \pm 7.50	0.04 \pm 0.03
B	+	-	14	71.1 \pm 72.0	1.90 \pm 2.09	0.03 \pm 0.01
C	-	+	16	72.9 \pm 70.4	2.22 \pm 2.42	0.23 \pm 0.01
D	-	-	10	19.4 \pm 19.9	0.35 \pm 0.36	0.01 \pm 0.01

The HBsAg positive rates were 86.7% and 95.7%, and HBxAg rates were 92.9% and 82.6% respectively in groups A and B (Table 2).

Table 2 HBsAg, HBxAg and HBV DNA in group A and B

Group	HBsAg		HBxAg		HBV DNA	
	Animal <i>n</i>	Positive <i>n</i> (%)	Animal <i>n</i>	Positive <i>n</i> (%)	Animal <i>n</i>	Positive <i>n</i> (%)
A	15	13(86.7)	14	13(92.9)	10	7(70.0)
B	23	22(95.7)	23	19(82.6)	16	12(75.0)
Total	38	35(92.1)	37	32(86.5)	26	19(73.1)

At wk 15, IGF-II positive liver cells in brown color were dispersely distributed in plasma. At wk 75, however, the positive cells were found to be near the margin of the proliferation foci of liver cells. The positive rate was quite different between wk 45 and wk 75 ($P < 0.05$, Table 3). Nuclear p53 was not found at wk 75. p21 positive rate was about 5% in groups A, B and C, with small brown grains in the plasma of liver cells.

Table 3 IGF-II at wk 45 and wk 75

Group	wk 45		wk 75	
	Animal <i>n</i>	Positive <i>n</i> (%)	Animal <i>n</i>	Positive <i>n</i> (%)
A	15	13(86.7)	15	5(33.3)
B	23	17(73.9)	20	13(65.0)
C	18	18(100.0)	17	11(64.7)
D	11	6(54.5)	11	4(36.4)

DISCUSSION

Hepatocarcinogenesis was found only in the precancerous phase of the tree shrews. The reason for the unequal numbers among the tests was that the LB tissue was too small to detect the marks.

Both HBsAg and HBxAg were found in the liver of tree shrew by immunohistochemistry. HBV-DNA was detected by *in situ* hybridization. These results showed that the tree shrew model for HBV infection was reliable.

GGT positive foci did not form in the early stage of the experiment. Small and irregular GGT

positive foci were found at wk 75. There were more GGT foci in group A (treated by HBV and AFB1) than in groups B and C (treated by HBV or AFB1), indicating the synergistic effect of HBV and AFB1 in hepatocarcinogenesis, which was also reported by other researchers. Group B (infected with HBV) had more GGT positive foci than group D (control), indicating that the effect of HBxAg trans-activation could induce precancerous lesions in the liver of tree shrew.

IGF-II was over expressed in human liver cancer and its surrounding tissues. Usually the expression of cancer-surrounding tissues is higher and is almost the same as that in fetal liver. In normal liver tissue, however, IGF-II was negative^[1,2]. IGF-II has high expression rate at wk 45, but significantly low at wk 75. In the HCC tissue of tree shrew, IGF-II was 100% positive^[3]. This revealed that IGF-II expression did not persist in a high level during hepatocarcinogenesis of tree shrew. IGF-II in group D probably caused by LB might repeatedly activate the expression.

Over expression of oncogenes and anti-oncogenes was found in AFB1 and HBV induced liver cancer. Many studies showed p21 in the early stage of carcinogenesis, and it was related with liver cell transformation. High rate of p21 was not observed. The expression of p21 in the later stage of the experiment is to be studied. p53 was not found in the precancerous tissues, which is in agreement with that reported in the literature^[4].

Antitumoral activity of low density lipoprotein-aclacinomycin complex in mice bearing H₂₂ tumor

Bi WX, Xu SD, Zhang PH and Kong F

Subject headings hepatoma cells; lipoprotein, low density; a clacinomycin; LDL receptor; mice

INTRODUCTION

Cancer cells, which proliferate rapidly need large amounts of cholesterol for new membrane synthesis, and high LDL receptor (LDLR) activity. LDL has been proposed as a useful discriminatory vehicle for the delivery of cytotoxic drugs to tumor cells^[1,2].

LDL presents many advantages as drug carriers that may circumvent many problems encountered with synthetic carriers^[3,4]: ① LDL may deliver highly lipophilic compounds with promising cytotoxic effect. On the other hand, the sequestered drug is protected from enzymatic action. ② Furthermore, LDL is not cleared by the monocytic macrophagic system and may prolong the serum half-life of antineoplastic drugs. ③ Tumor cells internalise and degrade LDL by the LDL receptor pathway. This potentially high efficient process may lead to different pharmacological effects.

It is possible to incorporate aclacinomycin (ACM) into LDL to form low-density lipoprotein-aclacinomycin (LDL-ACM) complex^[5,6]. In our recent study, the therapeutic activity of LDL-ACM complex and that of ACM were compared in experimental mice tumor with the potential effect of LDL-ACM complex.

MATERIALS AND METHODS

Materials

Male or female KM mice, 6-8 weeks old, were

purchased from Experimental Animal Center of Shandong Medical University. Murine Hepatoma 22 (H₂₂) cells were bought from Pharmaceutical Institute, Shandong Academy of Medical Sciences, and ACM from Shenzhen Wanle Pharmaceutical Co., Ltd.

Lipoproteins

Human LDL (density, 1.019 kg/L - 1.063 kg/L) was isolated by ultra centrifugation of serum from healthy blood donors^[7]. The isolated LDL was dialyzed against LDL buffer (Na₂HPO₄ 50 mmol/L, NaCl 100 mmol/L, Na₂EDTA 0.1 g/L, pH7.4) for 48 h, filtered through a membrane filter (Millipore, 0.22 µm pore size) and stored at 4 °C. Lipoprotein purity was assessed by agarose gel electrophoresis. All concentrations of LDL given refer to protein. The protein concentration was determined according to the method of Lowry *et al.*

Incorporation of ACM into LDL^[5]

ACM was incorporated into LDL by incubating 36 mg LDL with 40 mg ACM in LDL buffer for 3 h at 40 °C. The mixture was then subjected to extensive dialysis for 48 h against LDL buffer to remove free drug and thereafter filtered and stored at 4 °C. The LDL-ACM complex obtained had a drug: LDL protein weight ratio 0.35. The concentrations of LDL-ACM complex given in the text refer to ACM.

Assay for ACM

ACM was assayed fluorometrically in a HITACHI spectrophotofluorometer model F-3000 using 430 nm and 580 nm as excitation and emission wavelengths, respectively^[5]. ACM was extracted with chloroform: methanol (4:1 V/V). When LDL-ACM complex was assayed, the standards also contained LDL.

Therapeutic activity of LDL-ACM complex

On day 0, H₂₂ cells (2×10^6) were injected subcutaneously in the right upper armpit of KM mice. Free ACM (3.5 mg/kg) or LDL-ACM complex (3.5 mg/kg) was given intravenously in the tail vein q.d. on days 1-7. After 9 days, the animals were killed. Tumor and body weights were

Received 1999-06-30 **Accepted** 1999-09-11

recorded.

On day 0, H₂₂ cells (2×10^5) were injected intraperitoneally in KM mice. Free ACM (3.5 mg/kg) or LDL-ACM complex (3.5 mg/kg) was given intraperitoneally q.d. on days 1-7. Then survival times and body weights of mice were recorded.

In both types of experiments, eight mice were used for each schedule of administration and controls.

Statistical analysis

Results are expressed as $\bar{x} \pm s$. Difference between mean values was compared by the Student's *t* test.

RESULTS

Antitumoral activity of LDL-ACM complex in mice bearing subcutaneous H₂₂ tumor (Table 1)

When given intravenously, the complex had a marked therapeutic effect on mice with subcutaneous H₂₂ tumor ($P < 0.05$), whereas ACM had not. The average weight for mice in the group of LDL-ACM complex or ACM lost less during the treatment period.

Table 1 Antitumoral activity of LDL-ACM complex and free ACM against murine subcutaneous H₂₂ tumor

Drugs	Mean weight change (g)	Tumor weight ($\bar{x} \pm s$, g)	Inhibition rate (%)
Control	+5.4	1.74 ± 0.60	
Free ACM	+3.2	1.30 ± 0.57	25.3
LDL-ACM	+3.5	0.86 ± 0.44	50.2

Antitumoral activity of LDL-ACM complex in mice bearing intraperitoneal H₂₂ tumor (Table 2)

The survival times of mice bearing intraperitoneal H₂₂ tumor were all significantly prolonged in the groups of ACM ($P < 0.05$) and LDL-ACM complex ($P < 0.01$) when compared with that in the group of control. Administration of LDL-incorporated ACM resulted in a significant increase in antitumoral activity at the same dose as compared with the free ACM ($P < 0.05$). Abnormality in body weight has been noted in any lot of mice.

Table 2 Antitumoral activity of LDL-ACM complex and free ACM against murine intraperitoneal H₂₂ tumor

Drugs	Survival time ($\bar{x} \pm s$, d)	Life-prolonging rate (%)
Control	17.1 ± 3.44	
Free ACM	24.6 ± 7.50	43.9
LDL-ACM	33.4 ± 7.67	95.3

DISCUSSION

An LDL-ACM complex containing 212 drug molecules per LDL particle could be obtained by incubating LDL with a large excess of ACM at 40 °C. High-performance liquid chromatography studies of the mixture before and after the incubation showed that ACM was stable under these conditions^[5].

We investigated antitumoral activity of LDL-ACM complex in mice bearing H₂₂ tumor. Results showed that entrapment of ACM into LDL particles increased the antitumoral activity as compared with the free ACM in H₂₂ tumor model. The improved antitumoral activity could be the fact that the catabolism of the complex was related to the LDLR pathway. By LDLR pathway, tumor tissue took up more ACM by the LDL-ACM complex than normal tissue. Such targeting could lead to increased exposure of ACM to the tumor and consequently, increase the antitumoral efficacy.

LDL-drug complex might result in lesions in the organs like the liver and adrenals known to be the normal tissues with the highest LDL uptake. This problem might be circumvented since animal studies indicate that it is possible to down-regulate the LDL-uptake in these organs by pretreatment with bile acids and steroids without affecting the uptake by the tumor^[8]. Acetyl LDL (Ac-LDL) and Methyl LDL (Me-LDL) are rapidly cleared from the plasma. The endothelial cells of the liver have scavenger receptors and can remove these modified lipoproteins from the circulation. The endothelial cells of the spleen, bone marrow, adrenal, and ovary also participate in this rapid clearance. Internalization of modified LDL leads to the accumulation of large amounts of cholesteryl esters in the cells, which decreases the LDLR activity of these cells. Modified LDL does not affect the tumor LDLR activity. So giving Ac-LDL or Me-LDL in advance may protect the normal tissue having rich LDL receptors from LDL-drug complex during the treatment of tumors^[9,10].

This study has been performed with human LDL. Even if human LDL is recognised by the animal's receptor^[11], the competition from endogenous LDL is very different from the one in the human situation since there are pronounced species differences in the plasma lipoprotein pattern and metabolism. Therefore, the results must be interpreted with caution. It would be suitable to use an animal model close to the human one for the lipoprotein metabolism such as hamster or guinea pigs.

We used a technique which allowed a high entrapment level of lipophilic ACM into LDL. The

cytotoxic LDL-ACM complex so formed exhibited an increasing antitumoral activity in a murine tumor model. Further human clinical trials will depend on a better knowledge of the expression and the regulation of the LDL receptors by the tumor cells. Studies in this optic are now in progress in our department.

Effects of somatostatin on splanchnic hemodynamics in cirrhotic patients with portal hypertension

Zhu JY, Leng XS, Wang D and Du RY

Subject headings hypertension, portal; liver cirrhosis; somatostatin; hemodynamics

INTRODUCTION

Esophageal variceal bleeding (EVB) is one of the most common complications of cirrhosis with portal hypertension. In recent years, great progress has been made in medicinal treatment. Somatostatin has been widely used in clinics, for it can effectively lower the portal venous pressure (PVP) with little side effect. The aim of this study is to assess the effect of somatostatin on portal venous pressure and splanchnic hemodynamics in patients with liver cirrhosis and portal hypertension.

MATERIALS AND METHODS

Subjects

The study subjects were 20 cirrhotic patients with portal hypertension, including 12 men and 8 women. Their mean age was 46.6 ± 13.4 years. All patients had a history of hepatitis B with positive HbsAg and were pathologically diagnosed as having liver cirrhosis.

Methods

All patients were asked to fast and lie supine for 12 hours before somatostatin infusion. The inner diameter and blood velocity of the portal, left hepatic, middle hepatic and right hepatic veins were measured. Using ACUSON 128 × P/10 color Doppler ultrasonography. A continuous infusion of somatostatin was then administered via the peripheral vein at a rate of 250 µg/h. The measurement was repeated after an hour. The blood flow was calculated according to the formula $Q = 60 \pi r^2 V$. The πr^2 in the formula is the sectional area (cm²) of the vein, V represents the mean value of

maximum blood velocity (cm/sec) and Q is blood flow (mL/min). Seven days after the operation, portal venous pressure, blood pressure (BP) and heart rate (HR) were measured in 15 of the 20 patients who had undergone right gastroepiploic venous catheterization. The measurement was taken before infusion of somatostatin and after 1 and 1.5 hours. Students' *t* test was used to compare the data collected before and after the treatment.

RESULTS

Portal venous pressure was measured via the catheter in the right gastroepiploic vein of the 15 portal hypertensive patients at 0, 1.0, and 1.5 hour after somatostatin administration. The portal venous pressure decreased from 20.8 ± 2.0 mmHg (0h) to $18.2 \text{ mmHg} \pm 2.0 \text{ mmHg}$ (1h) and $18.0 \text{ mmHg} \pm 2.0 \text{ mmHg}$ (1.5h), respectively, the differences being statistically significant ($P < 0.01$). However, the difference between 1h and 1.5h was insignificant ($P > 0.05$). The infusion of somatostatin did not affect the systolic arterial pressure (SAP), diastolic pressure (DAP) and HR (Table 1).

Table 1 Effect of somatostatin on PVP, BP and HR

	<i>n</i>	0 h	1 h	1.5 h
PVP (mmHg)	15	20.8 ± 2.0	18.2 ± 2.0^b	18.0 ± 2.0^b
SAP (mmHg)	15	130.0 ± 14.0	134.1 ± 12.0	132.0 ± 16.0
DAP (mmHg)	15	82.0 ± 9.2	84.0 ± 14.0	83.1 ± 14.0
HR (beat/sec)	15	81.2 ± 7.3	79.1 ± 6.2	80.7 ± 6.9

^b $P < 0.01$ as compared to 0 h.

The hepatopetal flow was measured by color Doppler ultrasonography in all the 20 patients. The sectional area of portal vein decreased by 7.28% after the infusion of somatostatin but the difference being insignificant ($P > 0.05$). The average value of portal vein maximum blood velocity decreased by 18.96% from 19.72 ± 7.75 cm/sec to 15.98 ± 7.26 cm/sec, and the average total portal vein blood flow was decreased by 19.72% from $1643.21 \text{ mL/min} \pm 757.25 \text{ mL/min}$ to $1319.49 \text{ mL/min} \pm 622.39 \text{ mL/min}$ after the infusion, the difference being very significant ($P < 0.01$).

In 19 of the 20 patients, the total sectional area and the total blood flow of the three hepatic veins were calculated after somatostatin infusion. The

former increased from $0.72 \text{ cm}^2 \pm 0.21 \text{ cm}^2$ to $0.76 \text{ cm}^2 \pm 0.24 \text{ cm}^2$, and the latter increased from $1786.22 \text{ mL/min} \pm 923.37 \text{ mL/min}$ to $1836.17 \text{ mL/min} \pm 844.24 \text{ mL/min}$. The changes were not significant ($P > 0.05$).

DISCUSSION

It has been shown that humoral substances play important roles in the pathogenesis of portal hypertension. Due to liver function damage and the shunt of collateral circulation, changes occurred in the blood levels of these vasoactive humoral substances and some of them can regulate the portal venous pressure by interfering with blood vessel resistance or blood flow of the portal vein^[1]. The medicinal therapy is somewhat based on this hypothesis.

Somatostatin, one of the peptide hormones originating from neural-ectoderm, is able to inhibit the release of some hormones *in vivo* and lower the portal venous pressure by changing splanchnic blood flow. Treatment of variceal hemorrhage with somatostatin in portal hypertension has been successful according to many recent reports^[2,3]. Seven days after the 8 mm H-graft portacaval shunts (HGPCS), we measured the portal venous pressure via the catheter in the right gastroepiploic vein before and after the infusion of somatostatin and found that somatostatin could lower the portal venous pressure by 2.6 mmHg-2.7 mmHg. There was no significant difference in the portal venous pressure 1 or 1.5 hours after the administration. The results indicated that continuous infusion of somatostatin could decrease the portal venous pressure. At the same time, there was no significant changes in BP or HR. We concluded that somatostatin had fewer side effects than other drugs used to lower the portal venous pressure and had little influence on systemic hemodynamics. It appears that somatostatin can be used clinically to treat bleeding from esophageal varices of portal hypertension.

In order to find out the mechanism of how somatostatin lowers the portal venous pressure, we measured the sectional area and maximum blood velocity, and flow through the portal, left hepatic, middle hepatic and right hepatic veins using color Doppler ultrasonography before and after somatostatin administration. The color Doppler flowmetry in the study of portal hypertensive hemodynamics proved to be an accurate, simple, non-invasive and easily repeated method^[4]. Michel^[5] reported that there existed consistent results by both the pulsed Doppler and electromagnetic flowmetry methods in measuring the portal vein blood flow ($r = 0.918$). Under these

fixed conditions, the data has shed light on the changes in the portal venous blood flow in a same patient observed by a same examiner^[4-6]. Our study indicates that the inner diameter changed slightly and that the sectional area of the portal vein decreased by 7.28% with no significant difference after the infusion, suggesting that somatostatin itself can not directly constrict the portal vein. Our study also indicates that the maximum blood velocity and the maximum portal vein blood flow decreased significantly by 18.96% and 19.72% respectively after the use of somatostatin. This suggests that somatostatin can lower portal venous pressure by reducing blood velocity and blood flow, which was commonly found in other reports^[7]. However, how somatostatin reduces portal vein blood flow remains unclear. Glucagon is reported to be able to increase blood flow and portal venous pressure^[8] while inhibiting the effect of somatostatin in reducing portal vein blood flow^[9]. This suggests that somatostatin inhibits the release of glucagon. Somatostatin was also reported to be able to inhibit the renin-angiotensin-aldosterone system and lessen Na^+ retention^[10,11]. We also discovered that the summation of the three hepatic venous sectional areas and blood flow through these areas increased slightly without any significant differences. In conclusion, the role of somatostatin in splanchnic hemodynamics in cirrhotic patients with portal hypertension should be further investigated.

Radiotherapy of double primary esophageal carcinoma

Xiao ZF, Yang ZY, Zhou ZM, Yin WB and Gu XZ

Subject headings esophageal neoplasms/
radiotherapy; neoplasms, double primary/
radiotherapy

INTRODUCTION

Double primary esophageal carcinoma is defined as having two foci of squamous cell cancer simultaneously or consecutively developing in different sites of esophagus. This rare disease appears mostly in the literature as case reports^[1-4], reports about its treatment are even more infrequent. Here we present our experiences of radiation therapy in 37 patients with this disease and focus the discussion on the optimum method of treatment and complications.

MATERIALS AND METHODS

Materials

Criteria for diagnosing double primary esophageal carcinoma: ① typical findings seen in barium esophagograms, ② two separate lesions spaced ≥ 4 cm apart from each other, with intervening normal mucosa, ③ with endoscopic, pathologic or cytological proof of malignancy, ④ hypopharyngeal or gastric cardia lesions are excluded.

There were 25 males and 12 females, aged 41-80 years, with a peak range of 51-70 years (67.6%). Thirteen of 37 (35.1%) had supraclavicular lymph node metastasis before or during the treatment, 35.1% of patients had lesions in the upper-middle and 64.9% were in the upper-lower segments. The intervening normal mucosa varied from 4 to 13 cm. Length of both lesions was ≥ 5.0 cm in 12 patients, ≥ 5.0 cm in one and < 5.0 cm in the other in 21 cases, both lesions < 5.0 cm in four. The double primaries: developed simultaneously or within 6 months in 48.6%, those

developed beyond 6 months to 3 years in 35.1% and over three years in 16.2%. The longest interval of developing a second primary was 12 years and 8 months. All these were squamous cell carcinoma, among them, 33 were proved by pathology or cytology and 4 by pathology singly.

Treatment

Thirty-three patients received radiation therapy (separate field irradiation) for both lesions and 4 patients refused to have irradiation of the second lesion because of psychological reasons. Among them, two-thirds were treated by rolling technique, and one-third by antero-posterior irradiation, at 30-40 Gy/wk. The rest of the dose was delivered by two posterior oblique technique. In 59.5%, each individual lesion received a curative dose of 60GY-70GY/30F-35F/6 wk-7 wk and 40.5% received a palliative dose (≤ 40 Gy/20 F/4 wk) or with one lesion left untreated. Statistical calculation was done by Chi-square test.

RESULTS

The 1, 3 and 5-year survival rates were 27%, 5% and 0%, different from those with single lesion (38%, 13% and 8.4%) in 3798 patients treated in our hospital but with no statistical significance ($P > 0.05$, $\chi^2 = 1.854$, $\chi^2 = 2.1$). The failure due to metastasis was very high, giving no 5-year survivor.

The 1- and 3-year survival rates of patients who received curative doses were 27.2% and 9.1% and 26.7% and 0%; for those who received palliative doses. Only those with two lesions irradiated were able to survive more than one year, even with absence of supraclavicular lymph node metastasis, the curative group had no 5-year survival.

In the present series, 62.1% failed by local recurrence, 10.8% by pulmonary radiation injury and 29.8% by distant metastasis.

DISCUSSION

The 1-, 3- and 5-year survival rates of double primary esophageal cancer treated with radiation therapy were 27%, 5% and 0% as against 38%, 13% and 8.4% with only one lesion, without statistical significance ($P > 0.05$). The 1- and 3-year survival rates of curative dose were 27.3% and 9% vs 26.7% and 0% of those given palliative dose. The 1- and 3-year survival rates of those having no supraclavicular lymph node metastasis

were 38.5% and 15.4%.

In debilitated or those who already had supraclavicular node metastasis, palliative dose would give symptomatic relief and prolongation of life. But in cases in which one of the two lesions was left untreated, none lived for over one year.

To improve its prognosis, early diagnosis is essential. During the follow-up examination of post-irradiated esophageal cancer patients, care should be directed not to miss a second primary focus. About 83.3% of the second primary would appear

within 3 years after the detection of the first primary focus.

bFGF and TGF β expression in rat kidneys after ischemic/ reperfusional gut injury and its relationship with tissue repair

Yang YH, Fu XB, Sun TZ, Jiang LX and Gu XM

Subject headings ischemia-reperfusion injury, intestinal; basic fibroblast growth factor; transforming growth factor β ; gene expression

INTRODUCTION

Intestinal ischemia/ reperfusion (I/R) occur commonly in critically ill patients. It is well recognized that gut I/R may cause tissue damage and dysfunction of intestine, and induce remote organ injury including kidney, lung, and liver^[1]. It may also lead to complications after severe burn or injury. Previous studies have focused on cellular elements, cytokines and inflammatory mediators. Relatively little attention has been paid endogenous protective mechanisms, i.e. the growth factors.

Both bFGF and TGF β are important growth factors involved in tissue repair, these involve dermal and epidermal wound healing via promoting the initiation and regeneration of capillary vessels, effective chemotactants and increasing deposition of extracellular matrix^[2]. Recent studies demonstrated that given exogenous growth factors could accelerate internal organ repair after gut I/R injury^[3,4], however, little is known about its molecular mechanism.

The present study was carried out to evaluate endogenous bFGF and TGF β expression of renal origin in a gut I/R rat model, and to explore the role of bFGF and TGF β 's release in active repair.

MATERIALS AND METHODS

Animal model Male, pathogen-free Wistar rats were purchased from the Animal Center, Academy of Military Medical Sciences, weighing 200 g to 250 g. Animals were allowed water only for 24 hours before use, and anesthetized with pentobarbital sodium (30 mg/kg). Following midline laparotomy, intestinal ischemia was

achieved by placing a microvascular clip across the proximal superior mesenteric artery (SMA) for 45 min, animals were then allowed reperfusion for different periods after removal of the clip and randomly divided into ischemia group (IR0; $n = 12$), reperfusion for 6 hours (IR1; $n = 12$) and 24 hours (IR2; $n = 12$) groups. Time-matched, sham-operated animals underwent laparotomy and dissection of the proximal SMA without occlusion served as controls (control; $n = 12$). Experimental animals were sacrificed and kidney tissues were fixed in 4% paraformaldehyde in PBS and 10% formalin respectively for analysis.

In situ hybridization

Tissues were dehydrated in an ascending series of ethanol and were embedded in paraplast. Five micro-thick sections were cut and prehybridized sequentially in PBS, 0.2N HCl for 20 min, Proteinase K, 1 mg/L (Sigma) for 20 min in 42 °C, 2% glycine 15 min, post-fixation was performed with 4% paraformaldehyde in PBS for 20 min. Slides were dehydrated and prehybridized for 2 hours without probe and hybridized for 20 hours with probe at 42 °C bFGF and TGF β cDNA probes were obtained by polymerase chain reaction (PCR) and confirmed by sequencing analysis. The probes were labeled with DIG Labeling and Detection Kit (Boehringer Mannheim Co., Germany) with random primers. After hybridization, slides were washed with following solutions, 2 \times SSC, 0.1 \times SSC, maleic acid 0.1 mol/L, NaCl 0.15 mol/L, and 10% blocking solution. Sections were stained with NBT/BCIP. The positive staining was examined and photographed by a microscope equipped with camera.

Immunohistochemistry

Immunostaining was performed using polyclonal anti bFGF or TGF β antibody by an indirect Streptavidin / Peroxidase (SP) technique. Antibodies and immunohistochemical SP kit were products of Santa Cruz Co. and Zymed Co.. Experiments were performed following the manufacturer. Briefly, sections were incubated with polyclonal anti-rat bFGF or TGF β antibody for 12 hours at 4 °C. Slides were washed with phosphate buffered saline (PBS) solution. Biotinylated

secondary antibody IgG was added for 30 min, followed by horse radish peroxidase labeled streptomycin-avidin complex for 30 min. Slides were stained with diaminoben zidine and counterstained with Harris hematoxylin/eosin and examined under a light microscope equipped with a camera.

Statistical analysis

The percentage of positive staining cells of immunohistochemistry and *in situ* hybridization were expressed as mean \pm SD. Statistical analyses were performed using paired Student's *t* test. $P<0.05$ was considered significant .

RESULTS

Pathological alterations of kidney tissue

Multiple cross-sections of hematoxylin and eosin stained sections of kidneys were examined for pathological changes. Compared with control group, IR0 had slight alteration, while IR1 showed significant injury. In IR1 sections, clearly tubulointerstitium fibrosis and inflammatory cells infiltrating could be seen, accompanied with vessel wall thickening, tubule narrowing and glomeruli basement membrane destruction, etc. After reperfusion for 24 hours, IR2 recovered gradually.

Immunohistochemical localization of bFGF and TGF β

Both *in situ* hybridization and immunohistochemistry found expression of bFGF and TGF β in kidney tissues. bFGF was localized in cortex and glomeruli, particularly in mesangial cells, glomeruli epithelial cells and podocytes. TGF β , however, was found predominantly in mesenchymal cells and glomeruli epithelial cells. Both bFGF and TGF β positive staining of ISH were localized in the cytoplasm. While positive staining of immunohistochemistry was in cytoplasm or/and membrane.

Detection of bFGF and TGF β expression

Immunohistochemistry and *in situ* hybridization showed both bFGF and TGF β were expressed in controlled rat kidneys, and their expression level was enhanced slightly after 45min ischemia. While significant elevation of bFGF and TGF β expression was observed after reperfusion, peaking at 6 hours (IR1) and declined at 24 hours (IR2). Both bFGF and TGF β expression changes have significant difference after reperfusion compared with control ($P<0.05$), and positive correlation was found between bFGF and TGF β expression ($r=0.98$, $r=0.97$). Results of their expression of different groups are shown in Table 1.

Table 1 bFGF and TGF β expression levels after I/R injury in rat kidneys ($\bar{x}\pm s$)

DISCUSSION

Gut I/R has been implicated in the pathogenesis of intestine and other remote organs, and may potentiate the development of systemic inflammatory response syndrome (SIRS) and even multiple organ dysfunction syndromes (MODS). Much has been learned about the mechanisms that contribute to this injury process, which shows that this process is associated with activation of systemic inflammatory mediators including complement, cytokines, neutrophils, oxygen free radicals, gut derived bacteria and endotoxin. Great attention has been paid to the potential therapeutic effect of antibodies to these elements. Relatively little is known about the endogenous protective mechanism responding to the gut I/R injury. bFGF and TGF β are important growth factors involved in wound healing and tissue repair and may be important mediators for renal repair after intestinal I/R injury.

bFGF is a potent mitogen, angiogenic agent, and chemoattractant. It is expressed in many kinds of cells, including macrophages, smooth muscle cells, vascular endothelial cells and fibroblasts, bFGF accelerate wound healing through promoting the initiation and regeneration of capillary vessels, accelerating the growth of epithelial cells and fibroblasts, and formation of granulation tissue. It does not have a signal sequence and thus is released independently of endoplasmic reticulum-Golgi pathway. bFGF is stored in inactive form in cell cytoplasm and is activated by cell injury. TGF β is a growth factor having various functions, its biological activity depends on its concentration and cell types. TGF β is a potent chemoattractant for inflammatory cells and fibroblasts. It can promote connective tissue formation and accelerate collagen synthesis, induce the release of many other growth factors, such as bFGF, vascular endothelial growth factor (VEGF) in wound healing and tissue repair^[5,6].

In our present study, bFGF and TGF β mRNA and protein expressed after I/R injury in rat kidneys, and had close spatial and temporal association with the development of renal injury. Their expression levels were induced after I/R injury, peaking at 6 hours and decreased after 24

hours, correlated with the degree of tissue injury and compatible with other experiments of internal organ injury models. Iwata A *et al.*^[7] found in a model of transient focal ischemia, bFGF mRNA was markedly induced in the peri-infarcted white matter after reperfusion, persisted for 2 days and disappeared by 5 days. In rat livers after gut I/R injury^[8], endogenous bFGF and TGF β mRNA expression increased after reperfusion, and persisted for 24 hours. These results showed endogenous bFGF and TGF β mRNA in internal organs were induced after injury, peaking at the point of severe damage. At this time point, rat kidneys showed markedly tubulointerstitium fibrosis and glomeruli basement membrane destruction. Whereas developmental assembly of endothelial, mesangial and epithelial cells into glomerular requires a coordinated, temporally defined series of steps occurred in an ordered sequence, growth factors and their receptors are important mediators of many of these events. Our results showed that bFGF and TGF α might participate in this process. Experimental studies had also found that bFGF is a most potent angiogenic factor and TGF β played an important role in angiogenesis. The significantly elevated expression of bFGF and TGF β after renal damage suggests bFGF may be involved in renal blood vessel development. Furthermore, in inflammation reaction after injury accumulation of inflammatory cells, such as monocytes, neutrophils and macrophages etc results in release of large amount of TGF β , and high local concentration of TGF β induces the high expression of bFGF mediating the tissue repair. Our study shows that

I/R injury up-regulate endogenous bFGF and TGF β expression, and suggests this may serve as a compensatory protective response to remote organ injury.

Recent studies have demonstrated the feasibility of using exogenous growth factors *in vivo*, of which VEGF and bFGF can improve internal organ injury. Though the precise underlying mechanisms remain to be determined, the use of growth factors may represent a new therapeutic strategy for patients with gut I/R injury.

A chronic ulcerative colitis model in rats

Zheng L, Gao ZQ and Wang SX

Subject headings colitis, ulcerative; disease model, animal; rats

INTRODUCTION

In recent years, there have been many reports about animal model to investigate drugs for inflammatory bowel diseases (IBD). The experimental animal model often used is acetic acid-induced damage of colonic mucosa. In the present study, this animal model was investigated by administering various concentrations of TNBS.

MATERIALS AND METHODS

Materials

Animals Wistar male and female rats weighing 258 ± 25 g were used in this study. They were provided by the Department of Experimental Animals of Beijing Medical University. They were housed in rack-mounted cages with a maximum of 6 rats, and were fasted for 12h with access to water ad libitum before experiment.

Reagent Fifty mmol/L (pH=6.0) phosphate buffer, 0.5 % hexadecyltrimethylammonium bromide (HTAB, Beijing Xizhong Chemical Plant) in 50mmol/L (pH=6.0) phosphate buffer, 50mmol/L (pH=6.0) phosphate buffer containing 16.7% (g/L) o-dianisidine Dihydrochloride (Sigma chemical Co.) and 0.0005% hydrogen peroxide, TNBS (Sigma chemical Co. 5% w/v solution) solution of 30% ethanol, 20% (w/v) ethyl carbamate in 0.9% saline.

Instrument T25 Ultra-tukrax (German, JANKE & KUNKEL IKA-Labortechnik). 4710 series

Ultrasonic homogenizer (Cole-Parmer Instrument Co. America), GL20A Refrigerated Centrifuge (Hunan Instrument and Meter Plant China), UV-260 Spectrophotometer (Shimuduzu Co. Japan), PHSJ-4 pH meter (Shanghai Leici Instrument Plant China), Libror EB-2080M Electronic Animal Balance (Shimuduzu Co. Japan).

Methods

Effect of various TNBS doses on myeloperoxidase (MPO) activity, colon damage and weight A total of 30 rats were randomized into five groups, 6 rats each group (in a cage), consisting of a 30% ethanol control group as well as four dose TNBS groups. The animals were anesthetized with 20% ethyl carbamate (ip, 6mL/kg), and 0.5mL of either 30% ethanol (controls) or various concentrations of TNBS was slowly administered into the lumen of the colon via the anus using a rubber catheter (12cm long, external diameter 2mm). The rats were killed after 3wk, and the distal colon (8cm) was removed, opened longitudinally and washed to remove lumina contents, colon wet weight was weighed, and colonic injuries were evaluated. The excised colon was pinned out on a wax block washed with 0.9% saline and assigned a code number. The colon was immediately examined under a stereomicroscope and any visible damage was scored on a 0-5 scale (Table 1). Small sections of colon were taken from two distinct areas from each colon and placed in 10% formalin for histological examination. The colon was fixed, cut longitudinally into 5mm sections, stained with hematoxylin and eosin. The second segment (200mg-400mg) was immediately frozen for subsequent estimation of MPO activity^[1].

Table 1 Criteria for scoring the gross morphologic damage

Score	Gross morphology
0	No damage
1	Localized hyperemia with no ulcers.
2	Liner ulcers with no significant inflammation.
3	Liner ulcers with inflammation at one site.
4	More sites of ulcers and inflammation, the size of ulcers <1cm.
5	Multiple inflammations and ulcers, the size of ulcers ≥1cm.

The relationship of MPO and time-course Based on the results of dose-response studies, the dose of

TNBS used in subsequent experiments was 100 mg/kg per rat. A total of 40 rats (5 rats per cage) administered a single intracolonic dose of TNBS ethanol solution (0.5 mL/rat). In control experiments, 5 rats received 0.5 mL 30% ethanol. At various times (24 h and 1 wk-8 wk) after intracolonic administration of TNBS or one of the control solutions, 5 rats from each treatment group were randomly selected and killed, the colon tissue MPO activity was determined as the indices of inflammation.

Statistical analysis The data were expressed as $\bar{x} \pm s$, and analyzed using the Student's *t* test to compare the difference.

RESULTS

Assessment of MPO activity, colonic weight and damage score

The severity of colonic damage induced by TNBS increased with the dose (Figure 1). Rats that received the lowest dose of TNBS (25 mg/kg) had damage scores, colon weights and tissue levels of MPO activity were not significantly different from the control animals treated only with 30% ethanol vehicle ($P > 0.05$). When doses of TNBS (50 mg/kg - 150 mg/kg) were used, the damage scores, colon weights and tissue levels of MPO activity increased in a dose-related manner and there was a significant difference compared with control (30% ethanol).

Histological examination

Three weeks after TNBS/ethanol administration, the bowel wall was basically normal in the 25 mg/kg group, and "string of beads" was found in 1 rat. Medium hemorrhage, edema and ulcers, cryptoabscess in the mucosa were observed in animals that received 50 mg/kg of TNBS, in TNBS group (100 mg/kg), the bowel lumen became narrow with thickened wall (2 mm-3 mm), on the bowel lumen mucosal surface area there was adherent membrane with brown black, liner ulcers (1 mm-6 mm), proliferous lymphocyte tissue, inflammatory granulomas and submucosal neutrophils infiltration. Macrophages, lymphocytes, fibroblasts, and cryptoabscess were also observed. The TNBS (150 mg/kg) group had noticeable ulcers and inflammatory granulomas in their colon, neutrophil infiltration was obviously observed in mucosa and sub mucosa extensive necrosis of the colonic mucosa and exfoliation of the epithelia were found in other rats with intact

muscularis. In cases of severe ulcers, the colon had often adhered to surrounding intestinal tissues and abdominal wall (Figure 2).

Time-course study

A single instillation of TNBS at the dose of 100 mg/kg into the rat colon produced chronic ulcers and inflammation which had persisted for up to 7 wk. MPO activity reached a maximum value at 3 wk after TNBS, and was followed by a gradual reduction in activity. At 3 wk the MPO value was at near baseline level (Figure 3).

DISCUSSION

TNBS is a hapten, when it is bound with a substance of high molecular tissue proteins, it will turn into an antigen. It has been shown that it can elicit immunologic responses, induce generation of colitis^[2,3]. The histological features of the animals received TNBS (50 mg/kg-150 mg/kg) were chronic inflammation, relatively long duration of inflammation and changes in various inflammatory mediators such as prostaglandin E_2 , thromboxane B_2 , leukotriene B_4 , 6-keto-prostaglandin $F_{1\alpha}$, leukotriene C_4 , platelet activating factor and interleukin. This model is characterized by the simple process and reproducible colonic damage, inexpensive and short duration of the experiment, long-lasting damage with inflammatory cell infiltration and ulcers. Thus, the model is rather suitable for the assessment of the effects of potential agents. In the present study, the dose of TNBS producing a moderate colonic inflammation and ulcers was about 100 mg/kg, the severity of colonic inflammation induced by TNBS increased with the dose administered. So a TNBS dose of 100 mg/kg was chosen for an appropriate experimental dose, the results were similar to the reports in the literature^[4,5].

There was extensive colonic mucosal and submucosal damage characterized by infiltration of inflammatory cells and ulcers after different doses of TNBS (50 mg/kg - 150 mg/kg) were administered into the colons of rats. After the animals received TNBS (100 mg/kg), in acute phase, extensive infiltration of inflammatory cells constituted the main part; in chronic phase, the inflammatory granulomas and ulcers induced by TNBS made up the main part. MPO is an enzyme found in the neutrophils, and can be used as a quantitative index of inflammation in colonic tissue^[1]. MPO activity may be regarded as an index of inflammation damage^[6].

Figure 1 Rats were killed 3wk after intracolonic administration of 25 mg/kg-150 mg/kg of TNBS. Colonic damage, colon weight and tissue MPO activity were assayed. Data of TNBS-treated rats were compared with control (30% ethanol) group by Student's *t* test, ^a*P*<0.05, ^b*P*<0.01.

Figure 2 Histological findings in ulcerative colitis induced by different doses of TNBS ethanol. a: TNBS 25 mg/kg, the mucosa is normal. b: TNBS 50 g/kg, small mucosal ulcers and crypt abscess formation. c-d: TNBS 100 mg/kg, mucosal ulcers, inflammatory exudate, proliferous granulomas and cells infiltration. e-f: TNBS 150 g/kg, gross ulcers and proliferous granulomas, necrosis of epithelium at mucosal surface and inflammatory cell infiltration (He, $\times 100$)

Figure 3 The effects of intracolonic administration of 100mg/kg of TNBS on MPO activity 1 wk-8 wk after administration. Each bar represents the $\bar{x} \pm s$ of 5 animals. All data for TNBS-treated rats were compared with 0 wk (control group). ^a*P*<0.05, ^b*P*<0.01.

Tracing method study of bacterial translocation *in vivo*

Fu WL, Xiao GX, Yue XL, Hua C and Lei MP

Subject headings PUC19 plasmid trace; bacterial translocation; restriction map analysis; fluorescence labeling

INTRODUCTION

Endogenous infection plays an important role in nosocomial infection^[1-3]. By studying progress of bacteria translocation from intestinal tract, the concept of gut origin infection has been accepted gradually^[4-6]. Because of no ideal tracing method, there were some controversies. In order to solve the problem, the PUC19 plasmid vector tracing method with restriction map analysis and fluorescence labeling method were used to study gut-origin bacterial translocation. According to the characteristic of PUC19 plasmid, a special animal model was designed and two methods were compared.

MATERIALS AND METHODS

Material

PUC19 plasmid vectors (Promega): amplification of plasmid was in LB culture medium containing 100mg/L ampicillin. Fluorescence-labeling bacteria: 1/10000 acridine orange was added in culture fluid of *E. coli* CMCC 44102. The cells were grown in broth overnight at 37°C. Restriction DNA endonucleases: *Hind*-III, *Eco*R-I (Promega Co.). Plasmid was isolated as described by Kado *et al*^[3]. A total of 110 male Wistar rats, weighing 226 g±64 g were used. The animals were divided into PUC19 plasmid group and fluorescence-labeling one. The animals in fluorescence labeling group were sacrificed and examined at 4, 12, 24 and 48 h postburn with 10 rats at each time point, the normal control group contained 10 rats, with a total of 50

rats. The rats in PUC19 group were treated the same as those described above, another 10 rats were added at the time point of the 12th day postburn.

Methods

Fluorescence labeling group: 10¹²/L fluorescence-labeling *E. coli* were introduced into the stomach of rats by gastric tube. After 8 hours the animals had 30% TBSA (total burned surface area) full thickness burns. Three mL/100 g body weight saline was injected into rat's abdominal cavity for anti-shock. The rats were sacrificed at 6, 12, 24 and 48 h after burn. Mesentery lymph nodes (MLN), liver and subeschar tissue were collected by aseptic technique. The homogenates were divided into two parts, the first part cultured for enumerating microorganisms and second part examined under fluorescence microscope.

PUC19 plasmid tracer group: before burn, animals drank 300 mg/L ampicillin fluid for 3 days to "clean up" the intestinal tract. The PUC19 plasmid vector was introduced into the stomach by way of gastric tubing. Then the animals were again given ampicillin fluid (100 mg/L ampicillin) and examined to confirm whether PUC19 plasmid vector had colonized in the rat's intestinal tract. The animals were inflicted with 30% TBSA third degree burn and sacrificed at 6, 12, 24, 48 h and 12 d postburn. The methods were the same as those described above. Homogenates of mesenteric lymph nodes, liver, and subeschar tissues were incubated in LB broth containing 100 mg/L ampicillin (18 hours) at 37 °C with shaking at 50 min⁻¹-100⁻¹rpm.

Plasmid isolation of the bacteria was made according to Kado's method. The product was digested 1h at 37 °C by restriction enzymes *Eco*RI and *Hind* III. Ten g/L agarose gel with well sufficient to accommodate 40 µL samples was prepared and the gel was stained with ethidium bromide. Photographs of gel were taken and positioned over an ultra-violet (UV) ray source.

RESULTS

Fluorescence-labeling bacteria

Labeling bacteria were found to pass through damaged intestinal mucosal barrier and escaped from cleansing effect of liver and lymph nodes and finally reached the subeschar area.

Received 1999-07-14 Accepted 1999-09-15

Detection rates of fluorescence-labeling bacteria from mesenteric lymph nodes, liver and subeschar tissues were enumerated (Table 1). The quantity and rate of bacteria by fluorescence-labeling at different time points after burn are shown in Table 2.

Table 1 Detection rate of fluorescence-labeling bacteria

Organ and tissue	No. of samples	Positive rate (%)	No. of FB/ ^a 10×100
Mesenteric lymph nodes	40	38(95.0)	3.8
Liver	40	23(57.5)	2.1
Subeschar	40	13(32.5)	1.1

Table 2 Quantity and rates at different periods after burn

Group	t/h	Mesenteric lymph node		Liver	
		Rate	Quantity(cfu/g)	Rate	Quantity(cfu/g)
Burn	6	100	3.0×10^4	70	2.1×10^4
	12	100	8.5×10^4	70	3.1×10^3
	24	90	7.4×10^4	50	2.6×10^3
	48	70	8.2×10^3	40	1.5×10^3
Normal	6	40	8.0×10^3	0	0

PUC19 plasmid tracing

Bacteria that resist to apmicillin (AMP) could be separated from mesenteric lymph nodes, liver and subeschar tissues after burn. Isolation of plasmid and restriction enzymes analysis indicated that bacteria resistant to ampicillin that separated from intestinal and subeschar tissue had the same DNA restriction map (Figure 1).

Figure 1 Plasmid fragment generated by restriction endonuclease-1. Control; 2. HindIII λ DNA; 3. PUC19 vector bacteria; 4. bacteria from gut; 5. bacteria from subeschar tissue.

The detected quantity and positive rate of PUC19 tracing bacteria after burn are shown in Table 3. The positive rate of PUC19 bacteria in early and late stages after burn is shown in Table 4.

Table 3 Quantity and positive rate of PUC19 bacteria after burn

Group	t/h	Mesenteric lymph node		Liver	
		Quantity(cfu/g)	Rate(%)	Quantity(cfu/g)	Rate(%)
Burn	6	5.0×10^4	89.	2.3×10^3	60.
	12	4.0×10^4	80.	2.4×10^3	60.
	24	3.1×10^4	80.	2.6×10^3	50.
	48	8.0×10^3	62.	8.0×10^3	37.
	12(d)	5.1×10^3	25.	0	0
	6	1.0×10^5	20.	0	0

Table 4 Comparison of positive rates of PUC19 in early and late stages postburn

Organ	Early stage within 48 h postburn		Late stage 12 d postburn	
	No. of samples	Positive (%)	No. of samples	Positive (%)
Mesenteric lymph nodes	37	29(78.4)	8	1(12.5)
Liver	37	19(51.4)	8	0 (0.0)
Subeschar	37	4(10.8)	8	5(62.5)

DISCUSSION

In recent years, more and more studies in gut-origin infection have been reported. Gut-origin infection as an important way of infection in burn had been established. But there were still some disputes about its verification by tracing methods^[7-15]. In the past, these included the fluorescence and isotopes labeling methods. PUC19 plasmid was constructed in the 1980s, and was used extensively in molecular cloning and discrimination of gene recombination^[16]. The characteristics of the PUC19 plasmid were: ① plasmid vector carried ampicillin resistance gene; ② the plasmid possessed polyclonal restriction endonuclease sites, panning positive bacteria became easier to be discriminated; and ③ it lacked nic/bom site, hence gene transduction from conjugate of bacteria was impossible. These features indicated that PUC19 plasmid could be an ideal tracer for studying endogenous bacterial translocation.

Comparing the results of the two tracing methods used in our experiment, we could find the positive rate of fluorescence-labeling organisms was higher than that by PUC19 plasmid tracing method in bacteria reaching mesenteric lymph nodes and liver after serious burn. Because many factors can cause nonspecific reaction in fluorescence-labeling method, some false positive results may be present, but we think that fluorescence-labeling bacteria tracing method is still useful for gut bacterial translocation study, although not for quantitation study and long period study.

Helicobacter pylori infection

Vandenplas Y

Subject headings *Helicobacter pylori*, gastritis; Helicobacter infection

IS THERE ANYTHING NEW?

Helicobacter pylori has been for many years a forgotten bacterium, since the first report on this spiral organism dated from the 19th century^[1]. As early as in 1906, an association between a spiral organism and gastric carcinoma was suggested^[2]. Doenges reported in 1938 that on autopsy not less than 40% of human stomachs were found to be invaded by spiral organisms^[3]. In 1940, the therapeutic effect of bismuth in patients with peptic ulcer in the presence of spiral bacteria in the stomach was reported^[4]. Then, interest in this bacterium decreased. In 1982, two Australian researchers, Marshall and Warren, rediscovered the microbe^[5], and called it at first *Campylobacter pylori*, later *Helicobacter pylori*. Today, the complete genome (1590 genes) of *H. pylori* has been unmasked^[6] and published on the internet (<http://www.tigr.org>), probably paving the way for sequencing the genome of other organisms, including that of humans within a few years^[7].

WHY IS *Helicobacter pylori* SO IMPORTANT?

There is unequivocal evidence that *H. pylori* can be considered as a healthcare issue because of the mortality associated with the infection, due to the risk of ulcer bleeding and gastric cancer. Infection with *H. pylori* results in the development of gastritis in all infected humans, including children and adolescents^[8]. Peptic ulcer disease is a major cause of morbidity and distal gastric adenocarcinoma, which is the second biggest cancer killer worldwide^[9]. However, the majority of infected individuals remain free of symptoms throughout their lifetime; only a small number present with peptic ulcer disease (lifetime risk 15%), and an even smaller proportion will develop

gastric neoplasms including (mucosa-associated lymphoid tissue) lymphoma and adenocarcinoma (lifetime risk 0.1%)^[10]. Overall, *H. pylori* can be discovered in 92% of children with duodenal ulcers and in 25% of children with gastric ulcers^[11]. *H. pylori* infection is contracted primarily in childhood, and infection from childhood appears to enhance the risk for carcinogenesis^[12].

ABOUT THE BACTERIUM: VIRULENCE

The microaerophilic, gram-negative, urease-producing *H. pylori* fulfills each of Koch's postulates^[8]. In the normal living form, it is a spiral-shaped bacterium, but the coccoid form can also cause lesions. The bacterium colonizes the stomach of man and induces severe mucosal inflammation and a local and systemic immune response. It is capable of changing its membrane potential at external pH from 3.0 to 7.0 in order to maintain a neutral internal pH^[13]. Not all *H. pylori* strains are created equally^[14]; and not all are associated with clinical symptoms.

Some virulence factors such as urease and flagella are present in all strains and are necessary for pathogenesis and colonization. Flagella, and thus motility, are needed for persistent gastric colonization^[15]. The gene FlbA is needed for flagellar expression^[16]. Enzymes produced by *H. pylori* have mostly metabolic, antioxidant and toxic properties^[17]; most of these are produced by all isolates tested. Urease is required to establish infection, and is located intra and extracellularly^[15]. It is a nickel-containing metallo-enzyme, consisting of two structural subunits, UreA and UreB^[18]. Urease is primarily a cytoplasmic enzyme^[19], and hydrolyzes urea to bicarbonate and ammonia, resulting in a net increase in the ambient pH. Ammonia is a nutrient for the bacteria, and causes lesions to the gastric epithelium by many different mechanisms^[20]. Surface urease helps protect against acid exposure, but it is as yet unclear why it is found on bacteria deep underneath gastric mucus where the pH is thought to be neutral. Because there is no obvious urease export machinery, it has been suggested that some bacteria undergo autolysis, which released proteins, including active urease are absorbed onto the surface of remaining intact bacteria^[19,21]. Urease might function as an adhesin, although this suggestion has also been contradicted^[22]. Urease stimulates the

release of a variety inflammatory cytokines including interleukin- beta, interleukin-6, tumor necrosis factor-alfa, and chemokines such as interleukin-8^[23]. Although the exact mechanism by which urease functions in the pathogenesis of gastric disease remains unclear, it is likely that urease is an important virulence factor.

H. pylori can produce different kinds of phospholipases weakening the hydrophobicity of the gastric mucous and mucosa. Phospholipase can also generate ulcerogenic substances^[24]. Many other enzymes, such as mucinase, neuraminidase, fucosidase, alcohol dehydrogenase, etc. have been reported^[20].

The vacuolating cytotoxin A (VacA) gene is present in all strains, but is only expressed in 50% of *H. pylori* isolates^[25]. The vacuolating activity of VacA is increased by exposure to acidic pH values^[26]. The vacuoles are formed by merging of late endosomes and the mechanism causing this has been determined^[27]. The VacA gene exhibits different allelic combinations. Strains with the gene s1/m1 have the highest levels of cytotoxic activity; colonize the stomach more densely and are correlated with peptic ulcer, atrophic gastritis and gastric cancer; s2/m2 strains have no toxic activity^[20,28].

Other virulence factors, such as “cytotoxic-associated gene A” (cagA) encoded proteins are only found in a proportion of the strains. This might explain why not all strains are associated with clinical symptoms, although both cagA and the s1 vacA allele are unreliable as single markers in determining the risk of developing peptic ulcer disease^[29]. The cagA protein is a cryptic 128 kDa immunodominant antigen produced by *H. pylori*. CagA is a marker for a larger cluster of genes (40 different genes^[20]) carried on a pathogenicity island that exhibits variability between strains^[30]. CagA+ strains produce increased amounts of interleukin 8^[30]. Gastric atrophy, duodenal ulceration and gastric carcinoma are more common in patients infected with CagA+ than with CagA- strains^[31]. CagA negative strains are very rare in some Far East countries such as China and Korea but frequent in some other areas such as Hong Kong, and are reported to be not a marker of specific disease in these regions^[32]. However, allelic variations in the cagA protein are found in different parts of the world. In Western countries, cagA positive strains are associated with gastric atrophy and peptic ulcer disease^[33]. But, there appears also to be no association between cagA and clinical symptoms or ulcers in children^[32,34]. Other putative virulence determinants are being discovered, such as the neutrophil-activating protein (napA) gene, a gene

“induced by contact with epithelium” (iceA1), etc^[20]. However, according to the recent data, it is suggested that there is no correlation between the degree of inflammation and the presence of the cag-pathogenicity island, cytotoxin production, vacA alleles associated with cytotoxin expression in children^[35].

Auto-immunity and host mimicry by expression of blood group antigens may be a relevant phenomenon. Adhesion of *H. pylori* is nonspecific although preferential to epithelial cells and is enhanced at low pH, inducing epithelial cell reorganization and causing deep invagination of the apical membrane, explaining resistance to topical antibiotic treatment^[36]. One host receptor for adhesion appears to be a blood group O antigen, possibly explaining why ulcers are more common in people with this blood group^[37]. The *H. pylori* lipopolysaccharide (LPS) or endotoxin is unusually biologically inert compared with that from other bacteria. However, the mechanisms by which *H. pylori* LPS stimulates cells appears similar to that of other types of bacterial LPS^[38]. *H. pylori* LPS often contains Lewis x and Lewis y blood group antigens that are identical to those occurring in the gastric mucosa^[39]. *H. pylori* presents bacterial epitopes to the host which are similar to the structure on host gastric epithelium; therefore, the host reacts with an auto-antibody response recognizing gastric mucosa inducing atrophic gastritis^[40]. Patients with a large parietal cell mass and high acid secretion will have a predominantly antral gastritis, predisposing to duodenal ulcer^[41]. People with a small parietal mass and low acid output (or people on proton pump inhibitors) will be more prone to develop atrophic gastritis and gastric malignancy^[41]. The variability in occurrence of gastric cancer in different parts of the world may only be partly explained by the prevalence of *H. pylori*. Apoptosis of gastric epithelial cells is increased in *H. pylori* infection, stimulating crypt cell proliferation, increasing the risk for mutagenesis^[42]. Atrophic gastritis enhances the development of intestinal metaplasia, and is related to the intestinal type of gastric carcinoma but not to diffuse gastric carcinoma^[43]. Intestinal metaplasia is related to atrophic gastritis, which is in its turn related to *H. pylori* infection.

Symptoms

H. pylori infection in children is mostly asymptomatic and not associated with specific gastrointestinal symptoms^[44]. *H. pylori* gastritis, in the absence of duodenal ulcer, does not appear to be associated with specific symptoms^[11,45-49]. After eradication of *H. pylori* infection, symptoms are

improved only in those children with duodenal disease^[46]. Children with *H. pylori* gastritis cannot be distinguished from noninfected children on the basis of initial symptoms^[45,49]. Many studies failed to demonstrate a difference in *H. pylori* infection rate in children with or without recurrent abdominal pain^[11,49-51], although others did find this association^[52]. Recurrent abdominal pain would occur during the acute phase of *H. pylori* infection^[52]. It is unclear whether children with recurrent abdominal pain with *H. pylori* represent a different entity to those without *H. pylori*. *H. pylori* positive children might more often have pain related to meals than *H. pylori* negative children. Ulcer-like symptoms may be more closely associated with the infection than other symptom complexes^[53].

In adults, a significantly lower *H. pylori* prevalence was reported in patients with gastroesophageal reflux disease^[54]. The role of *H. pylori* in duodenogastric reflux is unclear. A decreased mean acid output in subjects with *H. pylori* gastritis might explain the inverse relation between reflux and *H. pylori*. Heartburn and epigastric pain might be more frequent in *H. pylori* infected patients. Pooled data from 18 studies suggest that the prevalence of *H. pylori* was greater in patients with dyspepsia than in controls^[53]. It is unclear whether *H. pylori* changes gastric emptying rate or not, although most data have suggested that gastric emptying is normal^[55-57]. In adults, *H. pylori* is also beyond any doubt associated with an increased incidence of gastrointestinal cancer. However, the high prevalence of early *H. pylori* infection and chronic gastritis in children contrasts with the rarity of gastric cancer in black African^[58]. Nevertheless, acquisition in infancy is in general considered to be a significant risk factor to develop gastric carcinoma^[48].

Similar to other chronic inflammatory conditions, infection with *H. pylori* has been linked to reduced growth^[59-65], although socioeconomic factors confuse the issue. Tumor necrosis factor- α is inversely correlated with growth, and is increased in *H. pylori*^[66]. However, studies have also failed to find differences in hemoglobin, leukocytes, thrombocytes, weight and height^[50,67]. Differences in growth seem to be limited to the developing countries^[62,63]. It has been speculated that *H. pylori* acquired in infancy could be "the key that opens the door" to enteric infection leading to recurrent diarrhea, malnutrition and growth failure^[62]. There is, however, no difference in diarrhea prevalence in relation to *H. pylori* status^[68]. After control for socioeconomic status,

there is no difference in the height of adults with and without *H. pylori*. *H. pylori* seropositivity is related to a late menarche^[69,70]. Socioeconomic status and malnutrition does not explain late menarche, since elevated body mass index is also independently associated with *H. pylori* in the same population^[70]. Incidentally, anemia, hemoptysis and vertigo have been reported^[71,72].

The association of *H. pylori* with extra-digestive diseases, such as functional vascular diseases and skin and endocrine autoimmune diseases, has been described^[73-76]. An interesting relationship between seropositivity to *H. pylori*, serum glucose and non-insulin dependent diabetes mellitus is worthy of further attention. Recent studies suggest that the association between *H. pylori* and coronary heart disease is rather weak^[65,73]. Primary Raynaud's phenomenon, observed in young women, which is defined by an intermittent vasospasm of the arterioles of the distal limbs that occurs mostly following exposure to cold or emotional stimuli, may be related to *H. pylori* in some cases^[74]. *H. pylori* may in addition cause headache^[74]. Vasoactive substances, such as cytokines (interleukins, interferon, gamma, TNF- α), prostaglandins, leukotrienes, oxyradicals, C-reactive protein and fibrinogen are released in chronic infection^[74]. Henoch-Schönlein purpura and Sjögren's syndrome have been correlated with the bacterium. Many patients with autoimmune thyroid diseases are reinfected with type I cytotoxic cagA-positive strains^[75]. Rosacea and recurrent urticaria may also be associated with *H. pylori* infection^[76]. Alopecia areata is related to atrophic gastritis and pernicious anemia, and thus with *H. pylori*^[74]. Until now, *H. pylori* has not yet been reported to cause hepatitis in human. Although a mice *Helicobacter* species has been reported to cause hepatitis in germfree mice, and *H. pylori* has been identified in the gallbladders of human^[77,78]. An Italian group showed a positive correlation between food allergy and *H. pylori*^[79].

H. pylori in infants and children

Independent risk factors for *H. pylori* infection in infants and children include living in lower socioeconomic and overcrowded circumstances and sharing a bed with a parent. Human lactoferrin can support *H. pylori* growth *in vitro* and *H. pylori* binding lactoferrin has now been identified. Infants born to seropositive mothers passively acquire maternal *H. pylori* IgG^[80,81]. Transplacentally transferred maternal anti-*H. pylori* IgG lasts until about the third month of life in most infants and disappears from nearly all by 6 months^[80]. IgA in mother's milk can protect the infant from *H. pylori*

infection^[82]. However, whether breast feeding is related to a low or high prevalence of *H. pylori* infection in infants remains unclear^[80,83,84] (protective effect of mother's milk versus intimate contact between infant and *H. pylori* positive mother). At the age of 14 months, 7.5% of infants in a population with a seroprevalence in 62% of young adults, had acquired *H. pylori*, an event demonstrated by a rise in IgM, quickly disappearing and preceding IgG^[80,85,86]. In Belgium, less than 1% of infants are seropositive at the age of 1 year^[87] (seropositivity in young adults is about 30%)^[87,88]. In Finland, 4% of children under the age of 7 years have a positive serology^[89].

Approximately 30% of 53 children (16/53) with dyspepsia were infected with *H. pylori* in the antrum, and about half of them a cytotoxic strain was present (anti-Cag A antibodies in 64% and anti-vacA antibodies in 43%)^[90]. In only 6/53 children, the *H. pylori* was also detected in the gastric body^[90]. Clinical evaluation showed a significant difference in favor of subjects positive for *H. pylori* only for epigastric burning and/or pain^[90].

Clinical symptoms associated with *H. pylori* infection have been reported in patients with human immunodeficiency virus (HIV)-1^[91,92]. Although *H. pylori* has been said to be rare in HIV-1 infected individuals (e.g., because of the repetitive and multiple administrations of antibiotics and immunoglobulins)^[92], recent data suggest that the prevalence of *H. pylori* infection in HIV-1 infected children is comparable to the prevalence in the non-infected control population^[91].

Diagnostic and screening tools

A large number of invasive and non-invasive methods have been used to diagnose *H. pylori* infection in humans^[93]. Culture of the organism is a standard method for the diagnosis of bacterial infection. *H. pylori* can be cultured from gastric biopsies. Culture of *H. pylori* requires a microaerobic atmosphere of 5% oxygen with 5%-10% CO₂. When *H. pylori* is cultivated on biopsy, sensitivity to antibiotics should be tested^[94]. Whether coccoidal forms also grow in blood agar or not is controversial^[95,96].

Histologic examination of Giemsa or Warthin-Starry stained gastric biopsy specimens is widely used for the diagnosis. The Sydney criteria for the classification of gastritis have been revised^[97]. Gastric biopsy urease tests make use of a change in color of phenol red which is present in the medium because of a pH increase related to the digestion of urea by the urease. Four rapid urease tests are available commercially: CLO-test (Delta West Ltd, Bentley, Australia), Hpfast (GI Supply,

Philadelphia, USA) and PyloriTek (Serin Research Corporation, Elkhart, USA), Jatrox (Röhm Pharma GMBH, Weiterstadt, Germany), although many hospitals prepare their own urease tests. These commercial tests have a high specificity and sensitivity and provide comparable results^[98]. PyloriTek has a shorter reading time than CLO-test^[99]. Antral and corpus biopsies provide comparable results, and in combination they increase the sensitivity by 4.3%^[100]. Although these biopsy urease tests have a high degree of sensitivity in adults, false negative results are common in children, possibly because of a smaller bacterial load^[101].

Molecular methods for biopsy material or other biological samples and current PCR methods for molecular fingerprinting of *H. pylori* have been developed^[102,103]. PCR techniques can quantitate the bacterial load in gastric samples^[103,104]. Several molecular methods have been applied to typing *H. pylori* isolates and demonstrating their genomic diversity. Unfortunately, all these tests necessitate endoscopy^[103].

Magnetic beads coated with anti-*H. pylori* rabbit antibodies permit detection of less than 10-million organisms per gram of feces^[105]. PCR-detection of *H. pylori* in feces is hindered by the presence of inhibitors of Taq polymerase, complex polysaccharides which can be eliminated by filtration on Qiagen and dilution. But, immunomagnetic separation-PCR is recently reported to be simple, rapid and reliable^[106]. Nevertheless, the technique is not available as routine.

The ability to detect antibodies in saliva rather than in serum would improve antibody tests by avoiding the need for blood collection^[107]. Sensitivity (84% - 93%) and specificity (70% - 82%) are too low, but comparable to rapid whole blood diagnostic tests^[107-109]. The discovery of the potential importance of the cagA-pathogenicity island has stimulated interest in the specific detection of the CagA protein.

Serologic testing for IgG antibodies against *H. pylori* requires validation of the assay in children, since antibody levels differ in children and adults, probably because of the duration of infection and the differences in bacterial load^[85,106,110,111]. In addition, commercially available serologic tests demonstrate lower accuracy compared with testing in a research setting^[112], with sometimes up to 33% false positive and 25% false negative results^[111,113,114]. Serology is more and more frequently reported to be unsatisfactory for screening for *H. pylori* infection in children^[106,111]. Testing should not rely on office

tests^[94]. After eradication, there is a slow decline in antibody titer. Many patients remain seropositive 1 year after eradication^[115]. At acquisition of the infection, there is a temporary rise in IgM^[80,85,86,111,116]. IgA is also reported to be a useful serologic screening tool^[117]. Immunoblot has become the reference method used to confirm doubtful results^[118]. Specific serologies for cytotoxic strains may be helpful in selecting patients for treatment^[90].

Carbon-13 and C-14 breath tests are based on the fact that urease from *H. pylori* will hydrolyze the ingested labeled urea into ammonia and labeled bicarbonate, which is exhaled as labeled carbon dioxide^[18]. Whether a test meal should be given, or whether the labeled urea should simply be given after a period of fasting, or whether addition of citric acid would be beneficial is not clear^[119-121]. A standardized and simplified C-13 breath test was recently described in children^[122]. The high sensitivity and specificity of the 13 C-breath test in the detection of *H. pylori* infection in children has been unequivocally demonstrated^[90,123,124]. The best cut off value is obtained after 30 minutes^[120]. False positive results can occur because of the presence of other urease containing gastric bacteria or because of extra-gastric bacterial urea metabolism (seldom). False negative results are mainly due to fast gastric emptying or previously administered urease-inhibiting drugs, such as antibiotics or bismuth-containing salts. There is a close correlation between the urea breath test and the intragastric bacterial load^[100,125], which is on its turn related to the severity of the gastritis. Unfortunately, carbon-13 breath tests are still expensive in many parts of the world. A less expensive method for the analysis of 13C-labeled carbon dioxide is nondispersive infrared spectrometry, with a comparable sensitivity and specificity^[126]. But, infrared spectrometry necessitates larger volumes of expired air, making the technique less suitable for (small) children. Alternatively, measurement of 14C-labeled carbon dioxide with a scintillation counter is relatively inexpensive^[127]. Although the dose required for one test is not greater than the natural background radiation, the use of 14C is considered unethical in pregnant women, adolescents and children because of its extremely long half-life, since 14C may be incorporated into the bicarbonate pool^[128]. The urea breath test is in general accepted to be the most reliable noninvasive diagnostic method^[90,129]. The urea breath test detects only current infection and can be used to screen for *H. pylori* infection and as the sole method for assessing eradication, and to evaluate treatment efficacy^[129].

Epidemiology

The prevalence of *H. pylori* infection in many populations and/or subgroups is currently well documented. The overall prevalence of *H. pylori* in children is 10% in developed countries but can be as high as 30%-40% in children from lower socioeconomic classes^[48]. In developing countries, the prevalence of *H. pylori* in children ranges from 80% to 100%^[48]. Like many other childhood bacterial infections, *H. pylori* is most frequently acquired in the preschool age group, with the associated effects of family size, clustering in families, low socioeconomic status and education and variable risks associated with gender^[89,130,131]. Recent sociocultural changes may result in changes in infection rates in children^[132], which is an important argument for the cohort effect. In general, it is thought that spontaneous eradication of *H. pylori* infection is extremely rare^[133,134]. However, recently some authors have suggested that from 1.5% up to 10% or even 20% of spontaneous eradication occurs in a period of 6 months during childhood^[111,135,136]. Although, others still report a zero incidence of seroreversion^[89]. These discrepancies may, however, be related to the methodology (serology versus urea breath test). Recent epidemiologic data suggest that serology underestimates *H. pylori* infection in children^[106,111], and antibodies may persist although *H. pylori* disappeared.

In the developed world, acquisition by adults and children is approximately 1% to 3% per decade^[131,136,137], which will result in a dramatic decrease in *H. pylori* infection in that part of the world in the coming decades. In The Netherlands, about 40% of the 60-69-year-old population is seropositive^[137]; since the prevalence in adolescents is below 10%^[138], it can be speculated that the seropositivity of this cohort will probably not be higher than 25% when reaching the age of 70 years. In Gambia, the prevalence of a positive breath test at the age of 3 months is about 19%, increasing to 84% at 30 months^[111].

Re-infection probably does not occur frequently and is, in many cases, considered recrudescence after treatment failure^[139]. Re-infection rates vary strongly with the effectiveness of the treatment protocol^[139,140]. In Chile, re-infection occurred in 4.2% after 1 year, with a treatment protocol that was 82% effective^[141,142]. Annual user-relapse rate in children with duodenal ulcer in whom *H. pylori* was eradicated was reported to be 9%^[143]. The percentage of re-infection does not appear to be much higher in developing countries than in developed regions. As a consequence, there is little reason for treating an entire family to prevent re-

infection, although spread from one adult to another has been suggested^[144]. Others do suggest family treatment^[183]. It seems more likely that re-infection comes from an external source. Of course, a more detailed specification of the *H. pylori* strain will contribute to the answer whether re-infection rather than relapse occurs. Repetitive extragenetic palindromic-PCR can group isolates into clusters that appear to have a different clinical expression^[102]. Oligonucleotide probes containing short repetitive sequence motifs can differentiate between different isolates of *H. pylori*^[146].

The major mode(s) of transmission of *H. pylori* are still unknown, oral-oral, gastro-oral and fecal-oral have been proposed^[147,148]. Infected parents, especially mothers, may play a key role in transmission of *H. pylori* within families^[81,149]. Houseflies could serve as vectors for *H. pylori*^[150]. Pets have been suggested as well as contradicted to be vectors^[151]. There is considerable evidence of transmission of oral bacteria between spouses and between family members^[144]. Vomiting and gastroesophageal reflux might also be a mode of oral-oral contamination^[152]. Mode of spread remains an active area of study, with water as a source of contamination still of potential interest. The coccoid form can cause cellular changes similar to the spiral form^[153], and may serve as the infectious form in environmental sources such as water^[154]. Studies on external water sources in Peru revealed PCR products of *H. pylori* in the municipal water, increasing 12 -times the risk for infection^[155]. The examples of studies in Peru and Chile suggest a role for water as a vehicle, but it does not seem to be the main route of acquisition since many studies in Korea^[132], Taiwan, or Turkey do not support this hypothesis.

Host response to *H. pylori*

Another factor contributing to the heterogeneity of *H. pylori* associated symptoms is the variability in host response to the infection. Duodenal bicarbonate secretion is decreased in ulcer patients, and returns to normal after eradication of *H. pylori*^[156,157]. Acute *H. pylori* infection has been associated with hypochlorhydria, possibly by stimulating the production of a histamine-3 receptor agonist, which inhibits gastric acid output. In contradiction to this finding is the observation that the same histamine-3 receptor agonist can stimulate parietal cells to produce acid via the histamine-2 receptor^[158]. Identification of Lewis carbohydrate structures on *H. pylori* lipopolysaccharide may provide an explanation for the development of autoantibodies, reacting with gastric mucosa ("molecular mimicry")^[159].

Treatment

Currently, there are no guidelines on the need to treat children^[48]. The regimens that have been studied to date have used bismuth preparations, H₂-receptor antagonists, ranitidine bismuth citrate, proton pump inhibitors and various antibiotics. The goal of any treatment should achieve an eradication rate of over 80% on a rigorous intention-to-treat basis^[94]. Most European *H. pylori* study groups now recommend (in adults) a triple regimen: a twice daily dose of proton pump inhibitor (PPI) in combination with two antibiotics [from the following 3 groups: clarithromycin; amoxicillin; nitroimidazoles (metronidazole or tinidazole)] for 1 week^[94,160,161]. There are no specific recommendations for children yet^[162]. It has been hypothesized that combination therapy is more effective because of the synergistic mechanisms between different drugs. The requirement is for a simple, well-tolerated regimen, with which it is easy to comply with, and is cost-effective. In a recent Irish study in children, the therapeutic approach consisted of colloidal bismuth subcitrate (480 mg/1.73 m² body surface for 4 weeks) in combination with amoxicillin (750 mg/day for 2 weeks) or metronidazole (20 mg/kg/day for 2 weeks)^[120]. In most European countries, eradication treatment in children consists usually of a PPI in combination with amoxicillin and either clarithromycin or nitroimidazole, based on the sensitivity of the prevailing strains. Although antibiograms are needed, there seems to be major discrepancy between *in vitro* testing and *in vivo* efficacy. Resistance to amoxicillin has recently been reported, but seems rare^[163]. Resistance to macrolides is rising with increasing use of the drugs, and for both macrolides and nitroimidazoles there is a huge regional variation in resistance patterns. Especially the determination of resistance to metronidazole may be relevant in regions with a high percentage of resistance^[164].

Bismuth triple therapy continues to achieve high eradication rates worldwide (78%-89%). Side effects leading to diminished patient compliance and the marked decline of eradication efficacy in cases of metronidazole resistance are considered to be the major drawbacks of this therapy. PPI dual therapy is better tolerated with fewer side effects than is bismuth triple therapy. The mean eradication rates vary from 55% to 75%, and the extremes lie between 24% and 93%. PPI triple therapies have been shown to be very effective against *H. pylori* with an eradication rate 80% - 90%. Eradication rate in children with 2 weeks of treatment with clarithromycin, amoxicillin and proton pump inhibitors (omeprazole or lansoprazole) is reported to be 75% and 92%, respectively^[165,166].

Omeprazole, clarithromycin and metronidazole or tinidazole for 7 days are reported to cause eradication in 87% and 89%^[167,168]. Dual therapy for 2 weeks with omeprazole and amoxicillin causes eradication in 70% of infected children, whereas a addition of clarithromycin for 2 weeks increases the eradication rate up to 92%^[169]. Amoxicillin, bismuth and metronidazole were reported to eradicate *H. pylori* in 96% of infected children^[143]. Quadruple therapy leads to a mean eradication rate of 96%. Thus, based on efficacy PPI triple or bismuth triple therapy are recommended as first-line treatment^[170]. The cost of PPI versus bismuth should be considered. However, compliance strongly influence the eradication rate, and may explain why, in contradiction to experience in adults, in children two drugs for 2 weeks are sometimes found to be equally effective than triple therapy for 1 week^[171].

Eradication therapy is not recommended for all *H. pylori* infected adults and children^[162]. However, the complex relationship between *H. pylori* and gastrointestinal cancer might stimulate physicians to prescribe eradication treatment, even in the absence of scientific evidence, especially in countries with a strong impact of legislation on health care, as in the case in the US in children, not one randomized prospective placebo-controlled study had been conduct ed. Whether children with symptomatic *H. pylori* gastritis alone will benefit from treatment is debated^[90,121]. Well-designed clinical trials showing a therapeutic gain of *H. pylori* treatment over placebo are still missing, with the exception in duodenal ulcer patients. The cost-benefit ratio of avoiding endoscopy in dyspeptic patients is only worthwhile considering if the cost of end oscopy is greater than \$500 USD^[172], as is the case in the USA; while the cost of upper gastrointestinal tract endoscopy in Belgium and Finland is only about \$100 and \$170 USD, respectively^[173].

Nevertheless, recommendations differ in Europe and the USA. The European consensus states that scientific evidence for the improvement of functional dyspepsia is equivocal, but the overall evaluation taking into account the expected benefit on the gastritis status makes it worthwhile to consider eradication therapy in such patients. In Europe, it is accepted, although not unanimously, that young patients, aged below 45 years, without alarm symptoms (anemia, weight loss, dysphagia, palpable mass, malabsorption, etc.) and who test positive for *H. pylori* for the first time with validated serology or breath test, can be treated with eradication therapy without further investigations (thus without endoscopy)^[94,160]. However, in the USA, the present consensus states

that there is no scientific evidence to recommend treatment for *H. pylori* in the absence of an established peptic ulcer disease^[156]. As a consequence, according to the North American consensus, non-invasive testing cannot replace endoscopy in t he initial diagnosis of *H. pylori* related gastrointestinal diseases (not in children either)^[174]. Eradication of *H. pylori* in patients who do not benefit from it may unnecessarily increase the risk of resistance of *H. pylori* to antibiotics.

H. pylori and non-steroid anti-inflammatory drugs (NSAIDs) are both ulcerogens; however, NSAIDs are not frequently prescribed in children, and moreover, there seems to be no cooperative effect between them. Consequently, eradication of *H. pylori* prior to NSAID administration is not recommended in the USA. In Europe, eradication of *H. pylori* before NSAIDs is considered "advisable".

Elimination of *H. pylori* increases the risk of developing gastroesophageal reflux and reflux esophagitis^[157,175]. *H. pylori* eradication results in a marked decrease in the pH-increasing effect of omeprazole and ranitidine^[176]. Nevertheless, long-term acid suppressive therapy with proton pump inhibitors (and to a lesser extent with H₂-antagonists) for reflux disease in *H. pylori* positive patients enhances the development of atrophic gastritis if *H. pylori* has not been eradicated beforehand^[177,178].

Eradication of *H. pylori* can be demonstrated by normalization of histology and negative culture of gastric biopsies, or with the use of urea breath tests^[94]. With respect to serology, a 50% fall in antibody titers is indicative of successful elimination. However, this usually requires up to 6 months to occur^[179]. When follow-up tests for eradication of *H. pylori* are necessary, they should not be made earlier than 4 weeks after cessation of treatment^[94]. The bacterial load could influence the success rate of eradicating treatment^[180].

Knowledge of the *H. pylori* genome provides major new insights into many aspects. Conversion of pyruvate to acetyl-CoA uses an unusual enzyme, only previously found in free-living bacteria from extreme environments^[181] and the genome sequence shows that acetyl-CoA is likely to be a crucial intermediary in several biosynthetic pathways. Therefore, blocking the enzyme should allow effective and selective drug activity against *H. pylori*. The same is true for many other enzymes.

Vaccination

Study of the *H. pylori* outer membrane is important for both understanding the pathogenicity but also

for development of vaccines since the outer membrane is involved in adherence to the host epithelium and stimulation of the host immune response. Vaccines should be able to confer preventive and curative immunity on humans. Oral immunization with a recombinant urease given in the absence of a mucosal adjuvant has been assessed unsuccessfully in *H. pylori* infected volunteers^[182]. However, recently, the recombinant *H. pylori* urease was given with an *E. coli* heat-labile toxin, provoking diarrhea in the majority of the volunteers, a side-effect which disappeared when the dose was reduced, but also showing an increase in urease specific IgA producing cells and a decrease in the density of gastric colonization by *H. pylori*^[183].

IgA antibodies are expected to play a prominent role in protection, since *H. pylori* is a non-invasive pathogen at the luminal surface of the gastric mucosa. This hypothesis has been supported by the observation that milk IgA protects infants against *H. pylori* infection^[82]. IgA and immunoglobulin G1 (IgG1) depend on T-helper type 2 (Th2) cells. According to different recent experiments, immunization is associated with an elevation of IgG1 levels, indicative of a Th2 cellular immune response, which might be a significant mechanism^[184-186]. The field of vaccination is still very controversial, and is being extensively studied.

CONCLUSION

Helicobacter pylori infection is worldwide one of the most frequent infectious diseases. There is a huge discrepancy in prevalence and incidence between the industrialized countries and the rest of the world (Africa, Asia, South-America). Infection occurs mainly in children. Well-designed studies to identify those infected children who are at risk of developing complications or have symptoms due to the infection are still lacking^[171]. Because of the cohort-effect which is related to the socio-economic status and/or hygienic circumstances, the annual infection rate in the Western world is dramatically decreasing. If this observation is confirmed, it can be speculated that a decrease in incidence of peptic ulcer disease and gastric cancer may occur in the more industrialized countries during the next decades. However, duodenal ulcer and gastric cancer are only related to some more virulent strains. Many children remain asymptomatic, and a clear relation between *H. pylori* and symptoms has only been demonstrated for ulcer-related symptoms. In addition, peptic ulcers are rare in childhood. Treatment of *H. pylori* is indicated in duodenal ulcer diseases. The relation between chronic abdominal pain, functional dyspepsia, and *H. pylori* is unclear.

Screening tests, including serology or the urea

breath test, are of interest for epidemiological studies. The urea breath test evaluates the actual colonization; serum antibodies might persist after eradication, which is only rarely spontaneous. According to the European consensus, eradication therapy can be considered in a child with functional dyspepsia and positive screening test. According to the North American consensus, treatment is only recommended in the presence of ulcer, necessitating endoscopy.

H. pylori strains are not created equal since important virulence factors are not detectable in all strains. The continuous decline of *H. pylori* prevalence as a result of changes in living conditions and active treatment is not unanimously considered to be beneficial^[14]. Unfortunately, screening tests rely on virulence factors which are detectable in all strains. Vaccines are not expected to be available in the near future.

Nevertheless, improvement of the socio-economic status and hygienic circumstances in all countries will result in a dramatic decrease of *H. pylori*.

Current concept of pathogenesis of severe acute pancreatitis

Wu XN

Subject headings pancreatitis/etiology; pancreatitis/diagnosis; pancreatitis/pathophysiology

The pathogenesis of severe acute pancreatitis is very complicated. It is a multifactorial as well as multifaceted disease. First of all, the etiologic agents initiate the pancreatic acinar injury by release of pancreatic enzymes and overstimulation of macrophages and neutrophils, then the cytokines and inflammatory mediators are liberated. There is also interaction between neutrophils and endothelial cells producing free radicals, the cytokines cause increasing vascular permeability, activating complement component, resulting in microcirculatory impairment and imbalance of thrombo-fibrinolytic system. Many of these events occur not only in the pancreas itself, but also in the other vital organs and tissues, leading to severe acute pancreatitis and complications. The sequential events are as follows.

PANCREATIC ACINAR INJURY

Pancreatic duct obstruction and bile reflux

Gallstone incarcerated in the distal common duct or biliary-pancreatic duct common pathway initiates bilereflux, activates pancreatic trypsin, produces acinar injury which is the traditional viewpoint, but is unexplainable in case when biliary and pancreatic ducts open into the duodenum individually and in those so called idiopathic acute pancreatitis. It had been found that 91% of such cases had microlithiasis or biliary sludge as the cause of transient incarceration. In animal experiments, ligation of pancreatic duct can also induce acute pancreatitis without having bile reflux, showing that pancreatic duct obstruction is also an important pathogenetic factor^[1]. Such microlithiasis could not be disclosed by the conventional cholecystography, but could be shown from the bile taken from the recovered patients. After centrifuged and observed under

microscope, clustered cholesterol crystals, bilirubin and calcium bicarbonate microgranules were found in 67% of cases^[2]. Many recurrent pancreatitis patients when followed up by ultrasound for 12 months, there were cholesterol crystals and microlithiasis, the biliary sludge and microlithiasis could also be seen in the gallbladder specimens, indicating there had been pancreatic obstruction^[3]. Pancreatic obstruction caused impedance of pancreatic fluid outflow resulted in elevation of pancreatic pressure and produced pancreatic acinar injury.

High fat, high protein diet

High fat and high aminoacid content in the duodenum can stimulate cholecystokinin (CCK) release, which promotes the acini to secrete enzymes. The zymogen granules located at the fusion of the apical cell membrane dislocate and scatter throughout the cell cytoplasm after stimulation. At this stage, the cells show vacuolation because the zymogen granules have been exocytosed. Alcohol can also sensitize the acini to CCK, activate the intracellular and intraluminal pancreatic enzymes, and initiate the catabolism of intracellular protein under the condition of low pH and ionic changes. Two mechanisms have been proposed to account for the intracellular activation of trypsinogen and the zymogen cascade: trypsinogen autoactivation and trypsinogen activation by the lysosomal enzyme cathepsin B. These are the earliest changes in acute pancreatitis^[4], then activated trypsin again activates other pancreatic enzymes, including pancreatic lipase, amylase, chymotrypsin, phospholipase A₂ (PLA₂), elastase, carboxylase, nucleotidase, etc. which induce autodigestion of the pancreas. In animal experiments, administering CCK or CCK analogue i.e., cerulein into ligated pancreatic duct, can induce edematous pancreatitis; and injecting taurocholic acid into ligated pancreatic duct can cause necrotizing pancreatitis.

Alcohol

Alcohol has deleterious effects on both pancreatic acini and Oddi's sphincter^[5]. ① It stimulates gastrin secretion and via the cholinergic pathway to stimulate pancreatic secretion, simultaneously, it can cause spasm of Oddi's sphincter, the two in combination can lead to pancreatitis. ② Alcohol

may change the composition of proteins secreted by the pancreas, resulting in the formation of protein plugs within small pancreatic ductules, this insoluble protein is formerly called stone protein. ③ It increases the amount of lysosomal enzymes and increases trypsinogen/ pancreatic trypsinogen inhibitor ratio. ④ Ethanol can change systemic and pancreatic lipid metabolism with accumulation of lipid droplets within the acinar cells, alter membrane fluidity and integrity. ⑤ Ethanol even sensitizes the acinar cells to CCK-stimulated intracellular zymogen proteolysis. In presence of combined-stimulation of CCK and alcohol, it is easier to induce acute pancreatitis.

Ischemia, decreased perfusion

Transient ischemia enhances enzymatic degradation of acinar cells which become more vulnerable. Hypotension during bypass surgery, pancreatic atherosclerosis with hyperfunction of sympathetic nervous system in the elderly, in combination with the above factors can result in acute pancreatitis with necrosis. Animal experiments on ligation of pancreatic duct and injecting cerulein or taurocholic acid, with additional clamping of upstream of pancreatic artery, that is the celiac artery and superior mesenteric artery for 40 min, can cause pancreatic necrosis, edema and inflammation.

Based on the above facts, severe acute pancreatitis can be induced by a combination of multifactors, which include pancreatic obstruction with or without bile reflux, high fat, high protein diet (hyperstimulation of CCK), alcohol, and ischemia, this is what we encounter in our clinical practice, these factors interact with one another and result in this disease.

CHANGES AFTER ACINAR INJURY

Activation and release of pancreatic enzymes

Activated trypsin again activates other pancreatic enzymes, among which, chymotrypsin promotes hydrolysis of tryptophan, tyrosine and phenylalanine peptide chain; elastase hydrolyzes elastic fibers of extracellular matrix, promotes spreading of protein degradation; carboxypeptidase A and B and RANase, each acts on the components of pancreatic tissue; pancreatic lipase hydrolyzes the lipids, triglyceride, produces free fatty acid which is toxic to the capillaries, leads to lipoperoxidation; and PLA² hydrolyzes phospholipids including cephalin, sphingophospholipids and lysocephalin, destroys structural phospholipid and microvasculature, activates platelet activating factor and increases vascular permeability and ischemia^[6]. The kallikren-kinin system produces bradykinin which dilates the blood vessel, increases vascular permeability and produces

hypotension, these are the earliest events occurring in acute pancreatitis. It had been found that injection of ascitic fluid containing high concentration of bradykinin to healthy animal produces hypotension^[7]. But by giving bradykinin antagonist, HOE 140, the pancreatic edema caused by bradykinin can be reduced^[8]. The above pancreatic enzymes not only induce autodigestion of pancreas, inflammation of peripancreatic fat, but also circulate in the blood together with the activated cytokines to the remote organs including the lung and brain causing damages. Besides, the release of pancreatic enzymes also activate complement system and thrombo-fibrinolytic system, producing thrombosis in the microvessels. In the ascitic fluid of severe acute pancreatitis patients, activated protease, phospholipase A₂, bradykinin, complement component, histamine and some inflammatory mediators as platelet activating factor (PAF) and prostaglandin are found.

Release of cytokines

During pancreatic necrosis and inflammation, IL-1 β , IL-6, TNF- α -mRNA expression can be detected in the pancreas. The macrophages release IL-1, IL-6, TNF- α and IL-8, among which, IL-6 produces acute phase proteins, IL-8 chemotacts neutrophils to the inflamed areas, including the pancreas and the lung. The macrophages are the sources of proinflammatory cytokines (IL-1, IL-6, TNF- α) and anti-inflammatory cytokines (IL-4, IL-10, IL-1ra), IL-1ra is IL-1 receptor antagonist, the IL-6 produced in severe acute pancreatitis is greater in amount than that produced in mild acute pancreatitis, and also persists longer^[9]. These proinflammatory cytokines induce intercellular adhesive molecules (ICAM 1) and vascular adhesive molecules (VCAM) expression, promote the spread of inflammation, also augment the elastase of neutrophils to produce free radicals damaging the endothelial cells, causing endothelial swelling, and circulatory stasis^[10]. In severe acute pancreatitis, increase of proinflammatory cytokines and decrease of anti-inflammatory cytokines are crucial factors in its progression, experimental study revealed that using TNF- α monoclonal antibody or recombinant IL-10, either of them could reduce the severity of the disease and increase the survival rates^[11-14].

PAF is the structural component of membrane lipid, it can be synthesized by endothelial cells, macrophages and platelets, and activated by PLA₂, producing chemotaxis, aggregation, releasing superoxides, initiating the interaction of neutrophils and endothelial cells and favoring the entrance of neutrophils into the tissue space. It also causes increased vascular permeability of the capillary network of the lung, kidney, heart and the GI

tract^[15]. Moreover, it enhances the tissue damage by the endotoxin liposaccharide, thus playing a crucial role in the pathogenesis of severe acute pancreatitis, it not only has autocrine and paracrine function, with high content it also has endocrine function, producing multiorgan dysfunction syndrome (MODS)^[11]. In cerulein and taurocholic acid experimental models, its concentration is increased in the blood, ascitic fluid, pancreas, and lung tissue, producing pancreatic ischemia and increasing the inflammatory cellular infiltration. Recently it is claimed by using PAF antagonist, Lexipafant could decrease vascular permeability, diminish IL-6 and IL-8, and decrease the severity of ARDS, and turn the blood amylase and lipase to normal. In neutropenic patients or using neutrophilic cell antibody, the inflammation in the lungs could be attenuated^[16]. 5-fluorouracil formerly used in the treatment of severe acute pancreatitis acted mainly via its upregulating effect of cytokine IL-4 and IL-10^[17].

Increased vascular permeability and Pancreatic microcirculatory impairment

During early stage of acute pancreatitis, the arterioles in the pancreatic lobules constrict, with stasis of neutrophils in the postcapillary venules^[18], in addition, there is increased vascular permeability, these further decrease the pancreatic perfusion. Ischemia causes Ca^{2+} ion influx, aggravating rupture of lysosomal membrane and release of lysosomal enzymes. On the otherhand, there is increase of TXB_2 and $\text{TXB}_2/\text{PGI}_2$ imbalance which constricts further the vessels and endothelin liberated by the damaged endothelium also decreases pancreatic blood flow. The release of $\text{TNF-}\alpha$ also promotes vascular permeability, enhances platelet aggregation, stimulates excessive production of nitric oxide. The vessels in the region dilate, hence, the overall effect is the decrease of pancreatic vascular perfusion and blood stasis in the venular net work, leading to local intravascular coagulation. One can see fibrin deposition in the pancreatic capillaries under microscope, the interstitial pressure become elevated, the red blood cells migrate outward to extravascular space, contributing to the hemorrhage, ischemia, necrosis, inflammation and edema^[18]. But the degree of edema is milder in the severe form. Not only is such in the pancreas substance, similar changes also occur in the pulmonary alveoli, the type II alveolar cells can be destroyed resulting in loss of pulmonary surfactant. Low molecular weight dextran and Dan Shen (*Salvia Miltiorrhiza*) liquid can improve the microcirculation and prevent pancreatic necrosis and lung changes^[19].

Infection-the second attack

In severe acute pancreatitis patients, the cellular immunologic function is compromised, and the CD_4^+ and CD_8^+ lymphocytes are markedly diminished, but their ratio remains unchanged, which is quite different from that seen in mild acute pancreatitis^[20]. Furthermore, because of increased vascular permeability due to PAF, there is loss of gastrointestinal epithelial barrier function^[21], the gut bacteria translocate from the colon to mesenteric lymph node, peritoneal cavity and blood circulation, IL-6 and IL-8 are further released by endotoxin, $\text{TNF-}\alpha$ and IL-1 induction, IL-8 chemotacts and attracts more neutrophils accumulating at the pancreas, lung and other vital organs and tissues. Because of the insufficient endogenous superoxide dismutase, the deletion of glutathione, and presence of various oxygen free radicals destroy the cellular membrane, plasmalemma and the organelles^[22]. Procoagulating factors are released leading to cascade of thrombo-fibrinolytic reaction, and produce inflammatory mediators from eicosanoid products. Moreover, the neutrophilic elastase is more destructive, causing multiorgan failure. Experimental studies showed that plasma neutrophilic elastase level paralleled the multiple organ failure in severe acute pancreatitis which were positively correlated. This is the so-called second attack theory^[23].

Serious complications of severe acute pancreatitis are mainly adult respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), infected necrosis and pancreatic encephalopathy, their pathogenesis are described as follows (Table 1).

Interstitial pulmonary edema and ARDS are caused by many factors: ① phospholipase A_2 arrives at the lung by way of circulation, and destroys the type II alveolar cells, which are then unable to produce surfactant; ② the macrophages become vasuolated simultaneously, being unable to phagocyte and digest the protease and clear away the fibrin; ③ neutrophils being chemotacted and accumulated in the lungs, release the destructive elastase and oxygen free radicals; ④ PAF activated by PLA_2 can damage the endothelium and increase the vascular permeability, causing ischemia, interstitial pulmonary edema and ARDS. If properly treated, this complication is now rarely seen.

DIC is often due to massive exudation in the peritoneal cavity and retroperitoneal space, hypoalbuminemia and hypovolemic shock, if colloid has not been instituted instantly, hypercoagulation might appear and followed by increased hematocrit, microcirculatory stasis and imbalance of thrombo-fibrinolysis. By given the author's treatment regime^[24], this complication has not been seen in recent years.

Table 1 Complications of severe acute pancreatitis and their mechanisms

Complications	Mechanisms
1. Local complication	
Intra and retro-peritoneal fluid collections	Bradykinin, TNF- α , PAF increase vascular permeability with fluid exudation
Pseudocyst	Hypoalbuminemia
Pancreatic fistula, transient	Unabsorbed fluid collection for long duration
2. Systemic complications	Pancreatic duct rupture, communicating with pseudocyst
Hypotension, hypovolemic shock	Increased vascular permeability, profuse exudation into peritoneal cavity
	Hypovolemia
	Hypoalbuminemia
Intestinal ileus, dehydration, hypokalemia	Peritonitis; loss of peristaltic function; large quantity of digestive fluid sequestered in intestinal lumen; infusion of large volume of crystalloid solution
Hypocalcemia	Formation of calcium soap plaques with fats on peritoneum and mesentery
Renal insufficiency	Hypotension, low blood volume, decrease of renal blood flow (PAF further decreases renal blood flow)
Gastric hemorrhage	Acute gastric mucosal bleeding
Jaundice	Pancreatic head edema in mild jaundice, choledocholithiasis in severe jaundice cases
Interstitial lung edema, ARDS	PLA ₂ destroys structural phospholipid; PAF and TNF- α increase vascular permeability; Neutrophils release elastase and free radicals damage type I & II lung epithelial cells with disability of producing surfactants, alveolar atrophy and interstitial edema
Disseminated intravascular coagulation (DIC)	Shock, hypercoagulable state; microcirculatory stasis; imbalance of thrombo-fibrinolytic system; deletion of antithrombin III
Pancreatic encephalopathy	PLA ₂ damages structural phospholipid of brain cell membrane; PAF increases intracerebral vascular permeability with brain edema and demyelination of grey and white matter
Transient blindness	Retinal ischemia; white cell emboli with exudation, increased vascular permeability
Infection, bacteremia, sepsis	Gut barrier dysfunction with translocation of gut bacteria and endotoxemia, bacteremia
Infected necrosis	Cellular immunity decreases, sepsis
Pancreatic abscess	Same as above, hemodynamic changes caused by inflammatory cytokines and inflammatory mediators
Heart failure	Underlying ischemic heart disease; overloading of circulation by massive infusion or too rapid intravenous dripping

Pancreatic encephalopathy is primarily due to the demyelination of the cerebral grey and white matter caused by PLA₂, which can induce increased vascular permeability, the intravascular osmotic pressure decreases and the brain becomes more vulnerable to transudation, resulting in brain edema. With proper treatment, the recovery in patients aged below 40 is uneventful, those older than 60 especially those with previous history of cerebral infarction may have some sequela.

Infected necrosis and pancreatic abscess. The former usually occurs two weeks after the onset of the disease, the latter occurs four to five weeks after the onset. The invading bacteria usually derive from one's own GI tract, including the bacilli and cocci. The first five bacteria are *B. Coli*, *Klebsiella*, *Enterobacillus*, *Streptococcus faecalis* and other *Streptococci*, there can also be *Staphylococcus*, *Pseudomonas aeruginosa* or *Bacteroid fragilis*^[25]. *E. coli* usually derives from

the colon, biliary tract, urinary tract or respiratory tract through hematogenous route, *Staphylococcus epidermis bacteremia* comes from venous catheterization or urinary catheterization. Pancreatic abscess rarely contains necrotic tissue, but frequently is composed of pure pus. If preventive measures are taken beforehand, sepsis and septicemia can be prevented and are now rarely seen.

Potential roles of tumor suppressor genes and microsatellite instability in hepatocellular carcinogenesis in southern African blacks

Roberts LR and LaRusso NF

See article on December 1999; 5(6): 470-476

Subject headings liver neoplasms; carcinoma, hepatocellular; tumor suppressor gene; microsatellite instability

MAJOR POINTS OF THE COMMENTED ARTICLE

Cumulative loss of heterozygosity (LOH) of chromosomal regions and tumor suppressor genes has been reported in hepatocellular carcinomas (HCCs) from China, Japan, and Korea. In this issue of the World Journal of Gastroenterology, Martins *et al*^[1] report an analysis of LOH and microsatellite instability in HCCs from a group of 20 southern African blacks. Six known tumor suppressor genes-p53, RB1, BRCA1, BRCA2, WT1, and E-cadherin-were analyzed for LOH. In addition, the p53 gene was analyzed for the codon 249 mutation that is commonly found in subjects exposed to high levels of dietary aflatoxin B1. The authors found LOH at the RB1 locus in 17% (3 of 18 informative subjects), at the BRCA2 locus in 10% (2 of 20 informative subjects) and at the WT1 locus in 8% (1 of 13 informative subjects). Two of the subjects had LOH at both the RB1 and BRCA2 genes. Thus, overall, LOH was found in 20%(4/20) of the HCCs. No LOH was found at the p53, BRCA1, or E-cadherin loci. In contrast to reports from other populations, mutations of the p53 and RB1 genes in combination were not seen in this population. Nine of 10 microsatellite loci examined showed changes in microsatellite repeat number in different HCCs, and changes at two or more loci were found in 15% (3/20) of the subjects. The p53 codon 249 mutation was found in 25% (5/20) of the subjects. Four of the 5 subjects with p53 codon 249 mutations had active or previous hepatitis B infection; the hepatitis B status of the fifth subject with a p53 codon 249 mutation was

unknown. These results provide initial information about the potential role of specific tumor suppressor genes and low level microsatellite instability mechanisms in the pathogenesis of HCCs in southern African blacks.

COMMENTARY

Different views of a single disease

HCC is a major cause of cancer death worldwide, particularly in Asia and Africa. The major risk factors for development of HCC are chronic hepatitis B virus and chronic hepatitis C virus infection, high dietary exposure to fungal aflatoxin B1, and other disorders causing cirrhosis such as hemochromatosis, alpha 1 antitrypsin deficiency, primary biliary cirrhosis, non-alcoholic steatohepatitis, and alcoholic cirrhosis. Over the past few decades, a number of approaches have been explored in an attempt to elucidate the details of hepatocarcinogenesis. These approaches have increased in their sophistication with advances in cell and molecular biology and genetics and have borrowed from and contributed to our general understanding of tumor biology. Techniques and experimental systems that have improved our understanding of the hepatocarcinogenic process include: ① the use of chemical tumor initiators and promoters in animal models; ② studies of growth factors and their signaling pathways such as insulin like growth factor 2 (IGF-2) and its intracellular mediator, insulin receptor substrate 1 (IRS-1); ③ transgenic mouse models overexpressing cytokines, growth factors, or oncogenes such as tumor necrosis factor alpha (TNFalpha), transforming growth factor beta (TGFbeta), or c-myc, expressed in isolation or in combination; ④ studies of immune-mediated mechanisms of hepatocellular injury; ⑤ analysis of the molecular genetic changes that occur in HCCs, including hepatitis B virus integration; and ⑥ studies of the protein products of the hepatitis B and C viruses and their interaction with host cell processes. More recently, there has been mounting evidence that common fragile sites, which are unstable regions in the genome, may also be involved in hepatocarcinogenesis.

These studies have contributed to our growing appreciation of the multiplicity of mechanisms and pathways that may contribute to the carcinogenic process in toxin affected, chronically inflamed or otherwise injured liver tissue. Unfortunately, we

are still far from a unified, comprehensive understanding of hepatocarcinogenesis. This is in part because HCC, although quite uniform in its final phenotype, is initiated in multiple genetic and environmental contexts and almost certainly emerges as a consequence of multiple possible pathways. However, the lack of a comprehensive view of the pathogenesis of HCC also prevents us from developing effective, targeted, preventive or therapeutic interventions that are elegant and also simple enough to be applicable to the vast majority of patients with this disease. In this commentary we will review current concepts of the mechanisms of human hepatocellular carcinogenesis and address the issue of geographic variation in carcinogenic mechanisms.

Tumor suppressor genes

Current concepts in molecular oncogenesis suggest that the chromosomal breaks and rearrangements or gene mutations found in cancer lead to activation of oncogenes or cause disruption of tumor suppressor genes. Tumor suppressor genes are normal cellular genes that, when homozygously deleted, can contribute to tumor development. Tumor suppressor genes generally operate in a recessive manner, requiring loss of both copies for tumorigenesis, in contrast to oncogenes, which can exert their effects in a dominant fashion. Loss of heterozygosity (LOH) is loss of one allele in a tumor cell from a chromosomal region for which the individuals' normal cells are heterozygous. LOH is detected using polymorphic DNA markers that can distinguish between the two alleles^[2]. If one allele of a tumor suppressor gene is inactivated by mutation, then deletion of the second allele, detected by LOH, is associated with loss of expression of the tumor suppressor gene. In human HCCs, LOH has now been reported in multiple chromosomal regions, including 1p, 1q, 2q, 4q, 5q, 6q, 8p, 8q, 9q, 10q, 11p, 12p, 13q, 14q, 16q, and 17p^[3,4]. In a number of these regions, there are known or putative tumor suppressor genes, such as at 17p13.1 (p53), 6q26-27 (mannose-6-phosphate/insulin-like growth factor 2 receptor), 8p21.3-22 (DLC-1), and 13q12-q32 (RB and BRCA2). For a few of these chromosomal loci, clinico-pathologic associations have been demonstrated, such as the association of LOH on chromosome 1p with early stage HCC^[5] and that of LOH on chromosome 16q with progression of HCC^[6]. In addition, patients with LOH at multiple regions have more advanced stage disease, less well-differentiated tumors, higher serum alpha-fetoprotein levels and a worse prognosis^[7]. Chronic hepatitis B viral infection and integration of the hepatitis B genome have also been associated with high rates of genomic instability^[8,9]. The use of the technique of comparative genomic hybridization (CGH) allows the identification of gains and losses of DNA

sequences across the entire tumor genome. Analysis of HCC tumors and cell lines by CGH has revealed genomic DNA copy number gains at 1p34.3-35, 1p33-34.1, 1q21-23, 1q31-32, 6p11-12, 7p21, 7q11.2, 8q24.1-24.2, 11q11-13, 12q11-13, 12q23, 17q11.2-21, 17q23-24, and 20p11.1-q13.2. Recurrent losses were found at 3p12-14, 3q25, 4p12-14, 4q13-34, 5q21, 6q25-26, 8p11.2-23, 9p12-24, 11q23-24, 13q12-33, 14q12-13, 15q25-26, 16q, 17p, 18q11.2-22.2, and 21q21-22^[10,11]. Significantly, a majority of the over-represented regions harbor known proto-oncogenes, and half of the under-represented regions coincide with sites of known or putative tumor suppressors^[11]. Notably, the recognition that there is gain of region 17q11-21, which harbors the ERBB-2 proto-oncogene, has led to the development of early clinical trials of anti-p185HER2/neu monoclonal antibody in appropriately selected HCC patients.

Investigation of p53 gene mutations in HCC has been particularly revealing, as HCCs from patients with high dietary exposure to fungal aflatoxin B1 have a high frequency of point mutations at the third position of codon 249 of the p53 gene, resulting in a G:C to T:A transversion^[12]. This mutational target appears to be specific for liver tumors of hepatocellular origin. A G to T transversion at the second position of codon 249 is commonly found in patients with chronic hepatitis B and C infection. The occurrence of this mutation correlates with oxyradical exposure. Both of these mutations lead to decreased binding of p53 to its nuclear DNA targets^[13]. p53 mutations have been demonstrated in nonneoplastic liver cells in subjects from communities with high dietary AFB1 exposure, suggesting that the mutations are early events in neoplastic transformation. However, p53 mutations can also occur late in tumor progression. The hepatitis B virus HBx gene product has also been shown to interact with p53 and strongly inhibit p53 sequence-specific binding, leading to inhibition of p53-mediated apoptosis. Abnormalities in the retinoblastoma gene have been noted in association with p53 mutations in advanced HCCs, particularly in poorly differentiated tumors, and a possible additive effect of p53 and Rb mutations during the progression of hepatocarcinogenesis has been suggested^[14].

Oncogenes

Proto-oncogenes are cellular genes involved in the control of cell growth. Mutation, overexpression, or amplification of these genes leads to oncogenic activity that contributes to neoplastic transformation. The oncogenes c-fos and c-myc are both overexpressed in HCC^[15]. c-myc overexpression may be a consequence of amplification of the c-myc locus in HCC^[10,11]. Activation of the c-myc and c-fos also occurs as a consequence of the transactivating function of the

hepatitis B virus x protein (HBx) and the carboxyterminal truncated middle hepatitis B surface protein (MHBs-t)^[16]. Oncogene activation may occur through reactive oxygen species mediated pathways or through protein kinase C or mitogen activated protein kinase pathways. Reactive oxygen species or lipid peroxidation mediated processes may also be important in the pathogenesis of chronic liver injury induced by alcohol, genetic hemochromatosis, and alpha 1 antitrypsin deficiency^[17,18].

Growth factors and growth factor signaling pathways

Insulin and insulin-like growth factors (IGF) 1 and 2 promote hepatocyte growth. IGF-2 is frequently over expressed in HCCs. In addition, insulin receptor substrate 1, a cellular mediator of insulin-like growth factor signaling, is also frequently overexpressed in HCCs^[19]. Signaling events downstream of IRS 1 lead to cell proliferation through upregulation of cellular growth genes and inhibition of apoptosis. Transforming growth factor alpha (TGF alpha) and the structurally related epidermal growth factor (EGF) are another potent class of hepatocellular growth factors. TGF alpha is overexpressed in the liver of patients with chronic hepatitis. As TGF alpha levels are often increased in HCCs, it is likely that it contributes to cellular proliferation in cancer, and may be a factor in tumor initiation or progression in patients with chronic hepatitis^[20]. Transforming growth factor beta 1 (TGF beta 1) inhibits cell proliferation and promotes cellular differentiation, fibrogenesis, and apoptosis. Increased TGF beta 1 levels may create an environment in which selection of hepatocyte clones resistant to TGF beta 1-induced apoptosis occurs.

Microsatellite instability

Microsatellite instability (MSI) is defined as a change of any length due to either insertion or deletion of repeating units, in a microsatellite within a tumor when compared to normal tissue. This form of genomic instability is associated with defective DNA mismatch repair in tumors, which is important in the pathogenesis of the hereditary non-polyposis colon cancer syndrome (HNPCC) and associated malignancies^[21]. To date, six mismatch repair genes have been identified in humans; hMLH1, hMSH2, hPMS1, hPMS2, hMSH3 and hMSH6. Colorectal cancers may be characterized as having high-frequency MSI (MSI-H) if greater than 30%-40% of more than 5 microsatellite loci analyzed show instability, low-frequency MSI (MSI-L) if less than 30%-40% of more than 5 loci analyzed show instability, or as being microsatellite stable (MSS) if 0% of loci show instability^[21]. Of sporadic colorectal cancers, 70% are MSS, 15% are MSI-L, and 15% are MSI-H. MSS or MSI-L colorectal cancers do not have an associated

defective mismatch repair phenotype or the clinicopathologic features of HNPCC tumors; instead they behave in the same manner as sporadic colon cancers. Clear criteria have not been defined for MSI in noncolonic tumors. To date, a number of studies, including the study by Martins *et al*^[1], have demonstrated a relatively low frequency of low-level MSI in HCC^[22,23]. As is the case with other tumors, it is unclear whether this finding is of significance in the etiology or pathogenesis of HCCs or is instead simply a consequence of the generalized genomic instability found in cancer. It has been suggested that cumulative low-level MSI at multiple loci leads to tumor progression. Further investigation is needed to resolve this potentially important question.

Chromosomal fragile sites

Chromosomal fragile sites are specific genetic loci which are susceptible to forming gaps, breaks, and rearrangements in metaphase chromosomes of cells cultured under conditions that inhibit DNA replication, such as treatment with the DNA α polymerase inhibitor, aphidicolin. Fragile sites are grouped into "common" or "rare" classes based on their frequency of occurrence and the culture conditions required for their expression. Thus far, 89 common and 28 rare chromosomal fragile sites have been identified. Common fragile sites are present in all individuals. The most frequently observed common chromosomal fragile sites occur at 3p14.2 (FRA3B), 16q23 (FRA16D), 6q26 (FRA6E), 7q32 (FRA7H), and Xp22 (FRAXB)^[24].

Common fragile sites span a distance of 250-500 kilobases and display characteristics of unstable, highly recombinogenic DNA *in vitro*. In particular, they are preferred sites for sister chromatid exchanges, chromosomal deletions and rearrangements, integration of viral sequences and transfected plasmid DNA, and initiation of bridge-breakage-fusion cycles, which lead to gene amplification. Due to these characteristics and the frequent coincidence of fragile sites with chromosomal breakpoints in malignant cells, it has been hypothesized that fragile sites are involved in carcinogenesis^[25]. The most convincing evidence of the potential significance of the fragile sites in carcinogenesis is the location of FRA3B, the most highly inducible common fragile site, at chromosome 3q14.2. This chromosomal region is frequently deleted in lung cancer, renal cell carcinoma, and pancreatic cancer, and is also the location of the fragile histidine triad (FHIT) gene^[26]. The FHIT gene has been proposed to be a tumor suppressor and has recently been identified as a preferential target in HCC^[27]. The cloning of additional fragile sites, particularly ones such as FRA16D (16q23) and FRA6E (6q26) that are located in regions at which there is known LOH in HCC, should provide additional information about

the potential role of fragile sites in hepatocarcinogenesis.

Telomere length and telomerase activity

Telomeres are specialized protein-DNA structures at the ends of chromosomes that contain long stretches of TTAGGG hexameric repeats. Telomeres are thought to prevent degradation of chromosome ends and end-to-end fusion with other chromosomes. Aging of somatic cells is associated with reduction in telomere length. In contrast, germ line and neoplastic cells express telomerase, an enzyme that restores telomere length. There is progressive shortening of telomeres with progression from chronic hepatitis to cirrhosis and eventually to HCC^[28]. This is thought to occur as a consequence of the multiple cycles of cell injury, death, and regeneration that occur in injured liver, leading to premature hepatocellular senescence. It is presumed that telomere shortening beyond a critical length leads to genomic instability of hepatocytes and the evolution of clones of hepatocytes with increased telomerase expression and an immortalized phenotype^[29].

Geographic variations in hepatocarcinogenic mechanisms

Because of the small number of subjects in many studies and the heterogeneity of etiologies of HCC, it has been difficult to conclusively identify geographic variations in hepatocarcinogenic mechanisms. The best evidence so far is for the role of aflatoxin B1 in generation of the G-to-T transversion at codon 249 of the p53 gene. The frequency of this mutation in HCCs increases proportionally to the level of dietary exposure to aflatoxins. LOH at different loci, including the p53 locus, does not show as clear a pattern. Fifty-eight % of 64 heterozygous Chinese patients had a tumor-specific p53 allele LOH^[30]. Reported rates of p53 LOH from Japan are 69% (55 of 80 informative cases) and 95% (34 of 36) in cases with a p53 mutation^[31]. Previously high reported rates of p53 LOH in HCCs from southern African blacks contrast with the results reported in this issue by Martins *et al*^[1,32]. It is unclear whether this represents an artifact due to the small numbers in both studies or is reflective of a real phenomenon. Higher rates of LOH of the retinoblastoma gene than were found in this study have also been previously found in HCCs from Korea, Japan, and Australia. In addition, coincident mutation of the p53 and RB1 genes has been observed in 25% of advanced HCCs from Japan and 12.9% of advanced HCCs from Australia. No coincident mutations of the p53 and RB1 genes were identified in this population of southern African blacks. For the BRCA1 gene, LOH has been reported only once, in 11.5% (3 of 16) HCCs in a Korean population. LOH of the region containing the E-cadherin gene has been reported in 64%-91% of HCCs from China

and Japan^[6,33]. No LOH in this region was found in the study by Martins *et al*^[1]. Further study of larger numbers of advanced HCCs from southern Africa will be needed to confirm the possibility of a significant geographic variation. Homozygous deletions of the tumor suppressor gene p16/CDKN2A, which is located on chromosome 9p, have been shown to be frequent in HCCs from South Korean patients (61%) but uncommon in HCCs from Australian and Japanese patients. CGH analysis of a small number of HCC cell lines derived from different geographic regions showed loss of the 9p12-14 region in all 6 of 6 HCC cell lines established in South Korea^[11]. This may reflect an association between hepatitis B virus infection, the major risk factor for HCC in Korea, and deletions of 9p.

In general, studies of different groups of patients from the same country have shown fairly high rates of variability of LOH. It appears that some patient populations have (or experimental methods result in) lower levels of LOH overall than other patient populations (or methods). In spite of this variability, there is remarkable consistency in the chromosomal locations of LOH across tumors and populations, suggesting that these are targets of the carcinogenic process of represent areas that are preferentially affected by genomic instability in HCC.

SUMMARY

Studies such as the one reported here by Martins *et al*^[1], in which limited numbers of HCCs are examined at a limited number of loci provide tantalizing clues to the potential genetic mechanisms of hepatocellular carcinogenesis, and point out areas where further work is needed. A few groups have recently reported studies with comprehensive coverage of the genome with several markers on each chromosome. However, even the most detailed of these genomic screens has used approximately twenty markers per chromosome. For chromosomes that have 100 megabases of DNA sequence, this translates into a marker every 5 megabases. Since the average gene stretches over from less than ten to a few tens of kilobases, it is clearly impossible with current technology to achieve a comprehensive mapping of all gene deletions or rearrangements occurring in HCC. However, the advent of techniques such as comparative genomic hybridization and array based genomic DNA and RNA expression technologies has greatly expanded our ability to determine the genomic and expression differences between normal, precancerous, and cancerous tissues. Studies comparing genomic and gene expression changes in enough patients from different geographic regions on whom detailed clinical information is available will be invaluable in improving our understanding of the role of particular genomic targets and changes in gene expression in the development of HCC. A number

of secular trends will also affect our ability to elucidate the path ways underlying development of HCC. First, there is a trend towards using ablative therapies and liver transplantation for treatment of HCC and away from the use of surgical resection. This trend, if it continues, may reduce the availability of tissue samples for use in research. It is therefore important that priority be given to the establishment of tissue banks and databases of clinicopathologic information on patients with HCC. Second, it is clear that few research groups have the clinical capacity and resources to independently perform the basic, translational, and clinical research initiatives that are needed to address the pressing questions of prevention, diagnosis, and treatment of HCC. There is therefore a clear need for the formation of international collaborative groups to cooperate in determining the molecular pathogenesis of HCC, to help us better understand the geographic differences in the pathogenesis of HCC, and also to collaborate in developing effective, technologically appropriate preventive, diagnostic and therapeutic alternatives. Major steps in this direction have included the development of joint projects between scientists in China, Africa and the United States and Europe and further collaborations should be actively encouraged.

Endoscopic treatment of non-variceal gastrointestinal bleeding: hemoclips and other hemostatic techniques

Moura RM and Barkin JS

Seen article on page 53

Subject headings gastrointestinal bleeding/therapy; endoscopic /therapy; hemoclip/therapy; hemostatic technique

Although the number of hospitalizations for non-variceal gastrointestinal bleeding has decreased in recent years, acute upper gastrointestinal hemorrhage continues to be a common reason for hospital admission, and peptic ulcers account for at least fifty percent of all cases. Despite the fact that bleeding from ulcer scases spontaneously in approximately 80% of patients, it is still a diagnosis associated with substantial medical costs and significant morbidity and mortality, the latter ranging between 8 and 14%^[1], especially in the elderly.

The most common risk factors associated with upper gastrointestinal bleeding are *Helicobacter pylori* infection and the use of nonsteroidal anti-inflammatory drugs and alcohol. The eradication of *H. pylori* decreases the rate of rebleeding in peptic ulcer disease with absolute reductions that range from 2.5% to 33% according to different studies^[2]. The eradication of *H. pylori*, the increased awareness of potential dangers of nonsteroidal anti-inflammatory drugs and the widespread use of H2 receptor blockers and proton pump inhibitors in recent years account for the reduction in the number of patients hospitalized for upper gastrointestinal bleeding from ulcers^[3].

Nonetheless, no proven effective medical therapy exists for treatment of active peptic ulcer bleeding. In randomized trials, patients have demonstrated better outcomes from endoscopic therapies than from medical therapies. Emergency endoscopy should be performed as soon as safely possible after resuscitation to detect the bleeding lesion, to define stigmata of recent hemorrhage and

to perform endoscopic therapy when required. The value of endoscopic hemostatic therapy in patients with active arterial bleeding and non bleeding visible vessel has been firmly established with 75% decrease in rebleeding and operation rates and a 40% reduction in mortality^[4]. It has been shown that shock on presentation, bright red blood in the nasogastric aspirate or in the stomach that fails to clear with lavage, the number and severity of concomitant illnesses, and the age of the patient as well as the presence of rebleeding after successful endoscopic therapy all can predict rebleeding and mortality.

Lau *et al* showed that the stigmata of hemorrhage in bleeding peptic ulcers are prognostic, and that they allow the risk of rebleeding to be quantified^[5]. As a basis for the diagnosis of endoscopic appearance of lesions, the Forrest's classification is commonly used:

FIA: active bleeding (spurting)

FIB: active bleeding (oozing)

FIIA: non-bleeding visible vessel

FIIB: adherent clot

FIIC: presence of many brown or red, flat pigmentations or only one large dark area on the ulcer surface (black base)

FIIL: white flat base without any signs of recent bleeding.

Unfortunately, the disagreement on the classification of ulcer features may happen in more than 25% of cases, as shown by Laine *et al*^[6]. Mondardini *et al* showed that good agreement was obtained on bleeding ulcers, both spurting and oozing^[7]. In Lau *et al* study, good agreement among international experts was obtained only on active spurters, but agreement was poor for visible vessels^[8].

Endoscopy is advocated for the treatment of active bleeding (spurting and oozing) and nonbleeding visible vessels and, in some cases, non bleeding adherent clots. Endoscopic treatment controls bleeding in up to 90% and reduces significantly the rates of further bleeding, the need for blood transfusions, hospital costs and emergency surgery. A second endoscopic treatment can be attempted in patients with further hemorrhage after the initial endoscopic therapy, and permanent hemostasis can be achieved in half of these cases.

A variety of endoscopic treatment methods for bleeding peptic ulcers have been tested in trials. These methods include thermal application (laser, heater probe and bicap), local injection (hypertonic saline, epinephrine or various sclerosing agents such as absolute alcohol and polidocanol) and mechanical hemostasis. Each method has both merits and problems related to the hemostatic mechanism and technical procedure itself, and which one of these methods is superior remains controversial, since comparative studies have in general failed to show any superiority of one technique over another.

Although laser photocoagulation was one of the earliest forms of effective endoscopic hemostasis, currently it is being used mainly for treatment of vascular lesions or tumors, given its limitations of high cost, lack of portability and technical difficulty^[9].

Injection therapy is a low cost effective and safe procedure that is easy to implement in a variety of clinical settings. No one hemostatic agent has been shown to be clearly superior and the main difference between the available agents is probably the safety profile. Complications are less common after epinephrine injection than a sclerosant injection, the latter being associated with transmural tissue necrosis and perforation.

Heater probe and bicap achieve hemostasis through direct coaptive application of the thermal probe to the bleeding site. Thermocoagulation probes can seal arteries as large as 2mm in diameter and contain irrigation devices, which are helpful during hemostasis. Limitations include the requirement of a therapeutic endoscope, probe sticking and precipitation of treatment induced bleeding from a nonbleeding visible vessel. Repeat therapy increases the risk of perforation^[9].

Argon plasma coagulation (APC) results in evenly applied uniform surface coagulation and the noncontact mode is an advantage since there is no adhesion to the tissue. The probe can be used tangentially on lesions and the depth of tissue injury is quite superficial, minimizing the risk of perforation. Cipolletta *et al* demonstrated faster hemostasis with APC when compared to heater probe^[10], but at this time there is not enough literature to justify its routine use.

Recent studies have reported that the use of a combination of epinephrine injections and thermocoagulation for initial endoscopic control of bleeding ulcers yields significantly better results than the use of either treatment alone^[11-14].

The use of metallic endoscopic clips for hemostasis was developed in the mid 1970s. Until recently, however, due to cumbersome application of the technique, there has been limited use in the hemoclip. Improvements in design of the device

have led to increased ease of use. The bleeding vessel is ligated, achieving immediate hemostatic effect, which is definitive if the vessel is properly ligated. When compared to thermal methods and injection of sclerosing agents, both of which may cause excessive tissue injury leading to necrosis and perforation, injury to the surrounding tissue is minimized with hemoclips. Hachisu reported permanent hemostasis of upper gastrointestinal bleeding in 84.3% of 51 patient treated with hemoclips^[15]. A prospective study from Binmoeller *et al* confirmed the efficacy and safety of hemoclips (clip application device HX- 3L Olympus Corp.) to a wide range of bleeding sources. Initial hemostasis was achieved in all 88 patients, and rebleeding rate was 5%^[16]. Lee *et al* applied the hemoclip in 139 patients with a variety of bleeding sources. Recurrent bleeding was seen in 24% of patients presenting with active spurting, 4% of those with oozing and 6% of those with nonbleeding visible vessels. Permanent hemostasis was obtained in over 85% of patients with no major complications^[17]. Ohta *et al* achieved hemostasis in all 10 critically ill patients with severe gastrointestinal bleeding from spurting and oozing gastric ulcers^[18].

In this present uncontrolled prospective study, Lai *et al* used a new rotatable clip device (HX-5LR-1, Olympus) for the application of hemoclip (MD 850, Olympus) to 40 patients with active bleeding (spurting or oozing) from peptic ulcers. The overall hemostatic rate was 93%, hemostasis failed in two patients due mainly to the location of the bleeding source, which made clipping difficult to perform. Rebleeding after hemoclip treatment occurred in three cases secondary to dislodging of clips associated with difficult to approach location when applying the clips in two patients and use of anticoagulants in the other. Hemoclip treatment reduced the rates of rebleeding to 15% in the spurting group and 4% in the oozing group. The study did not include non bleeding visible vessels and did not compare the efficacy of this new improved hemoclipping device to other forms of endoscopic therapy.

Villanueva *et al* compared injection with epinephrine alone versus injection combined with hemoclip in a randomized study with 78 patients with peptic ulcer bleeding. Rebleeding occurred in only 5% of patients with hemoclip and injection compared with 19% in the group with injection therapy alone^[19].

Takahashi *et al* have reported that hemoclipping is as effective as the pure ethanol injection or heater probe methods in controlling the bleeding from primary gastric lesions^[20].

Nagayama *et al* recently compared the efficacy of endoscopic clipping with topical ethanol injection

in a retrospective study. Endoscopic clipping was performed using the clipping devices Olympus HX-3L or HX-5LR and clips Olympus MD-750. Endoscopic clipping improved therapeutic outcome as determined by rebleeding rates, need for blood transfusion and duration of hospital stay^[21].

These studies demonstrate the efficacy and safety of hemoclips. The advantage of clips is that they do not result in chemical or electrical damage to the surrounding tissue, do not appear to impair healing of ulcers, the hemostatic rate is good and similar to other methods and recurrent bleeding and complication rates are low. There are virtually no limitations to the number of clips to be applied, and therefore, the technique can be used repeatedly.

Because hemoclippping is a local form of mechanical hemostasis, it cannot be performed without identification of the bleeding point. Loading of the clip onto the application device is cumbersome and time consuming. It is usually technically more difficult to clip a vessel when the angle of approach is tangential (upper two thirds of the posterior wall or the lesser curvature of the gastric body and the posterior wall of the duodenal bulb). This technical difficulty persisted even in the rotatable clip device used by Lai *et al.*

Besides hemostasis of peptic ulcers, clips can also be applied to Dieulafoy's lesions^[22], colonoscopic diverticular bleeding^[23], Mallory-Weiss tears, postpolypectomy bleeding, post sphincterotomy bleed^[16] and gastric cancers. Radiopaque clipping serves as a good landmark for radiologists to identify the bleeding point during angiography when clipping fails in hemostasis. The clips can also serve as markers for proper esophageal stent placement.

In summary, endoscopic hemoclip treatment provides an effective and safe modality for hemostasis in gastrointestinal bleeding. Controlled prospective studies comparing hemoclip with other endoscopic methods are still required before this modality becomes widely used.

Post-gastrectomy patients need to be followed up for 20-30 years

Tovey FI and Hobsley M

Subject headings gastrectomy; nutrition; iron; vitamin B₁₂; vitamin D

Abstract

AIM To investigate the incidence and management of nutritional deficiencies following a gastrectomy.

METHODS A gastrectomy population of 227 patients in London was followed up for 30 years after operation to detect and treat nutritional deficiencies.

RESULTS By the end of the first decade iron deficiency was the commonest problem. Vitamin B₁₂ deficiency became more important in the second decade. During the third decade both reached equal prevalence, being found in some 90% of the female and 70% of the male residual population. Vitamin D deficiency was a lesser problem, reaching its climax in the second decade. Overall, all women fared worse than men.

CONCLUSION The importance of long-term follow-up of gastrectomy patients for iron, Vitamin B₁₂ and Vitamin D deficiencies is emphasised.

INTRODUCTION

In 1981 and 1984, through the courtesy of The Chinese Academy of Medical Sciences, the first author visited centres in the north and south of China to gather information about the prevalence of duodenal ulcer and its relationship to the staple diets. It was noted that the standard operation for duodenal ulcer in many centres was either a Billroth II (gastrojejunal) or a Billroth I (gastroduodenal anastomosis) gastrectomy (Figure 1). This raises the possibility that at the present time there might be a gastrectomy population in China of 25-30 years standing, who may have developed nutritional disorders as a result of their operation. Our experience with the study of patients 25-30 years after gastrectomy and on a Western diet may serve as a guide to the frequency of these problems.

MATERIALS AND METHODS

Patients

We report the outcome of a longitudinal study in the UK. The study was performed at University College Hospital in London on patients who underwent a gastrectomy between 1955 and 1960^[1]. In 1969 contact was made with 227 patients, and although the number diminished from movement elsewhere or deaths, the remainder were followed up regularly until 1990. The population included 186 patients who had undergone a Billroth II gastrectomy (male 141, female 45) and 41 who had undergone a Billroth I gastrectomy (male 24, female 17). After an interval of 10-15 years following the operation they were screened annually, or more often when indicated, and the following investigations were made to detect possible nutritional disorders^[1].

Method

Clinical investigation (on first attendance) The patients were weighed. Compared with the patient's ideal pre-operative weight, a loss of up to 4.5kg was regarded as moderate loss and a greater loss as severe.

A record was made of any post-prandial symptoms including reduced capacity for food, early dumping and late dumping. A moderately reduced capacity was regarded as being able to take one-half of what the patient would normally expect to eat at a meal and severe as one third or less. A record was made of those with a reduced capacity who showed

Frank I. Tovey and Michael Hobsley
Department of Surgery, Royal Free and University College Medical School, London 67-73 Riding House Street, London W1P 7LD, UK
Frank I. Tovey OBE, ChM, FRCS (Eng) was born in England in 1921. After qualifying as a surgeon he worked in China between 1947 and 1949 and then in India from 1951 to 1967. In 1968 he was appointed as a consultant surgeon at Basingstoke in England and also as an honorary surgical research fellow at University College in London. His interests have been in leprosy reconstructive surgery and in aetiology and management of duodenal ulcer. He has travelled widely investigating the relationship between staple diets and the prevalence of duodenal ulcer in many countries. He is retired but continuing with his research projects.

Received 1999-09-28 **Accepted** 1999-11-15

discomfort or vomiting if the amount was exceeded. Early dumping consisted of weakness, fainting, sweating and palpitation 10-20 minutes after food. Those with late dumping had similar symptoms occurring about 30-60 minutes after the end of the meal.

Persistent diarrhoea was described as moderate if there were up to 3 loose stools a day and as severe if more. All of the 9 patients with diarrhoea had 24-hour faecal fat estimations and also as many of the other patients who were willing (total 158). A faecal fat output 6g/day-12g/day was regarded as a moderate steatorrhoea and above 12g/day as severe.

Nutritional deficiencies

Iron deficiency Full blood count included blood picture, serum iron and total iron binding capacity (TIBC). Iron deficiency was defined as an iron saturation (serum iron/total iron binding capacity) below 16%.

Vitamin B₁₂ deficiency Vitamin B₁₂ deficiency was diagnosed when two separated bioassays repeated one month apart showed a value of less than 110pmol/L.

Vitamin D deficiency Serum calcium, phosphate and alkaline phosphatase. The first sign was a rising serum alkaline phosphatase estimation. If this was found, liver function tests were done to exclude a hepatic cause. Other causes such as Paget's disease, a recent fracture or bony secondaries were excluded. A 24 h urinary calcium output below 2mmol/24 h supported the diagnosis^[2]. A therapeutic trial of calcium and vitamin D was then given as a diagnostic measure and a sustained fall in serum alkaline phosphatase levels gave confirmation of the diagnosis. Calcium and vitamin D BPC tablets (calcium lactate 300 mg, calcium phosphate 150mg, calciferol 12.5 µg), were given in a dose of 2 tablets, 4 times a day, and the dose was reduced to 2 tablets, 3 times a day when the serum alkaline phosphatase levels fell to normal.

Osteoporosis Until 1989 the right second metacarpal had been X-rayed and measurements taken from the X-ray of the second right metacarpal were used to calculate the Exton-Smith Index:

$$\frac{T^2 - M^2}{TL}$$

where T is the thickness of the bone, M is the medullary thickness at the mid-point and L is the overall length^[3].

After 1989 dual energy X-ray absorptiometry (DEXA) became available and was used to screen the remaining population. Only males were chosen because by then, all the female patients were

postmenopausal, introducing another potential factor for osteoporotic changes.

Statistics Statistical analysis was done using the Student *t* test or Fisher's exact test as appropriate.

RESULTS

Clinical findings

At the first follow-up consultation in this study 66 (29%) of the 227 patients had a moderate and 15 (7%) a severe loss of weight. 107 (47%) patients complained of a reduced capacity for food, which was severe in 41 (18%)

Early dumping was diagnosed in 39 (17%) and late dumping in 7 (3%). Persistent diarrhoea occurred in 9 of the 186 Billroth II patients (being severe in 1) but in none of the 41 with a Billroth I gastrectomy. The difference was not significant (Fisher's exact test $P = 0.2089$). Five of these 9 patients had moderate and 2 severe steatorrhoea.

Moderate steatorrhoea was found after both operations [Billroth I, 9 (24%) of 37; Billroth II, 14 (12%) of 121; not significant, $P = 0.2292$].

However, severe steatorrhoea only occurred after the Billroth II procedure [32 (26%) of 121, this was significantly different from the zero incidence in the Billroth I group, $P < 0.0001$].

Nutritional findings (including management)

Iron deficiency. The first sign was a rising TIBC, which often preceded a fall in serum iron by several months. Actual iron-deficient anaemia developed about 6 months later.

Ferrous gluconate was found to be well tolerated and the patients were given 300mg thrice daily until the iron deficiency was corrected and then a maintenance dose of 300mg daily.

The prevalence of iron deficiency is shown in Table 1. In the men the prevalence was significantly higher in those showing weight loss ($P < 0.02$) or reduced capacity for food ($P < 0.05$), but these differences were not seen in the women.

Vitamin B₁₂ deficiency In most patients a fall in serum B₁₂ concentration preceded any macrocytosis, neutrophil shift or anaemia. Patients were treated by intramuscular injections of 1000 µg hydroxocobalamin in alternate months. The prevalence in the remaining population is shown in Table 1. It can be seen that iron deficiency occurred much earlier than B₁₂ deficiency, appearing in many patients during the first 10 years after operation. Vitamin B₁₂ deficiency developed mostly 10-20 years after operation and its prevalence slowly increased to equal that of iron deficiency by the end of 25-30 years, when approximately 70% of men and 90% of women had developed either iron or B₁₂ deficiency, the deficiencies being combined in 51% and 70%, respectively.

Vitamin D deficiency Vitamin D deficiency occurred in 7.5% of Billroth II and 7.3% of Billroth I gastrectomies and was predominantly a problem of female patients. (F:M=19%:4%). It became apparent in many patients during the first 10 years after operation (Table 1). Of those investigated, 50% had severe and 28% moderate steatorrhea as compared with 20% and 14% respectively for the whole series.

Osteoporosis Osteoporotic changes in excess of normal ageing were seen in 24%, 20% and 22% of men and in 35%, 51% and 86% of women in 1969, 1974 and 1982, respectively. None of these had evidence of vitamin D deficiency. These measurements, however, were not sensitive enough to monitor any treatment over a short term^[4].

Dual energy X-ray absorptiometry was used in 16 active male patients, with no evidence of vitamin D deficiency, who were still attending the clinic. Six (37.5%) were found to have reduction of bone mineral density of the lumbar spine and upper left femur of more than 2 standard deviations. Initially they were treated with a calcium supplement (microcrystalline hydroxyapatite) 16g/day-32g/day and calciferol 0.25 mg daily but with no response. Following this they were given intermittent cyclical etidronate 400 mg nightly for 2 weeks, followed by calcium carbonate equivalent to 500mg calcium daily for 10 weeks. This 12-week cycle was repeated over 2 years. Only 2 patients responded with a return to within the normal range of values. So far no totally satisfactory treatment has been reported for postgastrectomy osteoporosis^[5].

Billroth I versus Billroth II gastrectomies There was no significant difference in overall, moderate or severe weight loss between the two operations in women (BI6/12:BI26/45, $P = 0.1567$). In men, although there was no significant overall difference in weight loss (BI10/24:BI37/141, $P = 0.1438$), significantly more patients showed a moderate weight loss after a Billroth II gastrectomy (BI1/24:BI31/141, $P = 0.0491$), by contrast more showed severe weight loss after a Billroth I procedure (BI9/24:BI6/141, $P < 0.0001$).

There was no significant difference with regards to capacity for food, early or late dumping. The difference in persistent diarrhoea was not statistically different, but in severe steatorrhea the difference between the two operations was significant (BI0/37:BI32/121, $P < 0.0001$).

No difference between the two operations was found in the incidence of nutritional deficiencies.

Sex differences Women on the whole fared less well than men. They had significantly more overall weight loss (F26/45:M37/141, $P = 0.0002$) after a Billroth II operation. There was no significant

difference in severe loss, but the difference in moderate loss was significant (F21/45:M31/141, $P = 0.0021$). Overall, they showed a significant difference in reduced capacity for food (F43/62:M64/165, $P < 0.0001$) and much more women showed a severely reduced capacity (F20/62:M21/165, $P = 0.0016$). Early dumping was more common in women than in men after the Billroth II operation (F15/45:M5/141, $P < 0.0001$). More women complained of discomfort and vomiting, if the irreduced intake was exceeded, after a Billroth II (F15/45:M10/141, $P < 0.0001$). They also showed more aversions to vitamin D containing food such as butter, cream, milk and eggs. Women fared worse with regards to the incidence of iron and vitamin B₁₂ deficiencies and more markedly in the occurrence of vitamin D deficiency (Table 1).

DISCUSSION

Several factors^[6-11] contribute to nutritional disorders after a gastrectomy. With the loss of the pyloric sphincter there is uncontrolled gastric emptying and the capacity for food becomes dependent on the ability of the small intestine to accommodate the meal. The rapid emptying stimulates peristalsis and there is rapid passage of food through the small intestine. Small molecules such as those of sugars and starches which are rapidly broken down in the small intestine, produce a severe osmotic effect which leads to the drawing into the gut of extracellular fluid amounting to 2-3 litres, resulting a fall in plasma volume and rise in haematocrit. This ingress of liquid distends the gut and there may be early satiety and reduced capacity for food. When the fall in plasma volume exceeds 7%, certain patients will develop early dumping with hypotension according to their vascular tolerance (Figure 2). In other patients the rapid absorption of glucose from the intestine leads to an oversecretion of insulin followed by hypoglycaemia and the symptoms of late dumping.

The increased water content of the material entering the large intestine may give rise to diarrhoea unless the colon is able to absorb the fluid. The presence of undigested sugars and starch may also act as irritants. The rapid passage of food through the small intestine results in a reduced mixing with the pancreatic and intestinal enzymes. This leads to impaired digestion and absorption of proteins and fats as shown by the presence of steatorrhoea in some patients. Short circuiting of the duodenum in the Billroth II operation (Figure 1) may cause pancreatic juices to lag behind the food as manifested by the presence of severe steatorrhoea in this group.

Absorption of vitamin D is dependent on fat solubility and the combination of steatorrhoea and reduced vitamin D intake may lead to vitamin D deficiency. As mentioned many patients, especially women, develop a selective aversion to certain food, particularly sources of vitamin D: this would explain the increased incidence of vitamin D deficiency in this group.

Iron metabolism may also be impaired. The intake of iron-containing foods may be reduced. Much of the intake is in the form of ferric iron or of iron

combined with protein. Acid is needed to convert ferric iron to ferrous, acid and pepsin are needed to convert organic to inorganic iron. Both acid and pepsin are reduced by a gastrectomy. In addition, most of the iron is absorbed in the duodenum and upper jejunum.

Vitamin B₁₂ deficiency may also develop. One factor is loss of the intrinsic factor that had been secreted by gastric mucosa removed by the gastrectomy. Rapid passage through the small intestine leads to less absorption.

Calcium absorption also occurs principally in the duodenum and upper jejunum and is impaired by intestinal hurry and loss of duodenal continuity. In addition, the presence of steatorrhoea, calcium absorption is further impaired by the formation of insoluble calcium soaps.

As a result of all these factors, postgastrectomy patients may develop iron deficiency anaemia, vitamin B₁₂ deficiency anaemia, vitamin D deficiency and osteomalacia, or osteoporosis in excess of normal ageing.

Conclusion This study in particular demonstrates the increasing prevalence of iron and vitamin B₁₂ deficiency in a population after gastrectomy, reaching approximately 75% in 20-30 years. This stresses the increasing importance with passing years of regularly monitoring iron saturation and B₁₂ levels. In addition, the increased serum alkaline phosphatase levels may indicate vitamin D deficiency and need to be investigated. Now that gastrectomy is rarely performed for peptic ulcer it is important to remember that there is still a large number of patients who underwent gastrectomy 20-30 years ago and are at risk of developing nutritional deficiencies.

Subject headings crohns disease; cytokine/analysis; intestinal mucosa

Abstract

AIM To determine levels of cytokines in colonic mucosa of asymptomatic first degree relatives of Crohn's disease patients.

METHODS Cytokines (Interleukin (IL) 1-Beta, IL-2, IL-6 and IL-8) were measured using ELISA in biopsy samples of normal looking colonic mucosa of first degree relatives of Crohn's disease patients ($n = 9$) and from normal controls ($n = 10$) with no family history of Crohn's disease.

RESULTS Asymptomatic first degree relatives of patients with Crohn's disease had significantly higher levels of basal intestinal mucosal cytokines (IL-2, IL-6 and IL-8) than normal controls. Whether these increased cytokine levels serve as phenotypic markers for a genetic predisposition to developing Crohn's disease later on, or whether they indicate early (pre-clinical) damage has yet to be further defined.

CONCLUSION Asymptomatic first degree relatives of Crohn's disease patients have higher levels of cytokines in their normal-looking intestinal mucosa compared to normal controls. This supports the hypothesis that increased cytokines may be a cause or an early event in the inflammatory cascade of Crohn's disease and are not merely a result of the inflammatory process.

INTRODUCTION

Numerous studies have proven that cytokines play an integral role in the pathogenesis of inflammatory bowel disease (IBD). These protein mediators have been shown to regulate the immune response, induce tissue injury, and mediate complications such as fibrosis and obstruction in patients with IBD^[1]. In our institution, we have measured cytokines IL-1B (Interleukin-1 Beta), IL-2, IL-6, and IL-8 from mucosal biopsies obtained during colonoscopy in patients with IBD and other colitides to see if there is any predictive pattern of cytokine elevation^[2-5]. Since there is evidence for a genetic predisposition in IBD^[6-10], we were also interested in determining if asymptomatic first-degree relatives of Crohn's disease (CD) patients exhibit elevated intestinal mucosal cytokine levels as well. If they do, is there any pattern to the cytokine elevations?

To our knowledge, there are no studies examining specific cytokine levels in first-degree relatives. Some studies suggest there is increased intestinal permeability in healthy relatives of CD patients^[11-14], pointing to a possible genetic defect in these patients. This study may add that even in asymptomatic relatives, there is evidence of subclinical expression of the disease at a cellular level. Elevated cytokine levels would also support the hypothesis that cytokines are a cause or an early event in the inflammatory cascade of CD and not a result of the inflammatory process, since these patients have no pathological signs or symptoms of disease.

MATERIALS AND METHODS

After obtaining prior approval of the Institutional Review Board in our hospital, we studied ten people without a family history of IBD who acted as controls, and nine first-degree relatives of patients with Crohn's disease, who did not exhibit signs or symptoms referable to CD.

The control patients included four males and six females ranging in age from 40 - 82 years (mean-64.3). Each patient underwent a routine colonoscopy. (Olympus, Lake Success, NY) after appropriate consent. Table 1 shows further data regarding the group. These patients underwent colonoscopy for causes other than IBD such as screening, Guaiac positive stools, abdominal pain (Table 1).

Eleven first-degree relatives were initially studied but only nine were used in the final analysis. Two relatives were excluded as one had a prior history of radiation proctitis and the other had a prior sigmoid biopsy consistent with nonspecific inflammation. These relatives included two males and seven females ranging in age from 21-79 years (mean-50.1). Two relatives were from the same family (i.e. brother and sister of a CD patient). Otherwise, the relatives were unrelated to each other. After obtaining informed consent each underwent a flexible sigmoidoscopy (Olympus) up to splenic flexure without a prior bowel prep. (Refer to Table 1). There was one patient in this group with abdominal pain and weight loss who was diagnosed with depression and anxiety but no pathologic condition was found. Also, as shown in the table, endoscopic findings were of minimal significance in both groups.

Demographic data of the eight CD patients (the index cases of the first-degree relatives) were analyzed and compared (Table 2).

*One of the patients had two first-degree relatives.

Tissue collection and analysis

Three mucosal biopsies were obtained from the sigmoid or descending colon in each patient in both groups. The biopsy samples, weighing between 15 mg and 30 mg each, were immediately wrapped in aluminum foil, placed in a container of liquid nitrogen and stored at -70°C until they were processed. Tissue was crushed and homogenized in diluent from IL-kits (Quantikine, R & D systems) for 30 seconds, then centrifuged for 15 minutes at 3000 r/min. The supernatant fluid was used for assaying interleukins. Histologic evaluation was only performed if endoscopic abnormalities were noted as it would have, otherwise, delayed the procedure.

A solid phase ELISA using Quantikine kits (Research and Diagnostic Systems, Minneapolis, MN, USA) was used to measure IL-1B, IL-2, IL-6, and IL-8. Results were expressed as mean±SEM. The Quantikine method had a sensitivity of 0.03 pg-0.08 pg and a standard curve linearity of 0.03 pg to 3.0 pg. A Student's independent test was used to compare data from the two groups and *P* value <0.05 was considered as statistically significant.

RESULTS

The concentrations of IL-2, IL-6, and IL-8 were significantly (*P* < 0.05) higher in the colonic mucosa of first-degree relatives (3.40 ng/g ± 0.56 ng/g, 1.19 ng/g ± 0.21 ng/g, 11.98 ng/g ± 2.62 ng/g, respectively, Figure 1) when compared to controls (1.86 ng/g ± 0.30 ng/g, 0.69 ng/g ± 0.01 ng/g, 5.41 ng/g ± 1.87 ng/g, respectively). No significant difference was found in the concentration of IL-1B between relatives (0.85 ng/g ± 0.17 ng/g) and controls (1.03 ng/g ± 0.15 ng/g).

Individually, seven of the nine relatives had significantly higher levels of IL-2 and IL-6 and six relatives had significantly higher IL-8 levels than the mean value of controls. Interestingly, mean IL-1B and IL-6 levels of the two relatives from the same family (0.23 ng/g ± 0.09 ng/g and 0.21 ng/g ± 0.09 ng/g, respectively) were significantly lower (*P* < 0.05) than that of the other relatives (1.03 ng/g ± 0.16 ng/g and 1.47 ng/g ± 0.14 ng/g, respectively).

We also compared various subsets of the CD index cases to see if there were any differences in the corresponding first-degree relative cytokine levels (Table 2). In analyzing age, severity, duration or extent of disease, medications, and history of surgery, there were no significant differences between the subsets of the relative group in any category.

Figure 1 Interleukin levels of first-degree relatives and controls.

DISCUSSION

There is evidence that inflammatory bowel disease is determined by genetic predisposition. Supporting data include familial aggregation^[6,15] and an increased concordance rate in monozygotic twins compared with dizygotic twins^[16]. CD patients have a more frequent positive family history than ulcerative colitis (UC) patients^[17]. Relatives of CD patients have a higher risk of IBD than those of UC patients^[18,19]. There is also a higher concordance rate for CD than for UC among either monozygotic or dizygotic twins^[16]. This suggests that hereditary predisposition may play a more important role in CD than UC.

Genetic studies have used subclinical markers in unaffected family members of IBD to either indicate the genetic abnormality predisposing to a disease or identify those in whom a subclinical phase of the disease process is occurring. These include serum antibodies (i.e. ANCA^[20,21], antibodies to viruses, bacteria, mycoplasma, food antigens^[22], and colonic epithelial cells^[23]), colonic mucin abnormalities^[24], obligate anaerobic fecal flora^[25], mucosal production of IgG subclasses^[26], and C₃ dysfunction^[27]. Abnormal elevations of these markers have been seen in healthy relatives of either CD or UC patients or both.

Most studies on relatives of CD patients have analyzed intestinal permeability in patients with CD and their first-degree relatives by measuring urinary excretion of poorly absorbed, water-soluble compounds such as polyethylene glycol (PEG-400) and large sugars, including lactulose, mannitol, and rhamnose^[28], 51 Cr-labelled ethylene diaminetetraacetic acid (EDTA)^[29] and luminal prostaglandin^[30] and hyaluronin^[31] release. Although initial studies have shown increased permeability in patients with CD^[29,32-34] and their first-degree relatives^[35,36], several additional studies^[37-39] have been inconsistent, showing no increased permeability in either group.

Hollander^[40] and May *et al.*^[41] in 1993,

reviewed earlier studies and found that most studies showed a significant increase in permeability in 10% of first-degree asymptomatic relatives as it is possible that only a subgroup of relatives of CD patients are genetically susceptible. A recent study^[42] has confirmed this by showing that the subset of asymptomatic relatives with increased intestinal permeability had increased CD45 (common leukocyte antigen) isoform in peripheral blood cells similar to CD patients. These findings suggest that the permeability defect in CD patients may serve as a subclinical and genetic marker for CD and is not secondary to intestinal inflammation^[34] or may indicate early intestinal damage (preclinical expression).

Our study is the first to our knowledge to determine cytokine levels, known to be elevated in the colonic mucosa of CD patients and in asymptomatic relatives of CD patients. The fact that IL-2, IL-6, and IL-8 were significantly elevated suggests a possibility of early intestinal damage in the relatives group similar to the studies of increased permeability in these patients. Although the number of cases were small ($n = 9$), six of the nine patients had significant elevations of all three cytokines (IL-2, IL-6, and IL-8) versus controls (the others had significant elevations of at least one or two of these cytokines). Whether a subset of these relatives are actually more predisposed to the disease than controls, as suggested in the permeability studies, has yet to be known. It is also of interest that we could not find any significant differences in cytokine levels between subsets of the relatives with regard to the various parameters of the index CD patients (listed in Table 2). The fact that the two relatives from the same family had significantly lower levels than the rest of the group is of questionable value. Future studies including more patients and the evaluation of other cytokines would be of interest and would help in determining the significance of these alterations in this group.

This study shows that asymptomatic relatives of CD patients have increased levels of cytokines in normal-looking colonic mucosa. Studies with intestinal permeability have been inconsistent. It may be possible that increased cytokines are an early event in the pathogenesis of the disease. Whether these increased cytokines lead to increased permeability and then to CD is something that needs further investigation.

Endoscopic hemoclip treatment for bleeding peptic ulcer

Lai YC, Yang SS, Wu CH and Chen TK

See invited commentary on page 42

Subject headings endoscopic hemoclippping; gastrointestinal hemorrhage/therapy; peptic ulcer; hemostasis

Abstract

AIM To evaluate the efficacy of endoscopic hemoclip in the treatment of bleeding peptic ulcer.

METHODS Totally, 40 patients with F1a and F1b hemorrhagic activity of peptic ulcers were enrolled in this uncontrolled prospective study for endoscopic hemoclip treatment. We used a newly developed rotatable clip-device for the application of hemoclip (MD850) to stop bleeding. Endoscopy was repeated if there was any sign or suspicion of rebleeding, and re-clipping was performed if necessary and feasible.

RESULTS Initial hemostatic rate by clipping was 95%, and rebleeding rate was only 8%. Ultimate hemostatic rates were 87%, 96%, and 93% in the F1a and F1b subgroups, and total cases, respectively. In patients with shock on admission, hemoclippping achieved ultimate hemostasis of 71% and 83% in F1a and F1b subgroups, respectively. Hemostasis reached 100% in patients without shock regardless of hemorrhagic activity being F1a or F1b. The average number of clips used per case was 3.0 (range 2-5). Spurting bleeders required more clips on average than did oozing bleeders (3.4 versus 2.8). We observed no obvious complications, no tissue injury, or impairment of ulcer healing related to hemoclippping.

CONCLUSION Endoscopic hemoclip placement is an effective and safe method. With the improvement of the clip and application device, the procedure has become easier and much more efficient. Endoscopic hemoclippping deserves further study in the treatment of bleeding peptic ulcers.

INTRODUCTION

Upper gastrointestinal bleeding is a frequently encountered clinical problem for both the endoscopist and surgeon^[1]. Acute hemorrhage from duodenal and gastric ulcers stops spontaneously in approximately 70% to 80% of cases^[2]. The remaining patients represent a high risk group requiring prompt identification and treatment to improve the high morbidity and death rate. The consensus is that patients who have peptic ulcer with spurting or oozing hemorrhage need active treatment^[3,4]. The death rate of patients with persistent or recurrent bleeding is 12% to 18%^[5-8].

There have been many endoscopic techniques, including thermal application (laser, heater probe, and bicap) and local injection (hypertonic saline, epinephrine, and ethanol), advocated effectively for the control of gastrointestinal bleeding^[9]. But, their results vary depending on the operators or the patients^[10,11]. Although the success rate of initial hemostasis is high, rebleeding has been reported to occur in 10% to 30% of patients^[12-14]. Thermal methods and injection of hemostatic agents can cause tissue injury leading to necrosis and possible perforation^[15-17]. Mechanical hemostasis by the application of a metal hemoclip to a bleeding vessel is an appealing alternative to the currently available techniques. It was first introduced in 1975 by Hayashi *et al*^[18]. However, the initial experience was discouraging because of its complexity and low retention rate. In 1988, Hachisu introduced a modified hemoclip for upper gastrointestinal hemorrhage with a permanent hemostatic rate of 84.3%^[19]. A newly improved rotatable clip-device with better grasping capability has been developed recently, which can make the procedure easier and save much time^[20]. We therefore used this newly improved metallic clip to prospectively evaluate its role in the hemostatic effect on bleeding peptic ulcers.

MATERIALS AND METHODS

From January 1997 to December 1998, totally 40 hospitalized patients were enrolled. All patients were proved to have active hemorrhage from peptic ulcer by endoscopic examination at Cathay General Hospital. All cases had F1a (spurting) or F1b (oozing) hemorrhagic activity by Forrest classification^[21]. Patients who had multiple bleeding sites or gastric cancer were excluded. Since active hemostatic treatment has been recommended

Received 1999-09-22 Accepted 1999-11-18

for acute bleeding from the upper gastrointestinal tract^[3,4], the present study did not include a control group which was treated conservatively.

Endoscopies were carried out using an Olympus GIF-XQ 200 endoscope (Olympus Corp., Tokyo, Japan). We used a hemoclip (MD 850, Olympus) device, which has a new rotatable clip-device (HX-5LR-1, Olympus) for hemostasis. The hemoclip was applied directly to the bleeding vessel. Vessels traversing the surface were clipped at both ends of the bleeding point. Initial hemostasis was defined as no bleeding from the ulcer for at least 5 minutes.

Patients were treated with intravenous H₂-blockers and oral antacid suspensions after endoscopic examination. A nasogastric tube was inserted to observe the bleeding condition. Blood transfusion was given if the hemoglobin level dropped to less than 90 mg/L, or if vital signs deteriorated.

Shock was defined as systolic blood pressure less than 13.3 kPa (100 mmHg) and a pulse rate greater than 100 beats/min, accompanied by pallor, cold sweating, and oliguria. Rebleeding or recurrent bleeding was defined as blood in the stomach 24 h after treatment, presence of unstable vital signs, and continued tarry or bloody stools, or hematemesis after treatment.

Endoscopic examination was performed again whenever there was evidence or suspicion of rebleeding. Hemoclips were used again if necessary and feasible. Surgical intervention was considered if re-clipping still could not control the bleeding. Ultimate hemostasis was defined as lack of rebleeding for 7 days after treatment. Follow-up endoscopy was performed 1 week after initial hemoclip treatment if patients agreed.

We used Student's *t* test or Wilcoxon 2-sample test for the analysis of continuous variables. Chi-square test and Fisher's exact test were applied for the analysis of nominal variables. A *P* value of less than 0.05 was considered significant.

RESULTS

Totally, 40 patients were included in this study over a 2-year period. There were 29 males and 11 females with a mean age of 62.3±3.3 years (range 26-85 years). Locations of peptic ulcers and their hemorrhagic activity by Forrest classification are listed in Table 1.

Two of our 40 cases failed to terminate hemorrhage in response to hemoclips. One failed case was due to torrential active bleeding from the posterior wall of the mid-gastric body, which prevented treatment feasibility. This patient subsequently received surgical intervention. Another case with F1a activity had hemorrhage from the lesser curvature of the high gastric body, which made clipping difficult to perform, and we were unable to clip this area efficiently. The patient

could not undergo surgery due to end-stage renal disease and sepsis, and he expired in spite of treatment. Rebleeding after hemoclip treatment occurred in three cases. The first patient had chronic liver disease, diabetes mellitus, and renal insufficiency. He had a gastric ulcer (F1b) on the posterior wall of the high body, where the application of clipping was difficult. Massive hemorrhage occurred 2 days after the first endoscopic clipping. Emergent operation was performed and clips were found to have dislodged during the operation. The second patient underwent anti-coagulant treatment for rheumatic heart disease. He had a gastric ulcer (F1a) on the lesser curvature of the antrum. Follow-up endoscopy revealed active oozing from the edge of the clips. Re-clipping successfully stopped the hemorrhage. The third case had a duodenal ulcer (F1a) on the posterior wall. Follow-up endoscopy revealed that the clip had dislodged. The rebleeding rates of F1a and F1b subgroups were 15% and 4%, respectively (Table 2). This difference is not statistically significant.

The final results of our study are shown in Table 3. The overall hemostatic rate was 93%. In patients with F1a ulcers, the rate was 87%, and in F1b ulcers was 96%; the difference between them is not significant. Two cases received emergent operation, and their post-operative courses were smooth and uneventful. Mortality occurred in only one patient who had serious underlying disease (end-stage renal disease and sepsis) and was unable to receive surgical intervention.

Table 4 shows the relationship between shock and the rebleeding rate. After hemoclippping, the rebleeding rate in the F1a shock subgroup was 20%, a rate not different from that 13% in the F1a non-shock subgroup. In the F1b group, the rebleeding rates did not differ between the shock and non shock groups (17% versus 0%, *P* = 0.07). In those patients without shock, the hemostatic rate was 100% in both F1a and F1b subgroups. In patients with shock, the hemostatic rates after hemoclippping were 71% in F1a cases and 83% in F1b cases (Table 5).

The number of clips used per patient in each subgroup is shown in Table 6. The average number of clips used in all cases was 3.0 (range 2-5). The average number was higher in the F1a subgroup (3.4, including gastric and duodenal ulcers) than in the F1b subgroup (2.8, including gastric, duodenal, and marginal ulcers, *p* = 0.04 by Wilcoxon 2-sample test). The number of clips (including F1a and F1b) did not differ between gastric and duodenal ulcers. We also tried to analyze the difference of clip number used in various locations of gastric and duodenal ulcers, but were unable to reach any definite conclusion because of limited case numbers.

Table 1 Number of patients by ulcer type and Forrest classification

Type	F1a	F1b
Gastric ulcer	10	14
Duodenal ulcer	5	9
Marginal ulcer	0	2
Total	15	25

Table 2 Number of rebleeding cases in each subgroup

Type	F1a	F1b
Gastric ulcer	1/8 ^a	1/14
Duodenal ulcer	1/5	0/9
Marginal ulcer	0/0	0/2
Total	2/13 ^b	1/25

Data are expressed as rebleeding/subgroup case number. ^aTwo cases without initial hemostasis are excluded. ^b $P = 0.27$.

Table 3 Outcome of endoscopic hemoclip treatment

Treatment	F1a (n = 15)	F1b (n = 25)	Total (n = 40)
Ultimate hemostasis ^a	13(87%)	24(96%)	37(93%)
Emergent surgery	1	1	2(5%)
Mortality	1	0	1(3%)

Data are presented as case number (percentage).

^aTwo patients with re-clipping are included. ^b $P = 0.28$.

Table 4 The relationship between shock and rebleeding rate

Subgroup	F1a	F1b
Shock ^a	1/5(20%) ^b	1/6(17%) ^c
Non-shock	1/8(13%)	0/9 (0%)

Data are expressed as rebleeding/subgroup case number. ^aTwo cases without initial hemostasis are excluded. ^b $P = 0.77$; ^c $P = 0.07$ compared with non-shock subgroups.

Table 5 The relationship between shock and ultimate hemostatic rate

Subgroup	F1a	F1b
Shock	5/7(71%) ^a	5/6(83%) ^b
Non-shock	8/8(100%)	19/19(100%)

Data are expressed as ultimate hemostasis/subgroup case number.

^a $P = 0.11$, ^b $P = 0.07$ compared with non-shock subgroups.

Table 6 Number of clips used per case in different subgroups

Type	F1a	F1b
Gastric ulcer	3.5 (n = 8)	2.9 (n = 14)
Duodenal ulcer	3.2 (n = 5)	2.7 (n = 9)
Marginal ulcer	—	2.5 (n = 2)
Average ^a	3.4 (n = 13)	2.8 (n = 25)

^a $P = 0.04$.

DISCUSSION

The rotatable clip-device we used was developed in 1995. This device has a dial at the center of the handle, which can rotate the clip and open at the tip of the device. The working length of HX-5LR-1 is 165 cm for an upper GI endos cope. Use of a special wire resistant to rotational distortion and a special coating facilitate rotation of the clips and markedly reduce the force required for clipping, as compared to the conventional device (HX-3/4 clip-device). As a result, precise clipping with application of a smaller force has become possible^[20]. HX-5LR-1 has advantages over the older HX-3/4 clip- de vice in its rotatability, which

can make clipping more accurate, and its durability including the ability to withstand sterilization by autoclaving^[20].

Mechanical clipping of a bleeding ulcer is appealing because the bleeding can be stopped immediately^[22]. This technique was once abandoned due to its complexity. In 1993, Binmoeller *et al* in Germany evaluated an improved metallic clip for endoscopic treatment of non-variceal hemorrhage from various sources in the upper gastrointestinal tract and concluded its highly effective hemostatic effect^[9]. Our results confirm the efficacy and safety of hemoclips for the treatment of peptic ulcer with active hemorrhage.

It is well recognized that about 50% of high risk patients had continuous hemorrhage or rebleeding during hospitalization^[23]. In our cases, hemoclip treatment reduced the rates of rebleeding to 15% in the F1a subgroup and 4% in the F1b subgroup. The ultimate hemostasis rate was 93%. The tangential application of clips is sometimes difficult, which is the same as for other therapeutic endoscopic modalities (e.g. laser or injection therapy). Application of clips should ideally be performed while approaching the bleeding spot *en face*^[22]. In two of our patients who failed to terminate the hemorrhage by using hemoclip treatment, the locations of the ulcers were such that it was difficult to use an *en face* approach.

Dislodging of clips is an another cause of rebleeding. Two of our patients had clips which dislodged, one on the posterior wall of the high gastric body and another on the posterior wall of the duodenal bulb. The locations of the ulcers were difficult to approach when applying the clips. Underlying diseases with bleeding tendency may influence the effect of endoscopic hemostatic procedure^[24]. In one patient with oozing from the site of clipping, the hemorrhage might be related in part to the use of anti-coagulant medications.

In those patients with hemorrhage from the upper gastrointestinal tract, the presence of shock on admission and visible vessel significantly predict rebleeding^[1,25,26]. Hsu *et al* reported that an adherent clot associated with hypovolemic shock had a 50% rebleeding rate. On the contrary, the presence of a clot without hypovolemic shock had a rebleeding rate of only 17%. Non-bleeding visible vessel associated with shock had a 40% rebleeding rate; without shock it decreased to 25%^[7]. The presentation of active hemorrhage, shock on a dmission, and low hemoglobin concentration predict a poor outcome^[23]. In our series, neither the rebleeding rate nor the ultimate hemostatic rate was influenced by the presence of shock. In our study, the F1a with shock subgroup had the highest rebleeding rate of only 20%, which suggests that endoscopic hemoc lippping be a useful and effective

hemostatic method.

Clipping allows clamping of bleeding vessels and achieves mechanical sealing without affecting the ulcer's depth or size. Clips dislodge spontaneously and pass through the gastrointestinal tract safely within 3 weeks^[22]. The damage to surrounding tissue was reported to be limited^[27,28]. In the present study, follow-up endoscopy showed no obvious clip-related tissue injury or impairment of ulcer healing. Our findings confirm that no obvious complications resulted from clip placement.

Both heater probe and injection therapies are widely used. Their hemostatic rates are about 75% to 95%^[1,2,5,29,30]. Our study shows that the hemostatic effect of hemoclips is 93% in peptic ulcers, which is comparable to the above reports. Our data are consistent with those of Takahashi's in which the outcomes of bleeding ulcers did not differ between injection and hemoclippping^[31].

The number of clips required for hemostasis depends on the bleeding activity, endoscopic accessibility of the bleeding site, and the characteristics of the vessel^[9]. Spurting lesions generally require more clips to achieve hemostasis than do oozing lesions. In our series, the average number of clips was higher in the F1a subgroup than in the F1b subgroup. Our results are comparable to the number of Binmoeller *et al*, who used an average of 3.2 clips per case for spurting bleeders and 2.7 clips for oozing bleeders^[9].

In conclusion, endoscopic hemoclip treatment for bleeding peptic ulcer is an effective and safe modality. It has a high initial hemostatic rate (95%) and a low rebleeding rate (8%). Ultimate hemostasis reached 93% in our study with no obvious complications. With the development of newly developed clips and clip application devices, the endoscopic hemoclip treatment has become easier and much more efficient. Endoscopic hemoclip treatment deserves further comparative studies with other hemostatic methods.

Cloning and expression of MXR7 gene in human HCC tissue

Zhou XP, Wang HY, Yang GS, Chen ZJ, Li BA and Wu MC

Subject headings human HCC tissues; MXR7 gene; gene expression; cDNA; mRNA

Abstract

AIM To clone and identify the whole cDNA of MXR7 gene and to find out its expression in human HCC, and normal tissues.

METHODS The DNA primers were designed and synthesized according to the whole cDNA sequence of MXR7 gene. The cDNA of human HCC was taken as the template while the cDNA of MXR7 gene was synthesized by polymerase chain reaction (PCR). Recombinant DNA conforming to reading frame was constructed by connecting purified PCR product of the cDNA of MXR7 gene with expression vector pGEX-5X-1 of fusion protein. The plasmid MXR7/pGEX-5X-1 was identified by sequencing. Using ³²P labeled MXR7 cDNA as probe, MXR7 mRNA expression was detected by Northern blot analysis in 12 different human normal tissues, 7 preoperatively untreated non-liver tumor tissues, 30 preoperatively untreated HCC, the paracancerous liver tissues and 12 normal liver tissues samples.

RESULTS Restriction enzyme and sequence analysis confirmed that the insertion sequence in vector pGEX-5X-1 was the same as the cDNA sequence of MXR7 gene. Northern blot analysis showed no expression of MXR7 mRNA in 12 kinds of normal human tissues including liver, 7 tumor tissues in other sites and 12 normal liver tissues, the frequencies of MXR7 mRNA

expression in HCC and paracancerous liver tissues were 76.6% and 13.3%, respectively. The frequency of MXR7 mRNA expression in HCC without elevation of serum AFP and in HCC <5 cm was 90% (9/10) and 83.3% (5/6), respectively.

CONCLUSION MXR7 mRNA is highly expressed in human HCC, which is specific and occurs at an early stage of HCC, suggesting MXR7 mRNA can be a tumor biomarker for HCC. The detection of MXR7 mRNA expression in the biopsied liver tissue is helpful in discovering early subclinical liver cancer in those with negative serum AFP.

INTRODUCTION

The cloned mitoxantrone-resistant 7 (MXR7) gene contains the whole open reading frame (ORF) screened by differential hybridization from λ complementary DNA expression library, from the mitoxantrone-resistant human gastric carcinoma cell line EPG85-257RNOV and is a full-length cDNA of 2263bp encoding a putative protein of 580 amino acids^[1]. With MXR7 mRNA expression at high level in hepatocellular carcinoma (HCC), its temporospatial expression in human resembles α -fetoprotein (AFP) gene expression^[2]. To probe into and clarify the relation between MXR7 gene and the tumorigenesis and progression and clinical diagnosis of HCC, we analyzed 30 human HCC and the corresponding paracancerous liver tissues, 12 normal liver tissues, 12 different normal tissues and 7 non-liver tumor tissues.

MATERIALS AND METHODS

Specimens

Tissue specimens used in the present study were sampled from 30 preoperatively untreated patients with pathologically confirmed HCC and the non-tumorous liver tissue (2 cm away from the carcinoma), including 28 males and 2 females, aged 21-70 years with a mean of 50.1 years. The controls were normal liver tissues from 12 patients with hepatic hemangioma, 12 different normal tissues from 2 accidental deaths, and 7 preoperatively untreated non-liver tumor tissues. The surgical specimens were immediately cut into small pieces under aseptic condition, snap frozen and stored in liquid nitrogen until use.

Plasmid

Expressing vector pGEX-5X-1 (4.9 kb) of fusion protein was provided by Max-Planck Institute.

Cell

E. coli DH5 α was preserved in our laboratory.

PCR primers design and synthesis

The sequences of the sense and antisense primers of *MXR7* were 5' GCGAATTCTCCTGCGAAGCAGGATG3' with the *EcoRI* (GAATTC) restriction site and 5' CGCTCGAGTCAGTGCACCAGGAAGAA3' with the restriction site *XhoI* (CTCGAG), respectively. The amplifying DNA fragments of above primers were 1774 bp and all primers were synthesized by Shanghai Biochemistry Institute, Chinese Academy of Sciences.

Plasmid construction

The 1774bp fragments of *MXR7* gene were amplified from the cDNA of human HCC by PCR and cloned into the expressing vector pGEX-5X-1. The positive clones selected from the transfected DH5 α were performed as described in the reference^[3]. The constructed plasmids (designated as *MXR7*-pGEX-5X-1) were identified by the restriction enzyme analysis and verified by sequencing.

Preparation and labeling of the probe

The purified PCR product was labeled with ³²P-dCTP as the probe by random primer method as described in the reference^[4] with Prime-a-Gene Labeling System (Promega) and purified with QIAquick Nucleotide Removal Kit Protocol (Qiagen).

Northern blot analysis

RNA extraction Total RNA was extracted using TRIZOL reagent (Gibco, BRL). The RNA from about 1.0 g tissue mass was dissolved in 0.5 mL water pretreated with diethylpyrocarbonate (DEPC) and then stored at -85 °C for use.

Preparation of the hybridization membrane Each 50 μ g denatured total RNA was transferred to nitrocellulose filters (BA85, Schleicher Schuell) by electrophoresis performed on 1% agarose-formaldehyde gels. The filters were dried in a vacuum drying oven at 80 °C for 2 h and then sealed in a plastic bag for use.

Northern blot analysis Northern blotting was performed as described in the reference^[5]. The amount and quality of the loaded RNA samples were evaluated carefully by ethidium bromide-stained 28S and 18S rRNAs, RNA samples with evidence of degradation and blots that fail to hybridize normally expressed genes were discarded.

Statistical treatment

Percentage of the specimens was compared by χ^2 test.

Follow-up

Through phone calls or by mails and re-examination at the outpatient department, we had followed 22 of 30 patients for more than 2 years or until death for further analysis.

RESULTS

Results of cloning and identification

The expected size of the amplified *MXR7* fragment was about 1800 bp. The expected size of the recombinant plasmid *MXR7*/pGEX-5X-1 after enzyme-cut by *EcoR*-I and *Xho*-I was about 4900 bp and 1800 bp, respectively. Sequence analysis of *MXR7*/pGEX-5X-1 confirmed that the insertion sequence of vector pGEX-5X-1 was the same as the translational region sequence of *MXR7* cDNA.

Result of Northern blot analysis

The results of Northern blot analysis were classified into positive and negative.

Expression of *MXR7* mRNA in HCC, normal tissue and tumor of other anatomical sites

Northern blot analysis showed: ① No expression of *MXR7* mRNA on 12 normal liver tissues of patients with hepatic hemangioma, *MXR7* mRNA was detected at low level in only 4 (13.3%) of 30 corresponding paracancerous tissue (all were cirrhosis), all of which had intrahepatic portal vein tumor thrombus and multiple daughter modules. By comparison, the frequency of expression of 2.3kb *MXR7* mRNA at high level was 76.7% (23 of 30 cases) in HCC samples, significantly higher than that with elevated serum AFP $\geq 400 \mu\text{g/L}$ (43.3%, 13 of 30 cases, $P < 0.01$) in this group (Figure 1, Tables 1 and 2). ② *MXR7* mRNA was undetectable in 12 different normal tissues, including liver, lung, kidney, heart, brain, small intestine, colon, testis, spleen, gastric, cyst and pancreas (Figure 2). ③ Among tumors of other anatomical sites including 3 gastric adenocarcinomas, 1 sigmoid adenocarcinoma, 1 malignant mesothelioma, 1 uterine myo-adenoma and 1 familial colonic adenomatosis, *MXR7* mRNA was undetectable too (Figure 3).

Clinicopathological profiles of 30 studied cases with HCC

These included 28 men and 2 women, aged 21-70 years with a mean of 50.1 years. Serum HBsAg was positive in 24 cases (80%). The serum AFP level was above 400 $\mu\text{g/L}$ in 13 (43.3%) and below 30 $\mu\text{g/L}$ in 10 (33.3%). The tumor size was $< 5 \text{ cm}$ (small HCC) in 6 and large in 24 (large

HCC). Histologically, all 30 tumors had invasion (invasive HCC), with portal vein thrombus in 24 (80%) and distant satellite nodule in 17 (56.7%). The differentiation of all tumors were Edmondson III-IV grade.

Figure 1 Northern blot analysis of *MXR7* in human HCC, paracancerous hepatic and normal liver tissues. L: paratumor tissue; K: hepatoma tissue; N: normal liver tissue. 28S and 18S rRNAs were used for evaluating the quality and quantity of RNA loading.

Figure 2 Northern blot analysis of *MXR7* in 12 different human normal tissues. Lane 1: liver; Lane 2: lung; Lane 3: kidney; Lane 4: heart; Lane 5: brain; Lane 6: small intestine; Lane 7: colon; Lane 8: testis; Lane 9: spleen; Lane 10: stomach; Lane 11: cyst; Lane 12: pancreas; HCC as a positive control. 28S and 18S rRNAs were used for evaluating the quality and quantity of RNA loading.

Figure 3 Northern blot analysis of *MXR7* in 7 non-liver tumor tissues. Lane 1: gastric adenocarcinoma; Lane 2: sigmoid adenocarcinoma; Lane 3: gastric adenocarcinoma; Lane 4: left colon-ileal malignant mesothelioma; Lane 5: gastric adenocarcinoma; Lane 6: uterus adenomyoma; Lane 7: colic familial polyadenomatosis; HCC as a positive control. 28S and 18S rRNAs were used for evaluating the quality and quantity of RNA loading.

Table 1 Expression of *MXR7* mRNA in human HCC, and the paracancerous liver and normal liver tissues

Surgical specimen	n	<i>MXR7</i> mRNA overexpression (%)
HCC	30	23(76.7)
Paracancerous tissue	30	4(13.3) ^a
Normal liver	12	0(0.0) ^b

^a $P < 0.005$ ($\chi^2 = 24.31$); ^b $P < 0.005$ ($\chi^2 = 19.32$), vs groups HCC.

Table 2 The correlation of *MXR7* mRNA expression and clinicopathological features in 30 patients with HCC

Clinical feature	n	<i>MXR7</i> mRNA overexpression (%)
Serum AFP ($\mu\text{g/L}$)		
≥ 400	13	10(76.9)
30-400	7	4(57.1)
≤ 30	10	9(90.0)
Tumor size (cm)		
≥ 5	24	18(75.0)
< 5	6	5(83.3)
Portal vein tumor thrombus		
Yes	24	17(70.8)
No	6	6(100.0)
Daughter tumor		
Yes	17	12(70.6)
No	13	11(84.6)
Serum HBsAg		
Yes	24	19(79.2)
No	6	4(66.7)
Age (years)		
≥ 50	16	12(75.0)
< 50	14	11(78.6)

MXR7 mRNA expression in relation to clinicopathological features As shown in Table 2, *MXR7* mRNA expression did not correlate with serum AFP elevation, tumor size, portal vein tumor thrombus, daughter nodules, HBsAg seropositivity and age. The frequency of *MXR7* mRNA expression in HCC was 70% (14 of 20 cases) with elevated serum AFP $> 30 \mu\text{g/L}$, but 90% (9 of 10 cases) with serum AFP $\leq 30 \mu\text{g/L}$. In HCC $< 5\text{cm}$, the frequency (83.3%, 5 of 6 cases) of *MXR7* mRNA expression was higher than that with elevated serum AFP (33.3%, 2/6 cases).

Association between *MXR7* mRNA expression in surgical specimens of HCC and prognosis of the patients In our study, 12 out of 22 patients survived for 2 years postoperatively, 10 of whom had no signs of recurrence nor metastasis, in the other two, there had been one recurrent tumor in the right and left lobes, respectively. The average survival period of the 10 deceased of 22 patients was 8.0 months (2-25 months). The main causes of death were tumor recurrence, portal vein tumor thrombosis and ascites. The survival rates for 1 year and 2 years were 59.1% and 54.5%, respectively. Our data did not show that *MXR7* mRNA expression was correlated with the prognosis of patients.

DISCUSSION

Although an elevated serum AFP level is regarded as a tumor marker for HCC, the frequency of elevated serum AFP in HCC is about 60% up to date, which is much lower in small HCC. The study showed no detectable expression of *MXR7* mRNA in 12 different normal tissues including liver, 7 non-liver tumor tissues and 12 normal liver tissues and the frequencies of *MXR7* mRNA expression in HCC and the corresponding paracancerous cirrhotic tissues were 76.7% and 13.3%, respectively. These findings indicate that *MXR7* mRNA overexpression in HCC is common and specific, suggesting that *MXR7* gene served as a sensitive marker for HCC.

Our observations confirmed only 33.3% (2 of 6 cases) of the patients with small HCC (<5 cm) had an elevated serum AFP level (>30 µg/L), which was lower than that of *MXR7* mRNA overexpression (83.3%, 5 of 6 cases), and the frequency of *MXR7* mRNA overexpression in HCC was 70% (14 of 20 cases) with serum AFP elevation but 90% (9 of 10 cases) without serum AFP elevation, suggesting that *MXR7* gene may be a sensitive early tumor marker for HCC and the detection of *MXR7* mRNA expression in liver biopsied tissues was able to discover small HCCs in the subclinical stage with negative serum AFP.

Four cases of *MXR7* mRNA expression in paracancerous cirrhotic tissues were 1 with two 4cm tumor masses in left-external and right-posterior hepatic lobe and 3 cases with >10 cm tumor masses accompanied by multiple daughter tumors, from which we can presume that retained carcinoma cells in the paracancerous hepatic tissue of the surgical specimens with large tumor mass and tumor invasion may be the cause of *MXR7* mRNA expression in the paracancerous liver tissue, this suggests that detection of *MXR7* mRNA expression in the paracancerous liver tissue can serve as one of indicators whether the tumor is completely resected or not and also as referential value in deciding further treatment.

The cDNA sequence of *MXR7* is 100% homologous to the cDNA of Glypican 3 (GPC3)^[1], which is a developmentally regulated gene localized to chromosome X_q^{26[6]}, GPC3 sequences are very well conserved through evolution, being highly

homologous among mice, rats and human being^[7]. GPC3 is believed to be involved in morphogenesis and growth control during development regulated by cell morphology and cell density at the transcription level^[8].

The familial aggregation and the heredity of susceptibility of the patients with HCC is well documented and the frequency of HCC among males is as about 10 folds that of females. The epidemiology study showed that the effect of heredity on maternal side is much higher than that of paternal one. Clinically, HCC responds poorly to the chemotherapy, which might be correlated with the common overexpression of *MXR7* mRNA in human HCC.

MXR7 mRNA expression is closely related to oncogenesis and progression, the heredity of susceptibility and the poor therapeutic effect of chemotherapy of HCC, but the molecular mechanism remains unclear. The construction of recombinant plasmid *MXR7*/pGEX-5X-1 expressing fusion portion is useful for studying the correlation of *MXR7* and HCC with the structure and function of the gene product.

Recurrence or metastasis of HCC: predictors, early detection and experimental antiangiogenic therapy

Jiang YF, Yang ZH and Hu JQ

Subject headings carcinoma, hepatocellular; neoplasm metastasis; angiogenesis; liver neoplasms

Abstract

AIM To investigate the predictors for recurrence or metastasis of HCC, and to evaluate the effect of antiangiogenic therapy on the growth of transplantable human HCC in nude mice.

METHODS RT-PCR was used to measure the expression of matrix metalloproteinase-9 (MMP-9) and vascular endothelial growth factor (VEGF) in 56 pairs of nontumorous liver and tumor samples. Sixty blood samples from human HCC were examined by nested RT-PCR to find out AFP mRNA. Recombinant human endostatin and polyclonal antibody against VEGF were administered to treat human HCC transplanted in nude mice.

RESULTS Thirty of 56 HCC samples showed stronger expression of MMP-9 in tumorous tissues than in nontumorous tissues. Fifteen of the 26 patients with relative expression level of MMP-9 more than 0.34 developed tumor recurrence or metastasis, whereas only 7 of 30 patients with relative expression level less than 0.34 developed tumor recurrence ($P < 0.05$). There was no significant difference in the relative expression level of VEGF between patients with postoperative recurrence or metastasis and those without recurrence. AFP mRNA was detectable in 53.3% of patients with HCC. The sensitivity and specificity of AFP mRNA as a marker to detect hematogenous dissemination of HCC cells was 81.8% and 84.4%, respectively. Recombinant human

endostatin and polyclonal antibody against VEGF inhibited the growth of transplantable HCC in nude mice by 52.2% and 45.7%, respectively.

CONCLUSION MMP-9 expression in HCC correlates with the postoperative recurrence or metastasis of HCC. Patients with high level of MMP-9 expression in HCC are susceptible to metastasis. AFP mRNA could serve as an indicator of hematogenous spreading of HCC cells in circulation and a predictor of recurrence or metastasis of HCC. Antiangiogenesis may be an adjuvant therapy for HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common cancer in China and in other Asian countries or in south part of Africa. Although some advances have been achieved in the diagnosis and treatment of HCC, the long-term outcome for patients with HCC is still very poor^[1]. The prognosis for HCC depends mainly on the clinico-pathological characteristic regarding invasion and metastasis. The major obstacle to the improvement of the prognosis for HCC is the high incidence of recurrence or metastasis after routine surgical treatment or transcatheter arterial chemoembolization (TACE). Therefore, the following prospective study was designed to investigate molecules responsible for postoperative recurrence of HCC by focusing on matrix metalloproteinase-9 (MMP-9) and vascular endothelial growth factor (VEGF). Furthermore, we also studied the detection of hematogenous spreading of HCC cells at a relatively early stage, and the experimental anti-angiogenic therapy for HCC in an animal model.

MATERIALS AND METHODS

Materials

Tumorous and nontumorous liver samples were obtained from 56 HCC patients who underwent hepatectomy. Peripheral venous blood samples were collected from 60 patients with HCC and 30 subjects as control (10 patients with liver cirrhosis and 20 healthy donors). Recombinant human endostatin and polyclonal antibody against VEGF were used to treat HCC transplanted in nude mice.

Methods

RNA preparation The total tissue RNA was extracted with TRIzol (Life Technologies, Inc. Gaithersburg, USA), precipitated in ethanol and resuspended in sterile RNAase-free water for storage at -70 °C.

Reverse transcription Moloney murine leukemia virus reverse transcriptase (M-MLV RT) was used to synthesize a complementary DNA strand in the presence of random primer from 6 µg single stranded RNA.

PCR amplification Primer sequences. Sense primer for VEGF: 5'-TTGCTGCTCTACCTCCAC-3'. Antisense primer for VEGF: 5'-AATGCTTTCTC-CGCTCTG-3'. Sense primer for MMP-9: 5'-CG-GAGCAGGAGACGGGTAT-3'. Antisense primer for MMP-9: 5'-TGAAGGGGAAGACG-CACGCACAGC-3'. Sense primer for internal control of β_2 -MG: 5'ACCC CCACTGAAAAAGATGA-3'. Antisense primer for β_2 -MG: 5'-ATCTTCAAACCTCCATGATG-3'. All primers were synthesized by Shanghai Sangon Biotec hunique Company. PCR reaction: the 25 µL of PCR mixture contained 2 µL of the synthesized cDNA solution, 2.5 µL of 10× polymerase reaction buffer, 1.5 mM MgCl₂, 200 µM-each of dCTP, dATP, dGTP, dTTP, 10 pmol of each primer (sense and antisense); and 1 unit of Taq DNA polymerase. The PCR mixture for VEGF was subjected to 40 cycles PCR amplification using protocol TOUCHDOWN in PTC 100 programmable thermal cycler (MJ Research, USA). Cycle conditions for amplifying MMP 9 included a 94 °C denaturation (30 s, first cycle 1 min), a 60 °C annealing (30 s), and a 72 °C extension (60 s). After the final cycle, tubes were placed at the extension temperature for 5 min.

Assay of PCR production A volume of 7 µL PCR products was added in 1.5% agarose gel containing 0.5 µg/mL EB, after electrophoresis, the gel was placed under ultraviolet ray to analyze the results. The density and area of each band were measured using Image Master VDS software (Pharmacia, Sweden). The relative mRNA level of VEGF of MMP-9 gene in tumor or nontumorous tissues was calculated using the house-keeping gene β_2 -MG as an internal control.

Nested RT-PCR amplifying human AFP A 5-mL heparinized blood sample from each patient was taken for AFP mRNA determination. Cell pellets were obtained from heparinized blood samples. The total RNA was extracted with TRIzol and resuspended in RNAase-free water. Reverse transcription was performed using random primers

and PCR using specific AFP primers. β_2 -microglobulin mRNA was co-amplified during the RT-PCR test as an internal control. The 25 µL of first PCR mixture containing external sense and antisense primer for AFP were subjected to 40 cycles PCR amplification using protocol TOUCHDOWN in PTC-100 programmable thermal cycler (MJ Research, USA). A volume of 8 µL PCR products was added in 2% agarose gel for electrophoresis. If no specific band of 176 base pairs was observable, 2 µL PCR product was reamplified with internal primers. The final product was electrophoresed on 2% agarose gel for the specific band of 101 base pairs.

Experimental antiangiogenic therapy of HCC

Preparation of recombinant human endostatin. The human endostatin cDNA which encoded 184 amino-acids was cloned from human fetal liver. The recombinant human endostatin was expressed in a prokaryotic system. The recombinant endostatin underwent denaturation in 8 mol/L urea and was refolded in Sephadex G-100 column.

The polyclonal antibody against human VEGF was prepared in our lab. Briefly, the recombinant human VEGF165 was expressed in a prokaryotic system, which was administered as antigen to stimulate the production of antibody against VEGF in rabbits. The antiserum was purified using affinity chromatography column of Sepharose CL-4B-VEGF.

RESULTS

Postoperative recurrence or metastasis of HCC patients

In the total of 56 HCC patients, 22 (39.3%) had relapsed within 20 months after operation. Fifty percent of the recurrence occurred within 6 months after operation. Tumor recurrence had no significant correlation with tumor size or degree of pathological differentiation ($P>0.05$, Table 1).

Table 1 Relationship between clinicopathological characteristics and recurrence or metastasis of HCC

Parameter	n	Recurrence of metastasis	
		Yes	No
Tumor size (cm)			
≤5 cm	29	10	19
>5 cm	27	12	15
Liver cirrhosis			
Absent	8	3	5
Present	48	19	29
Tumor differentiation			
Well	12	4	8
Moderate	23	8	15
Poor	9	5	4
Not determined	12	5	7
Clinical staging			
Stage I	2	1	1
Stage II	33	10	23
Stage III	18	8	10
Stage IV	3	3	0

MMP-9 expression in HCC correlated with tumor recurrence

In 35 of the 56 HCC samples, transcripts of MMP-9 were detected, 27 of 35 these samples showed significant elevation of MMP-9 expression (> 2 fold) compared with nontumorous liver tissues. Among the 30 patients with a relative expression level of MMP-9 in HCC less than 0.34, only 7 cases developed tumor recurrence, whereas 15 of the 26 patients with relative expression level of MMP-9 more than 0.34 had developed tumor recurrence or metastasis. Moreover, among the 22 HCC patients who suffered from postoperative recurrence or metastasis, 16(88.8 %) tumors (T) had significantly elevated level of MMP-9 expression compared with nontumorous liver tissues (N) ($T/N > 2$), while only 11(32.3%) of 34 HCC patients who had not yet relapsed had significantly increased level of MMP-9 expression in HCC. Patients with high level of MMP-9 expression in HCC were susceptible to tumor recurrence or metastasis.

VEGF expression in HCC not correlated with tumor recurrence

Transcripts for VEGF were detected in 48 of 56 HCC samples and in 36 of 53 nontumorous liver tissues. The level of VEGF expression was elevated significantly in 52% HCC samples compared to nontumorous liver tissues (Figure 1). The level of VEGF expression in HCC was not correlated with tumor size or the degree of pathological differentiation. Among the 25 patients with significantly elevated level of VEGF expression in HCC, 12 cases (48%) had tumor recurrence, whereas 10 of 31 patients with similar or decreased level of VEGF expression had tumor recurrence.

AFP mRNA in peripheral venous blood from clinical samples

The frequency of positive cases in 60 patients with HCC was 53.3% (32/60) (Figure 2). The frequency of AFP mRNA positivity in patients with liver cirrhosis and in healthy donors was 10% and 5%, respectively.

Relationship between AFP mRNA expression and intra or extra-hepatic metastasis

In 32 patients with detectable AFP mRNA in peripheral blood, 27 patients (84.4%) were accompanied with metastasis. Of the 11 patients with detectable AFP mRNA in peripheral blood but without metastasis at collected samples, 6 cases developed metastasis or tumor recurrence later. Six or 28 patients without detectable AFP mRNA developed metastasis. Serum AFP level was not correlated with cancer metastasis or recurrence.

Figure 1 Electrophoresis analysis of RT-PCR product sampled from cDNA obtained from HCC and nontumorous liver tissues. M, DNA marker (PGEM-7ZF(+)/Hae-III); T, tumor; N, nontumorous liver tissues. The positive bands of 417bp, 490 bp, and 121 bp represent VEGF165, VEGF189, and β_2 -MG, respectively.

Figure 2 Electrophoresis analysis of RT-PCR products from cDNA obtained from peripheral venous blood of patients with HCC. M, DNA marker (PGEM-7ZF(+)/Hae-III). Lane 1, lane 3, and lane 4 showed positive bands for AFP (176bp). All lanes showed positive bands for β_2 -MG (121bp).

Relationship between AFP mRNA expression and therapy

Of 60 patients with HCC, 14 cases underwent surgical treatment, 35 received transcatheter arterial chemoembolization (TACE). Fifteen of 33 samples collected before operation or TACE showed detectable AFP mRNA in peripheral venous blood. Twenty-one of 35 samples collected after therapy had detectable AFP mRNA ($P > 0.05$).

Recombinant human endostatin and polyclonal antibody against VEGF inhibited the growth of HCC

We used *E. coli*-derived human endostatin to study the effect of endostatin therapy on primary liver cancers. BEL-7402 hepatocellular carcinoma was implanted into nude mice. The refolded protein of recombinant endostatin was administered to the

mice via peritoneal injection once daily. The growth of primary tumors was inhibited by 52.2% at a dose of 7.5 mg/kg as compared with control mice treated with saline alone. The effect of polyclonal antibody against VEGF on the growth of primary liver cancers was also studied. The polyclonal antibody against VEGF was administered to the mice via peritoneal cavity injection at a dose of 10 mg/kg once daily. The growth of primary tumors was inhibited by 45.7%.

DISCUSSION

The long-term outcome of patients with HCC is still very poor. The major obstacle to the improvement of prognosis for HCC patients is the high incidence of postoperative recurrence or metastasis. The five year recurrence rate in liver cancers is as high as 40%-70%^[2]. Therefore, it is very important to investigate the molecular changes that correlate with recurrence or metastasis of HCC, which is useful to screen HCC patients with high risk of recurrence. Furthermore, the early detection of hematogenous spreading of HCC cells or recurrent lesions and the effective management of recurrent lesions are also important steps to improve the therapeutic effects. We performed a series of study on the recurrence or metastasis of HCC by focusing on some key steps mentioned above.

Metastasis is the spread of cancer from a primary tumor to distant sites of the body and is a defining feature of cancer. Escape of cells from the primary tumor, intravasation and extravasation are some necessary steps in the process of cancer metastasis^[3]. There are a series of collagen containing structural barriers that cancer cells must pass in all steps mentioned above. MMPs are a family of secreted or transmembrane proteins that are capable of digesting extra cellular matrix and basement membrane. MMP-9 is believed to be capable of degrading type IV collagen, which is a major constituent of basement membrane^[4]. Highly invasive tumor cells then, would be expected to secrete large amounts of proteolytic enzyme. The results presented here indicated that MMP-9 mRNA was expressed more frequently in HCC tissues than in corresponding nontumorous ones, and that the degree of MMP-9 mRNA expression in tumors was elevated in 30 of 38 samples with transcripts for MMP-9 compared with corresponding nontumorous tissues. With regard to the correlation of MMP-9 mRNA and tumor recurrence or metastasis, the tumors with high level of MMP-9 expression were more susceptible to relapse or metastasis than those with low level of MMP-9 expression. These results revealed that MMP-9 is an important molecule which participates in the invasion of HCC. MMP-9 expression in HCC is of prognostic significance.

MMP-9 can also serve as a potential target for prevention and treatment of tumor recurrence or metastasis.

Angiogenesis, the recruitment of new blood vessels, is required for the primary and metastatic tumors to grow beyond minimal size^[5]. Vascular endothelial growth factor (VEGF) is an important factor which can promote the proliferation of endothelial cells and the development of new blood vessels^[6]. In the present study, we investigated the expression of VEGF mRNA in HCC, we also examined the correlation between VEGF mRNA expression and the recurrence or metastasis of HCC. We found that VEGF mRNA was expressed in most of HCC specimens and nontumorous liver tissues (87.3% vs 67.9%). Fifty-two percent HCC specimens exhibited stronger expression of VEGF mRNA in tumorous tissues than in nontumorous ones. No apparent correlation was observed between VEGF expression and tumor size or the grading of tumor differentiation. There was also no significant correlation between VEGF mRNA expression level and tumor metastasis. In addition, the growth of HCC could be inhibited by antibody against VEGF. All these data indicated that VEGF may be involved in the growth of HCC, however, the level of VEGF mRNA expression cannot reflect the potential metastasis of HCC, namely, even if VEGF expression is not strong in HCC, tumor recurrence or metastasis may also occur.

Escape of cells from primary tumor into blood circulation is an indispensable step in the process of blood borne metastasis. The detection of tumor cells in peripheral blood by means of RT-PCR is a very attractive hypothesis^[7]. Theoretically, the test could be useful in assessment of prognosis and in predicting the increased probability of metastases. We choose the RT-PCR mRNA AFP as an indicator of liver cells to determine the clinical relevance of the test. Thirty-two of sixty HCC patients involved in this study has positive AFP mRNA test result. One tenth patients with liver cirrhosis and 1/20 healthy donors had positive AFP mRNA in peripheral blood. These data suggested that AFP mRNA in peripheral blood is a sensitive marker of presence of HCC cells in circulation, although false positive results may appear occasionally. The frequency of positive cases in patients with metastases was significantly higher than that in patients without occult metastases at collected samples (93.9% vs 29.7%), which indicated that the presence of AFP mRNA in peripheral blood correlated with metastasis of HCC. Six of 11 patients who were AFP mRNA-positive and metastasis-free at collected samples had clinically evident recurrence or metastasis later. Among 26 negative AFP mRNA, metastasis-free patients, 22

patients remained recurrence-free during the period observed. These data suggest that the detection of AFP mRNA in peripheral blood by means of RT-PCR was useful in predicting the increased probability of metastases, and in identifying a subpopulation of patients with HCC who are at high risk of recurrence. With no significant difference in AFP mRNA expression before and after surgical treatment or TACE, local treatment is insufficient to prevent tumor recurrence. For patients with tumor cells in circulation, more vigilant follow-up or more aggressive management, such as immunotherapy or systemic chemotherapy, should be made.

The effect of conventional chemotherapy on preventing cancer metastasis is not satisfactory mainly due to the multi-drug resistance^[8]. Therefore, it is highly necessary to search for new modalities in treatment of cancer metastasis. It is well known that the development of a tumor requires oxygen and nutrients, which are supplied through neovascularization. Therefore, antiangiogenesis and the suppression of the development of neovascularization may offer a novel strategy in overcoming the development and the metastasis of solid tumors^[9]. VEGF can promote the development of neovascularization, the antibody against VEGF may inhibit angiogenesis and consequently suppress the growth of tumor. We found that polyclonal antibody can inhibit the growth of human HCC transplanted in nude mice by 45.7%, but not inhibit the growth of tumor thoroughly possibly due to the fact that VEGF was not the only growth factor in the development of neovascularization. Endostatin is an endothelial-specific negative regulator of angiogenesis, previous report suggested that it inhibit the growth of some types of tumor in animal model^[10]. We found that the recombinant human endostatin inhibited the growth of human HCC by 52.2%. In addition, both endostatin and antibody against VEGF could

inhibit the lung metastasis of murine breast cancer dramatically in an animal model by 68.9% and 71.4%, respectively. It was also reported that antibody against VEGF could inhibit the experimental liver metastasis of human colon cancer in a mouse model^[11]. These data suggest that endostatin and antibody against VEGF are useful in prevention or treatment of tumor recurrence or metastasis of HCC. It warrants further research to investigate whether antiangiogenic therapy combined with routine chemotherapy or radiotherapy can improve the effect of treatment dramatically.

Expression of gap junction genes connexin 32, connexin 43 and their proteins in hepatocellular carcinoma and normal liver tissues

Ma XD, Sui YF and Wang WL

Subject headings connexin; gap junction; liver neoplasm; immunohistochemistry; *in situ* hybridization; carcinoma, hepatocellular; gene expression

Abstract

AIM To investigate the significance and mechanism of cx-32 mRNA, cx-43 mRNA and their proteins in hepatocarcinogenesis.

METHODS Sixty-one cases of HCC and 14 cases of normal liver tissues were detected by immunohistochemical and *in situ* hybridization (ISH) methods.

RESULTS In HCC grades I, II, III and normal liver tissues, the positive rates of Cx32 protein were 55.6%, 42.1%, 18.2% and 92.9%, respectively. The detection rates of Cx43 protein were 44%, 26.3%, 12.1% and 78.6%, respectively. There was significant difference in Cx32 and Cx43 protein between HCC and normal liver tissues ($P < 0.01$). ISH the positive rates of cx 32 mRNA shown by ISH in HCC grades I, II, III and normal liver tissues were 88.9%, 84.2%, 87.9% and 92.9%, respectively. Those of cx43 mRNA were 77.8%, 78.6%, 78.8% and 85.7%, respectively. There was no statistical difference in the positive rates of cx32 mRNA and cx43 mRNA between HCC and normal liver tissue ($P > 0.05$).

CONCLUSION The aberrant location of Cx32 and Cx43 proteins could be responsible for progression of hepatocarcinogenesis, and the defect of cx genes in post-translational processing might be the possible mechanism.

INTRODUCTION

Gap junctions are clusters of intercytoplasmic channels connecting neighboring cells which are composed of proteins called connexins (cx). Gap junction intercellular communication (GJIC) mediated by gap junction channels has been believed to be an important mechanism for the maintenance of tissues homeostasis and metabolic cooperation^[1]. Carcinogenesis is one of the pathological processes in which disorders of GJIC may play an important role^[2]. This study was designed to investigate the significance and mechanism of cx32 and cx43 genes and their proteins in hepatocellular carcinoma (HCC).

MATERIALS AND METHODS

Clinical data

The specimens of surgically removed 61 cases of HCC and 14 cases of normal liver tissues were collected at Xijing Hospital during the period of 1996-1998. The samples had not been treated with chemotherapy or radiotherapy before tumor excision. The pathological diagnosis was verified on the respective paraffin embedded material by histologic examination (HE). The specimens were derived from 9 cases of grade I HCC, 19 of grade II and 33 of grade III, and these were 4 μ m thick sections.

SP immunocytochemistry

SP immunostaining was performed as described by SP immunocytochemistry kit and DAB kit with mouse anti-cx32 mAb, mouse anti-cx43 mAb of Zymed Lab. Inc., USA. Diagnosis was made by brown or yellow coloration with varied intensities. Negative (-): stained cells < 5%, positive (+): stained cells 5%-50%, strongly positive (++) : stained cells > 50%.

Probe labeling

pGEM3-cx32 and pSG5-cx43 plasmids were kindly given by Prof. Gui Yuan Li in Hunan Medical University. After amplification, isolation and purification were done, pGEM3-cx32 plasmid was digested by Ecor-I (Gibco BRL, USA) and pSG5-cx43 by BamH-I (Gibco BRL, USA). Electroporate the digested plasmids on 7 g/L

agarose gel with λ DNA/Hind-III+-EcoR-I marker. Extract and purify the cx32 cDNA and cx43 cDNA from the gel as the protocol of Advantage™ PCR-Pure Kit from Clontech Lab. Inc., USA. Label the cx32 cDNA and cx43 cDNA using Dig DNA Labeling and detection kit of Boehringer Mannheim, Germany.

mRNA in situ hybridization

Slides were incubated in 0.2 mL/L DEPC at RT for 10 min, in 0.2 mL /L HCl for 10 min and in 5 mg/L PK at 37 °C for 10 min and in 0.1 mol/L glycine to stop the digestion reaction, and then fixed in 40 g/L PFA for 10 min in sequence. After being washed in PBS, the sections were dehydrated in ethanol and air dried. Prehybridized at 42 °C for 30 min, the labeled cDNA probes were denatured in hybridization buffer at 100 °C for 10 min, then -20 °C for 3 min, added on tissues and coverslipped at 42 °C overnight. Sections were washed with 2×SSC, 1×SSC, 0.5×SSC and buffer I, incubated in NSS at 37 °C for 30 min, and then Dig-Ap (1:500) for 2 h, and finally detected with NBT/ BCIP of Dig DNA labeling and detection kit. Diagnosis was made by blue colorat ion with varied intensities and compared with control sections. All results were analyzed by χ^2 test.

RESULTS

SP Immunochemical results

Cx32 and Cx43 proteins appeared as numerous individual spots intracytoplasmically (Figures 1,2), and in some as parts of the plasma membrane. There was fairly intense immunoreactivity in nearly all of the 14 normal liver samples (Cx32 13/14, 92.9%, Cx43 11/14, 78.6%).

In contrast, a clear difference was noted between that in normal tissue and in the HCC, the Cx32 and Cx43 positive spots decreased in the latter especially in grade III HCC, only 18.2% (Cx32) and 12.1% (Cx43) specimens exhibited very weak stainings. The expression of Cx32 and Cx43 proteins in normal liver tissue and I, II and III HCC grades were significantly different ($P<0.01$) (Table 1).

mRNA in situ hybridization results

After restriction digestion, 1.5 kb cx32 cDNA probe was obtained from pGEM3 -cx32 plasmid (Figure 3), and 1.11 kb cx43 cDNA probe from pSG5- cx43 plasmid (Figure 4).

Bright blue specific hybridization appearanc of cx32 mRNA and cx43 mRNA were observed intracytoplasmically in normal liver or HCC tissues (Figures 5-8). The detection rates of cx32 mRNA and cx43 mRNA in normal liver an dI, II and III HCC grades tissues were not significantly different ($P>0.05$).

Table 1 Positive rates of Cx32 and Cx43 proteins in HCC and normal liver

Group	n	Cx32			Cx43		
		+	++	%	+	++	%
HCCI	9	2	3	55.6 ^a	2	2	44.4 ^a
HCCII	19	6	2	42.1 ^a	3	2	26.3 ^a
HCCIII	33	5	1	18.2 ^a	4	0	12.1
Normal liver	14	4	9	92.9	4	7	78.6

^a $P<0.01$ vs normal liver.

DISCUSSION

Since the first cloning of *cx* gene in 1986, there have been rapid progress in identifying and characterizing a multigene family (including at least 13 members) which codes the gap junction proteins^[3]. The cloning sequence of cDNA shows that there is a highly homogenic and strict gene structure among these family members.

The expressions of *cx* genes in different tissues are specific. GJIC plays an important role in the rapid progress of cell society. Gap junctions contain channels that connect contacting cells, and have an apparent selectivity based principally on molecular size, allowing the movement of molecules smaller than M_r1000 , such as cAMP, but preventing the movement of proteins or nucleic acids.

Gap junction mediated GJIC has been postulated to be an important mechanism to maintain tissue homeostasis and to control growth and differentiation. The decreased level of GJIC has been found in many kinds of tumor cells, and this can be important in neoplastic progression by allowing tumor cells to escape local control mechanisms^[4].

Cx32 is widely expressed in many tissues, especially in normal liver, Cx43 is also involved in the gap junctional pathway in liver. This study revealed that Cx32 protein and Cx43 protein expressed at a high level in normal liver and even in pericancerous liver tissues, but at a decreased level in HCC tissues. The lack of Cx32 and Cx43 proteins reduced the number of GJIC between HCC cells and surrounding non-tumorous cells, finally resulting in progression of hepatocarcinogenesis.

In some studies, Cx43 protein was not detectable in normal liver, but could be found in HCC cells. These results suggested that certain tumors or transformed cells have normal levels of gap junction or GJIC and lack of functional gap junctions is not a general feature of malignancy^[5], the exact mechanisms remain to be elucidated.

Because there was no decrease in levels of *cx32* mRNA and *cx43* mRNA in HCC and normal liver tissues, the aberrant localization of Cx32 and Cx43 might be responsible for the reduced GJIC in HCC^[6]. It appears that the control mechanisms of *cx32* and *cx43* genes transcription are not affected during human liver tumorigenesis.

Figure 8 cx43 mRNA is positive in HCC. ISH×400

Not any mutation in the coding sequence of cx genes from any of the human tumors has been found. It is likely that the aberrant location of Cx32 and Cx43 in HCC cells is due to disruption of the mechanisms for construction of these proteins into gap junction plaques rather than to structural abnormality of the Cx32 and Cx43 themselves. The possibility is that there is defect in post-translational processing of Cx32 and Cx43 proteins, which may be essential for their transport to membrane. Post-translational phosphorylation^[7] may be the important factors controlling the GJIC mediated by Cx32 and Cx43 in HCC, it is also responsible for the assembly or function of these proteins.

In conclusion, the aberrant localization of Cx32 and Cx43 proteins in HCC is noteworthy, which has direct biological significance in the process of hepatocarcinogenesis. Recent results demonstrate that the cx gene family is a class of non-mutant tumor-suppressive gene^[8], it should be regarded as an effectual marker of early diagnosis or treatment for liver cancer.

TT viral infection through blood transfusion: retrospective investigation on patients in a prospective study of post-transfusion hepatitis

Yang SS, Wu CH, Chen TH, Huang YY and Huang CS

Subject headings blood transfusion; TT viral infection; hepatitis C; antibody, viral

Abstract

AIM To investigate the role of blood transfusion in TT viral infection (TTV).

METHODS We retrospectively studied serum samples from 192 transfusion recipients who underwent cardiovascular surgery and blood transfusion between July 1991 and June 1992. All patients had a follow-up every other week for at least 6 months after transfusion. Eighty recipients received blood before screening donors for hepatitis C antibody (anti-HCV), and 112 recipients received screened blood. Recipients with alanine aminotransferase level >2.5 times the upper normal limit were tested for serological markers for viral hepatitis A, B, C, G, Epstein Barr virus and cytomegalovirus. TTV infection was defined by the positivity for serum TTV DNA using the polymerase chain reaction method.

RESULTS Eleven and three patients, who received anti-HCV unscreened and screened blood, respectively, had serum ALT levels >90IU/L. Five patients (HCV and TTV:1; HCV, HGV, and TTV:1; TTV:2; and CMV and TTV:1) were positive for TTV DNA, and four of them had sero-conversion of TTV DNA.

CONCLUSION TTV can be transmitted via blood transfusion. Two recipients infected by TTV alone may be associated with the hepatitis. However, whether TTV was the causal agent remains unsettled, and further studies are necessary to define the role of TTV infection in chronic hepatitis.

INTRODUCTION

After hepatitis B screening in blood donors, the addition of antibody against hepatitis C virus (anti-HCV) has further reduced the occurrence of post-transfusion hepatitis dramatically^[1,2]. However, there still exists some post-transfusion hepatitis, that may be caused by cytomegalovirus (CMV) and other viruses. Among them hepatitis G virus (HGV) infections once had been considered^[1,3,4]. In 1997, a novel virus named TT virus (TTV) was reported by Japan^[5], and the virus is known to be an unenveloped, single-stranded DNA virus with a sequence of 3739 bases. The virus can transmit through blood transfusion^[5]. In Japan, 12% of blood donors and 46% of chronic non-A-G hepatitis patients have detectable TTV DNA in their serum^[6]. Taiwan is an area prevalent for viral hepatitis^[7,8], and the role of TTV has not documented. We therefore studied the role of TTV infection in those patients who received blood transfusions, using serum samples in a previous prospective study of post-transfusion hepatitis.

MATERIALS AND METHODS

We retrospectively studied stored serum samples, which were collected in a prior prospective study for post-transfusion HCV infection^[1] for TTV infection. These serum samples were collected from 192 blood recipients who underwent cardiovascular surgery at the Cathay General Hospital, Taipei, Taiwan from July 1991 to June 1992, before universal screening of blood donors for anti-HCV that was implemented in July 1992. All serum samples were stored at -70 °C. Among them, 19 recipients were healthy hepatitis B surface antigen (HBsAg) carriers with serum alanine aminotransferase levels (ALT) <45IU/L. No recipient had had a blood transfusion within 12 months before recruitment. Recipients already positive for anti-HCV before transfusion, and those having alcoholic, drug-related, autoimmune, or ischemic hepatitis were excluded.

Eighty and 112 recipients received anti-HCV unscreened and screened blood, respectively. For anti-HCV screening in the study, a second-generation enzyme immunoassay (EIA-III, UBI HCV EIA, United Biomedical, Inc., New York,

NY) was used. All recipients were tested for serum ALT levels and anti-HCV to exclude the presence of possible viral hepatitis C before transfusion. After transfusion, all patients had a follow-up every other week until 6 months after transfusion, and blood samples were also collected.

Recipients with two successive ALT > 2.5 times the normal upper limit were tested for serologic markers for viral hepatitis A, B, C, E, G, TTV, Epstein-Barr virus (EBV), and CMV as well as antinuclear antibodies. Acute viral hepatitis A, B, and E were defined if the recipients were positive for immunoglobulin M antibodies to hepatitis A virus (IgM anti-HAV; HAVAB-M EIA, Abbott Lab., Abbott Park, IL), hepatitis B core antigen [IgM anti-HBc; Corzyme-M (rDNA) Abbott Lab.], and hepatitis E virus (IgM anti HEV; HEV IgM ELISA, Genelabs Diagnostics PTE Ltd, Singapore Science Park, Singapore). Sero-conversion of anti-HCV using the EIA method and/or HCV ribonucleic acid (HCV RNA) using reverse transcription-nested polymerase chain reaction (RT-PCR) assay with primers derived from the 5'-untranslated region of HCV genome was used to define acute viral hepatitis C^[9]. A titer of $\geq 1:64$ for IgM antibodies to Epstein-Barr virus (IgM anti-EBV, IP Azyme, EB/VCA IgM, Savyon Diagnostic Ltd., Beer Sheva, Israel) and CMV (IgM anti-CMV, IP Azyme CMV IgM, Savyon Diagnostic Ltd.) using the immunoperoxidase assay were defined as having acute EBV and CMV hepatitis. Sera were tested for antinuclear antibodies using the immuno-fluorescent method (Fluoro HEPANA, Medical & Biological Lab., Nagoya, Japan).

Patients with positive HBsAg (Auszyme, Abbott Lab.) were also tested for hepatitis Be antigen [HBeAg; HBe (rDNA) EIA, Abbott Lab.] and antibody to hepatitis delta virus (anti-HDV; Wellcozyme, Wellcome Diagnostics, England) using the EIA method.

The occurrence of sero-conversion of GBV-C/HGV RNA was defined as acute HGV infection. The GBV-C/HGV RNA was identified with RT-PCR using nested primers from the 5'-untranslated region of the viral genome as previously described^[10].

The diagnosis of acute TTV infection was based on the occurrence of sero-conversion of TTV DNA determined using PCR method with semi-nested primers as previously described^[6,11]. Briefly, DNA was extracted from 100 μ L of serum using QIAMP Blood kit (QIAGEN Ltd., Crawley, UK) and re-suspended in 50 μ L of elution buffer. For the first round of PCR, 25 μ L of reaction mixture containing 2 μ L of the cDNA sample, 1 \times PCR buffer (10 mM tris-HCl pH 9.0, 50 mM KCl, 1.5 mM MgCl₂,

0.01% gelatin, and 0.1% Triton X-100), 10 mM of each dNTP, 100ng of each outer primer T-1 (sense: ACA GAC AGA GGA GAA GGC AAC ATG -3') and T-2 (anti-sense: 5'-CTA CCT CCT GGC ATT TTA CC-3'), and 1 unit of Taq DNA polymerase was amplified in a thermal cycler (Perkin-Elmer Cetus, Norwalk, CT) for 30 cycles. On a microliter of the PCR products was re-amplified for another 30 cycles with 100 ng of inner primers, T-3 (sense: 5'-GGC AAC ATG TTA TGG ATA GAC TGG-3') and T-4 (anti-sense: CTG GCA TTT TAC CAT TTC CAA AGT T-3'). The amplified products were separated by 3% agarose gel electrophoresis and stained with ethidium bromide.

Statistical analysis was performed using Student's *t* test, Yates' corrected Chi-square, and one-tailed Fisher's exact test where appropriate.

RESULTS

In the 80 and 112 recipients who received anti-HCV unscreened and screened blood, respectively, the gender (male/female = 43/37 vs 66/46, $P = 0.48$), age [mean \pm SD, (range)] = 44 \pm 20 years (4-76 years) vs 45 \pm 22 years (4-75 years, $P = 0.52$), number of HBsAg carriers (9 vs 10, $P = 0.60$), and volume of blood transfused [mean \pm SD, (range)] = 18.0 \pm 14.9 units (2-67 units) vs 18.8 \pm 12.7 units (1-70 units), $P = 0.58$ were not significantly different between the two groups. Eleven (13.8%) and three (2.7%, $P = 0.004$) subjects who received unscreened and screened blood had serum ALT levels >90 IU/L, respectively (Table 1). Among them, four (36.4%) and one (33.3%, $P = 0.72$) patients were positive for TTV DNA, respectively.

#Positive for TTV DNA before transfusion.

One patient (CSG) who received unscreened blood was positive for TTV DNA before transfusion (Figure 1). His maximum serum ALT level was 159 IU/L, and maximum serum total bilirubin level was 18.8 $\mu\text{mol/L}$. He was negative for any markers of active hepatitis A-G.

The remaining four subjects had a sero-conversion of TTV DNA. Only one (LYY) of them was negative for markers of hepatitis A-G, and her abnormal serum ALT level and TTV DNA were detected in the 3rd and 6th weeks after transfusion, respectively (Figure 2). Her maximum serum ALT level was 103 IU/L, and maximum serum total bilirubin level was 8.6 $\mu\text{mol/L}$. Two other patients (CSG, LYY) had abnormal serum ALT levels and positivity for TTV DNA until 6 months after transfusion.

The remaining three patients all had a co-infection with other types of hepatitis. All three patients had a transient appearance of TTV DNA lasting only 2 weeks. The first patient (PTT) had HCV and TTV co-infections. His HCV RNA, TTV DNA, abnormal serum ALT activity, and anti-HCV were detected at the 12th, 12th, 18th, and 18th weeks, respectively. His maximum serum ALT level was 109 IU/L, and maximum serum total bilirubin level was 13.7 $\mu\text{mol/L}$. He continued to have abnormal liver tests and positivity for HCV RNA until 27 weeks after transfusion when he finished the follow-up.

The second patient (STS) had HCV, HGV, and TTV co-infection (Figure 3). His HCV RNA, abnormal serum ALT level, anti-HCV, HGV RNA, and TTV DNA were detected at the 2nd, 2nd, 8th, 8th, and 12th weeks after transfusion, respectively. His maximum serum ALT level was 455 IU/L, and maximum serum total bilirubin level was 1.5 mg/dL. His HGV RNA lasted for 24 weeks, and his HCV RNA and abnormal serum ALT levels remained until 37 months after transfusion when he expired from congestive heart failure.

The third patient (CPL) had CMV and TTV co-infection (Figure 4). Her abnormal serum ALT level and IgM and immunoglobulin G (IgG) anti-CMV and TTV DNA were detected at the 2nd, 3rd, and 6th weeks after transfusion, respectively. Her maximum serum ALT level was 645 IU/L, and maximum serum total bilirubin level was 6.8 mg/dL. Her IgM anti-CMV lasted 4 months, and IgG anti-CMV lasted 38 months. Her serum ALT levels returned to normal at the 13th month after transfusion.

None of our patients with post-transfusion hepatitis developed fulminant hepatic failure. Of the five patients with TTV infection, only one patient (CPL), who was co-infected with CMV hepatitis, developed jaundice clinically.

Figure 1 A 64-year-old man who received unscreened blood was positive for TTV DNA before and after transfusion.

Figure 2 A 13-year-old girl who received unscreened blood had sero-conversion of TTV DNA after transfusion.

Figure 3 A 60-year-old man who received unscreened blood had sero-conversion of TTV DNA after transfusion. He was co-infected with viral hepatitis C and G.

Figure 4 A 65-year-old woman who received anti-HCV screened blood had sero-conversion of TTV DNA after transfusion. She was co-infected with cytomegalovirus infection.

DISCUSSION

In the present study, four patients experienced sero-conversion of TTV DNA after receiving blood unscreened or screened for anti-HCV. Our findings are consistent with recent studies that TTV infection can be transmitted through blood transfusion^[6,12-14]. Although the screening of blood donors with anti-HCV had dramatically reduced the post-transfusion hepatitis from 13.8% to 2.7%, one recipient who received anti-HCV-screened blood developed post-transfusion TTV infection. Our data also showed that the rate of TTV infection is not different between patients who received unscreened and screened blood. Therefore, anti-HCV screening in donor blood does not seem to affect the rate of TTV infection.

Three of our patients had co-infection of TTV infection and other types of hepatitis, and the appearance of serum TTV DNA was only transient. Although all three patients had abnormal serum ALT levels lasting more than 6 months, their chronic hepatitis was not necessarily related with TTV infection. In Japan, the prevalence of TTV infection was 12% in blood donors and was 46% in chronic hepatitis and/or cirrhosis sufferers^[6]. The prevalence of TTV infection in Taiwan was 10% in healthy adults and was 15%-36% in those with chronic hepatitis B or C^[11], findings similar to those in Japan^[6,14]. These findings indicate that TTV infection is common in East Asia. But, the rate of TTV-related post transfusion hepatitis in the present study was only 2.1%. The relative low prevalence of TTV-related post-transfusion suggests that most TTV infections are mild beyond detection clinically. This is further supported by only one patient with TTV infection developing jaundice clinically. Our findings are consistent with recent reports that most post-transfusion TTV infections are likely to be mild clinically^[11,12,15,16].

In the present study, all three patients with HGV infection were co-infected with other types of hepatitis. This is consistent with the findings that risk factors of HGV carriage to other body-fluid transmitted viruses. One percent of healthy adults in Taiwan have detectable HGV RNA^[3,4,17,18].

Our data also show that two patients, who were previously diagnosed as non-A-G hepatitis, were positive for TTV DNA. The one patient with detectable serum TTV DNA before and after transfusion most likely had TTV infection before transfusion. Another patient with sero-conversion of TTV DNA after transfusion is likely to have had an acute TTV infection. Both of these patients had chronic hepatitis with abnormal serum ALT levels for more than 6 months, and their chronic hepatitis may have been related to TTV infection. One patient (LYY) had a recent followed-up 7 years

after the blood transfusion. She had a serum ALT level, non-detectable serum TTV DNA, and positivity for anti-HCV (authors' unpublished observation). She has been a nurse for one year, and she becomes positive for anti-HCV 6 months ago. The blood transfusion 7 years ago was not likely the cause of HCV infection. Although we were determined to exclude other kinds of hepatitis, it is possible that these two patients may have developed hepatitis other than TTV infection. Further studies are necessary to understand the role of TTV infection in chronic hepatitis.

Stereoselective propranolol metabolism in two drug induced rat hepatic microsomes

Li X and Zeng S

Subject headings propranolol; enantiomers; rat hepatic micro some; phenobarbital; β -naphthoflavone

Abstract

AIM To study the influence of inducers BNF and PB on the stereoselective metabolism of propranolol in rat hepatic microsomes.

METHODS Phase I metabolism of propranolol was studied by using the microsomes induced by BNF and PB and the non-induced microsome as the control. The enzymatic kinetic parameters of propranolol enantiomers were calculated by regression analysis of Lineweaver-Burk plots. Propranolol concentrations were assayed by HPLC.

RESULTS A RP-HPLC method was developed to determine propranolol concentration in rat hepatic microsomes. The linearity equations for R(+)propranolol and S(-)propranolol were $A = 705.7C + 311.2C$ ($R = 0.9987$) and $A = 697.2C + 311.4C$ ($R = 0.9970$) respectively. Recoveries of each enantiomer were 98.9%, 99.5%, 101.0% at 60 $\mu\text{mol/L}$, 120 $\mu\text{mol/L}$, 240 $\mu\text{mol/L}$ respectively. At the concentration level of 120 $\mu\text{mol/L}$, propranolol enantiomers were metabolized at different rates in different microsomes. The concentration ratio R(+)/S(-) of control and PB induced microsomes increased with time, whereas that of microsome induced by BNF decreased. The assayed enzyme parameters were: 1. Km. Control group: R(+)30 \pm 8, S(-)18 \pm 5; BNF group: R(+)34 \pm 3, S(-)39 \pm 7; PB group: R(+)38 \pm 17, S(-)36 \pm 10. 2. Vmax. Control group: R(+)1.5 \pm 0.2, S(-)2.9 \pm 0.3; BNF group: R(+)3.8 \pm 0.3, S(-)3.3 \pm 0.5; PB group: R(+)0.07 \pm 0.03, S(-)1.94 \pm 0.07. 3. Clint. Control group: R(+)60 \pm 3, S(-)170 \pm 30; BNF group: R(+)111.0 \pm 1, S(-)84 \pm

5; PB group: R(+)2.0 \pm 2, S(-)56.0 \pm 1. The enzyme parameters compared with unpaired *t* tests showed that no stereoselectivity was observed in enzymatic affinity of three microsomes to enantiomers and their catalytic abilities were quite different and had stereoselectivities. Compared with the control, microsome induced by BNF enhanced enzyme activity to propranolol R(+)enantiomer, and microsome induced by PB showed less enzyme activity to propranolol S(-)-enantiomer which remains the same stereoselectivities as that of the control.

CONCLUSION Enzyme activity centers of the microsome were changed in composition and regioselectivity after the induction of BNF and PB, and the stereoselectivities of propranolol cytochrome P450 metabolism in rat hepatic microsomes were likely due to the stereoselectivities of the catalyzing function in enzyme. CYP-1A subfamily induced by BNF exhibited pronounced contribution to propranolol metabolism with stereoselectivity to R(+)enantiomer. CYP-2B subfamily induced by PB exhibited moderate contribution to propranolol metabolism, but still had the stereoselectivity of S(-)-enantiomer.

INTRODUCTION

Propranolol is a nonselective β -adrenergic blocking agent and widely used in clinic as a racemic mixture of R(+) and S(-) enantiomers. It is extensively metabolized and only a small amount of the drug is excreted unchanged^[1,2]. As a beta blocking agent, the optical isomers of propranolol exert different beta receptor blocking and membrane stabilizing effects^[3], therefore its stereoselective metabolism is of clinical importance. Propranolol is metabolized into a number of products *in vivo*. These products arise from naphthalene-ring hydroxylation^[1], N-dealkylation of the isopropanolamine side-chain and side-chain o-glucuronidation^[4,5]. When the influence by the hepatic blood flow^[6] and oxygen delivery^[7] *in vivo* is not considered, the metabolism by monooxygenation is mainly responsible for propranolol elimination in hepatic microsomes and O-glucuronidation was shown to be a minor pathway *in vivo*^[2] and *in vitro*^[5].

The oxidative metabolism of propranolol is catalyzed by cytochrome p-450. Experiments by Otton SV *et al*^[8] and Ishida R *et al*^[9] indicated that multiple isozymes were involved in propranolol metabolism in rat liver microsomes. Nelson *et al*^[10] have observed that stereoselectivity of propranolol metabolism in 9000 g liver supernatant differs depending on the positions of metabolism. Although the metabolic fate of propranolol in rat has been studied extensively, the impact of PB and BNF induction on stereoselective propranolol metabolism in rat hepatic microsome was rarely reported. This experiment studied the stereoselective metabolism of propranolol in rat hepatic microsomes induced by BNF and PB and the enzymatic parameters were compared with that of the control.

MATERIALS AND METHODS

Chemicals and solutions

R(+) and S(-)-propranolol (hydrochloride), β -naphthoflavone (BNF), phenobarbital (PB) NADP and NADPH were supplied by Sigma Chemical Co. (St. Louis, MO, USA). Tris-hydroxymethyl aminomethane (Gibco BRL) and bovine serum albumin (Serva) were purchased from Shanghai Reagent Station. All other chemicals were obtained from the common commercial sources.

Tris-HCl buffer (0.1 mol/L, pH 7.4): 1.21 g of Tris-hydroxymethyl aminomethane was dissolved in 60 mL of water. The solution was adjusted to pH 7.4 by concentrated hydrochloride acid and then diluted with water to the desired volume of 100 mL. This solution was used to prepare rat hepatic microsome.

Ammonium acetate buffer: 4.0 g of ammonium acetate was dissolved in 10 mL glacial acetic acid and then diluted with water to the desired volume of 1000 mL (pH 4.0). This solution was used to prepare mobile phase.

Preparation of hepatic microsomes

Sprague-Dawley rats (male, 160 g - 200 g) were divided into three groups. One group received i.p. injection of sodium PB dissolved in physiological saline (0.9% NaCl) (80 mg/kg-d) for 3 days, another group, BNF in cornoil (80 mg/kg-d) for 3 days and the last group received nothing as the non-treated control. About 24 h after the last treatment and with no food supplied for 16 h before taking the livers, the rats were sacrificed by decapitation. Liver samples were excised and perfused by the ice-cold physiological saline to remove blood and homogenized in ice-cold Tris-HCl buffer. Hepatic microsomes were prepared with the ultracentrifugation method described by Gibbons GG *et al*^[11]. All manipulations were carried out in a cold bath. Pellets were re-suspended in sucrose-Tris buffer (pH 7.4) (95:5) and immediately stored at -30 °C.

Protein concentrations of the microsomal preparations were measured by the method of Lowry *et al*^[12] using crystalline bovine serum albumin as the protein standard.

Incubation of propranolol and rat hepatic microsomes

0.5 mL incubation mixture containing 1 mg/mL microsomal protein per milliliter (85 mmol/L Tris-HCl buffer (pH 7.4), 50 mmol/L nicotinamide, 15 mmol/L MgCl₂, 3 mg/mL DL-isocitric acid tri-sodium salt, 0.4 units/mL isocitric dehydrogenase) was used. Phase I metabolism was performed with 0.5 mL of the mixture bubbled with oxygen for 1 min and R(+) or S(-)-propranolol enantiomer as the substrate. After 5 min pre-incubation under air at 37 °C, reaction was started by adding 10 μ L of NADPH regenerating system (10 mg NADP and 3 mg NADPH in 100 μ L of 1% NaHCO₃). The reaction was stopped after the indicated time by adding 0.5 mL of methanol and centrifuged at 4000 r/min for 10 min. 10 μ L of the supernatant was sampled into HPLC.

HPLC procedure for propranolol determination in rat hepatic microsomes

A HPLC procedure was established to assay propranolol enantiomers in rat hepatic microsomes. After the termination of the reaction with methanol, 10 μ L of the sample was applied to a reversed phase column (Shim-pack CLC-ODS 15 cm \times 0.6 cm id, 10 μ m particle size). Propranolol was monitored with a UV detector at 290 nm. The mobile phase was made up with ammonium acetate buffer (pH 4.0)-methanol (50:50). The flow rate was 1.0 mL/min. Figure 1 shows the typical elution of propranolol in incubation solution.

Statistical analysis of the data

The maximum velocity (V_{max}) and the Michaelis-Menten constant (K_m) values for propranolol were determined by regression analysis of Lineweaver-Burk plots. The $\bar{x} \pm s$ of three determinations of V_{max} and K_m was calculated for each substrate and metabolic reaction. Intrinsic clearance was calculated by the ratio of V_{max}/K_m. The statistical difference between propranolol enantiomers was tested using an unpaired *t* test.

RESULTS

Validation of HPLC

Linearity Drug-free microsomes were spiked with increasing concentrations of propranolol enantiomers (10 μ mol/L - 620 μ mol/L). The solution was constituted according to "Incubation of propranolol with rat hepatic microsomes" with no occurrence of metabolism reaction. Propranolol enantiomers were assayed by HPLC precisely described. Standard calibration curves were

constructed by performing a linear regression analysis of the peak area (Y) of propranolol enantiomers versus their concentrations (X), i.e., R(+)-propranolol: $Y = 705.7 + 311.2X$, $r = 0.9987$; S(-)-propranolol: $Y = 697.2 + 311.4X$, $r = 0.9970$. The limit of detection (single-to-noise ratio = 3) for propranolol was $3 \mu\text{mol/L}$.

Precision and accuracy The spiked drug-free microsomes at 3 concentration levels ($60 \mu\text{mol/L}$, $120 \mu\text{mol/L}$ and $240 \mu\text{mol/L}$) were assayed following the procedure of 2.1.1. Results were listed in Table 1.

Table 1 Accuracy and precision to assay propranolol in rat liver microsome

Target concentrations ($\mu\text{mol/L}$)	Recovery (%)	Precisions (RSD, %)	
		Intra-assay ($n = 3$)	Inter-assay ($n = 3$)
60	98.8	5.1	5.6
120	99.5	3.5	4.8
240	101.0	3.2	5.3

Concentration-time curves and variation of the ratio of R(+)/S(-) propranolol concentration in microsomes after incubation of different time Phase I metabolism was performed with 0.5 mL of the mixture and $60 \mu\text{mol}$ of propranolol enantiomers as the substrate. The incubation procedure was carried out according to 1.3. and 1 mL of methanol was added to stop the reaction at 0, 40, 80, 160, 320 min respectively. The mixtures were then analyzed by HPLC. Results are shown in Figure 2 and Table 2.

Table 2 Ratio of R(+)/S(-) propranolol concentration in incubation media at different incubation time

Group	Ratio of R(+)/S(-) propranolol					
	0	5	10	15	20	30 (min)
Control	0.989	9.99 ± 0.07	1.01 ± 0.10	1.02 ± 0.02	1.04 ± 0.04	1.07 ± 0.02
BNF	0.989	0.94 ± 0.05	0.93 ± 0.06	0.93 ± 0.04^a	0.95 ± 0.05^c	0.91 ± 0.05^{bc}
PB	0.989	1.05 ± 0.06	1.04 ± 0.08	1.05 ± 0.10	1.09 ± 0.05	1.09 ± 0.06

Values were obtained from propranolol concentration at $120 \mu\text{mol/L}$ for each enantiomer, BNF and PB: microsomes from the rats induced with BNF (β -naphthoflavone) or (phenobarbital) $80 \text{ mg}/(\text{kg}\cdot\text{d})$, ip, 3 d, respectively. $\bar{x} \pm s$, $n = 3$. $^aP < 0.05$, $^bP < 0.01$, compared with control; $^cP < 0.05$, compared with PB by unpaired t test.

It was indicated that at the propranolol concentration level of $120 \mu\text{mol/L}$, propranolol enantiomers were metabolized in different rate in different microsomes. The ratio of R(+)/S(-) propranolol concentration in incubation media in control and PB group increased, whereas that in BNF group decreased. The ratio of R(+)/S(-) propranolol concentration in BNF group was significantly different with the corresponding ratio

in control group or PB group at 15, 20 and 30 min ($P < 0.05$, 0.01).

Enzymatic kinetic parameters for propranolol metabolism in liver microsomes from control, BNF and PB induced rats The enzymatic kinetic parameters of propranolol enantiomers were calculated by Lineweaver-Burk method with the substrate concentrations of $20 \mu\text{mol/L}$ - $600 \mu\text{mol/L}$ in three forms of rat hepatic microsomes after 10 min incubation (1.3). The results were listed in Table 3.

Table 3 Enzymatic kinetic parameters in propranolol enantiomer metabolism *in vitro* in rat hepatic microsomes induced by β -naphthoflavone or phenobarbital

Group	Enantiomer	Km	V_{\max}	Clint	R(+)/Vmax:
		$\mu\text{mol/L}$	$\text{mmol/g}\cdot\text{min}$	L/min/g protein	S(-)/Vmax
Control	R(+)	30 ± 8	1.5 ± 0.2^b	60 ± 3^b	0.5
	S(-)	18 ± 5	2.9 ± 0.3	170 ± 30	
BNF	R(+)	34 ± 3	$3.8 \pm 0.3^{\text{th}}$	$111.0 \pm 1^{\text{th}}$	1.14
	S(-)	39 ± 7^d	3.3 ± 0.5^g	$84 \pm 5^{\text{eh}}$	
PB	R(+)	38 ± 17	$0.07 \pm 0.03^{\text{ef}}$	$2.0 \pm 2^{\text{ef}}$	0.038
	S(-)	36 ± 10^d	1.94 ± 0.07^c	56.0 ± 1^c	

Clint (intrinsic clearance) is the ratio of V_{\max}/K_m , mean $\pm s$, $n = 3$. $^aP < 0.05$, $^bP < 0.01$, $^cP < 0.001$, compared with S(-) propranolol; $^dP < 0.05$, $^eP < 0.01$, $^fP < 0.001$, compared with corresponding enantiomer in control group; $^gP < 0.01$, $^hP < 0.001$, compared with corresponding enantiomer in PB group with unpaired t test.

K_m of propranolol enantiomers in control group had no stereoselectivity ($P > 0.05$), whereas V_{\max} and Clint had stereoselectivity of S(-)-propranolol ($P < 0.01$). For BNF induced microsome, K_m and V_{\max} had no stereoselectivity between R(+), S(-)-propranolol ($P > 0.05$), and Clint had significant difference between the two enantiomers ($P < 0.05$). For PB group, K_m had no stereoselectivity ($P > 0.05$), and V_{\max} , Clint had stereoselectivity of S(-)-propranolol ($P < 0.001$).

Comparing the enzymatic parameters of R(+)-propranolol among three microsomes, K_m had no statistical difference ($P > 0.05$), whereas V_{\max} and Clint had statistical differences ($P < 0.05$, 0.01 or 0.001); compared with the control group, V_{\max} for BNF group increased 2.5 times and that for PB group decreased 20 times; clint for BNF and PB group increased or decreased 1.8 and 30 times, respectively. With the same way to compare those parameters of S(-)-propranolol, K_m s for BNF and PB group increased 2.2 and 2.1 times, respectively, but had no statistical difference with each other; V_{\max} for PB group decreased about 1.5 times and that for BNF group nearly remained the same, in addition, no statistical difference was found between PB and BNF group; Clint for BNF and PB group decreased 2 times and 1.5 times respectively and there was significant difference between BNF and PB group.

Figure 1 Chromatograms of propranolol after incubation with rat hepatic microsomes. A Shim-pack CLC-ODS column (15cm×0.6cm i.d.) was used. The mobile phase was constituted with ammonium acetate buffer (pH4.0)-methanol (50:50) with flow rate at 1.0mL/min. Propranolol was monitored at 290nm. Propranolol: $R=10.1$ min.

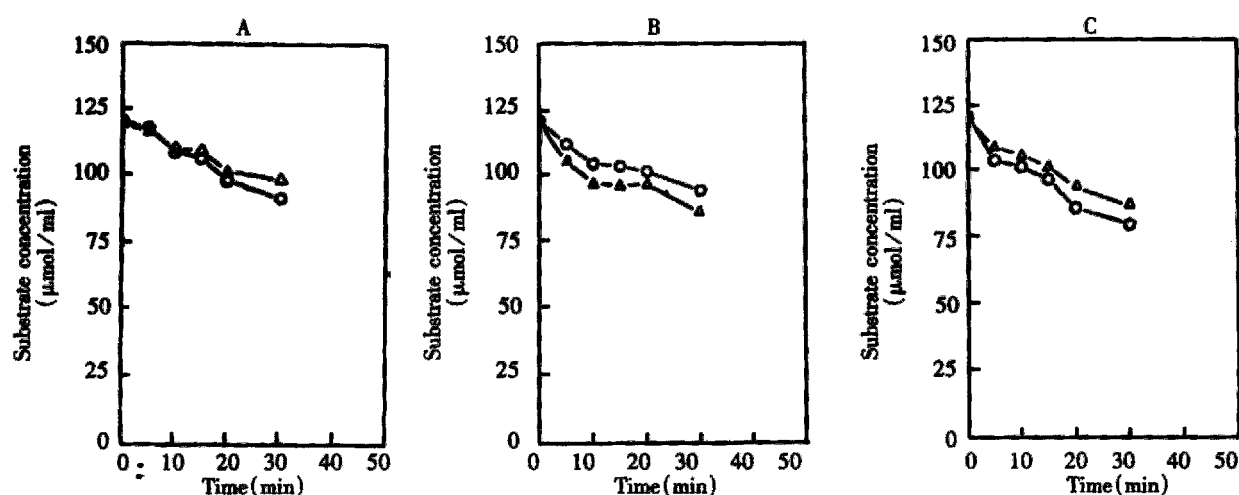

Figure 2 Concentration time curves for R(+) and S(-)-propranolol metabolism in rat hepatic microsomes.

DISCUSSION

In this *in vitro* study, stereoselectivity of propranolol occurred in catalyzing velocity and intrinsic clearance in control group, and no stereoselectivity was observed in enzyme affinity to the substrate. The introduction of BNF and PB caused changes in the composition of CYP subfamilies and therefore influenced the stereoselective catalyzing ability of microsome to propranolol metabolism, or even reversed the sequence of stereoselectivity, whereas the affinity of enzyme to substrate remained nearly the same and had no stereoselectivity. This phenomenon indicated that, regio-structure of binding site in the activity

center of enzyme was almost unchanged, and that of the catalyzing site was significantly changed in propranolol metabolism in rat hepatic microsomes after the introduction of PB and BNF, the influence of BNF and PB induction had reversed effect on the catalyzing stereoselectivity of microsome to propranolol.

BNF is an inducer of CYP-1A subfamily^[13-15] and PB is that of CYP-3A^[15], CYP-2B subfamily^[16,17] (IIB1 and IIB2^[18]). Different kinds of cytochrome P-450 may be involved in propranolol metabolism, depending on the metabolic positions^[10]. CYP-1A is suggested to catalyze 4, 5-

hydroxylation and *N*-desisopropylation stereoselectively^[19,20]. CYP-1A2 accounts for about 10% to 15% of the total CYP content of human liver and is the major enzyme involved in the metabolism of propranolol^[21]. Another subfamily CYP-2D6 mainly catalyzes 4, 5 and 7-hydroxylation stereoselectively^[22,23] and it has been confirmed that CYP-2D6 does not contribute to *N*-desisopropylation of propranolol^[8]. *N*-desisopropylation in propranolol enantiomer metabolism is mainly mediated by CYP-1A2^[24,25]. Masubuchi Y *et al*^[26] reported that there is competition between enantiomers of propranolol for the enzyme, probably the same enzyme, a cytochrome P450 isozyme in the CYP-2D subfamily. All of these showed that different cytochrome subfamilies have different functions in metabolism of propranolol enantiomers and the optical isomers of propranolol have different stereoselectivities in metabolism. Our results indicated that CYP-1A was involved in propranolol metabolism and showed the stereoselectivity of R(+)-enantiomer in general. CYP-3A, CYP-2B subfamily does not play a main role in propranolol metabolism *in vitro*, though it showed the stereoselectivity of S(-)-enantiomer.

Protective effect of early enteral feeding on postburn impairment of liver function and its mechanism in rats

Zhu L, Yang ZC, Li A and Cheng DC

Subject headings early enteral feeding; liver; postburn impairment

Abstract

AIM To study the protective effect of early enteral feeding (EEF) on the postburn impairment of liver function and its mechanism.

METHODS Wistar rats with 30% of total body surface area (TBSA) full-thickness burn were employed. The effects of EEF on the postburn changes of gastric intramucosal pH, endotoxin levels in portal vein, water contents of hepatic tissue, blood concentrations of tumor necrosis factor (TNF- α), plasma activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), as well as the blood contents of total (TB) and direct bilirubin (DB), total protein (TP) and albumin (ALB) were serially determined within 48h postburn.

RESULTS EEF could significantly improve gastric mucosal acidosis, reduce portal vein endotoxin level and water content of hepatic tissue, as well as plasma concentrations of TNF- α at all timepoints after severe burns ($P < 0.01$); postburn elevation of the plasma activities of ALT, AST and the contents of TB, DB were effectively prevented, whereas the plasma concentrations of TP and ALB were markedly increased 24 h and 48 h postburn in EEF group compared with that of the burn without EEF group ($P < 0.01$).

CONCLUSION EEF has significant beneficial effects on the improvement of hepatic function in

rats after severe burn, and is probably related with an increase in splanchnic blood flow, reduction of the absorption of gut-origin endotoxin and the consequent release of inflammatory mediators.

INTRODUCTION

Acute impairment of hepatic function is one of the most common serious complications after severe burns with an extremely high incidence^[1,2]; however, its prevention and treatment have not yet been effectively improved so far. In recent years, abundant researches have suggested that the posttrauma translocation of gut-origin endotoxin may lead to remote organ injury, and is also the major contributor to the hepatic dysfunction^[3-5]. Meanwhile, it has become increasingly apparent that early enteral feeding (EEF) in various pathological conditions may produce multiple beneficial effects, including the stimulation of splanchnic and hepatic circulation, maintenance of gut mucosal integrity, prevention of intramucosal acidosis and permeability disturbances, and alleviation of the translocation of gut-origin bacteria and endotoxin^[6-10]. We therefore presume that EEF might be possible to improve hepatic function in severe burns, which up to now has been seldom documented. Thus, the present study is designed to verify this hypothesis, and in an attempt to seek ways to improve further the treatment of severely injured patients. This is no doubt of both theoretical and practical importance.

MATERIALS AND METHODS

Animals

Healthy adult wistar rats of either sex, weighing 220 g \pm 30 g, were employed in the study. They were housed in individual metabolic cages in a temperature conditioned room (22 °C-24 °C) with a 12 h light-dark cycle, allowed access to standard rat chow (provided by Experimental Animal Center, Third Military Medical University) and water ad libitum, and acclimatized to the surroundings for 7 days prior to the experiments.

Operative procedure

All animals were weighed and anesthetized with 1%

pentobarbital sodium (30 mg/kg, ip). After laparotomy, a polyethylene catheter (1.5 mm in diameter) for enteral feeding was inserted into duodenum on the anterior wall 1.5 cm from pylorus via a puncture hole made by a metal needle. The catheter was appropriately fixed, tunneled under the skin and exited through the nape skin. Animals were housed and fed as described above after operation.

Burn injury and resuscitation

After a recovery period of 24 h, the animals inserted with feeding tube were anesthetized, dorsal hair shaved and then placed in a wooden template designed to expose 30% of the total body surface area (TBSA), and then immersed in water at 92 °C for 20 seconds, which resulted in a clearly demarcated full-thickness burn. One hour after burn injury, the animals were resuscitated with 10 mL of warm 0.9% NaCl (normal saline solution, 37 °C) given by intraperitoneal injection. Control animals were similarly anesthetized and shaved but not burned.

Feeding and experimental protocol

Nutrient liquid for feeding was prepared before use as one with a caloric value of 2.1 KJ/mL by mixing nutritional powder (ENSURE, USA) with appropriate amount of warm boiled water. According to different feeding regimens, animals were randomly divided into three groups: ① EEF group. Enteral feeding was initiated 1h postburn in burned animals via feeding tube with a total calorie of 202 KJ·Kg⁻¹·24 h⁻¹; the nutrient liquid required for 24 hours was administered evenly at 6 timepoints. ② Burn group. The animals were treated exactly the same as EEF group, except that the nutrient liquid was substituted by equal amount of saline. ③ Control group. Only the feeding tube was inserted, whereas no tube feeding and burn were conducted. The animals in this group were allowed access to standard rat chow, nutrient liquid and water ad libitum. Timepoints for different measurements and assays in all groups were made at the 3rd, 6th, 12th, 24th and 48th h postburn, except for the determination of liver tissue water content, which was performed at the 12th after thermal injury. For plasma assays, rats were sacrificed by decapitation at each timepoint and heparinized blood was collected in separate tubes, spun at 3 000 g for 10 min, and the plasma frozen at -20 °C until analysis.

Measurements

The gastric intramucosal pH (pHi) was determined with an indirect method as previously described^[11] with minor modification. Briefly, animals were anesthetized and given cimetidine (15 mg) intraperitoneally 1h prior to each timepoint, and then a polyethylene catheter was inserted into

gastric lumen through pylorus via a puncture hole on the anterior wall of duodenum made by a metal needle after a midline laparotomy. An amount of 2.5 mL normal saline was injected into gastric lumen through the catheter and aspirated out to get rid of intragastric residues, and then 1.5 mL normal saline was injected and retained in the gastric lumen. After an equilibration interval of 60 min, 1 mL of saline solution were aspirated and Pco₂ determined using the blood gas analyzer. A simultaneously obtained arterial blood sample was used for determining the [HCO₃⁻]. pHi was then calculated as:

$$\text{pHi}=6.1+\log([\text{HCO}_3^-]/[\text{Pco}_2\times 0.03])$$

The multifunction-biochemical analyzer Beckman Synchron CX-7 was used for performing performing liver function tests. The plasma activities of alanine aminotransferase (ALT), aspartate aminotransferase (AST), as well as the blood contents of total (TB) and direct bilirubin (DB), total protein (TP) and albumin (ALB) were determined at each timepoint.

Portal plasma endotoxin levels were assayed with the limulus-amoebocyte-lysate test (LAL)^[12]. In brief, plasma samples were diluted tenfold with pyrogen-free water and heated to 75 °C for 5 min to inactivate the plasma inhibitor. The samples were incubated with LAL at 37 °C for 33 min. The chromogenic substrate was added and the samples incubated for another 3 min. Acetic acid stopped the reaction. The optical density was read at 545 nm and endotoxin concentration was expressed as Eu/mL.

Radioimmunoassay of TNF-α levels in systemic circulation was conducted according to the instructions with kits from Dong Ya Research Institute of Immuno-technology.

Liver tissue water contents were determined with a method as reported in a previous study^[13] with minor modification. Eight Liver tissue samples for each group were harvested at 12 h postburn, weighed, put in oven at 90 °C for 24 h, and then weighed again. The liver tissue water contents were calculated as:

Liver tissue water contents=(wet weight-dry weight/wet weight)×100%

Statistical analysis

Data were expressed as mean±standard error of the mean. Experimental results were analyzed by analysis of variance and *t* tests for multiple comparisons. Statistical significance was determined at *P*<0.05.

RESULTS

Postburn EEF has beneficial effects on the hepatic functions as demonstrated by the significantly reduced plasma activities of ALT, AST and the blood contents of TB and DB, whereas the plasma

concentrations of TP and ALB were markedly increased 24 h and 48 h postburn in the EEF group compared with that of the burn group without EEF as shown in Tables 1 and 2.

Gastric mucosal acidosis was significantly improved in EEF group animals as indicated by the elevation of gastric pH_i at most of the postburn timepoints, however, gastric pH_i in the burn group sustained in lower levels until 48 h postburn (Table 3).

Table 4 displays the changes in portal endotoxin levels after severe burns. Three hours postburn, endotoxin concentration significantly increased in the burn group and reached a peak in 6 h; another increase appeared after 24 h and persisted until 48 h postburn. However, the portal endotoxin levels in

animals that received EEF markedly decreased at nearly all timepoints postburn compared with that of the burn group.

The data for plasma TNF- α levels are shown in Table 5. In accordance with other observations, EEF could also significantly reduce TNF- α levels in the systemic circulation at most postburn timepoints as compared with that of burn animals.

The hepatic tissue water contents in the three experimental groups were $71.17\% \pm 0.60\%$, $73.01\% \pm 0.52\%$ and $70.18\% \pm 0.52\%$ respectively. Evidently, the liver tissue water content in the EEF group was significantly lower than that in the burn group without EEF 12 h postburn ($P < 0.01$).

DISCUSSION

Nutritional support plays an important role in the management of critically ill patients for preventing and treating multiple organ failure^[14]. However, the concept of the administration of enteral nutrition very early after injury is relatively new^[8]. More than a decade ago, Moore *et al*^[15] reported that immediate postoperative feeding by needle catheter jejunostomy was safe and feasible; and that early nutritional support could decrease the incidence of septic complications in the severely injured patient. In a subsequent study, Mochizuki *et al*^[16] showed that immediate enteral feeding in burned guinea pigs was associated with a decrease in the hypermetabolic state. They demonstrated that early enteral feeding could suppress the expected rise in glucagon, cortisol and norepinephrine after major burn injury, compared with delayed enteral feeding. Since then results of a number of clinical and animal studies were reported, showing that very early enteral feeding could preserve the gut barrier function, diminish hypermetabolic response, maintain caloric intake, reduce infective complications and significantly shorten hospital stay following injury^[6,7,16-18]. Unfortunately, most of these studies paid more attention merely to its trophic and metabolic effects, whereas the other benefits such as its role played in the protection of splanchnic functions were greatly neglected. In the present study, we showed that postburn EEF could result in a low level of plasma ALT, AST activities and TB, DB contents, as well as a rapid restoration of plasma TP and ALB level that have significantly decreased after severe burns. These clearly meant that early enteral feeding could effectively improve hepatic dysfunction caused by burn injury. A previous study showed that circulating levels of bile acids could be a sensitive and specific indicator of liver function, an elevation of serum bile acid levels indicating a deterioration in liver function^[19]. In a rat model of hemorrhagic shock, Zaloga *et*

al^[19] found enteral administration of a peptide-based diet early after hemorrhagic shock, could significantly prevent the elevation of circulating bile acid levels, whereas a 3.6 times of serum bile acid level above baseline was noted in animals with same amount of enteral saline therapy. In a similar rat model, Bortenschlager *et al*^[20] also observed that enteral nutrient s significantly decreased liver injury. After hemorrhagic shock, AST in saline controls and enterally fed animals increased from 246 U/L±17 U/L to 1605 U/L±593 U/L and from 283 U/L±39 U/L to 551 U/L±94 U/L respectively; ALT increased from 60 U/L±4 U/L to 726 U/L±355 U/L in controls and 61 U/L±6 U/L to 161 U/L±38 U/L in enterally fed animals. These results further indicated that EEF could protect animals from liver injury in various forms of injury.

The mechanisms of EEF in improving postburn liver function so far have not been fully clarified yet. It has been noted that in severe trauma including burns, the loss of a large amount of body fluids and the release of stress hormones cause a sharp reduction of blood flow to many organs, especially the gastrointestinal tract. Reduced intestinal blood flow then leads to translocation of bacteria and/or their toxic products through the gut mucosa. Subsequent bacteria and/or toxin-induced persistent and excessive release of cytokines (i.e. tumor necrosis factor, interleukins) from hepatic macrophages and complement activation may initiate progressive multiple organ failure and even cause death^[21-23]. In accordance with this theory, many studies suggested that the hepatic ischemia and endotoxemia occurred in various pathological conditions and were the major contributors to liver dysfunction^[3-5,24]. However, Zaloga^[25] also proposed that deprivation of exogenous nutrients for a certain period of time, via a mechanism of substrate lack and tissue antioxidant system depletion, could also compromise organ function.

Postprandial gut hyperemia is a local vascular response to the presence of foodstuff in the lumen, an important physiological phenomenon for food digestion and absorption. Even though in some

pathological conditions, this phenomenon still exists. In burned guinea pigs, Inoue *et al*^[26] using radiolabeled microspheres demonstrated that during initial 24 h of enteral feeding, blood flow to the jejunum and cecum was higher in the fed group than in the control. Purcell *et al*^[27,28] studied oleic-acid-induced lung injury in dogs mechanically ventilated with positive end-expiratory pressure (PEEP) which limited hepatic blood flow and oxygen delivery, and found that in such dog receiving EEF there were a significant increase in hepatic blood flow and oxygen delivery, with a highest increase in portal blood flow. In a dog model of splanchnic ischemia induced with endotoxin, Eleftheriadis *et al*^[29,30] reported that after early enteral feeding, portal vein, hepatic and superior mesenteric artery blood flow; hepatic and intestinal microcirculation; hepatic tissue PO₂ and energy charge; and intestinal intramucosal pH, which were all reduced in the early septic condition, were significantly increased. In present study, we showed that postburn EEF could effectively restore reduced gastric intramucosal pH, decrease endotoxin concentrations in portal vein and TNF- α levels in systemic circulation, and alleviate liver tissue edema, as compared with saline feeding burn controls. All above indicate that in addition to provide nutrients, posttrauma EEF exerts its protective effect on liver function most likely via a mechanism of postprandial hyperemia to improve gut blood flow and splanchnic ischemic status, and to maintain gut mucosal integrity, which may block the vicious circle of mutual activation between the translocation of gut origin bacteria with their toxic products and the release of inflammatory mediators^[31], thereby reducing hypoxic and inflammatory tissue damage.

The fact that EEF may improve postburn hepatic function is of both theoretically and practically importance. Although the results from animal study can not be applied directly to humans, the data from this study might provide valuable clues to the further improvement of prevention and treatment of post-traumatic multiple organ dysfunction syndrome. Now, EEF should not be considered merely as a simple nutritional support. Further investigations are needed to demonstrate whether or not the results from this animal experiment can apply to clinical settings.

Reduced gastric acid production in burn shock period and its significance in the prevention and treatment of acute gastric mucosal lesions

Zhu L, Yang ZC, Li A and Cheng DC

Subject headings gastric mucosal lesions; gastric acid; burn shock

Abstract

AIM To investigate the changes of gastric acid production and its mechanism in shock period of severe burn in rats.

METHODS A rat model with 30% TBSA full-thickness burn injury was employed and the gastric acid production, together with gastric mucosal blood flow (GMBF) and energy charge (EC) were measured serially within 48h postburn.

RESULTS The gastric acid production in the acute shock period was markedly inhibited after severe burn injury. At the 3rd h postburn, the gastric juice volume, total acidity and acid output were already significantly decreased ($P < 0.01$), and reached the lowest point, $0.63 \text{ mL/L} \pm 0.20 \text{ mL/L}$, $10.81 \text{ mmol/L} \pm 2.58 \text{ mmol/L}$ and $2.23 \text{ mmol/h} \pm 0.73 \text{ mmol/h}$ respectively, at the 12th h postburn. Although restored to some degree 24 h after thermal injury, the variables above were still statistically lower, compared with those of control animals at the 48th h postburn. The GMBF and EC were also significantly reduced after severe burns, consistent with the trend of gastric acid production changes.

CONCLUSION Gastric acid production, as well as GMBF and EC was predominantly decreased in

the early postburn stage, suggesting that gastric mucosal ischemia and hypoxia with resultant disturbance in energy metabolism, but not gastric acid proper, might be the decisive factor in the pathogenesis of AGML after thermal injury, and that the preventive use of anti-acid drugs during burn shock period was unreasonable in some respects. Therefore, taking effective measures to improve gastric mucosal blood perfusion as early as possible postburn might be more preferable for the AGML prevention and treatment.

INTRODUCTION

Acute gastric mucosal lesion (AGML) is one of the most common visceral complications early after severe burns. In patients with thermal injury that involves 30% or more of the total body surface area (TBSA), there was a 14% to 25% incidence of clinically evident gastrointestinal complications and 83.5% of the patients had endoscopic evidence of gastrointestinal disease^[1]. Although it was reported recently that, burn-induced stress ulcer occurred less frequently with the advances of intensive care supports, AGML still caused a high mortality when complicated with severe bleeding^[2], which was recognized as a potentially life-threatening event in such critically ill patients^[3,4]. Therefore, such gastrointestinal complications after cutaneous thermal burn remain a problem of great interest and importance.

Several hypotheses have been proposed to explain the mechanism of burn-induced gastric mucosal injury, but no single factor appears to be invariably capable of producing lesions of the gastric mucosa^[5]. Traditionally, increased gastric acid production has been long considered as one part of the stress response and the main contributor to the pathogenesis of AGML after severe burns^[6]. Consequently, much attention has been paid to acid-neutralizing and/or inhibiting agents in the prevention and treatment of burn-induced gastrointestinal complications. In recent years, however, it is increasingly and widely assumed that

tissue ischemia resulting from hypoperfusion is the initial and principal factor, which may trigger re-perfusion injury, for the AGML formation^[7]. Meanwhile, the necessity and rationality of AGML prophylaxis by using acid-neutralizing and/or inhibiting agents have also been challenged^[8,9].

Gastric acid secretion is an active metabolic process with energy consumption, which requires sustained and adequate blood supply^[8]. It has well been documented that the splanchnic circulation is the first to be reduced in critical illness and the gut is one of the first organs to have the adequacy of its tissue oxygenation compromised in shock^[10,11]. We therefore presumed that the gastric acid production in burn shock period might be reduced, which is contrary to what we have thought of before but remains lack of direct evidence.

With this background, the present study is conducted to serially determine the gastric acid production, and the changes of blood flow and energy charge of the gastric mucosa during burn shock period, in order to elucidate the characteristics of gastric acid production in early postburn stage and their mechanisms, as well as to provide useful information for the AGML prophylaxis at clinical settings.

MATERIALS AND METHODS

Animals

Healthy adult Wistar rats of either sex, weighing 220 g±30 g, were employed in the study. They were housed in individual metabolic cages in a temperature conditioned room (22 °C-24 °C) with a 12 h light-dark cycle, allowed access to standard rat chow (provided by experimental animal center, Third Military Medical University) and water ad libitum, and acclimatized to the surroundings for 7 days prior to the experiments.

Burn injury and resuscitation

Animals were fasted for 12 h before burn injury, and during 48 h postburn period they were allowed water ad libitum. After induction of anesthesia with 1% pentobarbital sodium (30 mg/kg, ip), dorsal hair was shaved, and animals were placed in a wooden template designed to expose 30% of the total body surface area (TBSA), and then immersed in water at 92 °C for 20 seconds, which results in a clearly demarcated full-thickness burn. One hour after burn injury, the animals were resuscitated with 10 mL of warm 0.9% NaCl (normal saline solution, 37 °C) given by intraperitoneal injection. Control animals were similarly anesthetized, shaved and resuscitated but not burned.

The animals burned were randomly divided into five groups for the different measurements and assays that were performed 3, 6, 12, 24 and 48h

postburn (PBH₃, PBH₆, PBH₁₂, PBH₂₄ and PBH₄₈).

Measurement of gastric acid production

Three hours prior to each timepoint, animals were anaesthetized, laparotomized, and then the pylorus were ligated. After sacrificed by decapitation at each timepoint, rats were re-laparotomized to obtain the gastric juice. The pH and volume of each collection were recorded and by using a microtitrator its hydrogen ion concentration was measured by titration with 0.02 mol/L sodium hydroxide to an endpoint indicated by phenolphthalein. The total acidity and total acid output of each gastric juice collection were calculated.

Determination of gastric mucosal blood flow

GMBF was determined as previously described^[12]. Radioactive biomicrospheres were prepared with toad red blood cells labeled with ^{99m}Tc. At each timepoint, anesthetized animals underwent cannulation of right carotid artery for the injection of radioactive microspheres with PE-50 polyethylene tubing (inside diameter 0.58 mm and outside 0.97 mm). The catheter was carefully advanced into the left ventricle, as confirmed by the ventricular pressure curves monitored with a four-channel physiological recorder. Another catheter for drawing a reference blood sample was introduced into the aorta abdominalis via left femoral artery. The prepared suspension of radioactive microspheres was mixed vigorously for at least 2min before each injection. Then 0.2mL of the suspension in an injection syringe (approximately 1.5-2.0×10⁵ microspheres) was counted for radioactivity by a γ-scintillation counter before being slowly and uniformly injected into the left ventricle during a 30sec period and the infusion tube was flushed with 0.2 mL heparinized saline solution. The injection syringe was rinsed five times with saline solution into a counting tube for measurement of residual radioactivity in the syringe. Thus net radioactivity injected into the animal was the original minus residual radioactivity. Withdrawal of the reference blood sample, having started 20sec before the microsphere injection, was performed by a syringe pump at a constant rate of 0.4 mL/min for 90sec. After withdrawal of the reference blood, animals were killed with an overdose of sodium pentobarbital. The gastric mucosa was sampled, weighed and then counted in γ-scintillation counter. The GMBL was calculated by the following equation and expressed as "mL/min·g tissue"^[13]:

$$\text{GMBL (mL/min·g tissue)} = \frac{\text{Reference sample flow} \times \text{Tissue activity}}{\text{Reference sample activity} \times \text{Tissue weight}}$$

Biochemical assays of gastric mucosal energy charge

At each timepoint, the glandular mucosa of stomach was sampled by scraping with razor and stored in liquid nitrogen. On determination, adenine nucleotides were assayed as previously reported with some modifications^[14]. Briefly, the sample was powdered in a liquid nitrogen bath and then weighed and homogenized in 20 volume of 10% perchloric acid for deproteinization. The homogenate was centrifuged for 30 min at 12000×g. The pH of the resulting supernatant was adjusted to 7.0-7.6 with 5 mol K₂CO₃/L. Then another centrifugation was performed and the supernatant was used to assay for adenine nucleotides by using high-performance liquid chromatography with a reverse-phase column at a flow rate of 1 mL/min with a buffer of 0.1 mol PBS/L. The ATP, ADP and AMP concentrations in gastric mucosa were then obtained from the eluant fractions. The adenylate energy charge was calculated according to the following equation: Energy charge=(ATP+0.5×ADP)/(ATP+ADP+AMP)

Statistical analysis

Data are expressed as mean±SE. Experimental results were analyzed by analysis of variance and *t* tests for multiple comparisons. *P* values less than 0.05 were considered to be statistically significant.

RESULTS

The gastric acid production in the acute shock period was markedly inhibited after severe burn injury. At the 3rd h postburn, the gastric juice volume, total acidity and acid output were already significantly decreased, on decreasing, to reach the lowest point at the 12th h postburn. Although restored to some degree and kept 24 h after thermal injury, the variables above were still statistically lower as compared with those of control animals 48 h postburn (Table 1). The GMBF and EC were also significantly reduced after severe burns, and were consistent with the trend of gastric acid production changes (Tables 2, 3).

DISCUSSION

It has been long considered that certain amount of hydrogenion existing in gastric lumen is the prerequisite for the AGML formation^[15,16]. However, the roles of gastric acid in the pathogenesis of AGML have not been fully elucidated so far. In a clinical study, Pruitt *et al*^[6] noted that the mean outputs of total gastric acid in burn patients with normal mucosa, AGML, and AGML with complications (such as bleeding and perforation) were 1.42, 3.32, and 5.37 mmol/h respectively. Lucas *et al*^[17] also found an increase in gastric acid production was positively related the severity of AGML in traumatic patients observed with endoscopy. Interventions designed to decrease gastric acid production, such as vagotomy or administration of aluminum hydroxide or anticholinergic drugs, have all been shown to decrease the incidence of ulcers. In the case of a burn injury or other severe injury, the presence of acid even at subnormal levels may be sufficient to produce gastrointestinal complications. However, in humans and experimental animals there has not been a consistent association of acute gastric ulcerations after burn injury with hypersecretion of gastric acid^[18].

The early phase after severe burn is the critical period for AGML formation. It was reported that the incidence of AGML within 72h reached as high as 76%^[1,19]. Therefore, investigating the changes of gastric acid production in shock period is both theoretically and practically of importance for the further understanding of the pathogenesis of AGML and, on this basis, improving its treatment and prophylaxis. In present study, we showed that gastric juice volume, total acidity and acid output in burned rats during the early phase of severe burns

were significantly decreased compared with unburned controls, with the lowest at 12th h and persisting at lower levels until 48 h postburn. In particular, the total acid outputs at the 6th, 12th, and 24th h in burn animals corresponded only to 1/9, 1/63, and 1/2 of those in control rats. These results indicate that in burn shock period the gastric acid secretion is markedly inhibited.

The production of gastric acid is an active metabolic process with energy consumption, requiring sustained and adequate blood supply^[8]. It is well known that during the period of hypovolemic shock such as that induced by burn, blood is preferentially shunted to the "vital" organs, such as the brain and heart, at expense of the splanchnic circulation, causing a sharp reduce of blood flow to the gastrointestinal tract^[20]. Therefore, ischemia may be a major factor in the development of AGML after shock and injury. In a report by Horton, blood flow to the small intestine and stomach decreased significantly 5 h postburn, but flow returned to the normal level 24 h after burn only in the small intestine, but not in the stomach^[18]. In this murine burn model, we noted that there was a significantly decrease in GMBF and EC with a trend consistent with the serious inhibition of gastric acid production after severe burns. Thus, the decreased acid production might be resulted from ischemia and hypoxia of the gastric mucosa that are metabolically unable to produce normal quantities of acid. Furthermore, while being a causative factor for the AGML formation, gastric acid is also one of the most important barriers against invading pathogenic micro-organisms^[21]. Gastric pH<3.5 is usually bactericidal for most species^[22]. In this sense, the inhibition of acid secretion in early postburn period is the manifestations of both local impairment of gastric mucosal function, as well as the dysfunction of host defense mechanism as a whole.

Prophylaxis for stress ulceration continues to be an important part of the management of critically burned patients. However, controversy remains regarding the necessity and rationality of the regimen used^[23,24]. Available options at present include antacids, various H₂-receptor antagonists, prostaglandins, proton pump inhibitors, and sucralfate, nearly all of which exert their pharmacological actions, to more or less extent, through the acid-neutralizing and/or inhibiting mechanism^[25]. In fact, postburn acute mucosal lesions occurred not only in the gastric mucosa, but also in some organs that cannot produce acid such as small and large intestines, and even the gallbladder mucosa^[26]. In patients without titratable gastric acid, diffuse erosive gastritis remains occurring

within 72 h of burn injury^[18]. It was documented in some reports that the incidence of pathological changes in gastric mucosa was not alleviated by using antacids in clinical settings^[27], but could be prevented or reduced by satisfactory resuscitation and advanced intensive care support, even in a condition lack of anti acid prophylaxis^[28,29]. In burned rats, Skolleborg *et al*^[5] found with postburn fluid resuscitation sufficient to maintain aortic blood pressure, gastric mucosal erosions were prevented even when gastric pH was at 1.0. All of these, combined with our results, show in different aspects that gastric acid is not a leading and crucial, but an aggravating factor that functions on the basis of ischemic impairments, for the AGML formation. Whereas, the present AGML prophylaxis mainly by the use of anti-and neutralizing acid drugs is not only making the mucosa more susceptible to acid injury^[30], but also resulting in numerous side-effects including breaking the defensive barrier of gastric acid, which may lead to the colonization and translocation of gut organisms and thus increase the risk of nosocomical infections^[25,27,28,31]; therefore, taking effective measures to improve splanchnic blood perfusion as early as possible postburn may be more preferable than the mere blockade of gastric acid production for the AGML prevention and treatment.

Tumor growth inhibition effect of hIL-6 on colon cancer cells transfected with the target gene by retroviral vector

Xiao B, Jing B, Zhang YL, Zhou DY and Zhang WD

Subject headings interleukin-6 gene; gene transfection; gene therapy; colonic neoplasms

Abstract

AIM To observe the tumor inhibitory effects by transfecting IL-6 cDNA into colon cancer cell line HT-29 with retroviral vector pZIP cDNA.

METHODS Human IL-6 gene was reconstructed in retrovirus vector and transfected into incasing cells PA317 by lipofectamine mediated method, the clones of the cells transferred with hIL-6 were selected by G418, and targeted HT-29 cells were infected with the virus granules secreted from PA317 and also selected by G418. Test gene transcription and expression level by hybridization, ELISA and MTT assay, etc. Analyze tumor inhibitory effects according to the cell growth curve, plating forming rate and tumorigenicity in nude mice.

RESULT Successfully constructed and transfected recombinant expressing vectors pZIPIL-6 cDNA and got positive transfected cell lines. The colon cancer cell line (HT-29 IL-6) transfected with the hIL-6 gene by retroviral vector was established. The log proliferation period and the doubling time of this cell line was between 4 to 7 days and 2.5 days according to the direct cell count, the cell proliferation was obviously inhibited with MTT assay, the plating inhibitory rate was 50% by plating efficiency test. When HT-29 IL-6 cells were inoculated into the nude mice subcutaneously, carcinogenic activity of the solid tumor was found superior to the control group and the size of tumor was not significantly enlarged. Injection of combination virus fluid containing IL-6 gene into transplantation tumors could inhibit the growth and development of the tumor.

CONCLUSION IL-6 could inhibit the growth and proliferation of colon cancer cells by retroviral vector-mediated transduction.

INTRODUCTION

The incidence of colorectal carcinoma ranks top ten among the digestive system diseases. The clinical treatment so far is not satisfactory, which has been existed of the top ten malignancy threatening human life. The authors intended to use modern molecular biology technology to explore the new strategies in treatment of colorectal carcinoma. IL-6 is a multifunctional cytokine which has been confirmed to have anti-tumor effect^[1]. Here, we reported a colorectal carcinoma cell line transfected with IL-6 gene, which can secrete a large amount of IL-6 and study its tumor-inhibitory effect both *in vitro* and *in vivo*.

MATERIALS AND METHODS

Cell lines

The colorectal carcinoma cell line (HT-29 cell strain) was preserved in our laboratory, and PA317 package cell was generously provided by Professor Zhang Hong-Quan from the Academy of Military Medical Sciences of China.

Main reagents

Restrict enzyme, EcoRI, BamHI, Klenow enzyme and T4 DNA ligase were purchased from Sino-American Biotechnology Company (SABC).

Plasmid

pUCIL-6cDNA, pZIPcDNA was introduced Dr. Jiang Bo from the Academy of Military Medical Sciences of China.

Animals

Twenty BALB/c-nu/nu female nude mice, 3-4 weeks old, were purchased from Shanghai Tumor Institute.

Construction of hIL-6 expressing strain

By utilizing restrict enzyme digestion and DNA recombinant technology, we constructed a recombinant retroviral plasmid which was named pZIPIL-6cDNA. Then the plasmid was transfected into PA317 package cell by using liposome^[2]. After screening the positive (anti-drug) clones with G418, we collected supernatants of positive clones containing recombinant virus and transfected the adenocarcinoma HT-29 cell line with the supernatant and screening of drug-resistance clones by G418.

Cell growth and proliferation test

According to the direct count assay^[3], the log proliferation and the doubling time of HT-29 cells transfected with or without pZIPIL-6cDNA were calculated. The proliferation rate of the two groups was cultured in 96-well plate and observed by MTT assay at 48 h, 72 h, 96 h and 120 h, respectively^[4].

Plating efficiency test

Prepared double layer agar gel in 6-well plate (soft agar layer) containing 0.3% agar, 20% BSA; the lower layer containing 0.5% agar, 10% BSA, which was referred as hard agar layer. Then different amount of 2×10^3 HT-29/IL-6 cells or HT-29 cells was added per well to continue for 3-4 weeks, the colony formation efficiency was calculated, including the number of the average colonization unit/the number of cell added per well.

Tumor-inhibitory test in nude mice

Twenty mice were randomly divided into four groups and each five mice. The first two groups received inoculation of HT-29 cells. After tumor formation, one group was injected pZIPIL-6cDNA recombinant viral suppressant intratumorally, which was called IL-6 gene therapy group. The other served as control group. The other two groups were inoculated with pZIPcDNA or pZIPIL-6cDNA transfected HT-29 cells, respectively. 5×10^6 cells were injected at left front leg subcutaneously. Then observed after forty days and 6 items were recorded including the time of tumor formation (i.e. the time when tumor diameter was about 3 mm), the number of tumor-bearing mice, tumor growth rate, lesion size, and health condition of nude mice as well as pathologic characteristic of the tumor.

RESULTS

Screening for transfected cell clones

After recombinant vector (pZIPIL-6) was transfected into PA317 package cells, the positive clones were screened for 4-5 weeks and drug-resistant clones gradually formed, at the same time untransfected cells died completely after 1-2 weeks and no colonization was found. The recombinant viral suppressant titer was 5.1×10^8 cfu/L by using 3T3 cells as indicating system^[2].

The tumor inhibitory effect of IL-6 in vitro

By direct counting assay, the difference in growth between HT-29 cells and HT-29 IL-6 cells is shown in Figure 1, the doubling time of HT-29 and HT-29 pZIP was 1.5 and 1.6 days, respectively, and the log proliferation phase was 2 - 7 days and 3 - 8 days, respectively. But the doubling time of HT-29 IL-6 cells was 2.5 days, log proliferation phase was 4-7 days, with a maximal cell number of 2.5×10^5 ,

which was significantly lower than HT-29 cells. The results of MTT assay are shown in Figure 2, in which the cell proliferating curve of HT-29 IL-6 cells increased more slowly being more stabilized than other groups. These demonstrated that IL-6 inhibited the growth and proliferation of colon cancer cells (HT-29) significantly, and retroviral vector influenced neither the proliferation of HT-29 cells nor the biologic effect of IL-6.

The effect of IL-6 on colony formation of HT-29 cells on soft agar

The HT-29 cell and HT-29 IL-6 cell clones were formed gradually, between 12-14 days after inoculation on the soft agar, and a number of them only appeared 3-4 weeks after. A single cluster with more than 50 cells was regarded as a clone unit, and the efficiencies of colonization were calculated (Table 1). The efficiencies for HT-29 IL-6 cells and HT-29 cells were 2.21% and 4.29%, respectively, this demonstrated the clone inhibitory rate was 50% for transfected cells. Therefore, it was shown that transfected IL-6 gene could inhibit the capacity of HT-29 colonization. It might be of significance in the prevention of HT-29 tumor cell from proliferating and invasion.

The tumor-inhibitory effect of IL-6 in vivo

Local edema disappeared inoculation after 2-3 days. After 8-14 days there appeared tiny tumors which enlarged continuously (Table 2). The average tumor formation time of gene-transfected group was delayed 5.5 days as compared with the control group, and one mouse did not show any sign of tumor bearing. In IL-6 treated mice, the tumor grew slower, the health condition was much better, and no cachexia was seen, in particular in the intratumorously-injected mice. Pathology sections showed there was more distinct apoptosis (Figure 3).

Table 1 IL-6 effects on colony formation of HT-29 cells on soft agar

Cell	n	Number of colonies					χ	Colony formation
		1	2	3	4	5		
HT-29	5.0	86.0	89.0	92.0	80.0	97.0	84.2	4.21
HTIL-6	5.0	42.0	52.0	41.0	39.0	47.0	44.2	2.21 ^a

^a $P < 0.05$, rS.

Table 2 Growth sequel of transplantation tumors

Group	Nude mice number	Number of tumor-bearing mice	The time of tumor presentation (days)	Tumor size (mm)	Growth rate (mm/day)
HT-29	5	5	8	20.8	0.65
HT-29pZIP	5	5	8.5	18.2	0.57

DISCUSSION

Recently, pioneered studies showed that IL-6 could promote or inhibit the growth of tumor cell depending upon the cell type^[5]. For example, the IL-6 cDNA encoding sequences were inserted into the downstream of SV40 promoter in pH EBOSV plasmid, then the plasmid was transfected into ROHA-9MCEBV3-B cell. The observation showed that exogenous IL-6 gene expression could switch the cell to a tumor phenotype. 10-15 days after the injection of transfected ROHA-9MCEBV3 -B cell, tumor formations were observed, but the control group was not, which suggested that IL-6 secreted by the transfected cell promote cell proliferation in carcinogenesis. On the other hand, administration of IL-6 alone could inhibit the metastasis of tumor induced by xylene anthracene^[6]. Currently, the mechanism remained unknown, however, it may be associated with different IL-6R expression on tumor cell surface. Only when the latter reaches a certain level and binds to IL-6 with high affinity could it transmit IL-6 signals and showed significant inhibitory activity. IL-6 is a cytokine with multifunctions as stated above. For instance, when the IL-6 gene was transfected into D122 Lewis lung cancer cell line which has low immunity and high metastatic potential, growth of transfected cell was inhibited *in vitro*, and the density of MHC antigen expressed on cell surface was 2.5-4.5 times greater than that in the wild type of D122. Immunizing the mice with inactivated transfected cells, the mice showed an enhanced activity of CTL and macrophage, the immunization could prevent mice from challenge of wild type D122 cells. These phenomena demonstrated that IL-6 not only could inhibit tumor growth directly but also promote anti-tumor activity indirectly. Through activating host cellular immunity^[7]. Ullmann *et al*^[8] found that IL-6 could enhance CEA and HLA antigen expression on colon cancer cell surface and these antigens expression level correlated with IL-6 treatment dose and duration positively. Other reports showed that CEA expression level of IL-6 gene transfected into colon cancer cell line (HT-29 cells IL-6) was much higher than that of untransfected or transfected with unrelated gene cells^[9]. Apart from these studies, IL-6 could enhance the induction of LAK cell or NK cell, promote the maturity and differentiation process, and increase the tumor killing activity of LAK and NK cells in a dose-dependent manner. Overall, introducing IL-6 gene into cells may have wide biological effects on the regulation of immunological response by autocrine or paracrine pathways, thus inhibit or kill tumor cell directly or indirectly^[10,11]. Regulatory disturbance induced by apoptosis is closely associated with carcinogenesis, making

tumor apoptosis a new target for cancer therapy^[12]. Gene regulation and signal transduction are the key process of apoptosis. Tumor cells could escape surveillance of immune system, not only because of the downregulation of antigen expressed on cell surface and host immune response, but also the inhibition of apoptosis of abnormal cell. We reported the first time that many more apoptotic cells in the group injected with HT-29 IL-6 cells and IL-6 gene therapy group were induced than the control group. So far, we have not seen any report on apoptosis induced by IL-6, even some researchers reported IL-6 could inhibit the programmed cell death in M1 leukemia cell strain^[13]. IL-6 is a potent immunoregulatory factor, and participates in regulation of cell apoptosis. Thus, we conclude the apoptosis induction of tumor cell is the main mechanism of IL-6 for growth inhibition of tumor cells both *in vitro* and *in vivo*. Our laboratory studies provided the potential use of IL-6 gene therapy in colorectal cancer.

Effect of cholecystokinin and secretin on contractile activity of isolated gastric muscle strips in guinea pigs

Li W, Zheng TZ and Qu SY

Subject headings gastric muscle strips; cholecystokinin; secretin; guinea pigs

Abstract

AIM To study the effect of cholecystokinin-octapeptide (CCK-8) and secretin on contractile activity of isolated gastric muscle strips in guinea pigs.

METHODS Each isolated gastric muscle strip was suspended in a tissue chamber containing 5 mL Krebs solution constantly warmed by water jacketed at 37 °C and supplied with a mixed gas of 95% O₂ and 5% CO₂. After incubating for 1 h under 1 g tension, varied concentrations of CCK-8 and secretin were added respectively in the tissue chamber and the contractile response was measured isometrically on ink-writing recorders. **RESULTS** CCK-8 could increase ① all regional circular and longitudinal muscular tension at rest (fundus LM 19.7%±2.1%, $P<0.01$; fundus CM 16.7%±2.2%, $P<0.01$; gastric body LM 16.8%±2.3%, $P<0.01$; body CM 12.7%±2.6%, $P<0.01$; antrum LM 12.3%±1.3%, $P<0.01$; antrum CM 16.7%±4.5%, $P<0.01$; pylorus CM 12.7%±5.0%, $P<0.05$); ② contractile frequencies of body LM, both LM and CM of antrum and pylorus CM (5.1/min±0.2/min to 5.6/min±0.2/min, 5.9/min±0.2/min to 6.6/min±0.1/min, 5.4/min±0.3/min to 6.3/min±0.4/min, 1.3/min±0.2/min to 2.3/min±0.3/min, respectively, $P<0.05$); ③ the mean contractile amplitude of antral circular muscle (58.6%±18.4%, $P<0.05$) and ④ the motility index of pylorus CM (145.0%±23.8%, $P<0.01$), but decrease the mean contractile amplitude of gastric body and antral LM (-10.3%±3.3%, -10.5%±4.6%, respectively, $P<0.05$). All the

CCK-8 effects were not blocked by atropine or indomethacin. Secretin had no effect on gastric smooth muscle activity.

CONCLUSION CCK-8 possessed both excitatory and inhibitory action on contractile activity of different regions of stomach in guinea pigs. Its action was not mediated via cholinergic M receptor and endogenous prostaglandin receptor.

INTRODUCTION

CCK and secretin have important actions on gastrointestinal motility *in vivo* and *in vitro*, but few reports have covered the gastric smooth muscle motility in guinea pigs. In this paper, we studied the action of CCK and secretin on isolated gastric smooth muscle in guinea pigs and compared it with those of the corresponding regions in rats^[1].

MATERIAL AND METHODS

Guinea pigs, weighing 250 g-350 g, male or female, were fasted but with free access to water for 24 h, hit the head to lose consciousness and the whole stomach was removed. The stomach was opened along the greater curvature and muscle strips (8 mm×2 mm) were cut, parallel to either the longitudinal or circular fibers [longitudinal muscle (LM) and circular muscle (CM) of fundus, body, antrum and CM of pylorus]. After removal of mucosa, each strip was suspended in tissue chamber containing 5 mL Krebs solution and constantly warmed by circulating water jacketed at 37 °C and supplied with 95% O₂ and 5% CO₂. One end of the strip was fixed to hook on the bottom of the chamber while the other one was connected by thread to an external isometric force transducer (JZ-BK, BK) at the top. Preparations were subjected to 1 g load tension and washed with 5 mL Krebs solution every 20 min. The contractions of gastric strips in 7 tissue chamber were simultaneously recorded on ink-writing recorders (LMS-ZB, Chengdu)^[2]. After incubating for 1 h, CCK-8 (10⁻¹ μmol/L, 10⁻² μmol/L, 5×10⁻² μmol/L) or secretin (10⁻¹ μmol/L, 10⁻² μmol/L, 5×

Received 1999-05-30 Accepted 1999-09-11

10^{-2} $\mu\text{mol/L}$) was added to the tissue chamber separately. CCK-8 and secretin were added together at the same time. To attain the final concentration 50 μL of reagent were added in a 5 mL bath.

We measured the resting tension of every strip, mean contractile amplitude of muscle strips of gastric body and antrum and the motility index $[\text{MI} = \sum (\text{amplitude} \times \text{duration})]$ of CM strips of pylorus. Frequencies of contraction were calculated by counting the contraction waves per minute. The results were presented by the increased percentage (%) of spontaneous contraction ($\bar{x} \pm s_{\bar{x}}$ %). The data were analyzed by Student's *t* test, and *P* values <0.05 were considered as significant^[3].

RESULTS

Effects of CCK-8 on spontaneous contraction of gastric muscle strips

CCK-8 increased the resting tension of muscle

strips in various regions of the stomach (Table 1), the mean contractile amplitude of antral CM and the motility index of pyloric CM, but decreased the mean contractile amplitude of body and antrum LM (Table 2), which were concentration-dependent. It also increased contractile frequencies of body LM, both LM and CM of antrum and pylorus CM (5.1/min \pm 0.2/min to 5.6/min \pm 0.2/min, 5.9/min \pm 0.2/min to 6.6/min \pm 0.1/min, 5.4/min \pm 0.3/min to 6.3/min \pm 0.4/min, 1.3/min \pm 0.2/min to 2.3/min \pm 0.3/min, respectively, $P<0.05$).

Atropine (10^{-2} mmol/L) decreased the tension of gastric muscle strips the mean contractile amplitude and the motility index of gastric strips in varying degrees but did not significantly affect the frequency of contractions. Atropine (10^{-2} mmol/L) given 3 min before administration of CCK-8 (10^{-2} $\mu\text{mol/L}$) did not affect the CCK-8 action on gastric strips (Tables 1, 2).

L(C)M, longitudinal (circular) muscle; dose: CCK-8 10^{-2} $\mu\text{mol/L}$, secretin 10^{-2} $\mu\text{mol/L}$; atropine 10^{-2} mmol/L, indomethacin 10^{-2} mmol/L; ^a $P<0.05$, ^b $P<0.01$ vs control; 0, no effect; $\bar{x} \pm s_{\bar{x}}$ % increase.

Indomethacin (10^{-2} mmol/L) also decreased the resting tension and the mean contractile amplitude, but did not significantly affect the frequency of contractions. Indomethacin (10^{-2} mmol/L) given 3 min before administration of CCK-8 (10^{-2} μ mol/L) similarly did not affect the CCK-8 action on gastric strips (Tables 1, 2).

Effects of secretin on the spontaneous contraction of gastric strips

Secretin (10^{-1} μ mol/L, 10^{-2} μ mol/L, 5×10^{-2} μ mol/L) did not significantly affect the resting tension, the mean contractile amplitude, the motility index and the contractile frequency on gastric strips.

Effects of combined CCK-8 and secretin on the spontaneous contraction of gastric strips

When CCK-8 (10^{-2} μ mol/L) and secretin (10^{-2} μ mol/L) were combined, the effect was similar to CCK-8 (10^{-2} μ mol/L) alone (Tables 1, 2).

DISCUSSION

CCK-8 could increase the mean contractile amplitude of antral CM and motility index of pyloric CM of guinea pigs which was similar to that seen in rats^[1]. CCK-8 increased the resting muscle tension, the contractile frequency of body LM, antral LM and CM and pyloric CM, it decreased the mean contractile amplitude of body and antral LM, but did not affect the gastric strips of the corresponding regions in rats. Meanwhile, the mechanism of action of CCK-8 on gastric smooth muscle has not been elucidated. Grider *et al.*^[4] considered CCK-8 could contract isolated CM of body in guinea pigs, but it was not blocked by TTX and atropine, therefore CCK-8 might have direct effect on smooth muscle cell. Gerner^[5] believed that CCK-8 could increase the resting tension of fundus, and contractile amplitude of antrum which could be partly mediated via cholinergic nerve pathway. Our results demonstrated that the CCK-8 effect was neither blocked by atropine nor blocked

by indomethacin, it suggests that action of CCK-8 is not mediated via prostaglandin. The fact that CCK-8 increased the contractile frequency of gastric strips in guinea pigs as well as in dogs required further study^[6]. Secretin did not affect gastric strips activity obviously in guinea pigs and when CCK-8 and secretin were combined the effect was similar to that of CCK-8 alone. It showed that secretin neither affected the isolated gastric strips in guinea pigs nor affected the action of CCK-8 on gastric strips, but secretin decreased the resting tension of LM and CM of fundus, and body, the mean contractile amplitude of LM and CM of antrum in rats. When CCK-8 and secretin were combined, the action the increase in mean contractile amplitude of LM and CM of antrum by CCK-8 was eliminated in rats. There was marked discrepancy in response to secretin in isolated gastric strips of guinea pigs and rats. It was reported that guinea pig had a special gastrointestinal pancreas system^[7], whether these are related to the above factor as yet could not be answered. CCK-8 and secretin both have physiological modulating function on gastric emptying in rats^[8], whether the same occurs in the guinea pigs, need further studies.

Immunocytochemical identification and localization of APUD cells in the gut of seven stomachless teleost fishes

Pan QS, Fang ZP and Zhao YX

Subject headings stomachless teleost fishes; APUD cells; intestinal mucosa; immunocytochemistry

Abstract

AIM To study the cell types, localization, distribution density and morphology of APUD cells in the intestinal mucosa of stomachless teleost fishes.

METHOD By using the peroxidase-antiperoxidase complex (PAP) immunocytochemical staining technique the identification, localization and morphology of immunoreactive (IR) endocrine cells scattered in the intestinal mucosa of grass carp (*Cyropharyngodon idellus*), black carp (*Mylopharyngodon piceus*) and common carp (*Cyprinus carpio*) were investigated with 20 kinds of antisera prepared against mammalian peptide hormones of APUD cells, and likewise by using avidin-biotin-peroxidase complex (ABC) method those of silver carp (*Hypophthalmichthys molitrix*), bighead (*Aristichthys nobilis*), silver crucian carp (*Carassius gibelio*) and bluntnose black bream (*Megalobrama amblycephala*) were also studied with 5 different antisera. The replacement of the first antiserum by phosphate buffered saline (PBS) was employed as a

control. IR endocrine cells were counted with a square-mesh ocular micrometer from 10 fields selected randomly in every section of each part of the intestine specimen. The average number of IR endocrine cells per mm² was counted to quantify their distribution density.

RESULT Gastrin (GAS), Gastric inhibitory peptide (GIP), glucagon (GLU), glucagon-like immunoreactants (GLI), bovine pancreatic polypeptide (BPP), leucine-enkephalin (ENK) and substance P (SP)-IR endocrine cells were found in the gut of grass carp, black carp and common carp, and somatostatin (SOM)-IR endocrine cells were only seen in common carp. GAS, GIP and GLU-IR endocrine cells were found in the intestinal mucosa of silver carp, bighead, silver crucian carp and bluntnose black bream. Most of IR endocrine cells had the higher distribution density in the foregut and midgut, and were longer in shape. They had a long apical cytoplasmic process extended to the gut lumen and a basal process extended to adjacent cells or basement membrane and touched with it. Sometimes, the basal cytoplasmic process formed an enlarged synapse-like structure in the contiguous part with basement membrane. This phenomenon provided new morphological evidence for neuroendocrine and paracrine secretory function of these enteroendocrine cells.

CONCLUSION At least 8 kinds of IR endocrine cells were found in the gut of stomachless teleost species for the first time in China. These IR endocrine cells scattering in the gut mucosa belong to the APUD system. Among them, the hormones secreted by SP-, ENK-, SOM- and GLU-IR endocrine cells belong to the peptides of dual distribution in the brain and gut. This provided new evidence for the concept of brain-gut peptide. According to the cell types, distribution density, morphological characteristics and variety in shape of APUD cells in the gut of stomachless teleost fishes, it is deemed that the digestive tract of fishes is also an endocrine organ of great importance and complexity.

INTRODUCTION

Gastrointestinal endocrine cells are different from other cells of endocrine gland, are discrete cells spread among the gastrointestinal mucosal epithelial cells. Pearse first proposed that all endocrine cells which produced peptide hormones were called APUD (amine precursor uptake and decarboxylation) cells in 1968^[1,2]. APUD cells can be divided two groups: in one are those located in the nervous system, and in the other group are there distributed in the peripheral organs, mainly the digestive system. Many studies of the mammalian gastro-entero-pancreatic (GEP) endocrine system have been reported, which, to date, have resulted in the identification of about 18 endocrine cell types and at least as many hormones^[3-5]. Enteroendocrine cells of fishes are difficult to demonstrate. For example, most of the identification procedures, which were found to be positive for mammalian enteroendocrine cells, failed on adult fish species. There was only a faint reaction with argyrophilic stains and with lead haematoxylin^[6], and also could not identify the types or species of endocrine cells^[7]. Although endocrine cell types that exist in the fish gut may differ from those of mammals, the questions of a cross-species specificity of anti sera against mammalian hormones and whether these antisera will show immunoreactivity in the gut of fish are very important. Recent years immunocytochemical studies using antisera against mammalian hormones clearly showed the existence of endocrine cells in the digestive tract of some teleost fishes^[8-12]. Our series of studies also showed that antisera against mammalian hormones could be effectively used on teleost species, and identify the types of APUD cells in the GEP of fish species^[13-19]. This paper reports the cell types, localization, distribution density and morphology of APUD cells in the gut of 7 kinds of teleost fish species cultivated mainly in China. The studies will provide new informations about neuro-endocrinology (the concept of brain-gut peptide hormones) animals, physiology, pathology and gastroenterology of animals.

MATERIALS AND METHODS

Specimens

Seven kinds of teleost fishes, grass carp (*C. idellus*), black carp (*M. piceus*), common carp (*C. carpio*), silver carp (*H. molitrix*), bighead (*A. nobilis*), silver crucian carp (*C. gibelio*) and bluntnose black bream (*M. amblyocephala*), 3-6 fish of each species, were used in this studies. All fishes were reared temporarily and dissected after 2 days fasting. The digestive tract was drawn out, and the gut was divided into five pieces: the anterior segment of foregut, posterior segment of foregut,

midgut, anterior segment of hindgut and rectum. All specimens were fixed by immersion in Bouin's fluid for 24 h, dehydrated and made transparent through ethanol-xylene serial procedures, embedded in paraffin (54 °C) and sectioned (5 µm). The sections were mounted on slide, treated with gelatin and dried 12 h at 45 °C.

Antisera and main reagents

The details of antisera and main reagents used are listed in Table 1.

Immunocytochemical staining steps and counting

① Put into 3% H₂O₂-methanol for 10min at 20°C to block auto-peroxidase; ② to incubate with normal goat serum for 30min at 20 °C for preventing nonspecific reactivity; ③ drop in 20 different first antisera separately and incubate for 20 h at room temperature (for PAP method); ④ drop in 5 kinds of first antisera separately and incubate for 20 h at room temperature (for ABC method); ⑤ for PAP method to see reference 13, and for ABC method to consult reference 19; ⑥ the control was treated in step with adjacent continuous section of immunocytochemical staining slice except replacement of the first antisera with phosphate buffered saline (PBS). IR endocrine cells were counted and photographed with an Olympus photomicroscope (PM-10AD) from 10 fields selected randomly in every section of each part of the gut per specimen with a square-meshed ocular micrometer (0.5 mm). The average number of IR endocrine cells per mm² was counted to quantify their distribution density.

RESULT

Cell types and distribution characteristics of IR endocrine cells

GAS-, GIP-, GLU-, BPP-, ENK-, GLI-, SP- and SOM-IR endocrine cells were found in the intestinal mucosa of *C. carpio*; these cells, except SOM-IR endocrine cells, were seen in *C. idellus*, and *M. piceus*. Only GAS, GIP- And GLU-IR endocrine cells were found in the gut of *H. molitrix*, *A. nobilis*, *C. gibelio* and *M. amblyocephala*. The location, distribution and density of IR endocrine cells in the gut of 7 teleost fishes are listed in Table 2 & Table 3. Most of IR endocrine cells distributed in the foregut of 7 kinds of fish species. Only SP and GLI-IR endocrine cells were not found in the foregut of *C. carpio*, but they were most abundant in the midgut. SOM-IR endocrine cells distributed only in the foregut and midgut of *C. carpio*. In most conditions, the distribution of cell types and density were decreasing along the gut in a distal direction after the foregut. GAS-, GIP- and GLU-

IR endocrine cells distributed in the gut of all 7 kinds of fishes. GLU-IR endocrine cells were the most, up to 126 cell s/mm², in the midgut of *H. molitrix*. All controls for every IR endocrine cell in the gut of 7 kinds of fish species were negative. Eight kinds of IR endocrine cells distributed mainly

among the epithelium of intestinal mucosa, and only a few of them existed in the lamina propria (Figure 1). Some of the cells were dispersed in the middle and bottom part of the gut fold (Figure 2), but most of them were scattered in the apical part of the gut fold (Figures 3-10).

Morphological feature of IR endocrine cells

All the IR endocrine cells showed a dark brown colour, and in the cell body and cytoplasmic processes, the secretory granules were seen clearly (Figures 6-9). The shape of IR endocrine cells was distinctive and variform, and quite different from the epithelial and goblet cells. Most of them had one or two long cytoplasmic processes, causing the apical part to be long and thin, the basal part narrow and the middle part of cell body to be broader. The cell nuclei were located in the middle part of body, and showed an empty bubble shape. Sometimes, the cytoplasmic processes showed one or several expanded sacs which were filled with secretory granules (Figures 6-9). The basal cytoplasmic processes emerged an enlarged synapse-like structure in the contiguous place with basement membrane or adjacent cells (Figures 7-10). A few of IR endocrine cells had only one cytoplasmic process or none (Figures 2, 5).

DISCUSSION

The results of the present study revealed that 3-8 kinds of enteroendocrine cells in the gut of 7 stomachless teleost fishes could produce immunoreactive response with antisera which were prepared against mammalian hormone. At the present time, because of the absence of isolates gastro entero pancreatic hormones in fishes antisera

against fish hormones are not available, and so the other 12 antisera against mammalian hormones used in the present study did not cause immunoreactive response with enteroendocrine cells of teleost fishes. Therefore, further investigations into the enteroendocrine cells of teleost fishes are necessary.

The description of GAS-, SP-, GLI-, BPP- and ENK-IR endocrine cells in the present study was generally similar to the results of Rombout's study^[6,20] on the enteroendocrine cells in the stomachless fish *Barbus conchoniensis*. The result that the 8 kinds of IR endocrine cells which were more abundant in the first half of the gut of teleost fishes in our study was also similar to that of the study on *B. Conchoniensis*^[20]. Rombout^[6] considered SOM-IR endocrine cells only existing in the gut of stomach-containing teleosts; this was different from our study in which SOM-IR endocrine cells were found in the gut of a stomachless teleost fish *C. carpio*.

The distribution density and location of various endocrine cells have some relation to their function. For example, GAS-IR endocrine cells in the stomach of human and other mammals stimulate gastric acid secretion, but these cells distribute mainly in the anterior segment of foregut of 7 stomachless fish species. The anterior segment of the foregut (gut bulb) of stomachless teleosts is like the stomach, and serve a dual function of storing and digesting food-stuff^[7,13]. There is a great amount of food in the anterior segment of foregut, and because of the stimulation of undigested particles of food, the activation of endocrine cells there is increased, resulting in the release of greater amount of hormones^[15,20]. Substance P can stimulate a contractile function of smooth muscle^[1], and SP endocrine cells are more numerous in the rectum; thus these endocrine cells may enhance the contraction of smooth muscle while fish excretes^[7]. The differences of cell types and amounts of IR endocrine cells in various fish species relate to their feeding behavior and feeding habits^[14-16,21]. Owing to the differences of chemical composition and pH value of the contents in the gut, the amount of hormones released by endocrine cells is also affected^[13,14]. Our studies verify that IR endocrine cells of stomachless teleost fishes belong to the open type^[1,21], that is, hormones are carried to the gut lumen (lumen-endocrine) by a long apical cytoplasmic process^[2,21]. The sac-shaped enlargement of cytoplasmic process has the function of storing. The close type IR endocrine cells lacking the cytoplasmic process seem to be caused by the angle during sectioning^[7]. In fact, almost all enteroendocrine cells seem to be the open type^[1]. In addition, some IR endocrine cells' basal

cytopoasmic processes extend to the basement membrane or adjacent cells, and form the synapse like structure in the contiguous portions, there by providing morphological evidence for the paracrine and neuroendocrine functions, and furthermore the peptide hormones they secrete may have neurotransmitter function^[1,2,21,22]. Previous studies propounded the peptide hormones SP, ENK, SOM and GLU to be present only in the brain^[1], but the present study confirmed their existence also in the gut mucosa of stomachless teleost fishes. Wang *et al*^[1] thought that the area of gastrointestinal mucosa was very large; the sum total of gastrointestinal endocrine cells exceeded a lump sum of cells in all other endocrine gland; thus, the digestive tract mucosa was reputed to be the biggest and the most complex endocrine organ in body. Rombout^[6] concluded the endocrine system of digestive tract in teleost species was almost as complicated as in mammals. According to the present progress in the studies on the APUD cells in gastro-entero-pancreatic endocrine system of the fish species^[21], it is deemed that the digestive tract of fish species is also an endocrine organ of great importance and complexity.

INTRODUCTION

It is axiomatic that the most effective and soundly based plan of treatment of any disorder is one aimed at the mechanism or mechanisms responsible for its development^[1]. This basic notion, coupled with recent reports^[2-11] in which, surprisingly there is a total lack of reference to the probable involvement of autonomic-arc-reflexes in the physiopathogenesis of biliary acute pancreatitis have prompted this presentation. Undoubtedly, this disease entity has numerous causes, an obscure physiopathology, few effective remedies, and, often, an unpredictable outcome. At the turn of the century, Opie^[12,13] brought to light the association between gallstone migration and acute pancreatitis. When referring to the intimate evolving process, most authors steadily adhere to the Opie's theories: chemical and physical. The former is linked to the common-channel or biliary-reflux mechanism. The latter, to the stone -elicited Wirsung duct obstruction, with the resultant hypertension in the pancreatic ductal tree. What is indeed surprising is the lack of speculation on the subsequent steps that necessarily must follow the initial chemical and/or physical injuries that end up in an episode of acute pancreatitis. The core of our contention is that the pathophysiology of biliary acute pancreatitis is centered on two basic mechanisms: the activation of autonomic arc reflexes and the disruption of the

entero-pancreatic feedback loop. Superimposed on the aforementioned pivotal processes we must consider, in some cases, the aggravating role of alcoholism.

In this presentation we will also try to point out those features that justify to consider the Pfeffer method, or of the closed-duodenal-loop, as an experimental surgical model suitable to mimic the clinical condition of acute pancreatitis. Furthermore, we will analyze the properties of local anesthetics that, according to our contention, are valuable agents to either prevent and/or treat efficaciously an episode of biliary acute pancreatitis.

ACTIVATION OF AUTONOMIC-ARC-REFLEXES

The clinical or surgical circumstances that usually evoke an episode of biliary acute pancreatitis, e.g. a stone that migrates into the duodenum or gets impacted in the distal end of the common bile duct^[12,13], endoscopic maneuvers (sphincterotomy, sphinctero-manometry, retrograde cholangio-pancreatography), surgical manipulation , in or close to the duodeno-pancreas, percutaneous liver biopsy-associated hemobilia^[14], have as a main starting locus of activation of the autonomic-arc-reflexes the peri-Vaterian duodenum. This intestinal segment is the most sensitive area of what we have conceived as the trigger of an imaginary pancreatic revolver (Figure 1). Our choice of this pedagogical reference was suggested, on the one hand, by the morphologic resemblance with the gun that the pancreatic gland offers in its general anatomical outline, and, on the other, by its functional characteristics^[15,16]. The exquisite sensitivity of the trigger zone rests on its innervation density. This has been suggested, initially, by the macroscopic anatomical dissection findings in human cadavers and dogs^[17-19]. Recently , by those observed in rats and the opossum (Figure 2). Subsequently, histochemical studies^[20-23] and the utilization of very elaborate tracers^[21-23], allowed to fully ratify the initial gross anatomical observations. Some of the nerve fibres that jump the duodeno-pancreatic cleft belong to the vagal system. They arrive to the head segment of the pancreas following a pathway through the gastric and duodenal walls^[19,24-34]. Others contingents of nerve fibres are intrinsic to the duodeno-pancreas. They connect the enteric

nervous system of the stomach and duodenum with the pancreatic gland (Figure 3). Some of them are cholinergic, and many are serotonergic. They end either in the pancreon units^[15,16,18,19] and/or the intrapancreatic ganglia^[17-19, 20-23, 25,26]. Following the same route, nerve fibres that belong to the afferent component of the autonomic nervous system jump the duodeno-pancreatic cleft in search of either the nodose ganglion of the vagus or the dorsal root ganglia of the spinalcord^[35-46]. These duodeno-pancreatic nerve fibres are the basis of duodeno-pancreatic reflexes.

They are short, medium, and long^[17-20,24-26,33]. The short duodeno-pancreatic reflex connect the enteric nervous system of the duodenum with the intrapancreatic ganglia and/or the bullets of the pancreatic revolver: the pancreon units and the Langerhans islets^[21-23]. The medium duodeno-pancreatic reflex gets its integration in the celiac ganglia. The long duodeno-pancreatic reflex complete the arc reflex loop in the central nervous system, primarily in the hypothalamic-bulbar nuclei. A feature to emphasize is the presence of command neurons in the peri-Vaterian duodenum^[28-32]. They exert a pre-programmed control of the interdigestive motor complex. Concerning the source of the duodenal innervation, its proximal segment, at least in the rat, is under the control of the left or anterior vagal nerve. Contrariwise, the peri-Vaterian duodenum is primarily subjected to nervous influences coming from the celiac ganglia^[47-61].

The pancreatic gland innervation depends on the following complex systems: the vagal, the splanchnic-celiac, the entero-pancreatic and the sensory-afferent^[17-26, 40-46], (Figure 3). In the first two complexes, one should take into consideration the existence of three different kinds of impulses: cholinergic, adrenergic and peptidergic. The above description is valid for both the exocrine and the endocrine pancreas^[46]. Summarily, the vagal complex arrives to the pancreatic gland following the pathways of either the digestive tract wall (stomach-duodenum) or through the celiac ganglia. Its nerve fibres are essentially afferent. It also carries peptidergic influences and efferent impulses, primarily cholinergic. The splanchnic-celiac-ganglia-complex is also a nervous afferent pathway, namely of the pain sensation. From the efferent point of view, this complex is primarily of sympathetic impulses. Secondly, is a transmitter of peptidergic and cholinergic efferent impulses. The entero-pancreatic-complex is the result of neurons that project from the gut to the pancreas. According to the Gershon group^[21-23], the nerve cells are essentially cholinergic and serotonergic. They influence the activity of intrapancreatic neurons and

islet cells^[46]. The sensory-afferent of the autonomic nervous system, through the mediation of its fine, myelinated, capsaicin-sensitive type C fibres, constitute the basis of the neurogenic-inflammation^[35-39,59-65].

As a preamble to the consideration of the autonomic-arc-reflexes, it seems appropriate to point out that the autonomic ganglia in the extrahepatic bile ducts and the pancreatic gland display similar histoarchitectural and physiologic features to those of the enteric nervous system. This is explainable by their common embryological origin^[25,26]. When deprived of all outside neurons influences, the intrapancreatic ganglia can be shown to possess an intrinsic activity. The latter, coupled to outside cholinergic, sympathetic and peptidergic impulses give origin, within the gland, to what has been described, with tacit consensus, as cholinergic tone^[15-18, 25-27]. This is involved in an intricate interaction with the hormonal system. It has been ascertained on both pancreon segments: the acinar and the centroacinar-ductal, responsible, respectively, of the bicolic and the hydrolatic components of the exocrine pancreatic secretion^[15,16]. A feature to emphasize is the role of the celiac ganglia as an integration center of different kinds of autonomic arc reflexes^[17-19,21-25, 47-61]. The nerve fibres that arrive at the celiac ganglia come from different segments of the digestive tract, the extrahepatic bile ducts and the pancreas. In this autonomic nervous structure they establish an intricate interrelationship. The Faradic electrical stimulation of the celiac ganglia triggers an intrapancreatic ischemic process. This evolves as a result of the opening of arterio-venous shunts^[50-57]. We have delineated this autonomic-arc-reflex as sympatho-ischemic (Figure 4). It has been clearly observed subsequent to the instillation of bile or bile salts in the pancreatic ductal tree^[53]. The changes in the pancreatic vessels (spasms) and the gland's capillary circulation (ischemia) have been objectivized in plastic casts^[53]. The full development of the sympatho-ischemic autonomic-arc-reflex leads to a depression of the pancreon's secretory process. The exocrine pancreatic secretion inhibition can also be evoked through another type of autonomic-arc-reflex. We have pinpointed it as secretory-inhibitor. Its conception arose from our observation in canines equipped with duodenal Thomas cannula and studied in the conscious state (Pavlov frame). Indeed, when intemperate maneuvers are employed, especially if either liquid or air is injected abruptly into the main pancreatic duct (distention), a sudden arrest of exocrine pancreatic secretion is frequently observed. This secretory-inhibitor autonomic-arc-reflex can be elicited from other segments of the digestive tract. We have

observed it in rats when distending with a balloon either the antral-fundic junction of the stomach or the peri-Vaterian duodenum segment. A nervous reflex of this sort has been described by Warkentin *et al*^[49] on bile secretion when distending the colon or its nerve supply.

The pathway of this autonomic-arc-reflex is probably that of the afferent component of autonomic nervous system. At pancreas level, an antidromic mechanism (pseudo-axonic), and/or an arc reflex loop integrated either in the intrapancreatic or the celiac ganglia is a possibility. The involvement of a peptide like CGRP^[66], PP^[67] or some other agent, like serotonin could be a logical assumption to make. The intimate physiopathogenic mechanism is probably related to with the recent studies of Ohshio *et al*^[6] in rats. According to these authors, a short-term pancreatic duct obstruction interferes with the acinar cell secretory process down-stream of hormone-receptor binding, intracellular Ca^{2+} release and protein-kinase activation. The pseudo-axonic autonomic-arc-reflex, that leads to neurogenic inflammation, is evoked as a result of the irritation of the afferent component of the autonomic nervous system. Normally, through these nerve fibres a significant percentage of the information originated in the stomach, duodenum, extrahepatic bile ducts and pancreas reach the central nervous system. The impulses travel through special type of nerve fibres: thin, unmyelinated, capsaicin-sensitive (type C). In their course to the nodose ganglion of the vagus, or the dorsal roots ganglia of the spinal cord, they send collaterals where they exert a modulatory influence on the neural transmission (Figure 3 and 5). It is interesting that capsaicin (red-pepper agent), infused intraduodenally, evokes an exocrine pancreatic secretion equivalent to a 15 % of that obtained with a maximal dose of CCK^[63]. This pancreon's secretory response results from the activation of CCK-A receptors by the peptide CGRP released from the afferent nerve fibres. Others vasoactive peptides are involved, like SP, neurokinin-A, VIP, SOM and DYN. After synthesis in the somata of the afferent neurons, the bulk of the peptides is transported to their peripheral endings. The co-released peptides interact in the control of pancreatic function. Their antidromic release elicit vasodilatation and extravasation of plasma proteins and formation of edema (neurogenic inflammation)^[35-39,59-65,69-71]. A feature to take into account for its pathophysiologic implications is that SP, and other sensory peptides released in the pseudo-axonic reflex, are capable of activating mast-cells to release histamine and other factors. Furthermore, leukocytes, particularly neutrophils, granulocytes, monocytes and lymphocytes are stimulated to adhere

to the vascular endothelium and to emigrate to the surrounding tissue. Once neurogenic inflammation is triggered, monocytes release prostaglandins, thromboxane and cytokines^[36-39]. Some of the latter agents are vasoactive by themselves and, in addition, can activate afferent nerve endings and thereby provide a positive feedback loop which reinforces the initial stimulation of the afferent component of the autonomic nervous system (Figure 3 and 5). This whole process probably favors the absorption of endotoxin from the gut lumen into the blood stream. This agent is capable of inducing pancreatic lesions, depression of the exocrine pancreatic secretion and, in the liver, on the one hand, inhibition of albumin secretion, and, on the other, enhancing the secretion of both fibrinogen and C-reactive protein^[72]. In the afferent component of the autonomic nervous system it should be pointed out the presence of different types of receptors: chemoreceptors, chemonociceptors, polymodal nociceptors and warmth receptors^[60]. These nervous structures allow to detect those noxious stimuli that are potentially or actually harmful to the tissues. Besides, they also sense innocuous physiologic stimuli, such as pH, bile, distention. The afferent neurons represent a first line of defense against trauma, or, as in the stomach, to the injurious effects of ethanol^[62,63]. It is probable that the same happens in the pancreatic gland. That, normally, in this organ, the afferent component of the autonomic nervous system fulfill some sort of cytoprotective function against the deleterious effects of injurious agents, can be inferred by the fact that its permanent ablation, like the one that results from long-term surgical bilateral splanchnicectomy, aggravates the pancreatic lesions (necrosis) induced by 24h closed-duodenal-loop. This at least has been our experience in unpublished observations in rats^[73].

All the foregoing support the notion of autonomic-arc-reflexes involvement in the physiopathogenesis of biliary acute pancreatitis. Their degree of participation surely varies in each clinical case. This depending on the intrinsic characteristics of the injurious agent, its degree of persistence and the patient's neuroendocrine reactivity.

DISRUPTION OF THE ENTERO-PANCREATIC FEEDBACK LOOP

When bile and/or pancreatic juice cannot reach the duodenal lumen, the entero-pancreatic feedback loop gets interrupted. This triggers the rising of blood's CCK levels, and, through the induction of an increased cytosolic Ca^{2+} concentration, a supramaximal stimulation of the pancreon's acinar cells is elicited^[74-90]. The foregoing is linked to the

evoking of both positive and negative duodeno-pancreatic reflexes^[74]. Indeed, when in the duodenal lumen the influence normally exerted by bile, trypsin and chymotrypsin lessens (bile and/or pancreatic juice diversion bile and/or pancreatic duct obstruction) the releasing of CCK from the duodenal mucosa is markedly enhanced. This peptide through a paracrine mechanism in the duodenal wall, activates the autonomic nervous system. Thus, a positive duodeno-pancreatic-reflex (increased intrapancreatic cholinergic tone) is induced. This effect is potentiated by a concomitant annulment of a negative duodeno-pancreatic-reflex. The latter was postulated by us in the eighties^[74]. It might have as a pathway the entero-pancreatic nervous complex. A neurotransmitter (SOM ?, PP ?, serotonin ?) induced by the presence in the duodenal lumen of trypsin, chymotrypsin and/or bile, might be at the basis of restricting influences on the pancreon units (Figure 6).

Others features to take into account to better understand the entero-pancreatic feedback loop is that a monitor peptide in the pancreatic juice, and a CCK-releasing peptide, derived from the duodenal mucosa, exert a direct stimulating action on the CCK-releasing cells (I cells). These small peptides are normally inactivated by intraduodenal trypsin and chymotrypsin. Concerning bile, this secretion, besides activating the postulated negative duodeno-pancreatic-reflex, normally exerts an indirect feedback inhibition. The latter might result from the stabilization of pancreatic juice's protease by the calcium ions in it contained^[74,83-90]. A physiologic detail to emphasize is that unblocking of the bile obstruction allows the duodenal mucosa to release secretin^[91,92]. This hormone may help to dislodge, through an enhanced exocrine pancreatic secretion of water and bicarbonate, eventual intrapancreatic protein plugs. Besides, it may attenuate the noxious influences of CCK on the pancreon's acinar cells. The latter has been shown, initially by Kanno *et al*^[93], subsequently by Renner *et al*^[94], and, recently, through an agent (tetrafenyl actone) that has proved to possess a releasing capacity of this hormone from the intestine^[95]. A feature to be emphasized is that both secretin and VIP, through a second messenger (cAMP), either prevent or restore, in the acinar cells, the CCK-induced disrupted microtubules and microfilaments.

Aggravating role of chronic alcoholism

When the usual agents that elicit the biliary acute pancreatitis exert their actions superimposed on a background of chronic alcoholism, the degree and extension of the pancreatic acute inflammatory lesions are significantly enhanced^[96,97]. This notion is important because the incidence of a chronic

ethanol intoxication as a background of an episode of biliary acute pancreatitis is rampant. This assertion is confirmed by several recent papers^[96,97]. Experimentally, Gronr-os *et al*^[98-100] have ratified, in rats, our primary contention, described in dogs and rats^[101-118], that in the pathophysiology of ethanol-evoked pancreatic lesions two major factors play a crucial role: an elevated intrapancreatic acetylcholine level (high cholinergic tone) and an enhanced acinar cell response to CCK. At clinical level, Brugge *et al*^[119] have provided additional support to this postulation. Recently, we have suggested^[115,117,118] that the forementioned changes might be consequence of an alcohol-induced loss of a normal braking mechanism exerted by higher autonomic nervous centers. The braking on the pancreon units might depend on peptides like CGRP^[66], PP^[67] and/or SOM^[120,121].

As eventual aggravating influences associates to alcohol intoxication, one should consider the probable participation of an ethanol-evoked sphincter of Oddi dysfunction. Two reports give support to this assumption. The first one, performed in monkeys^[128], has disclosed that after the administration of a 130 mL/L ethanol solution there is a significant increase of the main pancreatic pressure. The second report^[121], has put in evidence, in humans, that acute intraduodenal ethanol induces an increase of the Vaterian resistance. This phenomenon is enhanced when performed in chronic alcoholics.

Others additional effects related to ethanol intoxication that merit their consideration are: the reduction of the capillary blood flow^[122] and the activation and migration of leukocytes in the pancreatic gland^[123].

Figure 7 Experimental mimicking of biliary acute pancreatitis in rats.

Modification of the classical Pfeffer method (closed duodenal loop), the temporary or short-term closed duodenal loop method. Filling of a duodenal loop (a) through the gastric antrum (b) with 7% sodium taurocholate and a few drops of methylene blue, at constant pressure. Height of liquid infusion column=110cm (c)

Experimental mimicking of biliary acute pancreatitis

At this stage, it seems relevant to analyze the data afforded by the experimental, surgical-induced acute pancreatitis of the Pfeffer method or of the closed-duodenal-loop^[124-131]. This procedure, according to our view, offers a suggestive approximation to those conditions which usually interplay, in a clinical setting, in an episode of biliary acute pancreatitis. Indeed, the closed-duodenal-loop model offers a series of conditions that somehow mimic those frequently seen in human cases of biliary acute pancreatitis, e.g. the distention and chemical injury of the peri-Vaterian duodenum, the bile-pancreatic hypertension, the eventual reflux of the duodenal content into the bile-pancreatic ducts, the disruption of the entero-pancreatic feedback loop due to the exclusion of both bile and pancreatic juice from the intestinal lumen and the bacterial aggression (endotoxemia).

In recent experiments in rats with a short-term closed-duodenal-loop method, that we have modified from Orda *et al*^[132] and De Rai *et al*^[133], we have observed changes of the pancreatic gland that, taking into account the brevity of the experiments, were unexpected^[134]. Indeed, after filling a duodenal loop with a 70 g/L taurocholate solution plus a few drops of blue-methylene, under a constant pressure of a 110 cm fluid column height, and keeping those conditions for only 3 min, the macroscopic evaluation of the pancreatic gland disclosed, 3 hours after, the presence of edema and spotty foci of acinar cell necrosis (Figure 7). Remarkably, the above changes were obtained under the total absence of any reflux of the duodenal content into the bile-pancreatic ducts. This crucial detail was verified by means of a constant visual observation of the duodeno-pancreas. Something we learned from the above test, is that it takes normally more than 20min, and sometimes even more than an hour, to appreciate the reflux of the duodenal content into the bile-pancreatic ducts. When this does indeed occur, a marked pancreatic edema is seen, and quite rapidly, a notorious hemorrhagic acute pancreatitis distinctly develops.

The above described results give further solid support to our contention that the irritation of the duodenum, at the level of the peri-Vaterian duodenum (trigger zone of the pancreatic revolver) is capable of activating autonomic-arc-reflexes. The latter, coupled with the changes evoked by the disruption of the entero-pancreatic feedback loop (bile-pancreatic obstruction) (Figure 6), probably explains, as we have already pointed out, the physiopathogenesis of the pancreatic lesions. This speculations of ours, that biliary acute pancreatitis is might pivot around the activation of autonomic-

arc-reflexes and a disruption of the entero-pancreatic feedback loop could perhaps be extended to explain, at least partially, the liver changes that recently have been pointed out by Iso gai *et al*^[135] in human patients with biliary acute pancreatitis. Indeed, in the reports of these authors, a feature to be emphasized is that both the liver's histopathologic changes and the biochemical abnormalities were of the same order of magnitude in patients with and without impacted stones in the Vaterian region. This set of circumstances allow to infer that besides bile duct hypertension other factors (autonomic reflexes) might be at the basis of the above findings. An anatomical detail that gives support to the precedent contention is that of the rich density of nerve fibres in the hepatic hilum that we have put in evidence in macroscopic dissection studies in human cadavers^[17-19].

Another observation that deserves to be emphasized because it affords additional indirect basis to presume an involvement of autonomic-arc-reflexes in the physiopathogenesis of biliary acute pancreatitis is the one associated to a pure distention of bile ducts without the intervention of any intemperate maneuver or the irritation of a chemical agent. This is what suggestively happens with the acute pancreatic inflammation that have been reported in cases of hemobilia, accidental or iatrogenic (post-percutaneous liver biopsy)^[14].

Preventive and therapeutic value of local anesthetics

All the above findings give coherent basis to consider an eventual beneficial effect of local anesthetics either as preventive and/or therapeutic agents of an episode of biliary acute pancreatitis. A long experience in conscious dogs with lidocaine spray in the peri-Vaterian duodenum^[19,24,28,30,33] has convinced us, on the one hand, of their efficacy to interrupt noxious autonomic-arc-reflexes and depress the intrapancreatic cholinergic tone, and, on the other, of their relaxing capacity on both the main pancreatic duct outlet and the duodenal motor activity. The above anesthetic-induced changes make easier the catheterization of the Vater papilla in man. Consequently, the changes of its traumatization are significantly reduced. A detail to be emphasized is that of the atropine-like effects evoked by local anesthetics (procaine, lidocaine) in the duodenum and the sphincter of Oddi described by Varela-López *et al*^[136,137], by Velasco Suarez^[138,139], Cottini^[24] and by our group^[24,28,30,33].

The forementioned authors have given convincing evidence of the local anesthetic value not treating clinical cases of sphincter of Oddi dysfunction or bouts of recurrent stone impaction in the distal common bile duct. The procedure most frequently used was of a duodenal infusion of

procaine clorhydrate (20 mL of a 10 g/L solution) or an oral ingestion of this anesthetic (0.2 g up to 1.2 g/24 h). With this latter approach, we succeeded in sparing a sphincterotomy in several patients with common bile duct residual stones following a laparoscopic cholecystectomy.

It is worth remembering that Albanese^[69], Longo and Sosa Gallardo^[64,65], Salazar^[59] and Ochsner^[70] have given solid accounts of the clinical therapeutic value of a temporary interruption of the autonomic-arc-reflexes by means of a local anesthetic of the celiac ganglia. This was experimentally ratified by the group of Waisman^[58]. Indeed, these authors have shown, in rats subjected to a 24 h closed-duodenal-loop procedure, that those animals in which a single infiltration with lidocaine was performed had a significantly longer survival than the controls.

Local anesthetic bathing of the duodenum, namely at the level of the peri-Vaterian duodenum, or the anesthetic infiltration of the duodeno-pancreatic cleft, and/or of the celiac plexus, during an eventual laparotomy, constitute, according to our postulation, an efficacious means to prevent, or attenuate, the intensity of autonomic-arc-reflexes. Furthermore, they surely contribute to depress the intrapancreatic cholinergic tone. This is important in cases of an episode of biliary acute pancreatitis superimposed on a background of chronic alcoholism. They might do this through the interruption, on the one hand, of cholinergic impulses that course through the gastro duodenal wall, and, on the other, by blocking the CCK release from the "I" endocrine cells and the subsequent evoking of duodeno-pancreatic reflexes^[18,19,25,26,63,140]. The latter is suggestively supported by the recent demonstration that vagal mucosal receptors are directly sensitive to CCK-8^[141,142]. Besides, as it has been pointed out by Bj-rck *et al*^[71] and Mc Cafferty *et al*^[143], many other properties of local anesthetics, in addition to those of inhibiting action potentials by blocking sodium channels, are surely involved. The foregoing might explain the therapeutic success reported with intrarectally infused lidocaine in the treatment of ulcerative colitis^[71]. In a recent report^[144], it has been shown that in patients subjected to ERCP and therapeutic endoscopy (e.g. sphincterotomy, stone removal, etc.) and randomly assigned to have ① 10 mL of 10 g/L lidocaine sprayed onto the ampulla before or after, or, ② saline, either pre or post ERCP, that local anesthesia applied to the ampulla before ERCP facilitates cannulation of the ampulla and appears to reduce hyperamylasemia whether given before or after ERCP. When considering further experimental evaluation with local anesthetics, related to either the prevention or treatment of

biliary acute pancreatitis, one should take into consideration the results recently reported in rats by Mc Cafferty *et al*^[143]. Indeed, it is remarkable that the intrarectal administration of 0.5 mL of 25 g/L carboxymethylcellulose, containing lidocaine hydrochloride, at dosis ranging from 5 mg/kg to 100 mg/kg had induced a significative reduction of the colitic score and of the myeloperoxidase activity.

In recent experiments in rats with our "short-term-closed-duodenal-loop" model^[134], we showed that previous bathing of the duodenum with lidocaine (20 mg/kg) reduced the histopathologic score of pancreatic necrosis observed in the control group. This was confirmed in a subsequent series^[145]. It is our postulation that through the interruption of autonomic-arc-reflexes one could interfere in the release of cytokines at pancreas level^[146-154]. This is also suggested by our recent findings in the opossum^[155].

Concerning the variable effects of a local anesthetic (lidocaine) on exocrine pancreatic secretion according to the route of administration, e.g. intraduodenal vs intravenous, we have acquired a long experience in dogs equipped with a duodenal fistula (Thomas cannula) and tested in the conscious state^[33]. From them, we have learned that spraying of the papillar zone (trigger of the pancreatic revolver) with lidocaine (50 mg each, 10 min for 2 h) induces a significant depression (60%) of the plateau levels of all secretin-induced parameters. Remarkably, and coherent with the anatomical details previously outlined, the above exocrine pancreatic secretion changes were not observed with lidocaine spraying outside the papillar zone. Other suggestive findings were, firstly, that the intravenous infusion of the same amount of lidocaine (500 mg dissolved in 200 mL physiological saline = 12.5 mg/kg), did not modify any of the exocrine pancreatic secretion parameters and secondly, that when the intraduodenal lidocaine testing was performed in alcohol-fed dogs (2-year), the degree of the anesthetic-induced depression of the exocrine pancreatic secretion was less notorious (35%) than when carried out in controls (65%). We have interpreted this difference as a reflection in the ethanol-fed animals of a higher duodeno-pancreatic cholinergic tone. It is interesting that at clinical level this assertion has been ratified by Brugge *et al*^[119]. Other considerations that seem relevant to point out is that of the extraneuronal effects of local anesthetics. In addition to our presumption that through the interruption of autonomic-arc-reflexes they interfere with the release of inflammatory mediators at pancreas level, they inhibit the phospholipase A2 enzyme and its interaction with its specific substrate: the cell membrane phospholipids. The latter was shown by

Aho *et al*^[151] following their experiments on acute pancreatitis treated with a procaine solution (40 mg/kg).

Finally, and in order to complete the attempt to interrupt the evolving of the mechanism that we have considered as pivotal in the physiopathogenesis of biliary acute pancreatitis, it would seem logical to add to local anesthetics the simultaneous administration of pancreatic enzymes^[75,83,86,87] and, eventually, of a calcium channel blocker^[89,152]. Concerning the former, the oral and/or the intragastric-intraduodenal administration of pancreatic enzymes, might accomplish, on the one hand, the depression of the CCK release from the intestinal mucosa, and, on the other, the evoking of our previously described neural mechanism of "pancreon" inhibition, the negative duodeno-pancreatic reflex. In relation with calcium channel blockade, it is interesting to point out the recent finding of Hughes *et al*^[153] in rats. Indeed, these authors have shown that the administration of diltiazem is associated with significant reduction in serum TNF- α levels as well as amelioration of pancreatitis by biochemical and pathological criteria. They emphasize that TNF- α mediates tissue injury through the activation of inflammatory cells, the up regulation of adhesion molecules, the production of nitric oxide and the release of other cytokines and mediators of inflammation.

INTRODUCTION

The word omentum derives from the ancient Egyptians who, when embalming human bodies, used to assess their "omens" by looking at the variations in what we recognise today as the omentum^[1]. Galen (128-199 AD) thought that the role of the omentum was to warm the intestines. This was on the basis of a gladiator who had an omental resection after a stab injury and suffered greatly from cold for the rest of his life^[2]. A more conventional view of the omentum is that it plays a central role in peritoneal defence by adhering to sites of inflammation, absorbing bacteria and other contaminants, and providing leukocytes for a local immune response^[3]. This review details current knowledge on the origins, structure, and function of the omentum, and discusses its role in the peritoneal cavity during various disease states.

ORIGINS

The omentum appears to have evolved as a primitive effector organ in lower vertebrates. It develops as a loose mesothelial sheet of tissue from the yolk sac and is capable of basic immune functions such as allorecognition, natural cytotoxic reactions and the elaboration of cytokines. This area resides in lower vertebrates within a region delineated by the anterior limbs, foregut and mesonephros. That region is analogous to the boundaries of the developing omentum in mammals^[4]. The immune system in humans has evolved from these origins to a very sophisticated level, yet the omentum has retained an important role in immune defence within the peritoneal cavity.

Departments of Surgery and Pathology*, The University of Western Australia

Dr Cameron Platell graduated in 1984 and is currently a Senior Lecturer and specialist Colorectal Surgeon within the Department of Surgery at the University of Western Australia. Dr Platell's main research interest is peritonitis.

DEVELOPMENT AND STRUCTURE

The greater omentum develops in the eighth week of gestation from the dorsal mesogastrium^[5]. It is composed of two mesothelial sheets which enclose predominantly adipocytes embedded in a loose connective tissue, and also aggregates of mononuclear phagocytic cells. The omentum has a rich vascular supply with numerous characteristic capillary convolutions which are termed omental glomeruli due to their similarity to renal glomeruli. These capillary beds lie directly under the mesothelium^[6]. The size of the omentum varies from 300 gm to 2000 gm with a surface area of 300 cm² to 1500 cm².

In the omentum, the leukocytes aggregate in the perivascular area to form what is termed milky spots. These structures were first described by the French anatomist Ranvier in 1874^[7]. The cells derive their origin from the mononuclear phagocyte system^[8] and are arranged around the omental glomeruli that lie directly beneath the mesothelium^[9]. These structures are supported by delicate networks of reticular fibres which constitute the framework of the organ^[10]. In humans, milky spots comprise of macrophages (70%), B-lymphocytes (10%), T-lymphocytes (10%), mast cells, and stromal cells. On an ultrastructural level, it has been found that the macrophages are present in different stages of maturation, and that they can readily enter or leave the milky spots^[11]. The mean number of cells in one milky spot is approximately 600^[12] (Figure 1). Milky spots develop as specific structures in the greater omentum between the 20th and 35th week of gestation^[5]. The number of milky spots is highest in infancy and gradually decreases with age^[13].

Both the endothelium lining the omental capillaries and the mesothelium overlying the milky spots are specially adapted to facilitate transmigration of leukocytes^[14], and for rapid fluid shifts. The endothelial lining of the blood vessels in the milky spots is either discontinuous or contains fenestrations^[15]. Similarly, there are intercellular pores (the classical stomata of von Recklinghausen) between the mesothelial cells overlying milky spots, and there is an absence of the associated basal lamina in the submesothelial connective tissue^[16] (Figure 1).

The macrophages in the mature omentum are essentially scavengers. They appear to differentiate from monocytic precursors in the milky spots and are not dependent on precursors derived from the bone marrow^[17]. They are dendritic in shape and

have marked phagocytic abilities. They avidly phagocytose intraperitoneally injected carbon particles and bacteria. When activated, the macrophage precursors in the milky spots proliferate, migrate to the mesothelial surface, and transform into dendritic-shaped macrophages. This process in mice is dependent on macrophage colony stimulating factor (MCSF) being locally produced in the milky spots^[17]. Interestingly, the omental macrophages, despite their dendritic shape, lack many specific features of true dendritic cells.

The omentum contains large numbers of B and T lymphocytes which are usually located in the periarteriolar area. Following antigen challenge of the peritoneal cavity, the number of lymphocytes in the milky spots may increase up to 40-fold. Although it is unclear whether this increase represents local proliferation or an influx of cells. With such stimulation, the B and T-lymphocytes are found to segregate into distinct areas *in situ*, and the lymphocytes appear to be associated with stromal cells. Nonetheless, these aggregates do not represent secondary lymphoid organs, because they do not contain interdigitating cells or follicular dendritic cells^[11,18]. The omentum appears to be a primary site of B-lymphocyte development^[19,20]. In experimental animals, the omentum is a source of unique B-lymphocytes that demonstrate specific surface markers. These B-lymphocytes are predominantly CD5+(Ly1+), and are common in not only the omentum but also the peritoneum. However, they are rare in the blood, spleen and lymph nodes. Conventional B and T-lymphocytes are not found in the omentum. The CD5+B lymphocytes develop in the omental milky spots independently from the thymus or bone marrow^[19,20]. Hence, the fetal omentum, like the fetal liver and bone marrow, acts as a primary site of B-lymphocyte development^[21] and may be considered as a sort of intestinal thymus^[4,22]. The function of these CD5+ B lymphocytes remains obscure, nonetheless, they are most likely a remnant of a more primitive immune system which is in keeping with the evolutionary origins of the omentum.

Mesothelial cells lining the peritoneal cavity and endothelial cells lining blood vessels share the same mesodermal origin^[23]. Human omental microvascular endothelial (HOME) and mesothelial (MESO) cells share many phenotypic properties. In distinguishing between the two cell types, HOME and not MESO cells express a number of specific surface markers (i.e. E-selectin, P-selectin (CD62), and Le-y) and form tube-like structures when cultured on Matrigel. MESO cells differ from HOME cells based upon the expression of cytokeratins; their rapid proliferation in response to platelet-derived growth factor, and a change from an epitheloid to fibroblast-like morphology in response to tumour necrosis factor and epidermal

growth factor. Both HOME and MESO cells express tissue plasminogen activator and plasminogen activator inhibitor, form typical cobblestone monolayers, and are immunoreactive to von Willebrand Factor and Ulex europaeus I lectin^[23,24]. Urokinase activity is only expressed by MESO cells^[24].

OMENTAL MIGRATION

In 1896, Stichler placed snails into the peritoneal cavity of dogs and observed that they were walled off by omentum^[25]. A few years later (1910), in his text entitled "Introduction to Surgery", Rutherford Morrison referred to the omentum as "a special protective agency the abdominal policeman. It travels around the abdomen with considerable activity, and is attracted by some sort of inflammation in neighborhoods in which mischief is brewing". These observations lead to a study in dogs where it was revealed with fluoroscopy that there is no movement of the omentum following the insertion of enterobacteria into the peritoneal cavity^[25]. In 1926, Florey and others^[26] conducted a series of experiments and concluded that there was no intrinsic omental movement, but rather passive movement. This movement resulted from both the general activity and the position of the animal, and also from the peristalsis of the gut and the action of the diaphragm. This allowed the omentum to move about the abdominal cavity and adhere either foreign bodies or areas of inflammation. It was also noted that the omentum was limited in its ability to attach to foreign bodies in the pelvis and above the liver because it was unable to make physical contact with them^[27]. This led Sir Charles Sherrington^[28] to comment "that the doubled-up posture of the acute abdominal case is precisely that which will cause the omentum to be moved low down in the abdominal cavity".

OMENTAL FUNCTION

Foreign bodies

Most surgeons have observed the ability of the omentum to adhere to intra abdominal foreign bodies such as drains and catheters. In dogs it has been noted that following the placement of various types of drains into the peritoneal cavity, that within seven days all tubes are surrounded and occluded by omentum^[27]. This may lead to drainage problems in patients requiring long term catheters placed in the abdominal cavity, such as those for peritoneal dialysis. In such patients, removing the omentum has been found in a number of retrospective and uncontrolled studies to reduce the incidence of catheter blockage and to improve drainage^[28-32]. In addition, omentectomy does not appear to alter the peritoneal diffusion capacity^[33]. Because of this, it has been advocated that partial omentectomy is integral to the surgical technique of peritoneal catheter placement^[28-32]. In contrast,

Lewis *et al.*^[34] argued that the absolute risk reduction with omentectomy in preventing catheter blockage was only 0.18 in a series of 38 patients undergoing 66 catheter placements. It also remains to be clarified whether omentectomy has other deleterious side effects such as an increased incidence of peritonitis. None of the reported trials have adequately addressed this issue.

Peritonitis

The omentum performs a number of functions during episodes of peritonitis. The first of these is the rapid absorption and clearance of bacteria and foreign material from the peritoneal cavity. The omentum is the only site, other than the diaphragmatic stomata, that has a documented ability to absorb particles from the peritoneal cavity^[35]. But unlike the stomata, the omentum contains potent local effector mechanisms that are mediated by especially macrophages (and probably also B lymphocytes) contained within the milky spots. These macrophages appear to be the principal site for the phagocytosis of particles and bacteria from the peritoneal cavity^[13].

The second function of the omentum is to supply leukocytes to the peritoneal cavity. In experimental animals with peritonitis, the omentum appears to be the principal site by which firstly macrophages and then neutrophils migrate into the peritoneal cavity^[36,37]. The macrophages are derived from the milky spots which provide the correct microenvironment and growth factors for

macrophage proliferation and maturation. The correct microenvironment and growth factors for macrophage proliferation and maturation. The structure of the milky spots and their associated capillary structures aids this process (Figure 1). Because the mesothelium is absent over the milky spots, and the basement membrane is discontinuous, there is rapid exposure of the resident macrophages to intraperitoneal stimulants. this activates the macrophages which then demonstrate marked surface membrane activity and migrate through the stomata of the milky spots into the peritoneal cavity^[37].

The omentum also allows for the easy migration of neutrophils from the circulation^[7]. Due to the structure of the milky spots, there is direct exposure of the postcapillary venules to inflammatory stimuli from the peritoneal cavity^[38]. The neutrophils are then recruited from the circulation and extravasate via the post-capillary venules in the glomerular tufts into the milky spots and then via the mesothelial stomata into the peritoneal cavity. In one study on mice with peritonitis, the post capillary venules in the milky spots of the omentum were the only abdominal sites detected where plasma extravasation occurred, and the omental milky spots were the major route through which leukocytes migrated into the peritoneal cavity^[38]. In addition, the omentum was the only abdominal organ which showed an increase in blood flow during peritonitis^[38]. Milky spots do not seem to serve as a source of dendritic cells^[7].

Figure 1 The basic structure of a milky spot in the omentum.

The third function of the omentum is to adhere to and attempt to seal off areas of contamination. The omentum can rapidly produce a layer of fibrin by which to adhere to the contaminated area at the point of contact. In the course of a few days, the fibrin begins to organise with the development of new blood vessels and fibroblasts. In the long term, if the host survives, the contaminated area will be walled off with collagen, and thereby forming dense adhesions^[46].

Removal of the omentum impairs peritoneal defence mechanisms^[3]. In experimental peritonitis, omentectomy has been found to reduce survival^[40], and influence a number of peritoneal defence mechanisms^[41]. In particular, there is a reduction in the total intra peritoneal cell counts, with macrophages being the most effected. There is also a reduction in neutrophil chemotaxis, although their phagocytic activity appears unchanged^[41]. In humans, omentectomy also appears to impair the peritoneal defence mechanisms^[42,43]. One retrospective analysis compared a group of 406 patients having omentectomy with proctocolectomy and ileoanal anastomosis with a group of 239 patients having a similar procedure without omentectomy^[42]. The patients were followed up for a mean of 4.3 years. The results showed that the omentectomy group had a significantly higher incidence of postoperative sepsis (4% vs 10%, $P<0.01$) and sepsis requiring reoperation (3% vs 8%, $P<0.01$) when compared with patients retaining their omentum. In addition, there was no difference in the incidence of partial or complete small bowel obstruction due to adhesions between the two groups.

Neovascularisation

It has long been recognised that the human omentum can promote angiogenic activity in adjacent structures to which it is applied. Indeed, lipid material obtained from the omentum has been found to induce angiogenesis in rabbit corneas after only a single injection. This angiogenic material obtained from the omentum is abundant in supply^[44]. Further evaluation of the factors involved in this process have found that the human omental microvascular endothelial cells (HOME cells) express the angiogenic peptide 'basic fibroblast growth factor'^[39]. This process of neovascularization allows the omentum to provide vascular support to adjacent tissues such as the gut and promote function and healing in ischaemic or inflamed tissue^[45,46]. Another example of the angiogenic activity of the omentum has been its ability to support splenic autotransplantations. Although the clinical practice of re implantation of splenic remnants following splenic injuries has largely been abandoned by surgeons, it is interesting

to note that such implants are supported by the omentum and function to a limited capacity^[47]. The omentum has also be found to be capable of supporting free structures such as the trachea, segments of intestine, sciatic nerve grafts. Such structure can then be used for reconstructive purposes^[48-50].

CLINICAL ISSUES

Primary pathology

In contrast to its numerous advantages, the omentum is rarely a site of primary pathologic change. There have been several case reports of primary omental torsion in both children and adults, and primary omental infarction in adults. Patients usually present with an acute abdomen and have localized signs of peritonism plus or minus a palpable mass. They are readily treated by partial omentectomy^[51-53]. In addition, both benign (lipoma, fibroma) and malignant (liposarcoma, fibrosarcoma, angiosarcoma) soft tissue tumours may occur in the omentum, although they are very rare.

Reconstruction

Surgeons have long exploited the unique structure and function of the omentum^[54]. In particular, its rich blood supply that supports a high absorptive capacity, its pronounced angiogenic activity which may support local tissues (and ischaemic tissues), its innate immune function, its ability to adhere to local structures, and finally its high concentration of 'tissue factor' which promotes haemostasis^[2,55]. In 1927, Perrotti^[56] used free and pedunculated flaps of omentum to enhance intestinal suture lines in dogs. Omentum has also been used: to close perforations in the gastro-intestinal tract; to reinforce gastro-intestinal anastomoses; to aid haemostasis during liver resections; to line the bed of hydatid cysts in the liver; as a pedicled graft to cover defects or to reconstruct areas from the chest wall to the perineum; to protect exposed carotid arteries; as free vascularized grafts in head and neck surgery; to repair bronchopleural fistula; and others^[54,57,58].

There are several reports of the use of an omental flap to reconstruct the mediastinum in patients with mediastinitis secondary to open heart surgery^[59-61]. These reports are retrospective and not adequately controlled. Nevertheless, they all comment that omental flaps are associated with fewer septic complications than pectoralis major flaps, and are associated with high rates of healing and lower mortality when compared with debridement. Similarly, there have been reports on the use of the omentum as a free transfer graft for the treatment of chronic ulcers, progressive hemifacial atrophies, and contused wounds. The transferred omentum appears to maintain its volume and nature under normal circumstances^[62].

Gastrointestinal anastomoses

There have been numerous studies evaluating the use of the omentum to support gastrointestinal anastomoses. In animals, there have been conflicting results as to whether reinforcing a compromised (i.e., ischaemic or technically inadequate) anastomosis with well vascularized omentum improves healing^[1,63,64]. However, the clinical relevance of studying anastomotic healing of grossly ischaemic segments of bowel is, I believe, questionable. In contrast, Carter *et al.*^[65] evaluated the ability of omental wrapping to improve the healing of anastomoses using non compromised large intestine. They observed no improvement in fatal leak rates.

There has been one large clinical trial evaluating this issue in humans. This included 705 patients undergoing elective resections from the caecum to the midrectum with a mean age of 66 years. Patients were randomized after colectomy to undergo either omental reinforcing of the colonic anastomosis or no reinforcing. The intraoperative findings were similar between the two groups, except that there were significantly more septic operations performed in the control group. When comparing the omental reinforcement group with the controls, there was no significant difference in either anastomotic leakage (4.7% vs 5.2%) or deaths (4.9% vs 4.2%). The authors concluded that omental reinforcement of colorectal anastomosis was of no clear benefit *et al.*^[66].

Neurosurgery

Placing the omentum on the brain surface by surgical transposition or transplantation has been found to result in the development of numerous neovascular connections between these two structures. This phenomenon occurs even in the absence of cerebral ischemia. In a series of 30 children with moyamoya disease, aged from 2 to 17 years, omental transplantation was used to improve vascularity in either the anterior or the posterior cerebral artery territory. All 19 patients treated with omental transplantation to the anterior cerebral artery and 11 (84.6%) of the 13 treated with omental transplantation to the posterior cerebral artery showed improvement in their neurological state^[67].

Vascular synthetic grafts

Synthetic vascular grafts lined with HOME cells appear to remain patent for longer periods^[23]. However, HOME cells remain difficult to extract and culture. In contrast, MESO cells can be readily harvested in large numbers from the omentum, and by culturing them in specific conditions their natural tendency to express tissue factor which is thrombogenic can be inhibited. Such cells are an

excellent alternative to HOME cells in seeding synthetic grafts^[68]. This technique has been used to line the luminal surface of small diameter prosthetic bypass grafts, thereby lowering the grafts thrombogenicity. These grafts were then implanted into the carotid artery of dogs and have been found not to develop neointimal hyperplasia or stenosis when compared with controls^[69].

Malignancy

The omentum has been observed to be a frequent site of metastatic disease for many malignancies. In animals, malignant cells inoculated into the peritoneal cavity preferentially infiltrate the milky spots in the omentum and grow into distinct metastatic^[70,71]. The omentum appears capable of supporting not only malignant cells in the milky spots but free intraperitoneal cells. It achieves this due to its intrinsic angiogenic properties. In animals, removing the omentum impacts on the survival of free intraperitoneal malignant cells and there by reduces the rate of local recurrence^[72,73]. Because of these observations, the omentum is frequently removed as part of resections for malignancies of various intra abdominal organs^[74].

Ovarian cancers, in particular, are characterized by their tendency to spread intraperitoneally and involve the omentum. Hence, there has evolved a general consensus that surgical management of ovarian cancer should include optimal cytoreduction^[75-78]. The minimum surgical requirements of this are to perform a total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. The apparent value of performing an omentectomy is that it provides staging information and selects patients for adjuvant chemotherapy^[79,80]. In addition, in patients with advanced disease, there appears to be a survival advantage in debulking tumour deposits^[81]. Nonetheless, with borderline ovarian tumours, omentectomy is also frequently advocated but the evidence to support this remains limited^[82].

The removal of the omentum in patients with ovarian cancer is not universal. In 1993, a United states national survey of the treatment of patients with ovarian cancer concluded that out of a total of 12, 316 patients with ovarian cancer, the requirements for what were defined as a minimum surgical resection were met in only around 60% of patients (bilateral salpingo-oophorectomy 67%; abdominally sterectomy 55%; and omentectomy, 59%)^[83]. Another analysis of omentectomy in patients with ovarian cancer found that the mean omentectomy size was only 203.5cm² (normal omentum = 792 cm²), and secondary ovarian cancer was present in 61%. Thus the optimal extent of omental resection and histological examination remains to be clearly defined^[80].

The omentum is intimately associated with the stomach and the gastric lymphatic drainage. Therefore, it is invariably removed as part of a curative resection for gastric cancer^[84,85]. Nonetheless, there is no clear evidence to provide guidance as to the extent of such a resection, and whether the entire omentum has to be removed^[86,87]. Pseudomyxoma peritonei is a rare neoplasm characterized by mucinous ascites and the mucinous involvement of peritoneal surfaces, omentum and bowel loops. Usually pseudomyxoma peritonei is associated with benign or malignant mucinous tumor of the appendix or ovary, and cytoreductive resections, including omentectomy, are advocated as the treatment of choice^[88,89].

CONCLUSION

Our concept of the omentum as an abdominal policeman has obviously evolved since the days of Rutherford Morrison. We now understand that it occupies a central position in the peritoneal defence mechanisms. It achieves this by virtue of its innate immune function, its high absorptive capacity, and its ability to adhere to adjacent structures to both seal off gastrointestinal defects and promote their healing with its pronounced angiogenic activity. Because of these attributes, surgeons have utilised the omentum in a variety of settings, from reconstructing soft tissue defects, to supporting tissues to promote healing. In managing patients with intra abdominal malignancies, the role of omentectomy requires further evaluation to determine whether it is associated with a clear survival advantage, and to evaluate how much needs to be removed. In conclusion, the omentum needs to be viewed as an important intra abdominal organ and hence careful consideration needs to be given before it is removed.

Wilcox CM. Etiology and evaluation of diarrhea in AIDS: a global perspective at the millennium. World J Gastroenterol, 2000;6(2):177-186

INTRODUCTION

It has now been almost 20 years since the initial descriptions of a heretofore unrecognized disorder afflicting homosexual men and manifesting as *Pneumocystis carinii* pneumonia and Kaposi's sarcoma. With the identification of the human immunodeficiency virus (HIV) as the etiology of this syndrome, there has been exponential growth in our understanding of this devastating immune disorder. During the first decade of the acquired immunodeficiency syndrome (AIDS), there was an explosion of cases in the United States and Africa. Subsequently, there have been successive waves of the epidemic throughout the world with cases now documented in essentially all countries. Elucidation of the infectious etiology and routes of transmission of HIV have provided opportunities for population-based preventative measures. Although these measures have been highly successful in many developed countries, the number of new cases worldwide still remains staggering. It is estimated that approximately 1 million people in the United States are HIV-infected. As of 1998 alone, more than 33 million people were infected with the AIDS virus worldwide with almost 6 million new cases occurring in 1998, representing approximately 16000 new cases each day, the majority of these occurring in developing countries^[1]. By the year 2000, it is estimated that there will be almost 40 million HIV-infected people throughout the world. The epidemic currently inflicts a heavy human and economic toll on sub-Saharan Africa, and although the number of cases is currently small, the Russian and China could potentially be poised for the next

wave of the epidemic. Given their present rate of infection, the Indian subcontinent and southeast Asia will likely bear the greatest burden of the disease early in the 21st century.

Since the initial descriptions, it was recognized that chronic diarrhea was one of the most common and debilitating complications of HIV infection, occurring in about 50% of patients in North America and in up to 100% of patients residing in developing countries^[2-4]. Chronic diarrhea is important in these patients because it results in significant morbidity and mortality, reduced quality of life, and higher health care costs^[5]. In the early stages of immunodeficiency, HIV-infected patients are susceptible to the same enteric pathogens that cause diarrhea in the immunocompetent host. However, as immunodeficiency progresses, these patients become susceptible to a wide variety of opportunistic infections (OI) many of which have a predilection for the gut^[1-3,5]. In general, most opportunistic disorders are not observed until the CD4 count falls below 200×10^6 cells/L, and usually $<100 \times 10^6$ cells/L^[4,6].

Across all continents, the introduction and rapid implementation of potent combination antiretroviral therapy, termed highly active antiretroviral therapy (HAART), has profoundly affected the incidence and complications of AIDS including diarrhea. Cohort studies have clearly shown a fall in AIDS-related OI, hospital admissions as well as mortality rate of HIV-infected patients which began several years prior to 1996, the time when protease inhibitors were released^[7-10]. These changes which occurred prior to protease inhibitors may be the result of combination therapy with reverse transcriptase inhibitors which have modest efficacy in reducing HIV RNA levels^[10]. Since 1996, however, there has been even more substantial improvement in these outcomes. Although expensive, HAART appears to be cost-effective given the reduction in the number of hospital admissions and AIDS-related complications^[11]. When effective, these drug regimens markedly and rapidly reduce HIV RNA while the CD4 lymphocyte count rises^[12]. Studies which examine viral burden and architecture of lymph nodes have also demonstrated salutary effects of HAART^[13]. Tangible evidence of immune reconstitution is that prophylaxis against *Pneumocystis carinii* pneumonia may be discontinued in patients who have an excellent

virologic response to HAART and a sustained rise in CD4 count to greater than $200 \times 10^6/L$ ^[14]. However, patients who have received multiple antiretroviral agents but who have persistently high level HIV viremia will not have such profound immunologic and virological effects with these new regimens due to drug-resistance^[15].

As the immune status of HIV-infected patients improves with HAART, they become less prone to opportunistic disorders and the infectious etiologies of diarrhea parallel that observed in immunocompetent patients. Nevertheless, several antiretroviral agents, particularly the protease inhibitors, can themselves cause diarrhea^[16]. Thus because of HAART, the number of patients in whom OI are identified as causes of diarrhea has fallen while the frequency of unexplained and drug-induced diarrhea appears to be rising^[17].

The identification of enteric pathogens in patients with diarrhea is important since a number of efficacious antimicrobial therapies are available^[18]. Also, the use of HAART as primary "therapy" of OI represents a new paradigm for management; when effective in raising the CD4 count and lowering HIV RNA levels, OI may completely remit with HAART alone^[19-20]. To best identify these OI, various approaches for the work-up of diarrhea in AIDS have been proposed^[6,21-25]. However, the diagnostic methods often differ between studies making comparisons difficult. In addition, most of these diagnostic algorithms were derived in developed countries where endoscopy and mucosal biopsy is widely available, and are therefore not universally applicable.

As we enter the new millennium, it seems appropriate to highlight changing concepts related to the etiology and evaluation of diarrhea in HIV-infected patients. Given that the spectrum of pathogens differs geographically and the resources for diagnostic evaluation vary widely, contrasts will be drawn based on these epidemiological and economic differences where applicable and where data is available to draw meaningful distinctions.

ETIOLOGY

The infectious causes of diarrhea in AIDS are extensive (Table 1), and the most important etiologic agents will be briefly discussed individually focusing on geographic differences in prevalence. Worldwide, the most common causes of diarrhea in HIV-infected patients are enteric bacteria including *Shigella flexneri*, *Salmonella enteritidis*, and *Campylobacter jejuni*. In contrast to the normal host, these bacteria have been identified in stool from patients with chronic diarrhea^[23,26,29]. *Clostridium difficile* is a prevalent pathogen typically reported in developed countries, whereas tuberculosis is a common complication of AIDS in

developing countries^[27,28]. Cryptosporidia is the most frequently identified parasitic cause of diarrhea throughout the world^[23,26,29]. Cytomegalovirus (CMV), cryptosporidiosis, microsporidia and *Mycobacterium avium* complex (MAC) the classic gastrointestinal OI of AIDS become important pathogens when immunodeficiency is advanced. AIDS-related neoplasms such as Kaposi's sarcoma or lymphoma and fungi rarely cause diarrhea. As noted above, medications, usually protease inhibitors, have recently become important causes of diarrhea^[16].

Fungi

Histoplasma
Candida albicans

Viral

CMV is one of the most common OI in AIDS patients from developed countries presenting late in the course of HIV infection; the median CD4 count in most reports is $<50 \times 10^6$ cells/L and the CD4 count is $<100 \times 10^6$ cells/L in almost all patients. Among patients with AIDS and diarrhea from developed countries, CMV has been identified in gastrointestinal biopsies in as many as 45% of cases^[22,30]. In contrast, one study of rectal biopsies from 29 African patients with chronic diarrhea and abnormal appearing rectal mucosa did not identify any patients histologically with CMV^[31]. It is unclear whether CMV is less commonly reported

from developing countries due to the infrequent use of endoscopy or true differences in infection. Another explanation for geographic disparities in the prevalence of CMV disease is the fact that AIDS patients from developing countries often die before immunodeficiency becomes so advanced that CMV manifests. Other viruses have been identified in stool from AIDS patients with chronic diarrhea including adenovirus, rotavirus, astrovirus, picobirna virus and coronavirus^[32,33]; given the lack of specific therapy, the clinical relevance of these viruses is unclear (Table 2). There are also reports that HIV itself can be isolated from and identified in enterocytes and colonic cells, and that HIV may have a direct cytopathic effect on the intestinal mucosa causing an enteropathy.

Table 2 Laboratory tests used to investigate diarrhea in HIV - infected patients

Stool studies
Stool cultures (<i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i>)
Toxin (<i>Clostridium difficile</i>)
Stool for ova and parasites (<i>Giardia lamblia</i> , <i>Entamoeba histolytica</i>) (using saline, iodine, trichrome and acid-fast stains)
Stool stains:
a. Modified Kinyoun acid-fast (<i>Cryptosporidium</i> and <i>Isospora belli</i>)
b. Concentrated stool (Zinc sulfate, Shethers sucrose flotation)
Fecal fat
Giardia antigen
Blood studies
CD4 cell count
White blood cell and differential
Creatinine, electrolytes
Liver function tests
Total albumin
Blood cultures (<i>Mycobacterium avium</i> -complex)
Tissue and fluids
Duodenal aspirate (<i>Giardia lamblia</i> , microsporidia)
Biopsy: duodenum, jejunum, ileum, colon, rectum
Biopsy stains:
a. Hematoxylin-eosin
b. Giemsa or methenamine silver (fungi)
c. Methylene blue-azure II-basic fuchsin (microsporidia)
d. Fite (mycobacteria)
Immunohistochemical stains (Cytomegalovirus)
In-situ hybridization (CMV)
DNA amplification (CMV)
Electron microscopy for cryptosporidia, adenovirus
Touch preparation
Culture of colonic mucosal biopsy
a. Cytomegalovirus
b. <i>Herpes simplex virus</i>
c. Bacteria

Bacterial and mycobacterial

The spectrum of bacterial pathogens causing diarrhea in HIV-infected patients is similar to the normal host. When comparing studies from throughout the world, no important differences, with the exception of *-C. difficile*, in the spectrum of bacterial infections are apparent. The most frequently identified pathogens are *Campylobacter*, *Salmonella*, *Shigella*^[23,26,34]. *Yersinia enterocolitica*, *Staphylococcus aureus*, and *Aeromonas hydrophila* have also been associated with severe enterocolitis in HIV-infected patients^[35]. *C. difficile* colitis is a frequent cause of diarrhea in

HIV-infected patients from developed countries likely because of these patient's frequent exposure to antimicrobials and requirement for hospitalization^[36]. Small bowel bacterial overgrowth does not appear to be common in AIDS patients with chronic diarrhea^[37].

Mycobacterium avium complex (MAC) is a common pathogen in AIDS patients with advanced immunosuppression; up to 39% of patients from the USA may develop this infection when the CD4 count remains $<10 \times 10^6$ cells/L^[38]. MAC infection has been less frequently reported in AIDS patients with diarrhea from developing countries^[27]. This apparent infrequency of MAC in third world countries is likely multifactorial and may relate to the fact that this infection is usually diagnosed by blood cultures or, like CMV, that patients from these countries die from other causes such as tuberculosis (TB) prior to developing such advanced immunosuppression required for MAC infection. The presentation of TB in AIDS is well recognized to be different and often extrapulmonary. Autopsy studies suggest that the gastrointestinal tract is commonly involved in disseminated TB and such involvement can result in gastrointestinal symptoms including diarrhea^[28]. In contrast to MAC, TB can manifest with less advanced immune deficiency, and CD4 cell counts may exceed 200×10^6 cells/L.

Parasites

Among the protozoa, *Cryptosporidium parvum* is the most frequently identified parasite causing chronic diarrhea in AIDS even in developed countries^[4,29,39]. Cryptosporidia is a very important cause of diarrhea in developing countries where prevalence rates of 20% are commonly reported^[40]. This high prevalence perhaps is due to the fact that contaminated water is a common source for this pathogen^[41]. Although a cause of acute diarrhea, cryptosporidiosis is typically identified in HIV-infected patients with chronic diarrhea. Microsporidia (*Enterocytozoon bienersi* and *Encephalitozoon intestinalis*) are now recognized as important causes of diarrhea in AIDS patients^[39-42]. In some studies of HIV-infected patients with chronic diarrhea, microsporidia are the most commonly identified pathogens. In a study from New York^[43], microsporidia were found in 39% of AIDS patients undergoing gastrointestinal evaluation for diarrhea; however, in other areas throughout the world and even the USA^[44], this pathogen is rarely identified even in patients undergoing small bowel biopsy. These geographic differences, both globally and in the same country, in the prevalence of microsporidiosis are unexplained. *Isospora belli* is a rare gastrointestinal pathogen in HIV-infected in North America, whereas it is endemic in some developing countries such as Haiti^[40]. The infrequency observed in

developed countries has been attributed to widespread *Pneumocystis carinii* prophylaxis with trimethoprim-sulfamethoxazole which is highly effective in the treatment of Isospora. Cyclospora have also been identified in HIV-infected patients with chronic diarrhea most often from developing countries^[45]. Despite a high frequency of stool carriage in asymptomatic homosexual men, amebic dysentery or invasive amebic disease (ameboma or liver abscess) have been rarely reported in HIV-infected patients, even from developing countries^[46]. Stool carriage of ameba in HIV-infected patients is not only limited to non-pathogenic strains of ameba such as *E. dispar*, *E. hartmanii* and *E. coli*, but also to non-pathogenic *E. histolytica*^[47]. Giardiasis is neither more common nor more severe among patients with AIDS than in the non-immunocompromised host and geographic differences in prevalence have not been reported^[4]. Helminths are rare causes of diarrheal disease but have been recognized most often in third world countries.

CLINICAL PRESENTATION

An overview

When evaluating the HIV-infected patient with diarrhea, one should first attempt to determine the site of origin of the diarrhea, i.e., small bowel ("enteritis") or colon ("colitis"), and the clinical history alone may be helpful^[48]. Not only will localizing the site of origin of diarrhea direct the diagnostic evaluation, but most pathogens have predilections for specific organs. For example, microsporidia and Giardia result in small bowel disease whereas bacteria cause colonic disease. Enteritis is classically manifested as large volume (often >2 L/d) watery stools, often associated with dehydration, electrolyte disturbances, malabsorption, and weight loss. Abdominal pain, when present, is usually crampy and periumbilical in location. Symptoms such as nausea, vomiting, bloating, distention, and borborygmi are also commonly associated with a small bowel diarrhea. In contrast, colitis is characterized by frequent, small volume stools, which may contain mucus, pus and/or blood, and is often accompanied by "proctitis" symptoms tenesmus, frequency, urgency, dyschezia and proctalgia. Abdominal pain is typical for colitis and tends to be localized to the lower abdomen. When colitis is severe, abdominal pain can be marked suggesting an acute abdomen. Fever is common with a systemic infection (e.g. MAC) or bacterial colitis. A fundoscopic examination may demonstrate retinitis consistent with CMV.

The value of clinical parameters for tailoring the work-up of diarrhea remains controversial. Wilcox *et al*^[48] demonstrated that the clinical presentation and severity of immunodeficiency were useful in predicting which patients with negative

stool tests may benefit from endoscopic examination. In this study^[48], patients with no identifiable pathogen after endoscopic examination had less systemic symptoms (weight loss) and a higher CD4 count. Indeed, diarrhea remained unexplained in patients who had not lost weight, and no OI was found in those patients with a CD4 > 50×10⁶ cells/L. Connolly *et al*^[49] also identified factors in a similar patient population which appeared to predict the presence of a gastrointestinal infection by endoscopic evaluation including weight loss^[49]. In a later study from the same group, however, Blanshard *et al*^[23] questioned the usefulness of clinical parameters. That study^[23] concluded that the presenting clinical features and hematological and biochemical parameters could predict neither the presence nor site of pathogens. Although there were significant differences in CD4 counts, stool volumes, and weight loss between the patients with and without an identified pathogen, there was such a large overlap that these clinical features could not be reliably used to identify those patients most likely to have a pathogen^[23]. The only presenting symptom and physical finding that was statistically significantly different between the two groups was the presence of abdominal pain, and this was most common in patients with CMV. Surprisingly, weight loss and malabsorption did not correlate with the presence of small bowel pathogens.

In contrast to the clinical presentation alone, however, all studies support the value of the CD4 count in stratifying the risk for opportunistic disorders particularly for patients with no prior AIDS-defining illness^[6,23,26,50]. When blood testing is not widely available, surrogate markers of severe immunocompromise may be helpful to stratify risk including the presence of thrush, oral hairy leukoplakia, or the wasting syndrome. In summary, although all studies have not come to similar conclusions, history and physical examination remain an important part of the assessment of the patient's general condition and hydration status and may help prioritize the evaluation.

CLINICAL MANIFESTATIONS BY ETIOLOGY

Viral

CMV infection of the colon characteristically presents with chronic watery diarrhea, abdominal pain, wasting, anorexia, weight loss^[51], and abdominal pain is an important clue to the diagnosis^[23]. Fever is not universal. Small bowel infection with CMV is far less common than colonic disease. The diarrheal stools may be semiformal or formed and may be accompanied by gross bleeding and fecal leukocytes. Lower gastrointestinal hemorrhage without diarrhea may be the initial manifestation and results from either severe colitis or isolated well circumscribed ulcers^[52]. When the

distal colorectum is involved, symptoms of proctitis are often reported. Toxic megacolon, intestinal perforation, mass lesions and colonic stricture have also been observed as complications of CMV enterocolitis^[53]. Localized or diffuse pain may be elicited on abdominal examination. Other physical findings are non-specific, and will primarily reflect CMV-related complications such as dehydration, perforation (acute abdomen), gastrointestinal bleeding, or altered vision (retinitis).

The most common colonic manifestation of HSV in HIV-infected patients is distal proctitis, which may be misinterpreted as diarrhea. If the disease extends to the proximal colon (very rare), proctocolitis with hematochezia and diarrhea may result^[53]. Other viruses such as astrovirus, adenovirus, picobirnavirus have been associated with chronic watery diarrhea^[32,33].

Bacteria

Although bacterial enterocolitis can occur at any stage of immunodeficiency, unusual presentations of these enteric bacteria became apparent early in the AIDS epidemic where *Salmonella* sp.^[54] and *Campylobacter* sp. bacteremia^[53] were reported as initial manifestations of AIDS. In general, however, the clinical presentation of these organisms in AIDS is similar to immunocompetent patients except that diarrhea may be chronic. Bacterial enterocolitis usually manifests as an acute diarrheal illness (less than 2 weeks duration). *Salmonella* gastroenteritis more commonly presents with watery diarrhea, abdominal pain, fever, nausea and vomiting but can manifest as an enteric fever. *Shigella* and *Campylobacter* usually present as a dysentery with the classic "colitis" symptoms mucopurulent bloody diarrhea, tenesmus and fever. Lower abdominal pain and fever may be prominent, while nausea and vomiting are infrequent. Physical findings include fever, tachycardia and abdominal pain which may be severe. Digital rectal examination may demonstrate frank blood or pus. Initial experience suggested that the clinical presentation of *C. difficile*-colitis was different in the HIV-infected patient^[55], but prospective studies have shown no differences as compared to non-immunocompromised patients^[56]. *C. difficile* can present fulminantly without diarrhea with clinical signs of peritonitis or even ascites^[53].

The most common manifestations of MAC infection are fever, wasting, chronic diarrhea, abdominal pain, night sweats and intestinal malabsorption^[4]. Frank colitis or hematochezia, which may be massive, are both rare presentations of gastrointestinal MAC infection^[53]. Although gastrointestinal tuberculosis may be symptomatic, the clinical picture is often dominated by fever and wasting and/or pulmonary disease^[27]. It is extraordinarily unusual for gastrointestinal TB to

present as chronic diarrheal illness. Most commonly, gastrointestinal TB is identified incidentally at the time of autopsy in patients with disseminated disease^[28].

Parasites

Cryptosporidia, microsporidia, cyclospora and *Isospora belli* are associated with chronic, watery diarrhea, dehydration, malabsorption and weight loss—features typical for a severe small bowel diarrhea. Cryptosporidiosis is more severe in patients with marked immunosuppression, but is generally self-limited if the CD4 count is $\geq 200 \times 10^6$ cells/L^[6]. The disease may be particularly devastating in developing countries. Overall, diarrhea due to microsporidiosis tends to be less severe than with cryptosporidia; weight loss is variable. Giardiasis characteristically presents with chronic diarrhea, abdominal bloating, borborygmi and intermittent abdominal pain.

TOOLS FOR INVESTIGATION

Perhaps the most important assessment in the evaluation of diarrhea in HIV-infected patients is the CD4 count, because the absolute value reflects the patient's stage of immunodeficiency thereby stratifying the risk for OI. As noted above, clinical surrogate markers, when present, can also be used to gauge the degree of immunodeficiency. Since most opportunistic disorders are not observed until the CD4 count falls below 200×10^6 cells/L, and usually $<100 \times 10^6$ cells/L, the method and extent of evaluation will depend on the absolute CD4 count. For example, if the CD4 count is higher than 100×10^6 cells/L, evaluation for MAC is not necessary given that MAC infection occurs primarily when the CD4 count is $<50 \times 10^6$ /L. Likewise, the yield of endoscopy for OI in a patient with a CD4 count $> 200 \times 10^6$ /L will be very low^[48,50].

Numerous stool culture media, histopathological stains of mucosal biopsies and molecular tools (e.g. polymerase chain reaction) have been employed to identify infectious agents as the cause of diarrhea in HIV-infected patients^[57-60]. The list of diagnostic tests to evaluate diarrhea in HIV-infected patients is extensive (Table 3); however, rarely will it be necessary to use more than a few of these tests. Limited resources will also play an important role in defining the extent of the diagnostic evaluation. Local epidemiology of infections should also dictate the approach.

Stool studies

Stool staining for fecal leukocytes with methylene blue is useful as their presence suggests an inflammatory origin of the diarrhea (colitis) and may help predict the presence of a colonic pathogen and yield of proctoscopy^[48]. Stool cultures for *Salmonella*, *Shigella* and *Campylobacter* should be

routinely submitted, even in patients with chronic diarrhea. A-C. difficile toxin screen is appropriate in developed countries and those at risk. Blanshard *et al*^[23] has shown that the yield of stool cultures increases with multiple stool samples. They found that the yield of one stool culture was 18%, 3 stool cultures 38.7%, and 6 stool cultures 46.7%^[23]. Culturing of colonic mucosal biopsies for enteric bacterial pathogens does not significantly increase the diagnostic yield^[61]. Additional stool tests should include ova and parasite examination, a modified acid fast stain to evaluate for cryptosporidia, Isospora and cyclospora and appropriate staining for microsporidia. Giardiasis may be difficult to detect on routine stool ova and parasite examination; a stool antigen test for Giardia is now available^[62]. As with any diagnostic strategy, the tests ordered should reflect the likely cause of infection, and in the HIV-infected patient, the history and immune status are most helpful.

Table 3 Drugs used in the therapy of diarrhea in AIDS

Condition	Treatment	Dosage	Duration
Cytomegalovirus	Ganciclovir	5mg/kg, 2/d	2-4wk
	Foscarnet	90mg/kg, 2/d	2-4wk
<i>Herpes simplex</i>	Acyclovir	400-800mg, 14d (5/d)	
	Foscarnet	60-90mg/kg, 2/d	14d
	Valacyclovir	500mg, 3/d	14d
	Famciclovir	500mg, 2/d	7-10d
Cryptosporidia	No definite therapy known		
	Paromomycin	25-35mg/kg, 3/d	14-28d
	Spiramycin	1g, 3/d	14-28d
	Azithromycin	900mg, 1/d	14-28d
	Letrazuril	50-100mg, 1/d	14-28d
	Bovine colostrum	50g, 1/d	14-28d
Microsporidia			
<i>Septata intestinalis</i>	Albendazole	400mg, 2/d	14-28d
<i>Enterocystozoon</i>	No definite therapy known		
	Albendazole	400mg, 2/d	14-28d
	Metronidazole	500mg, 3/d	14-28d
<i>Isospora belli</i>	TMP-SMX DS	1 tab, 4/d	10-14d
Cyclospora	TMP-SMX DS	1 tab, 4/d	10-14d
<i>Giardia lamblia</i>	Metronidazole	500mg, 3/d	10-14d
<i>Entamoeba histolytica</i>	Metronidazole	750mg, 3/d	10-14d
	Iodoquinol	650mg, 3/d	10-14d
MAC	Clarithromycin	500mg, 2/d	4wk
	EMB, Cipro, RFP		
<i>Clostridium difficile</i>	Metronidazole	500mg, 3/d	10-14d
	Vancomycin	250mg, 4/d	10-14d
Salmonella	Ciprofloxacin	500mg, 2/d	10-14d
	TMP-SMX DS	1 tab, 4/d	10-14d
Shigella	Ciprofloxacin	500mg, 2/d	10-14d
	Ampicillin	500mg, 4/d	10-14d
<i>Campylobacter</i>	Ciprofloxacin	500mg, 2/d	10-14d
	Erythromycin	500mg, 4/d	7-14d

RFP=Rifampicin, EMB=Etrhambutol, TMP-SMX=trimethoprim sulphamethoxazole, DS=double strength.

Blood tests and serology

Serologic studies for CMV antibodies are not diagnostically helpful in AIDS given the high positivity rate in these patients. The role of CMV

antigenemia as a diagnostic test or predictor of subsequent disease of the gut has been best studied in the transplantation setting where high level CMV antigenemia seems to be predictive of subsequent clinical disease^[63]. In addition, when disease is active, CMV antigenemia is also usually present. Although CMV antigenemia is common in HIV-infected patients, particularly in those with advanced immunodeficiency, the diagnostic value for the symptomatic patient as well as the predictive value for subsequent gastrointestinal disease remains unknown. Positive cultures of blood or bone marrow biopsy establish the diagnosis of disseminated MAC, but do not prove active gastrointestinal involvement. Entamoeba antibody titer (ELISA) is only useful for the evaluation of invasive amebiasis (e.g. liver abscess) and not for the diagnosis of amebic dysentery.

Radiographic studies

Plain abdominal X-rays are not generally helpful for the evaluation of chronic diarrhea. With severe colitis, however, colonic dilation and "thumbprinting" of the mucosa may be observed, and computed tomography (CT) may reveal circumferential thickening of the wall of the colon with inflammatory infiltration of the mesentery. Barium studies including small bowel follow-through or barium enema play no role in the evaluation of AIDS-related diarrhea, but may be useful if Crohn's disease is considered. If barium studies are clinically indicated, stool studies must be obtained first as barium interferes with the stool microscopic examination.

Histology

Histology plays a primary role in the diagnosis of most mycobacterial, viral and fungal etiologies of diarrhea. Parasitic infections may also be diagnosed histologically but are typically identified first on stool studies. Cytology, culture and *in situ* hybridization are also reliable diagnostic techniques. Immunohistochemical stains of mucosal biopsies to confirm various viral infections may be required, but in most cases, their use does not offer an advantage over conventional light microscopy when reviewed by an experienced pathologist^[58]. Viral culture of biopsy specimens are generally less sensitive and specific than multiple mucosal biopsies but when positive may help support the histologic findings^[64].

Although electron microscopy of small bowel biopsies is considered the gold standard for the diagnosis of microsporidiosis, recent studies have shown hematoxylin and eosin, Gram stain, Brown-Brenn, Giemsa, or modified trichrome staining of small bowel biopsies to have sensitivities of 77%-83% with specificities approaching 100%^[53,59,60]. In one study^[60], electron microscopy only resulted in the detection of an additional 4% of cases. These

results suggest that the value of electron microscopy over conventional staining techniques for the detection of parasitic pathogens is negligible especially microsporidia.

Endoscopy

A number of studies have investigated the yield and impact of upper and lower endoscopy for the evaluation of diarrhea in AIDS (Tables 4-6). An obvious advantage of endoscopy is that it permits direct visualization of the gut and opportunity for mucosal biopsy. Conversely, the procedure is invasive, expensive and not readily available worldwide. The diagnostic yield of colonoscopy in HIV-infected patients with chronic diarrhea and negative stool studies ranges from 27% to 37%, with CMV being the most common etiology identified (Table 4). Since CMV usually involves the distal colon, sigmoidoscopy with biopsy may represent a sufficient work-up^[23,25,48,52]. Nevertheless, in 13%-39% of patients, CMV infection can be limited to the right colon^[24,51]. Therefore, if CMV is suspected as the cause of diarrhea and the distal colon is normal at sigmoidoscopy, a full colonoscopy is warranted. It is still not clear whether colonoscopy has a higher yield than flexible sigmoidoscopy for the detection of clinically relevant pathogens in addition to CMV^[24]. This is an important issue worldwide as a limited valuation, which includes a rectal biopsy obtained by proctoscopy or sigmoidoscopy, is easier to acquire and more readily available than colonoscopy.

The value of upper endoscopy (EGD) for the evaluation of chronic diarrhea has also been demonstrated (Table 5). As with colonoscopy, most studies focus on the diagnostic yield in patients with negative stool tests. The most common organisms detected by EGD and biopsy are cryptosporidia and microsporidia comprising > 90% of the identified pathogens. Wilcox *et al*^[48] obtained small bowel biopsies in 48 HIV-infected patients with chronic diarrhea and nondiagnostic stool tests. In this study^[48], a potential pathogen was detected in 21 patients (44%) with 7 patients (17%) having small bowel disease; microsporidia was most commonly found. In this study, ileal biopsies were not routinely obtained at colonoscopy. In another study patients with previous negative work-up by stool studies underwent duodenal, ileal, and colonic biopsies^[50]; cryptosporidia were detected in 53% of biopsies. In contrast to these studies^[48,50], Blanshard *et al*^[23] published their experience using endoscopy (EGD and flexible sigmoidoscopy) with biopsy in conjunction with stool testing as the initial evaluation in patients with chronic diarrhea. The usefulness of first-line endoscopy was demonstrated by the high yield (83%) of potential pathogens identified during the initial evaluation. Although this more aggressive

approach resulted in a high yield, it may not be applicable to most clinical practices. More recently, Kearney *et al*^[25] studied 79 patients with chronic diarrhea and negative stool studies. The authors examined the yield of an endoscopic work-up (EGD and colonoscopy which included biopsies of the terminal ileum) including comparisons of proximal and distal colon biopsies. An infection was diagnosed in 22 of 79 patients (28%); biopsy of the left colon yielded an enteric pathogen in 17 of these 22 patients and in 100% of patients (15 of 15) with CMV colitis. Combined colonic and terminal ileal biopsies missed no pathogens. Duodenal biopsies yielded no additional pathogens beyond those identified by colonoscopy and terminal ileal biopsy. The authors concluded that for patients with CD4 counts less than 100×10^6 cells/L and negative stool studies, flexible sigmoidoscopy with biopsy was a sufficient initial endoscopic evaluation, and if colonoscopy was performed, biopsies of the terminal ileum should be obtained.

Table 4 Yield of colonoscopy with biopsy in HIV infected patients with chronic diarrhea

There remains some disagreement on the most cost-effective approach for the evaluation of diarrhea in AIDS, but the published data does provide the evidence to propose a reasonable diagnostic algorithm. Various authors^[2,4], and more recently the American Gastroenterology Association^[6], have proposed a stepwise approach for the evaluation of chronic diarrhea in AIDS. The first step includes at least three sets of stool samples to investigate for bacterial pathogens (*Salmonella*, *Campylobacter* and *Shigella*) and parasites (cryptosporidia and microsporidia). Testing for *C. difficile* was recommended for patients at risk for this infection (use of antibiotics, recent hospitalization). In HIV-infected patients with a CD4-count $< 100 \times 10^6$ cells/L and fever, blood cultures should be drawn to investigate for MAC. If these tests are negative, the second step is to perform flexible sigmoidoscopy. Colonoscopy was recommended only in selected patients (i.e. patients with marked immunosuppression and clinical manifestations of dehydration, wasting, diffuse abdominal pain)^[6]. If no etiology was found after steps one and two, EGD with biopsy of the duodenum was recommended to exclude microsporidia and cryptosporidia^[6].

Although the available literature demonstrates that both upper and lower endoscopy play a crucial role in the work-up of HIV-patients with chronic diarrhea, the main question is at what point during the work-up should endoscopy be undertaken and should both lower and upper endoscopy be performed in the same session. A stepwise approach seems reasonable when evaluating these patients, but it may not be ideal given the high diagnostic yield when performing stool studies combined with upper and lower endoscopy. Nevertheless, this aggressive approach^[23] may not be widely applicable given the fact that in routine clinical practice stool studies are relatively inexpensive, noninvasive, and often positive. We still believe stool studies should generally be obtained before endoscopic evaluation. The predictive value of quantitating fecal fat and measuring d-xylose absorption for intestinal disease in HIV-infected patients with chronic diarrhea has not been established.

When all tests are negative, symptomatic therapy with antidiarrheal agents is frequently successful in alleviating symptoms^[66]. Occasionally, despite antimicrobial treatment of an identified pathogen, the diarrhea may continue. Under this circumstance, further investigations are warranted as the patient may be co-infected with other pathogens or have another cause for the diarrhea. Discontinuation of all antiretroviral agents may help determine if a drug-induced diarrhea is causative.

CONCLUSIONS AND RECOMMENDATIONS

A thorough history and physical examination are essential to evaluate the patients' general condition and will help focus the work-up of diarrhea in

AIDS. In addition, routine blood tests are useful to evaluate objectively the severity of the diarrhea, such as hydration status and electrolyte disturbances. A markedly elevated white blood cell count may suggest bacterial colitis or a complication such as perforation or intra-abdominal abscess formation. A critical factor that will determine the diagnostic algorithm (s) is the immune status as reflected by the absolute CD4 count and/or surrogate markers. We believe that a stepwise approach is reasonable and the first step should include stool studies. Although the positivity rate increases with the number of submitted samples, obtaining three or more stool samples is often difficult. We recommend at least one complete set and additional stool samples to further exclude parasitic diseases in the patient who has no localizing symptoms. From the published evidence, it is clear that endoscopy with biopsy should be performed sooner rather than later in patients in whom noninvasive tests are nondiagnostic especially those with CD4 counts $< 100 \times 10^6$ cells/L. When either upper or lower gastrointestinal tract symptoms are present and stool studies are negative, endoscopy directed to the probable or organ of involvement is appropriate. If the patient is undergoing colonoscopy and there is additional suspicion for small intestinal pathogens, an attempt should be made to intubate and biopsy the terminal ileum during colonoscopy, as the yield of detecting microsporidia may be equivalent to EGD with small bowel biopsies^[25]. If localizing symptoms are absent and stool studies are negative, the most appropriate test is sigmoidoscopy with biopsy.

Emphasis should be placed on the changing epidemiology of diarrhea in AIDS in this era of HAART^[67]. Combination antiretroviral therapy has been shown to lead to resolution of diarrhea caused by organisms such as microsporidia and cryptosporidia^[19] and thus represents a new paradigm for the management of OI. In addition, combination antiretroviral therapy improves the immune status of the HIV-infected patient making them less susceptible to opportunistic disorders. For patients receiving HAART, the infectious causes of diarrhea appears to be decreasing, while antiretroviral agents such as protease inhibitors (most commonly nelfinavir) are increasingly important as a cause of diarrhea^[17]. The implications of these etiologic changes on the overall management of HIV-infected patients with diarrhea require further study.

THERAPY

The objective of this article was to emphasize the investigation of diarrhea in AIDS, therefore the reader is referred to recent publications on the therapy of gastrointestinal infections in AIDS^[18,66]. A table with the current drugs and dosages and duration of therapy for the most common gastrointestinal pathogens is provided (Table 3).

gallbladder; carcinoma bile duct

Huang ZQ. New development of biliary surgery in China. *World J Gastroenterol*, 2000; 6(2):187-192

CHARACTERISTICS OF BILIARY CALCULOUS DISEASES IN CHINA: THE CHANGING SCOPE

Diseases of the biliary tract in China is complicated with the prevalence of primary infection of the bile duct system. In the middle of the 20th century, biliary infection, biliary parasitic infestation, and biliary stones made up the three chief components of biliary diseases in China. As to the calculous diseases of the biliary tract, the relative incidence of primary bile duct stones accounted for 50% of the total cases. Therefore, calculous disease accounted for 60.1% among 228 surgical cases in the Chongqing Southwest Hospital, and 60 of the 80 common bile duct stones were primary bile duct origin (including primary intrahepatic duct stones)^[1,2].

Among 2390 autopsies in Chongqing area, 50 cases were found to harbor stones in the biliary tract, and intrahepatic stones accounted for 38% of the cases^[3]. Furthermore, among 2398 cases of biliary calculous disease reported in the Chinese Journal of Surgery and analyzed by Huang Chia-Su, 36% were with gallbladder stone, 14.3% with secondary bile duct stones and 49.3% with primary bile duct stones (including intrahepatic stones)^[4]. These findings witnessed the importance of primary bile duct stones, especially the intrahepatic stones, in the surgical treatment for biliary calculous diseases in China.

In the years of 1983-1985, we conducted the first nationwide survey under the sponsorship of the Chinese Surgical Association, totally 11342 surgical cases of gallstones were collected and analysed^[5]. The results showed that 52.8% were gallbladder stones, while 20.1% were primary bile duct stones

and 16.1% intrahepatic stones. The second survey was conducted in 1992, 10 years after the first survey, the results showed a further increase of relative incidence of gallbladder stones (79.9%) with the decrease of relative incidence of primary bile duct and intrahepatic stones (6.1% and 4.7% respectively). This trend of changes was mostly marked in the metropolitan cities^[6].

This change of the spectrum of gall stone disease in China was explained by: the improvements of people's living standard and sanitary conditions; and the widespread use of ultrasound for diagnosis and screening purpose.

Revisit of clinicopathology and surgical treatment of intrahepatic lithiasis

In general, there is a trend of decline in prevalence of intrahepatic stones accompanied with the decrease of new patient number. However, it is not a disappearing disease in China. Intrahepatic lithiasis complicated with biliary obstruction and hepato-biliary infection is still the most frequent cause responsible for the death from benign biliary diseases.

Intrahepatic stone is a common disease in East Asian countries. The prevalence is 4.1% in Japan. In 1986, Nakayama reported a prevalence of 53.5% in Taiwan, which is obviously deviant because of the limitation of data source. Recently, Su *et al* reported a retrospective review of 17182 cases with biliary calculous surgery performed over the years from 1971 to 1990 in 28 Chinese hospitals in Taiwan and found the prevalence of 20.3% for intrahepatic stones which was higher than 16.1% in mainland China^[7-9].

The classical clinical picture of intrahepatic stones is often a debilitated patient with wide spread intrahepatic stones, and has received a number of operations. Patients usually come to the hospital for treatment of severe complications. Surgery was often limited to control biliary infection. Therefore, in the analysis of 4197 cases of intrahepatic lithiasis collected from 71 hospitals in 1988, 90% of them showed hypoproteinemia, one third showed marked anemia, 37% had previous operations, more than 30% complicated with postoperative residual stones and serious morbidity complicated the postoperative course in 13% of the cases^[10].

Scanning electronic microscopic observations of the microvasculature of resected liver specimens that

The Research Institute of General Surgery, The General Hospital of PLA, Beijing 100853, China

Dr. Zhi Qiang Huang, graduated from the former National Zhong Zheng Medical College in 1944. He is now the academican of the Chinese Academy of Engineering, Professor of Surgery of the Postgraduate Military College, Beijing, and the Director of the Research Institute of General Surgery, the General Hospital of PLA, Beijing.

Correspondence to: Zhi Qiang Huang, The General Hospital, PLA 28 Fuxing Road, Beijing 100853, China

Received 2000-01-23 Accepted 2000-02-28

harbored intrahepatic stones revealed that there were marked changes of portal venules i.e. distorsion, narrowing and obliteration of the lumen together with extensive fibrosis and disappearance of liver parenchymal tissue. These changes were strictly segmental, confined to that segment where intrahepatic stones located and causing mechanical obstruction. Furthermore, these changes leading to the atrophy of liver parenchyma were irreversible in the late stage of disease^[11]. However, in the recent 10-20 years, owing to the wide spread use of antibiotics in the treatment of biliary infections and the improvement and accessibility of modern imaging facilities (BUS, CT scan, etc.), intrahepatic stones at its earlier stage with minimal infectious complications or clinical symptoms can be diagnosed with certainty. In the early stage, intrahepatic stone was often found to be a very localized lesion, strictly confined to one segment or two subsegments (most frequently the II and VI segment of Couinaud's classification), while the remaining portion of the liver was found to be normal grossly^[12].

Since hepatic lobectomy for the treatment of intrahepatic stones was advocated by Huang in 1958^[13], liver resection has become widely accepted as a routine for management of intrahepatic stones, especially those in the left lateral segment of the liver^[14-19]. In a survey of 4197 surgical cases of intrahepatic stones^[10], lobectomy or segmentectomy was used in 728 cases (17.3%). However, in those hepato-biliary surgical centers, adoption of liver resection for the treatment of intrahepatic stones was around 50% of the total operations, this was also true in the reports from hospitals in Taiwan and Hong Kong^[9,18]. But, if those data were subjected to detailed analysis, one would find that more than 85% of the liver resections were done on the left side of the liver. This is in disaccordance with the distribution of stone inside the liver, in which right side of the liver is not excepted. The main reason of the less use of right liver resection in intrahepatic stones is technical. A complete removal of intrahepatic stones requires a regular lobectomy or segmentectomy, it differs from those irregular resections commonly practised in the treatment of liver cancer^[12].

In 1994, the author advocated the use of systemic regular segmentectomy or subsegmentectomy in the treatment localized intrahepatic stones especially in right side of the liver. The operations were technically feasible and theoretically correct.

The results of surgical treatment of intrahepatic stones has been much improved in the past decades. However, the aim of complete cure still awaits solution of some serious problems such as residual

stones, recurrence and progressive liver damages. The types of surgical operations have been variable, but they can be categorized into three main types: liver resection, hepaticojunostomy and choledocholithomy. Clinically they were often used in combination. We have evaluated the long-term results of surgical treatment of 959 cases of intrahepatic stones in a period of 40 years in the Southwest Hospital, Chongqing, according to three different periods (1963-1975, 1975-1981, 1983-1992). Satisfactory results were obtained in 73.9%, 80.1%, and 87.1% respectively^[6]. Therefore, results appeared to be improving, but, only half of the patients could obtain a complete relief from symptoms.

Among the surgical modalities, resection was found to give the best outcome, as demonstrated by a 91.16% success rate among 439 cases. This result has been proved by many other reports in China. Liver resection usually combined with hepaticojunostomy to solve the problem of bile stasis, however, our clinical experience tended to favor resection alone for localized intrahepatic stones which might be more suitable for those earlier cases, since it might give better long-term benefit than combined hepaticojunostomy.

THE PROBLEMS OF HEPATIC DUCT STRICTURES

Strictures of the large hepatic ducts as the results of inflammation and cicatrization was responsible for more than 80% of the surgical failures of intrahepatic stone operations^[20,21]. However, stricture of the hepatic duct is a common complication of intrahepatic stones, it was seen in 25% to 65% of surgical intrahepatic stone cases. In a review of 3938 cases of intrahepatic stones, stricture of the hepatic duct occurred in 6.96% to 41.94%, being 24.28% on an average^[4,10,20]. The strictured segment of hepatic duct was usually circumscribed and accompanied with destruction of elastic fibers, ductal and periductal fibrosis. Stricture of the hepatic duct was found more frequently in repeated bile duct operations.

As to the treatment of accompanied hepatic duct strictures, a series of novel operative procedures have been developed by the author^[18,21,22]. The basic surgical principles of these procedures include wide incision of the strictured site, excision of the stenotic valve and approximation of posterior bile duct wall to create a wide hepaticojunostomy stoma by using the incised stricture segment as its posterior wall and the Roux-en-Y limb anteriorly. Such operation may be combined with hepatic resection to ensure complete removal of the lesion. It was called combined procedure.

Plastic operation on hepatic duct strictures

made a better result on surgical treatment of intrahepatic stone. Therefore, in 107 cases of intrahepatic lithiasis complicated with hepatic stricture, good result was obtained in 87.9% of the cases. In some cases, the combination of wide hilar incision and partial liver resection enables larger exposure of the bile duct over hepatic hilum. This wide incision may especially benefit the cases with widespread intrahepatic stones and markedly dilated intrahepatic bile ducts, and good results, whether evaluated on short-term or long-term base, can be anticipated^[23,24].

CARCINOMA OF THE BILIARY TRACT

Primary carcinoma of the gallbladder and the bile duct appeared to be more frequently seen in recent years. However, it is not certain whether there was an actual increase in case instances or only more of these patients were diagnosed correctly as a result of more availability of modern imaging facilities. In a nationwide survey of surgical cases of biliary tract cancer in 1989, 1098 cases were analysed^[25]. Extrahepatic bile duct cancer was found in 75.2% of the total cases, and gallbladder cancer accounted for 24.4%, with preponderance of bile duct cancer. While Shi from the Xi'an Medical University Hospital reported^[26] a retrospective analysis of 830 cases covering the past 40 years in the 7th National Biliary Surgical Conference held in Xi'an in 1997 that carcinoma of the gallbladder occurred in 72.4%, in comparison with 27.6% of extrahepatic bile duct carcinoma. This discrepancy reflected the variations of the disease prevalence in different portions of China.

CARCINOMA OF GALLBLADDER

Carcinoma of gallbladder accounted for about 1%-2% of cholecystectomies as revealed through analysis of 31 series totally of 2300 cases reported in the 7th National Biliary Surgical Conference, 1997. Other clinical characteristics of gallbladder cancer in China were: the female to male ratio 2:1, the average age was 57 years, and 60% of the patients complicated with gallstone. Zou in a second gallbladder cancer survey in 1999^[27], analysed 3776 cases, the prevalence of carcinoma of gallbladder was 0.4%-3.8% of gallbladder operations, averaging 1.96%. This result corresponds well with that obtained in 1997.

The prognosis of surgical treatment of carcinoma of gallbladder is still grave except in those lesions confined to Nevin I, II grade. According to Zou's report that the 3 and 5-year survival rate of Nevin IV, V grade tumors in 211 patients treated by radical cholecystectomy was 2.8% and 0% respectively, while among 189 patients treated with extended radical resection was

5% and 1.3% respectively. The main problem in the treatment of gallbladder cancer was the lack of early diagnosis, for most of the patients, even at the present, were still admitted to the hospitals with clinical triads (abdominal pain, abdominal mass and jaundice). Cholecystectomy for carcinoma of gallbladder in situ and in those patients with malignant changes of adenoma of the gallbladder carried an excellent result for long-term survival.

Both clinical and pathological observations support the concept of gall adenoma-carcinoma sequence, but how many primary gallbladder carcinoma came from adenoma is still unclear. Adenoma of gallbladder is often diagnosed as "gallbladder polyps" by ultrasoundists. In a survey of 341 cases of gallbladder polyp in 1989 by the author, cholesterol polyp accounted for 57.7%, inflammatory polyp 12.0%, adenoma 17%, myoadenoma 1.7%, hyperplasia 5.5%, and carcinoma 5.8%. In a series of 235 cases of gallbladder carcinoma, 23 was proved to be of malignant change of adenoma, accounting for 10% of the total cases of gallbladder carcinoma.

BILE DUCT CARCINOMA

Clinically, prevalence of carcinoma of the bile duct was found to be increased in recent years. In a review of cancer of the biliary tract, we are of the opinion that the entire bile duct system, for simplicity, may be divided into three parts, that is the intrahepatic bile duct, the hilar bile duct, and the extrahepatic bile duct. Hilar bile duct is the most common site of extrahepatic bile duct carcinoma (exclude the ampullary cancer), it covered 58%-75% of the total cases. The diagnosis of hilar bile duct cancer was difficult and the resectability rate was low, about 10% of the surgical cases. However, marked improvement was noted both in the preoperative diagnosis and the surgical treatment since the middle of the 80s due to the accessibility of modern imaging facilities, the earlier diagnosis, the better selection of operative patients, and the improvement in surgical technique. The resectability rate, at present, of hilar bile duct carcinoma has been increased to about 50% with a mortality rate below 5%. From 1986 to 1990, Huang ZQ from The General Hospital of PLA, Beijing reported a series of 50 cases of hilar bile duct carcinoma in which resection was completed in 31, with a resectability rate of 62% and no postoperative 30-day mortality^[28,29]. In the Fifth National Biliary Surgical Conference held in Guangzhou, 1991, 139 resections of hilar bile duct carcinoma were reported with a mortality rate of 0%-22%, being 5% on average. Furthermore,

recent reports from the Beijing Surgical Week, 1999, that in a period of 12 years (1987-01/1999-01), the General Hospital of PLA, Beijing, treated 157 cases of hilar bile duct carcinoma, 106 cases completed the resection, with a resectability rate of 67.5%. Among those resections, 59 (37.6%) were considered to be radical (no macro-or microscopic tumor residuals in the resected margins)^[30]. Another report from the Southwest Hospital, Chongqing, showed that from 1978 to 1997 totally 181 cases of hilar bile duct carcinoma were treated, in which 97 were resected, the resection rate being raised to 66.3% in the second period after 1991, and the radical resection rate was also increased from 18% to 38% after the year 1991.

Carcinoma of the hepatic duct bifurcation often known as Klatskin tumor, was considered to be a slowly growing malignancy and might be with a better prognosis. However, from recent experience, this conclusion has been challenged. The long-term result of surgical resection of hilar bile duct carcinoma has been far from satisfactory. The 5-year survival rate of the radical resection group was from 13.2% to 17%^[30,31]. Patients often died of local recurrence and hepatobiliary failure. Therefore, researches on the mode of recurrence in hilar bile duct carcinoma was undertaken by the author and his collaborators.

Coordinated clinical and pathological studies showed that metastasis of hilar bile duct cancer occurred rather early in the clinical cases. Therefore, in 32 cases of resections, metastasis was evidenced in 26(83.9%) of the cases, but the mode of spread was particular, such as nerve invasion in 57.7%, direct liver invasion in 42.3%, soft tissue infiltration in 42.3%, liver metastasis in 7.7%, and lymph node metastasis was only found in one case (1.8%). Histologically, 21 (65.6%) of the 32 resected specimens were well differentiated adenocarcinoma, 6 papillary adenocarcinomas, 3 were of low differentiation, and 2 carcinoma simplex^[29].

In 40 resected cholangiocarcinoma specimens, perineural space infiltration index (PNI) by cancer cells in relation to the median survival time was investigated, the result showed a reverse correlation (Table 1).

Table 1 Neural infiltration index and median survival time

Differentiation of tumor cells	PNI*	Median survival time (m)
Papillary	0.31±0.12	32
High diff.	0.39±0.18	13.5
Moderate diff.	0.74±0.39	10.8
Low diff.	0.85±0.41	7.2

*PNI>7.0=severe nerve infiltration.

In 78 surgical cholangiocarcinoma resection specimens (collected between 1989-1996), the significance of neural cell adhesion molecule (ECAM) in relation to clinicopathological findings was investigated, 68 of the 78 specimens showed nerve infiltration, blood vessels infiltration in 72, and lymphatic infiltration was present in 68. In 68 cases with neural infiltration, NCAM expression was found positive in 51 cases. Furthermore, a reverse relationship was found between the positive NCAM expression and the degree of tumor cell differentiation (Table 2).

Table 2 Expression of NCAM and tumor differentiation

Cell type	NCAM expression	
	(-)	(+)
Papillary	5	3
High diff.	10	12
Moderate diff.	8	16
Low diff.	3	21

$$P=0.0267, \chi^2=9.20$$

For further demonstration of the spread of cholangiocarcinoma cell along the perineural space, observations of computer assisted 3 dimensional reconstruction of the pathological section was performed in 2 cases, totally 110-200 slides were selected for reconstruction using a SHOW 3D image analysis system. The results showed that a dense net-work of small vascular and lymphatic channels together with a branching net-work of tumor infiltrates are in close relationship along the nerve fiber. By using the "wire framing" technique to visualize the structures, it was demonstrated that the tumor cells stayed sporadically in perineural space, lymphatics, and small vessels far from the primary focus of carcinoma. Probably, carcinoma cells involving a nerve at a place far from the original site must have reached there via lymphatics, vascular vessels or by direct invasion. These facts might be important in explaining the high recurrence rate of hilar bile duct carcinoma after conventional radical resections.

In a clinical pathological study of 40 resected hilar bile duct cancer specimens, a research group from the Third Military Medical University reported that 72.5% had near-by lymphatic invasion by the tumor, 77.5% showed blood vessels invasion within the tumor, 82.5% had perineural space invasion; the density of blood vessels inside the tumor and the perineural space infiltration index are positively correlated with metastasis of the cancer. In the presence of metastasis, 100% recurred within 3 years after the resection with an average of 9.6 months, while in the cases without metastasis, 64.3% recurred 3 years after the

resection with an average 17.5 months^[32].

INTRAHEPATIC LITHIASIS COMPLICATED WITH HEPATIC DUCT CARCINOMA

Since Sanes and McCallum (1942) first reported 2 cases of bile duct cancer complicating intrahepatic stones, sporadic cases reports were found in the world medical literatures. But, however, prevalence of bile duct cancer on the background of intrahepatic stones seemed to be increased in recent decade. Chijiwa from Japan reported 8 (7.3%) cases of hepatic duct carcinoma among 109 intrahepatic stones in 1973-1992^[33]. Chen (1993) from the Cheng Gang Hospital, Taipei reported 35 cases of bile duct carcinoma in 255 cases of intrahepatic stones in a period of 3 years duration (1988-1990)^[34]. In Mainl and China, hepatic duct carcinoma was found in 1.46% to 1.5% of intrahepatic stones operations as was reported by Huang (1981) and Guo (1995) from Chongqing. In the recent 6 series, of 661 cases of lobectomies for intrahepatic stones, 16 hepatic bile duct cancers were found, with a prevalence rate of 2.4%. Transition of hyperplasia and atypical hyperplasia from hyperplastic mucosa to bile duct cancer may be seen during pathological investigations^[35,36]. Carcinoma usually developed on the background of chronic biliary infection. Patients may have 10-40 years of biliary disease history and often had multiple operations including biliary enterostomy.

Hepatic duct carcinoma complicating intrahepatic lithiasis offered a very poor prognosis because of delay in diagnosis, and this is the another reason of advocating early resectional treatment of intrahepatic stones.

IMPACT OF LAPAROSCOPY ON CONVENTIONAL BILIARY SURGERY

Laparoscopic cholecystectomy was first introduced to China in February 1992. Presently, trained personnels and facilities are available in most parts of China. The largest series of patients treated by laparoscopic cholecystectomy in a single institution has been well over 20000. Almost 90% of gallbladder stone disease can be treated by laparoscopic cholecystectomy with minimal risk. In a review of 3986 cases of laparoscopic cholecystectomy from 28 institutes in 1992, the average bile duct injury rate (the most serious complication of cholecystectomy) was 0.31%. In a review of collected series of 39238 cases from 1992 to 1995 by Huang *et al*^[38] showed that the incidence of bile duct injuries was 0.32% and a biliary complication rate of 0.6%. Data of 142 946 laparoscopic cholecystectomies from 222 institutes collected in 1998 by Liu GL showed the bile duct injury rate dropped to 0.19% and the biliary

complication rate lowered to 0.14%. At present, the rapid development of medical technology, the tendency of minimally invasive operation and the application of laparoscopic cholecystectomy changed the leading position of conventional cholecystectomy as the "gold standard" of treatment for gallbladder stone disease since Carl Langenbuch in 1882^[38-40].

INTRODUCTION

Radiology has been greatly advanced in China since its founding in 1949 and has been developed faster and further more since China adopted the policy of socioeconomic reform in 1978. It plays an increasingly important role in the medical health care and treatment in the country and has reached the world's advanced level in certain fields. We now briefly review the history of China's radiology so as to give a clear picture of its development.

BRIEF REVIEW OF THE HISTORY OF CHINA'S RADIOLOGY

The first X-ray machine was imported and used in clinic by Kailuan Hospital of Hebei Province in 1911^[1], followed by a few missionary hospitals in Beijing and Shanghai. The first X-ray machine designed and produced by China was born in Shanghai in 1952^[2]. The early head and body CT sets were imported to Beijing, Shanghai and Tianjin, respectively from the beginning of the 1980's. It was a great event representing the commencement of CT imaging epoch in China. From then on, more and more scanners were imported and till now distributed in majorities of large and medium-sized hospitals. In the Chinese radiologic history, several eminent radiologists who made great contributions to the development of Chinese radiology in different generations are worthy to be mentioned and commemorated.

The pioneer of Chinese radiologists was Professor Zhi-Guang Xie (C.K. Hsieh) of Peking Union Medical College (PUMC). After graduation he worked in the Department of Radiology in PUMC Hospital in 1923, and studied under the instruction of a famous American radiologist, Paul. C. Hodges, and became the chairman of that

department in 1928 after completing his radiologic research career in Michigan University of America. He also was the first Chinese doctor who held the membership of American College of Radiology. In 1948, he returned back to his hometown Guangdong Province and continued his practice and research in some affiliated hospitals of Sun Yat-Sen University of Medical Sciences until he died in 1966.

Among many radiologists trained by Professor Xie, and Drs. Du-Shan Rong and Zhao-Xuan Wang who are the most famous and regarded as the pioneers of China's radiology just as Professor Xie. Both of them graduated from PUMC in 1929 and 1933, respectively and worked as research fellows in radiology in America in the 1930s. After the year of 1949, Professor Rong became the Director of the Department of Radiology, Zhongshan Hospital, Shanghai Medical University and Professor Wang was the Director of Radiological Department, the First Affiliated Hospital, Beijing Medical University. Both of them owned the honorable membership of American College of Radiology. The three professors were considered as the founders of China's radiology. In 1952, they established the National Committee of the Chinese Society of Radiology and Chinese Journal of Radiology in Beijing. They contributed to the progress of China's radiology in training radiologists and initiating the clinical and research work, e.g., studies on the relationship between early lung cancer discovered by conventional X-ray examination and pathology, and establishing the criteria for the X-ray diagnosis and staging of silicosis. In 1956, Professors Xie and Wang collaborated in creating the formulae (called Wang-Xie Formulae) to calculate the surface area of the heart of the Chinese people. Professor Wang passed away in 1986. Professor Rong had a very important book entitled "X-ray diagnosis" published with three volumes in 1978 as the chief editor. By now, the second and third edition of the book have been published and still considered as the classical and necessary reference for Chinese radiologists. Professor Rong died of renal cancer in 1988.

Among the 2nd or the 3rd generations of Chinese radiologists, there are also many distinguished radiologists who have made great contributions to the Chinese radiology, especially in the advanced modern radiologic techniques and researches. Among them, Professor Guo-Zhen Li, Yu-Qing Liu and En-Hui Wu are admitted as the most distinguished ones. Professor Li is now working at Beijing Hospital. She also graduated from PUMC in 1943 and spent three years in Billing's Hospital, Chicago University during 1948-1950. Recently she was awarded as the honorary

Department of Radiology, Zhongshan Hospital, Shanghai Medical University, Shanghai 200032, China

Dr. Meng Su Zeng, graduated from Nanjing Medical University in 1986, and earned M.D. from Shanghai Medical University in 1995, now associated professor of radiology, and specialized in radiologic diagnosis and studies of abdominal diseases, having over 30 papers and two books published.

membership in the committee of RSNA. Her book entitled "Clinical Body CT Diagnosis" published in 1986 and 1994, which helps a great deal in popularizing and enhancing CT knowledge throughout the country. Professor Liu is the major founder of cardiovascular radiology in China, now working in Fuwai Hospital of PUMC and has been appointed as the Honorary President of Chinese Society of Radiology since 1993. He is the academician of Chinese Academy of Engineering (Division of Medicine and Health), the only one working in the field of radiology. Professor Wu, presently working in the General Hospital of Tianjin Medical University is one of the founders of neuroradiology in China. He is the first Chinese radiologist ever elected to the honorary membership by the Committee of RNSA in 1988. These three radiologists have made great contributions to the development of Chinese radiology. Now many eminent radiologists of new generation have emerged in different fields of radiology.

RADIOLOGICAL EQUIPMENT AND DISTRIBUTION IN CHINA

There is great difference in the radiological equipment distribution between urban and rural areas in China because of the obvious difference in the medical care system and economic conditions. In general, the amount of radiological equipment in cities and rich areas (e.g. eastern coastal area) is larger than that in rural and poor areas. In general, large hospitals such as university hospitals, teaching hospitals and provincial hospitals have all been equipped with DSA, CT, MRI, ECT, color Doppler US, etc., some of them are in the state-of-the-art (e.g., spiral/helical CT, ultra-fast CT, PET and super magnetic strength MRI). Those hospitals represent the whole medical care level of our country. Medium-sized hospitals such as city central hospitals and county hospitals have also been supplied with conventional CT and Doppler US in the developed economic areas, and some of them even with the spiral CT, MRI, ECT and DSA. A few of district hospitals and community health centers have also purchased the conventional CT and Doppler US, but majority of city central hospitals and county hospitals still have not been installed with CT and Doppler US in the undeveloped economic areas, especially those hospitals of the impoverished rural areas possess only the conventional X-ray machines and ultrasounds (including GI X-ray machine and fluoroscopic X-ray machine). Basically all of hospitals (including urban community health station and rural community health central) have been equipped with conventional X-ray machines and ultrasounds around the whole nation. According to the statistics, there are approximately 100 thousand X-ray machines of all kinds, 3 thousand CT, 3 hundred MRI and 2 thousand Doppler US by the end of 1997 in China^[3]. Simultaneously great step

progress has been made in the design and home-made radiological equipment since China adopted the reform and open-up policy in 1978. So far, China can make a variety of conventional X-ray machines with the capacity below 800mA, and some of them have been exported to African and Asian countries. Through setting up the joint enterprises with GE and Siemens companies, the whole body CT scanners were produced in China beginning from 1987. The Chinese Academy of Sciences has produced the real time ultrasound of high quality in cooperation with some developed countries in 1988. Meanwhile the 0.15T MRI of permanent magnet model, was developed and produced successfully, with some imported electronic elements. The imaging quality of this MRI machine is high enough to display the neuro-system with recent improvement of both software and hardware. Now China has began to study and develop the 0.2T MRI of new type which already has been installed and put into use in some hospitals. All these indicated that China has the capability of producing some imaging equipment^[4-13] in some aspects.

MODES OF RADIOLOGICAL DEPARTMENT AND EDUCATION IN CHINA

In general, the mode of the department of radiology in Chinese hospital is quite different from that of western countries. The divisions of ultrasound and nuclear medicine are independent disciplines and separated from the department of radiology in most of the hospitals, with little involvement in the academic activities. Ultrasonographers are trained differently from radiologists. Only a few hospitals, have merged the US, nuclear medicine and radiology into a unified department in both organization and specialty. The Ministry of Public Health has pronounced in 1990 that the department of radiology should become a clinical department if it is able to carry out interventional therapy independently. This means that the staff of radiological department shared the same responsibility and right as those of clinical department. Since then, the interventional therapy in China has made a great progress, and many hospitals have established the division of interventional therapy within the department of radiology and trained a lot of doctors under this discipline.

Great importance has been attached to the medical education and the training of radiologists as well. Among the 126 medical universities (schools) or colleges with clinical medical discipline, 7 medical colleges had medical imaging discipline^[14]. A part of students enter the department of radiology as residents after 5-7 years of study at college. A proportion of young radiologists pursued graduate studies for 3-6 years if they passed the required examinations. They are promoted through several years of practice to a higher position according to their experiences, achievements of clinical work and

number of published papers (generally, become an associated professor after 2-5 years, and a professor after 5-7 years). The title and length of education for fellows are different from that of America. Ph.D. (namely medical fellowship in America) can be trained and obtained in only 8 authorized medical schools, including Beijing Medical University, Shanghai Medical University, Tianjin Medical University, Peking Union Medical College, West China Medical University, Sun Yat-Sen University of Medical Sciences, The Second Military Medical University and the Fourth Military Medical University^[15,16].

CURRENT RADIOLOGIC CLINICAL PRACTICE AND RESEARCH IN CHINA

During the past 15 years, Chinese radiologists have accumulated a lot of clinical experience and made some valuable researches in CT, MRI, interventional radiology, angiography, ultrasound, nuclear medicine, etc., Approximately 10 thousand papers have been published in all kinds of Chinese radiological journals and periodicals (Table 1), but relatively a small number of research articles are submitted to western journals, because of the English language barrier.

CT

Clinical applications of CT technique have gradually been popularized throughout the country. Before the invention of spiral CT, dynamic incremental CT enhancement scanning was performed and adopted in most of the hospitals, mainly for detection of focal hepatic lesions. In addition, CTA and CTAP were also used for discovering the small primary and secondary hepatic lesions in the selected cases. In recent years, imported spiral CT scanners were installed in most of the large hospitals, some new techniques and researches regarding spiral CT (such as CT angiography, multi-planar or 3D imaging of bronchus, bone, etc.) were developed, particularly in university hospitals. Dual phase or multiphase spiral CT enhancement procedures were studied primarily in small hepatocellular carcinoma as well as in pancreatic and renal cancers. It was proved to be very sensitive in detecting the small neoplastic

lesions, in particular the hypervascular masses in liver during the arterial phase or combined phases. HRCT technique was used routinely in pulmonary cancer, single pulmonary nodule and diffuse pulmonary diseases. Special CT procedures for digestive tract, including mainly recto-colonic cancer and gastric cancer by filling those organs with ordinary water were successfully investigated, and the protocol accompanied by pronounced enhancement improved greatly the accuracy of the tumor staging. All kinds of CT training programs for radiologists were offered annually by the senior radiologists in order to improve their clinical experiences, master the new techniques and overcome some pitfalls. In a couple of hospitals in Beijing and Shanghai, electronic beam CT (UFCT) was available and the comparative studies of the detection and quantitative measurement of the calcification on the coronary arterial wall with angiography were performed to estimate the risk of the coronary heart attack^[17-22].

MRI

Since 1990, more MRI equipment have been imported to our country, different magnetic strengths of MRI machines have been installed in lots of large hospitals as well as in a few of medium-sized hospitals. In many hospitals, most cases of MRI inspection are still devoted to neurological system and skeletal system. MRI examination is mainly carried out to find the early cerebral ischemia and neurological tumors in many hospitals. Some university hospitals have used MRI to investigate a series of changes about cerebral ischemia and hemorrhage and compare with pathology in order to guide the clinical treatment. Investigation of MRI in skeletal system includes mainly the tumor of bone and soft tissue, trauma and other diseases of the joints. Significant achievements and good experiences have been obtained in studies on cardiac ischemia, cardiac infarction and reperfusion after infarction with dynamic enhanced MRI scans in comparison with isotope examination and coronary angiography in some hospitals (main university hospitals). MR angiography (MRA) was done successfully in cerebral, carotid and limb arteries, but with unsatisfactory results in thoracic and abdominal aorta and their branches. Over the past two years, 3D dynamic contrast enhanced MRA has been developed with improvement of imaging quality, such enhanced MRA technique was also applied to venous system, particularly to the portal venous system which can be shown simultaneously with hepatic veins and inferior vena cava as well as their collateral in cirrhotic cases. The good results have been yielded in more than 100 cases by this exams from Zhongshan Hospital, Shanghai Medical University. Other new MRI techniques such as MR cholangiography (MRC), MR cholangiopancreatography (MRCP), MR urography (MRU) and

MR myelography (MRM) aroused great interest and were improved with introduction of single shot SE sequence. According to the report of Zhongshan Hospital of Shanghai Medical University, fast dynamic enhanced MRI was superior to SE sequence in identifying the early lesions and making differential diagnosis for abdominal organ diseases. For small hepatocellular carcinoma, it might be better than dual phase contrast spiral CT and should be considered as a supplementary method. Currently, some new techniques like MR spectroscopy, MR with specific liver contrast media, rectal endocoil for pelvic organs, diffusion and perfusion for early cerebral ischemia, functional MRI, etc. are being developed and will be applied in the near future^[23-30].

Interventional radiology and angiography

Interventional radiology as a new branch of radiology was introduced into China in the mid 80's, and since then it has made spectacular progress. Transcatheter management of neoplasm is a very active field in interventional radiology and has been applied to the treatment of tumors at various sites of the body, especially for tumors of lung and liver. According to the statistics of Zhongshan Hospital of Shanghai Medical University, interventional treatments for liver cancer have been given to approximately 8000 advanced cases. The 1-, 2-, 3- and 5-year survival reached 65.2%, 35.3%, 24.6% and 9.8% respectively. In Changhai Hospital of the Second Military Medical University, the same work was carried out with similar result. The Chinese People's Liberation Army General Hospital and China Medical University Hospital have reported that they used TIPS technique for the treatment of portal hypertension and massive bleeding in about 500 cases with fruitful result. Several hundred cases with mitral stenosis have been treated by non-operative methods with excellent results in Fuwai Hospital of Peking Union Medical College, Guangdong Provincial Hospital and Jiangxi Medical University Hospital. In addition, percutaneous transluminal angioplasty was also widely used to dilate pulmonary valve, coronary and renal arterial stenosis and Budd-Chiari syndrome. Vascular and nonvascular stent implantation for vessels, bronchus, esophagus, bile duct, etc. have also been performed, and preliminary clinical experience has been achieved. Percutaneous aspiration biopsy guided by X-ray, CT and ultrasound is widely performed in diagnosis and treatment for the lesions of liver, lung, kidney, pancreas and bone. The interventional diagnosis and treatment, (e.g. thrombolytic therapy for cerebral ischemia) are not very common in China and MRI interventional therapy is still unavailable. Many large and medium-sized hospitals have the advanced DSA X-ray machines used for all kinds of angiography such as coronary angiography and cardioangiography, but

the application is gradually decreasing as noninvasive procedures (i.e., MRA, CTA and color Doppler US), have come into being^[31-35].

Ultrasound and nuclear medicine

Sonography is very popular in China, even being used for physical checkups because it is cheaper and safer and needs less time than other imaging modalities and easy to operate. The hospitalized patients basically received ultrasound examination on admission. Ultrasound (including color Doppler US and 3D US) is widely used for abdominal disease and heart disease and gynecologic and obstetrical diseases (including congenital and acquired heart diseases). The pregnant women undergo US examinations every 3 to 4 months in order to monitor the growth of the baby according to the physician's suggestion. In recent years, some new ultrasonic techniques have been put into clinical practice in a few hospitals such as contrast-enhanced US and endosonography.

Nuclear medicine departments and labs have been set up since the 1950s in many large hospitals and a few medium sized hospitals. Single photon emission computed tomography (SPECT) is mainly used for radiopharmaceutical studies and as a routine examination, it can provide diagnostic information in the setting of a nuclear medicine clinical services. Most of university hospitals have equipped this facility in China and has used it routinely and frequently in the investigation of the brain, the heart and the skeleton, especially in detecting the metastasis of bone. On the other hand, radioimmunological assay and analysis are also important parts of nuclear medicine. Positron emission tomography (PET) has been put into clinical practice in Shandong Province, Shanghai and Beijing, respectively. The Ministry of Public Health has approved Beijing and Shanghai to set up respectively clinical center of PET.

RADIOLOGICAL TRENDS OF CHINA IN FUTURE

In short, radiology of China has been greatly advanced over the past two decades and has played very important roles in the prevention and treatment of diseases, however, it is still in its developing stage. Some renowned radiologists in China have predicted that lots of hospitals will be supplied with spiral CT to replace conventional CT being used widely in clinical practice in 2-3 years. Some university hospitals will purchase the most advanced multislices spiral CT and multiple-functional MRI machine (e.g., possessing of EPI) in order to catch up the latest step of the world. Due to the need of clinical practice, development of PACS (picture archiving and communications system) continues to be a subject of intense interest and some university hospitals will be equipped with PACS, making the imaging transfer easier and quicker between radiological departments and clinical departments or among the divisions within the departments of radiology (including CT, MRI,

SPECT and US).

In regard to radiological research, the Chinese Society of Radiology recommended the improvement of early detection for small cancer such as small liver carcinoma, lung cancer and pancreatic cancer as the research objectives. In many hospitals, noninvasive procedures (i.e., MRA, CTA, MRCP and Dopple US) are being gradually substituted by the invasive procedures in radiological examination. Further studies are needed to get the optimal protocol of imaging modalities. Experimental researches in the field of radiology ought to be strengthened.

Lastly, radiology ultrasonography and nuclear medicine should be incorporated as a unified subject in term of administration and academic exchange in order to increase the accuracy of diagnosis and decrease unnecessary imaging examination. We are convinced that radiology of China will have a vigorous prospect and play more and more important roles in the care of people's health.

Dharmarajan TS, Sipalay M, Shyamsundar R, Norkus EP, Pitchumoni CS. Co-morbidity, not age predicts adverse outcome in *Clostridium difficile* colitis. *World J Gastroenterol*, 2000;6(2):198-201

Abstract

AIM To examine whether age alone or co-morbidity is a risk factor for death in older adults who developed *Clostridium difficile* (Cd) colitis during hospitalization.

METHODS A retrospective, observational study design was performed in our Lady of Mercy Medical Center, a 650-bed, urban, community-based, university-affiliated teaching hospital. 121 patients with a positive diagnosis of Cd colitis (aged 23-97 years) were studied, and data pertinent to demographic variables, medical history, co-morbidity, physical examination, and laboratory results were collected. Age was examined as a continuous variable and stratified into Age1 (<80 vs 80+); Age2 (<60, 60-69, 70-79 and 80+); or Age3 (<60, 60-69, 70-79, 80-89, 90+).

RESULTS Cd colitis occurs more frequently with advancing age (55% of cases >80 years). However, age, *per se*, had no effect on mortality. A history of cardiac disease ($P=0.036$), recurrent or refractory infection >4 weeks ($P=0.007$), low serum total protein ($P=0.034$), low serum albumin ($P=0.001$), antibiotic use >4 weeks ($P<0.01$), use of over

4 antibiotics ($P=0.026$), and use of certain classes of antibiotics ($P=0.035-0.004$) were predictive of death. Death was strongly predicted by the use of penicillin-like antibiotics plus clindamycin, in the presence of hypoalbuminemia, refractory sepsis, and cardiac disease ($P=0.00005$).

CONCLUSION Cd colitis is common in the very old. However, unlike co-morbidity, age alone does not affect the clinical outcome (survival vs death).

INTRODUCTION

Infection with the *Clostridium difficile* (Cd) bacterium is associated with a wide spectrum of gastrointestinal disorders that range from asymptomatic, to mild and sporadic diarrhea, to life threatening colitis^[1]. In older people, Cd colitis occurs frequently and is associated with high morbidity and mortality^[2]. In addition, epidemiological studies of Cd-induced diarrhea have identified an almost exclusive relationship to both antibiotic use and advancing age^[3]. Those most commonly affected are older people, the immunocompromised, and patients who undergo gastrointestinal surgery^[4]. In this report, we examined whether age alone or co-morbid conditions are risk factors for an adverse clinical outcome (death) in a sample of 121 patients who developed Cd colitis during hospitalization.

MATERIALS AND METHODS

This study was conducted at a 650-bed community teaching hospital in the Bronx, New York. We performed a retrospective review of the medical records of all patients who were admitted from the community or nursing homes during 2a (1995-02/1997-02). 121 patients with a positive diagnosis of Cd colitis were identified. Most Cd patients were older adults from the inner city. Demographic variables were collected, as were all data pertinent to their past and present medical history and their recent physical examinations. A positive diagnosis of Cd colitis was based on medical history,

Received 2000-02-12 Accepted 2000-03-08

gastrointestinal symptoms or signs plus a positive enzyme-link fluorescent immunoassay of *Cd* cytotoxin in A, and/or endoscopic biopsy-proven pseudomembranous colitis. Patient ages ranged from 23 to 97 years (78 ± 14). Included were 13 patients below 60 years (10 females and 3 males), 16 patients from 60-69 years (7 females and 9 males), 25 patients from 70-79 years (14 females and 11 males), 52 patients from 80-89 years (35 females and 17 males), and 15 patients from 90-97 years (9 females and 6 males). Study variables included patient's age, sex, and length of hospital stay. Data referring to pre-existing medical conditions (diabetes, dementia, tube feeding, COPD, hypertension, cardiac disease), gastrointestinal symptoms, fever, and the number, class, and duration of all antibiotics used were collected. Sepsis or infection were defined as the presence of a body temperature $>38^{\circ}\text{C}$, heart rate >90 beats/min, respiratory rate >20 /min, and WBC count $>12 \times 10^9/\text{L}$. Sepsis not responsive to therapy after four weeks was defined as refractory. Laboratory results (total protein, albumin, BUN, creatinine, creatinine clearance, CBC) were noted.

The effect of age was examined using age both as a continuous variable and stratified into integer variables as follows: Age1 (2 groups; 23-79 years and over 80), Age2 (4 groups; 23-59, 60-69, 70-79, and over 80 years), Age3 (5 groups; 23-59, 60-69, 70-79, 80-89, and over 90 years). Study variables [low total protein ($<70\text{g/L}$), low albumin ($<35\text{g/L}$), elevated BUN (7.15mmol/L), high creatinine ($132.6\mu\text{mol/L}$), low creatinine clearance ($<50\text{mL/min}$)] were examined using Fisher's exact test, Student *t* test for unpaired data, and (simple, multiple, and logistic) regression analysis to determine whether age, co-morbidity, antibiotic use, or specific laboratory chemistries were associated with an adverse clinical outcome (death). Statistical analyses were performed on an IBM-compatible PC using STATA-TM (version 5.0, Stata Corp., College Station, TX, <http://www.stata.com>) and a two-tailed significance level of $P < 0.05$ was considered to be significant.

RESULTS

In this sample of 121 *Cd* colitis patients ranging in age from 23-97 years, we observed that *Cd* colitis occurred more frequently in those with advanced age, (55% of our subjects were >80 years). Nevertheless, when age was examined as a continuous variable (23-97 years) or stratified into different integer variables (Age 1, Age 2, and Age 3) it was not associated with increased mortality (Table 1). We also found that a number of co-morbidity related variables were predictive of an adverse outcome (Table 2). For example, the

presence of cardiac disease ($P=0.036$), an elevated serum BUN ($P=0.039$), low serum total protein ($P=0.034$), and low serum albumin ($P=0.001$) predicted death. In addition, recurrent or refractory infection over 4 weeks ($P=0.007$), prolonged antibiotic use ($P=0.010$), use of 4 or more antibiotics ($P=0.026$), and use of different classes of antibiotics ($P=0.035-0.004$) were found to predict death. The strongest predictor of death was the combined use of penicillin-like-antibiotics plus clindamycin, in the presence of hypoalbuminemia and refractory sepsis >4 weeks, in a patient with a history of cardiac disease ($P=0.00005$).

Table 1 Patient age and sex vs outcome at discharge
(n,%, $\bar{x} \pm s$)

Variable	Alive	Dead	P value
Patient age (yrs)	76.1 ± 15.0	78.9 ± 13.5	0.383(1,a)
Patient sex (M/F)	36/58	10/17	0.546(2)
Age 1 (yrs)			
23-79	45(83%)	9(17%)	0.192(2)
80-97	48(73%)	18(27%)	
Age 2 (yrs)

60-69	12(75%)	4(25%)	
70-79	21(84%)	4(16%)	
80-89	37(71%)	15(29%)	
90-97	12(80%)	3(20%)	

(1):Student *t* test; (2):Fisher's exact test; (a):Additional log istic regression analysis.

Age (as continuous variable) did not predict adverse outcome or death ($P=0.382$).

Table 2 Co-morbidity vs adverse outcome at discharge

Variable	Not predictive	Predictive	P value
Co-morbidity			
Cardiac disease (1)	—	×	0.036
COPD	×	—	0.200
Dementia	×	—	0.075
Diabetes	×	—	0.622
Hypertension	×	—	0.387
Elevated BUN	—	×	0.039
High creatinine	×	—	0.106
Low creatinine clearance	×	—	0.928
Nutrition related			
Tube-fed	×	—	0.241
Low serum total protein	—	×	0.034
Low serum albumin	—	×	0.001
Sepsis related			
Aminoglycosides	×	—	0.034
Clindamycin	—	×	0.004
Penicillin-like (2)	—	×	0.035
Antibiotic use $>4\text{wk}$	—	×	0.010
Use of >4 antibiotics	—	×	0.026
Fever ($>38.3^{\circ}\text{C}$)	×	—	0.181
Infection $>4\text{wk}$	—	×	0.007

Results are given as predictive or not predictive of death as the adverse outcome and were determined using logistic regression analysis.

(1): 64 cardiac patients were identified with 19 deaths during hospitalization.(2): Excluding cephalosporins.

DISCUSSION

Our study revealed that the use of broad spectrum penicillins (ampicillin, amoxi cillin clavulanic acid, nafcillin, piperacillin, ticarcilin-clavulanate, ampicillin-sulbactam), cephalosporins (cefazolin, cefuroxime, cefoxitin, ceftaz idime, ceftriaxone), macrolides (erythromycin, clarithromycin, azithromycin), aminoglycosides (gentamicin, amikacin), vancomycin, clindamycin, ciprofloxacin, trimetoprim-sulfamethoxazole, and doxycycline was associated with an increased risk of *Cd* colitis. In particular, we found that clindamycin, aminoglycosides and penicillin-like antibiotics were positively related to an adverse outcome (death). Interestingly, although cephalosporins are among the most common agents associated with the development of *Cd* colitis, reflecting their widespread use, our study did not identify their use to correlate with increased mortality^[5].

Our patients ranged in age from 23 to 97 years with the majority (108/121) over the age of 60 years and advancing age is often referred to as a risk factor for developing *Cd* colitis^[2-4]. Other factors reported to be associated with an increased risk of *Cd* colitis are immunosuppression, hospitalization, surgical procedures involving the gastrointestinal tract and medications that alter intestinal motility or intestinal flora^[3-8]. Among medications, the key factor appears to be antibiotic therapy that can alter the normal equilibrium of colonic flora and create an environment that permits *Clostridium difficile* to flourish^[7]. Many antibiotics have been linked to *Cd* infection, but broad spectrum antibiotics with activity against enteric bacteria are the most frequently implicated agents^[7]. Clindamycin is notorious for its association with *Cd* colitis^[8]. The literature further suggests that the most common antibiotics associated with *Cd* colitis are the broad spectrum penicillins and cephalosporins which may simply reflect their widespread use^[5]. *Cd* colitis infection may be induced by oral, parenteral, or topical antibiotic therapy^[9].

Antibiotic associated *Cd* colitis has been linked to *Clostridium difficile* bacterium and to the cytotoxin produced by the organism^[9-11]. Antibiotic-associated diarrhea and colitis are important and increasingly frequent complications of antibiotic therapy that occur often in hospitals, nursing homes, and in the community^[12]. Population based studies in Sweden showed that the incidence of *Cd* toxin positive stools increases 20-100 fold when persons aged 10-20 yr are compared with those over 60^[13]. Multivariate analysis of hospitalized patients, colonized with the *Cd* bacterium, also show that increasing age correlates

positively with the clinical expression of the disease^[14]. This finding suggests that aging promotes susceptibility to *Cd* colonization, *Cd* toxin production, and the onset of *Cd* colitis^[15].

While most studies demonstrate that *Cd* colitis occurs commonly in the geriatric population, few comment on patient age as a variable that could affect an adverse outcome. We analyzed age as a continuous variable and as different integer variables and our analyses did not reveal that age was directly associated with an adverse outcome (death). As presented in this report, we believe that other factors associated with the aging process such as cardiac disease, refractory sepsis and/or low serum albumin were the more likely contributory factors linked to an increased risk of death. Among comorbid factors, coronary artery disease and congestive heart failure appeared to be the strongest predictor of death. Of our 64 cardiac patients, 19 died during hospitalization.

Other co-morbid factors studied such as diabetes mellitus, hypertension, COPD, and dementia did not affect mortality. In addition, the use of tube feeding, the presence of gastrointestinal symptoms, fever, and laboratory abnormalities such as high serum creatinine or low creatinine clearance were not predictive of increased mortality. On the other hand, we observed that an elevated BUN alone was predictive of increased mortality ($P=0.039$). Elevated BUN may have resulted (in these patients) from one or more of several pre-renal factors such as cardiac failure, volume depletion, catabolic states, and gastrointestinal bleeding as the basis. Also, factors predictive of death were refractory or recurrent infection lasting longer than 4 weeks ($P=0.007$), the use of penicillin-like antibiotics, ($P=0.035$), clindamycin ($P=0.004$) or aminoglycosides ($P=0.034$), and antibiotic use over 4 weeks ($P=0.01$). Obviously, the presence of recurrent or refractory infection usually requires prolonged use of antibiotics. Thus, it is conceivable that long-standing infection alone led to the increased mortality, while prolonged use of antibiotics was merely an association or a contributing factor to the adverse outcome. While we did not study treatment failure or relapse, previous work from our institution examined the factors influencing treatment failure and relapse, age, sex, co-morbid illnesses, and found that the type(s) of antibiotics that precipitate colitis were not associated with either the response to therapy or relapse^[16,17].

Nutritional status also appears to influence outcome in *Cd* colitis patients. In our study, hypoalbuminemia was strongly predictive of an adverse outcome ($P=0.001$). The literature states that serum albumin (<25 g/L) is a risk factor for

increased mortality, more significantly, a fall in serum albumin of greater than 11g/L at the onset of symptoms of *Cd* infection is positively associated with poor outcome^[17].

Hypoalbuminemia probably results from a loss of body protein in the stool caused by the inflammatory exudate, or by depressed hepatic protein synthesis in response to sepsis or malnutrition which is common among hospitalized elderly^[18]. Low serum albumin is a well-recognized marker for malnutrition^[19] and is strongly associated with poor clinical outcome in *Cd* colitis^[17].

While *Cd* colitis is more common in older individuals, our study suggests that age, per se, does not influence clinical outcome (survival/death). We observed that refractory sepsis, requiring use of antibiotics (in particular, certain classes of antibiotics) for over four weeks in the presence of hypoalbuminemia and coexisting cardiac disease were strongly predictive of adverse outcome (death) in *Cd* colitis in our hospitalized patients ($P < 0.00005$). Other factors such as COPD, dementia, hypertension, elevated creatinine or low creatinine clearance, and tube feeding were found not to affect the outcome in *Cd* colitis.

Abstract

AIM To study the agglutination pattern of *Helicobacter pylori* coccoid and spiral forms.

METHODS Assays of agglutination and agglutination inhibition were applied using fifteen commercial lectins.

RESULTS Strong agglutination was observed with mannose-specific *Concanavalin A* (Con A), fucose-specific *Tetragonolobus purpureus* (Lotus A) and N-acetyl glucosamine-specific *Triticum vulgaris* (WGA) lectins. Mannose and fucose specific lectins were reactive with all strains of *H. pylori* coccoids as compared to the spirals. Specific carbohydrates, glycoproteins and mucin were shown to inhibit *H. pylori* lectin-agglutination reactions. Pre-treatment of the bacterial cells with formalin and sulphuric acid did not alter the agglutination patterns with lectins. However, sodium periodate treatment of bacterial cells were shown to inhibit agglutination reaction with Con A, Lotus A and WGA lectins. On the contrary, enzymatic treatment of coccoids and spirals did not show marked inhibition of *H. pylori* lectin agglutination. Interestingly, heating of *H. pylori* cells at 60°C for 1 hour was shown to augment the agglutination with all of the lectins tested.

CONCLUSION The considerable differences in lectin agglutination patterns seen among the two differentiated forms of *H. pylori* might be attributable to the structural changes during the events of morphological transformation, resulting in exposing or masking some of the

sugar residues on the cell surface. Possibility of various sugar residues on the cell wall of the coccoids may allow them to bind to different carbohydrate receptors on gastric mucus and epithelial cells. The coccoids with adherence characteristics like the spirals could aid in the pathogenic process of *Helicobacter* infection. This may probably lead to different clinical outcome of *H. pylori* associated gastroduodenal disease.

INTRODUCTION

Helicobacter pylori has established firmly as a human pathogen causing chronic active gastritis and peptic ulcer^[1-3]. In addition, there are epidemiological data that support association between *H. pylori* infection and the development of varieties of gastric cancers^[4-6]. However, the pathogenetic mechanisms of *H. pylori* induced gastroduodenal disease are not well established^[7-9].

The widespread prevalence of *H. pylori* infection indicates its infectivity. In general, the success of a pathogen depends on both its virulence and pathogenicity^[8-9]. Of these, adherence to surface receptors is an essential step in the pathogenesis for many bacteria^[10]. The attachment is mediated by adhesins or ligands which may be soluble or cell-associated and can be demonstrated by haemagglutination of various species of erythrocytes^[10-11]. Previously, it was reported that the surface of *H. pylori* contains lectins or adhesins which may influence its adherence to the membrane of surface mucous cells^[12]. Since lectins have the ability to bind to a wide variety of microbial substances containing simple or complex carbohydrates, they have been used to detect cell wall modifications, elucidate complex cell wall carbohydrates and detect intra-strain variations in cell wall carbohydrates or carbohydrate linkages^[13-14].

The specificity of lectin binding to bacterial surface carbohydrates has been reported^[15] and exploited as a tool for typing microorganisms, such as *Neisseria*^[16,17], *Staphylococcus*^[18], *Legionella*^[19], *Bacillus*^[20], *Campylobacter*^[21-22], *Helicobacter*^[23] and *Streptococcus species*^[24-25]. bacteria, including *H. pylori*, were found to have cell wall associated lectins which allow them to bind selectively to mucus and epithelial cells^[8,12]. Emody et al (1988)^[26] also showed that *H. pylori* lectins attach to red cells from various animal species. Moreover, it was suggested that bacterial surface haemagglutinins and lectins play a significant role in pathogenesis of many mucus-associated infections^[11]. However, lectins were studied only on spiral forms of *H. pylori*. In this study, we applied lectin agglutination to characterize the carbohydrate residues on the cell wall of *H. pylori* coccoids as compared to spiral and to examine the agglutination profiles of *H. pylori* coccoids and spirals.

MATERIALS AND METHODS

Bacterial strains and spiral forms of *H. pylori*

Two local strains, RH 54, V₂ and a standard strain, NCTC 11637 were grown on moist chocolate blood agar at 37°C for 3 days in a humidified, 5% CO₂ incubator (Forma Scientific) to provide homogeneous spiral forms as described in Khin and Ho (1994)^[27]. The spiral nature was observed under phase contrast microscope (Nikon Microphot-FXA, Japan).

Preparation of coccoid forms

Ageing coccoids were obtained as described in Khin et al (1996)^[28]. Additionally, induced coccoids were also prepared by culturing the 3-day-old spirals in brain heart infusion medium supplemented with 10% horse blood and 0.4% yeast extract and exposed to amoxicillin (Sigma) in a final concentration of 5mg/L. The broth containing coccoid forms when inoculated onto moist chocolate blood agar and incubated in a humidified incubator (Forma Scientific, USA) at 37°C with 5% carbon dioxide did not show any growth after 12 days of incubation.

Both spiral and coccoid forms were washed in PBS (pH 7.4) for 3 times. The bacterial cells were resuspended to a final concentration of 1×10^{10} cells/mL in PBS. Spirals and coccoids were enumerated in triplicates using a bacteria counting chamber under phase contrast microscope.

Lectins

The lectins used (Table 1) were selected on the basis of their reported specificities, to cover the widest possible range of sugars. All are commercially available from Sigma (St. Louis, USA). The lectins were resuspended at 1µg/L in PBS (pH 7.4) and stored at -20°C until use.

Agglutination assay

Agglutination assay was carried out according to

the method described by Ascencio et al (1990)^[23]. The assay was performed in triplicates. Binding of lectins to coccoids and spirals were assayed using glass slides by mixing 20µL of bacterial suspension with an equal volume of lectin solution. A negative control was included for each strain by adding 20µL of PBS instead of lectin solution. The agglutination reaction was scored as follows:

3=strong positive reaction with large clumps;
2=strong- positive reaction with moderate size clumps;
1=positive agglutination with fine clumps; w=weak agglutination; -=no agglutination.

Table 1 Major sugar specificities of lectins used in this study

Lectin	Abbreviation	Carbohydrate specificity
Arachis hypogaea	PNA	β-D-Gal(1-3)GalNAc
Bandeirae simplicifolia	BS-I	α-Gal, α-GalNAc
Concanavalin A	Con A	α-D-Man, α-D-Glc
Datura stramonium	DSA	(D-GlcNAc) ₂
Glycine max	SBA	D-GalNAc
Helix promatia	HPA	D-GalNAc
Lens culinaris	LcH	α-D-Man
Narcissus pseudonarcissus	NPA	α-D-Man
Pisum sativum	PEA	α-D-Man
Tetragonolobus purpureas	Lotus A	α-L-Fuc
Triticum vulgaris	WGA	(D-GlcNAc) ₂ , NeuNAc
Vicia faba	VFA	D-Man, D-Glc
Vicia sativa	VSA	D-Glc, D-Man
Vicia villosa	VVA	D-GalNAc
Vigna radiata	MBA	α-Gal

Gal=D-Galactose; GalNAc=N-acetyl galactosamine; GlcNAc=N-acetyl glucosamine; NANA=N-acetyl neuraminic acid; Man=Mannose; Glc=Glucose; Malt=Maltose; Suc=Sucrose; Fuc=L-Fucose.

Agglutination Inhibition Assay

To test whether the agglutination was inhibited by specific glycoproteins or carbohydrates, 20µL of each lectin solution was incubated with an equal volume of the test substance at 20°C for 1 hour before adding 20µL of bacterial suspension. The agglutination reaction was scored accordingly.

Carbohydrates (Gal, GalNAc, GlcNAc, NANA, Man, Glc, Malt, Suc and Fuc) were dissolved at a final concentration of 0.1M in PBS (pH 7.4). Glycoproteins (bovine submaxillary mucin, porcine stomach mucin, fetuin, asialofetuin, bovine orosomucoid and gangliosides II) were dissolved at a final concentration of 0.1% in PBS. All these chemicals were purchased from Sigma.

Pre-treatment of bacterial cells

H. pylori RH 54 spirals and coccoids were treated with sodium periodate (0.075 M), sulfuric acid (0.025N), formalin (1% w/v) and glycine hydrochloride buffer (pH 2.2). Bacterial cells were also heated at 60°C for 1 hour. Alternatively, these spirals and coccoids were treated with neuraminidase, trypsin, pepsin, proteinase K and chymotrypsin each at 0.1µg/L for 1 hour at 37°C.

After treatment, bacterial cells were washed three times with PBS and resuspended to 10^{10} cells/mL in PBS and used for the agglutination assay.

Reproducibility

Reproducibility of lectin agglutination was confirmed by repeating the test three times.

RESULTS

The coccoids and spirals of all three strains of *H. pylori* tested showed different agglutination reactions to the 15 lectins. The sugars recognized by *H. pylori* coccoids and spirals were Man, Fuc, Glc, Gal, GalNAc and (GlcNAc)₂ (Table 2). Among the 15 lectins tested, strong agglutination patterns were observed with Man-specific Con A, Fuc-specific Lotus A and (GlcNAc)₂-specific WGA lectins (Table 2). All of the coccoids and spirals were agglutinated by the Man-specific Con A, PEA and VFA lectins, GalNAc-specific HPA and Glc-specific VSA lectins (Tables 2 and 3). RH 54 coccoids reacted with all the 15 lectins tested (Table 2) whereas NCTC 11637 coccoids were found to be non-reactive with WGA and VVA lectins. Similarly, SBA, VVA and MBA lectins were not reactive to V₂ coccoids (Table 2). The spirals were refractory to agglutination with Man-specific LcH and NPA lectins (Table 2). Interestingly, NCTC 11637 spirals were non-reactive with Fuc-specific Lotus A, Gal-specific PNA and BS-I and (GlcNAc)₂-specific DSA and WGA lectins.

α -D-Man/Con A, LcH, NPA, PEA and VFA binding

It is interesting to note that Man was recognized by all the coccoids as compared to the spirals, since all the coccoids were agglutinated by the Man-specific Con A, LcH, NPA, PEA and VFA lectins (Tables 2 and 3). In contrast, three strains of spirals were agglutinated by Con A, PEA and VFA, but none of the spirals was reactive to LcH or NPA lectins (Tables 2 and 3).

α -L-Fuc/lotus A affinity

Three strains of *H. pylori* coccoids were agglutinated by Fuc-specific Lotus A lectin (Tables 2 and 3). All the spirals except NCTC11637 spirals reacted with Lotus A (Table 2). Strong agglutination pattern was shown by RH 54 and HpV₂ coccoids as well as spirals (Table 2).

(D-GlcNAc)₂/DSA and WGA binding

Both RH 54 and V₂ coccoids as well as spirals had an affinity for GlcNAc residue as shown by agglutination with DSA and WGA lectins. NCTC 11637 spirals were non-reactive to both DSA and WGA but their corresponding coccoids showed agglutination with DSA (Table 2).

D-GalNAc/HPA, SBA and VVA binding

Among the three strains of coccoids, only RH 54 coccoids reacted with GalNAc-specific HPA, SBA and VVA lectins. Among these three lectins, HPA was the only lectin which agglutinated all the coccoids tested. Interestingly, V₂ coccoids lacked the affinity to both SBA and VVA lectins (Table 2). On the other hand, NCTC 11637 coccoids were agglutinated by SBA but not by VVA lectins (Table 2). All the spirals tested were found to be agglutinated by HPA, SBA and VVA lectins (Table 3).

D-Glc, D-Man/VSA binding

Three strains of *H. pylori* coccoids and their corresponding spirals were observed to be agglutinated by VSA lectin (Tables 2 and 3). Strong agglutination was given by NCTC 11637 and V₂ coccoids (Table 2).

β -D-Gal or α -Gal/PNA, BS-I and MBA binding

The coccoids of RH 54 and NCTC 11637 showed affinity to Gal-specific PNA BS-I and MBA lectins but V₂ coccoids were non-reactive to MBA lectin (Table 2). On the other hand, MBA lectin agglutinated with all the spirals tested (Tables 2 and 3). Among the spirals, only NCTC 11637 spirals were non-reactive with PNA and BS-I lectins (Table 2).

Table 2 Lectin agglutination patterns of *H. pylori* coccoids and spirals

α -Gal/MBA	2	3

Reproducibility testing revealed that lectin patterns were not altered after subculture. Among the three *H. pylori* strains, RH 54 was chosen since it showed agglutination with at least 13 out of 15 lectins tested. Of the 15 lectins, Con A, Lotus A and WGA which gave strong agglutination were chosen for further studies on the specificity of these lectin agglutination (Tables 4 and 5). Specific sugars, glycoproteins and mucin altered the lectin-bacterial agglutination reactions. As shown in Table 4, bovine submaxillary mucin reduced RH 54-Con A agglutination but did not alter the Lotus A and WGA binding patterns. Of great interest was the porcine stomach mucin, which not only reduced the binding ability to Con A and Lotus A but also completely inhibited RH 54-WGA binding. Fetuin slightly reduced RH 54 coccoids-WGA binding and the spirals-Con A agglutination patterns. Other glycoproteins like asialofetuin, bovine orosomucoid and gangliosides II display a considerable inhibitory ability on binding of RH 54 by Con A and WGA. More importantly, *H. pylori* Lotus A agglutination patterns were strong and were not inhibited by various glycoproteins with the exception of porcine stomach mucin that slightly reduced the coccoids-Lotus A binding capacity.

In the same way, Gal, GalNAc, GlcNAc, NANA, Glc and Suc affected inhibition on *H. pylori* lectin agglutination reactions except Lotus A agglutination pattern (Table 4). It was interesting to note that Man and Malt completely inhibited coccoids and spirals-binding to Con A. On the other hand, the strong agglutination of Lotus A with coccoids and spirals was completely inhibited by fucose (Table 4). In general, agglutination to Con A was either weakened or completely inhibited by carbohydrates. In contrast, WGA agglutination remained unaffected with *H. pylori* spirals whereas the agglutination with coccoids reduced.

RH 54 spirals and coccoids exhibited different agglutination patterns according to their pre-treatment (Table 5). Pre-treatment of the bacterial cells with formalin (1.0%), glycine HCl buffer (pH 2.2) and sulphuric acid (0.025 N) did not alter the agglutination patterns with lectins. In contrast, sodium periodate treatment of bacterial cells was shown to entirely inhibit agglutination reaction with Lotus A and WGA lectins, but reduce the agglutination with Con A. Of interest was the heating of *H. pylori* cells at 60°C for 1 hour which was shown to augment the agglutination reaction with all three lectins (Con A, Lotus A and WGA) tested (Table 5).

Enzymatic treatment of coccoids and spirals did not show marked inhibition of helicobacter-lectin binding patterns (Table 5). Neuraminidase, trypsin, pepsin, proteinase K and chymotrypsin did not change bacterial cells-Lotus A or bacterial cells-WGA agglutination. However, prior treatment of RH 54 coccoids with enzymes decreased agglutination with Con A.

Table 4 *H. pylori* lectin-binding inhibition

Inhibitor	RH 54 coccoids			RH 54 spirals		
	Con A	Lotus A	WGA	Con A	Lotus A	WGA

DISCUSSION

In this study the carbohydrate residues on the cell wall of *H. pylori* spirals and coccoids were characterized by lectin agglutination performed on the glass slides. The observations that the use of glass slides for helicobacter-lectin agglutination is simple, cost-effective and rapid, was supported by Davidson *et al* (1982)^[18] and Wong *et al* (1986)^[21] in their studies on *Staphylococcus* and *Campylobacter* species, respectively. The microtitre plates were also used to study the interaction between bacterial cells and lectins for testing large numbers of strains^[20,29-30]. However, slide assays have the advantages of yielding results in less than two minutes. This finding concurred with that of Wong *et al.* (1986)^[21] who reported that slide agglutination assay was the procedure of choice for determining lectin reaction patterns among *Campylobacter jejuni* and *Campylobacter coli*. More importantly, interference from auto-agglutination is less frequent because bacterial cells-lectin agglutination occurs rapidly on glass slides before non-specific agglutination in the controls become evident.

The fifteen lectins evaluated in this study were selected because their major specificities were for common saccharides present on the bacterial surface. Typing of bacterial strains in epidemiological studies using plant lectins was found to be a powerful method for differentiating strains of related species^[18,20-21]. In this study, RH 54, NCTC 11637 and V₂ spirals were refractory to agglutination with LcH and NPA lectins, specific for mannose residues, implying that the spirals might have less affinity for mannose (Table 2). On the other hand, NCTC 11637 spirals did not react with Fuc-specific Lotus A, Gal-specific PNA and BS-I and (GlcNAc)₂-specific DSA and WGA lectins. It indicates that different lectin agglutination pattern shown by NCTC 11637, may be useful for discriminating it from RH 54, V₂ and other *H. pylori* strains.

Moreover, among *H. pylori* coccoids, RH 54 reacted with all lectins while NCTC 11637 was non-reactive with GalNAc-specific VVA and (GlcNAc)₂-specific WGA lectins (Table 2). In contrast, V₂ coccoids did not show reactivity to Gal-specific MBA and GalNAc-specific SBA or VVA lectins. The possible reason of different lectin agglutination patterns seen among the spiral and coccoid forms of three *H. pylori* strains studied, might be attributable to the considerable differences among different strains as well as the two morphological forms of the same strain in the affinity for the carbohydrate receptors of the host. This may eventually influence the adherence capabilities of *H. pylori* in gastric colonization resulting in different gastroduodenal pathology. It is

suggested that lectins can also be used for characterization of *H. pylori* strains which will confer as a useful method for epidemiological studies to determine the natural history and mode of transmission of *H. pylori* as was also reported by Ascencio *et al* (1990)^[23].

Lectins have been used to identify and distinguish microorganisms based on different sugar components on their cell surfaces^[14]. All the coccoids tested were shown to recognize Man-specific lectins, in contrast to the spirals (Table 3), suggesting that the coccoid forms of *H. pylori* might have predilection for Man-receptors of the gastric tissues. This could possibly be due to acquisition of Man-residues which may become available for binding gastric tissues during transformation from spirals to coccoids. Baczako *et al.* (1995)^[31] reported the differences in lectin binding properties of the antral and body surface mucosa of the human stomach and questioned whether it may be relevant for *H. pylori* affinity. The lectins from the jack bean, Con A as well as fava bean, VFA known to have an affinity for Man>Glc residues and another mannose-specific lectin, PEA reacted with three strains of *H. pylori* coccoids and spirals (Table 4). It indicates that Man/Glc residues present on the cell surface may contribute to their binding. Lectin histochemistry studies showed that the staining for mannose and glucose (bound by succinylated Con A) was negative in normal mucosa but was positive in *H. pylori* infected mucosa^[31]. It is therefore possible that *H. pylori* coccoid form having stronger affinity for mannose residues (Tables 3 and 4) might mediate its adherence to the corresponding mannose receptors existing in the gastric mucous cells for its colonization. It is suggested that the two differentiated forms of *H. pylori* might have various forms of Man-associated lectins which allow them to bind selectively to the mucous and epithelial cells thereby facilitating gastric colonization.

The specificity of bacterial agglutination by lectins resides in the unique cell surface structures of the bacteria interacting with the carbohydrate-specific lectins^[18,32-33]. The lectin from asparagus pea, Lotus A shown to an affinity for Fuc residues were recognized by three strains of *H. pylori* coccoids and spirals with the exception of NCTC 11637 spirals (Table 2). It was reported that fucose was more likely to function as a receptor for *H. pylori* related adhesion^[34]. It is possible that both the coccoid and spiral forms might have different Fuc specificities on the surface of the cells, contributing to the various degrees of *H. pylori* adhesion. Such different affinities might mediate their binding to gastric mucosa resulting in various forms of gastroduodenal pathology.

H. pylori coccoid forms may have retained the

lectin binding sites for Fuc determinants, in an unmodified form or could have been the components of the surface of the coccoids. Support of this view comes from the observations that several *Bacillus cereus* expressed different lectin binding sites on spores and vegetative cells^[20]. In addition, the lectin-staining pattern of surface mucous cells demonstrates, that there are mainly neutral carbohydrates (fucose and galactosamine) localised within the mucous granules^[12]. Therefore, it is possible that cell wall of *H. pylori* coccoids and spirals bearing different affinity for Fuc residues might influence the binding to different gastric mucous cells receptors to obtain various pathogenic potentials in *Helicobacter* infection.

N-acetylglucosamine specific lectins from wheat germ, WGA and jimson weed, DSA showed agglutination with RH 54 and V₂ spirals and coccoids (Tables 2 and 3). On the other hand, DSA agglutinated only NCTC 11637 coccoids. Interestingly, the refractory of NCTC 11637 spirals and coccoids agglutination with WGA suggests either masking of GlcNAc-residues, absence of these units, or exposure of these units may differ between *H. pylori* strains. RH 54 and V₂ spirals showed stronger agglutination reaction with WGA lectins than the coccoids (Table 2). This could be due to the acquisition of thick polysaccharide capsule on the coccoidal cells^[35] resulting in weaker agglutination with WGA lectin. A similar mechanism was demonstrated on *Neisseria* species in which WGA was shown to specifically agglutinate *Neisseria gonorrhoeae* but not the encapsulated *N. meningitidis* suggesting that agglutination with WGA is due to the lack of a capsule on the gonococci^[16].

All the spirals studied were shown to recognize GalNAc-specific lectins from HPA, SBA and VVA (Table 3) as was shown earlier by Ascencio *et al* (1990)^[23]. *H. pylori* coccoids showed weaker affinity for GalNAc residues (Tables 2 and 3) suggesting that structural modifications might occur on the cell wall of the coccoids during morphological transformation from the spirals. It is proposed that *H. pylori* coccoids, a morphological variant of the spirals, might bind with different capacities to galactosamine receptors localised within gastric mucous granules, as was also observed for the spirals by Bode *et al.* (1988)^[12]. After binding to the host cells, it may then take part in various mechanism of adhesion resulting in the gastroduodenal disease. Adhesion is considered as one of the virulence factors that allow *H. pylori* spirals to survive in the hostile gastric environment. Its ability to adhere to gastric mucosal cells and mucus^[7,9,36] suggests that the coccoids may also use the same adherence mechanism for gastric colonization.

The ability of three strains of coccoids as compared to all spirals in agglutinating Glc-specific lectin (VSA) (Table 3) could be due to the retention of Glc residues on the cell surface of the coccoid forms during morphological conversion. Since the cell wall is an important virulence factor in many bacteria^[25], the cell wall of *H. pylori* coccoids bearing similar Glc residues like the spirals, may be attributable to the virulence.

The absence of agglutination with PNA, which detects β -D-Gal (1-3) GalNAc and with BS-I, which detects α -Gal and α -GalNAc, suggests that these carbohydrates are not present on the reactive surface of NCTC 11637 spirals (Tables 2 and 3). This agglutination pattern might aid in differentiating *H. pylori* spirals. It was also shown by Ascencio *et al.* (1990)^[23] who developed the lectin typing system of 50 *H. pylori* strains for epidemiological studies. On the other hand, Gal-specific MBA lectin did not agglutinate V₂ coccoids (Table 2) indicating the lack of this sugar on the cell wall of the coccoids.

Porcine stomach mucin completely inhibited RH 54-WGA binding (Table 4) verifying that the agglutination is specific and this glycoprotein has the highest affinity for that lectin. Inhibition studies with various carbohydrates suggest that Glc, Fuc, Man, Gal and GlcNAc are present on the surface of *H. pylori* coccoids and spirals indicating that this application may provide valuable information about the specific sugars present on the cell surface of the two differentiated forms of *H. pylori*. In an earlier study, Facinelli *et al.* (1994)^[30] stated that *Listeria*-lectin binding inhibition studies were useful for characterization of specific sugars present at the cell surface of an organism.

RH 54 coccoids and spirals were found to be non-reactive with Con A, Lotus A and WGA lectins after sodium periodate treatment (Table 5) suggesting that NaIO₃ probably had destroyed the surface carbohydrate structures of these cells. A similar observation was made by Ascencio *et al.* (1990)^[23]. However, the reactions were shown to be resistant to sulphuric acid (0.025N), glycine hydrochloride (pH 2.2) and formalin (1.0%) indicating that these chemicals were not effective to alter the *H. pylori* lectin binding.

Treatment of *H. pylori* cells at 60°C for 1 hour was shown to give stronger agglutination capacities with Con A, Lotus A and WGA lectins (Table 5). It could be possible that heating releases the concealed carbohydrate residues to be exposed onto the surface of *H. pylori* spirals and coccoids. Heating was found to eliminate interference of non-specific cell agglutination. A comparable finding was reported on *Campylobacter jejuni* and *C. coli* that bacterial interaction with lectins was greatly

enhanced by heating the cultures to 100°C and holding for 30 to 60 minutes^[21]. They found that heating had made it feasible to type most rough and auto-agglutinating strains as well as smooth cultures. Pre-treatment may therefore be a prerequisite for agglutination with lectins. Pre-treatment was shown to augment the agglutination reactions of *Streptococcus* species^[25] although it increases the time required to carry out the assay^[24,37].

RH 54 coccoids-Con A agglutination patterns changed after treatment with enzymes such as, neuraminidase, trypsin, pepsin, proteinase K and chymotrypsin (Table 5). It could be due to the partial destruction of the bacterial surface structures by enzymes resulting in weaker agglutination reactions. However, Lotus A and WGA lectins did not alter the agglutination patterns, indicating that pretreatment with enzymes could probably be necessary for the lectin typing assays. It agrees with the studies on streptococci that when trypsin or other proteolytic enzymes partially hydrolyse proteoglycans, some carbohydrate residues may become available for binding^[25,37]. At the same time, other carbohydrate residues may be destroyed or modified. This study shows that lectin-bacterial agglutination patterns may differ according to the pre-treatment of the bacteria. In addition, the bacterial surface structures might be partially destroyed by enzyme treatment as carbohydrate residues dissolve in the buffer while others, previously hidden, then become exposed on the surface^[25]. Enzymatic treatment may therefore be useful for typing *H. pylori* as was also reported by Ascencio *et al.* (1990)^[23].

Lectin reactions provide an attractive alternative method for typing microorganisms with minimum specialised facilities. In addition, lectin agglutination assay is rapid, inexpensive, reproducible, require no special equipment, simple to perform and a useful method for epidemiological studies. This study shows that lectins are stable and easy to store, commercially available and active at low concentration. However, lectin agglutination may be affected by culturing conditions, growth on solid or liquid media and is affected by specific treatment such as trypsin treatment or boiling before assay. More importantly, amoxicillin-induced coccoids tend to give auto-agglutination reaction. This could explain the divergence of structural changes on the cell surface of the coccoids due to the antibiotics or aging process.

It is apparent that the surface of *H. pylori* contains a variety of carbohydrates which may play a role in adherence phenomenon. Comparison of lectin agglutination reactions between the coccoids and spirals show that different kinds of sugar residues might be present on the two forms which might provide evidence for the complexity of the

adherence process. It is possible that *H. pylori* coccoids and spirals, bearing different affinities for carbohydrate receptors on the cell surface may account for the variation in the adhesive properties of the organism for antral mucous cells in the stomach. This may probably reflect different strategies used by the two differentiated forms of *H. pylori* in colonizing gastroduodenal tissues, resulting in different disease profiles such as acute and chronic gastritis or peptic ulcer.

With regard to bacterial surface lectins, which often play a role in the initial step of immune defence against phagocytosis, it is assumed that both spiral and coccoid forms may involve in the interaction of *H. pylori* host immune mechanisms. As a rule, *H. pylori* infection is almost always associated with inflammation^[9]. However, peptic ulcer disease and gastric carcinoma occur only in a subset of individuals infected chronically with *H. pylori*^[9]. Therefore, it is proposed that, like spirals, coccoid forms also play an important pathogenic role in *H. pylori* infection.

Abstract

AIM To investigate the effects of taxol on SMMC-7721 human hepatoma and its mechanisms.

METHODS *In vitro* cell growth was assessed by trypan blue exclusion method. Experimental hepatoma model was established by seeding SMMC-7721 cells subcutaneously into Balb/c (nu/nu) nude mice. *In vivo* tumor growth was determined by measurement of tumor diameter with Vernier calipers. The syntheses of DNA, RNA and protein were analyzed by incorporation of ³H-thymidine, ³H-uridine and ³H-leucine respectively. Using light and electron microscopes to observe the morphological changes of cells including mitosis and apoptosis.

RESULTS Taxol was effective against SMMC-7721 human hepatoma cell growth in the ranges of 2.5nmol/L-10nmol/L- with mitotic arrest and apoptosis *in vitro*. DNA, RNA and protein syntheses in cells were also obviously suppressed by *in vitro* treatment of taxol for 72h. Taxol at 2.5nmol/L reduced ³H-thymidine uptake to about 34% of the control value ($P < 0.05$). Increasing the dose of taxol to 20nmol /L resulted in a greater decrease in ³H-thymidine incorporation to 60% of the control value ($P < 0.01$). At a concentration of

20nmol/L, the ³H-uridine and ³H-leucine uptakes were reduced to 52% ($P < 0.05$) and 63% ($P < 0.01$), respectively. *In vivo*, taxol significantly inhibited SMMC-7721 tumor growth at 10mg/kg, i.p. once daily for 10d. A more than 90% decrease in tumor volume was observed by day 11 ($P < 0.01$) similarly with mitotic arrest and cell apoptosis.

CONCLUSION Taxol has a marked anticancer activity in SMMC-7721 human hepatoma both *in vitro* and in nude mice. Its mechanisms might be associated with mitotic arrest, subsequently, apoptosis of the hepatoma cells. No obvious toxicity was observed with *in vivo* administration of taxol.

INTRODUCTION

Taxol, a stimulator of tubulin polymerization and microtubule assembly, was initially considered promising because of its cytotoxic activity against several tumor cell lines *in vitro*^[1,2]. Subsequent *in vivo* studies demonstrated that taxol was effective against a variety of murine tumors and human xenografts^[3,4], especially advanced human carcinomas refractory to conventional chemotherapy^[5,6]. Now, taxol has emerged as one of the most active anticancer agents in clinic for the therapy of ovarian, breast, and non-small-cell lung cancer^[7,8]. Hepatocellular carcinoma (HCC) is among the most common malignancies in the world. The incidence rate is as high as 34 persons per 100000 per year in some high-incidence areas in Asia such as China. However, few studies show that taxol is effective against HCC, especially *in vivo*^[9-13]. Furthermore, HCC is usually insensitive to chemotherapeutic drugs used previously in clinic and there is thus an urgent need for the evaluation of new active drugs against HCC. Therefore, we systematically investigated the activities of taxol against HCC *in vitro* and in nude mice.

Apoptosis is an active cellular death process induced by physiological or pathological factors^[14]. Most anticancer agents cause cell death by apoptosis^[15]. Incubation of cells with taxol has been

found to result in cell cycle arrest at G₂/M phase and cell apoptosis in many tumor cell lines^[16,17]. Our previous *in vitro* studies also show that SMMC-7721 human hepatoma cells treated with taxol exhibit significant G₂/M phase arrest and subsequently occurred apoptosis^[18]. However, Milross *et al.*^[11] reported that taxol caused mitotic arrest but could not induce apoptosis in hepatoma cells. The present studies indicate that taxol can induce mitotic arrest and apoptosis in SMMC-7721 cells not only *in vitro* but also *in vivo*.

MATERIALS AND METHODS

Drugs

Taxol was obtained from Shanghai Hualian Pharmaceutical Factory, Shanghai, China. For *in vitro* experiments, it was dissolved in dimethyl sulfoxide (DMSO) to make stock solution, which was then diluted to desired concentrations with the culture media. The DMSO concentration was kept under 0.001% in all the experiments that did not exert any detectable effect on cell growth or apoptosis. For *in vivo* experiments, taxol was dissolved in a Cremophor EL vehicle (Cremophor: alcohol=50:50, v/v) at a concentration of 6 µg/L. This stock solution was further diluted with normal saline (1:5.2, v/v) immediately before injection. 5-Fluorouracil was from Shanghai Puguang Pharmaceutical Factory, Shanghai, China and diluted with normal saline to desired concentration before injection.

Cell culture and cell viability assay

SMMC-7721 human liver carcinoma cell line was obtained from Chinese Type Culture Collection (Shanghai Institute of Cell Biology, Chinese Academy of Sciences, Shanghai, China). The cells were grown on monolayer cultures in 37°C, 5% CO₂ incubator in RPMI 1640 media (Gibco, Grand Island, NY) supplemented with 15% heat-inactivated new-born calf serum with or without compounds as described above. At assay time, cells were collected, mixed with an equal volume of phosphate buffer salt solution containing 4g/L trypan blue dye, and manually counted. Actual cell numbers were calculated by multiplying diluted times compared with initial cell numbers.

Animal

Female Balb/c (nu/nu) nude mice (18 g - 20 g; 6wk-8wk of age) were purchased from Shanghai Institute of Materia Medica, Chinese Academy of Sciences and maintained in our own specific pathogen-free mouse colony. All experiments involving animals were performed in accordance with the guidelines of the Institutional Animal Care and Use Committee.

Measures of biomacromolecular synthesis

According to the previous literature^[19], the syntheses of DNA, RNA, and protein of cells were measured by quantitating ³H-thymidine, ³H-uridine, and ³H-leucine incorporation, respectively, in the presence and absence of taxol. Briefly, cells were seeded into each well of 96-well Costar flat-bottom culture plates (Costar, Charlotte, NC) at 5×10³ cells/well in 100 µL of culture medium. After 24h, taxol was added into each well according to the desired concentrations. Control samples contained culture medium and DMSO. After 48h, the cells were incubated with ³H-thymidine, ³H-uridine, or ³H-leucine (1 µCi/well) for 24h at 37°C respectively. At the end of the incubation, the plates were immediately placed on ice and frozen at -80°C. After thawing, ³H-labeled DNA, RNA, or protein were precipitated onto glass fiber discs (Whatman Ltd, Maidstone, UK) using a micro-harvester. For harvesting, the wells were extensively rinsed with distilled water, then, air-dried. The discs were then added to scintillation vials along with 1 mL of scintillant. Radioactivity was measured on a Beckman LS6000 TAβ counter (Beckman Instruments, Irvine, CA).

Human hepatoma implantation into nude mice

SMMC-7721 human solitary hepatoma was implanted into the right flank of female nude mice by subcutaneous injection of 2.5×10⁶ viable cells. Tumor size (mm³) was evaluated by measurement of two perpendicular diameters with Vernier calipers and using the formula 1/2LW², where L is the longest diameter and W is the diameter perpendicular to L^[20]. Palpable tumors were usually detected after 1wk and reached 5mm to 10mm in diameter by day 10. When tumor grew to 5mm-10mm in diameter, the mice were treated with taxol or vehicle by i.p. injection in a volume of 0.2 mL per mouse, once daily for 10 days. Body and internal organ weight of animals were also observed to assess the toxicity of taxol.

Microscopic observation

In vitro, cells were fixed with 25 g/L glutaraldehyde, and postfixed with 20g/L osmium tetroxide. After dehydration, the samples were embedded in Epon 812 epoxydic resin, and then sectioned. The sections were routinely stained. *In vivo*, after the mice were killed by cervical dislocation, tumor tissue was immediately excised and placed in neutral-buffered formalin. The tissue was then imbedded in paraffin blocks from which 4 µm sections were cut and stained with hematoxylin and eosin. The morphologies of cells including mitosis and apoptosis were examined under electron and light microscopes.

Data analysis

The data of *in vitro* cell growth and the incorporation of ^3H -thymidine, ^3H -uridine and ^3H -leucine into cells were analyzed by Student's *t* test. Statistical comparisons of tumor volumes were performed by analysis of variance at different time points after initiating treatment.

RESULTS

In vitro studies

SMMC-7721 cells were treated with different concentrations of taxol for different times and the effect of taxol on the cell growth was examined by trypan blue exclusion method. As shown in Figure 1, the growth of SMMC-7721 cells was markedly inhibited by taxol in the ranges of 2.5 nmol/L-10 nmol/L. Moreover, taxol-induced cytotoxicity was found to be time-dependent when the cells were exposed to the agent for 48h-120h.

Taxol was significantly effective at inhibiting ^3H -thymidine incorporation with dose-dependent relationship when SMMC-7721 cells were continuously exposed to taxol for 72h. Taxol at 2.5 nmol/L reduced ^3H -thymidine uptake to about 34% of the control value ($P < 0.05$). Increasing the dose of taxol to 20 nmol/L resulted in a greater decrease in ^3H -thymidine incorporation to 60% of the control value ($P < 0.01$) (Figure 2). Taxol also displayed similar dose-dependent efficacy at suppressing ^3H -uridine and ^3H -leucine incorporation when the cells were constantly exposed to the drug for 72h. At a concentration of 20 nmol/L, the ^3H -uridine and ^3H -leucine uptake was reduced to 52% ($P < 0.05$) and 63% ($P < 0.01$), respectively (Figure 2).

These results show that taxol has significant inhibiting effects on DNA, RNA and protein syntheses of SMMC-7721 cells. The results from light microscope observation indicated that taxol at 10 nmol/L caused obvious morphologic changes of SMMC-7721 cells when compared with untreated cells (Figure 3A). After 24h treatment (Figure 3B), the cells got round, dipter-enhanced. As time went on for 48h, cells detached and blebbed (Figure 3C). By analysis with electron microscope, it was found that SMMC-7721 cells exposed to taxol 10 nmol/L for 24h presented mitotic arrest (Figure 4B), and some cells appeared in pre-apoptotic sign as compared with untreated cells (Figure 4A). After cells were treated by taxol for 48h, the nuclei were shrank, and the chromatin was condensed to form high density clumps, which were located along the nuclear envelope (Figure 4C), or formed regularly shaped crescents at the nuclear edges. It is suggested that taxol could induce typical characteristic morphological changes of mitotic arrest and apoptosis of cells.

Figure 1 Effect of paclitaxel on SMMC-7721 cell growth.

Figure 2 Effects of taxol on ^3H -thymidine, ^3H -uridine and ^3H -leucine incorporation.

In vivo studies

Nude mice bearing SMMC-7721 tumors were treated with different doses of taxol. The taxol response of SMMC-7721 human hepatoma depicted as tumor growth curves in Figure 5 showed that tumors were significantly responsive to taxol when treated at 10 mg/kg, i.p. once daily for 10d, although treatment with 2 mg/kg proved less effective. Tumor regression was evident by day 3 after taxol treatment ($P < 0.05$), and a greater than 90% decrease in tumor volume was observed by day 11 ($P < 0.01$). In contrast, the tumors in animals that only received corresponding solvent continued exponential growth. Mice treated with low or high doses of taxol did not display a body weight loss by day 11 ($P > 0.05$). No difference of internal organ weight was found between treated and control groups. No obvious other toxicity was observed in mice receiving either 2 mg/kg or 10 mg/kg taxol for 10 d.

Animals were sacrificed at various times among 24h and 120h after administrating taxol. As seen in Figure 6, taxol treatment caused marked morphological changes in SMMC-7721 tumor. Compared with control (Figure 6A), slight mitotic arrest and apoptosis of hepatoma cells were observed in mice with 2 mg/kg taxol treatment for 10 days (Figure 6B). However, most cells exhibited the characteristic appearance of agent-induced

apoptosis after treated with 10mg/kg taxol for 10 days (Figure 6C). These results suggested that taxol-induced mitotic arrest and apoptosis of human hepatoma cells might be dose-dependent. Time-effect analysis indicated that taxol at 10mg/kg, i.p. for 24h caused mitotic arrest of most tumor cells with slight apoptosis (Figure 6D). By 48h, apoptosis became the dominant morphological features (Figure 6E). This phenomenon was more significant after 120h treatment than ever before (Figure 6F). Apoptotic cells were characterized by overall shrinkage and homogeneous dark basophilia. Frequently, several small apoptotic fragments were encountered in close proximity. On the basis of size and clustering, such fragments were considered to represent the remains of a single cell or apoptotic body.

Figure 3 Morphological changes of SMMC-7721 cells observed by light microscope after treatment with taxol for different times. (A) Untreated cells; (B) SMMC-7721 cells got round, dipter-enhanced after exposure to 10 nmol/L taxol for 24 h; (C) SMMC-7721 cells detached and blebbed after exposure to 10nmol/L taxol for 48h. $\times 400$.

Figure 4 Ultrastructures of SMMC-7721 cells with or without treatment by taxol. Following 24h treatment of taxol, cells presented more mitotic Figure (B 7680 \times). For 48h, the cells appeared with regularly shaped crescents (C 7680 \times). The nuclei of untreated cells were very irregular in shape, with many gulfs and protrusions. (A 5760 \times)

Figure 5 Effect of taxol on SMMC-7721 human hepatoma in nude mice.

Figure 6 Histological changes of SMMC-7721 tumors after taxol treatment. (A) untreated control. (B) 2mg/kg taxol, i.p. once daily for 10d. Only slight morphological changes were presented. (C) 10mg/kg taxol, i.p. once daily for 10d. Most cells showed apoptotic changes and many apoptotic bodies were presented. Apoptosis were widespread. Apoptotic bodies were the small ovoid structures. (D) 24h after i.p. injection of 10mg/kg taxol. Mitotic arrest was marked. (E) 72h after i.p. injection of 10mg/kg taxol. Mitotic arrest could still be presented with more apoptotic cells. (F) 120h after i.p. injection of 10mg/kg taxol. Apoptosis was dominant phenomenon than ever before. Hematoxylin and eosin. $\times 400$

DISCUSSION

This study has demonstrated that taxol is significantly effective against SMMC-7721 human hepatoma growth both *in vitro* and *in vivo*. In most reports the arrest of cells in G₂/M phases and cell apoptosis caused by taxol are responsible for its anticancer activities^[21,22]. We have also found that taxol causes SMMC-7721 cell mitotic arrest and apoptosis *in vitro* and *in vivo*. It suggests that the anti-hepatoma effects of taxol are related to its mitotic arrest and cell apoptosis. Emphasis has been placed on the anti-hepatoma effects of taxol *in vivo*. Previous studies showed that taxol had no significant anticancer effect in HCC patients^[13]. Others reports also suggested no statistically significant hepatoma growth inhibition in mice

treated with taxol at 40 mg/kg, i.v.^[11]. The results presented herein indicate that taxol at 10 mg/kg, i.p. once daily for 10 days has significant inhibiting activity on HCC with more than 90% suppressive percentage and without any obvious toxicity. It is inferred that taxol may cause hepatoma growth inhibition at low dose and continuous administration. Our present studies also clearly demonstrate that taxol causes profound mitotic arrest and apoptosis. A time-course microscopic analysis of tumor cell mitosis and apoptosis in nude mice treated with taxol revealed that mitotic arrest occurred previously to apoptosis. Development of apoptosis lagged several hours behind mitotic arrest. Moreover, either the mitotic arrest or apoptosis of hepatoma cells induced by

taxol was clearly dose and time- dependent. These data have important therapeutic implications in HCC.

In conclusion, this is the first report of the anti-hepatoma effect of taxol, its mechanisms, and the relationship between the mitotic arrest and apoptosis both *in vitro* and *in vivo*.

Wu WY, Xu Q, Shi LC, Zhang WB. Inhibitory effects of *Curcuma aromatica* oil on proliferation of hepatoma in mice. *World J Gastroenterol*, 2000;6(2): 216-219

Abstract

AIM To reveal the inhibitory effects of *Curcuma aromatica* oil (CAO) on cell proliferation of hepatoma in mice.

METHODS Two tumor inhibitory experiments of CAO on hepatoma in mice were conducted. The inhibitory effects of CAO on proliferation of hepatoma in mice were evaluated by DNA image cytometry and immunohistochemical staining of proliferating cell nuclear antigen (PCNA).

RESULTS The tumor inhibitory rates of CAO were 52% and 51% in two experiments, respectively. Compared with those of the saline-treated control groups, both differences were statistically significant ($P < 0.01$). In the group of mice treated with CAO, the cellular nuclear DNA OD value (249 ± 70), are as ($623 \mu\text{m}^2 \pm 228 \mu\text{m}^2$) and DNA (2.38 ± 0.67) index of hepatic carcinomas were significantly lower than those of the control group (430 ± 160 , $1073 \mu\text{m}^2 \pm 101 \mu\text{m}^2$ and 4.48 ± 0.71). CAO also could increase diploidy cell rates ($29.00\% \pm 9.34\%$ vs $2.97\% \pm 5.69\%$, $P < 0.01$) and decrease pentaploidy cell exceeding rate ($30.04\% \pm 15.10\%$ vs $70.89\% \pm 14.94\%$, $P < 0.01$). In the group of mice treated with CAO, the labeling indexes of proliferating cell nuclear

antigen (PCNA-LI) were $30\% \pm 4\%$, which were significantly lower than $40\% \pm 6\%$ of the control group ($P < 0.01$).

CONCLUSION The inhibition of CAO on the growth of hepatoma in mice might be associated with its depression on cellular proliferative activity.

INTRODUCTION

Curcuma aromatica oil (CAO) is a volatile oil extracted from a traditional Chinese herb, *Curcuma aromatica* Salisb, which exerts various medical activities such as promoting blood circulation to remove blood stasis and treating cancers^[1]. It contains several major anti-tumor active ingredients: elemicin, curcuminol, curdione, etc^[2-5]. Our previous clinical and experimental studies revealed that CAO infused via hepatic artery had ideal therapeutic effects on both the patients with primary liver cancer and the rats with transplanted hepatoma^[6,7]. However, the anti-hepatoma mechanisms of CAO remain unresolved. The aim of the current study therefore is to determine the inhibitory effects of CAO on proliferation of hepatoma in mice.

MATERIALS AND METHODS

Materials

Ten g/L of CAO injections were prepared by the department of preparations in our hospital (Lot. 97041601). The 5-fluorouracilum (5-FU) was produced by Hebei Pharmaceutical Factory (Tianjin, Lot 970277). EMAIL-100 type automated Image Cytometry (ICM) was purchased from Yiming Company (Guangzhou). Immunohistochemical LSAB kit (K0679) and monoclonal antibody PC10 (M0879) to proliferative cell nuclear antigen (PCNA) were purchased from Dakopatts, Glostrup, Denmark. The statistics software package named Medical Statistics of China Medical Encyclopedia was provided by Department of Health Statistics of West China Medical University.

Animals

Kunming mice, male, weighing 18g-22g, were provided by the Laboratory Animal Center, the First Military Medical University. The ascites

hepatoma carried by mouse was produced by the Cancer Institute of Sun Yat-Sen University of Medical Sciences.

Anti-hepatoma experiments

Two anti-tumor experiments were performed in the Grade II animal laboratory of our hospital. The hepatoma ascites carried by mouse was collected and was diluted with normal saline (NS) to 2×10^{10} cancer cells/L. The diluted hepatoma cells were put on ice during the implantation, and 0.2mL of hepatoma cells were subcutaneously transplanted to the right axilla in mice. All operations were performed under sterile conditions. After transplanted for 24h, the mice were numbered and randomly allocated into three groups: negative control group, receiving 0.2mL NS, ip; positive control group, given 20mg and 40mg/kg of 5-FU, ip; and treatment groups, given 100mg/kg of CAO, ip. The mice were housed in plastic cages under a 12-hour light/dark cycle and fed with a standard pellet diet and distilled water *ad libitum*. Some of the experimental details are shown in Table 1. At the following day of the termination of treatment, the mice were sacrificed with dislocation of neck. All tumors were peeled off, weighed and the tumor inhibitory rates were calculated. After the second experiment, all tumor specimens were fixed with 100mL/L neutral formalin for less than 48 hours, embedded in paraffin, and cut into 4 μ m thick series.

DNA image cytometry

The sections were dewaxed with xylene, rehydrated in decreasing concentrations of ethanol and the DNA staining was ordinarily performed with Foulgen (Figure 1). The cells in the selected visual fields were scanned in super-speed with a television monitor and the DNA histograms were obtained by calculating the integrated optical density with a computer (EMAIL-100). Several visual fields were randomly observed and 50-100 nuclei were detected for each section. The DNA in the normal mouse hepatic cells at G₀/G₁ phase was employed as the diploid (2C) control. The measurable cellular parameters and paraphrases by ICM were displayed as the follows. DNA optical density (DO) and nuclear area (NA) reflect respectively DNA quantity and nuclei size in hepatoma cells. DNA index (DI) represents the ratio of DNA quantities at G₀/G₁ phase between hepatoma cells and normal mouse liver cells, 5CER, 2C and 3-5C stand for pentaploidy cell exceeding rate, percentages of diploid cells and of the cells except 5CER and 3C-5C, respectively.

PCNA staining

Immunohistochemistry with monoclonal antibody against mouse PCNA was performed by the link

streptoavidin-biotin peroxidase method (LSAB kit). Briefly, after sections were deparaffinized with xylene and rehydrated through graded alcohol, they were treated with 30mL/L H₂O₂ for 10 minutes to inactivate endogenous peroxidase activity. Following a 20-minute blocking step with normal horse serum, the sections were sequentially incubated with PC10 antibody diluted 1:100 for 30min, then in anti-rabbit IgG and in avidin-peroxidase complex for 30 minutes each. The immunoreaction was developed using 3',3'-diaminobenzidine in the presence of H₂O₂ to produce a brown precipitate. The sections were counterstained with hematoxylin. Positive and negative controls were included in each experiment. Specifically, for the latter the primary antibody was substituted with nonspecific rabbit IgG.

PCNA labeling index

All of the brown nuclei were regarded as positive for PCNA. The PCNA labeling index (PCNA-LI) was determined by observing more than 2000 nuclei in a few areas of the sections, and the percentage of PCNA-labeled nuclei was used for the analysis. To reduce any interobserver bias, the PCNA-LI of all sections was examined by two experienced pathologists who had no knowledge of the experimental grouping. The mean of the two counts of each observer was considered to be the PCNA-LI.

Statistical analysis

A statistical evaluation was performed using analysis of variance and *t* test. All statistical analyses were considered to be significant at a *P* value of 0.05 or less.

RESULTS

Inhibitory effects of CAO on hepatoma in mice

The results from the two experiments showed that the tumor inhibitory rates of CAO on hepatoma were 51.85% and 51.2%, respectively (*P*<0.01) (Table 1). Up to the termination of anti-tumor experiment, the body weight in the mice treated with 5-FU tended to decrease, while in the mice treated with CAO, it increased but lighter than that in the negative control group (*P*<0.05).

Effects of CAO on the DNA in the hepatoma cells of mice

As shown in Table 2, the DO, NA, DI and 5CER in the mice treated with CAO were lower than those in the control mice. CAO could increase the percentage of 2C hepatoma cells and had no significant effect on the percentage of 3.5C cells.

Effects of CAO on the expressions of hepatoma PCNA in mice

As shown in Table 3 and Figures 2 - 3, the percentages of PCNA positive nuclei in the mice treated with either CAO or 5-FU were statistically lower than those in the negative control mice (*P*<0.01).

Table 1 Inhibitory effects of CAO on growth of hepatoma in mice

Experiment	Drugs	Dose (kg ⁻¹ ·d ⁻¹)	Number	Body weight change (g)	Tumor weight (g)	Tumor inhibitory rate (%)
1	Ns	0.2mL	7	6.90	1.08±0.22	
	5-FU	40mg	7	-2.00	0.35±0.13	67.6 ^b
	CAO	100mg	7	4.35	0.52±0.16	51.8 ^b
2	Ns	0.2mL	10	5.55	1.72±0.45	
	5-FU	20mg	10	-1.85	0.45±0.15	73.8 ^b
	CAO	100mg	10	4.60	0.84±0.31	51.2 ^b

Results are expressed as $\bar{x} \pm s$, $n=10$, ^b $P<0.01$, vs negative control group.

Table 2 Effects of CAO on the hepatoma DNA parameters detected with ICM in mice

Group	DO	NA(μm ²)	DI	5CER(%)	2C(%)	3-5C(%)
Negative control	430±160	1073±101	4.48±0.71	70.9±14.9	2.97±5.69	28.2±16.0
CAO	249±70 ^b	623±228 ^a	2.38±0.67 ^b	30.0±15.1 ^b	29.00±9.34 ^b	41.0±17.4

Results are expressed as $\bar{x} \pm s$, $n=10$, ^a $P<0.05$, ^b $P<0.01$, vs negative control group.

Table 3 Effects of CAO on the expressions of hepatoma PCNA in mice

Group	PCNA-LI (%)
Negative control	40.0±5.7
Positive control	25.1±3.6 ^b
CAO	29.9±3.9 ^b

Results are expressed as $\bar{x} \pm s$, $n=10$, ^b $P<0.01$, vs negative control group.

DISCUSSION

The early literature reported that CAO extracted from Chinese herb, *Curcuma aromatica* Salisb, could inhibit the growth of various cancer cells *in vitro* and *in vivo*^[1]. The recent studies showed that CAO was a compound consisting of many kinds of anti tumor ingredients such as β-elemene, curcuminol, curdione, etc^[2-5]. However, up to date, few researches on anti-hepatoma mechanisms of CAO compound have been conducted. In our previous clinical study, CAO infused via hepatic artery displayed a remarkable therapeutic effect on the patients with primary liver cancer^[7]. Our recent animal experimental results revealed that transcatheter infusion of CAO into hepatic artery could significantly inhibit the growth of the implanted hepatoma^[6]. The present *in vivo* study indicated that the tumor inhibitory rates of CAO were around 50%, which coincided with the results reported by the literature. The changes in body weight of the mice treated with CAO might result from their tumors being smaller than those carried

by the control group mice and the toxicity of CAO being much less than 5-FU.

Some studies have confirmed that ICM used for the DNA quantitative analysis of cancer cells have advantages of briefness, sensitivity and precision as compared with flow cytometry^[8,9]. In the various parameters obtained by ICM, the DO, NA and DI are positively correlated with cellular proliferation. The percentages of aneuploid cells reflect not only cellular malignancy but also the cellular proliferation. ICM has been employed for analyzing various biological features of cancer cell such as proliferation, differentiation, metastasis and prognosis. Zheng *et al*^[10] with ICM revealed that the invasiveness and the metastasis of the hepatic tumors enhanced with the increasing DNA synthesis of hepatocellular carcinoma in the patients with liver cancer. Our present study showed that CAO could significantly decrease the DNA quantity (DO, DI) in the hepatoma cells and shrink the nucleus area. In the untreated mice, the higher 5CER and the lower 2C reflected abnormal increasing proliferation. CAO could decrease the percentage of 5CER cells and increase the percentage of 2C, which showed its inhibition of cellular proliferation.

PCNA functions as a cofactor for DNA polymerase δ are associated with DNA repair in both the S phase and in DNA synthesis^[11,12]. Hino *et al*^[13,14] found that the expressions of PCNA were closely related to the malignancies of human hepatocellular carcinoma. With immunohistochemical methods, Irene *et al*^[15] and Suehiro *et al*^[16] affirmed that PCNA-LI was correlated with the metastasis and the prognosis of hepatocellular carcinomas. Therefore, PCNA is an important mark for evaluating the proliferation of hepatocellular carcinomas. In the present study, we used LSAB immunohistochemistry to stain the hepatoma nuclei of mice and the positive PCNA cells were at late G₁ and early S phases. The results indicated that CAO could remarkably decrease the hepatoma PCNA-LI in mice. Therefore, we assume that the inhibition of CAO on the growth of hepatoma in mice might be associated with its depressing PCNA protein, decreasing DNA-polymerase δ activity and interfering with DNA synthesis. Combining with the ICM results, we have drawn a preliminary conclusion that the depression of CAO on cellular proliferation could contribute to its inhibition on hepatoma growth in mice. The other possible mechanisms of the inhibitory effects of CAO on hepatomaremains further clarification.

Cloning and expression of core gene cDNA of Chinese hepatitis C virus in cosmid pTM3

Rong Long Jiang, Qiao Sheng Lu and Kang Xian Luo

Subject headings hepatitis C virus; gene, viral; cDNA; cosmid vector; gene expression

Jiang RL, Lu QS, Luo KX. Cloning and expression of core gene cDNA of Chinese hepatitis C virus in cosmid pTM3. *World J Gastroenterol*, 2000;6(2):220-222

Abstract

AIM To clone core gene cDNA of Chinese hepatitis C virus (HCV) into eukaryotic expression vector cosmid pTM3 and to express HCV core antigen in HepG2 cells.

METHODS Core gene cDNA of HCV was introduced into eukaryotic expression vector cosmid pTM3. Using vaccinia virus/bacteriophage T7 hybrid expression system, HepG2 cells were transfected with the recombinant plasmid pTM3-Q534 by lipofectin.

RESULTS From the transfected bacteria Top10F', 2 pTM3-Q534 clones containing the recombinant plasmid were identified from randomly selected 10 ampicillin-resistant colonies. By reverse transcription PCR and indirect immuno fluorescence technique, HCV RNA and core protein was identified in HepG2 cells transfected with the recombinant plasmid.

CONCLUSION The construction of a recombinant plasmid and the expression of core gene cDNA of HCV in HepG2 was successful.

INTRODUCTION

Although the genome of several strains of hepatitis C virus (HCV) have been cloned and sequenced, the HCV particles have not been observed so far. Currently, because of very low infection efficiency, one of the major impediments to the structural analysis of HCV genome and genetic analysis of viral replication is the lack of a reliable cell culture system permissive for HCV replication. In this study, using recombinant DNA technique, we constructed a recombinant plasmid by subcloning core gene cDNA of Chinese HCV isolated into a eukaryotic expression vector pTM3 and expressed HCV core antigen in transfected HepG2 cells by using vaccinia virus/bacteriophage T7 hybrid expression system.

MATERIALS AND METHODS

Directional cloning of core gene of HCV in cosmid vector pTM3

Details of the plasmid construction are as follows. First, plasmid pQ534^[1] containing core gene cDNA of Chinese HCV (provided by Prof. QI Zhong-Tian, Second Military Medical University) was digested partially with *Pst*-I and *Sma*I, cosmid vector pTM3 (provided by St. Mary's Hospital, London University, England) was digested thoroughly with *Pst* I and *Sma*I, and the target gene and large fragment vector was purified by agarose gel electrophoresis. The 559 base pairs (bp) *Pst* I and *Sma* I target gene fragment was ligated with a 7418bp *Pst* I and *Sma* I linearized plasmid vector of pTM3 by bacteriophage T 4 DNA ligase overnight at 37°C, and stored at -20°C. The ligation product was routinely transformed into bacteria Top10F', and was incubated in an LB plate containing ampicillin overnight at 37°C. Ten bacterial colonies were individually transferred into 2mL of LB medium containing ampicillin in a loosely capped 15mL tube, and the culture was incubated overnight at 37°C with vigorous shaking. To confirm that the culture did contain the correct plasmid, we prepared a small amount of plasmid DNA and analyzed it by digestion with restriction enzymes. Then, we propagated the transformed positive bacterial colony, prepared and purified a large amount of plasmid DNA, and stored it at -20°C for transfections.

After the inoculum was removed, the cells were transfected with 1mg of pTM3-Q534 plus lipofectin (GIBCO-BRL) 1mg for 4 h at 37°C. For the

Received 1999-05-19 **Accepted** 1999-12-24

control experiment, the infected cells were transfected with pTM3 instead of pTM3-Q534 for 4h. The cells were then incubated at 37°C for 4h in DMEM containing 2% fetal bovine serum.

Transient-expression experiment based on recombinant vaccinia virus

Briefly, HepG2 cells were seeded into 6-well plate and were approximately 80% confluent 24h later. The cells were infected with the recombinant vaccinia virus vvT-7-3 (provided by St. Mary's Hospital, London University, England) at the multiplicity of infection of 8 plaque-forming units (PFU)/cell for 1h at 37°C in Dulbecco's Modified Eagle Medium (DMEM) containing 2% fetal bovine serum.

Identification of HCV replication by reverse transcription PCR (RT-PCR)

Production of core region HCV-RNA in the transfected HepG2 cells was examined by RT-PCR using primers located at the core region of the HCV genome. (First PCR: sense 5'CCCAAACCTCAAA-GAAA3', antisense 5'AGCGGTATGTACCCC-ATG3'; second PCR: sense 5'CAGATCGTTG-GTGGAGTT3', antisense 5'GCAGCCCTCATTGC-CAT3'). RT-PCR was performed using a standard procedure described previously. In all experiments, RNA extracted from a liver specimen known to contain HCV was included as positive control and cloned HBV-DNA transfected HepG2 cells (HepG2 2.2.15 cell line) as negative control.

Identification of the transfected HepG2 cells by indirect immunofluorescent technique

After infection/transfection, the medium was removed and cells were washed once with PBS and were fixed with methanol/acetone (50:50) for 20min at -20°C. The methanol/acetone was removed and the cells were rinsed with PBS. For immunofluorescent assays, the fixed cells were incubated for 1h at 37°C with a 1:50 dilution of the clinical HCV positive human serum in PBS for 5min per wash. FITC-conjugated secondary antibody IgG (goat anti-human) were added at 1:5 dilution in PBS and incubated for 1h at 37°C. The cells were washed for 4-5 times as above. The stained cells were observed with a Meridian-ACAS 470.

RESULTS

Cloning of core gene cDNA of HCV in cosmid vector pTM3

In order to satisfy the directional cloning and the correct reading frame, plasmid pQ534 was double digested with *Sma*I and *Pst*I. Since there are 2 *Sma*I recognition sites in the core gene cDNA of HCV, partial digestion has to be carried out, so at first, pQ534 was digested with the restriction enzyme *Pst*I for 1h at 37°C, and then digested

with the second enzyme *Sma*I for 10min at 37°C. The 559bp segment containing core gene cDNA of HCV was purified by agarose gel electrophoresis (Figure 1).

Figure 1 Incomplete digestion of plasmid pQ534 by restriction endonucleases *Sma*I and *Pst*I.

Lane 1: DNA molecular weight marker, lane 2: pQ534 digested with *Pst*I first, and then digested incompletely.

Identification of the recombinant plasmid pTM3-Q534 with restriction enzyme

From the recombinant plasmid transformed bacteria Top10F', 2 pTM3-Q534 clones were identified from 10 randomly selected ampicillin-resistant colonies. Plasmid DNA obtained by alkaline lysis was cleaved with restriction enzyme *Eco*RI/*Pst*I, a 534bp insertion segment was observed in 2 of the 10 colonies (Figure 2, lane 3, 4). The plasmid DNA of positive clones was digested with *Eco*RI, and actually only a 7970bp band was found after electrophoresis (Figure 2, lane 5). Because an *Eco*RI site also existed in the core gene cDNA of HCV (9 base pairs near the 5' terminus of core gene cDNA), if the target gene was reverse-inserted, the length between the site and the *Eco*RI site of the polyclonal site of plasmid pTM3 was 550bp, so a 550bp *Eco*RI-*Eco*RI fragment (7970bp) after electrophoresis. It was confirmed that construction of core gene cDNA of HCV in cosmid vector pTM3 was successful.

Figure 2 Identification of the recombinant plasmid pTM3-Q534 with restriction endonucleases.

Lane 1: 500ng Hind-III/*Eco*RI DNA marker; lane 2: pTM3 digested with *Sma*-I and *Pst*I; lanes 3 and 4: pTM3-Q534 digested with *Eco*-RI and *Pst*I; lane 5: pTM3-Q534 digested with *Eco*-RI.

RT-PRC

Positive-strand HCV RNA was detected in HepG2 cells over a 6-week period after transfection with pTM3-Q534. Negative-strand HCV RNA was detected over a 4-week period after transfection with pTM3-Q534. However, there was no HCV-RNA specific strand found in the control cells. It was demonstrated that there was HCV replication in the HepG2 cells transfected with pTM3-Q534.

Indirect immunofluorescence

In the experimental group, some of the HepG2 cells transfected with pTM3-Q534 were positive for HCV core protein. The other cells were negative. The negative control HepG2 cells transfected with pTM3 were all negative for HCV core protein (Figure 3), and the same results were obtained in the repeated experiments of transfection and indirect immunofluorescence.

Figure 3 Indirect immunofluorescence staining of transfected HepG2 cells.

A: A part of the HepG2 cells infected with vvT-7.3 and transfected with pTM3-Q534 showing intracellular immunofluorescence; B: In control, no staining can be seen in the HepG2 cells infected with vvT-7.3 and transfected with pTM3.

DISCUSSION

More and more studies about the expression of HCV gene in mammalian cells have been reported in the world^[2,4,6,8,9], but no reports from China. In this study, we successfully cloned core gene cDNA of HCV into eukaryotic expression vector pTM3. To achieve transcription with high efficiency and sufficient translation and expression of the HCV genome, we used a vaccinia virus/bacteriophage T7 hybrid expression system^[3,5,7]. In this system, T7 RNA polymerase was expressed in the cells infected with a recombinant vaccinia virus vvT-7.3, and the

transfected target genes controlled under the T7 promoter sequence were transcribed with high efficiency. Thus, the core protein of HCV can be efficiently produced in the cells. Lipofectin reagent interacts spontaneously with DNA to form a lipid-DNA complex. The fusion of the complex with tissue culture cells could result in the efficient uptake and expression of the DNA. Compared to transfection methods employing calcium phosphate, a protocol using lipofectin reagent has been shown to be 50-100 fold more efficient. Cloning of core gene cDNA of HCV into eukaryotic expression vector pTM3 and expression of HCV core antigen in HepG2 cells confirmed that the recombinant plasmid pTM3-Q534 which contains core gene cDNA of HCV possesses the property of propagation in HepG2 cells. As all the results were reproducible, a solid foundation was laid for the further investigation in the expression of HCV genes in mammalian cell lines and the detection of the function of the various regions in HCV genome.

Abstract

AIM To investigate the clinical features of FADD and TRADD expressions in primary hepatocellular carcinoma (HCC) and to determine their relationship with hepatic apoptosis.

METHODS FADD and TRADD expressions were detected by immunohistochemistry and hepatic apoptosis were determined by *in situ* end-labeling (ISEL).

RESULTS Ten (25.6%) cases of HCC were detected to express FADD protein. The positive rate in HCC is lower than that in non-cancerous adjacent liver tissues (62.5%) ($P<0.05$). In those of grade I-II, 8 (38.1%) cases were FADD positive, while only 2/18 (11.1%) cases of grade III-IV had detectable FADD protein ($P<0.05$). No relationship was found between FADD expression and other clinical features, such as gender, age, tumor size, differentiation or metastasis. ISEL positive cells can be seen in all cases of HCC. The hepatic apoptosis was associated with FADD expression as more apoptotic cells were detected in those cases which had moderately to strongly positive FADD, as compared with negative or weak positive FADD cases ($P<0.05$). No relationship was found between FADD expression and hepatic apoptosis in non-cancerous adjacent liver tissues. Fifteen of 39 (38.5%) cases of HCC were found positive for TRADD protein, and similar positive rate (37.5%) in non-cancerous adjacent liver tissues ($P>0.05$). The expression of TRADD is correlated with HCC differentiation,

as only 22.2% of moderately to highly differentiated HCC showed positive TRADD protein, while as high as 52.4% of poorly differentiated HCC had TRADD ($P<0.05$). No relationship was found between TRADD expression and gender, age, tumor size or grade or metastasis, although 42.9% of HCC of grade I/II showed positive TRADD which was slightly higher than that of grade III/IV (33.3%, $P>0.05$). Hepatic apoptosis was not related to TRADD expression in HCC or non-cancerous adjacent liver tissues.

CONCLUSION Loss of FADD expression plays an important role in HCC carcinogenesis, and expression of TRADD also contributes to HCC development. The cell apoptosis in HCC is associated with FADD expression. However, the expression of TRADD does not correlate well with hepatic apoptosis in HCC.

INTRODUCTION

Apoptosis is an area of intense scientific interest, which encompasses the study of and triggers mechanisms involved in mediating the cell biology of programmed cell death. Deregulation of apoptosis is generally considered as a critical reason for tumorigenesis. In addition to uncontrolled cell proliferation, decreased cell death is also involved in increase of tumor cell population^[1]. Fas, TNF α and TGF β play prominent roles in regulating liver cell apoptosis^[2]. Trimerization of the Fas receptor (CD95, APO-1), a membrane bound protein, after binding to Fas ligand, triggers cell death by apoptosis. The main death pathway activated by Fas receptor involves the Fas-associated death domain (FADD) adapter protein that connects Fas receptor to the caspase cascade. Transient expression of a dominant-negative mutant of FADD impairs Fas/Apo1-mediated apoptosis. TNFR-1 recruits and assembles, as a consequence of TNF α binding to TNFR-1, a signaling complex containing a number of death domain (DD)-containing proteins, including the TNFR-associated death domain (TRADD) adapter protein. The subcellular interactions of TNF-R1 and the TRADD adapter protein serving as anchor for the subsequent recruitment of other proteins into the signaling

complex that directly lead to cell death or nuclear factor-kappaB (NF- κ B) induction^[3,4]. Silencer of death domains (SODD), a widely expressed approximately 60-kilodalton protein, was found to be associated with the death domain of TNF-R1 preventing constitutive TNF receptor 1 signaling^[5]. Hepatocellular carcinoma (HCC) is one of the tumors known to be resistant to Fas-mediated apoptosis. To elucidate the possible mechanisms of this resistance, we examined the FADD and TRADD protein expression in a series of primary HCC and observed the relationship between FADD and TRADD protein expression and hepatic apoptosis.

MATERIALS AND METHODS

Patients and samples

The surgically resected specimens employed in this study were obtained from consecutive patients with primary HCC who had undergone potentially curative tumor resection in the Department of General and Hepato-Biliary Surgery, Tongji Hospital during 1996-1997. A cohort of 39 cases was involved in this study. All cases were selected on the basis of availability of frozen material for study and on the absence of extensive chemotherapy-induced tumor necrosis. Materials were composed of 3 cases of grade I, 18 cases of grade II, 11 cases of grade III, the remaining 7 cases were of grade IV according to TNM system (1987). Twenty-one were poorly differentiated, 9 moderately and 9 well differentiated HCC. There were 34 males and 5 females aged from 24 to 71 years with an average of 46.1 ± 12.5 years. Eight cases of non-cancerous adjacent liver tissues were also included in the study. Routinely processed 4% paraformaldehyde-fixed, paraffin-embedded blocks of containing principal tumor were selected. Serial sections of 5 μ m were prepared from the cut surface of blocks at the maximum cross-section of the tumor.

Immunohistochemistry

Goat monoclonal antibody that recognizes the human FADD and TRADD protein was Santa Cruz product. StreptAvin- Biotin- enzyme Complex (SABC) kit was purchased from Boster Biotechnology Inc. (Wuhan, China). Briefly, 5 μ m tissue sections were deparaffined, rehydrated through a graded series of ethanol, and heated in 0.01mol/L sodium citrate solution in microwave oven for 15min. The primary antibody was used at a dilution of 1:30 (for FADD) and 1:50 (for TRADD). After incubated overnight at 4°C, biotinylated anti-goat immunoglobulin and streptavidin conjugated to horseradish peroxidase were subsequently applied. 3,3'-diaminobenzidine was used for color development, and hematoxylin

was employed for counterstaining. Representative tissue sections were immunolabeled with normal goat serum as a negative control for the immunohistochemistry. The intensity of FADD and TRADD immunostaining was scored according to the percentage of positive cells: (-) no positive signal was found; (+) positive cell <25%; (++) 25%-50 %; (+++) >50%.

Histochemical detection of apoptosis

Tumor cell apoptosis was identified by DNA fragmentation detection kit (QIA33-Kit, Calbiochem). Briefly, deparaffinized and rehydrated sections were permeabilized with proteinase K (20mg/L in 10mmol/L Tris, pH 8.0) for 20 min at room temperature and washed with 1 \times ATBS (20mmol/L Tris pH 7.6, 140mmol/L NaCl). After endogenous peroxidases were inactivated by using 30mL/L hydrogen peroxide for 5min and washed with 1 \times ATBS, equilibration buffer was added to each section and incubated at room temperature for 20min. Terminal deoxynucleotidyl transferase (TdT) enzyme in TdT labeling reaction mixture at a 1:20 dilution was pipetted onto the sections, followed by 1.5h incubation at 37°C. After terminating the reaction by immersing sections into stop solution and washing with blocking buffer for 10min at room temperature, the anti-digoxigenin-peroxidase was added to the sections. DAB solution was used for color development. Sections were counterstained by methyl green. A positive control was generated covering specimen with DNase I (1mg/L) for the first procedure. Specific positive tissue sections were used for negative control by substituting distilled water for the TdT in the reaction mixture. Positively stained tumor cells with morphological characteristics of apoptosis were identified using standard criteria, including chromatin condensation, nuclear disintegration and formation of crescentic caps of condensed chromatin at the nuclear periphery. According to, with small modification, Liang's report^[6], the positive ISEL was determined in least five areas at $\times 400$ magnification and assigned to one of the three following categories: (+) only sporadic positive cells were detected; (++) a cluster of apoptotic cells were observed; (+++) positive cells in a large scale or multi-cluster apoptotic cells were seen in representative tissue sections of each individual case.

Statistical analysis

The association between the variables was assessed using the Chi-square and Fisher exact tests. Differences in frequencies were considered statistically significant if *P* values less than 0.05.

RESULTS

Expression of FADD in HCC

Ten (25.6%) out of 39 cases had detectable FADD protein expression, the positive rate being lower than that of non-cancerous adjacent live tissues (62.5%). The positive signal was predominantly located at cytoplasm (Figure 1). In 18 cases of moderately-well differentiated HCC, the positive rate was slightly higher, however with no statistical significance, than that of poorly differentiated HCC (33.3% vs 19%, $P>0.05$). No relationship was found between FADD expression and other HCC clinical features including gender, age, tumor size and metastasis with exception for tumor grade, which showed that 38.1% were positive for FADD in cases of grade I/II and 11.1% in cases of grade III/IV ($P<0.05$, Table 1).

Expression of TRADD in HCC

Fifteen cases of HCC were immunolabeled by anti-TRADD antibody. The positive rate (38.5%) was similar to that of non-cancerous adjacent liver tissues (37.5%, $P>0.05$). The TRADD expression selectively restricted to cytoplasm (Figure 2). The intensity of TRADD staining was usually homogeneous within a case tested. Although TRADD was detected in 9 (42.9%) cases of grade I/II, the difference was not statistically significant as compared with that of grade III/IV which showed 33.3% of positive TRADD ($P>0.05$). Negative relationship with statistical significance was found between TRADD staining and HCC differentiation, because 52.4% of moderately/highly differentiated HCC were TRADD detected by IHC while only 22.2% of poorly differentiated HCC harbored TRADD protein ($P<0.05$). None of the other clinical parameters analyzed in TRADD-positive cases, including gender, age, metastasis and tumor size reached statistical significance ($P>0.05$, Table 1). TRADD and FADD coexpression was found in six cases of HCC, but without relationship between TRADD and FADD expression ($P=0.08$).

Relationship between tumor cell apoptosis and TRADD or FADD expressions

Apoptotic cells and bodies were found in all cases of HCCs examined by *in situ* end-labeling (Figure 3) according to the criteria described in Material and Methods. In the cases with moderately-strong positive FADD immunoreaction, more cells underwent apoptosis than those with weak or negative FADD expression ($P<0.05$). FADD protein expression was not related to hepatic apoptosis of non-cancerous adjacent liver tissues ($P>0.05$), and no significant differences were observed between TRADD expression and apoptosis in either HCC or adjacent liver sample ($P>0.05$, Table 2).

DISCUSSION

Cancer results from excessive uncontrolled accumulation of cells. This may be the consequence of enhanced cell proliferation or of reduced cell death, or both. Inappropriate hepatic apoptosis is the critical link in liver injury and diseases. In hepatocarcinogenesis, the balance is disturbed between cell proliferation and death, which is precisely controlled in normal liver. Fas ligand and Fas receptor, tumor necrosis factor (TNF) and its receptor, and transforming growth factor β 1 (TGF- β 1) and its receptor are currently known as well established ligand/receptor interactions causing hepatocyte apoptosis^[2]. After binding to Fas ligand, Fas can interact with FADD protein via its death domain, leading to the activation of initiating cysteine proteases of the caspase family, e.g., caspase 8, and trigger apoptosis. TNF α -induced apoptosis need the presence of TRADD protein, which will transduce the signal from the binding of TNF α -with TNF-R1^[7]. Thus, loss of FADD and TRADD function will prevent apoptosis by failing to actively initiate caspase.

In our previous study, we found that the expression of Fas/FasL was not correlated with hepatic apoptosis in certain cases of HCC. So we detected the FADD protein expression in HCC. In this study, the FADD protein was expressed in HCC with a lower incidence than in positive cases in noncancerous adjacent liver tissues (25.6% vs 62.5%, $P < 0.05$). A similar expression pattern of FADD was observed in a research consisting of 6 HBV-related HCC and 10 HCC cell lines by Shin *et al*^[8], FADD expression was dramatically reduced in both HCC specimens and cell lines, while FAP (for FAS associated protein) which pronounced antiapoptotic effect when overexpressed, increased in HCC. The result suggested that loss of FADD expression plays a critical role in HCC carcinogenesis and development. In addition, we found no significant correlation between FADD expression and HCC clinical parameters including age, gender, tumor size or metastasis, except for

tumor grade. The positive rate for FADD was 38.1% of grade I/II, a little higher than that of grade III/IV (11.1%), with statistical significance ($P < 0.05$).

FADD alone can trigger apoptosis in a FAS-independent way. Kondo *et al*^[9] had used a selected group of malignant glioma cell lines containing negative or low-level Fas protein for study. The results indicated that about 85% of malignant glioma cells, regardless of Fas/APO-1 expression levels, underwent apoptosis after transient transfection with FADD expression vector. The retroviral transfer of FADD gene significantly enhanced the transduction efficiency and effectively inhibited both *in vitro* and *in vivo* survival of malignant glioma cells through induction of apoptosis. Chemotherapeutic drugs were reported to induce the accumulation of the FADD adapter molecule in several human cancer cells^[10]. It is proposed that FADD expression will contribute to HCC apoptosis. In this study, the apoptotic cells can be seen in all HCC samples and the intense is correlated to the FADD protein level. We found that more apoptotic cells were detected in HCC with moderate to strong FADD expression than those with weak positive or negative FADD. This relationship was not observed in non-cancerous adjacent liver tissues. The results indicate that FADD expression is associated with HCC hepatic apoptosis, but not in the noncancerous liver tissues.

TRADD protein was detected in 15 cases of HCC. The difference of TRADD expression in HCC and noncancerous adjacent liver tissues was not statistically significant. We proposed that the TRADD expression may be related to tumor differentiation of HCC because positive rate in moderately to well differentiated cases (52.4%) was higher than that in the poorly differentiated ones (22.2%). No relationship was observed between TRADD expression and tumor size, metastasis, age or gender of patients. Unlike the expression of FADD, TRADD expression was not significantly related to hepatic apoptosis. In fact, it is believed that in addition to FADD, TRADD can bind to RIP, preventing cell apoptosis via NF- κ B dependent and independent pathway^[2]. TRADD was also demonstrated to interact with death receptor 6 causing cell apoptosis^[11]. No relationship was found between FADD and TRADD expression, indicating that different mechanisms are involved in the regulation of FADD and TRADD expression.

There have been many studies on the mechanisms by which death receptor triggers apoptosis. Our knowledge of the intracellular signaling mechanism will enable us to improve the therapeutic strategies for the treatment of liver cancer^[1].

Abstract

AIM In order to study the association between the null genotypes of GSTM1 and GSTT1 and the genetic susceptibility to hepatocellular carcinoma (HCC).

METHODS The genotypes of GSTM1 and GSTT1 of 63 cases of HCC and 88 controls were detected with the multiple PCR technique.

RESULTS The frequency of GSTM1 null genotype was 57.1% among the cases, and 42.0% among the controls, the difference being statistically significant ($\chi^2=3.35$, $P=0.067$), but χ^2 value approaching the significance level. The odds ratio was 1.84 (95% CI=0.91-3.37). The frequency of GSTT1 non-null genotype was 87.3% among the cases and 62.5% among the controls, the difference being statistically significant ($\chi^2=11.42$, $P=0.0007274$). The odds ratio was 4.13 (95% CI = 1.64-10.70). According to the cross analysis, the GSTT1 non-null genotype was more closely associated with HCC than GSTM1 null genotype, and these two factors play an approximate additive interaction in the occurrence of HCC.

CONCLUSION The persons with GSTM1 null genotype and GSTT1 non-null genotype have the increased risk to HCC.

INTRODUCTION

Some previous studies have shown that glutathione s-transferase M1 (GSTM1) null genotype is a susceptible genotype to hepatocellular carcinoma (HCC)^[1]. A recent research has found that glutathione transferase T1 (GSTT1) also has the null genotype^[2], which is similar to GSTM1. GSTM1 and GSTT1 are the members of GST family, which can detoxify some extraneous chemicals^[3]. Persons with two null genotypes have no ability to do so^[2-4]. Few reports have been found on the association between GSTT1 null genotype and HCC as well as the interaction between GSTT1 and GSTM1 null genotype to HCC. We used the multiple PCR technique to detect GSTM1 and GSTT1 genotypes of 63 HCC cases and 88 healthy controls in an attempt to provide scientific ground on which the screening among high risk population is based.

MATERIALS AND METHODS

Sources of specimens

The specimens of non-cancerous liver tissue and peripheral blood of 63 HCC cases were provided by Qidong Institute for Liver Cancer, Zhongshan Hospital attached to Shanghai Medical University and the teaching hospital Nantong Medical College. The peripheral blood specimens of 88 healthy controls were provided by Qidong Institute for Liver Cancer, Haimen Municipal Anti-Epidemic and Health Station and Clinic of Shanghai Medical University. The cases were pathologically diagnosed as HCC. No consanguineous relationship existed among controls. The subjects mainly came from east China. There were 47 males and 16 females among the 63 cases, and 67 males and 21 females among the 88 controls.

Extraction of genomic DNA

The extraction of genomic DNA from liver tissues and peripheral blood was carried out according to the methods by Hoelzel^[5] and Tas^[6].

Multiple PCR

The corresponding fragments of GSTM1, GSTT1 and β -globulin genes were amplified with 3 pairs of primers synthesized according to the method recommended in the literature (Table 1)^[7-9]. The amplificate of β -globulin gene was designed as the internal control with the purpose to remove false negative outcome. Whether GSTM1 null genotype existed or not was judged by the fragment of

650bp, while GSTT1 null genotype by the fragment of 480bp. The total reaction volume was 50 μ L containing 100ng-600ng templates, 0.5 μ mol/L primers (3 pairs), 200 μ mol/L dNTP, 2.0mmol/L MgCl₂, 2.5U *Taq* DNA polymerase (Promega) and corresponding buffers. The reaction condition was: predenaturation at 95°C for 5 minutes; denaturation at 95°C for 1 minute; annealing at 58°C for 1min; extension at 72°C for 1.5min; and extension at 72°C for 5min after 30 cycles. The amplicates were separated with agarose gel electrophoresis for 50min at 120V, and inspected by ultraviolet reflector and pictured by ImageMaster VDS (Pharmacia) (Figure 1).

Table 1 The sequence of primers for PCR

Gene	Location	Sequence	Length of amplicates (bp)

Figure 1 Agarose gel electrophoresis of amplicates from multiple PCR. Lanes 1 and 10 are PCR markers, lanes 2 and 3 indicate non-null genotypes of GSTM1 and GSTT1, lanes 4 and 5 indicate null genotypes of GSTM1 and GSTT1, lanes 6 and 7 indicate null genotype of GSTM1 and non-null genotypes of GSTT1, lanes 8 and 9 indicate non-null genotype of GSTM1 and null genotypes of GSTT1. Fragments of 268bp indicate internal controls.

RESULTS

The DNA templates used by the multiple PCR was extracted from the noncancerous liver tissues and the peripheral blood of HCC cases and the controls. The frequency of GSTM1 null genotype was 57.1% among cases and 42.0% among controls. The difference was not statistically significant, but χ^2 value approached the significance level ($\chi^2=3.35$, $P=0.067$). When GSTM1 null genotype was regarded as the exposure factor, odds ratio (OR) was 1.84 (95% CI=0.91-3.73). It was suggested that persons with GSTM1 null genotype had a 84% of increased risk to HCC as compared with persons with GSTM1 non-null genotype (Table 2).

Table 3 shows that the frequency of GSTT1 null genotype was 12.7% among cases and 37.5% among controls. The difference was statistically significant

($\chi^2=11.42$, $P=0.0007274$). The odds ratio was 4.13 (95% CI=1.64-10.70) when GSTT1 non-null genotype was regarded as the exposure factor, suggesting that in persons with GSTT1 non-null genotype the risk to HCC increased by 3.13 times as compared with persons with GSTT1 null genotype.

To study the interaction of GSTM1 and GSTT1 in the occurrence of HCC, the cross analysis was carried out. The results indicated that when GSTM1 null genotype and GSTT1 non-null genotype were regarded as exposure factors, and that GSTM1 non-null genotype and GSTT1 null genotype as non-exposure factors, for those only exposed to GSTM1 null genotype, only exposed to GSTT1 non-null genotype and exposed to both, their OR was 6.95, 11.8 and 23.00, respectively. It was suggested that GSTT1 non-null genotype was more closely associated with HCC than GSTM1 null genotype and these two factors exerted an additive interaction in the occurrence of HCC. According to trend χ^2 test, the rank association existed among these exposure factors.

DISCUSSION

Numerous epidemiological studies have shown that HBV, aflatoxin and pollutants in drinking water are the main environmental hazard factors to HCC in China. The association between HBV and HCC has been universally accepted. But only 20%-25% of chronic HBV infected persons developed HCC. Therefore attention should be paid to the effect of

chemical carcinogen in the occurrence of hepatocarcinoma.

GST is a supergene family composed of 4 kinds of isoenzymes (α , μ , π , θ), which plays an important role in the second stage of biotransformation by conjugating extraneous chemicals with glutathione. Moreover, GST can combine itself with chemicals directly. After being absorbed, aflatoxin B₁ is transferred to the ultimate carcinogen, i.e. aflatoxin B₁-8, 9-epoxide, by the catalyzation of cytochrome P₄₅₀. GSTM1 can transfer aflatoxin B₁-8, 9-epoxide to be untotoxic metabolite which is highly-soluble and can be excreted out of body^[10]. Three alleles exist on GSTM1 gene locus, including a, band null. In persons with null genotype, GSTM1 can not be expressed in the liver and therefore has no ability to detoxify AFB1 and other chemicals^[10].

With regard to the research into the association of GSTM1 null genotype and HCC, 4 of the 5 case-control studies showed significant difference^[1,11]. The result from one study is almost identical to ours. It is likely that the sample size plays a role in it. Summarizing these results, we believe that GSTM1 null genotype is a susceptible genotype to HCC.

GSTT1 is also a member of GST family. GSTT1 and GSTM1 are mutual isoenzymes and both have the null genotypes. There has been no report on whether GSTT1 participates in the metabolism of aflatoxin or not. Our research shows that GSTT1 null genotype frequency is 12.7% among cases, and 37.5% among controls, the difference being significant ($P=0.0007274$). The association between GSTT1 null genotype and HCC was reverse to that of GSTM1 null genotype and HCC. GSTT1 null genotype is a protective factor to HCC, thus lowering the risk to HCC. In other words, GSTT1 non-null genotype is a hazard factor to HCC. Its OR is 4.13 indicating that persons with GSTT1 non-null genotype increased the risk to HCC by 3.13 times as against persons with GSTT1 null genotype. The results imply that certain procarcinogens such as AFB1 or other chemicals can be activated by GSTT1 and the metabolites are carcinogenic. It was reported that GSTT1 could activate dichloromethane into mutagen, inducing lung and liver cancer in mice^[2]. This report has provided evidence for our study.

We used cross analysis to study the interaction of GSTM1 and GSTT1 in the occurrence of HCC. When GSTM1 non-null genotype and GSTT1 null genotype were regarded as the non-exposure factors, for those only exposed to GSTM1 null genotype, only exposed to GSTT1 non-null genotype and exposed to both, their OR are 6.59, 11.89 and 23.20, respectively. GSTT1 non-null genotype is more closely associated with HCC than GSTM1 null

genotype and those two factors exert an additive interaction in the occurrence of HCC. According to the trend χ^2 test, the rank association existed among the different exposures.

In summary, we think that both GSTM1 and GSTT1 are the susceptible loci to HCC. The degree of accordance between their genotype and phenotype was as high as 98.5%-100%^[2,7]. Persons with GSTM1 null genotype have an increased susceptibility to HCC on account of lacking for GSTM1 activity in liver. Likewise, persons with GSTT1 non-null genotype, who possess GSTT1 activity in liver, have an increased susceptibility to HCC in which procarcinogen is activated by GSTT1.

ACKNOWLEDGMENTS We sincerely thank JIANG Feng, LU Meng and LIU Cha-Zhen for their help in this work.

Yuan ST, Hu XQ, Lu JP, KeiKi H, Zhai WR, Zhang YE. Changes of integrin expression in rat hepatocarcinogenesis induced by 3'-Me-DAB. *World J Gastroentero*, 2000;6(2):231-233

Abstract

AIM To investigate the expression of integrins in rats liver during 3'-Me-DAB induced hepatocarcinogenesis and to find out the relationship between integrins and liver cancer metastasis.

METHODS The expressions of integrins α_1 , α_2 , α_3 and α_5 and epidermal keratin (EK) were observed by immunohistochemical PAP method.

RESULTS In the normal liver tissues, hepatocytes express integrins α_1 and α_5 and in the bile duct epithelium, EK. In liver cirrhosis, hepatocytes highly express integrins α_1 , α_2 , α_3 and α_5 and in hyperplastic bile duct epithelium, integrins α_1 , α_5 and EK. Expression of integrins α_1 , α_2 , α_3 and α_5 were obviously decreased in the preneoplastic nodules and primary carcinoma but expressions of integrins α_1 and α_5 in metastasis in the lung and diaphragm were higher than those in primary carcinoma.

CONCLUSION Integrins α_1 and α_5 may play a major role in chemically induced hepatocarcinogenesis and metastasis in rats.

INTRODUCTION

The integrin superfamily of heterodimeric cell-surface receptors composed of distinct α and β subunits mediates the adhesion of cells to the extracellular matrix and in some instance, the intercellular adhesion. The integrins are thought to play important roles in differentiation and development, cell migration, and the complex process of tumor cell invasion and metastasis, as well as adhesion^[1]. Alterations in integrin expressions upon malignant transformation and in naturally occurring human malignancies are now well established. However, the mechanisms that give rise to altered integrin protein expression following malignant transformation are poorly understood. We investigate the expression of integrins α_1 , α_2 , α_3 and α_5 in rat liver during 3'-Me-DAB induced hepatocarcinogenesis and expect to find out the relationship between integrins and liver cancer metastasis.

MATERIALS AND METHODS

Animal model^[3]

Male Wistar rats ($n=100$, provided by Experimental Animal Center, Shanghai Medical University), weighing 100g-150g, were divided into four groups: group A ($n=44$), fed with low choline maize powder and 0.03% 3'-Me-DAB for 12 weeks; group B ($n=28$), fed with low choline maize powder only for 12 weeks and group C ($n=28$), fed with standard diet only. After 12 weeks, the rats of group A and B were fed with standard diet. Four to rats were killed in each group at week 3, 6, 9, 12 and 16 and 8-12 at week 20.

Tissue preparation

Small pieces of liver samples (including tumor and metastasis) were divided in two parts, one embedded in O.C.T (Miles, USA), rapidly frozen and stored at -70°C , and the other was fixed with 10% neutral buffered formalin, embedded in paraffin and used for routine histological examination.

Immunohistochemistry

The antibodies against integrins α_1 , α_2 , α_3 and α_5 were purchased from Chemicon International INC and those against epidermal keratin (EK) from Nichi Lei Co. Tokyo, Japan. The rabbit PAP kits were prepared by our department^[4]. Integrins α_1 , α_2 , α_3 and α_5 and EK in normal liver, liver cirrhosis

and liver tumor were detected by PAP method. Briefly, 5 μ m cryostat sections of the frozen tissues were fixed with cold acetone and 10% neutral buffered formalin (9:1) for 10min, and washed in 0.01mol/L phosphate- buffered saline (PBS, pH 7.4) for 5 times, each for 3min. The sections were treated with methanol (containing 0.2 mL/L H₂O₂) at 37°C for 30min and washed in PBS, and then incubated in PBS with 100mL/L normal goat serum at 37°C for 30min. The sections were incubated with rabbit anti-integrins α_1 (1:1200 dilution), α_2 (1:1200 dilution), α_3 (1:1200 dilution), α_5 (1:1500 dilution) and EK (1:1000 dilution) respectively at 37°C for 30min and the n at 4°C overnight. The sections were washed in PBS and incubated with goat anti-rabbit IgG (1:200 dilution) at 37°C for 40min. After washing in PBS, the sections were incubated with rabbit PAP complex (1:200 dilution). The color was developed with 0.5g/L 3, 3'-diaminobenzidine/0.5mL/L H₂O₂/0.05 mol/L PBS (pH 7.6) for 10min. Normal rabbit serum instead of the specific primary antibodies was used as negative control.

Semiquantitation of the results

Only cells with membranous staining were considered; cells with intense dotlike cytoplasm immunoreactivity caused by endogenous peroxidase were ignored. The intensity of staining was divided into +++ (strong), ++(moderate), + (weak), +/- (equivocal), - (negative). Variable patterns were indicated by combining the two extremes of staining intensity, e.g. +++/+/-.

RESULTS

Morphologic changes

Liver cancer model of the rats in group A was successfully induced by fed 3'-Me-DAB with low choline maize powder. In the early experiment (week 1-9), the main morphologic changes were steatosis and necrosis of hepatocytes, proliferation of oval cells and cholangiofibrosis. In the middle of the experiment (week 10-16), massively proliferated oval cells, and extensive areas of cholangiofibrosis were visible. In some livers, few hepatocytes remained; they were either entrapped in cholangiofibrotic structures or located at the peripheries of these lesions. Then, liver cirrhosis and preneoplastic nodules were obvious. At the end of the experiment, most of the rats in group A had liver tumor, mainly mixed hepatocarcinoma (HCC) and cholangiocarcinoma (CCC). Tumor metastasized to the lung, spleen and diaphragm in some rats (Figure 1). There were no obvious morphologic changes in the livers of rats in group B and C.

Expression of integrins and EK

The overall staining patterns are shown in Table 1.

Table 1 Pattern of integrins and EK in normal liver, liver cirrhosis and liver tumor

	α_1	α_2	α_3	α_5	EK
Normal liver tissue					
Hepatocytes	+	-	-	+	-
Sinusoidal endothelial cells	+	-	-	+	-
Bile duct epithelium	-	-	-	-	+++
Liver cirrhosis					
Hepatocytes	+++	++	++	+++	-
Sinusoidal endothelial cells	++	+	+	++	-
Oval cell	+/-	+/-	+/-	+/-	+++/-
Hyperplastic bile duct epithelium	++	-	-	++	+++
Preneoplastic nodules	+	+/-	+/-	+	-
Tumor					
Primary	-/+	-	-	-/+	+++/-
Metastasis	+++/-	-	-	+++/-	+++/-

Figure 1 Tumor metastasis in diaphragm. HE×200

Figure 2 In liver cirrhosis, the expression of integrin α_1 was increased in hepatocytes and sinusoidal endothelial cells. PAP×200

Figure 3 Expression of α_1 was obviously decreased in the primary carcinoma(right) and in para-tumor liver cirrhosis(left), the expression of integrin α_1 was increased in hepatocytes and sinusoidal endothelial cells. PAP×100

Figure 4 Expression of α_1 in metastasis in the lung was higher than in primary carcinoma. PAP×200

In the normal liver tissues, integrins α_1 and α_5 were weakly expressed in hepatocytes and sinusoidal endothelial cells but not in bile duct epithelium. The predominant staining was located on the sinusoidal side plasma membranes of hepatocytes. EK was highly expressed in the bile duct epithelium but not in hepatocytes.

In liver cirrhosis, the expression of integrins α_1 , α_2 , α_3 and α_5 were increased in hepatocytes and sinusoidal endothelial cells but the distribution did not significantly change (Figure 2). However, hyperplastic bile duct epithelium only moderately expressed α_1 and α_5 . Oval cells were equivocal on expression of integrins but most of them highly expressed EK.

Expression of integrins α_1 , α_2 , α_3 and α_5 were obviously decreased in the preneoplastic nodules and primary carcinoma (Figure 3) but expression of integrins α_1 and α_5 in metastasis in the lung and diaphragm were higher than in primary carcinoma (Figure 4).

DISCUSSION

The β_1 subgroup of the integrin superfamily of cell-surface receptors (also known as VLA integrins) contains six heterodimers (VLA-1 to VLA-6), in which different α -subunits share a common β_1 subunit. They serve as receptor for extracellular matrix components as laminin (VLA-1, VLA-2, VLA-3, and VLA-6), collagen (VLA-1, VLA-2, and VLA-3), and fibronectin (VLA-3, VLA-4, and VLA-5) and are involved as counter-receptors for other cell-surface molecules (VLA-4 recognizes the vascular cell adhesion molecule-1 [VCAM-1]) in a cell-to-cell type of interaction^[2].

The integrins are thought to play important roles in differentiation and development, cell migration, and the complex process of tumor cell invasion and metastasis, as well as adhesion. The integrin β_1 and fibronectin were mainly distributed along sinusoids in normal liver, and the expression was weak in adult normal liver^[5]. The distribution did not significantly change during the regeneration and proliferation, but the expression was increased. They acquire some characteristics of fetal and neonatal hepatocytes, including alternations in cell surface properties, such as the composition of glycoconjugates, and the level of receptors for hormones and growth factors and of proteins involved in cell-cell contacts. In the early phase of liver carcinogenesis, proliferation of oval cells, cholangiofibrosis, proliferation of hepatocytes and the extracellular matrix (cirrhosis) were obvious. The high expression of integrins plays an important role in cirrhosis^[6].

Alterations in integrins receptor expression upon malignant transformation and naturally occurring human malignancies are now well established^[7,8]. It was one of the properties of tumor cells that the expressions of integrins and fibronectin were decreased^[9]. Integrins such as fibronectin receptor transduce important growth inhibitory stimuli from the extracellular matrix. Integrins are involved not only in the adhesive, motile and invasive behavior of tumor cells but also in their growth regulation.

Expression of integrins α_1 , α_2 , α_3 and α_5 was obviously decreased in the preneoplastic nodules and primary carcinoma but expression of integrins α_1 and α_5 in metastasis in the lung and diaphragm was higher than in primary carcinoma. Integrins α_1 and α_5 may play a major role in chemically induced hepatocarcinogenesis and metastasis in rats, and it was necessary for tumor cells to adhere to the extracellular matrix in metastatic focus^[10,11].

EK is a mark of epidermal cells. EK was highly expressed by the bile duct epithelium but not by hepatocytes and might be a helpful tool in the differential diagnosis between HCC and CCC. Some oval cells expressed EK but some not. It suggested that oval cells are the progeny of hepatic stem cells, which might differentiate into preneoplastic parenchyma cells and might give rise to HCC.

Lin GY, Chen ZL, Lu CM, Li Y, Ping XJ, Huang R. Immunohistochemical study on p53, H-rasp21, c-erbB-2 protein and PCNA expression in HCC tissues of Han and minority ethnic patients. *World J Gastroenterol*, 2000; 6(2):234-238

Abstract

AIM To find out the difference of human primary liver carcinoma between Han and minority ethnic patients in Xinjiang.

METHODS Expression of p53, c-erbB-2, H-rasp21 protein and proliferating cell nuclear antigen (PCNA) in tumor tissues of 50 patients (Han 38, minority 12) with primary hepatic carcinoma was detected by immunohistochemistry (LSAB).

RESULTS The positive frequency of p53, c-erbB-2, H-rasp21 and PCNA expression was 46.0% (23/50), 70.0% (35/50), 68.0% (34/50) and 82.0% (41/50) in tumor tissues; 4.0% (2/50), 22.0% (11/50), 64.0% (32/50) and 52.0% (26/50) in peritumors respectively and a significant difference, except for H-rasp21, of oncogene alteration was found ($P < 0.05$) between tumor and non-tumorous tissues. Combined the three oncogenes alteration, 26% (13/50) tumor tissues had positive immunoreactivity, but in peritumor and normal livers it was negative. The positive rate of p53, c-erbB-2 and H-rasp21 protein expression was 39.5% (15/38), 60.5% (23/38) and 39.5% (15/38) in tumors of Han patients; 66.7% (8/12), 100% (12/12) and 75.0% (9/12) in minorities respectively, with statistical difference

($P < 0.05$).

CONCLUSION Overexpression of p53, c-erbB-2 and H-rasp21 in human primary liver carcinoma is an important biomarker of genetic alteration. The different frequency of these oncogenetic changes may reflect some environmental or/and ethnic hereditary factors affecting the liver carcinogenesis. The special life style of Han, Uygur, Kazak and Mongolia nationalities in Xinjiang may also be related to the etiopathogenesis of this disease.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major cancers with highest mortality in the world. There is a striking variety of HCC incidence rates between countries, with a highest to lowest of 112.5 for males and 54.7 for females. The high-risk populations are clustered in Sub-Sahara Africa and eastern Asia^[1]. Although many etiological factors, e.g., HBV, aflatoxin B1, heavy alcohol drinking, etc. have been established^[2-4], the exact mechanisms of HCC carcinogenesis is still poorly understood. The natural environment, multiple ethnic groups with different hereditary background, and special life style in Xinjiang are quite different from other areas in China, which may implicate the etiopathogenesis of HCC.

A great number of studies have demonstrated that human HCC hepatocarcinogenesis is a multistepwise and multigenetic alteration induced by various pathogens with the involvement of multifactorial etiology. Alterations of cytogenes, including mutation, amplification, allelic loss of oncogenes and tumor suppressor genes, are most common in many forms of human cancers, including HCC. Overexpression of p53 protein, c-erbB-2, c-myc and H-ras oncoprotein and proliferating cell nuclear antigen (PCNA) were observed in the tumor tissues of patients or experimental animals with HCC^[1-10]. In order to understand the possible mechanism of hepatocarcinogenesis and if there is any difference among various ethnic patients with HCC, we detected the expressions of p53 protein, c-erbB-2 and H-rasp21 oncoprotein, and PCNA in

tumor, peritumor and normal liver tissues by immunohistochemistry.

MATERIALS AND METHODS

Patients

A series of 50 patients with HCC, including 38 Han, 12 minorities (Uygur 8, Kazak 2 and Mongolia 2); males 34, females 16; aged from 18 to 72 (average 50.1) years, was collected from the 1st Teaching Hospital of Xinjiang Medical University from 1991 to 1995.

Specimens

All the tumor and peritumor tissues of 50 cases and 10 specimens of normal liver tissue as a control were fixed in 100mL/L formalin and embedded in paraffin for routine histopathologic examination, and these paraffin blocks were obtained from the pathologic record. The blocks including 50 tumors, 50 peritumors and 10 non-tumors were cut into five sections of 4 μ m in thickness and underwent H.E. and immunohistostaining, respectively.

Immunohistochemical staining

Four- μ m thick sections were dewaxed, and rehydrated according to routine procedures. Nonspecific binding was blocked by incubation with bovine albumin for 10 minutes and endogenous peroxidase activity was blocked with 30mL/L hydrogen peroxide for 5 minutes. The sections were pretreated in a microwave oven at 750W for 10 minutes in citrate buffer (pH 6.0), and then incubated for 5 minutes in microwave oven with primary antibodies, including monoclonal anti-p53 protein (Do-7), anti-H-rasp21 oncoprotein, anti-PCNA (P-c 10) (1:40) and polyclonal anti-c-erbB-2 oncoprotein (1:200) (Dako), respectively. We used the LSAB kits (Dako) for immunostaining, the secondary antibodies and reagents were treated by the routine procedures in microwave oven. The colour was developed using 3-amino-9-ethycarbazol (AEC). The sections were counterstained with Meyer's hematoxylin.

Assessment of staining reaction

Only tumor cells with distinct nuclear immunostaining in both p53 protein and PCNA were considered positive. Tumors were recorded as positive for c-erbB-2, H-rasp21 oncoprotein if more than 5% of tumors showed distinct membrane and cytoplasm staining. The immunoreactivity was registered semiquantitatively. The positive cells were scored as (-) negative; (+) 1-5 positive cells per high magnification (400 fold); (++) 6-20 positive cells; (+++) more than 21 positive cells found in p53 protein and PCNA immunostaining respectively.

Statistics

The immunoreactivity for p53, c-erbB-2, H-rasp21 and PCNA parameters were considered to represent discrete values in various lesions. The Chi square test (χ^2) was used and $P < 0.05$ was accepted as a statistically significant difference.

RESULTS

The immunostaining p53 protein and PCNA appeared red-brown in nucleus and tumor or peritumor cells with various densities were distributed unevenly (Figures 1, 2). The immunoreactivity of c-erbB-2 and H-rasp21 oncoprotein showed distinct membrane and cytoplasm staining (Figures 3, 4). Table 1 summarizes the different frequencies of immunostaining positive cells for p53 protein, H-rasp21, c-erbB-2 and PCNA in tumor and non-tumor tissues.

There was a significant difference among three oncogenes expression respectively except PCNA between Han and minorities ($P < 0.05$). The oncoprotein expression was lower in Han than in the three minorities. Table 2 summarizes the three oncogenes expression in tumor and non-tumor tissues and distribution of different nationalities.

Table 3 shows the combined expression of three oncogenes in HCC of different nationalities. The frequency was higher in minorities (41.7%) than in the Hans (21.1%), without statistical difference ($P > 0.05$).

DISCUSSION

Alterations of oncogenes and tumor suppressor genes were critical events in hepatocarcinogenesis induced by HBV/HCV, chemical carcinogens, etc. have been demonstrated by biopathological and experimental researches^[7-10]. Cerutti^[11] and Tong^[12] reported that the mutagenesis of H-ras proto-oncogene and p53 tumor suppressor gene may be the most important events change in hepatocellular carcinomas. Fujimoto *et al*^[13] observed some allelic loss of tumor suppressor genes in Chinese patients with hepatocarcinomas. Scor sone *et al*^[14] demonstrated that p53 gene mutations clustered at codon 249 in HBV positive hepatocarcinoma patients in China. Recently, Ming *et al*^[15] also found that frequency of 249 codon mutation of p53 gene was much higher in high prevalent area of hepatocellular carcinomas than that in the low-risk area in China. More than 95% (20/21) cancer specimens exhibited strong intranuclear accumulation of p53 protein, which can be detected by immunohistology. However, Biersing *et al*^[16] and Vesey *et al*^[17] found little or no point mutations of p53 gene in human hepatocarcinoma in Swedish and Aust ralian patients. Therefore, the overexpression of p53 protein in hepatocarcinoma specimens can be used as the mutant p53 biopathological mark in tumor tissues. Liu *et al*^[18] and Zu *et al*^[19] found that the frequency of intranuclear positive immunoreactivity of p53 protein was significantly different between high-risk and low-risk HCC areas, and HBxAg can enhance p53 protein accumulation, suggesting that HBxAg was capable of binding p53 and formed a protein-protein complex which might reduce or inactivate the antiproliferative activity of p53 and played an important role in the pathogenesis of HBV-associated hepatocarcinomas. In this study, the overexpression of p53 protein revealed very significant difference between tumor (46%) and peritumor (4%) tissues, and negative in normal liver samples ($P < 0.05$), indicating that p53 gene mutations played similar roles in hepatocarcinogenesis in Xin Jiang regardless of the etiological factors. Su *et al*^[20], Nakapoulou-*et al*^[21] and Yu *et al*^[22] have reported that c-erbB-2 oncogene was related to the dysregulation of proliferation and differentiation of the hepatocytes in hepatotumorigenesis, and over expression in various pathological lesions had different frequencies. We observed that overexpression of c-erbB-2 oncoprotein in tumor (70%) and in peritumor (22%) and in normal liver tissues also showed very distinct difference ($P < 0.05$), suggesting that c-erbB-2 oncogene and tumor suppressor genes jointly participate in the occurrence and development of HCC, and related to

the abnormal regulation even malignant transformation of hepatocytes induced by various pathogenes. Ushijima *et al*^[23], Imai *et al*^[24], Tamano *et al*^[25] found that mutations of ras oncogene may be the early events, and the expression in tumor or non-tumor tissues can be detected with different rates. Lin *et al*^[7] found that the expression of N-ras in liver tumor was correlated to the differentiated status of altered liver cells. In this study, there was no statistical significance between tumor (68%) and peritumor (64%) tissues in the expression of H-ras oncoprotein. Positive cells were also found in 30% of normal liver specimens, reasonably which can not be explained. Proliferating cell nuclear antigen (PCNA), as an index of cellular proliferative status was determined in various lesions. Waga *et al*^[26], Maeda *et al*^[27] found that p53 tumor suppressor gene can control the cyclin-dependent kinases to regulate DNA replication involving PCNA interaction by p21 protein pathway. The overexpression of PCNA with high frequency was usually used as a reliable marker for assessment of tumor progress, premalignant evolution and clinical prognosis of patients with various malignancies. We found that the positive frequency of PCNA in tumor (82%) was significantly higher than in peritumor (52%) tissues ($P<0.05$), indicating that the non-neoplastic tissues surrounding the hepatocarcinomas may have premalignant lesions including cellular hyperplasia, dysplasia, even *in situ* carcinoma. Therefore, these multiple molecular indexes in combination could be used as the biomolecular standard for diagnosis of malignant and benign lesions. The inactivation of tumor suppressor gene p53, Rb, p16, etc. was demonstrated in different forms, and implied the pathogenesis of human malignant diseases. Slagle *et al*^[28] and Shao *et al*^[29] found the loss of heterozygosity on chromosome 17p near the p53 gene or 1p in HBV-positive HCC in China.

It is noteworthy that the alteration of p53 tumor suppressor gene and c-erbB-2 and H-ras oncogenes in different ethnic patients with HCC revealed significant difference. The expression of p53 protein and c-erbB-2 and H-ras oncoprotein in carcinoma specimens was higher in the minority than in Han patients by immunohistochemical detection ($P<0.05$). Moreover, the three combined abnormal expression of p53 protein and c-erbB-2 and H-rasoncoprotein in tumor tissues was higher in minority (41%) than in Han (21%) patients. This may reflect, to a certain extent, the differences of ethnic gene-susceptibility to various carcinogenes and effect on hepatocarcinogenesis. The pathogenesis of primary hepatic carcinoma is a multistage process with the involvement of multifactorial etiology, and the gene-environment

interactions are involved in the development of HCC in humans. In order to understand the exact difference concerning the etiopathogenesis of HCC among different ethnic groups, further studies with more samples are needed, especially in minority ethnic patients.

DNA-based vaccination induces humoral and cellular immune responses against hepatitis B virus surface antigen in mice without activation of C-myc

Lian San Zhao^{1,2}, Shan Qin^{1,2}, Tao You Zhou¹, Hong Tang^{1,2}, Li Liu^{1,2} and Bing Jun Lei^{1,2}

Subject headings hepatitis B virus; DNA vaccine; HBsAg; cellular immunity; oncogene C-myc

Zhao LS, Qin S, Zhou TY, Tang H, Liu L, Lei BJ. DNA-based vaccination induces humoral and cellular immune responses against hepatitis B virus surface antigen in mice without activation of C-myc. *World J Gastroenterol*, 2000;6(2):239-243

Abstract

AIM To develop a safe and effective DNA vaccine for inducing humoral and cellular immunological responses against hepatitis B virus surface antigen (HBsAg).

METHODS BALB/c mice were inoculated with NV-HB/s, a recombinant plasmid that had been inserted S gene of hepatitis B virus genome and could express HBsAg in eukaryotes. HBsAg expression was measured by ABC immunohistochemical assay, generation of anti-HBs by ELISA and cytotoxic T lymphocyte (CTL), by MTT method, existence of vaccine DNA by Southern blot hybridization and activation of oncogene C-myc by *in situ* hybridization.

RESULTS With NV-HB/s vaccination by intramuscular injection, anti-HBs was initially positive 2 weeks after inoculation while all mice tested were HBsAg positive in the muscles. The titers and seroconversion rate of anti-HBs were steadily increasing as time went on and were dose-dependent. All the mice inoculated with 100 µg NV-HB/s were anti-HBs positive one month after inoculation, the titer was 1:1024 or more. The humoral immune response was similar induced by either intramuscular or intradermal injection. CTL activities were much stronger (45.26%) in NV-HB/s DNA immunized mice as

compared with those (only 6%) in plasma-derived HBsAg vaccine immunized mice. Two months after inoculation, all muscle samples were positive by Southern-blot hybridization for NV-HB/s DNA detection, but decreased to 25% and all were undetectable by *in situ* hybridization after 6 months. No oncogene C-myc activation was found in the muscle of inoculation site.

CONCLUSION NV-HB/s could generate humoral and cellular immunological responses against HBsAg that had been safely expressed *in situ* by NV-HB/s vaccination.

INTRODUCTION

Infection with hepatitis B virus (HBV) is the most important and most common cause of acute and chronic liver disease worldwide. Some of them eventually progress to cirrhosis or/and liver failure. Persistent HBV infection is associated with a high risk of primary hepatocellular carcinoma. Hepatitis B virus surface antigen (HBsAg) is the protein product of the S gene of the HBV genome and is the protective immunogen used for developing vaccine against HBV infection. The current commercial HBV vaccines which were divided into plasma-derived HBV vaccine and recombinant HBV vaccine by genetic techniques induce neutralizing antibody (anti-HBs) against HBV. Unfortunately, up to 5% of the adult population may not respond to the currently available HBV vaccines, so great efforts have been made to develop more successful vaccines to prevent and even treat chronic HBV infection^[1]. The newest approach is the use of naked DNA vaccine, the so-called genetic immunization, which has been shown to be effective at generating protective immune responses against a wide variety of diseases^[2-18]. This technique involves the transfer of a viral gene into muscle or skin cells of host by a plasmid vector with subsequent endogenous production and intracellular processing of the viral structural proteins into small antigenic peptide. Such peptides are expressed subsequently on the cell surface in the context of major

histocompatibility complex (MHC) molecules, and may be secreted from the cells to stimulate a humoral and T-helper cell immune response. After genetic immunization, both humoral and cell-mediated immune responses developed^[19-24]. In this study, we evaluated both humoral and cellular immune responses against HBsAg, which were generated in a mice model by DNA-based immunization with naked DNA vaccine NV-HB/s.

MATERIALS AND METHODS

Preparation of nucleic acid vaccine NV-HB/s
S sequences encoding surface antigen of HBV were inserted into eukaryotic expression vector pRc/CMV (Invitrogen, San Diego, CA) under the transcription control of the cytomegalovirus early promoter. The reconstructed plasmid was then amplified in *E. Coli* DH5 α . After extraction and purification plasmid DNA was dissolved in PBS (pH 7.2) at the concentration of 1 μ g/L as the DNA vaccine NV-HB/s and stored at -70°C until use for animal immunization.

DNA vaccine immunization in mice

Vaccine trials in mice were accomplished by the administration of NV-HB/s to 6-week-old BALB/c mice. Dosage of DNA vaccine inoculation was 100 μ g/100 μ L, 10 μ g/100 μ L, and 1 μ g/100 μ L. DNA vaccine was administrated by the following routes: ① intramuscular injection (I.M.) into both sides of tibialis anterior muscles, half dose for each side; ② intradermal injection (I.D.) at 1cm distal from the tail base; and ③ inoculated sites of tibialis anterior muscles were pretreated with the injection of bupivacaine (0.2 μ g per site) 7 days before the vaccination by I.M. at the same sites. The control groups included: pRc/CMV (as negative control), PBS (as blank control); commercial plasma-derived HBV vaccine which was the purified HBsAg (as positive control).

Serum samples were collected 3 days, 1 and 2 weeks, 1, 2, 4 and 6 months after inoculation through retrobulbar puncture and stored under -70°C. Tibialis anterior muscle samples were collected from sacrificed mice 7 times with the same time schedule of the serum sample collection. Each muscle sample was divided into 2 pieces, one was stored at -70°C, the other was fixed in formalin and embedded with paraffin for making into slides.

For detection of CTL activity, another group of mice was inoculated I.M. with 100 μ g NV-HB/s (commercial plasma-derived HBV vaccine as control) and boosted one month later with the same dosage. After one week of boosting, the mice were sacrificed to collect spleen cells for detection of CTL activity.

Detection of HBsAg and anti-HBs

By ABC immunohistochemistry assay, all muscle

tissue samples collected from the inoculation sites were tested for HBsAg expression; and by enzyme-linked immunoadsorbent assay (ELISA), all sera samples were detected for anti-HBs, which were immunologically induced by HBsAg.

Detection of CTL activity

Spleen cells were collected from the sacrificed mice, washed and suspended with HEPES solution at a concentration of 5 \times 10⁶ cells/mL as effect cells. SP2/0-HBs cells (myeloma cell line SP2/0 derived from BALB/c mice had been transfected with NV-HB/s DNA *in vitro*) were suspended with HEPES at a concentration of 5 \times 10⁴ cells/mL as target cells. The effect cells were pre-cultured with stimulating cells, which were SP2/0-HBs irradiated with 10000 rad, and mixed with target cells by the optimal ratio. After a 3h incubation at 37°C, 5% CO₂ and 95% relevant humidity, CTL activities were detected according to the manual described for MTT test kit of CTL activity detection (Boehringer Mannheim Company). In brief, the mixtures were spinned and the supernatant was collected, then LDH substrates were added to the supernatants. Half an hour later, O.D. value of the solution was measured. The percentage specific cytolysis was determined by the following formula: the specific cytolysis (%) = (experimental release-spontaneous release of effect cell-spontaneous release of target cells)/(maximum release of target cell-spontaneous release of target cells) \times 100%.

Existence of NV-HB/s plasmid in the muscles tissue

To find out how long the plasmid DNA could exist in the muscle tissue at the injection sites after inoculation, NV-HB/s was detected by *in situ* hybridization and Southern blot hybridization with Dig-pRc/CMV probe prepared in our laboratory with the protocol described by Zhao *et al*^[25,26]. For *in situ* hybridization, the fixed muscle samples slides were hybridized with Dig-pRc/CMV probe and for Southern blot hybridization, the frozen muscle samples at -70°C were thawed, homogenized, digested with protease, and extracted with phenol/CH₃CL, and the cell DNA recovered was precipitated with ethanol and dissolved in T.E. solution for Southern blot hybridization.

Pathological examination and detection for C-myc activation

Special attention was paid to the health condition of mice after inoculation. Routine pathological examination was made for all mice to know if there is any pathological change. The muscle slides were detected for C-myc mRNA by hybridization *in situ* with Dig-C-myc-cDNA probe with the protocol described by Zhao *et al*^[26,27].

RESULTS

HBsAg expression and antibody induction

After 3 days of inoculation, no HBsAg was detected in the muscle samples. However, 1/3 mice after 1 week of inoculation and 3/3 mice after 2 weeks, were HBsAg positive in the muscles collected from the mice vaccinated with NV-HB/s (Table 1). On the other hand, there was no detectable HBsAg in all sera samples.

Anti-HBs were initially positive 2 weeks later after inoculation while all mice were HBsAg positive in the muscles. The titers and seroconversion rate of anti-HBs were steadily increasing as time goes on. All the mice inoculated with 100 μ g NV-HB/s were anti-HBs positive one month later after inoculation, the titer could be 1:1024 or more. Titers and seroconversion rate were dosage-dependent. For the mice inoculated with 1 μ g or 10 μ g NV-HB/s, the positive rate of anti-HBs was only 3/6 or 5/6 respectively even 2 months after inoculation, while their titers of anti-HBs were also lower than that of mice inoculated with 100 μ g NV-HB/s ($P < 0.05$).

Humoral immune response induced with NV-HB/s vaccination were similar by either intramuscular or intradermal injection. The positive rates of anti-HBs were nearly the same although the titers induced by I.M. were higher than those by I.D. Pretreatment with bupivacaine before I.M. did not promote the humoral immune response in this experiment.

Table 1 HBsAg expression and anti-HBs induction in the mice inoculated with DNA vaccine against hepatitis B (NV-HB/s)

	Positive rate after inoculation						
	3d	1wk	2wks	1mo	2mos	4mos	6mos
HBsAg(%)	0 (0/4)	33.3 (1/3)	100 (3/3)	75 (3/4)	5 (3/4)	83.3 (5/6)	75 (6/8)
Anti-HBs(%)	0 (0/4)	0 (0/3)	66 \pm 7 (2/3)	100 (4/4)	100 (4/4)	100 (6/6)	100 (8/8)

HBsAg was detected from mice muscle tissue samples of injection sites by ABC immunohistochemistry. Anti-HBs was detected from sera samples by ELISA. The numbers in parenthesis indicate the number of mice with positive detection results/the total number of mice detected.

NV-HB/s vaccination induces HBsAg-specific CTLs

In our data, CTL activities were much stronger in NV-HB/s immunized mice (45.26%) as compared with those in plasma-derived HBsAg vaccine immunized mice (only 6%) ($P < 0.01$). Certainly there was no CTL activity detected from any negative control groups.

Persistence of NV-HB/s DNA in the muscles

Two months later after inoculation, all muscle samples were positive by Southern-blot hybridization for NV-HB/s DNA detection.

However, 6 months after inoculation, the positive rate decreased to 25%, and all the muscle samples were negative by *in situ* hybridization for NV-HB/s DNA detection. Considering that the DNA detection sensitivity by *in situ* hybridization is lower than by Southern-blot hybridization, the above-mentioned result implies that the amount of NV-HB/s existed in the muscle was very low and degenerated rapidly as time goes on.

Effect of NV-HB/s vaccination on oncogene C-myc

In mice sacrificed 3 days after injection, hyaline degeneration was observed, including swollen muscular fiber, disappearance of cross striation and red stain of myocytes plasma, which were slightly more apparent in mice inoculated with NV-HB/s or pRc/CMV than those inoculated with PBS or plasma-derived vaccines. In the former groups, some lymphocytes aggregated, and in one of them neutrophil clustering was found. These pathological changes disappeared 1 week later in the PBS-injected mice and 4 weeks later in NV-HB/s or pRc/CMV injected mice. During the experiment the mice looked healthy, and no C-myc mRNA was detected in all the muscle sample collected from the mice inoculated.

DISCUSSION

In this study, we evaluated the humoral and cellular immune response induced in BALB/c mice by DNA-mediated immunization with NV-HB/s, a recombinant plasmid which had been inserted S gene and could express HBsAg in eukaryotes. The results showed that even after a single intramuscular injection of DNA, a detectable antibody response could be induced and sustained which resembles that of natural HBV infection in terms of the fine specificity. There was no significant difference between the humoral immune response induced with NV-HB/s by intramuscular injection and those by intradermal injection^[28]. These data provided evidence that the envelope proteins encoded by the recombinant DNA has adopted a conformation similar to that of the proteins present during natural infection. This conclusion validates the use of DNA-based *in vivo* synthesis of the antigen for immunization purposes.

It is the important feature that DNA-based immunization is the *in situ* production of the expressed protein subsequent to the introduction of DNA carrying the protein coding sequences, mimicking in this respect a viral infection^[29]. In our data, the muscle samples had positive HBsAg expression in 1 week for 1/3 mice, and in 2 weeks after NV-HB/s inoculation for all the mice detected by ABC immunohistochemistry assay. However, no HBsAg was detected from any sera sample, which suggested that the quantity of HBsAg protein expression was high enough to induce immune

response in mice. Such endogenous protein synthesis could allow presentation of antigens by class I molecules of the major histocompatibility complex (MHC), thus resulting in the induction of CD8⁺ cytotoxic T lymphocytes (CTL). Therefore, the potential of DNA-mediated immunization in partially mimic viral infection promises the efficacy of live attenuated vaccines without the risk of inadvertent infection^[30-31].

DNA-based immunization was shown to induce a broad range of immune responses, including neutralizing antibodies, CTL, T-cell proliferation, and protection against challenge with the various pathogens. In this study, direct injection of NV-HB/s DNA encoding for HBsAg into the muscle of mice could induce humoral and, more important, cell-mediated immune responses.

Compared with immunizations with soluble recombinant proteins or peptides (e.g. the commercial plasma-derived HB vaccine), the advantage of DNA-mediated immunization is to induce a more Th1-like immune response with the production of inflammatory CD4⁺ T cell as well as cytotoxic T cell activity, presumably due to the intracellular processing of viral proteins into peptides and subsequent loading onto MHC class I molecules in transfected muscle cells and to be defined interactions of the complex with APCs. Immunization with soluble protein primarily leads to a humoral immune response due to processing through the MHC class II pathway. The disadvantage of the immunization with foreign peptides is that there is only a limited number of epitopes available for stimulation of the host immune response. In contrast, all naturally occurring B and T cell epitopes encoded for each protein by the DNA construct of interest are presumably preserved for recognition by TCRs and will consequently generate very broad humoral and cellular immune responses. In our data, NV-HB/s vaccination generated much stronger CTL activities (45.26%) than plasma-derived HBsAg vaccine inoculation could (6%) ($P < 0.01$).

Some types of local APCs will take up and process antigens to induce MHC class I and II restricted T-cell responses in DNA-mediated immunization. For intramuscular inoculation, myoblasts and myotubes express MHC class I molecules but not MHC class II and other co-stimulatory molecules^[32]. It was reported that pretreatment of the tissues with the anesthetic bupivacaine could dilate local vessels, thus enhancing DNA uptake by myocytes^[33]. Our data did not prove that the use of bupivacaine could improve responses to HNV-HB/s vaccination^[34]. As CTLs can recognize cells that are already infected, it might be desirable particularly in the prevention, and even treatment of chronic viral infection. Moreover, unlike antibody responses, which are usually type specific CTLs can crossreact

against different viral epitopes, thus potentially affording greater protection against disparate viral strains. During active viral replication, HBV has a very high mutation rate^[35]. In this approach, the vaccine escape mutants HBV strains could be conquered.

It is known that cytotoxic T lymphocyte (CTL) activity against HBV structural proteins is not detectable in peripheral blood lymphocytes derived from the individuals with persistent HBV infection. Some chronic HBV-infected individuals who had spontaneous clearance of HBV DNA from sera are often accompanied by increased CD4⁺ T-helper responses and acute exacerbation of liver disease. So an attractive hypothesis for the development of persistent viral infection is that HBV-specific CTLs are unable to clear virus from the liver because of substantially decreased intrahepatic levels or qualitative changes in CTLs activity^[36,37]. On the other hand, the observation of spontaneous HBV clearance in some individuals indicated that the suboptimal cellular immune response may be reversible. Therefore, strategies designed to boost the HBV-specific immune response or to alter the balance between the cytopathic and the regulatory component of the response may be able to terminate persistent infection. There is strong evidence that the efficacy of the CTL response to HBV structural proteins may be crucial for eradication of persistent viral infection. It has been shown that the adoptive transfer of HBsAg-specific CTLs into HBV transgenic mice was associated with HBV clearance from the liver by antiviral effects of secreted IFN- γ and tumor necrosis factor α derived from sensitized cells, without killing hepatocytes^[38,39].

In this study, we presented evidence that DNA vaccine inoculation is capable of eliciting Ag-specific immune responses in both effector pathways of the immune system: the humoral and cellular immune responses. We have shown that NV-HB/s vaccination is able to induce humoral and CTL activity in mice using this approach. Our data may be beneficial for possible antiviral therapy of chronic HBV infection. Thus, NV-HB/s could be promising candidates as antiviral agents for persistent viral infection of the liver by inducing a strong cellular immune response after intramuscular immunization. However, it was noteworthy that the generation of such protective immune responses in humans remains to be established.

Finally, the safety of DNA vaccine remains theoretical concerns, for example, if the foreign DNA may integrate into the host genome with the possibility of disrupting normal genes and malignant transformation^[33]. Our study showed no proof of oncogene C-myc activation with specific immune response induced by NV-HB/s inoculation. The mice looked healthy except a brief trauma reaction at the inoculation site caused by injection.

Wu P, Li X, Zhou T, Zhang MJ, Chen JL, Wang WM, Chen N, Dong DC. Role of P-selectin and anti-P-selectin monoclonal antibody in apoptosis during hepatic/renal ischemia-reperfusion injury. *World J Gastroenterol*, 2000;6(2):244-247

Abstract

AIM To evaluate the potential role of P-selectin and anti-P-selectin monoclonal antibody (mAb) in apoptosis during hepatic/renal ischemia-reperfusion injury.

METHODS Plasma P-selectin level, hepatic/renal P-selectin expression and cell apoptosis were detected in rat model of hepatic/renal ischemia-reperfusion injury. ELISA, immunohistochemistry and TUNEL were used. Some ischemia-reperfusion rats were treated with anti-P-selectin mAb.

RESULTS Hepatic/renal function insufficiency, up-regulated expression of P-selectin in plasma and hepatic/renal tissue, hepatic/renal histopathological damages and cell apoptosis were found in rats with hepatic/renal ischemia-reperfusion injury, while these changes became less conspicuous in animals treated with anti-P-selectin mAb.

CONCLUSION P-selectin might mediate neutrophil infiltration and cell apoptosis and contribute to hepatic/renal ischemia-reperfusion injury, anti-P-selectin mAb might be an efficient approach for the prevention and treatment of hepatic/renal ischemia-reperfusion injury.

INTRODUCTION

Visceral ischemia-reperfusion injury is very common clinically. Up to now, there has been no effective measure for its prevention and treatment, so this pathological injury process has aroused great attention. Recently, it is proved that neutrophil infiltration, oxygen free radical, some cell factors (TNF- α and IL- β), adhesion molecules and cell apoptosis are related to ischemia-reperfusion injury^[1,2]. Depletion or functional inactivation of neutrophils has been demonstrated to prevent effectively reperfusion-induced tissue damage^[3,4]. P-selectin is expressed by activated platelets and endothelium, and contributes to the interactions of these activated cells with polymorphonuclear neutrophils (PMN) or monophages. It is also involved in the early stages of inflammation, thrombogenesis and tissue injury induced by these cells^[5,6]. In this article, the role of P-selectin in cell apoptosis in hepatic/renal ischemia-reperfusion injury, as well as the preventive and curative effect of P-selectin monoclonal antibody (mAb) were studied with the rat model of ischemia-reperfusion injury.

MATERIAL AND METHODS

Animal model

Ninety male Wistar rats (Shanghai Experimental Animal Center, Chinese Academy of Sciences), weighing 200g \pm 5g, were given free access to water for three days before experiment. The rats were anesthetized with 2.5% sodium pentobarbital intraperitoneally, and randomly divided into 2 groups. In one group of rats, the ligament linking liver, diaphragm and abdominal wall were separated, portal vein and liver artery that drain blood to left hepatic lobe were freed by blunt dissection and blocked with a microvascular clamp for 60 minutes, then the clamp was removed, and reperfusion was performed; while in another group, the left renal artery was freed, and blood flow was also blocked with a microvascular clamp for 60 minutes, then the clamp was removed and reperfusion was given, simultaneously, the right kidney was cut off. The two groups of rats were randomly divided into P-selectin monoclonal antibody treatment group ($n=20$) and non treatment group ($n=20$). They were divided into 4

subgroups according to the indicated time 1, 3, 6, and 24 hours after reperfusion. Five minutes before reperfusion, animals were randomly injected with P-selectin mAb (2mg/kg, Suzhou Medical College), or 0.9% NaCl solution intravenously. Sham-operated group ($n=5$) (anesthesia and opening celiac cavity were performed, not blocking hepatic or renal blood flow) served as control.

Collection and measurement methods of specimens

Blood and left hepatic lobe and renal tissues were harvested at the indicated time. Serum levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and blood urea nitrogen (BUN) and creatinine (sCr) were measured with a 747 automatic analyzer (Hitachi Boehringer Mannheim, Mannheim, Germany). Plasma P-selectin levels were estimated with ELISA method. Left hepatic lobe and renal tissues were fixed with 10% formalin, and embedded routinely in paraffin. Sections were cut 5 μ m thick and stained with hematoxylin and eosin for light microscope examination. Expression of P-selectin in hepatic and renal tissues was assayed by immunohistochemical method with labelled streptavidin biotin (LSAB) kit (Fujian Maixin Biotechnology Co, Products of Biotechnology Co. CA, USA)^[7]. Apoptotic cells in hepatic and renal tissues were detected by TUNEL kit (Boehringer Company). Ten HP visual fields ($\times 400$) were selected randomly within each section to count out apoptotic cells, cell with blue-purple nucleolus belonged to positive cell.

Statistical analysis

Data was presented with $\bar{x} \pm s$, and Student's t test was used to determine changes between different groups.

RESULTS

Hepatic and renal function evaluation

At 24 hours after hepatic ischemia-reperfusion, serum AST (667U/L \pm 142U/L) and ALT (491U/L \pm 94U/L) levels in saline-treated group were much higher than the sham group (74U/L \pm 19U/L and 55U/L \pm 12U/L, respectively), $P<0.05$. Treatment with P-selectin mAb resulted in significantly lower levels of AST (271U/L \pm 65U/L) and ALT (233U/L \pm 44U/L) compared with saline-treated group ($P<0.05$).

At 24 hours after renal ischemia-reperfusion, the levels of serum BUN (52.49 mmol/L \pm 8.91 mmol/L) and Cr (456.31 μ mol/L \pm 65.25 μ mol/L) in saline-treated group were much higher than the sham group (7.16 mmol/L \pm 1.42 mmol/L and 53.65 μ mol/L \pm 8.91 μ mol/L, respectively), $P<0.01$. Treatment with P-selectin mAb, significantly lowered the levels of BUN (20.28 mmol/L \pm 3.82 mmol/L) and Cr

(167.75 μ mol/L \pm 32.81 μ mol/L) as compared with saline-treated group ($P<0.01$).

Histopathologic changes of liver and kidney

After 1 hour of ischemia of left hepatic lobe, reperfusion was performed. With the observation of naked eye, the left hepatic lobe was more swollen than the right lobe while under light microscope, edema, degradation with different extent and necrosis of hepatic cells, interstitial congestion and infiltration of inflammatory cells were observed. After 1 hour of left renal blood flow blocking on rats, reperfusion followed, with the observation of naked eye, the renal cortex was paler, renal medulla displayed blood stagnation and dark colored; under light microscope, swell, degradation with different extent and necrosis of renal tubular epithelial cell were exhibited; simultaneously, interstitial congestion, edema and infiltration of inflammatory cells were also observed. While in the P-selectin mAb treatment group, the outward appearance of liver and kidney was similar to that of normal. Renal cells and tubular cells showed less swelling and no denaturalization or necrosis, and interstitial changes were not obvious.

Plasma P-selectin level changes

At 24 hours after hepatic/renal ischemia-reperfusion, plasma P-selectin levels of saline-treated group (5.16 μ g/L \pm 1.08 μ g/L and 8.92 μ g/L \pm 3.17 μ g/L, respectively) were much higher than the sham group (1.59 μ g/L \pm 0.25 μ g/L and 3.57 μ g/L \pm 0.89 μ g/L, respectively), $P<0.05$. Treatment with P-selectin mAb, resulted in significantly lower levels of P-selectin (2.89 μ g/L \pm 0.72 μ g/L and 6.02 μ g/L \pm 2.15 μ g/L, respectively) compared with saline-treated group ($P<0.05$).

The expression of P-selectin in hepatic and renal tissue

P-selectin expressed widely within hepatic and renal tissues in early stage of ischemia-reperfusion, which was distributed on small vessels of left hepatic lobe, part of hepatic cellular membrane, renal glomerulomesangium, capillary loops, tubules and interstitium, it was especially remarkable on hepatic small vessels and tubular epithelium. After the treatment with P-selectin mAb, the expression of P-selectin was not displayed in essence.

Cell apoptosis in hepatic and renal tissue

It was displayed with TUNEL method that there was few apoptotic bodies in hepatic and renal tissues in the control group. After 1 hour of hepatic and renal ischemia and reperfusion, a few apoptotic bodies emerged in hepatic tissues, renal tubules and interstitium; after 3-6 hours, a large quantity of apoptotic bodies were observed in the hepatic or renal tissues, especially in renal tubules; and after

24 hours apoptotic bodies gathered in flakes, and inclined to necrosis. The quantity of apoptotic bodies in the tissues of P-selectin mAb treated group was smaller than that in the non-treatment group, especially in renal tubules, there was much fewer apoptotic bodies. The examination results of cell apoptosis in hepatic and renal tissues of each group are shown in Table 1.

Table 1 The quantity of apoptotic bodies in hepatic and renal tissues of each group ($\bar{x} \pm s$, number/ $\times 400$)

	Renal ischemia -reperfusion group		Hepatic ischemia -reperfusion group	
	<i>n</i>	Quantity of apoptotic bodies	<i>n</i>	Quantity of apoptotic bodies
Control group	5	9.0 \pm 3.2	5	8.5 \pm 3.4
Non-treatment group				
1hr of reperfusion	5	23.4 \pm 2.9 ^{ab}	5	18.3 \pm 3.5 ^{ab}
3hrs of reperfusion	5	131.6 \pm 7.6 ^{ab}	5	74.9 \pm 6.8 ^{ab}
6hrs of reperfusion	5	209.6 \pm 8.4 ^{ab}	5	94.6 \pm 8.1 ^{ab}
24hrs of reperfusion	5	427.8 \pm 37.1 ^{ab}	5	397.4 \pm 40.2 ^{ab}
mAb treatment group	20	13.0 \pm 3.9 ^a	20	13.1 \pm 3.7 ^a

Compared with control group: ^a $P < 0.01$; compared with mAb treatment group: ^b $P < 0.01$.

DISCUSSION

Recently, the role of neutrophil and cell adhesion molecules in ischemia-reperfusion injury of multiple organs has aroused extensive attention^[5]. Investigators have used mAb directed against key adhesion domains^[8]. As a potential member of selectin family, P-selectin is mainly found in both weibel-plade body of epithelial cell of middle and small blood vessels and α -granule of platelet. It is expressed rapidly on the surface of these cells after their activation. In the earliest stage of inflammation, P-selectin initiates the adhesion, rolling of neutrophils, and then recruits them to injured site^[6]. Blockade of P-selectin expression or interaction with its ligands can attenuate leukocyte adherence and infiltration during ischemia/reperfusion injury or acute inflammation affording impressive functional and morphologic protection^[9-11]. Neutrophils participate in pathological injury through releasing oxygen free radicals and some enzymes. As a large number of neutrophils gather in the injured tissues of ischemia-reperfusion, reducing the infiltration of neutrophils can alleviate the ischemia-reperfusion injury evidently.

The expression of P-selectin and effect of P-selectin mAb on ischemia-reperfusion injury were observed in this study based on the established rat model of ischemia-reperfusion injury. Hepatic and renal tissue exhibited heavy histopathologic damages after hepatic/renal ischemia-reperfusion, while the serum AST and ALT levels as well as BUN and Cr were increased. It is indicated that ischemia-

reperfusion induced hepatic and renal injury which could be significantly attenuated when P-selectin mAb was administrated 5 minutes before reperfusion as shown by improved hepatic/renal function and less pathologic damage. The results suggested that P-selectin mAb has a protective effect on renal ischemia/reperfusion injury by means of inhibiting interaction of neutrophils and endothelium.

Up-regulated expression of P-selectin in plasma and hepatic/renal tissue after rat hepatic/renal ischemia and reperfusion indicated that P-selectin is associated with hepatic/renal ischemia-reperfusion injury. The leukocyte rolling and recruitment was delayed when P or E-selectin deficient mice were infected, suggesting that P-selectin is involved in the early events of inflammation mediated by leukocyte^[7,12]. Another study demonstrated that P-selectin might maintain chronic inflammatory state^[13]. Increased plasma P-selectin level indicates that: P-selectin was markedly released into blood circulation from activated platelets/endothelial cells by inflammatory mediators during acute hepatic/renal injury, and platelets or endothelial cells were activated *in vivo* to enhance hepatic/renal injury. P-selectin was widely expressed in hepatic/renal tissue in the early stage of injury, particularly in hepatic small vessels and tubular epithelium, suggesting that P-selectin might play a functional role in the early events of leukocyte adherence, activation and infiltration within the liver and kidney.

Results obtained in this study showed that P-selectin expression in hepatic/renal tissue was inhibited and plasma P-selectin level was significantly lowered in P-selectin mAb-treated group. It is consistent with down-regulated expression of sialyl Lewis X, a ligand for P-selectin located mainly in neutrophils, as with anti-P-selectin therapy (unpublished data). The experiment suggested that in the process of hepatic and renal ischemia-reperfusion injury, P-selectin mediated the infiltration of neutrophils in hepatic and renal tissues, neutrophils released a set of inflammatory media, which could aggravate the injury of tissues. When the effect of P-selectin was impeded, less neutrophils infiltration and pathological lesions could be observed in the tissue. This phenomenon showed that P-selectin mAb played a protective role in the injury of hepatic and renal tissues caused by ischemia-reperfusion.

Cell apoptosis, which is also named programmed cell death, is an active death process of cell, its imbalance or changes are relative to the occurrence of many kinds of diseases^[14]. Schumer et al^[15] studied the death form of cells at different times of renal ischemia-reperfusion in rats, and found that transient renal ischemia mainly led to cell apoptosis, permanent and severe renal ischemia

brought about necrosis of cells, so it was proved that cell apoptosis took part in cell injury process of acute renal ischemia. Besides this, Sasaki *et al*^[16] discovered that by 3 hours of reperfusion after hepatic ischemia in rats, the quantity of apoptotic cells increased markedly, and reached their peak. Therefore, study of the occurrence rule of cell apoptosis during hepatic and renal ischemia-reperfusion is helpful in the treatment of liver and kidney transplantation as well as the disturbance of renal function in acute renal tubular injury, moreover, it is also beneficial in seeking effective measures to promote the recovery of injured renal function.

We discovered that, after 1 hour of reperfusion following 1 hour of hepatic and renal ischemia, a few apoptotic bodies emerged, after 3-6 hours of reperfusion, large quantities of apoptotic bodies appeared and after 24 hours of reperfusion, the number of apoptotic bodies reached their peak and inclined to necrosis. This indicated that the time of reperfusion is closely related to the occurrence of cell apoptosis. After the treatment with P-selectin mAb, the situation of cell apoptosis in hepatic and renal tissues of rat became better than that of the control group, possibly due to the fact that P-selectin mAb impeded the adhesion and infiltration of neutrophils, and alleviated cell apoptosis in hepatic and renal tissues during reperfusion after ischemia.

It is considered currently that the death of renal tubular epithelial cells during reperfusion after transient renal ischemia is not caused by ischemia itself, but because the swollen cells can compress blood vessels during ischemia, which makes the corresponding tissue in a state of less blood flow during reperfusion, the insufficiency of blood flow can lead to a large scale of renal cell apoptosis^[17]. Our previous studies displayed that P-selectin expressed not only on the surface of platelet and endothelial cell, but also on that of renal tubular epithelial cells^[18]. So we speculate that ischemia may stimulate the up-regulation of the expression of P-selectin on the renal tubular epithelial cells. We discovered in this experiment that inhibiting the effect of P-selectin could reduce the apoptosis of renal tubular epithelial cells, so it was proved that P-selectin is an important factor causing renal tubular injury during the renal ischemia-reperfusion process.

It is suggested that P-selectin mediates the infiltration of neutrophils and the injury of renal tubular epithelial cells in tissues during hepatic and renal ischemia-reperfusion process in rats, inhibiting P-selectin can alleviate the accumulation of neutrophils and cell apoptosis in hepatic and renal tissues, and relieve hepatic and renal ischemia-

reperfusion injury. So research into the P-selectin and its inhibitor offers a new thought for the treatment of human liver and kidney transplantation as well as acute renal failure caused by renal tubular injury.

Optic properties of bile liquid crystals in human body

Hai Ming Yang¹, Jie Wu¹, Jin Yi Li², Jian Li Zhou¹, Li Jun He¹ and Xian Fang Xu¹

Subject headings cholecystolithiasis; liquid crystals; optic properties

Yang HM, Wu J, Li JY, Zhou JL, He LJ, Xu XF. Optic properties of bile liquid crystals in human body. *World J Gastroenterol*, 2000;6(2):248-251

Abstract

AIM To further study the properties of bile liquid crystals, and probe into the relationship between bile liquid crystals and gallbladder stone formation, and provide evidence for the prevention and treatment of cholecystolithiasis.

METHODS The optic properties of bile liquid crystals in human body were determined by the method of crystal optics under polarizing microscope with plane polarized light and perpendicular polarized light.

RESULTS Under a polarizing microscope with plane polarized light, bile liquid crystals scattered in bile appeared round, oval or irregularly round. The color of bile liquid crystals was a little lighter than that of the bile around. When the stage was turned round, the color of bile liquid crystals or the darkness and lightness of the color did not change obviously. On the border between bile liquid crystals and the bile around, brighter Becke-Line could be observed. When the microscope tube is lifted, Becke-Line moved inward, and when lowered, Becke-Line moved outward. Under a perpendicular polarized light, bile liquid crystals showed some special interference patterns, called Malta cross. When the stage was turning round at an angle of 360°, the Malta cross

showed four times of extinction. In the vibrating direction of 45° angle of relative to upper and lower polarizing plate, gypsum test-board with optical path difference of 530nm was inserted, the first and the third quadrants of Malta cross appeared to be blue, and the second and the fourth quadrants appeared orange. When mica test-board with optical path difference of 147nm was inserted, the first and the third quadrants of Malta cross appeared yellow, and the second and the fourth quadrants appeared dark grey. **CONCLUSION** The bile liquid crystals were distributed in bile in the form of global grains. Their polychroism and absorption were slight, but the edge and Becke*Line were very clear. Its refractive index was larger than that of the bile. These liquid crystals were uniaxial positive crystals. The interference colors were the first order grey-white. The double refractive index of the liquid crystals was $\Delta n = 0.011-0.015$.

INTRODUCTION

Researches of recent years show that there are liquid crystals in the bile of the patients with gallbladder stone^[1-4]. Some scholars inferred the function of bile liquid crystals^[2]. In order to find out the properties of bile liquid crystals, probe into the relationship between bile liquid crystals and the formation of gallbladder stone and provide evidence for the prevention and treatment of cholecystolithiasis, we used the method of crystal optics, and determined the optic properties of bile liquid crystals in human under polarizing microscope with plane polarized light and perpendicular polarized light. No similar reports have been found so far.

MATERIALS AND METHODS

Materials

The bile was collected from the gallbladder extirpated surgically in the Second Affiliated Hospital of Kunming Medical College and kept at 4.0°C in the refrigerator for use.

Methods

Extraction of bile liquid crystals Firstly, the bile was centrifuged at 4000r/min for 30min with type

800 centrifuge sedimentor made in China. Secondly, the supernatant was centrifuged at 30000r/min for 40min of equivalent time of centrifugation through 50g/L-150g/L linear concentration gradients of sucrose solution with Hitachi RPS 50-2 swing-out rotor and model SCP85H Hitachi automatic preparative ultracentrifuge at 25°C. After centrifugalization, the bile was taken out in different colors and put into different sample cups. After examination under a polarizing microscope, liquid crystals were selected for microslide preparation.

Microslide preparation Bile (6.0μL) was taken with China-made W-104 micropipet (0.2μL), and dropped to a slide and covered with a glass. It was stretched into a slice naturally for observation and measurement.

Measurement of bile refractive index With China-made 2WA871430 Abbe refractometer (0.0005), bile refractive index was measured after gradient centrifugation of sucrose density.

Measurement of bile liquid crystals thickness With China-made 0mm-25mm micrometer screw gauge (0.01mm) the area of cover glass was measured and the thickness of liquid crystals was worked out according to the volume taken out from the micropipet.

Polarizing microscopic observation Under a Japan-made BHSP Olympus advanced polarizing microscope, observations were made on the outside character of bile liquid crystals, the optical nature involved with light wave absorption and optical nature related with refraction rate. Under a perpendicular polarizing microscope, interference patterns of bile liquid crystals, disappearing phenomenon and mobility were examined. The size of Malta cross was measured with micrometer eyepiece (0.1mm) and micrometer objective (0.01mm). In the vibration direction at 45° angle relative to upper and lower polarizing plate, gypsum test-board with optical path difference of 530 nm and the mica test-board with optical path difference of 147nm were inserted to measure the optical symbol, interference color level and double refraction rate of the bile liquid crystals.

RESULTS

Under a polarizing and a perpendicular polarized light microscope, 100 pictures of different bile liquid crystals from 17 cases of cholecystolithiasis were observed and measured.

Outside character of bile liquid crystals

Under a polarizing microscope, bile liquid crystals were found scattered in the bile, appearing round, oval or irregularly round in shape (Figure 1a).

The optical nature of bile liquid crystals related with light wave absorption

Under a polarizing microscope, the color of bile liquid crystals was a little lighter than that of the bile being around. When the stage was turned round, no obvious changes occurred in the color of bile liquid crystals or the darkness and lightness of the color.

The optical nature of bile liquid crystals related with refractive index

Under a polarizing microscope, on the border between bile liquid crystals and bile being around, darker edge can be observed with a brighter line nearby, i.e., Becke-Line (Figure 1b). When the microscope tube was lifted, Becke-Line moved inward (to the liquid crystals), and when lowered, Becke-Line moved outwardly (to the bile). The refractive index of bile liquid crystals was bigger than that of the bile being around (1.3408-1.3494) (Table 1).

Table 1 The refractive index of the bile in human body

No.	Refractive index	No.	Refractive index	No.	Refractive index
001	1.3470	007	1.3441	013	1.3446
002	1.3494	008	1.3418	014	1.3443
003	1.3485	009	1.3408	015	1.3451
004	1.3486	010	1.3416	016	1.3454
005	1.3479	011	1.3435	017	1.3456
006	1.3473	012	1.3445	018	1.3457

Interference patterns and extinction of bile liquid crystals

Under a perpendicular polarized light, bile liquid crystals in human body presented some special interference patterns, called Malta cross. These Malta crosses had various kinds of shapes, which can be divided generally into three types. The first one was round in shape, with four symmetry, equal and broad bright double refraction areas, and the middle part was a narrow, dark cross; the second one was irregularly round in shape, with four symmetry bright double-refraction areas but not equal each other, in the middle, the narrow dark cross was lean towards different directions; and the third one shaped oval with four narrow bright double-refraction areas, in the middle there was a bigger dark cross (Figure 2a, b).

Brightness or darkness of Malta cross was changed regularly when the stage was rotated, which changed once for each 45° turning. If there was a turning of 360°, four times of brightness and darkness appeared, i.e., four extinction and four interference color phenomena occurred.

Mobility of bile liquid crystals

Little distilled water was added to the space between a slide and a cover glass containing bile liquid

crystals. Under a perpendicular polarized light, Malta cross was observed from bile liquid crystals, flowing swiftly accompanying with the mobile of the water. In the process of flowing, the shape of Malta cross changed incessantly with the flowing of liquid crystals. When it flew to the edge, Malta cross was changed into crystal grains of double refraction after drying.

Optical symbol and interference color level of bile liquid crystals

Under a perpendicular polarized light, in the relative direction of 45° angle of vibration of upper and lower polarizing plate, a plaster test-board with optical path difference of 530nm was inserted, the first and the third quadrants of Malta cross was found present in bile liquid crystals being blue in color, and the second and the fourth quadrants being orange, and the black cross being purplish. When a mica test-board with optical path difference of 147nm was inserted, the first and the third quadrants of Malta cross appeared light yellow, and the second and the fourth quadrants appeared dark grey (Figures 3a, b, c). It is suggested that optical symbol of bile liquid crystals is uniaxial positive and interference color level is the first level grey^[5].

Size of Malta cross

Under a perpendicular polarized light microscope, the diameter (or long axis) of Malta cross was measured to be between 6.2×10^{-3} mm and 2.9×10^{-2} mm.

Figure 1 (a) The shape of bile liquid crystals under a polarizing microscope. $\times 400$
(b) The Becke-Line of bile liquid crystals. $\times 400$

Figure 2 The interference pattern of bile liquid crystals under a perpendicular polarized light microscope-various shapes of Malta cross. $\times 400$

Figure 3 (a) Interference pattern of bile liquid crystals in human body before inserting test-board. $\times 400$
(b) Interference pattern of inserting plaster test-board with optical path difference of 530nm. $\times 400$
(c) Interference pattern of inserting mica test-board with optical path difference of 147nm. $\times 400$

Double refractive index of bile liquid crystals

It was measured that the area of bile was $328.3\text{mm}^2 \pm 0.7\text{mm}^2$, the thickness of liquid crystals $d = (1.8 \pm 0.1) \times 10^{-2}\text{mm}$, the interference color level was the first level grey-white, and optical path difference was $200\text{nm}-270\text{nm}^{[6]}$. According to the formula of that optical path difference: $R=d(N_e-N_o)=d\Delta n$, the double refractive index of bile liquid crystals was calculated as $\Delta n=0.011-0.015$.

DISCUSSION

Under plane polarized light, the outside character of bile liquid crystals was observed, which were not steric pattern, but a section contour of a certain direction formed by bile liquid crystals crossed with cover glass. Because the direction of section varies, different shapes can be observed, based on which its outside character can be determined. Under a polarizing microscope, the section of bile liquid crystals appeared totally round, oval or irregularly round, which only occurred in the section of different directions of a ball, indicating that bile liquid crystals existed in the bile in the form of ball-shaped grains.

Under a polarizing microscope, when the microscope stage is turned round, changes take place in the color of many crystals and the darkness or lightness of the color. This phenomenon which makes the color of crystals change by different vibrating directions of the light waves of the crystals is called polychromatophilia. The phenomenon which makes the darkness or lightness of the color change is called absorptivity^[5]. Under a polarizing microscope, when the stage was turned around, changes did not take place distinctively in the color of bile liquid crystals and the darkness or lightness of the color, indicating that polychromatophilia and absorptivity of bile liquid crystals were not prominent.

In the view of kinetic theory, in the surface layer of liquid, the direction of the absorptive force among the liquid elements points to the interior part of the liquid. If a slice of liquid is not acted upon by the outer force, it is bound to be in the shape of a ball under the action of element pressure, in fact, the little liquid drop is therefore, in the shape of a total ball^[7]. Liquid crystals in the bile existed in the bile in the form of ball grains, which confirmed that bile liquid crystals did have the character of liquid. Under the microscope with perpendicular polarized light, when little distilled water was added between a slide and a cover glass containing bile liquid crystals, the bile liquid crystals were found flowing swiftly along with water flow. In the process of flowing, the interference pattern shown by the bile liquid crystals-the shape of Malta cross, was changing continuously along with the flowing of bile liquid crystals, indicating that mobility of bile liquid crystals was very good.

Crystals are anisotropic substance, which is also called optical anisotropic substance. Its optical nature is different in directions. When light waves

enter anisotropic substance, double refraction occurs except the direction of optical axis, and they are separated into two kinds of polarizing light whose vibrating directions are vertical one another, with different travelling speeds, and unequal refractive indexes. When anisotropic substance is observed under a polarizing microscope with perpendicular polarized light, destructive interference pattern and four times extinction can be observed. Under a polarizing microscope with plane polarized light, on the boundary plane of two kinds of crystals, because of the reflection and refraction of light, darker edge and brighter Becke-Line could be observed^[5]. Under a polarizing microscope with perpendicular polarized light, bile liquid crystals in human body appeared in special interference pattern and four times extinction. The optic symbol was uniaxial positive. Under a polarizing microscope with plane polarized light, darker edge and brighter Becke-Line could be seen on the edge of bile liquid crystals contacting the bile around. It is shown that bile liquid crystals did have the character of crystals and the optical nature was similar to uniaxial positive crystals.

Bile in human body is a solution composed of water, bile pigment, bile salt, cholesterol, fatty acid, lecithin and inorganic salt. Under the physiological condition, the scale of bile salt, cholesterol, bile pigment lecithin, etc. in the bile was maintained in a proper scope, and the bile was in a liquid state, but when their scale was out of order, the cholesterol might produce crystals in the bile to form the concretion^[8]. In 1983, B.H. Brown *et al.*^[2], an American scholar, for the first time put forward that bile liquid crystals were the preform of gallstone. Under polarizing microscope with plane polarized light and perpendicular polarized light, we have observed that bile liquid crystals had the character of both crystals and liquid. Malta cross shown by bile liquid crystals after drying turned into grains of double refraction. The results support the views mentioned above, which are of important value of reference to the research in the form of gallstone and the prevention and treatment of cholelithiasis.

Abstract

AIM To evaluate the possibility of using cultured human hepatocytes as a bridge between bioartificial liver and liver transplantation.

METHODS In this experiment, the efficacy of extracorporeal bioartificial liver support system (EBLSS) consisting of spheroidal human liver cells and cultured hepatocytes supernatant was assessed *in vivo* using galactosamine induced rabbit model of fulminant hepatic failure.

RESULTS There was no difference of survival between the two groups of rabbits, but in the supported rabbits serum alanine aminotransferase, total bilirubin and creatinine were significantly lower and hepatocyte necrosis was markedly milder than those in control animals. In addition, a good viability of human liver cells was noted after the experiment.

CONCLUSION EBLSS plays a biologic role in maintaining and compensating the function of the liver.

INTRODUCTION

The recent development of bioartificial liver support system containing hepatocytes is an important event in the research of the artificial liver^[1]. This system possesses the potential metabolic and synthetic functions of the liver and may provide certain nutrients and cytokines necessary for the regeneration of liver tissues^[2,3]. Further development is expected in the research of the bioartificial liver to provide a new therapeutic procedure in the treatment of fulminant hepatic failure. Based on the studies of isolation and culture of human liver cells, we established an extracorporeal bioartificial liver support system (EBLSS) with cultured human hepatocytes and hollow fiber bioreactor. Its support efficiency was investigated preliminarily *in vivo* with animal model of hepatic failure.

MATERIALS AND METHODS

Animal

Male and female rabbits weighing between 2 kg and 3 kg were provided by the Experimental Animal Center of Third Military Medical University. All animals were allowed free access to food and water.

Induction of fulminant hepatic failure

A model of fulminant hepatic failure (FHF) in the rabbits was prepared by the method of Blitzer *et al*^[4] with slight modifications. D-Galactosamine (D-Gal, purchased from Chongqing University) at a lethality dose of 1.2 g/kg of body weight was dissolved in 9 mL of 50 g/L dextrose in water and pH was adjusted to 6.8 with sodium hydroxide. The solution was then given intravenously over 5 min via ear vein.

Bioartificial liver system

The bioartificial liver system consisted of liver cells, hollow-fiber bioreactor and circulating unit. The cells were harvested from 4 month old human fetal liver by a two step collagenase perfusion technique modified from the method of Seglen^[5] and the hepatocytes and liver nonparenchymal cells were obtained by centrifugation at 50×g for 3 min and 500×g for 3 min respectively. Cell viability was initially >96% for all devices assessed by trypan blue exclusion and they were successfully cultured as multicellular spheroids with a synthetic technique. About 1×10⁸ viable cells were placed onto the outer space of the hollow fiber bioreactor. The hollow fibers (porous, 0.2 μm) were polysulfone with a

100kDa nominal molecular weight cutoff and a 1128 cm² surface area. Thirty mL anti-coagulate blood came from normal rabbit was perfused into the intracapillary space of hollow fiber bioreactor and the circulatory tube. A roller pump (Millipore ultrafiltration device) was used to circulate blood and a heater was used to maintain the animal blood and bioreactor temperature at 37°C-39°C. With this condition the system was ready for *in vitro* application.

Artificial liver support

The experimental animals were divided into two groups: group I animals ($n=5$) were treated with EBLSS inoculated with viable liver cells; group II, animals ($n=5$) were treated as control with EBLSS but without cells. Animals in both groups were anesthetized by pentobarbital (0.03g/kg, intravenously) and femoral artery and vein catheters were placed before experiment. Four hours after the induction of FHF, the femoral artery and vein was cannulated for EBLSS access. Hemoperfusion was through the EBLSS at a rate of 15 to 20mL/min. Heparin was administered at 150U/kg firstly and at 50U/kg every 30min. Perfusion was carried out for 4h. About 15mL supernatant of cultured hepatocyte and liver nonparenchymal cells was administered into the extracapillary space for an assisting treatment during the experiments.

Assay methodology

Blood samples were obtained at the initiation of the EBLSS hemoperfusion, during the treatment and at hourly intervals for 5h after liver support. Serum alanine aminotransferase (ALT), total bilirubin (TB) and creatinine (Cr) were determined in the clinical laboratory using a Beckman CX-7 autoanalyzer (Beckman Instruments, Inc., Fullerton, Calif.) by standard methods.

Liver biopsy specimens were obtained from each of the animal postmortem and fixed in 10% formalin. Histological analyses were carried out in the pathological laboratory using standard procedures. The liver cell spheroids loaded in EBLSS were collected and dispersion by 0.01% pancreatin and 0.1 mmol/L EDTA. Their viability was determined again by trypan blue exclusion. The rate of adherence to dish coated collagen was obtained by phase contrast microscope after 24 h of normal culture.

RESULTS

Survival of FHF rabbits

The survival time of FHF rabbits in the control group was 9.2 h, 14.6 h, 15.7 h, 24.2 h and 34.1 h (19.6 ± 9.7 h). In EBLSS support group, besides one animal which died 10min after the initiation of artificial support, the survival time was 11.4 h, 14.9 h, 24.2 h and 25.1 h respectively (18.9 ± 6.8 h). There was no difference between the two groups ($P>0.05$).

Biochemical changes

In both groups of animals, there was a progressive increase in the concentration of serum ALT, TB and Cr in 10h after injection of D-Gal, but there was no statistical difference. Afterwards, a significant increase of serum ALT, TB and Cr was observed in control group. At the same time phase, serum ALT, TB and Cr were also increased in EBLSS support group, but the extent of increment was small relatively (Figures 1-3).

Pathological change

Histological examination of liver biopsy specimens obtained from the control rabbits demonstrated characteristic of classic acute hepatic necrosis, which contained multiple areas of lytic necrosis, disappearance of lobule construction, dissociation of hepatic cords and a large number of inflammatory cells infiltrated into the portal triads. In artificial liver support group, besides the large area of necrosis observed only in one animal, hepatocyte degeneration and focal necrosis were the main manifestation in the rest animals. The regeneration of hepatocytes was observed easily in this group (Figures 4, 5).

Figure 1 Serum ALT changes in FHF animals.

Figure 2 TB changes in FHF animals.

Figure 3 Serum Cr changes in FHF animals.

Figure 4 Liver biopsy specimens from control group. Large area of necrosis. LM, $\times 200$

Figure 5 Hepatic histology of support animals: mild liver necrosis. LM, $\times 200$

Cell viability

Both liver cell viability and spheroids adherence rate were decreased by 13.1% and 26.2% respectively after the artificial liver support as compared with those before the experiment.

DISCUSSION

Medical treatment of fulminant hepatic failure is still not satisfactory, and the mortality is about 90%. It has been recognized that the liver transplantation is the only process in saving these patients. However, there is a shortage of donors and most patients have no sufficient time in waiting for the emergency transplantation. Therefore, many investigators devote their efforts to the development of artificial liver device as a liver support system to help maintain patients in alive and intact mentality until an organ donor becomes available. The liver is known as a complex metabolic organ with multi-functions essential for surviving, including gluconeogenesis, synthesis of blood proteins amino acid metabolism, urea synthesis, lipid metabolism, drug biotransformation, and removal of wastage. So the early artificial liver systems such as hemodialysis, hemadsorption and charcoal hemoperfusion that had limited purifying function can not bring a satisfactory result to these patients^[6]. A bioartificial liver comprising viable hepatocytes on a mechanical support has been considered to provide these essential functions more likely than a purely mechanical device^[7]. Up to now, a lot of data show that this new bioartificial liver system not only possesses the ability of specific detoxication and metabolism but also has synthetic functions^[8,9].

Bioartificial liver system could maintain a suitable internal environment for the FHF patients to wait for the chance of liver transplantation.

In this study, after the human liver cells were isolated by an alternative extracorporeal two step perfusion method with a good viability, we succeeded in carrying out the aggregate culture of hepatocytes and nonparenchymal cells. Subsequently, we place the multicellular spheroids and supernatant of cultured hepatocyte into a hollow fiber bioreactor to form a simple EBLSS and its liver support function was assessed *in vivo* by D-Gal-induced rabbit model with fulminant hepatic failure. The biochemical results show that the increase of serum ALT, TB and Cr was restrained effectively in support group animals. At the same time, we found the pathological change of supported animals was markedly improved and active regeneration of hepatocytes was easily seen in these animals. These data indicate that this EBLSS possesses the effect of liver support to the fulminant hepatic failure animal in certain extents. The results of EBLSS *in vitro* show that it protects the cultured hepatocyte from injury by the D-Gal induced toxic metabolites and promotes the regeneration of hepatocytes by the substances afforded from the hepatocytes and supernatant of cultural medium. Nevertheless, the effectiveness of EBLSS has not been satisfactorily demonstrated in *in vivo* animal experiment due to the difficulty in establishing extracorporeal circulation and maintaining a stable experimental condition, and because the animal is hard to endure the heavy hemodynamic burden.

A study of preoperative methionine-depleting parenteral nutrition plus chemotherapy in gastric cancer patients

Wei Xin Cao¹, Qin Min Cheng¹, Xu Feng Fei¹, Shu Fa Li², Hao Ran Yin² and Yan Zhen Lin²

Subject headings stomach neoplasms/drug therapy; methionine; parenteral nutrition

Cao WX, Cheng QM, Fei XF, Li SF, Yin HR, Lin YZ. A study of preoperative methionine-depleting parenteral nutrition plus chemotherapy in gastric cancer patients. *World J Gastroenterol*, 2000;6(2):255-258

Abstract

AIM To investigate the interference of methionine-free parenteral nutrition plus 5-Fu (MetTPN+5-Fu) in gastric cancer cell kinetics and the side effects of the regimen.

METHODS Fifteen patients with advanced gastric cancer were randomly divided into two groups, 7 patients were given preoperatively a seven-day course of standard parenteral nutrition in combination with a five-day course of chemotherapy (sTPN+5-Fu), while the other 8 patients were given methionine-deprived parenteral nutrition and 5-Fu (MetTPN+5-Fu). Cell cycles of gastric cancer and normal mucosa were studied by flow cytometry (FCM). Blood samples were taken to measure the serum protein, methionine (Met) and cysteine (Cys) levels, and liver and kidney functions.

RESULTS As compared with the results obtained before the treatment, the percentage of G₀/G₁ tumor cells increased and that of S phase decreased in the MetTPN+5-Fu group, while the contrary was observed in the sTPN+5-Fu group. Except that the ALT, AST and AKP levels were slightly increased in a few cases receiving -MetTPN+5-Fu, all the other biochemical parameters were within normal limits. Serum

Cys level decreased slightly after the treatment in both groups. Serum Met level of patients receiving sTPN+5-Fu was somewhat higher after treatment than that before treatment; however, no significant change occurred in the MetTPN+5-Fu group, nor operative complications in both groups.

CONCLUSION -MetTPN+5-Fu exerted a suppressive effect on cancer cell proliferation, probably through a double mechanism of creating a state of "Met starvation" adverse to the tumor cell cycle, and by allowing 5-Fu to kill specifically cells in S phase. Preoperative short-term administration of -MetTPN+5-Fu had little undesirable effect on host metabolism.

INTRODUCTION

Methionine (Met) has been reported to be an essential amino acid in tumor cell metabolism. Recent researches have demonstrated that proliferation was inhibited in some tumor cell lines when Met in the culture medium was replaced by its precursor homocysteine (Hcy), whereas normal cells grew well as controls; and once regaining Met, tumor cells recovered their usual activity of proliferation; these characteristics of tumor cells were referred to as Met dependency^[1,2]. In the Met depleted environment, the metabolism of nucleic acid, protein and biological membrane of the tumor cells were disturbed and their cell cycle deranged. If Met starvation was combined with the application of phase-specific chemotherapeutic agents, it would prohibit the proliferation and metastasis of tumor cells. On the basis of our previous experiments, further studies are designed to elucidate the influence of preoperative Met deprived parenteral nutrition plus 5-Fu on the cell cycle in the advanced gastric cancer (AGC) patients, and to explore whether any adverse effect to host metabolism could be produced, by monitoring the serum Met and cysteine (Cys) levels and blood biochemistry parameters.

PATIENTS AND METHODS

Patients

From June to December 1996, fifteen AGC patients (8 males and 7 females) diagnosed by endoscopy and pathology, entered into the study. Their average age was 55 (39-71) years and the average body weight was 55 (33-78) kg. All the patients had normal liver and kidney functions and were free from metabolic diseases.

Groups

The patients were randomized to 2 groups, 7 patients of the control group were administered Met-containing standard parenteral nutrition plus chemotherapy (sTPN+5-Fu), and 8 of the study group were given Met-deprived parenteral nutrition plus chemotherapy (MetTPN+5-Fu).

Regimens of nutritional support and chemotherapy

All patients were permitted to take a small amount of soup and water, no blood products were used. The non-protein energy in the TPN was supplied by glucose and fat emulsion (20% Intralipid, SSPC). The amino acid solution used in the control group was HBC11S (Amino Acid Company, Tianjin) while that used in the study group was prepared cooperatively by Rui Jin Hospital and Shanghai Chang Zheng Pharmaceutical Plant (No. S 95-001 Rui Jin, Shanghai, China). The amount of fat-soluble and water-soluble vitamins, trace elements and electrolytes was same for both groups. The mean non-protein energy was 125 kJ/(kg·d) for both groups; the nitrogen intake was 0.165g/(kg·d) and 0.163g/(kg·d) respectively for the control and the study groups. The TPN was administered from d1 to d7, and 500mg/d of 5-Fu from d2 to d6. Operation was carried out on d8.

Laboratory tests

Cell kinetics Tissue samples of gastric cancer and normal gastric mucosa obtained through endoscopy at the beginning of the study and during gastrectomy were managed mechanically to produce monocellular suspension, and were then submitted to flow cytometry (FCM) study for cell kinetics.

Blood biochemistry Blood samples were collected before and after the treatment for biochemical studies: liver function tests: ALT, AST, γ -GT and AKP; kidney function tests: BUN and Cr; serum proteins: total protein (TP), albumin (Alb), transferrin (Tf) and prealbumin (PA); and serum Met and Cys.

Statistical analysis

Paired *t* test and Student *t* test were used.

RESULTS

Cell cycle study

In 2 patients of the control group, the number of tissue samples was incomplete because gastrectomy was not performed eventually, resulting in a total of 13 patients who entered the FCM analysis. In the study group, compared to the pre treatment data, the percentage of tumor cells in G₀/G₁ phases increased after the treatment, while the percentage of S phase cells decreased; there was no obvious change in the percentage of 2/M cells, but the percentage of S+G₂/M (representing phases of cell proliferation) decreased. In the control group, the percentage of G₀/G₁ of tumor cells decreased after the treatment while that of S phase increased. There were no obvious changes of G₂/M and S+G₂/M percentage (Table 1).

Table 1 Changes in tumor cell cycle before and after treatment ($\bar{x}\pm s$)

Phase		sTPN+5-Fu (n=5)	MetTPN+5-Fu (n=8)
G ₀ /G ₁	Before	67.10 \pm 27.68	78.30 \pm 11.01
	After	63.35 \pm 28.72	83.45 \pm 9.26
S	Before	22.22 \pm 18.60	11.96 \pm 6.41
	After	26.08 \pm 26.02	9.25 \pm 7.16
G ₂ /M	Before	10.66 \pm 9.87	8.49 \pm 3.89
	After	8.56 \pm 3.76	8.50 \pm 4.17
S+G ₂ /M	Before	32.88 \pm 27.68	21.21 \pm 7.18
	After	34.64 \pm 28.76	18.85 \pm 7.62

Regarding to the cell kinetics of normal mucosa, there was no significant change in both groups either before or after the treatment.

Liver and kidney function

Initially, all the patients of both groups had normal liver functions. After the treatment, blood biochemical parameters remained within normal limits in the majority of cases except that some of the parameters were slightly higher than normal in a few cases. All the patients had normal kidney functions during the study.

Serum proteins

Serum protein parameters of both groups rose after the treatment ($P>0.05$), except the Tf value in the control group. The increment was slightly higher in the control group than that in the study group, but there was no statistical significance (Table 2).

Table 2 Changes of serum protein levels before and after treatment ($\bar{x}\pm s$)

Serum protein	sTPN+5-Fu (n=7)		-MetTPN+5-Fu (n=8)	
	Before	After	Before	After
TP(g/L)	69.86 \pm 4.49	75.14 \pm 4.85	68.75 \pm 7.67	72.88 \pm 3.94
Alb(g/L)	38.89 \pm 5.95	42.29 \pm 5.22	35.57 \pm 4.98	37.85 \pm 6.09
Tf(g/L)	2.68 \pm 0.49	2.68 \pm 0.36	2.20 \pm 0.82	2.36 \pm 0.44
PA(mg/L)	225.83 \pm 44.36	312.43 \pm 96.14	181.57 \pm 49.85	219.88 \pm 70.17

Serum Met and Cys

The mean serum Met level was increased after the treatment in the control group ($P=0.03738$), while there was no obvious change in the study group. Serum Cys level had little changes after the treatment in both groups, with no statistical significance (Table 3).

Table 3 Changes of serum Met and Cys levels before and after treatment ($\bar{x} \pm s$)

	sTPN+5-Fu (n=7)		-MetTPN+5-Fu (n=8)

DISCUSSION

More than twenty years ago, Kreis *et al*^[3] explored by histoculture and animal experimentation, the possible role of Met deprivation in the diet or TPN in suppressing tumor growth and metastasis. By means of the FCM technique, Usami *et al*^[4] studied the effect of Met-deficiency on tumor cell growth and cell kinetics and found that the environment of “Met starvation”, either *in vivo* or *in vitro*, could effectively interfere with cell recycling and block the tumor cells in G₁ phase. Hoffman *et al*^[5] noticed that by a method named the three-dimensional histoculture, when Met in the culture medium was replaced by Hcy, the proliferation of most Met-dependent tumor cells was inhibited in the latter Sphase/G₂ phase. In spite of certain diversities in their experimental results, these authors shared the common view that the life cycle of tumor cells could be disturbed by “Met starvation”. This concept favors the simultaneous use of phase-specific chemotherapeutic agents in an attempt to improve the overall therapeutic effects of neoplastic diseases.

Tumor tissues are composed of proliferating cells, non-proliferative and un-proliferating cell masses. The proliferating cells are those that are undergoing mitosis and are most sensitive to the phase-specific antitumor drugs, while those belonging to the non-proliferative or un-proliferating masses are not. By inference, more tumor cells are in the state of active proliferation, the greater effects would the phase-specific drugs exercise on the tumor cells. Maeta *et al*^[6] used preoperatively the MetTPN+5-Fu therapy to a group of AGC and colorectal cancer patients, found that the inhibition rate to thymidilate synthetase in the tumor cells was significantly higher than that in the control group, the name of “biochemical modulator” was thus coined to 5-Fu by these authors. Hoshiya, Goseki, Kitamura, Taguchi and

others proved the effectiveness in combining 5-Fu, cisplatin or adriamycin to -MetTPN in the treatment of gastric cancer and breast cancer. Kitamura *et al* and Taguchi *et al* further applied a new amino acid solution free of Met and Cys, named AO-90; this regimen was especially satisfactory in patients with distant metastasis and ascites, mounting the response rate to 45.5%^[7-10].

Our previous studies^[11-13] confirmed that the influence of sTPN on cell kinetics was to stimulate the tumor cells to enter into S phase; this would create an optimal condition for 5-Fu to exercise its greatest effect on tumor cells. In the present study, the effect of preoperative MetTPN+5-Fu on tumor cell kinetics in AGC patients was compared with that of sTPN+5-Fu. The results showed that, in the MetTPN+5-Fu group the percentage of tumor cells in G₀/G₁ phase increased and the percentage of cells in S and S+G₂/M phases decreased. The underlying rationale was not certified whether it was due to the decline in S phase cells caused by killing effect of 5-Fu, or an improved biochemical modulator effect of 5-Fu as described by Maeta *et al*^[6].

As a special therapeutical method which utilized the metabolic defect of tumor cells, there was still doubt that whether the -MetTPN+5-Fu regimen would bring about undesirable effects to the metabolism of normal cells remains to be clarified. Goseki *et al*^[14] studied the nutritional status of experimental rats after administration of a Met-free amino acid solution; no obvious side effects were found except slight decrement of a few nutritional parameters. Kurihara *et al*^[15] used the AO-90 amino acid solution plus chemotherapy in recurrent AGC patients, who manifested only a slight increase of nausea and anorexia. In rats with experimental gastric cancer submitted to the -MetTPN treatment, only a slight weight loss was observed as a side-effect; the serum protein levels and liver and kidney function underwent no significant change after a preoperative -MetTPN+5-Fu therapy for one week; serum Met and Cys levels were not obviously influenced; no operative complications occurred in any of the patients under study^[16].

In conclusion, a short-term preoperative -MetTPN+5-Fu in AGC patients did not cause any negative effect on normal host metabolism, while producing an evident interference with gastric cancer cell kinetics.

Improved technique of vascular anastomosis for small intestinal transplantation in rats

Yuan Xin Li, Jie Shou Li and Ning Li

Subject headings rat; intestinal transplantation; vascular anastomosis; survival rate

Li YX, Li JS, Li N. Improved technique of vascular anastomosis for small intestinal transplantation in rats. *World J Gastroenterol*, 2000;6(2):259-262

Abstract

AIM To establish a new improved vascular anastomotic technique to simplify the surgical technique and increase the survival rate of small intestinal transplantation in rats.

METHODS The graft removed en bloc consisted of entire small intestine, portal vein and aortic segment with superior mesenteric artery. The graft was perfused *in situ* and the gut lumen was irrigated during the operation. Heterotopic small bowel transplantation was performed by microvascular end-to-side anastomosis between the donor aortic segment with superior mesenteric artery and the recipient abdominal aorta, and by the formation of a "Cuff" anastomosis between the donor portal vein and the recipient left renal vein. Both ends of the grafts were exteriorized as stomas.

RESULTS A total of 189 intestinal transplantations were performed in rats, 33 of which were involved in the formal experimental group, with a survival rate of 84.8%. The average time for the donor surgery was 80min±10min; for graft repair 10min±3min; and for recipient surgery 95min±15min. The average time for the arterial anastomosis and the vein anastomosis was 18min±5min and 1min, respectively. The warm ischemic time and cold ischemic time were 22min±5min and less than 60min, respectively. The whole operation was completed by a single surgeon, the operative time being about 3 hours.

CONCLUSION The vascular anastomosis used

in this study could simplify surgical technique, reduce the operative time and elevate the survival rate of small intestinal transplantation in rats.

INTRODUCTION

Small intestinal transplantation may eventually become the most logical definitive treatment for small bowel syndrome. The small intestinal transplantation in rats has been the most frequently used animal model in the experimental investigation since it was first described by Monchik and Russel in 1971^[1]. However, the surgical technique of intestinal transplantation is rather complex and difficult, and the vascular anastomosis is a key technique for successful transplantation. We began to explore intestinal transplantation in rats in 1995, and have accumulated some experience and developed a stable and easy vascular anastomosis technique for small intestinal transplantation in rats.

MATERIALS AND METHODS

Animal and preoperative care

Male outbred Sprague-Dawley rats, inbred F344/N rats and inbred Wistar/A rats weighing between 150g and 400g were used as donors and recipients which were selected according to the protocol design. The rats received 5% glucose and 0.9% saline ad libitum for 24 hours (donors) and 12 hours (recipients) in the metabolic cage. They were anesthetized with intraperitoneal injection of pentobarbital sodium (40 mg/kg) and atropine (0.05mg/kg). Both donors and recipients received lactated Ringer's solution at a rate of 4mL/h via the tail vein during surgery, the injection being controlled by a microdosage transfusion pump. Polyethylene (PE) catheter (4 mm in length) with an inner diameter of 1.5mm was used to make a cuff, two-thirds of the circumference diameter of the lower half part (2mm in length) of the PE catheter was cut off to form a holder in order to be grasped, and a shallow slot was cut out in the middle of outer tube wall of the upper half part (2mm in length) in order to be ligated.

Donor operation

The abdomen was opened via a cross incision. The distal abdominal aorta was ligated beneath the level of renal artery to maintain adequate blood flow to the graft. Left renal vein, both sides of renal arteries and the origin of tuncus coeliacus were mobilized, ligated and divided. The origin of the superior mesenteric artery was mobilized, and the lumbar arteries from the aorta were meticulously ligated with 5-0 silk sutures. A segment of aorta with superior mesenteric artery was thoroughly liberated. The jejunum was divided just below the Treitz, sligament, the terminal of ileum was separated from the ileocecal valve, and the entire colon was removed. The portal vein and the superior mesenteric vein were met iculously separated from the pancreas and the surrounding conjunctive tissues, the pyloric and splenic veins which refluxed to portal vein were ligated and divided with 7-0 silk suture. Five mL 0.2% amikacin was slowly and gently infused into the intestine from the break-off of the jejunum to irrigate the gut lumen. The proximal end of the prepared aorta segment was ligated, the distal part of the aorta was cannulated with a fine polyethylene, and the graft was perfused *in situ* with 2mL-3mL cold heparinized (25U/mL) lactated Ringer, ssolution at a rate of 40mL/h controlled by a microdosage transfusion pump. At the same time, the portal vein was separated from the hepatic hilus, smashed ice crystal was put on the graft for rapid cooling. When the wall of intestine and mesentery turned white, and when a clear effluent from the portal vein appeared, the intestine and its vascular supply were removed en bloc (Figure 1) and stored in lactated Ringer,s solution at 4°C. Under condition of 4°C, the distal end of the aortal segment was ligated, the proximal of the aortal segment was made smooth, the holder of the Cuff was gently fixed with microsurgical vascular forceps, the portal vein was everted and covered onto the outer wall of the cuff, and fixed with ligation with 5-0 silk suture.

Recipient operation

The abdomen was opened via a midline and left abdominal wall horizontal incision was made to form a shape incision. The operative field was exposed with a self-retaining retractor. The left kidney and its surrounding tissues were mobilized. The origin of the left renal artery was ligated, and the tributaries of the left renal vein were ligated and divided. The left renal blood vessel was ligated at the level of renal hilus. The ligated suture remained counter-retracted, and the left kidney was then

removed. Segments (about 1cm-1.5cm long) of the recipient,sabdominal aorta was mobilized below the vessels to the left kidney. The small branches of this segment was carefully ligated. The mobilized segments were controlled proximally and distally with two microvascular clamps, and open ed via a longitudinal arteriotomy. The incision of arteriotomy was made to suit the anastomosis of the abdominal aorta of the donor. Heparinized (25U/mL) normal saline was used to wash away the residual blood clot in the vessel. The graft was placed on the lower left quarter of the abdominal cavity, and was ad justed to ensure that the vessels of donor, ssmall intestinal were not twisted and had no tension when they were anastomosed. The graft was surrounded by a tampon packed with ice crystals for cooling. The end-to-side anastomosis between the segment of aorta with superior mesenteric artery of the donor and the abdominal aorta of the recipient was performed with the aid of a binocular operating microscope. Two 9.0 nylon stay sutures were placed at both proximal and distal points of the arterial anastomosis to act as self-retaining retractors, and the anastomosis was performed using continuous 9-0 nylon suture. The essentials of the arterial anastomosis were that the interval of the sutures and the edge distance of the anastomosis should be homogenous, and the intimae of the arteries should be everted to form intima-to-intima anastomosis so as to prevent blood clotting. Eighteen to twenty sutures were needed for the anastomosis. When the venous vessels were anastomosed, a microvascular clamp was used to block the origin of the venous vessels of the left kidney. A hemostat was used to counter retract the ligated suture of left kidney hilum to fully unfold the renal venous vessel. A "T" shape incision was made on the anterior wall of the distal segment of left renal vein, and two angles of the incision was counter retracted with 9-0 nylon suture (Figure 2). Heparinized (25U/mL) normal saline was used to flush the venous vessel, the position of graft was adjusted. After ensuring that the venous vessel was not twisted, the Cuff of the portal vein of the donor was inserted in the left venous vessel of the recipient, and a ligation of 5-0 suture was used to fix the Cuff anastomosis (Figure 3). After the venous clamp was released, followed by the distal and proximal arterial clamps, pulsation of the superior mesentery artery of the graft turned to be distinguished, and the wall of the transplanted intestine appeared fresh red, and the ice-cream intestinal juice secreted from the intestinal lumen. Both ends of the graft were exteriorized as stomas. After flushing the abdominal lumen with normal saline containing cefazolin (10g/L) of 37°C, the abdominal wall was closed.

Figure 2 Exposure of the cavity of the left renal venous vessel of the recipient.

IVC: inferior vena cava; AO: aorta.

Figure 3 The vascular reconstruction for small intestinal transplantation.

IVC: inferior vena cava; AO: aorta.

Observation of surgical effect

The recipients were under meticulous observation after operation. Autopsy was performed if the recipient died, and the graft, the anastomosis of the vessels, heart, lung, liver, spleen, kidney and the native intestine of the dead recipient were harvested for pathological examination to find out the cause of death. Any death within 5 days was considered technical failure, and survival exceeding 5 days was considered technical success.

RESULTS

Our study was carried out in 3 stages and 189 operations were performed. Thirty-two operations were made to familiarize the anatomy of rats and train the surgical skill in the first stage. The second stage was the pre-experiment, 124 operations were performed to set up the surgical procedure, which was standardized and routinized, the longest survival of the recipient being longer than 10 months. The third stage was formal experiment, 28 cases of 33 operations succeeded. The cause of failure in the remaining 5 cases was anaesthesia accident (1), thrombosis of the arterial anastomosis (1), massive haemorrhage in abdominal lumen on postoperative day 3 (1), and hypovolemic shock followed by massive haemorrhage during operation (2). The success rate of the formal experiments was 84.8%.

The average time for the donor surgery was $80\text{min} \pm 10\text{min}$; the preparation time for the graft was $10\text{min} \pm 3\text{min}$; the operative time for the recipient was $95\text{min} \pm 15\text{min}$, and the time for arterial anastomosis and the venous anastomosis being $18\text{min} \pm 5\text{min}$ and 1min, respectively. The warm ischemic time of the graft (the interval when the graft was taken away from low temperature preservation) was $22\text{min} \pm 5\text{min}$, and the cold ischemic time was limited within 60min. The entire surgery was completed by a single surgeon, and the total operative time being about 3 hours.

DISCUSSION

There are five anastomosis patterns for small intestinal transplantation in rats: ① end-to-side arterial anastomosis between a segment of abdominal aorta/superior mesenteric artery of the donor and abdominal aorta of the recipient, and end-to-side venous anastomosis between the portal vein of the donor and inferior vena cava of the recipient^[2,3]. This is a classical pattern, and adopted by most investigators. ② End-to-side anastomosis between the carrel's patch of abdominal aorta with superior mesenteric artery of the donor and the abdominal aorta of the recipient, end-to-side anastomosis between the portal vein of the donor and the portal vein of the recipient^[4]. Compared with the cava-refluxing pattern, this portal-vein-refluxing pattern accords with physiology, and delays occurrence of rejection.

However, this surgical technique is more difficult, the incidence of complication is rather high, and a segment of the intestine of the recipient should be removed. ③ End-to-side vascular vessels a nastomosis between the superior mesenteric artery of the donor and the abdominal aorta of the recipient, and between the superior mesenteric vein of the donor and the inferior vena cava of the recipient^[5]. The main advantage of this model is that the donor operation is simplified by obviating the tedious dissection of portal vein and aorta which are very easily injured. However, a limitation of this pattern is that only a 10cm-25cm segment of jejunum can be used for transplantation rather than the total small bowel, and the small lumen of peripheral superior mesenteric artery and superior mesenteric vein may increase the vascular complication^[6]. Gordon compared pattern 1 with pattern 3 and discovered that there was no significant difference between these two patterns in the operation time, technic complexity and the experimental result^[7]. ④ The left native kidney is removed and revascularization of the graft is completed by two end-to-end anastomoses between the donor superior mesenteric artery and portal vein and the recipient renal vessels with the Cuff technique^[8]. The advantage of this pattern is that the technique for vascular anastomoses is simple, and has significantly reduced the graft warm ischemic time. However, the graft can only get 33% of the volume of blood supply that the native intestine can obtain, and the graft may lead to dysfunction because of chronic ischemia^[7]. ⑤ End-to-end anastomoses between the donor superior mesenteric vessels and the recipient superior mesenteric vessels, respectively. In this pattern, only a segment intestine is transplanted, and a segment of the native intestine should be removed. Furthermore, the incidence of vascular complication is very high^[9].

In our study, we combined the advantage of pattern 1 and pattern 4, and adopted arterial anastomosis by microvascular end-to-side anastomosis between the donor aortic segment with superior mesenteric artery and the recipient abdominal aorta, and performed the vein anastomosis by the formation of a "Cuff" anastomosis between the donor portal vein and the recipient left renal vein. This pattern can avoid hemodynamic unstability of the recipient because there is no need to block the inferior vena cava of the recipient while there is a need in pattern 1. At the same time, it can avoid performing anastomoses of both the artery and vein vessels on the adjacent location of the abdominal aorta and the inferior vena cava of the recipient. Thus, exposure of arterial anastomosis is more clear, making the

arterial anastomosis very easy. In the arterial end-to-side anastomosis between a segment of the abdominal aorta of the donor and abdominal aorta of the recipient, the caliber of the anastomotic vessels is large enough to make the graft get sufficient blood supply. Therefore, this pattern can avoid chronic ischemia of the graft because of the end-to-end anastomosis between the superior mesenteric artery of the donor and the left renal artery of the recipient in pattern 4. The venous anastomosis with the Cuff technique can be accomplished within 1 minute, and the time for venous anastomosis is much shorter than that for traditional venous anastomosis. Thus, the warm ischemic and operation time is reduced, the surgical strike of the recipient is decreased, and the warm ischemic injury of the graft is reduced. The leakage of venous anastomosis is not taken into account after reperfusion because of the Cuff venous anastomosis technique, and no venous thrombus occurs after transplantation because the Cuff venous anastomosis is an intima-to-intima anastomosis of the vessel, and venous thrombus is one of the commonest causes of technique failure in traditional venous anastomosis. In summary, our improved vascular anastomosis technique, in which the arterial anastomosis is adopted by microvascular end-to-side anastomosis between the donor aortic segment with superior mesenteric artery and the recipient abdominal aorta, and the venous anastomosis is performed by the formation of a "Cuff" anastomosis between the donor portal vein and the recipient left renal vein, could simplify the surgical process, reduce the operation time and increase the survival rate of small intestinal transplantation in rats.

INTRODUCTION

The antitumor activity of norcantharidin (NCTD), the demethylated analogue of cantharidin, was studied in the early 1980s in China. NCTD has no side effects on urinary organs which cantharidin has shown and is easier to synthesize, and it can inhibit the proliferation of several tumor cell lines as well as transplanted tumors. Clinical trials with NCTD as a monotherapeutic agent indicated that NCTD had beneficial effects in patients with different kinds of digestive tract cancers, such as primary hepatoma, carcinomas of esophagus and gastric cancer, but no depressive effect on bone marrow cells. NCTD can increase the white blood cell count by stimulating the bone marrow and has some antagonistic effect against leukopenia caused by other agents. The exact cellular and molecular mechanisms of NCTD on tumor cells have not yet been elucidated to date^[1-3].

MATERIALS AND METHODS

Human tumor cell lines

Human hepatoma cell line BEL-7402, as monolayer cultures in RPMI-1640 medium supplemented with 20% FCS, was routinely grown at 37°C and 5% (V/V) CO₂. The response of tumor cells to NCTD

was studied during the logarithmic growth phase.

Reagents

NCTD was synthesized from furan and maleic anhydride via the Diels-Alder reaction. RNaseA and proteinase K were purchased from E. Merck, primary antibody (human Bcl-2 specific, rabbit polyclonal antibody) from Santa Cruz Biotechnology, In c, secondary antibody (biotinylated anti-rabbit IgG) and horseradish peroxidase streptavidin from Vector Laboratories, Inc, and NP-40 and DAB from Sigma.

Electron microscopy

Cell suspensions were centrifuged (200×g, 10min), and fixed as a pellet in 2.5% glutaraldehyde-1% osmium tetroxide buffered with PBS (pH 7.2). The cell samples were dehydrated in a graded ethanol series, embedded in Spury Resin and analyzed with standard procedures.

Isolation and analysis of apoptotic DNA fragments

Apoptotic fragments were isolated as described^[4]. After harvesting, the cell samples were washed with PBS and pelleted by centrifugation. The cell pellets were then treated for 10s with lysis buffer (1% NP-40 in 20mmol/L EDTA, 50mmol/L Tris-HCl, pH 7.5; 10 μL-/10⁶ cells). After centrifugation for 5min at 1600×g, the supernatant was collected and the extraction was repeated with the same amount of lysis buffer. The supernatants were brought to 1% SDS and treated for 2h with RNaseA (a final concentration of 5g/L) at 56°C followed by digestion with Proteinase K (a final concentration of 2.5g/L) for at least 2h at 37°C. After addition of 1/2 volume 10mol/L ammonium acetate, the DNA was precipitated with 2.5 volume ethanol, dissolved in gel loading buffer, and separated by electrophoresis in 1% agarose gels.

Immunocytochemical detection of Bcl-2

Apoptotic gene bcl-2 product was analyzed by standard SABC procedures. After washed with 0.01mol/L PBS (pH 7.4) three times for 5 min, cells were fixed with PLP (periodate-lysine-paraformaldehyde fixative) for 20 min at room temperature. Washed with PBS again, and cells covered with 3% H₂O₂ for 10min, 0.3% Triton x-100 for 30min and 3% sheep serum for 40min before

primary antibody was added. Cells were covered with primary antibody (1:50) overnight at 4°C. Biotinylated secondary antibodies (1:200) were reacted for 30min at room temperature, then incubated cells with horseradish peroxidase streptavidin (1:400) for 30min at room temperature. Cells were washed in PBS three times for 5min between each step. Cells were incubated in DAB solution for 5min and examined under microscope. Cells were rinsed in distilled water and dehydrated through alcohol and xylene and mounted coverslip using a permanent mount medium for analysis by microspectrophotometer (LE ITZ DMRBE, Leica). Three to five sample slides in each group were chosen for analysis and 90 cells in each group were determined for mean light absorbance. The significance of difference between experimental data was validated using the *t* test.

Western blot

Approximately 5×10^6 cells were collected, and lysed in 100μL 2× electrophoresis loading buffer, boiled for 10min and electrophoresed through 12.5% SDS-polyacrylamide gels. Proteins were electrotransferred onto the nitrocellulose membrane. Filters were blocked overnight at 4°C with TBST [10 mmol/L Tris-HCl (pH 8.0), 0.15 mol/L NaCl, 0.05% Tween 20] containing 3% nonfat milk. All additional immunostaining steps were performed in TBST at room temperature. Filters were incubated with primary antibody (1:1000) for 2h. Biotinylated secondary antibodies (1:2000) were reacted for 30min. Immunoblots were reacted with horseradish peroxidase streptavidin (1:2000) for 30min. Filters were washed in TBST for 3 times for 20min between each step and were developed with DAB, and enhanced with H_2O_2 (0.03%).

RESULTS

Morphological changes of human hepatoma cells

The morphology of human hepatoma BEL-7402 cells changed significantly (Figures 1-3) after 24h-10mg/L NCTD treatment. Some cells condensed and some showed membrane bubbling aspect. Stained with Wright Giemsa, the cells showed M phase arrest and chromosome multipolar distribution. Nuclear chromatin compactions were observed under electron microscopy. At the same time, many membrane-enclosed bodies with cytoplasm and chromatin fragments were formed. These morphological changes are similar to the description of apoptosis^[5].

DNA agarose gel electrophoresis

A characteristic DNA "ladder" of apoptosis occurred in NCTD treated groups but did not appear in control groups (Figure 4).

Analysis of protein Bcl-2

Exist site of protein Bcl-2 presented yellow-brown reactant by immunocytochemical stain. Protein Bcl-2 was not expressed in the negative control group, and cells in control group were stained brown, showing that protein Bcl-2 expressed strongly in tumor cells. Treated with 10 mg/L NCTD for 24 h, the staining was weakened to light yellow-brown between negative control group and control group. The mean light absorbance of cells in the control group was 0.12 ± 0.01 ($n = 90$), while 0.08 ± 0.01 ($n = 90$) in treatment group. Compared with control cells, the expressions of Bcl-2 in treatment group were significantly decreased ($P < 0.001$). The result of Western blot analysis (Figure 5) showed that though protein Bcl-2 had a strong expression in BEL-7402 cells when treated with 10 mg/L NCTD for 24 h, 48 h and 72 h, the expression was weakened sharply.

DISCUSSION

Apoptosis is an active, inherently programmed phenomenon. Morphologically, it involves rapid condensation and budding of the cell, with the formation of membrane-enclosed apoptotic bodies. A characteristic biochemical feature of the process is double-strand cleavage of nuclear DNA at the linker regions between nucleosomes leading to the production of oligonucleosomal fragments^[6]. Obviously, NCTD can inhibit the growth of tumor cells mainly by inducing apoptosis.

Great progress has been made in researches on genetic regulation of apoptosis in recent years^[7]. Proto-oncogene bcl-2, might participate in the apoptotic process under some certain circumstances. The expression of Bcl-2 protein in BEL-7402 cells significantly changed in apoptotic process induced by NCTD. With the treatment time of NCTD prolonged, the expression of protein Bcl-2 decreased and paralleled with the apoptotic process. We believe that the decrease of protein Bcl-2 may play an important part in apoptosis of tumor cells induced by NCTD.

In a continuous observation, we found the treated BEL-7402 cells became round and separated from adjoining cells in the early stage, then bubbled, and membrane-enclosed bodies were formed. Stained with Wright-Giemsa, the round and bubbled cells were all presented with M phase arrest, and chromosome breaking, multipolar distribution, chromatin clumping and membrane-enclosed bodies with chromatin fragments forming were observed. All these indicated that the apoptosis induced by NCTD in BEL-7402 cells had a close relationship with tumor cell M phase arrest. More studies on the relationship between apoptosis and tumor cell M phase arrest are in progress.

Inhibitory effect of IGF-II antisense RNA on malignant phenotype of hepatocellular carcinoma

Dong Hua Yang¹, Ming Qing Zhang¹, Jiang Du², Chong Xu², Qiao Ming Liang², Ji Fang Mao³, Han Rong Qin¹ and Zi Rong Fan¹

Subject headings carcinoma, hepatocellular; insulin-like growth factor II; genes, suppressor, tumor; RNA, antisense; liver neoplasms

Yang DH, Zhang MQ, Du J, Xu C, Liang QM, Mao JF, Qin HR, Fan ZR. Inhibitory effect of IGF-II antisense RNA on malignant phenotype of hepatocellular carcinoma. *World J Gastroenterol*, 2000;6(2):266-267

INTRODUCTION

According to the therapeutic effect and strategy of antisense RNA for hepatocellular carcinoma (HCC), we have specifically synthesized partial cDNA of human insulin-like growth factor II (IGF-II) and constructed IGF-II cDNA antisense eukaryotic expression vector. The constructed vector was introduced into hepatoma cell line SMMC-7721 to block the intrinsic IGF-II expression. The biological behavior changes of hepatoma cells were observed. All these would provide scientific basis for IGF-II antisense RNA in the treatment of HCC.

MATERIALS AND METHODS

Plasmid pIGF-II containing partial cDNA of IGF-II was constructed by ourselves^[1]. Eukaryotic expression vector pcDNA-3 was a gift from Professor Mao Ji-Fang in the Second Military Medical University. Hepatoma cell line SMMC-7721 was provided by our own lab. Geneticin (G418), 1640 cultivation liquid and Lipofectamine were provided by Gibco/BRL (USA).

The construction and transduction of IGF-II antisense RNA expression vector: plasmid pIGF-II was doubly digested by Eco-RI/-Xba-I and the 106bp IGF-IIcDNA fragment was retrieved with

DNA purification kit (product of Huasun Company). Plasmid pcDNA₃ was doubly digested by Eco-RI/XbaI and the large fragment was retrieved. The two fragments were co-incubated overnight with T₄ DNA ligase under 14°C, then transferred to *Escherichia coli* DH5 α . The transformed colony was screened on LB agar containing amoxicillin. The transformed plasmid was extracted and then identified through dot blot (probes were made by ourselves) and PCR. The primer sequences of PCR were 5' CTAGA GCTTA CCGCC CCAGT GAGA 3', 5' AATTC TCGCG GCCTG CTGAA GTAG 3'. Because it belonged to the directional cloning, the positively transformed colony was reversely inserted into plasmid fragment, i.e., pIGF-IIAs. According to the method in reference^[2], 10 μ g pIGF-IIAs was introduced into 5 \times 10⁵ SMMC-7721 cells. The screening was performed in 1640 culture solution containing 400 mg/L G418, and pcDNA₃ was used as blank vector control.

The influence of pIGF-IIAs on hepatoma cell line SMMC-7721. ① cell growth curve: a total of 1 \times 10⁴ logarithmic period growing cells were inoculated in 24-well culture plates. The cells were incubated at 37 °C with 5% CO₂ for 24 hrs, then the cells were collected, 3 wells once, the number of cells was counted after trypan blue staining, and the average value was calculated. ② Cell cycle analysis: 5 \times 10⁶ logarithmic period growing cells were washed twice by PBS. One mL 70% ethanol was added to cell sediment. The cells were placed at 4 °C, were stained with PI 12 hours later and then measured with Elite Coulter flow cytometry. Cell cycle was analysed by Multicycle software. ③ Soft-agar colony formation experiment was made as reference.

RESULTS

The construction of pIGF-IIAs (Figure 1). IGF-II cDNA was reversely inserted into pcDNA₃ vector, PCMV maintained high copies of the original vector in mammalian cells. There were multi-colony sites in BGHpa region, which were favorable for IGF-II cDNA insertion. The inserted sites located in Eco-RI and XbaI region. Neo and Amp were the selective marks of the gene in mammalian cells and bacterial cells. IGF-II cDNA was reversely inserted into pcDNA₃ vector, because it belonged to directional colony. The dot blot of the properly

transformed plasmid showed that 106bp hybridization band was amplified by PCR. The positively identified band was pIGF-IIAs (Figure 1).

Figure 1 The constructional sketch map of pIGF-II.

pIGF-IIAs and pcDNA₃ were introduced into SMMC-7721 cells. After screening with G418 for 4 weeks, the number of transformed colonies was 26.00 ± 2.83 and 52.00 ± 4.66 (mean \pm SE), respectively.

After screening with G418, the growth curves of SMMC-7721 cells and transgenic cells are shown in Figure 2.

Figure 2 Growth curves of the three cell groups.

Cell cycle analysis was made with flow cytometry (FCM) (Table 1).

Table 1 Cell cycle analysis with FCM

Group	G ₀ /1	S	G ₂ /M
7721	72.40	21.50	6.10
pcDNA ₃	72.40	20.30	7.20
pIGF-IIAs	43.00	41.20	15.80

Colony formation in soft-agar cultivation. Cultivated on double layer soft-agar for 14 days, 10^4 cells were incubated in each culture dish. The cells in group 7721 and pcDNA₃ grew well and formed obvious clustered cell colonies. The number of colonies was 205.17 ± 72.02 and 146.50 ± 74.17 , respectively, while there was no colony formed in group pIGF-IIAs.

DISCUSSION

Antisense IGF-II gene was introduced into hepatoma cell line SMMC-7721 with antisense technique. The antisense RNA sequence matched with target mRNA, would selectively block the autocrine or paracrine growth stimulation mechanism of hepatoma cells, attaining to the purpose of antisense gene therapy. We found that the number of transformed colonies in pIGF-IIAs transfected SMMC-7721 was significantly less than that in pcDNA₃. This may be due to IGF-II antisense RNA suppressing the growth of transfected SMMC-7721. It may imply that IGF-II antisense RNA had the remarkable biological effect of suppressing the growth of hepatoma cells. The growth curves of the three group cells had no significant difference with G418 screening, which was consistent with Cajot's research on p53 gene transduced lung cancer cell line^[3].

The number of S-phase cells increased in pIGF-IIAs transfected group. However, there was no significant difference of the cell cycle in the other two groups. It was inferred that IGF-II antisense gene suppressed the overexpression of IGF-II and partially up-regulated IGF-II receptor and IGF-IR, which activated the kinases p34^{cdc2} related to DNA duplication^[4].

Cells of both pcDNA₃ and SMMC-7721 groups could form colonies on soft-agar, while cells in the antisense pIGF-IIAs group could not form colonies. It demonstrated that the malignant phenotype of hepatoma cells inclined to disappear. This was the phenomenon of tumor cells reversing gradually to normal cells.

This study demonstrated that the transduction of antisense IGF-II into hepatoma cells had the biological effect of suppressing the carcinogenesis of hepatoma cell *in vitro*.

INTRODUCTION

A newly discovered DNA virus, transfusion transmitted virus (TTV), was reported as a cause of post-transfusion hepatitis of unknown etiology in Japan^[1]. In order to investigate TTV prevalence in southern China, a study was carried out among blood donors, patients with liver diseases and hemodialysis to determine the epidemiological characteristics.

MATERIALS AND METHODS

Samples

Sera or plasma samples (471) were obtained from volunteer blood donors from Shenzhen Baoan Blood Center and commercial blood donors from Dongguan Blood Center. Sera samples (117) from patients with liver disease and hemodialysis were collected from Shenzhen Baoan People's Hospital. All the sera or plasma samples were stored at -70°C for detection.

Reagents

Hepatitis B surface antigen (HBsAg), antibodies to hepatitis C virus (HCV), antibodies to human immunodeficiency virus (HIV) EIA kits were purchased from Abbott Laboratories (Abbott Park, IL). Syphilis TPHA kits were purchased from Randox Laboratories Ltd. IgM antibodies to hepatitis A virus, antibodies to hepatitis E virus ELISA reagent kits, HBV, HCV and HGV polymerase chain reaction (PCR) reagent kits were

purchased from the Institute of Hepatology of Beijing Medical University.

Laboratory tests

The serum specimens from blood donors were tested for alanine aminotransferase (ALT) levels (less than or equal to 40 IU/L), HBsAg, antibodies to HCV, antibodies to HIV and syphilis TPHA. The patients with liver disease were further detected for markers of HAV, HBV, HCV, HEV and HGV infection.

Detection of TTV DNA by nPCR^[2]

Nucleic acid was extracted from 100 µL serum with AcuPure DNA/RNA extraction kit (Biotronics Tech. Corp.) following the manufacturer's recommended protocol. According to the sequence of TTV TA278 strain (GenBank accession number AB008394) two pair nested primers were designed for nested polymerase chain reaction (nPCR). The first-round PCR was performed with P1 (sense: 5'-CCAGGAGCATATACAGAC-3') and P2 (anti-sense: 5'-TACTTCTTGCTGGTGAAAT-3') for 30 cycles (pre-denaturing for 180s at 94 °C, denaturing for 40s at 94 °C, annealing for 40s at 55 °C, extension for 40s at 72 °C). The second-round PCR was carried out with P3 (sense: 5'-CAGACAGAGGAG-AAGGCAAC-3') and P4 (anti-sense: 5'-ACAGGCACATTACTACTACC-3') for 30 cycles for amplification of 309bp product. The second-round PCR was done in the same manner as the first-round. Amplified products were separated in 2% agarose gel electrophoresis, stained with ethidium bromide and observed under ultraviolet light.

Cloning and sequencing of TTV genome

The purified products of PCR were directly ligated into pBluescript-T vector (Invitrogen Company), and with recombinant plasmid obtained by introduction into *E. coli* XL1-blue, sequences were determined for both strands by the Sanger dideoxy chain termination methods, and with sequencer (model ABI373; Applied Biosystems, Foster City, CA).

Data analysis

The sequences of TTV genome were analyzed by the computer program CLUSTALW version 1.1 and the computer program GOLDKEY version 1.1.

Statistical analysis was made using statistical program SYSTAT version 3.0.

RESULTS

The results of TTV DNA determined by nPCR in blood donors

Four hundred and seventy-one sera samples from volunteer blood donors and commercial blood donors were all negative for markers of HBsAg, anti-HCV, anti-HIV and TPHA. Fifty-eight of 471 sera samples had an elevated ALT (mean 89 IU/L \pm 45 IU/L) and with no markers of hepatitis A-G virus infection. The results of TTV DNA detected by nPCR from blood donors are shown in Figure 1 and Table 1. Among volunteer blood donors with normal transaminase levels, 30 (14.7%) of 204 were positive for TTV DNA. In contrast, 48 (23.0%) of 209 commercial blood donors with normal transaminase levels, and 18 (31.0%) of 58 blood donors with elevated transaminase levels were positive for TTV DNA. The prevalence of TTV in blood donors with elevated transaminase levels was significantly higher than in volunteer blood donors ($P < 0.01$) and commercial blood donors with normal transaminase levels ($P < 0.05$). There was no significant difference between the commercial blood donors with normal transaminase levels and the blood donors with elevated transaminase levels.

Table 1 The results of TTV DNA detected by PCR in sera of blood donors

Blood donors	No. of sample	TTV DNA (+)	
		<i>n</i>	%
Commercial blood donors with normal ALT levels	209	48	23.1
Volunteer blood donors with normal ALT levels	204	30	14.4
Blood donors with elevated ALT levels	58	18	31.0

The results of TTV DNA detected by PCR in patients with liver diseases and hemodialysis

One hundred and five serum specimens from patients with liver diseases were detected for TTV

DNA by nPCR. The results are shown in Table 2. Among 36 non-A to E hepatitis patients, 15 (41.6%) were PCR positive for TTV DNA. One of 13 (7.7%) patients with hepatitis A virus infection was positive for TTV DNA, 3 (23.1%) of 13 patients with hepatitis B virus infection and 8 (18.6%) of 43 patients with hepatitis C virus infection were positive for TTV DNA. The prevalence of TTV in non-A to E hepatitis patients was significantly higher than in patients with HAV or HBV and HCV infection. Among 12 cases of hemodialysis, 5 (41.7%) were PCR positive for TTV DNA.

The sequencing results of TTV partial genome from blood donors

The anticipated DNA fragments amplified by PCR from 5 blood donors were cloned and sequenced for both strands. The similarity of nucleotide sequences of partial gene within TTV ORF1 region among 5 isolates from blood donors ranged from 98.4% to 99.4%. There was a 97% nucleotide identity among AB008394 (from Japan), TTVCHIN1 (from northern China) and our 5 isolates from blood donors (Figure 2 and Table 3).

DISCUSSION

Transfusion transmitted virus (TTV) is a newly discovered virus associated with the patients with post-transfusion hepatitis of unknown etiology in Japan. The preliminary studies showed that TTV was a single-stranded DNA virus, and the nucleotide sequence of TTV DNA genome was composed of approximately 3.7 kp, including two open reading frame (ORF) which encodes for 770 amino acids (aa) and 202 aa, respectively^[3]. TTV resembles to some known animal single-stranded DNA viruses, such as chicken anemia virus and human parvovirus B19. Some studies reported that TTV was associated with post-transfusion and acute and chronic hepatitis of unknown etiology. So far, no reliable serologic assay for antibodies against TTV infection has been developed. Thus, PCR was utilized to determine the prevalence of TTV infection in different populations.

Based on the conserved nucleotide sequence of TTV ORF1 gene, a nested-PCR for TTV DNA was established in our study. The specificity of amplified targets was documented by sequencing the PCR products selected from 5 blood donors positive for TTV DNA (Figure 2). The epidemiological investigation indicated that there was a high prevalence of TTV infection in volunteer blood donors and commercial blood donors. Simmonds *et al*^[4] reported that TTV viraemia was detected in 19 (1.9%) of 1000 non-remunerated regular blood donors from Scotland, 10% from England. Forty-four to 56% factor VIII and IX had a TTV contamination. In this study, nearly 15%-31% of blood donors from southern China were TTV DNA positive. Hemodialysis patients were considered at "high-risk" for exposure to parenterally transmitted viruses, such as HBV and HCV. TTV DNA positive rate was 41.7 % in our data. The results suggested that TTV can be parenterally transmitted to recipients of blood or blood products.

Fifty-eight blood donors with elevated serum

ALT levels were tested without markers of hepatitis A to G viruses. The positive rate of TTV DNA was 31%, which was higher than in volunteer blood donors with normal ALT levels (14-7%). The results indicated that some blood donors with abnormal ALT was associated with TTV infection.

The pathogenicity of TTV is unclear. The clinical and epidemiological studies showed that the TTV infection was found among patients with fulminant hepatitis, acute and chronic liver disease of unknown etiology^[3,5]. In our study, the prevalence of TTV was higher in patients with non-A to G hepatitis (41.6%) than in patients with hepatitis A to C virus infection, indicating that TTV may be responsible for some cases of non-A to E hepatitis. Recent studies demonstrated that TTV may cause epidemic outbreak of hepatitis of unknown etiology by fecal-to-mouth way^[6]. The high prevalence of active TTV infection (14.7%) in the general population was found in our study, suggesting that TTV, similar to HBV, may have "symptom-free carriers". Further studies are urgently needed to determine the pathogenicity of TTV and the significance of "symptom-free carriers".

We amplified and sequenced the ORF1 partial gene of TTV genome from 5 blood donors and compared these sequences with those of isolates from Japan and northern China. Our preliminary results showed that there are less than 2% nucleotide divergence among 5 isolates from blood donors. Compared with the isolates from Japan and northern China, the similarities of nucleotide sequences were above 97%. The data suggest that the ORF1 region of TTV genome is conserved in different geographic areas.

INTRODUCTION

Although liver transplantation for irreversible liver diseases is increasingly prevalent worldwide, patient die while waiting for donors because of organ short ages. One important problem commonly encountered is that fatty livers often affect the outcome of liver transplantation. It is reported that the incidence of abnormal fatty livers in autopsies after accidental death ranged from 15% to 24%. Since fatty livers may result in a primary nonfunction (PNF) liver graft, which contributes to an increased risk of mortality^[1], they are usually out of consideration in liver transplantation. However, some fatty livers can be successfully transplanted. Therefore, how to choose fatty livers as donor organs correctly is the crux of success in liver transplantation.

In this study, we preserved fatty livers of rats fed with a choline-deficient diet in cold Lactate Ringer's (LR) solution for various periods, and evaluated the effects of cold preservation on fatty liver in terms of portal perfusion pressure, endothelin-1, enzyme release in the effluent and mortality of sinusoid lining cell (SLC) using isolated perfused rat liver model.

MATERIALS AND METHODS

Animals and induction of fatty livers

Male Wistar rats, weighing 240 g - 260 g, were obtained from the Experimental Animal Center of Harbin Medical University. To induce fatty deposition in the livers, experimental rats were fed with a choline deficient diet (CDD) for 14, 28 or 42 days. The composition of this diet is shown in Table 1^[2].

Surgical procedures and experimental groups

We used isolated nonrecirculating perfused rat liver as preservation-reperfusion model^[3]. Animals were anesthetized with pentobarbital (30mg/kg, ip). After cannulation of the bile duct and portal vein, the liver was flushed with 20 mL 0 °C LR solution via portal vein. The liver was removed immediately and stored in 0 °C LR solution. After cold storage for various periods, the liver was reperused for 30 min via the portal vein at 3 mL·g⁻¹·min⁻¹ with Krebs-Henseleit bicarbonate buffer (pH 7.4, 37 °C) saturated with a 95% O₂:5% CO₂ mixture in a nonrecirculatory system. Animals were divided randomly into four groups: ① control group (n=21) fed with a standard diet including three subgroups containing 0 h (n=7), 6 h (n=7) and 12 h (n=7) cold storage; ② mildly fatty liver group (n=7) fed with a CDD for 14 days was preserved for 12 hours; ③ moderately fatty liver group (n=14) fed with a CDD for 28 days including two subgroups containing 6 h (n=7) and 12 h (n=7) cold storage; and ④ severely fatty liver group (n=14) fed with a CDD for 42 days consisting of two subgroups containing 0 h (n=7) and 6 h cold preservation.

Macroscopy and histology of livers before storage

The morphology of livers before cold storage was assessed by macroscopy and light microscopy. Liver biopsy specimens taken from the right lobes of the same site were stained with hematoxylin and eosin.

Portal perfusion pressure

The portal perfusion pressure was detected at the 30th min of reperfusion period when livers were reperused at 3 mL·g⁻¹·min⁻¹ constantly.

ET-1 assay

Two ml effluent was taken at the 30th min of reperfusion period for ET-1 assay. ET-1 values were detected by standard radioimmunoassay methods using a commercial radioimmunoassay kit (General Hospital of PLA)^[4]. Standard curves were obtained with known concentrations of ET-1.

Bile volume

The total bile volume was collected within 30 min reperfusion period. Bile volume was expressed as bile secretion $\mu\text{L}\cdot\text{min}^{-1}\cdot\text{g}^{-1}\cdot\text{wet weight}$.

Enzymes in the effluent

Two ml effluent at the 30th min of reperfusion period was collected for detection of aspartate aminotransferase (AST), alanine aminotransferase (ALT) and lactic dehydrogenase (LDH) with an automated GEMSTAR Biochemistry Analyzer (USA).

Mortality of SLC

Trypan blue staining is indicative of loss of cell viability. After 30 min reperfusion, the liver was perfused with trypan blue (200 μm) for 5 min and fixed with a 2% paraformaldehyde: 2% glutaraldehyde solution in the perfusion buffer. Livers were sectioned at the same level in the left lobes and were paraffin-embedded and stained in two sets. One staining with hematoxylin and eosin allowed quantitating of SLC and the other staining with eosin alone permitted determination of the number of trypan blue positive (nonviable) SLC. Five pericentral and five periportal regions within a field measuring 325 $\mu\text{m}\times 325 \mu\text{m}$ were examined under high power ($\times 400$). Mortality of SLC was expressed as the ratio of the number of trypan blue positive SLC to the total amount of SLC.

Statistics

Statistical evaluation was done by Student's *t* test. The results were expressed as $\bar{x}\pm s$. Means were considered significantly different when $P<0.05$.

RESULTS

Macroscopy and histology of livers before storage

In the control group, the morphology of livers before cold storage was normal under macroscopy and light microscopy. The livers of the rats fed with a CDD for 14 days had no abnormality in the appearance, but their specimens contained fatty vacuoles in less than one third of the liver cells. They belonged to mildly fatty livers. The livers of rats fed with a CDD for 28 days were a little larger than normal and appeared slightly yellow. The specimens of these livers contained fatty vacuoles in more than one third of the liver cells but less than two thirds of the cells. They pertained to

moderately fatty livers. The livers of rats fed with a CDD for 42 days were obviously larger than normal and appeared grossly yellow. The specimens contained fatty vacuoles in two thirds or more of the liver cells and scattered hepatocyte necrosis occasionally, which were considered as severely fatty livers.

Portal perfusion pressure and ET-1 values

There was significant increase of portal perfusion pressures in each group in parallel with the duration of preservation (Table 2). No remarkable difference of portal perfusion pressures was found between mildly fatty liver group and control group after 12 h preservation, between moderately liver group and control group after 6 h preservation, between severely fatty liver group and control group without preservation. Portal perfusion pressures were significantly higher in moderately fatty liver group than in control group after 12 h preservation ($P<0.01$) and in severely fatty liver group than in control group after 6 h preservation ($P<0.01$). The changes of ET-1 values in the effluent were consistent with those of portal perfusion pressures (Table 2).

Bile secretory volume

Bile secretory volume in each group decreased significantly as the preservation time prolonged (Table 2). There was no obvious difference between mildly fatty liver group and control group after 12 h preservation, between moderately liver group and control group after 6 h preservation, and between severely fatty liver group and control group without preservation. Bile production was markedly lower in moderately fatty liver group than in control group after 12 h preservation ($P<0.05$) and in severely fatty liver group than in control group after 6 h preservation ($P<0.01$).

Enzymes in the effluent and mortality of SLC

The changes of enzymatic levels (AST, ALT and LDH) in the effluent and mortality of SLC were consistent with those of portal perfusion pressures (Table 3).

DISCUSSION

Although progress in organ retrieval, preservation, recipient implantation and the rarity of hyperacute rejection, has improved patient survival after orthotopic liver transplantation (OLT), PNF still occurs in 2%-23% of transplanted livers. Transplantation of a fatty liver may lead to PNF. Some researchers hold that fatty liver grafts are unsuitable for elective OLT, since clinical experience evidenced that such grafts may lead to PNF more frequently than nonfatty ones. But others disagree about this because of successful OLT cases with fatty liver grafts. In order to increase the usage of donor livers on the premise of the unaffected outcome of OLT, it is vital to decide whether to choose fatty livers as donor organs and how to choose them properly.

The CDD-induced fatty liver was produced according to methods described elsewhere. Free fatty acid (FAA) synthesized in the liver bind to phospholipid apoprote in B complex, which is excreted into the blood as very-low-density lipoprotein (VLDL). Choline is a precursor of phosphoryl choline and is important in lipoprotein production. Choline deficiency suppresses the synthesis of the phospholipid-apoprotein B complex, and inhibits VLDL-secretion from the liver. Furthermore, sucrose-rich diet elevates the triglyceride concentration in the liver. These factors may cause fatty deposition in the rat liver after 14 days of CDD.

In clinical transplantation, fatty livers are generally graded to three scales depending on the degree of fatty infiltration: mildly (<30%), moderately (30% to 60%) and severely (>60%)^[5]. According to these criteria, the liver of rats fed with a CDD for 14, 28 and 42 days should be classified as mildly, moderately and severely fatty livers, respectively. Anchony reported that the overall incidence of fatty infiltration in 124 liver donor biopsies was 24.4%, with 12.3% of biopsies exhibiting mild changes, 8.9% moderate changes, and 3.2% severe changes.

Fatty infiltration of the liver can occur in a variety of conditions. Common causes of fatty infiltration include alcohol intake, obesity, nutritional disorders (particularly malnutrition), drug therapy and diabetes although the reason diabetic patients may develop fatty deposition could be related to obesity.

Our experiment showed that there was no obvious difference in the preservative effects between mildly fatty liver group and control group after 12 h preservation and between moderately fatty liver group and control group after 6 h preservation. In view of this, if we gave up using all the fatty livers as donor organs, a lot of available donor livers would be wasted. Meanwhile, the present study demonstrated that preservation reperfusion injury was more severe in moderately fatty liver group than in control group after 12 h preservation and in severely fatty liver group than in control group after 6 h preservation. The increase in the preservation reperfusion injury was manifested as significantly higher portal perfusion pressure, higher ET-1 values, lower bile production, higher enzymatic levels in the effluent and increased mortality of SLC. Therefore, in order to lower the occurrence of PNF, some fatty livers, such as severely fatty livers, should be discarded resolutely although their function was normal or basically normal before storage.

The etiology of increased preservation reperfusion injury of fatty livers has not been clarified^[6,7]. To explain the loss of viability in fatty liver grafts after cold preservation, four underlying mechanisms are suggested: ① The solidification of triglycerides during cold storage causes the rupture of the hepatocytes containing fat upon rewarming. The rupture of these cells results in the release of fat globules into the hepatic microcirculation with disruption of sinusoidal architecture, focal hemorrhage and hepatocellular necrosis. ② The increase in Kupffer cell activation was possibly caused by the increased number of Kupffer cells in fatty livers. Activated Kupffer cells can produce

many types of chemical substance and peptide mediators, which may play a significant role in microcirculatory disturbance and reperfusion injury. ③ FFA accumulation in the hepatic mitochondria cause inhibition electron transport in the respiratory chain, affects oxidative phosphorylation activity, reduces the production of ATP, leading to disturbance of energy metabolism. ④ Cellular disruption and release of triglycerides and free fatty acids activate phospholipases and lipid peroxidation, with free radical formation, thereby causing further cellular damage.

In summary, the present study confirms that moderately and severely fatty livers are highly susceptible to cold preservation reperfusion injury and are likely to lose their viability after cold storage more easily than the nonfatty livers, while no obvious difference of the preservative effects is found between mildly fatty livers and nonfatty livers. Fatty livers should not be discarded blindly only for its high incidence of PNF. However, fatty livers should not be used arbitrarily only for the shortage of donor organs either. To use only hepatic function test to assess donor liver is not enough, since the functions of fatty livers are always within normal range. The use of preoperative donor liver biopsies in many sites is considered the most valuable means for the assessment of abnormal hepatic pathology and the correct selection of donor livers. We proposed the following criteria for the

use of a fatty liver as a graft: ① a mildly fatty liver can be used in the same way as a nonfatty liver; ② a moderately fatty liver can be used depending on the time of preservation and the balance of the emergent needs of recipient and the donor organ supply; and ③ a severely fatty liver should be discarded without hesitation.

Cloning and sequence analysis of human genomic DNA of augmenter of liver regeneration

Jun Cheng, Yan Wei Zhong, Yan Liu, Jing Dong, Ji Zhen Yang and Ju Mei Chen

Subject headings augmenter; liver regeneration; cloning; gen omic DNA; intron; exon

Cheng J, Zhong YW, Liu Y, Dong J, Yang JZ, Chen JM. Cloning and sequence analysis of human genomic DNA of augmenter of liver regeneration. *World J Gastroentero*, 2000;6(2):275-277

INTRODUCTION

The liver is one of the organs, which have potential regenerative capability in mammalian animal^[1]. The study of the canine model indicated that the liver could regenerate to original size after 70% hepatectomy in only two weeks^[2]. So it is a hot research topic for the cellular and molecular mechanism of liver regeneration. Accumulated results demonstrated that the hepatocyte growth factor (HGF)^[3], insulin-like growth factor I and II (IGF-I, II)^[4], epidermal growth factor (EGF), transforming growth factor alpha (TGF alpha)^[5] and insulin^[6] are among the most important growth factors for liver regenerative regulation. In recent years, a heat-stable protein in the serum of the patients with various liver diseases has been noted for its potential stimulation effects on the liver regeneration, and this growth factor is called hepatocyte-stimulatory substance (HSS). Gradient purification and sequence analysis of HSS protein indicated that the HSS protein itself is the augmenter of liver regeneration (ALR)^[7], or called hepatopoietin (HPO)^[8]. The immunohistochemical staining indicated that the expression of the ALR mainly existed in platelets and the sperm cells in testes, and ALR also could be found in the liver and the spleen which contain many platelets^[9]. The analysis of the protein structure of the human and mouse ALR indicated that the primary protein structure of ALR does not contain a typical signal peptide sequence, and it is unknown if a specific

receptor is necessary for the effect of the ALR. Therefore, it is important to clone the genomic DNA sequence of the ALR and it is also very helpful for the analysis of the structure of the ALR genomic DNA and regulation at the transcriptional and post-transcriptional levels.

METHODS

Molecular cloning of human ALR genomic DNA

Using human ALR cDNA sequence as a reference, and BLAST search path as a tool, the GenBank established by National Center for Biological Information (NCBI), USA, has been searched for the homologous sequences.

Definition of the intron-exon structure of the human ALR genomic DNA

According to the Breathnath-Chambon rule and the human ALR cDNA coding sequence, the intron-exon structure of human genomic DNA was defined.

Homologous analysis of human and mouse ALR genomic DNA sequences

The homology of human and mouse ALR genomic DNA sequences was analyzed for their 5'-UTR, intron-exon structure and 3'-UTR sequences.

RESULTS

The retrieval results from the GenBank

Using human ALR cDNA (AF124604, human HPO2 mRNA, complete coding sequence) sequence as a reference, and BLAST path as a search tool, homologous DNA sequence was searched on GenBank. It was found that 5 cDNA and DNA fragments were homologous to human ALR cDNA sequence, including mouse ALR genomic DNA, rat ALR cDNA, human HPO1 cDNA partial sequence, human ERV1 cDNA and DNA sequence of human genomic DNA P1 clone derived from human chromosome 16 (Table 1).

Table 1 Homology sequences of human ALR cDNA searched from GenBank

GenBank No.	Name	Character
U31176	Human ERV1 mRNA	Complete coding sequence

From Table 1, it is clear that human ALR cDNA has a high homology to P1 clone 109.8C (LANL) which is 16 (GenBank No. AC005606). Further analysis of human HPO2 cDNA complete sequence and HPO1 cDNA partial sequence showed that human ALR genomic DNA was between 44742-46554nt of P1 clone 109-8C (LANL). Human ALR genomic DNA consisted of 1813bp (Figure 1).

Figure 1 Genomic DNA sequence of human ALR.

Structural analysis of human ALR genomic DNA sequence

Human genomic DNA consists of introns and exons. According to the Breathnath-Chambon rule of intron-exon junction structure, in conjunction with the coding sequence of human ALR cDNA, we found that human ALR genomic DNA has 3 exons and 2 introns. The 3 exons were located between 158nt-175nt, 446nt-642nt and 1565nt-1727nt of P1 clone 109-8C (LANL) of human chromosome 16, respectively.

Comparison of human and mouse ALR genomic DNA structures

To compare human and mouse ALR genomic DNA sequences, we found that the 3 exons were similar in length, but different in their 5'-UTR, introns and 3'-UTR regions in length. The 3 exons for both human and mouse ALR were 18nt, 197nt and 163nt, respectively. The comparative results are shown in Table 2.

Table 2 Comparison between human and mouse genomic DNA structure

	Human	Mouse
5'-UTR1	57 nt	252 nt
Exon 1	18 nt	18 nt
Intron 1	270 nt	398 nt
Exon 2	197 nt	197 nt
Intron 2	922 nt	483 nt
Exon 3	163 nt	163 nt
3'-UTR	86 nt	535 nt

Chromosomal location of human ALR genomic DNA

The human ALR genomic DNA was homologous to a genomic DNA fragment derived from P1 clone 109-8C (LANL) of human chromosome 16p13.3, so human ALR genomic DNA should be assigned to human chromosome 16p13.3.

DISCUSSION

Augmenter of liver regeneration (ALR) plays a very important role in the regulation of liver regeneration. The expression sites were mainly located in platelets and sperm cells of testes. But the mechanism of triggering the expression, transportation and secretion of ALR from platelets and testes remained unknown. It is not clear if the secreted ALR function as a liver tropic factor via specific receptor on the hepatocyte membrane. Molecular cloning of human cDNA has been completed, but the transcription and post transcriptional regulation based genomic structure of ALR is still unclear. So it is very important to know the structure of human ALR genomic DNA. The regulation of human gene expression occurred at multiple levels, but there is no doubt that the transcription and post-transcriptional regulation is among the most important steps of their expressive regulations. In this study, we conducted DNA sequence homology search on the World Wide Web (WWW) in an attempt to find the homologous DNA sequence to human ALR cDNA in GenBank using BLAST as a tool, and found that human ALR genomic DNA consisted of 1813nt (GenBank accession number: AF146394). According to the Breathnath-Chambon rule and ALR cDNA coding sequence, we defined 3 exons and 2 introns in the genomic DNA sequence. Human ALR gene was also highly conserved, indicating that ALR plays a very important role in the whole evolution process.

Human genome project (HGP) has been planned to complete before the year of 2005. But in recent years, along with more scientists involved in this project and large investment into this project, there is strong evidence to predict that this HGP will be finished soon. The conduction of HGP will result in a big database of human genomic DNA

nucleotide sequence, and will define the final restriction map for human whole genome. The GenBank is a good and important information resource for both analysis and functional DNA cloning.

Wells *et al* used conserved motif sequence of chemokine as a reference, searched on the GenBank and obtained a gene coding for a new chemokine. This is the first example to clone a new gene only from GenBank database homology DNA sequence search^[10]. In the research of apoptosis, the CED-3 gene in *C. elegans* was demonstrated as a dead gene. Miura *et al* used this sequence as a reference to search homology DNA sequence to CED-3 gene in GenBank and found that interleukin-1 beta converting enzyme (ICE) is homologous gene to CED-3 gene in *C. elegans*. Later studies demonstrated that the gene transduction of ICE expressive vector could induce apoptosis in the NIH 3T3 murine fibroblast cell line^[11]. As a result, the gene homologous analysis is a good means to define the new functional gene. We also used the principle of gene homology and cloned a parasite surface protein amastin coding DNA for *Leishmania major* parasites^[12]. So the GenBank is not only a accumulated data bank of cloned nucleotide sequence, but a good channel to define new gene and new functional gene. After the HGP was completed, the post-HGP works will need the GenBank to identify new genes, and this will be a good alternative for the molecular biological studies.

ACKNOWLEDGEMENT The human ALR genomic DNA sequence described in this paper was accepted by GenBank, GenBank accession number for it is AF146394.

A preliminary study on ras protein expression in human esophageal cancer and precancerous lesions

Jian Li¹, Chang Wei Feng¹, Zhi Guo Zhao¹, Qi Zhou² and Li Dong Wang²

Subject headings esophageal neoplasms; ras protein; oncogene; gene expression; precancerous condition

Li J, Feng CW, Zhao ZG, Zhou Q, Wang LD. A preliminary study on ras protein expression in human esophageal cancer and precancerous lesions. *World J Gastroenterol*, 2000; 6(2):278-280

INTRODUCTION

The esophageal carcinoma is a common malignant tumor in Linzhou City (Linxian) of Henan Province in northern China. Although the etiology and natural history of esophageal carcinoma are not clear, a substantial amount of evidence has been provided to suggest that the development of human esophageal squamous cell carcinomas (SCC) is a multistage progressive process^[1-4]. An early indicator of abnormality in persons predisposed to esophageal SCC is an increased proliferation of esophageal epithelial cells, morphologically manifested as basal cell hyperplasia (BCH), and dysplasia (DYS), and carcinoma *in situ*, which could be considered precancerous lesions of esophageal SCC^[1-4]. Current molecular biology has suggested that many genes could participate in the different stages in esophageal carcinogenesis, and the synthetic effect of these different molecules might result in the malignant transformation of human esophageal mucosa^[5,6], e.g., the amplification and/or overexpression of certain gene such as *hst-1*, *int-2* and *c-myc*, have been observed in esophageal tumor s, moreover, the alteration of tumor suppressor gene *p53* is one of the important molecular changes in the early stage of esophageal carcinogenesis^[2-6].

Recent evidence has suggested that oncogene *ras* may play a role in cell growth and differentiation^[7,8]. The *p21* protein encoded by the *ras* gene family functions as G protein that

participates in membrane signal transduction pathways^[7]. Some sites of point mutation of *ras* oncogene, especially codons 12, 13, and 61, could be involved in malignant transformation cells^[7]. Several reports have suggested a close association between specific *ras* gene mutation patterns and suspected etiological factors in some human cancers, for example, N-*ras* mutations have been associated with melanomas induced by sunlight^[7]. *ras* gene mutations have been found in a significant percentage of human tumors, e.g. 75%-93% in pancreas adenocarcinoma, 7%-44% in colon cancer^[7]. No *ras* point mutations have been found in DNA extracted from primary human esophageal tumors in France and South Africa, this is in sharp contrast to some reports in which rat esophageal papillomas were induced by *methylbenzyl-nitrosamine*^[8]. This prompted us to re-evaluate the role of the *ras* family of oncogene in human esophageal carcinogenesis. In the present study, we analyzed the expression of *ras* protein in cancerous and precancerous tissues of the esophagus collected from the subjects in Linzhou, a high incidence area of esophageal carcinoma in China.

MATERIALS AND METHODS

Tissue collection and processing

Esophageal biopsies were taken from 54 symptom-free patients who volunteered to participate in a routine endoscopic screening for esophageal carcinoma in Linzhou City, China. Of the 54 subjects examined, there were 29 males (30-72 years of age, with a mean±SD of 47±15 years) and 25 females (32-70 years of age, with a mean±SD of 44±17 years). The surgically resected specimens were obtained from patients (36 patients, aged 40 to 74 years, with a mean±SD of 55±10 years) with primary esophageal carcinoma in Linzhou City, China. The patients had received no radiation therapy or chemotherapy before surgery. All of the tissues were fixed in 80% alcohol and embedded in paraffin. The section was 5 μm in thickness. Three or four adjacent ribbons were collected for histopathological analysis (hematoxylin and eosin stain), and for immunohistochemical staining.

Histopathological analysis

Histopathological diagnoses for esophageal epithelia were made according to the cellular morphologic

Received 1999-04-15 **Accepted** 1999-06-13

changes and tissue architecture using previously established criteria^[1-4]. In brief, the normal esophageal epithelium contained one to three proliferating basal cell layers; the papillae were confined to the lower half of the epithelium. In BCH, the number of proliferating basal cells was increased to more than three cell layers; DYS was characterized by nuclear atypia (enlargement, pleomorphism, and hyperchromasia), loss of normal cell polarity, and abnormal tissue maturation. SCC was characterized by confluent and invasive sheets of cohesive, polymorphous cells with hyperchromatic nuclei.

Antibodies and reagents

The monoclonal antibodies (Pan-ras) Ab-3 (Oncogene Science Inc, USA) were mouse antibodies against human ras protein. Twenty mL/L crystalline bovine serum albumin (BSA), (Sigma Chemical Inc, USA) and ABC and DAB kits (Vector Laboratories Inc, USA) were used for immunohistochemical assay.

Immunohistochemical staining

The avidin-biotin-peroxidase complex (ABC) method was used for ras protein. Briefly, after dewaxing, inactivating endogenous peroxidase activity, and blocking cross-reactivity with normal serum, the sections were incubated overnight at 4 °C with a diluted solution of the primary antibodies (1:100 for ras). Locations of the primary antibodies were achieved by subsequent application of a biotinylated anti-primary antibody, an avidin-biotin-complex conjugated to horseradish peroxidase, and diaminobenzidine. Normal serum blocking and omission of the primary antibody were used as negative controls.

The positive reaction was graded according to the number of brown-yellow particles appearing in cytoplasm. The diagnostic criteria for immunoreaction was based on previous reports^[2-4].

RESULTS

Histopathological analysis

Histopathologically, among 54 esophageal biopsies, 12 had normal esophageal epithelium (22%), 34 had BCH (63%), and 8 had DYS (15%). All of 36 surgically resected specimens were found to have esophageal invasive SCC.

Immunohistochemical analysis

By immunohistochemical analysis, immunostaining of ras protein was predominantly observed in cytoplasm. The positive immunostaining of ras protein was not found in the normal tissues and the tissues with different severity of lesions from esophageal precancerous biopsies. The

immunoreactivity of ras protein was observed in 9 (25%) of the 36 surgically resected esophageal cancer specimens (Table 1).

Table 1 Expression of ras protein in different severity of lesions from esophageal biopsies and carcinomas

Histological types	n	ras positive immunoreaction n(%)
Normal epithelium	12	0 (0)
Basal cell hyperplasia	34	0 (0)
Dysplasia	8	0 (0)
Esophageal carcinoma	36	9 (25)
Total	90	9 (10)

DISCUSSION

The unique observation in this study is that, the expression of ras protein was not observed in the normal esophageal epithelial and precancerous tissues, and the immunoreactivity of ras protein was observed in 9 (25%) of the 36 surgically resected esophageal cancer specimens. These results suggested that the expression of ras protein only occurs in the late stage of esophageal cancers, but not in early stage, and it might not be the important molecular change in the carcinogenesis of esophageal squamous epithelium.

The mutation of ras family of genes occurs extensively in human tumors, particularly tumors of the gastrointestinal tract and lung, the incidence being about 40% in colon cancers. Many researchers agree with the concept that the mutation of oncogene ras plays an important role in carcinogenesis of colon cancers^[7,8]. However, the conclusions of oncogene ras in esophageal carcinogenesis were not consistent. Hollstein *et al*^[9] found that tumor suppressor gene p53 had G-T transversion of mutation pattern in lesions of esophageal cancer in the areas where the tumor is closely associated with tobacco consumption, but the mutation of oncogene ras was not found in the same areas. No ras mutation was found with PCR technique in other areas of the world with high incidences of esophageal SCC, such as China^[10] or South Africa^[11], where N-nitrosamines and fungal toxins could play major roles. Experimentally, activating point mutation at codon 12 of H-ras was reported in rat esophageal tumor (papillomas) induced by the carcinogen methylbenzyl-nitrosamine^[12]. This was a typical example that the results of human molecular research was obviously unsimilar to animal studies. On the other hand, two recent studies reported that genomic amplification rates of K- and H-ras gene were up to 14% (7/51) and 40% (4/10) of esophageal cancer, respectively from France^[13] and Canada^[14], and one

immunohistochemical study of esophageal SCC from Italy and America showed that the positive staining of the ras protein was 88.5% (46/52)^[15]. Our results in the present study suggested that in the normal tissues and the tissues with different severity of lesions from esophageal biopsies, the expression of ras protein was not detected. Ras protein immunoreactivity was observed in 9 of the 36 surgically resected esophageal cancer specimens, accounting for 25%. The different results from the world suggested that the environmental factor might play an important role in esophageal carcinogenesis. Obviously, comparison with the molecular changes in the similar tumors in populations from different areas, is of great importance to reveal its carcinogenesis and further to understand its related etiology.

Tian XJ, Wu J, Meng L, Dong ZW, Shou CC. Expression of VEGF₁₂₁ in gastric carcinoma MGC803 cell line. *World J Gastroenterol*, 2000;6(2):281-283

INTRODUCTION

Vascular endothelial growth factor (VEGF) which is also known as vascular permeability factor (VPF) is a heparin-binding, dimeric polypeptide growth factor and a potent mitogen for endothelial cells. VEGF can stimulate the endothelial cell growth and enhance the motility through its two known receptors flt-1 and KDR^[1]. Acting through these receptors, VEGF may stimulate angiogenesis and promote tumor progression. VEGF₁₂₁, as one of the four VEGF protein isoforms containing the least number of amino acids, has all the biological function of VEGF and is the ideal isoforms for further studying VEGF at molecular levels^[2]. In this study, we cloned VEGF₁₂₁ cDNA from gastric carcinoma cell MGC803 and had it expressed in *E.coli* bacterial. Further identification of its expression products was carried out with anti-VEGF monoclonal antibodies. This gives new evidence to clarify the source of VEGF in tumor tissues.

MATERIALS AND METHODS

Materials

Balb/c mice, female, 6-8 weeks old, was purchased from the Animal Center of the Chinese Academy of Medical Sciences. HUVEC was obtained from the Academy of Preventive Medical Sciences and cultured in RPMI1640 with 15% fetal cow serum (full growth medium) at 37°C with 5% CO₂. MGC803 cell line was established from a

primary poorly differentiated mucoid adenocarcinoma of human stomach. Recombinant human VEGF₁₂₁ was obtained from the Department of Immunology, Beijing Medical University. ³H-thymidine was purchased from Shanghai Institute of Atomic Energy.

Preparation of VEGF₁₂₁ monoclonal antibodies

Balb/c mice were immunized subcutaneously with the purified fusion protein GST-VEGF₁₂₁ and hybridoma cell clones were obtained by traditional hybridoma technology. ELISA was used to screen hybridoma clones with recombinant fusion protein GST-VEGF and GST-P21 as antigen. The clones which reacted with GST-VEGF, but not with GST-P21, were subcloned. After three rounds of subcloning by limited dilution, VEGF₁₂₁, which had proliferation activity on HUVEC, was used as antigen to select the positive clones. The antibodies were purified through protein A-Sepharose CL-4B chromatography and their subclasses were measured.

Inhibition of the monoclonal antibody on HUVEC proliferation induced by VEGF₁₂₁

Assay of ³H-thymidine incorporation was used on HUVEC for neutralizing the activity of anti-VEGF₁₂₁ monoclonal antibody. HUVEC was seeded at a density of 2×10⁴ per well of 24 well plates and incubated with full growth medium for 48 hrs at 37°C. The cells were then incubated with serum free medium for 24 hrs, and the testing groups were added with VEGF₁₂₁ (10 µg/L) and anti-VEGF₁₂₁ monoclonal antibody at various concentrations. After 30 hrs culture, ³H-thymidine (37 KBq/mL) was added, and after 6 hrs, the cells were collected and measured in a liquid scintillation counter.

RT-PCR of VEGF₁₂₁ from MGC803 cells and HUVECs

Total RNA of both cell lines was extracted respectively by TRISOLV™ isolation of RNA kit (GIBCO BRL). First-strand cDNA was synthesized using the Superscript™-II Preamplification System for First Strand cDNA Synthesis Kit (GIBCO BRL) with 5 µg total RNA in a 20 µL reaction volume. Two µL cDNA was used as template in a 100 µL-PCR reaction volume. The primer for VEGF reverse transcription was oligodT. The cDNA

encoding VEGF was amplified using forward primer (5'-GGG GGA TCC GCC TCC GAA ACC ATG AAC TT-3' containing Bam-HI restriction endonuclease site) and reverse primer (5'-CCC GAA TTC TCC TGG TGA GAG ATC TGG TT-3', containing Eco-RI restriction endonuclease site), and PCR was carried out in a DNA Engine™- Peltier Thermal Cycler Model PTC-200 (MT Research Inc, USA) at 95 °C for 5 min first, then at 94 °C for 45sec, 55 °C for 40sec, and 72 °C for 1min for 36 cycles, followed by 5 min at 72 °C.

Recombinant of VEGF on plasmid PGEX-2T vector

The PCR products were purified with DNA purified kit (QIAEGN), digested with Bam-HI/Eco-RI and ligated with fusion protein prokaryotic expression plasmid PGEX-2T. E. coli-XL-1 blue was transformed and the positive clones were selected by restriction endonuclease mapping.

Expression and identification of GST-VEGF₁₂₁ protein

Positive clones were selected and cultured with LB until the OD₆₀₀ reached to 1.0, then the 5 mmol/L IPTG was added for 4 h culture to induce the protein expression. The expression products were analysed by SDS-PAGE, and Western blot was carried out for further identification of the products.

RESULTS

Preparation and identification of anti-VEGF monoclonal antibodies

After three rounds of subcloning and selecting by ELISA with recombinant fusion protein GST-VEGF₁₂₁ and GST-P21, six clones stably secreting anti-VEGF₁₂₁ antibodies were obtained. Screened with purified VEGF₁₂₁, clone 5C₅, which showed more specific binding activity to VEGF, was selected for preparing ascites. The ascites were purified through chromatography with ProteinA- Sepharose CL-4B column. Its subclass is IgG2b.

Neutralization activity of anti-VEGF₁₂₁ monoclonal antibody

We measured the effects of anti-VEGF antibody 5C₅ at various concentrations on HUVEC proliferation induced with VEGF at a concentration of 2 µg/L. The results from analysis of ³H-thymidine incorporation showed that the VEGF antibody 5C₅ neutralized the activity of VEGF in a dose-dependent manner and blocked the VEGF-induced cell growth completely at a concentration of 10 mg/L (Figure 1).

Amplification of VEGF₁₂₁ cDNA

The VEGF₁₂₁- cDNA was amplified with its specific primers from MGC803 cells. Following 0.8% agarose gel analysis, a clear band about 550bp, which matched the predicated size, was generated (Figure 2, lane 2). No specific band was obtained from HUVEC (Figure 2, lane 3).

Recombinant of VEGF₁₂₁ and its expression

The recombinant PGEX2T-VEGF₁₂₁ digested with Eco-RI/Bam-HI released a fragment about 550 bp (Figure 2, lane 4). After induced by IPTG, the positive transformed E. coli XL-1 blue can stably express fusion protein GST-VEGF at the molecular weight about 40 KD. The proportion of expressed VEGF₁₂₁ to total bacterial protein was about 25% and it existed in the inclusion body (Figure 3).

Western blot analysis

Induced by IPTG, further identification of the expressed product was carried out by Western blot analysis. The results showed that 5C₅ can be specifically reacted with denatured GST-VEGF₁₂₁ (Figure 4).

DISCUSSION

Inhibition of tumor blood vessel growth is an important research area for tumor biotherapy in recent years. The process of angiogenesis involves stimulation of endothelial cell growth, motility and the release of proteases and the degradation of extracellular matrix. Blocking the overexpression of VEGF in tumor tissues and neutralizing its activities by monoclonal antibodies cast much light on VEGF related tumor therapy^[3]. In this study, by using

anti-VEGF monoclonal antibodies, we successfully neutralized the VEGF-induced HUVEC growth. These also clearly made the specificity of the prepared monoclonal antibodies.

There are different opinions on which kind of cells in tumor tissues can express VEGF. Wizigmann *et al*^[4] proved that VEGF is mainly expressed by tumor cells. It can bind to its receptors on HUVEC and stimulate cell growth by paracrine ways. However, Plate Hetal^[5] discovered that VEGF can be expressed by HUVEC in tumor tissues. Brown^[6] said that the HUVECs both in the tumor tissue and the normal tissue can express VEGF. In our study, we demonstrated, by RT-PCR, the expression of VEGF in gastric carcinoma MGC803 cells. We also found, by ³H-thymidine incorporation that the supernate of MGC803 cell s can promote the proliferation of HUVEC (data not shown). These suggested that MGC803 can express VEGF, but we failed to amplify VEGF cDNA from HUVEC.

To make clear about which kind of cells in tumor tissue can express VEGF is important for the blocking of its expression at genetic levels. We are preparing human anti-VEGF monoclonal antibodies by the phage display method to obtain the useful anti-VEGF antibodies for further research and its clinical application.

A clinical and long-term follow-up study of peri-operative sequential triple therapy for gastric cancer

Shou Chun Zou, Hua Sheng Qiu, Cheng Wu Zhang and Hou Quan Tao

Subject headings stomach neoplasms/surgery; stomach neoplasms/drug therapy; intra-arterial chemotherapy; intra-peritoneal chemotherapy; curative resection; survival rate

Zou SC, Qiu HS, Zhang CW, Tao HQ. A clinical and long-term follow-up study of perioperative sequential triple therapy for gastric cancer. *World J Gastroentero*, 2000;6(2):284-286

INTRODUCTION

Although the long-term postoperative survival rate of gastric cancer (GC) patients has been improved significantly since the local dissection of lymph node was widely used in China, yet the low curative resection rate and the high recurrence rate from peritoneal and hepatic metastases hinder it from further improvement. To alter the current unsatisfactory status of GC treatment, a sequential triple therapeutic scheme (STTS), consisting of pre-operative regional intra-arterial chemotherapy, curative resection of GC, and intra-operative or early postoperative intraperitoneal chemotherapy, was designed and adopted in this department since 1989. The follow-up data demonstrated that the therapeutic response of STTS is rather satisfactory. The results are reported as follows.

MATERIAL AND METHODS

General data

From February 1989 to October 1997, a total of 211 patients with GC were treated in this department, among them 167 were treated by surgical resection of GC, and follow-up data were obtained in 134 cases, with a rate of 80.24%, and a follow-up period of 5.144 months, averaging 34.6 months. Among the followed up patients, 112 had curative resection and 22 had palliative resection.

Sequential triple therapeutic scheme (STTS)

One or two times of selective intra-arterial chemotherapy with FAP or FMP scheme was done

by DSA, and then surgical operation was performed in 2 weeks. The surgical operation was performed as follows: D1 resection for TNM staging I, D2+ or D3 resection (including combined organ resection) for TNM staging Ib to IIIb, D4 resection for only a few cases, palliative resection for TNM staging IV patients. Hyperthermic intraperitoneal chemotherapy was performed immediately after operation, MMC 40mg+ CDDP 200mg were dissolved in 4000mL NS, lasting 15 minutes at 42°C-45°C, the abdominal wall was sutured after the chemotherapy was completed. Among the 134 followed up cases, 81 received STTS treatment and 53 underwent only simple resection. Based on the new TNM staging system, the staging of two groups was essentially similar and comparable (Wilcoxon test, $P>0.05$).

Table 1 The TNM staging of STTS group and simple operation group

Stage	STTS group (n)	%	Simple operation group (n)	%
I	Ia	2	2	3.8
	Ib	6	4	7.5
II		15	11	20.7
III	IIIa	21	12	22.6
	IIIb	25	15	28.3
IV		12	9	17.0
Total	81		53	

Statistical analysis

Based on the data from the case with simple operation as a control, the treatment response of STTS was evaluated, the comparison between the two groups was analysed by Chi-square test, the cumulative survival rate was calculated by the life-table method. P value of less than 0.05 was considered as significant.

RESULTS

Effect of preoperative regional intra-arterial chemotherapy on the curative resection rate

Among the 211 patients, 101 were treated by preoperative regional intra-arterial chemotherapy, of whom 80 (79.2%) had curative resection. But among 110 cases treated by simple operation, only 68 (61.8%) had curative resection, hence the curative resection rate was significantly different between the two groups ($P<0.01$).

Comparison of survival rate between STTS and simple operation group

Among the 134 followed up cases, 43 died, the survival rates of 1, 3, 5 and 7 years were 87%, 64.6%, 60.9% and 55.2%, respectively. Statistical data demonstrated significant difference of survival rate between STTS and simple operative group except the 3-year survival rate. Among the 112 cases with curative resection, 71 cases received STTS treatment, and 41 received simple operation, the survival rate of the two groups was significantly different except for the 3 and 7-year survival rate (Table 2).

Table 2 Comparison of survival rate and curative survival rate between STTS group and simple operation group

Group	Survival rate (%)					Curative survival rate (%)				
	<i>n</i>	1	3	5	7 (yrs)	<i>n</i>	1	3	5	7 (yrs)
STTS	81	92.9 ^c	68.1 ^a	68.1 ¹	62.5 ^c	71	98.0 ^c	79.2 ^a	79.2 ^c	72.6 ^c
Simple operation	53	79.7	55.5	49.1	45.6	41	90.0	72.3	64.3	60.6

^a*P*>0.05, vs simple operation, ^c*P*<0.05, vs simple operation.

Effect of STTS on postoperative metastasis and recurrence rate

Of all 134 patients, 43 died from cancer metastasis and recurrence during follow-up period, 25 had peritoneal metastasis and 10 had hepatic metastasis. Statistical data showed that there was significant difference of the peritoneal and hepatic metastasis rate between STTS group and simple operation group (Table 3).

Table 3 Comparison of main recurrence and metastasis rate between STTS group and simple operation group

Recurrence (<i>n</i>)	Group (<i>n</i>)	<i>n</i>	Rate (%)	<i>P</i> value
Peritoneal (<i>n</i> =25)	STTS (<i>n</i> =81)	7	8.6 (7/81)	$\chi^2=13.53$
	Simple operation (<i>n</i> =53)	18	33.9 (18/51)	<i>P</i> <0.005
Hepatic (<i>n</i> =10)	STTS (<i>n</i> =81)	2	2.4 (2/81)	$\chi^2=7.39$
	Simple operation (<i>n</i> =41)	8	15.1 (8/53)	<i>P</i> <0.01

Relationship between free cancer cells in peritoneal cavity and TNM staging and intra-peritoneal chemotherapy

Of all 134 cases, peritoneal lavage was examined in 45 cases to detect the intra-peritoneal free cancer cells. It was positive in 11 (24.4%) cases and, 1, 1, 2, 3 and 4 cases were found at stage of I, II, IIIa and IV, respectively. In 5 followed up patients, 2 without intra-peritoneal chemotherapy died of peritoneal metastasis in 1 year and 2 years and 3 months, while in the 3 patients with intra-peritoneal chemotherapy, 1 died 5 years later and the remaining 2 were alive 5 and 8 years later respectively. Sixteen of the cases with negative free

cancer cells, were followed up, only 1 of them died from peritoneal metastasis 2 years after the operation.

Relationship between STTS and survival rate of lymph node positive cases

Among 112 cases with curative resection, lymph node metastasis was found in 66 cases, 47 of which were treated by STTS and 19 cases by simple operation. Statistical analysis showed that the survival rate of 1, 3, 5 and 7 years in STTS group were all higher than those in simple operation group, but they were not significant in log rank test.

DISCUSSION

Selection of the appropriate time for chemotherapy

The post-operative recurrence of GC arises mostly from the remnants of micro-cancerous foci. In the past, chemotherapy was done mostly post-operatively, when the vascular and lymphatic channels of the primary tumor had been cut and ligated in operation, and the cancer cells were embedded in the adhesion one week after operation. The remnant micro-cancerous foci cannot be exposed to chemotherapeutic drugs or the concentration of the drugs is insufficient, so the chemotherapy is rarely effective. Besides, during operation, free cancer cells are promoted to exfoliate and metastasis. The pre-operative chemotherapy can reduce the viability of cancer cells, reduce the tumor size, and decrease the chance of iatrogenic dissemination and hepatic metastasis so as to increase the opportunity for curative resection. Averbach *et al*^[1] and Ajani *et al*^[2] suggested that pre-operative, intra-operative and early post-operative period are the best time for chemotherapy.

Among the 211 cases, curative response of pre-operative regional intra-arterial chemotherapy was 79.2%, the 5-year survival rate of STTS group being 79.2%, but 61.8% and 64.3% respectively in the simple operation group (*P*<0.05). The results indicated that pre-operative regional intra-arterial chemotherapy, intra-operative and early post-operative intra-peritoneal chemotherapy can increase significantly the curative rate and the 5-year survival rate.

Indications for intra-operative and early post-operative intra-peritoneal chemotherapy

Peritoneal metastasis is the main cause of recurrence in GC, its rate was about 50%-60% in the literature^[3], and was 58% in this paper. The 3-year survival rate of cases with free cancer cells in peritoneal cavity was only 15.6%^[4]. Bonen Kamp reported that the median survival period was only

1.1 years^[5]. Recently, the positive rate of free cancer cells was reported to be 22.2%-32.5% in China^[6,7], and was 24.4% in this paper. According to Suzuki, free cancer cells were found in peritoneal lavage in 24% of stage Ib and 40% of stage II-III patients. False positive rate was less than 5%^[8]. The difference between Chinese and international reports may be due to the following factors: ① the results of examination are not exactly correct; ② the examination of lavage is usually performed after opening the abdomen before the operation, free cancer cells may turn from 'negative' to 'positive' at the end of the operation. In our series, one patient with negative free cancer cells and without intra-peritoneal chemotherapy died from peritoneal metastasis post-operatively. Among those with positive free cancer cells and without intra-peritoneal chemotherapy, 2 were of stage I and II respectively, and 3 survived more than 5 and 8 years. As a result, the stages more than Ib in GC patients are indications for intra-peritoneal chemotherapy.

About curative resection

Curative resection is the most important means to determine whether the GC patient is cured or not. The following standards should be achieved: ① No tumor invasion of the cut ends; ② the number of stations of regional lymph nodes dissected should exceed that of positive lymph nodes (D>R); ③ no remnant cancer tissue in adjacent organs and tissues. The results should be confirmed by pathological examination, but this is often too late. In other words, even the operation has achieved the requirements of curative resection, if there are some risk factors, such as sub-clinic cancer foci, invisible free cancer cells in peritoneal cavity, indistinct potential hepatic metastasis, etc., the so-called curative resection need pre-operative, intra-operative or early post-operative chemotherapy to compose a composite therapeutic approach so as to attain the real curative resection.

About lymph node metastasis

It is well-known that the prognosis of GC patients is

closely related to the lymph node metastasis. It is suggested in this paper that there was no significant difference in long-term survival rate between STTS lymph node positive group and simple operation group. This may be related to the insufficient number of cases accumulated, or due to the fact that the lymph node metastasis is an independent prognostic factor, and it depends mainly on the thoroughness of the dissection. It is impossible for various chemotherapeutic approaches to replace the curative resection at all.

CONCLUSION

We suggest that the STTS is a rational therapeutic scheme for GC. Follow-up results have demonstrated that STTS treatment can significantly increase the curative resection rate and the 5-year survival rate and decrease the post-operative recurrence rate as well. But this is still a preliminary report of the feasibility of STTS, more cases should be accumulated for further studies.

INTRODUCTION

Macrophages play an important role in tumor lysis and growth inhibition. They can be activated to a tumoricidal state by a variety of agents such as IFN γ , TNF α or IL2. The killing mechanisms of activated macrophages have been extensively investigated^[1,2]. Recently, it has been proved that antibody dependent cellular cytotoxicity (ADCC) is one of the potent arms to lyse tumor cells resistant to cytotoxic macrophages, and that the antitumorous effect of a macrophage activator is significantly augmented by the combined use of mAbs capable of inducing ADCC to tumor cells^[3].

The present study was undertaken to investigate these possibilities using Capan-2 human pancreatic carcinoma cell line. IL2 and YPC3 mAb inducing ADCC of murine splenic lymphocytes served as activators. The anti-pancreatic carcinoma efficacy of activated macrophages derived from murine peritoneal effusion cells (PEC) was observed *in vitro*.

MATERIALS AND METHODS

Media and reagents

The medium used for all experiments and cell maintenance was RPMI 1640 (Gibco, USA). ABC kit and IL2 were purchased from Vactastain and

Ellite Co. Ltd, USA respectively. Na₂⁵¹CrO₄ was supplied by the Isotope Institute of Chinese Academy of Medical Sciences.

Animals and cell lines

Capan-2 cell line was obtained from the University of California, USA, and Balb/c mice from the Experimental Animal Center of Sun Yat-Sen University of Medical Sciences.

Monoclonal antibodies

YPC3 mAb was extracted from acites pretreated with YPC3 hybridoma cells in Balb/c mice and purified as described previously^[4,5]. 1-F/7 mAb against Dengue fever virus was provided by the Department of Microbiology of Sun Yat-Sen University of Medical Sciences. Both mAbs were dissolved in pH 7. 4, 0.01M PBS (0.5g/L). Immunoreactivity was assessed by enzyme-linked immunosorbent assay (ELISA) on Capan-2 cells and avidin-biotin-peroxidase complex (ABC) immunohistochemistry of Capan-2 xenograft samples according to the methods described previously.

Effector cells (E)

One mL of incomplete RPMI 1640 medium was injected into the peritoneal cavity of Balb/c mice for 3 days in order to increase the number of PEC in mice. PEC was harvested by lavage of the peritoneal cavity of mice, washed, centrifuged twice and suspended in RPMI 1640 medium with 15% FBS at a concentration of 3-5 \times 10⁶/mL. PEC was further fractionated into non-adherent and adherent cells by 2 h incubation in glass dish. Non-adherent cells were removed by washing three times with warm medium. Adherent cells (more than 85% of macrophages) were resuspended to a final density of 10⁶ cells/mL. PHA and IL2 (1000 U/mL) were added to adherent cell culture flasks. The flasks were incubated at 37 °C for 3 days at a humidified 5% CO₂ atmosphere. The cells were then collected, washed and resuspended in complete medium. Adherent PEC without r-IL2 served as control cells. Lymphocytes generated from murine splenic cells were used for experimental comparison.

Cytotoxicity test^[6,7]

Four hours ⁵¹Cr-release assay was used to evaluate the cytotoxicity of peritoneal macrophages and lymphocytes activated by r-IL2. ⁵¹Cr labeled Capan-2 cells acted as target cells (T). E/T ratio was 25/1. The percentage of specific cytolysis in triplicate cultures was calculated by the formula:

$$\% \text{ specific cytolysis} = \frac{\text{Experimental cpm} - \text{spontaneous cpm}}{\text{Maximum cpm} - \text{spontaneous cpm}} \times 100$$

Maximum cpm was measured after incubation with 0.1N HCl. The spontaneous cpm, measured by incubation of the target cells alone, should be less than 30% of maximum cpm. To test ADCC, 25 mg/L of mAbs was incubated with the target cells for 30 min before addition of the effector cells. The percentage of specific cytolysis for ADCC was determined as described above.

RESULTS

mAb immunoreactivity assessment

Measured by ELISA on Capan-2 cells, the titer of YPC3 mAb (0.5 g/L) was more than 1:1000. YPC3 mAb was reacted with most of the pancreatic carcinoma cells determined by ABC immunohistochemistry on Capan-2 xenograft samples. No immunoreaction was found with control 1-F/7 mAb in ELISA and ABC immunohistochemistry. The results showed that YPC3 mAb might combine selectively with Capan-2 human pancreatic carcinoma cells.

The cytotoxicity of peritoneal macrophages activated by r-IL2 and YPC3 mAb

Table 1 shows that the cytolysis of peritoneal macrophages was evidently enhanced after activated by r-IL2 and YPC3 mAb. The percentage of cytolysis of peritoneal macrophages+Y-IL2+YPC3 mAb was 70.0%, 67.1% and 39.4% higher than the single peritoneal macrophages, peritoneal macrophages+Y-IL2 and peritoneal macrophages+YPC3 mAb, respectively. 1-F/7 mAb had no significant effect on cytotoxicity of peritoneal macrophages against Capan-2 cells.

Table 1 Cytolysis of peritoneal macrophages with different agents

Groups	n	Cytolysis (% , $\bar{x} \pm s$)
Macrophages	3	27.72 \pm 1.52 ^a
Macrophages+ γ -IL2	3	22.47 \pm 4.32 ^a
Macrophages+YPC3 mAb	3	26.67 \pm 1.58 ^a
Macrophages+ γ -IL2+1 F/7 mAb	3	27.02 \pm 2.78 ^a
Macrophages+ γ -IL2+YPC3 mAb	3	37.06 \pm 10.78

^aP<0.05, vs macrophages+Y-IL2+YPC3 mAb.

The comparison of ADCC between the effect of peritoneal macrophages and splenic lymphocytes activated by γ -IL2

Y-IL2 is a multifunctional protein which influences

numerous cell types and activates both macrophages and lymphocytes. Essentially similar cytotoxicity levels of activated macrophages and lymphocytes were obtained with 25 mg/L of YPC3 mAb (37.06 \pm 10.78 and 30.13 \pm 9.15 respectively, P>0.05). The results indicated that ADCC depended mainly on the reaction of antibodies with membrane antigens expressed on the target cells.

DISCUSSION

ADCC is a mechanism of immunologic lysis, in which cellular targets sensitized by specific antibodies are selectively lysed by FcR bearing nonsensitized effector cells^[6]. Macrophages bearing Ig-FcR have ADCC effect on tumor cells mediated specific anti-tumor mAbs. This ADCC is one of the important killing mechanisms of macrophages^[3].

Murine YPC3 mAb, belonging to IgG1 isotype, was produced against the human pancreatic carcinoma cell line. It reacted with pancreatic carcinoma in 28/32 patients, did not react with 11 normal human pancreas tissues and only 9/78 non-pancreatic tumors showed weak cross-reaction by ABC immunohistochemistry^[4]. Radioimmunolocalization of human pancreatic carcinoma by ^{99m}Tc labeled YPC3 mAb was achieved in Balb/c nude mice^[5]. YPC3 mAb increased the anti pancreatic carcinoma efficacy of splenic LAK cells *in vitro* and the simultaneous injection of LAK cells and YPC3 mAb completely inhibited the growth of Capan-2 cell line in nude mice^[7]. In this experiment, YPC3 mAb showed good affinity with Capan-2 cells and good synergism with Y-IL2. When combined with r-IL2, YPC3 mAb enhanced the cytolysis of peritoneal macrophages on Capan-2 cells, which was 70% more than peritoneal macrophages alone, and was higher than that of 1-F/7 mAb.

Some curative effects of lymphokine-activated killer cells and interleukin 2 alone on metastatic carcinoma of serosa cavity have been progressed. But the therapy needed a lot of effector cells and large doses of activators with obvious side-effect^[8,9]. Kawase *et al*^[3] reported that combined therapy of C3H/HeN mice bearing ascitic MH134 hepatoma with ip injection of γ -IL2 and tumor specific 11G2 mAb brought about potent suppression of the tumor growth, resulting in the significant increase in the number of tumor-free mice, whereas neither Y-IL2 nor the mAb could exhibit such a potent antitumor effect when used alone. The results provided possibility that antitumor mAbs capable of inducing ADCC could overcome a limitation of LAK therapy.

The prognosis of pancreatic carcinoma remains poor because of early peritoneal metastasis and lack of effective therapy in advanced patients^[10,11]. The combination of γ -IL2 and YPC3 mAb can increase

the effect of anti-pancreatic carcinoma *in vitro*. Ip injection of γ -IL2 and YPC3 mAb may provide a new way for local treatment of pancreatic carcinoma. But the research in the host bearing pancreatic carcinoma will be continued.

Subject headings pancreatic insufficiency/diagnosis; amino acid consumption test; cerulein cholelithiasis

Lei ZM, Li DY, Li J, Wang Q, He K, Zheng SL, Gan YG. Diagnostic value of amino acid consumption test on exocrine pancreatic insufficiency. *World J Gastroentero*, 2000;6(2):290-292

INTRODUCTION

Amino acid consumption test (AACT) has a high sensitivity and specificity in evaluating exocrine pancreatic insufficiency^[1,2], but its diagnostic value to exocrine pancreatic insufficiency in Chinese has not been well understood. In this study, the oral reagent stimulating pancreatic secretion (O-AACT) was used instead of cerulein (I-AACT) for amino acid consumption test and the diagnostic efficiency of O-AACT was evaluated and compared with I-AACT on the exocrine pancreatic insufficiency in Chinese.

MATERIALS AND METHODS

General data

A total of 176 volunteers and patients, divided into three groups, were studied after giving written informed consent.

Group 1. Normal controls consisting of 12 males and 8 females, aged 20-51 years. None of them had evidence of digestive diseases, and were alcoholics.

Group 2. Cholelithiasis group consisting of 31 males and 45 females, aged 22-60 years, including 44 cases with gallstone, 5 with common bile duct stone and 27 with intrahepatic lithiasis. Those who had any evidence of pancreatitis, acute cholangitis, or diabetes mellitus had been excluded.

Group 3. Pancreatic disease group consisting of 49 males and 31 females, aged 23-71 years, including 28 cases of pancreatic cancer, 19 of periampulla of Vater tumor, 12 of chronic pancreatitis (CP) complicated with pancreatic cysts, 12 with

common bile duct cyst complicated with CP, and 9 of CP. Those diagnoses were supported by the typical clinical manifestations and based on generally accepted morphologic alteration suggestive of pancreatic disease found in at least one of the following procedures: CT, surgery and/or pathology.

All patients received I-AACT and N-benzoyl-L-tyrosyl-para-aminobenzoic acid (purchased from Chongqing Medicine Industrial Laboratory) test (BT-PABA test). Among them, 12 in Group 1, 36 in Group 2 and 48 in Group 3, were also examined by O-AACT. Each test was made at an interval of two or three days. Gallbladder volume was determined by ultrasonography (US) at 0, 30, 45, 60, 90 and 120 min in 6 volunteers in Group 1 after drinking one of the three kinds of reagents stimulating pancreatic secretion at an interval of two days.

Methods

BT-PABA test This test was performed according to Imondi's method^[3]. The cut off limit for normal results was 45.0% of the orally administered dose.

I-AACT test According to Gullo's method^[2], the test was made in the morning after an overnight fast. Each of 176 subjects received a continuous intravenous infusion of cerulein (50ng/kg·h) (Purchased from Sigma Com., USA.) for an hour dissolved in 0.9% NaCl solution. During each study blood samples for amino acid determination were taken before the infusion was started at 0 min and during the infusion at 45 min, 60 min and 30 min after the infusion was stopped. Total plasma amino acid was estimated by the sodium-β-naphthoquinone-4-sulfonate salt colorimetric method. The individual basal amino acid level was taken as 100% standard for final calculations, the relative reduction rate of the amino acid levels at each time was calculated. Decrease by over 14.0% in plasma amino acid concentration was used as a normal limit index of pancreatic function.

O-AACT Oral reagent stimulating pancreatic secretion was used instead of infusion cerulein in AACT, the other procedure was similar to I-AACT. The oral reagent stimulating pancreatic secretion consists mainly of:

A. Salad oil 1 mL/kg, 0.1 mol/L HCl

¹Department of Hepatobiliary Surgery, Affiliated Hospital of Luzhou Medical College, Luzhou 646000, Sichuan Province, China
Zheng Ming Lei, graduated from West China Medical University as a master in 1990, now associate professor of hepatobiliary surgery, having 29 papers published.

Correspondence to: Zheng Ming Lei, Department of Hepatobiliary Surgery, Affiliated Hospital of Luzhou Medical College, Luzhou City 646000, Sichuan Province, China

Received 1999-05-09 **Accepted** 1999-12-19

0.2 mL/kg, saccharose 0.5 g/kg added with water to 100 mL.

B. Salad oil 1.5 mL/kg, 0.1 mol/L HCl 0.2 mL/kg, saccharose 0.5 g/kg, added with water to 200 mL.-C. Salad oil 2.0 mL/kg, 0.1mol/L, HCl 0.2 mL/kg, saccharose 0.5 g/kg added with water to 200 mL.

Gallbladder volume Gallbladder volume (Ellipsoid formula $V=0.52 \times l \times b \times h$)-was measured by US each time before and after drinking the reagent stimulating pancreatic secretion.

Statistical analyses were made using Chi-square test, and analysis of variance.

RESULTS

The change of plasma amino acid level in I-AACT

Basal amino acid (AA) levels of all subjects varied between 1.12 mmol/L and 6.8 mmol/L. During intravenous infusion of cerulein, the levels of plasma AA in all subjects of three groups gradually decreased, the 13,45 and 5 cases had relative decline rate over 14.0% in Groups 1-3 at 45 min respectively, and 18, 68 and 11 cases at 60 min. Thereafter, plasma AA levels returned slowly toward initial AA values. The relative decline rate of plasma AA levels of 8 cases in Group 2 and 67 cases in Group 3 were still lower than 14.0% at 90 min.

The selection of oral reagent stimulating pancreatic secretion

When reagent A or B was selected, all volunteers, except two people who had slight flatulency, could drink all the reagent without discomfort. But after drinking a cup of reagent C, three volunteers had vomit and exited from the study, and gallbladder contraction occurred earlier in other three volunteers (Table 1). Reagent A was finally selected as the reagent stimulating pancreatic secretion in O-AACT because it caused steady gallbladder constriction.

Table 1 Gallbladder volume change after taking reagent

Time	$(\bar{x} \pm s, \text{ml})$		
	Reagent A $n = 3$	Reagent B $n = 6$	Reagent C $n = 6$
0 min	17.22±3.55	16.58±3.04	14.97±5.23
30 min	12.85±6.34	13.78±2.69	8.87±2.10
45 min	12.12±2.25 ^a	13.27±2.96	8.70±1.13
60 min	9.68±3.30 ^a	6.71±2.66 ^a	12.03±3.05
90 min	6.28±3.51 ^a	4.93±1.89 ^a	13.97±9.06
120 min	12.27±5.42	11.40±4.79	15.47±5.94

^a $P < 0.05$ in comparison with 0 min in the same group. Analysis of variance: $F_A = 4.2799$ ($F_{45} = 8.8133$, $F_{60} = 14.4901$, $F_{90} = 28.7727$), $F_B = 12.1610$ ($F_{60} = 35.8538$, $F_{90} = 63.6581$)

The change of plasma amino acid level in O-AACT

During O-AACT, plasma AA levels gradually decreased, then returned slowly toward initial AA values. The change was similar to that in I-AACT (Table 2).

Table 2 The change of plasma amino acid level in O-AACT and I-AACT ($\bar{x} \pm s$, mmol/L)

AACT	Time (min)	Group 1 ($n = 12$)	Group 2 ($n = 36$)	Group 3 ($n = 48$)
I-AACT	0	4.23±0.78	4.64±1.49	3.91±1.32
	45	3.13±0.068 ^{a1}	3.53±1.49 ^{a6}	3.65±1.19
	60	2.68±0.85 ^{a2}	3.09±1.21 ^{a7}	3.49±1.19
	90	3.67±0.90	4.08±1.47	3.66±1.24
O-AACT	0	4.24±1.19	4.67±1.45	3.99±1.26
	45	2.73±0.99 ^{a3}	4.05±1.43	3.57±1.24 ^{b1}
	60	2.05±0.94 ^{a4}	3.01±1.17 ^{a8}	3.60±1.20 ^{b2}
	90	2.94±1.12 ^{a5}	3.84±1.49 ^{a9}	3.89±1.29

^a $P < 0.05$, in comparison with 0min in the same group and the same method. Analysis of variance:

^{a1} $F = 13.679$, ^{a2} $F = 21.45$, ^{a3} $F = 11.487$, ^{a4} $F = 25.095$, ^{a5} $F = 7.637$, ^{a6} $F = 9.938$, ^{a7} $F = 23.792$, ^{a8} $F = 28.622$, ^{a9} $F = 5.799$.

^b $P < 0.05$, in comparison with Group 1, analysis of variance:

^{b1} $F = 4.746$, ^{b2} $F = 17.379$.

Comparison of the diagnostic value of BT-PABA, O-AACT and I-AACT

Table 3 shows the number of cases of each group diagnosed as exocrine pancreatic insufficiency by BT-PABA, O-AACT or I-AACT. The diagnostic value of BT-PABA, O-AACT and I-AACT to exocrine pancreatic insufficiency is summarized in Table 4.

Table 3 The number of cases in each group diagnosed as exocrine pancreatic insufficiency

%	Group 1	Group 2	Group 3
O-AACT	12	36	48
>14.0%	11	30	13
14.0%	1	6	35 ^a
I-AACT	20	76	80
>14.0%	20	68	13
>14.0%	0	8	67 ^b
BT-PABA	20	76	80
>45.0%	20	62	16
>45.0%	0	14	64 ^c

$P < 0.05$ in comparison with groups 1 and 2. Chi-square test (χ^2): a=33.439, b=102.208, c=77.848.

Table 4 The diagnostic value of BT-PABA, O-AACT and I-AACT in exocrine pancreatic insufficiency

	Sensitivity (%)	Specificity (%)	Accuracy (%)
O-AACT	72.9	85.4	79.2
I-AACT	83.8	91.7	88.1
BT-PABA	80.0	85.4	83.0

Chi-square test: $P > 0.05$.

DISCUSSION

Exocrine pancreatic function test is generally divided into direct test (e.g., pancreozymin-secretin test, cerulein test, etc.) and indirect test (pancreolauryl test, BT-PABA test, etc.). Although it is more sensitive and accurate in diagnosis of exocrine pancreatic insufficiency, the direct test is not widely used in clinical practice because it is complex, time consuming, and bringing more sufferings to patients. Indirect test is simple, but with low specificity and accuracy in diagnosis of exocrine pancreatic insufficiency. Domschke detected the change of plasma AA level before and after intravenous infusion of cholecystokinin and secretin to diagnose exocrine pancreatic insufficiency, and the accuracy being 91.0%, which was confirmed further by Gullo who used cerulein instead of cholecystikinin and secretin stimulating pancreatic secretion.

The diagnostic value of AACT in exocrine pancreatic insufficiency in Chinese has not been well understood because of the difference in race, living custom, geography, and the high fat and protein food and higher incidence of chronic pancreatitis in Europe and America, but more carbohydrate food and lower incidence of chronic pancreatitis in this country. Our study shows that the diagnostic accuracy of AACT for exocrine pancreatic insufficiency in Chinese was similar to that in European and American people. But attention should be paid to the following points: ① The relative decline rate over 14.0% of plasma AA was found only in 13 and 45 cases of Groups 1 and 2 during intravenous infusion of cerulein at 45 min, and in 18 and 68 cases at 60 min, the maximum decrease of plasma AA occurred later than that of

Gullo's report. Therefore, the results should be analyzed in combination at 45 min, 60 min and 90 min. ② Venous blood should be collected gently to avoid hemolysis. Incorrect deproteinization or not done in time will lead to bias in results.

To further reduce the test cost and illumed by the idea of Lundh test, we used oral reagent free from amino acid instead of intravenous infusion of cerulein in AACT. Because the volunteers would not like intubation in duodenum, gallbladder contraction function was observed after drinking of reagent A to view indirectly the effect of the oral reagent stimulating pancreatic secretion, based on the theory that hydrochloric acid and fat stimulate bile and pancreatic fluid secretion, and gallbladder contraction.

In this study, we found that O-AACT, based on the same design theory of I-AACT, is simple, inexpensive and easy to accept and plays a good screening role in evaluating severe exocrine pancreatic insufficiency. But whether it is applicable to diagnosis for slight and moderate exocrine pancreatic insufficiency should be further studied.

Effect of emodin and sandostatin on metabolism of eicosanoids in acute necrotizing pancreatitis

Jian Xin Wu¹, Jia Yu Xu² and Yao Zong Yuan²

Subject headings pancreatitis; eicosanoids metabolism; emodin ; sandostatin

Wu JX, Xu JY, Yuan YZ. Effect of emodin and sandostatin on metabolism of eicosanoids in acute necrotizing pancreatitis. *World J Gastroenterol*, 2000;6(2):293-294

INTRODUCTION

In order to study the therapeutic mechanisms of emodin, an extract of Rhubarb (*Rhizoma et Radix Rhei*, a traditional Chinese herbal medicine), and sandostatin in the treatment of acute necrotizing pancreatitis (ANP), we used the two drugs in rat models of the disease and observed the changes of plasma thromboxane -2 (TXB₂), 6-keto-prostaglandin F_{1α} (6-keto-PGF_{1α} and prostaglandin E₂ (PGE₂).

MATERIAL AND METHODS

Animals and reagents

One hundred and sixty male Sprague-Dawley (SD) rats (Shanghai Birth Control Institute, Shanghai) weighing 220g-280g were used. Emodin (Natural Medicine Institute, Pharmacology School of Shanghai Medical University, Shanghai); sandostatin (Sandoz Co.); sodium taurocholate (Sigma); radioimmunoassay kits of PGE₂, 6-keto-PGF_{1α} and TXB₂ (Institute of Thrombosis and Coagulation, Suzhou Medical College).

Methods

The rats were divided randomly into 4 groups. After fasted (water allowed over 12 hours, the rats were anesthetized with 2.5% pentobarbital (0.1 mL/100g, i.p.), and a constant venous infusion route (1 mL/h) was established via *vena femoralis*. The peritoneum cavity was then cut open and the pancreatocolangioduct was cramped at both the duodenal and hepatoportal ends before 5% sodium taurocholate solution (0.1 mL/100 g)

was injected into the duct for 1 minute followed by a pause of 4 minutes. Then, the following drugs were infused intravenously: emodin, 0.25 mg/100 g, every 6 hours in emodin group; or sandostatin, 0.2 μg/100 g in sandostatin group, or normal saline in sham-operation group in which no taurocholate was used or in controls. The rats were killed 3, 6 and 12 hours after onset of the disease and the survival number was recorded. Samples of blood, ascites and pancreas were collected for detection of PGE₂, TXB₂, 6-keto-PGF_{1α} (RIA), serum amylase, lipase (Bechman Biochem System and Kits) and pathological observation under light microscope or transmission electronmicroscope (TEM). Pancreatic pathological scoring was made by Schmidt method^[1] double-blindly.

Statistics

Test of homogeneity of variance, analysis of variance, Student-Newman-Keuls (SNK) test, *t* or *t'* test and χ^2 test.

RESULTS

Survival rate of the rats

The 12 hour survival rate in emodin group was 56.3% (9/16) and 62.5% (10/16) in sandostatin group; both were significantly higher than that of control group (23.8%, 5/21; *P*<0.05, *P*<0.01). However, no significant difference was found between emodin and sandostatin groups.

Metabolites of eicosanoids

TXB₂ detected at 3, 6, and 12 hours after ANP in control group was significantly higher than that of sham-operation group, the highest value, 4.5 times was at 6 hours (*P*<0.01, Table 1), while 6-keto-PGF_{1α} in each detection was lower as compared with that of sham operation group, but no significant difference was found. TXB₂ was decreased obviously in each detection in both emodin, and sandostatin groups in comparison with that of control group (*P*<0.01). But at 12 hours after ANP, TXB₂ was lower in emodin group than that of sandostatin group. PGE₂ or 6-keto-PGF_{1α} was higher in the 2 drug-given groups than that of control group, but with no statistical significance.

Enzyme activities, ascites volume and pathological findings

Serum amylase, lipase and ascites were significantly

lower in two drug-given groups than that in control group ($P<0.05$). In sandostatin group, two enzyme parameters were lower than that in emodin group, but only amylase showed significant difference ($P<0.01$). Compared with that in control group, the pathological scores of necrosis of acinar cells were markedly lower either in emodin or sandostatin group ($P<0.05$; $P<0.01$, Table 2), but there was no significant difference between the

2 drug-given groups. Obvious karyopyknosis, nuclear degeneration, cytolysis, and lots of microthrombi in capillaries were found under TEM in control group, while in 2 drug-given groups, there were much less acinar necrosis and microthrombosis, and the major changes were pachynesis, autophagocytic vacuoles or bodies, swollen mitochondria and distorted endoplasmic reticulum.

Notes: compared with control group, ^a $P<0.05$, ^b $P<0.01$.

DISCUSSION

Rats with taurocholate-induced ANP might simulate human biliary (bile reflux) pancreatitis. The predominant pathophysiological change is severe disturbance of pancreatic microcirculation accompanied by abnormal metabolism of eicosanoids which precedes pancreatic bleeding and necrosis. Pancreas is the main site of the abnormal metabolism of eicosanoids in ANP; after that is the blood (platelet)^[1]. TXB₂ and 6-keto-PGF_{1 α} are stable metabolites of TXA₂ and PGI₂, respectively. The former is a strong microvascular constrictor and an agonist of platelet aggregation as well. It can induce deformation, release and secretion of platelets, resulting in local or systemic disorders of coagulation and bleeding. Pancreatic ischemia became worse with complete destruction of pancreatic cytoprotection^[2]. Some authors employed selective inhibitors of synthesis of TXB₂, or exotic PGE₂ in rats with ANP, and discovered that the mortality was reduced^[3]. These results, together with ours, suggested the role of abnormal metabolites of eicosanoids in the pathogenesis of ANP and possible therapeutic strategies to be adopted. Meanwhile, our study demonstrated that,

besides traditional viewpoints, inhibition of abnormal metabolism of eicosanoids, promotion of pancreatic cytoprotection, prevention of coagulation and microthrombosis and improvement of pancreatic microcirculation should also undoubtedly be included in the mechanism of the therapeutic roles of emodin as well as sandostatin in the treatment of ANP.

In conclusion, it can be suggested that, the mechanisms of emodin or sandostatin in the treatment of ANP should include modulation of abnormal eicosanoid metabolism and restoration or promotion of pancreatic cytoprotection which might be more important than the well-known "anti-enzyme" or "anti-secretion" speculation.

INTRODUCTION

The treatment of human epithelial malignancies is limited by drug resistance and toxic and side effects, which results in the failure in the treatment of majority of advanced cancer victims. To seek for a new, and specific antineoplastic therapy will provide hope for tumor treatment. Although disordered intermediary metabolism in cancer cells has been known for many years, much of the work focused on abnormal glucose catabolism. At the same time, little attention has been paid to fatty acid synthesis in tumor tissues, despite of the significance of fatty acid synthase (FAS) in some clinical human ovarian^[1], breast^[2], colorectal^[3], and prostatic cancers^[4,5]. Tumor cells which express high levels of fatty acid synthesizing enzymes use endogeneously synthesized fatty acids for membrane biosynthesis and appear to export large amounts of lipid. In contrast, normal cells preferentially utilize dietary lipid.

The mechanism by which inhibition of fatty acid synthesis produces its antitumor effects remains unexplained. In this study, we studied the effect of fatty acid synthase inhibitor-cerulenin, on the proliferation and apoptosis of colonic cancer cells.

MATERIAL AND METHODS

Cell lines and culture condition LoVo cells were maintained in RPMI 1640 with 10% fetal bovine serum. Cultures were incubated at 37°C in a humidified 5% CO₂ atmosphere. A 5 g/L stock

solution of cerulenin (Sigma Chemical Co.) in DMSO was diluted to a final concentration of 5 mg/L or 10 mg/L. Human fibroblasts (collected from clinical operation) were cultured in RPMI 1640 for six generations, and then were maintained in the same growth medium as LoVo cells.

Morphological evaluation Exponentially growing LoVo cells were incubated with or without cerulenin in RPMI1640 for 24h and collected after trypsinase was digested. The cells were spun onto glass slides, fixed in methanol, and stained by Wright-Giemsa's method. The slides were observed under Olympus light microscope.

Clonogenic assay Using limiting dilution method, LoVo cells were inoculated at 50 colony-forming cells/well into 96-well plates and incubated for 10 days, with triplicate cultures plated at each drug concentration (1.0×10⁻⁵ mol/L-1.0⁻⁹ mol/L). Colonies of greater than 50 cells were counted for all clonogenic assays. The rate of colony forming = (average colony number/planted single cell number)×100%. The rate of colony forming inhibition = (control colony forming rate-experimental colony forming rate)/control colony forming rate×100%.

Cell proliferation inhibition experiment (MTT) LoVo cells were inoculated at 8×10⁴ cell/mL into 96-well plates and incubated 24 h. Cerulenin of 1.13×10⁻⁵ mol/L-1.13×10⁻⁹ mol/L in concentration was given to the experimental group. Each well was added with 20 μL (5 g/L) MTT and incubated for 4 h. The plates were read on Dynatech microplate reader MR600 at 570 nm.

DNA fragmentation assay LoVo cells were incubated with or without cerulenin in RPMI1640 for 12h and collected after trypsin was digested. At harvest, medium and trypsinized cells were combined, and DNA was extracted from pelleted cells and subjected to 1.5% agarose gel. DNA was electrophoresed for 3 hours at 5 v/cm. The results were observed and photographed by UV light.

RESULTS

Inhibition of cell proliferation in human colonic cancer cells by cerulenin

The effects of fatty acid synthase inhibitor on cell

growth were examined by MTT method. The inhibitory effects on proliferation are shown in Figure 1. Cerulenin can inhibit significantly the proliferation of LoVo cells and showed dose-response relationship. Therefore, FAS inhibitor-cerulenin might suppress the proliferation of human colonic cancer cells.

Figure 1 Cell proliferation inhibition experiment (MTT).

Reduction of clonogenic potential of human colonic cancer cells after cerulenin treatment

To assess the cellular consequences of fatty acid synthesis inhibition, the clonogenicity of LoVo cell was determined after a 10-day exposure to cerulenin (Table 1). LoVo cell line exhibited dose-dependent reduction in clonogenic potential.

Induction of apoptosis of human colonic cancer cells by cerulenin

The cytotoxic effects of cerulenin must occur within the context of cellular response. A wide variety of cellular injuries in cell death by initiating a cellular program for autodestruction, or apoptosis. Fragmentation of genomic DNA to high molecular weight (180 kb-200 kb) fragments is a characteristic early event in apoptosis and may represent the committed step of the process. Agarose gel electrophoresis was used to evaluate whether high molecular DNA fragmentation was a feature of the cellular response to cerulenin. LoVo cells generated detectable high molecular weight DNA fragments within 12 h after exposure to cerulenin. So, internucleosomal DNA can be detected on agarose gel as a ladder of DNA fragment (Figure 2). To confirm that the cytotoxic effects of cerulenin were mediated via apoptosis, and the treated cells were examined for morphological changes of apoptosis.

Figure 2 DNA fragmentation assay by agarose gel electrophoresis.

DISCUSSION

Fatty acid synthase played an important role in de novo biosynthesis of fatty acid and consists of two identical subunits each with M 250000 in cancer cells. Pizer *et al* reported that OVCAR-3 cells showed a range of elevation fatty acid synthesis in the carcinoma lines, which elevated approximately 10-fold above the level of control skin fibroblasts^[1]. The fungal metabolite, cerulenin, (2S-3R)-2-epoxy-4-oxo-7E, 10E-dodecadienamide], a specific, non-competitive inhibitor of fatty acid synthase, binds covalently to the condensing enzyme site on fatty acid synthase, causing complete inactivation^[6,7]. The condensing enzyme site on fatty acid synthase utilizes a biochemically distinctive catalytic mechanism which is not shared by other vital cellular enzymes and is thus well suited to be a therapeutic target. Our data showed that fatty acid synthase inhibitor-cerulenin could suppress the proliferation of LoVo cells *in vitro*, at the same time, it showed a dose-response relationship. We also found that cerulenin is indeed cytotoxic to cancer cells by clonogenic assay.

It is emphasized that there was a close relationship between apoptosis and proliferation in malignant neoplasm cells^[8,9]. In this study, we found that cerulenin could induce LoVo cells to die via apoptosis. Apoptotic cells demonstrated cell shrinkage, condensation and fragmentation of chromosomes. Nuclear DNA of apoptotic cells displayed ladder bands characteristic of internucleosomal DNA fragmentation. The data reported here demonstrated that inhibition of fatty acid synthesis inflicted rapid, lethal injury to carcinoma cells via activation of the cell death program. It is similar to that both FAS inhibitors produced rapid, profound inhibition of DNA replication and S phase progression in human cancer cells, meanwhile, apoptosis changes were detected^[10].

Table 1 The effects of cerulenin on proliferation of LoVo cells by means of clonogenic assay ($\bar{x} \pm s$)

	1×10^{-5} mol/L	1×10^{-6} mol/L	1×10^{-6} mol/L	1×10^{-6} mol/L	1×10^{-6} mol/L

Cerulenin	100 ^b	96.58 \pm 4.14 ^a	51.19 \pm 4.38 ^b	39.52 \pm 2.93	33.53 \pm 3.98 ^a

^a $P < 0.05$, vs DMSO control; ^b $P < 0.01$, vs DMSO control.

The strategy of cancer chemotherapy by FAS inhibition was based on the therapeutic index provided by elevated fatty acid synthesis in tumor cells and the apparent tumor preference for the endogenous pathway. Our data proved in principle that the metabolic pathway leading to *de novo* fatty acid synthesis was selective target for antimetabolic chemotherapy of cancer. Selectivity was conferred by two major factors ① LoVo cells, like some other human cancers, appear to be dependent on *de novo* fatty acid biosynthesis and therefore sensitive to FAS inhibition; and ② normal tissues (e.g. fibroblasts) seem predominantly to utilize dietary lipid and therefore to be resistant to the cytotoxic effects of FAS inhibition^[8]. Possible functional roles for endogenously synthesized fatty acid in cell growth include synthesis of structural lipids for membrane biosynthesis and lipid mediators of intracellular, autocrine or paracrine signals, as well as acylation of other macromolecules. It does appear, however, that for unclear reasons, certain tumors have an apparently obligatory requirement for endogenous fatty acid biosynthesis whereas normal cells do not, suggesting that inhibition of fatty acid biosynthesis may be a fruitful target for chemotherapy development.

Effects of endotoxin on endothelin receptor in hepatic and intestinal tissues after endotoxemia in rats

Bao Hua Liu, Hui Sun Chen, Ji Hong Zhou and Nan Xiao

Subject headings endotoxin; endothelin receptor; liver; intestines; rats

Liu BH, Chen HS, Zhou JH, Xiao N. Effects of endotoxin on endothelin receptor in hepatic and intestinal tissues after endotoxemia in rats. *World J Gastroenterol*, 2000;6(2):298-300

INTRODUCTION

Endothelins (ETs) has a potent and sustained vasoconstrictive effect on a variety of blood vessels. The vascular smooth muscle cell (VSMC) is the target for ETs. VSMC of the whole body contains endothelin receptor (ETR)^[1]. A great number of experiments have shown that three distinct complementary DNAs of ETR have been identified i.e., endothelin A receptor (ET-A receptor), endothelin B receptor (ET-B receptor) and endothelin C receptor (ET-C receptor). ET-A receptor was expressed in VSMC responsible for the contraction^[2]. The aim of this study is to confirm the effects of endotoxin on the activity of ETR, and the transcription and expression of ET-A receptor mRNA in hepatic and intestinal tissues.

MATERIALS AND METHODS

Materials

Endotoxin (O111:B4) and porcine endothelin-1 (ET-1) were purchased from Sigma Chemical Co. ¹²⁵I-ET-1 was supplied by Isotope Institute of Chinese Academy of Sciences. Digoxigenin DNA labeling and Detection Kit was provided by Boehringer Mannheim Co.

Methods

Thirty male and female Wistar rats weighing 210 g-215 g were fasted with access to water and libitum for 24 hours before experiment. Six rats were used as the control group. The others were given endotoxin at a dose of 10 mg/kg as an endotoxin-

treated group. All rats were killed at the 3rd, 6th, 12th, and 24th hour after administration of endotoxin and saline, with 6 rats in each group at each time point. After sacrifice by decapitation at the respective time points, the right hepatic and intestinal tissues were immediately removed and preserved in liquid nitrogen for use.

The hepatic and intestinal plasma membrane was prepared by the method of Koseki and Imari^[3] with minor modifications. The hepatic and intestinal tissue was homogenized in 10 vol (wt/vol) of 0.25 mol sucrose including 1mmol EDTA, and the homogenate was centrifuged at 10000×g for 10 minutes. The supernatant was centrifuged at 100000×g for 1 hour. The entire procedure was performed at 4 °C. The resulting pellet was resuspended in 200 μL of 0.25 mol/L sucrose including 1mmol EDTA, and kept in the deep freezer for assay. Twenty μL aliquot of the microsomal fraction, containing 20 μg- protein in 0.25 mol sucrose including 1mmol EDTA, was kept at 4 °C for 24 hours, with various concentrations of ¹²⁵I-ET-1 in 20 μL of the incubation solution. Twenty μL of ice-cold incubation solution was added and then centrifuged at 80000×g at 4 °C for 30 min. The supernatant was rapidly aspirated. The radioactivity was determined with an FJ-2108 liquid scintillation counter. Specific binding was determined by the total binding minus the nonspecific binding. The maximal binding capacity (Bmax) and affinity (Kd) of ETR were obtained using Scatchard plot analysis.

Total cellular RNA was isolated from the hepatic and intestinal tissue with guanidinium thiocyanate-phenol-chloroform method^[4]. Dot blot was used to identify and quantify ET-A receptor mRNA. Results were scanned in the computer to determine their quantity.

Statistical analysis

The data were expressed as mean±SD. The difference between the groups was analyzed with Student's *t* test. The difference was considered significant at *P*<0.05.

RESULTS

The change of activity of hepatic and intestinal ETR

The values of the Bmax and Kd of ETR of the

normal hepatic and intestinal tissue are shown in Figures 1, 2. The K_d of ETR was 0.0328 in normal hepatic tissue, and 0.1263 in normal intestinal tissue. The B_{max} of ETR was 1.0288 in normal hepatic tissue, and 1.2303 in normal intestinal tissue. The B_{max} of ETR of the hepatic and intestinal tissue decreased gradually during endotoxemia. The B_{max} of ETR in the endotoxin-treated group decreased more significantly than that in the control group at the 3rd hour after endotoxin administration ($P<0.01$). The decrease of B_{max} lasted 24 hours. But the K_d of the hepatic and intestinal tissue did not change (Table 1).

The change of the relative quantity of ET_A receptor mRNA of hepatic and intestinal tissue
The relative quantity of ET_A receptor mRNA of hepatic tissue in the endotoxin-treated group increased more significantly than that in the control group at 3-24 hour ($P<0.01$). It increased most obviously at the 6th and the 12th hour after endotoxin administration (Table 2). Compared with the control group, the relative quantity of ET_A receptor mRNA of intestinal tissue in endotoxin-treated group also increased significantly between the 3rd and 12th hour after endotoxin administration ($P<0.01$) (Table 2).

DISCUSSION

ETs have been shown to be one of the most potent vasoconstrictors, which are produced not only by vascular endothelial cells, but also by a variety of non-endothelial cells, and have many biological functions^[5]. ETs should be combined with ETR of target cell, and activate a variety of signal transduction pathways so as to produce specific cellular responses^[6]. This study showed that the Kd of ETR of hepatic and intestinal tissue did not change during endotoxemia. The Bmax of ETR of hepatic and intestinal tissue in endotoxin-treated group decreased more significantly in early stage than that in control group. Decrease of the Bmax of ETR lasted 24 hours. The Bmax of ETR number of hepatic and intestinal tissue was the lowest at the 12th hour. After giving endotoxin, decrease of the ETR number of the hepatic and intestinal cell membrane was correlated with increase of ET-1 concentration (unpublished observation). Roubert *et al*^[7] reported that the 50% receptors of VSMC in culture were induced by 10^{-9} mol ET-1. During endotoxemia, the higher level of ET-1 was, the more ET-1 combined with the receptor, the lower number of receptor of cell membrane was, because the receptors of cell membrane combining with ET-1 squeezed into cells.

The relative quantity of ET_A receptor mRNA of hepatic and intestinal tissue increased obviously after endotoxin administration. This study showed that endotoxin could regulate transcription and translation of ET_A receptor mRNA. The results of ETR binding assay and ET_A receptor Dot blot

analysis showed that the ETR number of hepatic and intestinal cell membrane decreased, but the relative quantity of ET_A receptor mRNA of hepatic and intestinal tissue increased obviously in endotoxemia. It was likely that a mechanism of auto-regulation existed in the body. Down-regulation of ETR may be helpful in preventing endothelin from hypercontraction and reducing damage of tissues and organs. So it suggested that ETR may play an important role in the hepatic and intestinal pathophysiologic process following endotoxemia.

TEffects of rhubarb and the active ingredients of rhubarb on the cytoplasmic free calcium in INT-MNC of rabbits

Xiu Zhen Lin, De Lu Ma, Zhi Qing Cui and Yi Kang

Subject headings Fura-2/Am; rhubarb; emodin; sennosides; intestinal mononuclear cells; calcium

Lin XZ, Ma DL, Cui ZQ, Kang Y. Effects of rhubarb and the active ingredients of rhubarb on the cytoplasmic free calcium in INT-MNC of rabbits. *World J Gastroenterol*, 2000; 6(2):301-303

INTRODUCTION

The recent studies have shown that rhubarb has not only the effect of removing stasis by purgation, but also intestinal barrier effects^[1,2]. In order to further clarify the intestinal barrier mechanism of rhubarb, we studied the effects of rhubarb decoction and the active ingredients of rhubarb on the cytoplasmic free calcium in isolated intestinal mononuclear cells (INT-MNC).

MATERIALS AND METHODS

Materials

Fura-2/Am was purchased from the Shanghai Institute of Physiology, the Chinese Academy of Sciences. Eagle's MEM was purchased from Nissui Pharmaceutical Company, Japan. Collagenase (type IV) and emodin (EMD) were products of Sigma Chemical Co. Sennosides (SEN) was provided by the Department of Plant Chemistry of the Tianjin Institute of Materia Medica. Rhubarb decoction (equal to 1 g/mL of protophyte) was provided by the Department of Pharmacology of the Tianjin Acute Abdominal Institute of Integrated Traditional Chinese and Western Medicine. Dithiothreitol (DTT) was purchased from Feibiochemi.

Animals

Rabbits weighing 2.2 kg±1.2 kg, in either sex, supplied by the Animal Department of Tianjin Medical University. They were randomly divided into control, rhubarb, EMD and SEN groups.

Department of Pharmacology, Tianjin Medical University, Tianjin 300070, China

Xiu Zhen Lin, graduated from Chongqing Medical University in 1969, now professor of pharmacology, specialized in studies on mechanism of the acute abdomen by combined traditional Chinese and western medicine, having more than 30 papers published.

Preparation of INT-MNC suspension and Fura-2/Am loading

The rabbits were killed by a blow on the head and the abdomen was opened. Take 30 cm-40 cm of the ileum 10cm from the ileocecal part, wash out the stool and mucoid on the surface of the mucosa with Hank's solution (NaCl 137, KCl 5, Glucose 5.6 and Hepes 10 mmol/L, pH 7.4) which is Ca²⁺ and Mg²⁺ free. Take the intestinal mucosa gently with coverglass and put it into a conical flask containing Dithiothreitol (DTT, 1mmol/L) solution, swing and wash for 20 min at 37 °C, then put the mucosa into 5 mmol/L EDTA solution and swing for 30 min at 37 °C, and wash out the free epithelial cells using Hank's solution. Repeat the procedure of EDTA for 3 times. Then put the intestinal mucosa into Hank's solution containing collagenase. To digest it, swing for 3 h at 37 °C, filter 3 times with stainless sieve of 100 mesh. Put the cells into the lymphocyte separate solution and centrifuged at 500 rpm for 5 min. Take the cells of the middle layer (INT-MNC), wash with ice-cold Ca²⁺ and Mg²⁺ free Hank's solution and resuspend in Eagle's MEM solution and dilute to a concentration of 1-2×10⁸ mL/L.

Two mL cell suspension was incubated at super-thermostat water bath vibrator for 30 min in the presence of 5 µmol/L Fura-2/AM dissolved in dimethyl sulfoxide (DMSO) and 0.1% bovine serum albumin (37 °C, 40 rev/min, 95% O₂ + 5% CO₂). The Fura-2/AM-loaded INT-MNC was washed with Ca²⁺ and Mg²⁺ free Hank's solution and centrifuged at 1000 rpm for 10 min for three times. The INT-MNC was resuspended in 2 mL Ca²⁺ and Mg²⁺ free Hank's solution until use.

Fluorescence measurement and [Ca²⁺]_i calculated

The 2 mL Fura-2 loaded INT-MNC was incubated for 10 min at 37 °C for measurement. After the drugs were added and before measurement, the cell suspensions were blown and inspired 5-6 times with pipet to make the cell well distributed. Fura2/AM fluorescence was measured with RF-510 spectrofluorophotometer (Shimadzu, with thermostat). Emission wavelength (EM) was fixed at 490 nm. The excitation wavelength (EX) at 380 or 350 nm, the grating was 10 nm. The scanning speed was 100 nm/min. The changes of 350/380 nm fluorescence ratio were recorded by

alternating rapidly the EX of 350 nm and 380 nm manually (the rotating was finished within 4s-6s). The $[Ca^{2+}]_i$ was calculated using the general formula^[3] with K_d of 224 nmol/L: $[Ca^{2+}]_i = K_d \times (R - R_{min}) / (R_{max} - R) \times S$. Before calculation, the auto-fluorescence unloaded with Fura-2 should be subtracted.

Statistical analysis

The results were expressed as mean values of groups $\bar{x} \pm s$. The Student *t* test was used for statistical comparison of difference of mean values between groups.

RESULTS

The effects of $CaCl_2$ on $[Ca^{2+}]_i$

In the resting status, the INT-MNC $[Ca^{2+}]_i$ was $252.55 \text{ nmol/L} \pm 42.54 \text{ nmol/L}$ ($n = 10$) in Ca^{2+} free Hank's solution containing ethyleneglycol-bis (β -aminoethyl ether)- N,N',N',N' tetraacetic acid (EGTA) 0.5 mmol/L. After adding $CaCl_2$ (0.25 mmol/L, 0.75 mmol/L, 1.5 mmol/L and 2.5 mmol/L) to INT-MNC suspension sequentially, the $[Ca^{2+}]_i$ levels were obviously elevated as compared with that at resting state ($P < 0.01$, Figure 1). This indicated that $[Ca^{2+}]_i$ was increased with the extracellular calcium level.

The effects of rhubarb decoction and SEN on $[Ca^{2+}]_i$

The INT-MNC was pretreated with rhubarb decoction (1 mg/L, 2 mg/L) or SEN (0.021 mmol/L, 0.084 mmol/L) for 15 min, in the resting state or after adding the above doses of $CaCl_2$, the INT-MNC $[Ca^{2+}]_i$ was more obviously lowered than the control groups ($P < 0.01$, Figures 1,2). The results showed that both rhubarb and SEN decreased the INT-MNC $[Ca^{2+}]_i$.

Figure 1 Effects of rhubarb decoction on the increase of $[Ca^{2+}]_i$ induced by $CaCl_2$ in isolated rabbits intestinal mucosal INT-MNC. ^a $P < 0.05$, ^b $P < 0.01$ vs control. ● Control ($n = 8$); △ Rhubarb decoction 1mg/L ($n = 5$); ▲ Rhubarb decoction 2mg/L ($n = 5$).

Figure 2 Effects of SEN on the increase of $[Ca^{2+}]_i$ induced by $CaCl_2$ in isolated rabbits intestinal mucosal INT-MNC. ^a $P < 0.05$, ^b $P < 0.01$ vs control. ● Control ($n = 6$); △ SEN 0.021 mmol/L ($n = 5$); ▲ SEN 0.084 mmol/L ($n = 5$).

Figure 3 Effects of EMD on the increase of $[Ca^{2+}]_i$ induced by $CaCl_2$ in isolated rabbits intestinal mucosal INT-MNC. ^a $P < 0.05$, ^b $P < 0.01$ vs control. ● Control ($n = 10$); △ EMD 9.2 $\mu\text{mol/L}$ ($n = 10$); □ EMD 18.5 $\mu\text{mol/L}$ ($n = 8$); ■ EMD 37 $\mu\text{mol/L}$ ($n = 7$).

The effects of EMD on $[Ca^{2+}]_i$

After pretreated with EMD (9.2 $\mu\text{mol/L}$, 18.5 $\mu\text{mol/L}$, and 37 $\mu\text{mol/L}$) for 15 min, in the resting status or adding the above doses of $CaCl_2$, the INT-MNC $[Ca^{2+}]_i$ was significantly increased as compared with that of the control groups ($P < 0.01$, Figure 3). The results showed that EMD promoted not only the release of intracellular Ca^{2+} but also the extracellular influx.

DISCUSSION

Intestine is one of the largest immune organs. Intestinal mucosa immune defence system is made up of correlative lymphoid tissues. INT-MNC mainly consists of macrophage and lymphocytes. The separated INT-MNC produces immunoglobulin (Ig) spontaneously *in vitro*^[4]. It has an important effect on the immune regulation. Intracellular Ca^{2+} can regulate the endocrine system. When the Ca^{2+} level increases, Ca^{2+} produces physiologic effect as a

stimulant. But when intracellular Ca^{2+} has overloaded, the function of cell arrests, eventually initiated the cascade of deleterious events leading to cell death. This study indicates that the INT-MNC pretreated with rhubarb decoction or SEN, decreased the $[Ca^{2+}]_i$ dose-dependently as compared with the control groups ($P < 0.01$) when it is resting or is added with an equivalent amount of $CaCl_2$. This is consistent with the previous results that the rhubarb has a Ca^{2+} channel blocking activity^[5-7]. The antagonizing Ca^{2+} effects of rhubarb or SEN may be responsible for the intestinal barrier protective effect. On the contrary, the EMD promotes not only the release of intracellular Ca^{2+} , but the extracellular influx. This shows that the EMD can improve body immune function. Both SEN and EMD are active ingredients of rhubarb. The different effects of rhubarb and the different active ingredients of rhubarb on the Ca^{2+} level suggest that rhubarb has many kinds of immunological regulatory effects on INT-MNC.

Effect of gastrin on protein kinase C and its subtype in human colon cancer cell line SW480

Bin Xie¹, Shuang Wu He¹ and Xiao Dong Wang²

Subject headings gastrin; protein kinase C; colon neoplasms; cell line

Xie B, He SW, Wang XD. Effect of gastrin on protein kinase C and its subtype in human colon cancer cell line SW480. *World J Gastroenterol*, 2000;6(2):304-306

INTRODUCTION

Gastrin is a trophic gastrointestinal hormone which is secreted by G cell. Gastrin has long been considered a growth stimulatory hormone for mucosa of the gastrointestinal tract^[1]. The growth responses of certain colorectal cancer cells, and xenografts, can be stimulated by endogenous gastrin^[2]. Protein kinase C (PKC) is a family of isozymes that plays a crucial role in transducing signals of many hormones, growth peptides, neurotransmitters, and its activation is crucial in tumor promotion^[3]. PKC is also involved in regulating cellular proliferation^[4]. On the basis of gastrin's effect on the growth of human colon cancer cell, we further studied its effect on PKC and its subtype so as to elucidate the molecular basis in signal transduction mechanisms regulating SW480 cell proliferation and provide an experimental evidence of antineoplastic therapy for patients with colon cancer.

MATERIALS AND METHODS

Materials

Pentagastrin (PG) was purchased from Shanghai Li Zhu Biochemical Co., proglumide (PGL) from Shanghai No.11 Pharmaceutical Factory, PS, Histone III-s from Sigma Chemical Co., and γ -³²P-ATP from Beijing Yuhui Co. Human colon cancer line SW480 was obtained from Sikon-Kittling Cancer Center (American), and PKC- α , β , γ cDNA probes from Biological Department of Beijing Teacher's University. Dig-labelling and detection kit was

purchased from Boehringer Mannheim Co.

Methods

Cell in culture Cells were maintained in culture medium (RPMI 1640), containing 100 mL/L fetal calf serum in a humidified atmosphere of 950 mL/L air and 50 mL/L CO₂ at 37 °C.

Extraction of PKC from SW480 Cells were incubated with or without stimulating agents at the desired time intervals (1 min, 2 min and 5 min), and the reaction was terminated by the rapid addition of an ice cold homogenizing buffer. The preparations were centrifuged at 200×g for 5 min at 4 °C. The supernatants were discarded and the pellets were suspended in chilled buffer and were sonicated on ice for 45 min at 4 °C. The resulting supernatants (cytosolic fraction) were removed and kept on ice. The pellets were resuspended and centrifuged at 100 000×g for 45 min at 4 °C, and the supernatant represented the membrane fractions. The cytosolic or membrane fractions were used directly.

Measurement of PKC activity PKC was assayed by measuring the incorporation of ³²P from [γ -³²P] ATP into a specific peptide substrate (Sigma). The reaction was then terminated, and aliquots from each sample were spotted on specific binding papers. The papers were allowed to soak, and then were washed twice individually and processed for counting as described previously^[5]. Protein content of each sample was measured by the Bradford method, using bovine serum albumin as a standard^[6]. The assays were constantly made for linear range of enzyme activity with regard to protein concentration and incubation condition. Assays were performed in duplicate and the results were expressed as picomoles of ³²P incorporated in the peptide substrate/minute/mg protein.

Preparation of in situ hybridization samples Cells (approximately 1×10⁶/mL), which were plated and cultured in 24-well tissue culture plates (each well had a coverslip on the bottom) for 48 hours, and were incubated in the presence of PG (25 mg/L) for 24 hours. Control group cells were incubated with RPMI1640 containing 10% FCS instead of PG. Cells were incubated for 24 h, then the supernatants were discarded. The remains were washed with D-Hanks buffer for three times, fixed

with formaldehyde for 5 min and stored in 4 °C ice-box.

Dig-labelling and detection of probe The probe was labelled by random hexade primer (RHP) method using Dig-labelling and detection kit-(Boehringer Mannheim Co.)

In situ hybridization of samples The procedures with some modifications were mainly as follows^[7]: the samples were baked at 85 °C for 5 min, deparaffinized and rehydrated in graded alcohol, then put into 200 mL/L cold acetic acid and at 4 °C for 20 min. Hybridization buffer with the concentration of the probe (1mg/L) was added to the slides and incubated at 42 °C for 20 h. After washed thoroughly, the slides were darkly developed with NBT-BCIP at room temperature for 0.5 h-1 h, and then slightly stained with 0.5% methyl green, and mounted by glycerine-gelatin.

Controls The slides were treated with 20 mg/L RNase at 37 °C for 30 min before hybridization. No probe was put into the prehybridization buffer.

Statistical analysis

A one-way analysis of variance (ANOVA, Excel 6.0 band) was used to test for statistical significance between paired or unpaired data. All values were expressed as mean±SEM and $P<0.05$ was considered statistically significant and $P<0.01$ was considered as very significant difference.

RESULTS

Effect of gastrin on PKC activity

We examined the effect of gastrin on PKC activity (including cytosol and membrane) in SW480 cells for the desired time intervals. The PKC activity of membrane was increased obviously and the PKC activity of cytosol was decreased when cells were treated by PG for 1 min. After 2 min, the PKC activity of membrane and cytosol was still higher than in control group, and after 5 min it turned basically to the previous level (Table 1).

Effect of proglumide on PKC activity

To investigate whether PKC activity is part of a receptor-mediated pathway, cells were incubated with the gastrin receptor antagonist PGL. The result shows that PGL (32 mg/L) almost abolished the effect of PG (25 mg/L) on PKC activity in SW480 cell (Table 2).

Effect of gastrin on expression of PKC- α , β , γ mRNA

Expression of PKC- α , β , γ -mRNA all existed in SW480 cells at some extent, but after PG treatment, the expression of PKC- β mRNA was increased more than that of α , γ mRNA (Figures 1-4).

Figure 1 Expression of α -mRNA in PG group. ISH×200

5 min	2.28±0.49	0.98±0.18

Note: ^a $P < 0.05$ vs control ($n = 5$).

DISCUSSION

It is well known that the stimulation of PKC is a critical step in signal transduction pathways, and the translocation of PKC from cytosol to membrane was recognized as a symbol of PKC activation. Gastrin can increase the translocation effect^[8,9]. Differences in the distribution of PKC activities were reported in certain cultured cell lines, such as human stomach, colon and breast cancers due to the expression of various PKC subtypes^[10]. It is clear that cell growth is regulated by various growth factors through their specific receptors and receptor-linked signal transduction pathways^[11], such as the cAMP pathway, the tyrosine kinase pathway, PI hydrolysis, or mobilization of intracellular calcium. It has been observed that gastrin exerted a growth-promoting effect on colonic epithelial cells *in vitro*^[5], and the effect was mediated by the activation of PKC. But the mechanisms of gastrin as to how to regulate growth have not been clarified.

Our data showed that PG decreased the activity of PKC in the cytosol of cancer cells, while increased the activity of PKC in the membrane, and that the effect of PG on PKC possessed time-dependent character. In this experiment, we have also demonstrated that PGL, a gastrin receptor antagonist, blocked the effect of PG on PKC activation. The result indicated that PG stimulated PKC through a specific receptor-mediated pathway. It is clear that the signal pathway through PKC appears to be absolutely necessary for the control of gene expression and the cell cycle in the nucleus^[12]. Persons *et al*^[13] reported that transfected NIH3T3 cells carrying high-level expression vectors of rat *bra* in PKC-1cDNA displayed enhanced tumorigenicity when inoculated into nude mice. Yang XH *et al*^[14] reported that overexpression of PKC- β resulted in a high rate of cell growth. To further elucidate the role of specific PKC subtype in growth control and tumor promotion, we have

observed the effect of gastrin on expression of PKC- α , β , γ mRNA. The result showed that the differences among expression of PKC- α , β , γ mRNA originally existed in SW480 cells, but after gastrin treatment, the expression of PKC- β mRNA was increased more than that of PKC- α , γ mRNA. These results indicated that PKC- β may play a critical role in cell proliferation.

Chemo-endocrine chemotherapy with gastrin receptor antagonist, such as proglumide, can prevent the recurrence after resection of liver metastasis in colorectal cancer^[15]. In accordance with the role of PKC in gastrin stimulating cancer cells proliferation, PKC antagonists, such as staurosporine and bryostatin, have been used to treat colon cancer. So we can design and choose "signal drugs" for antineoplastic therapy for patients with colon cancer.

Endoscopic appearance of esophageal hematomas

Rodica Ouatu-Lascar, Gayatri Bharadhwaj and George Triadafilopoulos

Subject headings esophagus; hematoma/etiology; endoscopy; gastrointestinal hemorrhage/diagnosis; hematoma/classification; wounds; injuries

Ouatu-Lascar R, Bharadhwaj G, Triadafilopoulos G. Endoscopic appearance of esophageal hematomas. *World J Gastroenterol*, 2000;6(2): 307-309

INTRODUCTION

Esophageal hematomas develop from the dissection of the mucosa from the muscular layers of the esophageal wall and represent an uncommon condition affecting all ages^[1-3]. Although the most common cause of esophageal hematomas is iatrogenic mechanical injury-induced by prolonged nasogastric intubation, difficult or forceful endoscopic intubation, or the result of variceal injection sclerotherapy—some may be spontaneous, particularly in patients receiving anticoagulants^[3-6]. Presenting symptoms most commonly include dysphagia, hematemesis, and sub-sternal or epigastric pain^[5,9].

In this report, we present four cases of esophageal hematomas diagnosed endoscopically, describe their clinical and endoscopic characteristics and propose a classification. As our cases exemplify, therapy is conservative and a favorable prognosis is the rule. Although the diagnosis has traditionally been made by barium esophagography^[1] or CAT scanning^[1,10], the increased use of endoscopy will allow increased recognition of esophageal hematomas even at a subclinical (asymptomatic) stage and ultimately lead to a better understanding of their etiopathogenesis and their prevention.

CASE REPORTS

Case 1 A 90-year-old man with a history of

hypertension, congestive heart failure, and mild aortic stenosis was referred for upper endoscopy to determine the cause of iron deficiency anemia. A colonoscopy had previously revealed diverticular disease. Laboratory values included a hematocrit of 30%, iron of 90 mg/L and a TIBC of 358. Coagulation studies were normal. Endoscopy revealed salmon-colored mucosa extending from 28 cm–34 cm from the incisors, consistent with Barrett's esophagus. A densely red, elevated lesion, consistent with a hematoma was noted at 19 cm (Figure 1a). No therapy was given. A follow-up endoscopy, performed one week later, showed complete resolution of the hematoma. Because of its location, the hematoma was attributed to a difficult, possibly traumatic, endoscopic intubation.

Case 2 A 59-year-old man was referred for upper endoscopy because of chronic reflux symptoms. His medications included omeprazole 20 mg po-daily, and aspirin 325 mg po-daily. Endoscopy revealed confluent esophageal erosions and ulcers consistent with Savary stage III esophagitis from 36 cm–33 cm. Upon biopsy of the esophagus, a purple-red, elevated lesion, consistent with a hematoma was noted at 35 cm (Figure 1b). Histologic examination of the biopsy sample revealed changes consistent with reflux esophagitis. The hematoma was attributed to the mucosal biopsy obtained in the context of aspirin intake.

Case 3 A 90-year-old man with solid food dysphagia was referred for esophageal dilation. He had a history of metastatic (stage 4) squamous esophageal cancer treated with radiation therapy and esophageal dilation. He had mild anemia, but no thrombocytopenia or coagulation abnormalities. Endoscopy revealed a mid-esophageal stricture at 5 cm–29 cm which was dilated with minimal resistance using Savary dilators over a guide wire. This resulted in a 1 cm-long submucosal hematoma at 26 cm (Figure 1c). No biopsy was obtained. Because the patient's dysphagia resolved, there was no follow-up endoscopy.

Case 4 A 51-year-old male with a history of rheumatic heart disease, status post aortic valve replacement, was hospitalized for mitral valve replacement. Because his postoperative course was complicated by enterococcal sepsis, a transesophageal echocardiogram was performed which excluded the presence of endocarditis. The

following day, hematemesis was noted. Coagulation parameters were within the expected therapeutic range for prosthetic valves. An emergency upper endoscopy revealed a 3 cm-long, dark red esophageal mass at the GE junction, completely obliterating the esophageal lumen (Figure 1d). Biopsies obtained from the surface of the mass revealed organized clot and acute esophageal mucosal inflammation (not shown). Broad spectrum antibiotics and H₂ receptor antagonists were administered intravenously; effective anticoagulation was also continued. Although there was no more evidence of gastrointestinal hemorrhage, the patient eventually succumbed to sepsis ten days later. Autopsy revealed severe herpetic tracheobronchitis without any evidence of esophageal injury.

DISCUSSION

Esophageal hematomas appear as raised purplish-red lesions, mostly sub-mucosal in location, but occasionally obliterating the esophageal lumen. Depending on their etiology, they may be classified as spontaneous or traumatic. Based on the above observations, we propose that esophageal hematomas can be further classified according to the degree of involvement of the lumen in four stages (Table 1). Esophageal hematoma formation^[11,12], is an uncommon condition in which an intramural hemorrhage leads to a variable degree of submucosal dissection of the esophageal wall ranging from single or multiple localized hematomas to complete dissection of the esophagus^[1]. Esophageal hematomas may be spontaneous, associated with sudden changes in the transmural wall pressures due to a variety of causes including coughing, retching or protracted vomiting^[13], or may result from iatrogenic instrumentation, such as esophageal variceal sclerotherapy^[3,14,15] or transesophageal ultrasonography^[6] (Table 2). Hematomas may also be associated with direct trauma from abrasive foodstuffs such as taco shells^[16], pill-induced esophageal injury^[17], or with a coagulopathy, with little or no history of esophageal barotrauma^[5]. Other probable causes include esophageal stricture, diverticulum, esophageal arteriovenous malformation, and aspirin use^[18]. The majority of patients with esophageal hematomas are older than 70 yr, although isolated reports of patients as young as 21 yr have been made. In some studies, there seems to be a predilection for the female gender^[1].

Table 1 Stages of esophageal hematomas

I: Hematoma without surrounding tissue edema
II: Hematoma with surrounding tissue edema
III: Hematoma with edema plus compression of esophageal lumen
IV: Complete obliteration of the lumen with hematoma, edema, and organized clot formation

Figure 1 Endoscopic appearance of esophageal hematoma as. a: Stage I esophageal hematoma. There is no surrounding edema. Patient was asymptomatic. b: Stage II esophageal hematoma after an esophageal biopsy. Note the surrounding tissue edema. c: Stage III hematoma induced by esophageal dilation of a stricture. There is edema and separation of the surface mucosal layer that is partially obliterating the lumen. Patient was asymptomatic. d: Stage IV esophageal hematoma related to recent transesophageal echocardiography. Edema and clot formation led to complete obliteration of the esophageal lumen and hematemesis.

Table 2 Causes of esophageal hematomas

Spontaneous	Associated with coughing, retching, protracted vomiting Esophageal barotrauma Pill-induced esophageal injury Use of anticoagulants or aspirin Esophageal diverticulum A-V malformation
Traumatic	Endoscopic intubation, biopsy, dilation Variceal sclerotherapy Transesophageal echocardiography Foreign body ingestion

The clinical presentation is variable. Although mostly asymptomatic, esophageal hematomas may present with dramatic chest pain, severe dysphagia, and hematemesis. In such instances, they should be differentiated from Mallory-Weiss tear and Boerhaave's syndrome, conditions which they may closely mimic^[19-21]. Typically barium swallow or CAT scan have been used for the diagnosis, showing intraluminal filling defects or a double-barrelled appearance of the esophagus^[22]. More recently, endoscopy is the preferred investigation, especially when hematemesis is the presenting symptom^[23]. Because spontaneous resolution is the rule, the treatment of esophageal hematomas is conservative

and consists of a regimen of nil by mouth, intravenous alimentation and antibiotics in severe cases^[1]. Surgery is reserved only for rare instances, to drain a hematoma and close an esophageal mucosal tear^[24].

In our study, all four patients were male, the hematoma was visualized endoscopically, and was traumatic either from insertion of the scope (cases 1 and 4), or from endoscopic manipulation (cases 2 and 3). In 3 out of 4 of our patients the hematomas were asymptomatic. Because of the increased utilization of endoscopy for diagnosis and therapy, it is expected that esophageal hematomas will be encountered more frequently. This is particularly true in cases of esophageal dilation of strictures, repetitive multiple biopsies for surveillance of Barrett's esophagus, esophageal variceal sclerotherapy, and transesophageal echocardiography.

Hematomas related sclerotherapy seem to occur 2 d-4 d after injection, when tissue necrosis that extends into the submucosa reaches its maximum. Contributing factors include volume of sclerosant per injection, interval between treatments, paravariceal *versus* intra-variceal injection, bleeding diathesis, and occurrence of retching or prolonged Valsalva during or shortly after the treatment^[3-5]. Early endoscopy is useful in establishing the diagnosis and reveals an intraluminal bulge of the mucosa with dark blue discoloration.

The blind insertion of a transesophageal endosonographic probe for diagnosis of valvular heart disease^[25], and its increased utilization during cardiothoracic surgery^[6] represents an additional risk for esophageal hematoma formation, as exemplified in case 4 of this report. A recent review of the literature on the association of transesophageal echocardiography during cardiac surgery and gastrointestinal bleeding revealed that the overall percentage of postoperative gastrointestinal complaints following the procedure was 11%, and frank upper gastrointestinal bleeding was 2.1%^[6]. Another multicenter survey of 10419 examinations on the safety of transesophageal echocardiography revealed only 2 patients who developed bleeding complications which necessitated interruption of the examination^[7]. Realising that the risk of gastrointestinal bleeding is small but present, most authors recommend careful review of upper digestive symptoms to rule out preexisting esophageal pathology, ample lubrication of the endosonographic tip, and avoidance of fixation of the probe in a flexed position for prolonged periods in order to avoid contact pressure and esophageal mucosal damage^[8].

In conclusion, our study reviews the endoscopic features of esophageal hematomas and classifies

them in terms of etiology and appearance. With the widespread use of esophageal instrumentation, these lesions will be increasingly recognized endoscopically. Depending on their severity and endoscopic stage, esophageal hematomas may or may not be associated with symptoms. Treatment is generally conservative and favorable prognosis is the rule.

INTRODUCTION

Since the observation by Labenz *et al* that eradication of *Helicobacter pylori* (*Hp*) infection may be followed by development of reflux esophagitis in a relevant proportion of duodenal ulcer patients previously not affected by gastroesophageal reflux disease (GERD)^[1], a growing attention has been given to the potential interactions between *Hp* and GERD. Epidemiological studies have now demonstrated that the prevalence of GERD is steadily increasing in the developed countries^[2], as is the incidence of adenocarcinoma of the esophagus^[3], its most dangerous complication, while the prevalence of peptic ulcer and gastric cancer is falling^[4], in parallel with a falling prevalence of *Hp* infection in the western countries^[5]. It is therefore tempting to causally relate these phenomena. Despite the number of original papers and of reviews dealing with this topic, at least 3 issues are still debated: ① Does *Hp* infection interfere with the pathogenesis of GERD? ② Is the anti-secretory effect of *Hp* infection of any clinical relevance in the management of GERD patients? ③ Does long-term proton pump inhibitors (PPI) therapy accelerate development of atrophic changes in *Hp* +ve GERD patients? Finally, the relationship(s) between *Hp* and Barrett's esophagus may deserve some importance.

The present review will focus on these 4 issues. The interested reader may also refer to some recent papers, dealing with the same subject^[6-9].

Hp AND PATHOGENESIS OF GERD

Several studies have now convincingly shown that the prevalence of *Hp* infection in patients with reflux esophagitis is somewhat lower than in normal subjects; in a careful review of 26 papers on this topic, O'Connor summarizes the data existing as follows: the overall prevalence of *Hp* infection in 2182 adult GERD patients is 40.3%, as compared with 50.2% in the 2010 controls^[9]. He concludes that this "difference in prevalence (is) intimating that the pathogenesis of GERD might be related in some way to the absence of *Hp*". In our view, more simplistically, the only link between *Hp* infection and GERD lies on the degree of gastric acid secretion, and through this, on esophageal acid exposure. In patients with a predisposition to GERD but without a clinical manifestation of GERD (symptoms and/or esophageal lesions), eradication of *Hp* may trigger it, disclosing the clinical picture. On the contrary, patients harboring the infection, may be protected if the infection involves the corpus (i.e. the acid-producing part of the gastric mucosa), because the amount of acid secretion and hence the esophageal acid exposure is reduced. In fact, no single paper has ever been published so far focusing on *Hp* infection as a pathogenetic (aggressive or defensive) factor of GERD-perse. On the contrary, El-Serag *et al* have now clearly demonstrated that, for the above reasons, corpus gastritis is protective against reflux esophagitis^[10]. They have investigated 302 subjects, 154 of whom with endoscopic signs of esophagitis; there was no difference between patients with and controls without esophagitis in the overall infection rates with *Hp* infection. Compared with controls, corpus gastritis was less frequent and less severe in patients with esophagitis. Finally, in a multivariate logistic analysis, age, sex, smoking status, and the presence of chronic corpus gastritis exerted a significant influence on the presence of reflux esophagitis. This latter variable, however, showed an odds ratio of 0.46% only (95% confidence interval of 0.27-0.79), a value which is, albeit statistically significant, of doubtful clinical relevance.

In summary, the pathogenetic relationship

between *Hp* infection and GERD are probably weak and of indirect nature, being related to the amount of gastric acid secretion, a factor which is necessary but not indispensable for inducing GERD. The most relevant GERD pathogenetic factor is, as universally known, the occurrence of transient relaxation of the lower esophageal sphincter^[11], a factor which has not, to the best of our knowledge, been observed to be influenced by *Hp* gastric infection.

Is the antisecretory effect of *Hp* infection of any clinical relevance in the management of GERD patients?

A profound inhibition of acid secretion is the mainstay of treatment for reflux esophagitis, in particular in cases of moderate to severe RE^[12]. Therefore, the influence of *Hp* on the efficacy of acid-lowering treatment may be important for patients with RE. Verdu *et al*^[13] showed that omeprazole produces a greater decrease in gastric acidity in subjects with *Hp* infection than in those who are *Hp* negative, and that omeprazole produces a smaller decrease in gastric acidity after *Hp* infection has been cured^[14]. Similar findings have been obtained by Labenz *et al*^[15], who showed that in 17 FU patients, *Hp* eradication resulted in a marked decrease of the pH-increasing effect of omeprazole (24h median gastric pH: 5.5 vs 3.0, $P < 0.002$) that was most pronounced during night time. Base line intragastric pH remained unchanged after eradication (median gastric pH: 1.0 vs 1.1, $P = 0.05$). The same authors have also shown that this effect persisted for at least 1 year after *Hp* eradication^[16], whereas others have been shown that it is shared by other PPIs, such as lansoprazole^[17].

Despite this *Hp* mediated exaggeration of the effect of acid-suppressive drugs on intragastric pH is clearly proven, there is little evidence that this effect has any clinical relevance for the treatment of GERD patients with PPI. One reason is that the effect, due to the logarithmic scale of pH, a variation of one pH unit from 5 to 6 is 10 000 times less important than a variation from 1 to 2. The small variation in acid secretory capacity due to *Hp* colonisation is only "visible" when the acid secretion is already potentially reduced by PPI, but is otherwise unimportant.

Direct evidence shows in fact that, during acid suppressive therapy with ranitidine or omeprazole, *Hp* +ve or -ve GERD patients show a similar reduction of esophageal acid exposure, the entity of which is only influenced by the type of drug received^[18]. Furthermore, both groups of GERD patients require the same dose of omeprazole during long-term maintenance treatment to prevent symptomatic and endoscopic relapse^[19], and *Hp* status seems not to be an important prognostic

factor during long-term maintenance therapy with PPI; in a study conducted on 103 patients with RE grade 1 or 2, randomized to maintenance therapy with lansoprazole 15 or 30 mg daily for 12 months, it was observed that *Hp* infected patients relapsed as early as patients who were not infected^[20].

The only discordant piece of evidence comes from the very large study of Holtman *et al*^[21], who claims of a significantly better acute response of *Hp* +ve GERD patients treated with the PPI pantoprazole in comparison to *Hp* -ve; however, the difference of healing rates between the two groups after 8wk of 40mg daily was quite small (96.4% vs 91.8%, $P < 0.05$) and no difference at all was observed in GERD symptoms between infected and noninfected patients. There is therefore enough evidence to say, at least, that PPI maintenance therapy does not need to be titrated upon *Hp* status^[19]. It is therefore to be fully agreed upon the recommendation that "testing for *Hp* infection is not indicated in patients on long term treatment or in those considered for treatment with a proton pump inhibitor for GERD", as stated by the recent guidelines of the American College of Gastroenterology^[22].

Does long-term proton pump inhibitors (PPI) therapy accelerate development of atrophic in *Hp* +ve GERD patients?

Several studies have shown that treatment with PPI is associated with the worsening of gastritis (increase in severity score, spreading from the antrum to corpus and fundus)^[23-25]. Because superficial corpus gastritis may lead to atrophic gastritis, the increased body inflammation in *Hp* positive patients observed during short term PPI therapy may lead to atrophic gastritis during long term PPI treatment. This has been observed so far after omeprazole administration^[26], but the study was criticized in particular for the incorporation of an inappropriate control group^[27]. Moreover, the findings have not been confirmed by a randomized Swedish study comparing the efficacy of omeprazole maintenance treatment and antireflux surgery over a 3-years follow-up^[28]. Thus, on the basis of available evidence, long-term treatment with PPI up to 10 years appears to be a perfectly safe therapy^[29].

***Hp* INFECTION AND BARRETT'S ESOPHAGUS**

The interest in BE is still growing since the early description of this entity in 1950^[30] for two main reasons: ① BE is associated with GERD, and also with an increased risk of adenocarcinoma^[31], thus representing a link between a common benign condition and a rare very malignant disease; ② The incidence of adenocarcinoma of the esophagus and cardia is increasing at the fastest rate among gastrointestinal (and also non GI) human

cancers^[3]. Since *Hp* exhibits a special affinity for gastric-type epithelium, and since *Barrett's* metaplasia contains columnar-lined epithelium, it is to be expected that *Hp* will also be able to attach the *Barrett's* epithelium, at least of the gastric type, independently from any involvement of *Hp* infection in the pathogenesis of esophageal mucosal inflammation.

It seems that the prevalence of *Hp* infection of the stomach in BE patients is not different from that exhibited by controls, roughly one third of the subjects^[9]. The colonization of metaplastic epithelium by the bacterium has been tested only in a minority of studies, but appears to be marginally lower^[9]. It seems therefore that the stomach represents the primary site of infection, with secondary colonization of columnar mucosa in the esophagus. Furthermore, most *Hp* positive patients show a very low bacterial load in their metaplastic epithelium, and no significant difference has been found in the severity of inflammatory changes between *Hp* +ve and *Hp* -ve *Barrett's* esophagus patients^[32]. Finally, recent work has confirmed that within the esophagus, *Hp* adheres only to gastric type metaplasia, which is not considered premalignant for adenocarcinoma^[33]. In conclusion, it is most probable that *Hp* has no etiologic role on the development of *Barrett's* esophagus, nor in the esophagitis associated with this metaplastic change; the colonization of *Barrett's* epithelium probably reflects only a shift from gastric antrum.

Another intriguing point is the prevalence of *Hp* infection and the intestinal metaplasia of the gastric cardia. It is in fact at present not known whether inflammation of the cardia indicates GERD and/or is a manifestation of gastritis caused by *Hp*. Recently two studies have shed some light on this issue^[34,35]: in the first, biopsies were obtained from the antrum, corpus and cardia from 135 *Hp*-infected patients with gastritis, ulcer disease, or RE. One hundred and thirty-two (97.7%) of them showed active carditis, resembling antral gastritis in most patients, but with less marked bacterial density and inflammatory process^[34]. The authors conclude that *Hp* gastritis commonly involves the cardia, that intestinal metaplasia in the cardia is a common finding in *Hp* gastritis, but that the cardia lower histologic density of the bacteria and inflammatory responses in comparison to the antrum are not clear. In the second work^[35], 22 GERD patients and 11 controls were compared in relationship to endoscopic and biptic evaluation of inflammation, *Hp* infection and intestinal metaplasia in distal esophagus, cardia, fundus and antrum. It turned out that neither the prevalence of *Hp* infection (controls 48%; GERD 41%) nor cardia inflammation (controls 41%; GERD 40%) differed between the two groups. All 11 controls and 22 of

23 (96%) patients with GERD and cardia inflammation had *HP* infection. Cardia intestinal metaplasia was more common among controls (22%) than among GERD patients (3%, $P \leq 0.01$); all patients with cardia intestinal metaplasia had cardia inflammation, 7 had *Hp* infection, and 6 had metaplasia elsewhere in the stomach. The authors conclude that the prevalence of cardia inflammation is similar in patients with and without GERD, and is associated with *Hp* infection. Also, in this study, cardia intestinal metaplasia is associated with *Hp* related cardia inflammation ($P = 0.01$) and intestinal metaplasia elsewhere in the stomach, indicating that it is distinct from *Barrett's* esophagus.

The final point is the association, if any, between *Hp* infection and *Barrett's* associated adenocarcinoma. Again, two recent works have contributed to the improvement of our knowledge on this previously uninvestigated issue^[36,37]. Qaddus *et al* report on 19 cases of adenocarcinoma arising in BE, who were examined for the presence of *Hp* after staining with three different techniques: all sections of BE, with or without dysplasia, adenocarcinoma and stomach (when available) were uniformly negative for the presence of *Hp*. The authors conclude that neither gastric nor esophageal infection with *Hp* is a requisite for the development of adenocarcinoma in BE^[36].

The second study aimed at comparing the prevalence of *Hp* and increasing grades of dysplasia. Biopsies from 19 malignant and 94 benign cases of BE were analyzed histologically for *Hp*; 34% of non-dysplastic *Barrett's* epithelium was colonized with *Hp* compared with only 17% of dysplastic/malignant-cases ($P = 0.04$). No relationship was found between *Hp* status and ① length of BE; ② the presence of strictures or ulcers; ③ previous anti-reflux surgery. The authors therefore confirmed that *Hp* colonization of BE is not particularly common, and that a negative correlation exists with increasing severity of dysplasia^[37].

To summarize, from both studies it appears that it is unlikely that a causal relationship exists between *Hp* infection and *Barrett's* associated adenocarcinoma.

INTRODUCTION

Medical care of patients with inflammatory bowel disease (IBD) comprises general measures and specific pharmacological, nutritional, endoscopic and surgical therapies (Table 1)^[1-3]. In this paper, current management options for patients with two commonly difficult presentations of IBD, acute severe ulcerative colitis (UC) and steroid-refractory or dependent ileocaecal Crohn's disease (CD), are discussed. Practical considerations and newer developments are emphasized.

MANAGEMENT OF ACUTE SEVERE ULCERATIVE COLITIS

These patients should be admitted immediately to a gastroenterology ward for close joint medical, surgical and nursing care. The nutrition team and a stoma therapist in patients likely to need surgery should be involved promptly. Patients undergoing an acute attack of UC need to be made aware from the outset that they have a one in four chance of failing to respond to the primary treatment (intravenous steroids), and thus need either cyclosporin or colectomy during their admission (Table 1).

Establishing the diagnosis, extent and severity of disease

A carefully targeted history and appropriate investigations can help establish the diagnosis (Table 2) in patients presenting for the first time and, in those with established UC, to exclude infection and to assess disease extent (if not already known) and severity.

Blood and stool tests Stool should be sent to look for

pathogens, and serology checked for amoebiasis, strongyloidiasis and schistosomiasis. Blood tests are better for establishing the activity of UC than making the diagnosis or identifying its extent. However, a raised platelet count is more common in UC than in infective colitis. The best measures of disease activity are haemoglobin, platelet count, ESR, C-reactive protein^[4] and serum albumin.

Sigmoidoscopy and rectal biopsy Cautious rigid or flexible sigmoidoscopy in the unprepared patient, and without excessive air insufflation, provides immediate confirmation of active colitis. Sigmoidoscopy also allows biopsy for histology: to minimise the risks of bleeding and perforation a small superficial biopsy should be taken from the posterior rectal wall less than 10 cm from the anal margin using small-cupped forceps. Anecdotally, colonoscopy may cause colonic perforation and dilatation in acute severe UC, and although some authorities have reported that it is both safe and useful for decision-making^[5], most patients can be managed satisfactorily without it. In patients with established UC, rectal biopsy is not routinely necessary. However, in those presenting for the first time, infective colitis may be suggested by an acute, focal and superficial inflammatory infiltrate with minimal goblet cell depletion and preservation of crypt architecture^[6]. Although colitis due to *Clostridium difficile*, cytomegalovirus, amoebiasis and *Crohn's* disease often has characteristic macroscopic appearances, histology may confirm these diagnoses.

Plain abdominal X-ray A plain film at presentation can be used to assess disease extent, since faecal residual visible on X-ray usually indicates sites of uninfamed colonic mucosa. Plain abdominal X-ray is also used to assess disease severity and in particular to exclude colonic dilatation (diameter > 5.5 cm) in sick patients, however, the gas pattern on a plain film may be misleading if there has been excessive air insufflation during a sigmoidoscopy or colonoscopy done shortly beforehand. In patients with suspected colonic perforation, the diagnosis can be confirmed by erect chest X-ray or a lateral decubitus abdominal film.

Radiolabelled leucocyte scans The intensity and extent of colonic uptake one hour after injection of autologous ⁹⁹Tc-HMPAO or ¹¹¹Indium-labelled leukocytes provides information about disease

activity and particularly extent, respectively, where doubt exists in patients with UC. Colonic uptake of leucocytes is not of course specific for UC and positive results are obtained in other inflammatory colonic diseases.

Table 1 Principles of management of acute severe ulcerative colitis

GENERAL MEASURES	
Explanation, psychosocial support	- patient support groups
Specialist multidisciplinary care	- physicians, surgeons, nutrition team, nurses, stoma therapist, counsellor
ESTABLISHING THE DIAGNOSIS, EXTENT/SITE AND SEVERITY	
	- clinical evaluation
	- FBC, ESR, C-reactive protein, albumin, LFTs, amoebic serology
	- stool microscopy, culture, C. difficile toxin
	- limited sigmoidoscopy and biopsy
	- plain abdominal X-ray
	- consider radiolabelled leucocyte scan
MONITORING PROGRESS	
	- daily clinical assessment
	- stool chart
	- 4-hrly temperature, pulse
	- daily FBC, ESR, C-reactive protein, urea and electrolytes, albumin
	- daily plain abdominal X-ray
SUPPORTIVE TREATMENT	
	- i.v. fluids, electrolytes (Na, K), blood transfusion
	- nutritional supplementation
	- heparin s.c.
	- haematinics (folate)
	- avoid antidiarrhoeals (codeine, loperamide, diphenoxylate), opiates, NSAIDs
	- rolling manoeuvre (if colon dilating)
SPECIFIC TREATMENT	
Medical	- corticosteroids i.v. (hydrocortisone or methylprednisolone) then p.o. (prednisolone)
	- continue 5-ASA p.o. in patients already taking it; otherwise start when improvement begins
	- antibiotics for very sick febrile patients, or when infection suspected
	- consider cyclosporin i.v. then p.o.) for steroid non-responders at 4-7 days
Surgical (for non-responders at 5-7 days, toxic megacolon, perforation, massive haemorrhage)	- panproctocolectomy with ileoanal pouch or permanent ileostomy
	- subtotal colectomy with ileorectal anastomosis (rarely)

Table 2 Management of active ileocaecal Crohn's disease. General measures, monitoring progress and supportive treatment are essentially as for ulcerative colitis

ESTABLISHING THE DIAGNOSIS, EXTENT/SITE AND SEVERITY	
	- clinical evaluation
	- FBC, ESR, C-reactive protein, ferritin, folate, B12, albumin, LFTs, Ca, Mg, Zn
	- stool microscopy, culture, C difficile toxin
	- plain abdominal X-ray
	- consider colonoscopy and biopsy, small bowel barium radiology, ultrasound, CT, MRI, leucocyte scan
SPECIFIC TREATMENT (separately or in combination)	
Medical	- corticosteroids i.v. (hydrocortisone or methylprednisolone) then p.o. (prednisolone or budesonide CR)
	- continue high dose mesalazine (Pentasa or Asacol) in patients already taking it; otherwise start when improvement begins
	- consider metronidazole, ciprofloxacin; also broad spectrum antibiotics for very sick febrile patients, or when infection/collection suspected
	- consider azathioprine/6-mercaptopurine (slow response) or anti TNF antibodies (infliximab) for steroid non-responders
Nutritional	- liquid formula diet
Endoscopic	- balloon dilatation
Surgical	- resection or stricturoplasty

Monitoring progress

Progress is monitored by twice daily clinical assessment, stool chart and 4-hourly measurement of temperature and pulse. Blood count, ESR, C-reactive protein, routine biochemistry and plain abdominal X-ray should be done daily in sick patients. The two most useful variables in predicting the outcome of the acute attack are stool frequency and C-reactive protein at three days: patients with values above 8 stools/day or 45 mg/L, respectively, have an 85% chance of failing to respond to intravenous steroids and needing cyclosporin or surgery during their admission^[4] (Table 1).

Supportive treatment

Intravenous fluids and blood Most patients require intravenous fluids and electrolytes, particularly potassium, to replace diarrhoeal losses. Serum potassium concentration should be maintained at or above 4 mmol/L, since hypokalaemia may predispose to colonic dilatation. Blood transfusion is recommended if the haemoglobin falls below 100g/L.

Nutritional support Patients can usually eat normally, with liquid protein and calorie supplements if necessary. Very sick patients may need total parenteral nutrition.

Anticoagulation Because active UC is associated with a high risk of venous and arterial thrombo-embolism^[7], patients should be given prophylactic subcutaneous heparin (e.g. low molecular mass heparin 3000-5000 U daily). Heparin does not appear to increase rectal blood loss even when given intravenously^[8].

Drugs to avoid Antidiarrhoeal drugs (loperamide, codeine phosphate, diphenoxylate), opioid analgesics, antispasmodics and anticholinergic drugs should not be prescribed in active UC since they may provoke acute colonic dilatation^[9]. Patients should also avoid NSAIDs in view of their adverse effects on the clinical course of IBD^[10]. If relief of mild pain is needed, oral paracetamol appears to be safe, while severe pain suggests colonic dilatation or perforation needing urgent intervention.

Rolling manoeuvre In very sick patients, particularly those with clinical and/or radiological evidence of incipient colonic dilatation, rolling into the prone or knee-elbow position for 15 minutes every two hours may aid in the evacuation of gas per rectum, particularly from the transverse colon^[11].

Specific medical treatment

The cornerstone of specific medical treatment of acute severe UC remains corticosteroids^[1,12]. Aminosalicylates and antibiotics have minor roles. Cyclosporin has become a useful option, but oral

azathioprine and 6-mercaptopurine are too slow to work in patients with acute steroid-refractory attacks (Table 1).

Corticosteroids Hydrocortisone (300 mg/d-400 mg/d) or methyl prednisolone (40 mg/d-60 mg/d) are given intravenously. There is no advantage in giving higher doses, although continuous infusion may be more effective than once or twice daily boluses^[12]. On this treatment, about 70% patients improve substantially in 5 d-7 d. They are then switched to oral prednisolone (40 mg/d-60 mg/d), the dose being tapered to zero over 2-3 months. Conventionally, failure to respond to intravenous steroids after 7 d indicates urgent colectomy, but introduction of intravenous cyclosporin can now be considered as an alternative.

Aminosalicylates Aminosalicylates in full dose are continued in patients already taking them at the time of admission, and well enough to take oral medication, but do not have a primary therapeutic in acute severe UC. In case patients given aminosalicylates for the first time prove to be allergic to, or intolerant of them, initiation of these drugs is best delayed until the patient shows sufficient improvement on intravenous steroids to switch to oral treatment.

Antibiotics Although one study has suggested a role for adjunctive oral tobramycin^[13], the use of antibiotics is usually restricted now to very sick febrile patients, or to those in whom an infective component to their colitis is strongly suspected. Under such circumstances, a combination of antibiotics, for example ciprofloxacin or a cephalosporin with metronidazole, is often given.

Cyclosporin The only current evidence-based indication for cyclosporin in IBD is steroid-refractory acute severe UC. In a single small controlled trial^[14], the results of which have been largely confirmed by subsequent experience^[15,16], intravenous (4 mg·kg⁻¹·d⁻¹) for about 5 d) followed by oral (5 mg·kg⁻¹·d⁻¹-8 mg·kg⁻¹·d⁻¹) cyclosporin, given with continued corticosteroids, averted colectomy in the acute phase in 80% of patients failing to respond to 5 d-7 d of intravenous steroids alone. Enthusiasm for this approach has to be tempered by the frequency of relapse necessitating colectomy (up to 50%) that follows withdrawal of cyclosporin, and by its serious adverse effects which in turn demand frequent monitoring of cyclosporin blood levels and serum biochemistry in treated patients. The therapeutic range for monoclonal radioimmunoassay is 250 µg/L⁻¹-400 µg/L⁻¹ during intravenous treatment, and 150 µg/L⁻¹-300 µg/L⁻¹ as the trough level on oral treatment. Biochemical disturbances induced by cyclosporin include

hyperkalaemia, hypomagnesaemia and hyperuricaemia, as well as renal dysfunction. The most serious side effects of cyclosporin are opportunistic infections (20% patients) including pneumocystis carinii pneumonia, on account of which co-administration of prophylactic trimethoprim/sulphamethoxazole may be advisable; renal impairment, including a small reduction in glomerular filtration rate in most patients and, sometimes, an interstitial nephritis which is not always reversible on stopping cyclosporin; hypertension (30% patients); hepatotoxicity (up to 20%); and epileptic fits (3%), due to penetration of the blood-brain barrier by a vehicle, cremophor, in cyclosporin and essentially confined to patients with low serum cholesterol and/or magnesium concentration. Less serious side-effects include nausea, headache, paraesthesiae and hypertrichosis.

Further studies are needed to determine optimal usage of cyclosporin in UC. For example, precisely when should patients be given the drug, will a lower dose (2 mg·kg⁻¹·d⁻¹ iv) be as effective but safer, should trimethoprim/sulphamethoxazole be coprescribed as prophylaxis against pneumocystis carinii infection, and should oral cyclosporin or azathioprine be prescribed after the intravenous treatment? It is clear, however, that intravenous cyclosporin can be invaluable in patients with steroid-refractory acute severe UC, not least for buying time for improving their nutrition prior to, and/or preparing them psychologically for surgery.

Azathioprine and 6-mercaptopurine Oral azathioprine and 6-mercaptopurine are very effective in inducing and maintaining remission in patients with steroid-refractory or dependent IBD. Unfortunately, however, they take up to 4 months to exert their effect and are thus inappropriate for acute severe UC.

Possible new treatments The possible roles of anti-TNF-α antibody^[17], antibodies and antisense oligonucleotides to leucocyte/endothelial cellular adhesion molecules^[18], and intravenous heparin^[8] require further evaluation in controlled clinical trials.

Surgery

A colorectal surgeon should be involved in the care of patients with acute severe UC throughout their admission. Indications for urgent colectomy, which is required in about 25% of patients with acute severe colitis, include toxic colonic dilatation which does not respond within 24 h to intensification of medical treatment with rolling^[11,12], antibiotics and nasogastric suction, and deterioration or failure to improve on medical therapy in 5 d-7 d. Emergency surgery, after immediate resuscitation, is required in the rare patients, who develop colonic perforation or massive colonic haemorrhage.

Details of the surgical options available (pan-proctocolectomy with ileoanal pouch or permanent ileostomy, or, rarely, sub-total colectomy with ileorectal anastomosis) and their elective indications, are beyond the scope of this review.

MANAGEMENT OF ACTIVE CROHN'S DISEASE

Treatment of CD depends not only on disease activity and site, as in UC, but also needs to be tailored according to the patient's clinical presentation^[2,3]. Inflammation (Table 2), obstruction, abscess and fistula require different therapeutic approaches, and need to be distinguished by appropriate investigation before specific treatment is begun.

Assessment of disease activity

Its heterogeneous presentation makes assessment of disease activity in CD more complicated than in UC. For clinical trials, a large number of multifactorial clinical and/or laboratory-based scoring systems, such as the Crohn's Disease Activity Index (CDAI), has been devised, but none is suitable for ordinary clinical use^[2]. The working definitions of the American College of Gastroenterology^[2] are more practicable. Many patients with active CD can be looked after as outpatients, but those with moderate-severe and severe-fulminant disease need prompt, and in the latter instance immediate, hospital admission.

General measures

As for UC, patients with active CD should be looked after by a multi-disciplinary team with special expertise in IBD in a gastroenterology clinic or ward. Options for treatment (medical, nutritional, surgical) are wider than in UC, and it is essential that the patient is kept fully informed about his/her illness, and takes a place at the centre of the therapeutic decision-making process^[2,3].

Establishing the diagnosis and clinicopathological problem

In many patients, the diagnosis of CD and identification of its principal site will have been made before the current relapse. Investigations, therefore, are directed primarily to clarifying the dominant clinicopathological process so as to optimise subsequent treatment. In those individuals presenting acutely for the first time, the diagnosis needs to be established (Table 2).

Clinical evaluation Terminal ileal and ileocaecal CD usually present with pain, diarrhoea and/or a tender mass in the right iliac fossa. Inflammation and abscess tend to cause constant pain, often with fever; in patients with small bowel obstruction, the pain is more generalised, intermittent, colicky and associated with borborygmi, abdominal distension and vomiting. Where the diagnosis of CD has not yet been made, an appendix mass, caecal

carcinoma, lymphoma and, in some ethnic groups, ileocaecal tuberculosis require careful consideration.

Blood tests As in UC, the main value of blood tests is in assessing and monitoring disease activity, which is related directly to the platelet count, ESR and C-reactive protein and inversely to serum haemoglobin and albumin. However, in very sick patients, particularly with extensive small bowel disease and steatorrhoea, there may be laboratory evidence of malnutrition and malabsorption (anaemia, low serum iron, folate, Vit.B12, albumin, calcium, magnesium, zinc, essential fatty acids).

Endoscopy and biopsy In patients with right iliac fossa pain where the diagnosis of CD is in doubt, colonoscopy to the terminal ileum, with biopsies, is helpful. It can also be used to balloon-dilate short strictures. In established Crohn's colitis, colonoscopy during acute relapse is not routinely necessary and may be unsafe. In previously undiagnosed patients, digital rectal examination and sigmoidoscopy may show rectal induration or ulceration, or the presence of perianal disease. Furthermore, biopsy of macroscopically normal rectal mucosa may reveal epithelioid granulomata in a minority of patients with overt CD more proximally.

Plain abdominal X-ray A plain film is essential if intestinal obstruction is suspected. It may also hint at a mass in the right iliac fossa, and is often helpful, as in UC, in estimating extent or severity of Crohn's colitis.

Barium radiology Because it may exacerbate obstructive symptoms and pre-existing perforation, conventional barium follow through and small bowel enema should be avoided in severely ill patients with small bowel disease. In many centres, colonoscopy, because it allows biopsy and when necessary balloon dilatation of strictures, is used in preference to barium enema in patients with suspected large bowel and terminal ileal disease. Contrast fistulography is useful for the clarification of anatomical connections in patients with abdominal sinuses or fistulae.

Radiolabelled leucocyte scans ⁹⁹Tc-HMPAO or ¹¹¹Indium-leucocyte scanning can be helpful to identify, non-invasively, not only sites of large bowel inflammation, as in UC, but also in the small intestine. Delayed scanning can also be helpful in identifying intra-abdominal abscesses.

Ultrasound, CT scan and magnetic resonance imaging (MRI) Abdominal ultrasound and CT scan can be very useful in active CD, allowing not only the evaluation but also the percutaneous drainage of localised collections. CT also plays a central role in

defining abdominal fistulous tracks and sinuses, while endoluminal ultra sound and MRI are particularly useful for the anatomical delineation of perianal abscesses and fistulae.

Supportive treatment

Patients with active CD, like those with acute severe UC, need meticulous supportive treatment, including, as necessary, intravenous fluids and electrolytes, blood transfusion and prophylactic subcutaneous heparin^[7](Table 2).

Dietary advice and nutritional support All patients should be carefully assessed in relation to their nutritional intake and status, the latter clinically by measurement of body mass index [mass (kg)/height (m)²; (normal >20)]. Patients with stricturing small bowel CD should avoid high residue foods (e.g. citrus fruit segments, nuts, sweetcorn, uncooked vegetables) which might cause bolus obstruction. Special dietary and nutritional modifications are needed for patients with extensive small bowel CD or short bowel syndrome. Sick inpatients may need enteral or parenteral nutrition to restore nutritional deficits, while liquid formula diets offer effective primary therapy for some patients with active small bowel CD.

Smoking Patients with CD who smoke should be strongly advised to stop, since this habit has a major adverse effect on the long-term natural history of the disease, particularly in women^[19].

Drugs Codeine phosphate and loperamide are useful for the control of diarrhoea in patients with small bowel CD or resection; they should, as in UC, be avoided in active Crohn's colitis in case they provoke colonic dilatation. Cholestyramine sachets (4 g one to three times daily) reduce watery diarrhoea due to bile salt malabsorption induced by extensive terminal ileal disease or resection. Haematinics (Fe, folate, Vit.B12), calcium, magnesium, zinc and fat soluble Vit. (A,D,E,K) may be needed for the replacement of particular deficiencies, as may appropriate drugs for incipient or established osteoporosis.

Drugs to avoid NSAIDs may precipitate relapse of CD, as of UC^[10], and should be avoided. Likewise, in patients with small bowel stricturing due to CD, delayed release drugs should not be prescribed in case they cause bolus obstruction.

SPECIFIC TREATMENT OF ACTIVE ILEOCAECAL CROHN'S DISEASE

Therapeutic options include drugs, liquid formula diet and surgery, as separate alternatives or in combination, depending on the individual patient's age, presentation and personal preference (Table 2)^[2,3].

Drug therapy

Corticosteroids In active disease, oral steroids provide the quickest and most reliable response, 60%-80% patients improving in 3 wk-4 wk. Conventionally, prednisolone (40 mg·d⁻¹-60 mg·d⁻¹) is used, the dose being tapered by 5 mg every 7 d-10 d once improvement has begun. Very sick patients, or those needing to be fasted because of intestinal obstruction, need intravenous corticosteroids at least initially (e.g. hydrocortisone 300 mg·d⁻¹-400 mg·d⁻¹, methyl prednisolone 40 mg·d⁻¹-60 mg·d⁻¹). In patients able to take oral treatment in whom systemic steroid side effects are a major problem, a useful recent advance is the introduction of an oral controlled ileal release formulation of budesonide (Entocort CR, Budenofalk) (9 mg·d⁻¹). This steroid approaches prednisolone in efficacy, but because of first-pass metabolism, has fewer systemic side-effects and causes much less adrenocortical suppression, albeit at greater financial cost^[20]. Up to 20% of patients with CD may be difficult to wean off steroids after relapse. Of these, many will be able partially or totally to discontinue steroid therapy on introduction of an aminosalicilate or immunomodulatory agent.

Aminosalicilates Patients with only moderately active ileocaecal disease, most of whom can be treated as outpatients, can be tried on high dose oral mesalazine (e.g. Pentasa 2 g b.d., Asacol 1.2 g t.d.s.)^[21,22]; about 40% will go into remission in 2-3 months on such treatment, which may be preferred by individuals reluctant to use prednisolone.

Metronidazole and other antibiotics Metronidazole alone^[23] or in combination with ciprofloxacin^[24] is moderately effective in mild moderately active CD, but is insufficiently potent for use as sole therapy in patients ill enough to need hospital admission. Treatment needs to be given for up to 3 months, but may be confounded by nausea, vomiting, an unpleasant taste and/or patients' unwillingness to abstain from alcohol during this time. More seriously, metronidazole taken long-term may cause a peripheral neuropathy not always reversible on its discontinuation. The place of other antibiotics such as clarithromycin, clofazimine and rifabutin has not yet been adequately established in controlled trials. Conventional antituberculous therapy was not beneficial in a controlled trial in CD^[25]. Antibiotics such as amoxycillin, trimethoprim, ciprofloxacin and metronidazole are sometimes useful for the treatment of diarrhoea or steatorrhoea due to bacterial overgrowth in patients with small bowel CD.

Azathioprine and 6-mercaptopurine Patients not

responding to or dependent on corticosteroids who, because of extensive disease or previous resection, need to avoid operative treatment, can be treated with adjunctive oral azathioprine ($2\text{--}2.5\text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$) or 6-mercaptopurine ($1\text{--}1.5\text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$); the dose of steroids is reduced as improvement occurs^[26-28]. Such patients must be well enough to wait for up to four months for this to become apparent. Hopes that intravenous azathioprine could be used to accelerate response in active Crohn's have not been confirmed in a controlled trial^[29]. Up to 20% of patients cannot tolerate azathioprine because of nausea, rash, fever, arthralgia, upper abdominal pain and headache; in a minority of these patients, a switch to 6MP may avert these problems. More seriously, both drugs may cause acute pancreatitis in about 3% of patients, particularly in the first few weeks of treatment. Their other potentially serious side effects, bone marrow depression (which occurs in 2% patients) and cholestatic hepatitis, necessitate blood tests every two weeks for the first two months of therapy: thereafter, white cell count, platelet count and liver function tests should be monitored every 2 months^[30]. Opportunistic infections and a serious form of glandular fever have been reported in patients on azathioprine or 6MP. Although existing data in IBD is reassuring^[31], very long-term use, as in transplant patients, may yet prove to increase the risk of malignancy. Indeed, the risk of skin cancer makes it advisable to recommend to white patients on azathioprine or 6MP that they avoid excessive exposure to sunlight. Homozygous deficiency of 6-thiopurine methyl transferase (6TPMT), the enzyme responsible for the safe metabolic breakdown of azathioprine and 6-MP, occurs in about 0.2% of the population and may contribute to the occasionally serious side-effects of both drugs and its routine assay is not yet available. Allopurinol, by inhibiting xanthine oxidase, reduces metabolism of azathioprine. Patients on this drug should not be given either thiopurine. Usage of azathioprine and 6-mercaptopurine in CD is long term. However, in patients maintained in remission on azathioprine or 6MP, the risk of relapse after four years of treatment appears to be similar whether the drug is continued or stopped^[32]. In view of the potential toxicity of the long-term use of these drugs, their withdrawal should be considered in patients still in remission after four years treatment.

Methotrexate Methotrexate, given weekly as a 25 mg intramuscular injection, improves symptoms and reduces steroid requirements in chronically active steroid-dependent CD^[33], but its potential side effects (bone marrow depression, hepatic fibrosis, pneumonitis, opportunistic infections) restrict its use to the very small number of patients

with difficult CD refractory to safer treatments. Although a lower dose (12.5 mg weekly), given orally, may also prove beneficial in CD^[34], all patients given methotrexate need careful blood monitoring.

Mycophenolate mofetil In an unblinded trial in complicated CD, this newer immunomodulatory drug appeared to act quicker and produce fewer side-effects than azathioprine^[35] and double-blind controlled trials are needed to confirm these results.

Cyclosporin Has not been confirmed as useful in active ileocaecal CD^[38-40].

Anti-TNF-alpha antibody The first specific cytokine-related therapy to reach the bedside in CD is infliximab, a mouse-human chimeric (cA2) antibody to-TNF-alpha^[36-38]; this drug was launched in the USA in 1998 and in Europe in 1999. In patients with CD refractory to steroids and/or conventional immunosuppressive drugs, a single infusion of infliximab produced, at 4 weeks, some improvement in 64% patients, compared with 17% after placebo; remission occurred in 33% patients treated with infliximab but only 4% of those given placebo^[39]. Relapse tends to recur in the ensuing months: repeated infusions every 4 wk-8 wk may produce more lasting remissions^[40]. Infliximab is administered as a single^[40] or, to obtain a more prolonged response, multiple intravenous infusions^[40,41] at 4 wk-8 wk intervals, each given over 2 hours. The dose is $5\text{ mg}\cdot\text{kg}^{-1}$ per infusion, and the cost about £1000 (US \$1600) per infusion. Common minor side-effects include headache, nausea and upper respiratory tract infections. Serious, but not opportunistic, infections including salmonella enterocolitis, pneumonia and cellulitis have been reported. Infusion reactions occur in up to 20% patients, are usually mild and respond to antihistamines: however, adrenaline and corticosteroids should also be available when infusions are given. The development of human antichimeric antibodies (HACA) in up to 15% patients may cause a serum sickness reaction and diminished clinical response to repeated infusions. A lupus syndrome has been associated with anti-double-stranded DNA antibodies and cardiolipin antibodies in rheumatoid patients given infliximab. Rapid healing and fibrosis may precipitate bowel obstruction in patients with small intestinal strictures. Lastly, there are several reports of lymphoma in rheumatoid and Crohn's patients given infliximab, although whether these are due to the drug or the underlying disease is not yet clear. The benefits, or otherwise, of coprescription of azathioprine or 6-mercaptopurine in patients given anti-TNF antibody are not yet established. By analogy with the effects

of methotrexate in infliximab-treated patients with rheumatoid arthritis, conventional immunosuppressive drugs may have a synergistic effect and reduce the incidence of the development of autoantibodies and other adverse effects. It is conceivable, however, that immunosuppressive agents could increase the risk of lymphoma in patients on infliximab^[42]. In the future, selection of patients to be treated with anti-TNF antibody may depend not only on the disease phenotype (eg fistulating disease), but also their genotype. Preliminary evidence suggests that CD patients who are pANCA positive, and have particular TNF microsatellite haplotypes, for instance, show a poor response to infliximab.

Dietary therapy

In patients with a poor response to, or preference for avoiding corticosteroids, in those with extensive small bowel disease, and in children, an alternative primary therapy is a liquid formula diet. This can be either elemental (amino acid-based), protein hydrolysate (peptide-containing) or polymeric (containing whole protein and not therefore hypoallergenic), and is given for 4–6 weeks as the sole nutritional source^[43]. This approach is probably as effective as corticosteroid therapy in the short term, about 60% patients achieving remission. Unfortunately, after the resumption of a normal diet, many patients relapse (50% at six months). Whether this can be prevented by selective and gradual reintroduction of particular foods to which individual patients are not intolerant^[44], or by the intermittent use of further enteral feeding for short periods, remains to be proven. The success of enteral nutrition as a primary therapy for CD is also limited by its cost, the unpleasant taste of some of the available preparations and the need often to give the feed by nasogastric tube or percutaneous gastrostomy. Such therapy does, nevertheless, offer a valuable alternative in the compliant minority of adults for whom it is appropriate.

Surgery

In patients whose ileocaecal disease fails to respond to drug or dietary therapy, particularly if they have short segment (less than 20 cm) rather than extensive disease, surgery is indicated. Indeed, some patients prefer surgery at presentation to the prospect of pharmacological or nutritional treatment of uncertain duration; there is no controlled data to confirm which approach is best. After surgery, there is a 50% chance of recurrent symptoms at 5 years and of further surgery at 10 years.

SPECIFIC TREATMENT OF OTHER PRESENTATIONS OF ACTIVE CROHN'S DISEASE

Obstructive small bowel Crohn's disease In patients presenting with obstructive symptoms and signs,

with appropriate abnormalities on plain abdominal X-ray, the principal difficulty lies in deciding whether stricturing is due to active inflammation, fibrosis with scarring or even adhesions. Sometimes laboratory markers (e.g. raised platelet count, ESR, C-reactive protein) and/or radiolabelled leucocyte scan can help to identify individuals with active inflammatory Crohn's, but in most instances a short trial of intravenous corticosteroids is given in addition to intravenous fluids and, if necessary, nasogastric suction. Parenteral nutrition is required if resumption of an oral diet is not likely in 5–7 d. If the stricture is in the upper jejunum, terminal ileum or colon, enteroscopic or colonoscopic balloon dilatation can be undertaken^[45]; the value of concomitant local injection of triamcinolone around the stricture is as yet unclear. In patients not settling after 48 h–72 h of conservative treatment, surgery is needed, options being local resection or, for short and/or multiple strictures, stricturoplasty. Patients responding to conservative therapy should be advised to take a low residue diet to reduce the chance of recurrent symptoms.

Intra-abdominal abscess Ultra sound, CT scan and/or radiolabelled leucocyte scan are usually used to confirm suspected intra-abdominal abscess in patients with Crohn's. Broad spectrum antibiotics are given and the abscess drained percutaneously under radiological control, and/or surgically. Subsequent treatment is usually of the underlying pathological process, for example, ileocaecal inflammation.

Intestinal fistula The relevant anatomical connections are clarified using contrast radiology, CT, endoluminal ultra sound and/or MRI. Restitution of nutritional well being is required using enteral or parenteral nutrition. Where there is no obstruction distal to the site of intestinal fistulae, medical therapy with oral, rectal or intravenous metronidazole and/or oral azathioprine or 6-mercaptopurine^[26] cause some fistulae to heal. Uncontrolled reports suggest that intravenous cyclosporin may heal fistulous Crohn's, while a controlled trial shows anti-TNF- α antibody (infliximab) infusions to be a promising option^[41]. Most patients with enterocutaneous, vesical or vaginal fistulae, however, require surgical resection of the fistula and local resection of involved intestine and/or other viscera.

Perianal disease Non-suppurative perianal CD may respond to oral metronidazole^[46] and/or ciprofloxacin given for up to three months, and to azathioprine or 6-mercaptopurine in the long term^[26]. Successful healing of >50% perianal (and other) fistulae was reported in 62% patients treated with three intravenous infusions of anti-TNF- α

antibody (infliximab) compared with 26% of those given placebo^[41]. Although in this study it is not clear whether the fistulous tracks, rather than simply their openings on to the skin, healed, and reopening of fistulae was common in the 6 months after treatment was stopped, infliximab may prove a useful advance in therapy. Patients with suppurating perianal CD need surgery, minimised as far as possible and abscesses should be drained and loose (seton) sutures inserted to facilitate the continued drainage of chronic fistulae. Defunctioning ileostomy or colostomy is of uncertain benefit.

Crohn's colitis The treatment of active Crohn's colitis closely resembles that of active UC (Table 1). In contrast to UC, oral metronidazole (400 mg b.d. for up to three months), if tolerated, can be used in patients with only moderately active disease who wish to avoid corticosteroids or aminosalicylates: the response rate is up to 50%^[23]. There is no data to support the use of cyclosporin. Meta-analysis data suggest that Crohn's colitis, like ileocaecal disease, responds to a liquid formula diet^[43]. In patients who require total colectomy, permanent ileostomy is usually preferred to an ileoanal pouch because of the high incidence of pouch breakdown and sepsis in CD. Ileorectal anastomosis is an option in patients with rectal sparing, though recurrence requiring further surgery is far more common than after ileostomy. In rare individuals with refractory segmental colitis, local resections of short diseased segments can be performed. Toxic megacolon is even more rare in acute severe Crohn's than it has become in UC.

Oral and upper gastrointestinal Crohn's disease

Treatment of oral and upper gastrointestinal CD follows the usual principles outlined above. Patients with oral Crohn's are best managed in close conjunction with specialists in oral medicine: controlled trial data are lacking, but options include topical, intral esional and oral steroids as well as oral thiopurines and liquid formula diet. Duodenal Crohn's may respond to omeprazole^[47]; endoscopic balloon dilatation of strictures can be helpful, but surgery other than stricturoplasty may be technically demanding and complicated by fistulation.

MEDICAL TREATMENT OF IBD—THE FUTURE

Improvements in future medical treatments are likely to take several directions. First, conventional therapies, such as steroids and aminosalicylates, are likely to be made available in formulations which focus delivery more accurately on the site of disease and thereby further reduce systemic side effects. More excitingly, the increase in our knowledge of the aetiology and pathogenesis of IBD will inevitably lead to the development of more selectively targeted pharmacological agents, of

which the first to reach clinical application has been anti-TNF-alpha antibody. Gene therapy, for example applied topically to involved gut mucosa, may prove an important step forward in UC and Crohn's as in other chronic inflammatory diseases outside the gut. The choice of treatment in individual patients with IBD will depend not only on the phenotypic expression of their disease, but also on their genotype.

Whatever therapeutic advances are made in the coming years, the management of patients with IBD, whether apparently straightforward or difficult, will continue to depend on close collaboration between physicians, surgeons, specialist nurses, dieticians, radiologists, pathologists and counsellor, and a clinical geneticist may need to join this team. Most importantly, the patient with IBD must be looked upon as a person rather than a case. As treatment becomes more complex, and the options more varied, it is essential that the patient remains at the centre of the decision-making process, and the individual with IBD must be the final arbiter of the type of treatment he or she is to be given.

INTRODUCTION

Eradication of *Helicobacter pylori* (*Hp*) infection is generally not easy. Various clinical regimens have been recommended in the literature. With the experience from the other countries and the practice in China, Chinese doctors have tried many regimens. In this study, we collected and pooled the data from Chinese literature to evaluate the effect of different regimens in Chinese patients infected with *Hp*.

MATERIALS AND METHODS

Papers published from 1990 to 1997 were reviewed. The papers were cited from the index "Chinese Literature of Science and Technology, (Medicine)", Published by the Medical Information Institute of China, Beijing, and from the Chinese biomedical disks (CBMDISC). Papers were selected according to the following criteria: ① the papers must be published in full text; ② data must be from original studies from author's own unit; ③ *Hp* status must be determined using histology, microbiology and urea breath test; and ④ the studies should be appropriately designed and reported. If several papers were published from the same data source, the one with the best data was included.

RESULTS

Monotherapy Monotherapy has been fully proved to be not effective in *Hp* eradication, with a eradication rate between 10%-45%.

Dual therapy Proton pump inhibitor (PPI) dual therapy was introduced from western countries to China, whereas furazolidone was developed in China. The data are shown in Tables 1,2.

Triple therapy PPI and bismuth triplies were main regimens recommended. Furazolidone was fully practiced in China. Their results are shown in Tables 3-5.

Department of Gastroenterology, First Municipal People's Hospital of Guangzhou 510180, Guangdong Province, China

Correspondence to: Prof. Yu Yuan Li, Head of Department of Gastroenterology, First Municipal People's Hospital of Guangzhou, 602 Ren Min Bei Road, Guangzhou 510180, Guangdong Province, China

Received 2000-01-23 **Accepted** 2000-03-19

Quadruple therapy Only two studies were available using 1 week course of bismuth, PPI and two antibiotics. The eradication rates were 91% and 93%, and the occurrence rate of side effect being 33%^[19,20].

DISCUSSION

Eradication of *Hp* is considered to be confirmed when the tests of *Hp* continue to be negative for at least 4 weeks after the discontinuation of treatment^[21]. Great efforts have been made to establish regimens with good efficacy and safety. It is recognized in western countries that a good regimen should reach the eradication rate of intention to treat (ITT) > 80% and per protocol (PP) > 90%^[22]. In most Chinese papers only the rate of PP was available, therefore used in this review. In consideration of high resistant rates to antibiotic and the high prevalence of *Hp* in the country, a regimen with a PP eradication rate > 85% should be accepted in our practice. With this standard we found that both PPI triple therapy and bismuth triple therapy with a two-week course were good for Chinese patients. The former had high adverse events and the latter was more expensive. In most treatment, the dosage of antibiotics was cut down in order to reduce the side effects. It was shown that the low-dose triple therapies could yield high eradication rates in Chinese patients because they had lower body weight. The limited data with one-week quadruple therapy showed that it could be a good alternative especially for the patients who failed to other regimens. Monotherapy and dual therapy were not suitable in practice because of their poor efficacy. These findings agree with the data from western literatures^[23].

The presence of resistant *Hp* strains is a severe problem in China and influences the efficacy of treatments. The resistant rates to metronidazole were reported to be between 28%-80%, and clarithromycin, <5%. However, there has been no reported resistance to bismuth, amoxycillin, furazolidone and tetracycline. These antibiotics should be used to replace metronidazole if the resistance exists. Some studies recommended furazolidone, which was less expensive, with low resistance but more adverse events.

Recently the consensus reports from European, American and Asia Pacific areas recommended the following regimens^[22,24,25]: ① PPI (ome 20 mg or lan 30 mg) + Cla 500 mg + Amo 1000mg; ② PPI + Cla 250/500 mg + Met 400 mg; ③ RBC/Bis + Cla 500 mg + Met 400 mg/Amo; and ④ PPI + Bis + Met + Tetra.

All were used twice daily for the one-week course. These regimens had a good efficacy in western countries, but have not been extensively examined in China. RBC is still unavailable in China. The preliminary results from our group showed that Lan30 + Cla500 + Met400 regimen reached a 93% eradication rate, but Lan30 + Cla250 + Met400 only 77%^[26]. More studies are needed before their establishment in this country.

INTRODUCTION

Numerous studies have demonstrated the protective action of prostaglandin E1 (PGE1) on experimental animal models of liver injury and on patients with fulminant viral hepatitis. It could act on PGE1 receptor of the diseased vessels to dilate them and increase portal venous flow, improve the microcirculation of the liver, clear the metabolites of the liver cells, and increase oxygen supply to the liver tissues. PGE1 could also accumulate at the inflammatory portion, inhibit the release of lethal factors, stabilize the membrane of liver cells and lysosome, inhibit the active oxygen, and promote the proliferation of the liver cells. It is now used to treat fulminant hepatic failure.

PROTECTIVE ACTION OF PGE1 ON EXPERIMENTAL ANIMAL MODELS OF LIVER INJURY

The protective action of PGE1 has been shown on both experimental animal models of liver injury and patients with fulminant viral hepatitis. Beck *et al*^[1] examined the effects of long-term PGE treatment on liver and stomach in cirrhotic rats. Cirrhosis was induced by bile duct ligation. Sham-operation was performed as controls. Half of the rats received a PGE1 analogue, misoprostol (PGE1) (10 µg orally, daily) on d 1-d 29 postoperation, and the others received placebo only. Liver chemistry, portal pressures, and levels of prostaglandin E2, leukotriene B4, myeloperoxidase, and collagen in hepatic and gastric tissue of all rats on d 31 were determined. PGE1-treated cirrhotic rats had less hepatosplenomegaly, lower serum alanine aminotransferase levels, and portal pressures and higher arterial pressure than placebo-treated

cirrhotic rats. Hepatic and gastric leukotriene B4, myeloperoxidase and collagen levels were significantly lower in the PGE1-treated compared with placebo-treated cirrhotic rats. Placebo-treated cirrhotic rats had greater spontaneous and ethanol-induced gastric damage and failed to show gastric hyperemic response to ethanol, whereas PGE1-pretreated rats did. PGE1 did not significantly affect sham-operated rats. Beck suggested that long-term PGE1 administration was cytoprotective for both the liver and gastric mucosa in cirrhotic rats.

An animal model of hepatocytic necrosis was established by Gu^[2] with injection of D-galactosamine into peritoneal cavity. Examination at regular intervals after injection of PGE showed that the level of increased serum TB, ALT and GST and the degree of histological changes in the liver were less marked in PGE-treated animals ($n = 34$) than those in PGE-untreated animals ($n = 29$), suggesting that PGE has definite protective effect on experimental hepatocytic necrosis.

The effects of PGE1.CD on dimethylnitrosamine (DMN)-induced acute liver damage with intravascular coagulation in rats were biochemically and histopathologically investigated by Suzuki^[3]. PGE1.CD was administered i.v. 30 min before and 24 h after DMN-intoxication (pretreatment) and 30 min or 4 h to 24 h after DMN-intoxication (post-treatment). Pretreatment with PGE1.CD ($0.2-2 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) dose-dependently suppressed the decrease of platelet counts and the elevation of blood biochemical parameters (PT, HPT, GOT, GPT, LDH, LAP, T-Bil) caused by DMN-intoxication. PGE1.CD ($0.5 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ or over) significantly suppressed the DMN-induced histopathological changes (occurrence of hemorrhage and necrosis). Post-treatment with PGE1.CD ($2 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) also suppressed the liver damage. Furthermore, pretreatment with PGE1.CD ($2 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) not only suppressed the disruption of hepatocytes, but also prevented the damages of sinusoidal endothelial cells and lysosomal membrane, and it reduced the increase of lipid peroxidation. PGE1.CD ($1 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ or over) significantly suppressed the decrease of hepatic tissue blood flow caused by DMN-intoxication. These results demonstrate that PGE1.CD has therapeutic efficacy against DMN-induced acute liver damage in rats, therefore, it will be clinically useful for the treatment of severe hepatitis such as fulminant hepatitis with intravascular coagulation in the sinusoid.

PGE1 AND SEVERE HEPATITIS

The effect of PG on patients with fulminant and subfulminant viral hepatitis (FHF) was studied by Sinclair^[4]. Seventeen patients presented with FHF secondary to hepatitis A ($n = 3$), hepatitis B ($n = 6$), and non-A, non-B (NANB) hepatitis ($n = 8$). Fourteen of the 17 patients had stage III or IV hepatic encephalopathy (HE). The mean aspartate transaminase (AST) was $1844 \text{ U/L} \pm 1246 \text{ U/L}$, bilirubin $232 \mu\text{mol/L} \pm 135 \mu\text{mol/L}$, prothrombin time (PT) $34 \text{ s} \pm 18 \text{ s}$, partial thromboplastin time (PTT) $73 \text{ s} \pm 26 \text{ s}$, and coagulation Factors V and VII $8\% \pm 4\%$ and $9\% \pm 5\%$, respectively. Intravenous PGE1 was initiated 24 h-48 h later after a rise in AST ($2195 \text{ U/L} \pm 1810 \text{ U/L}$), bilirubin ($341 \mu\text{mol/L} \pm 148 \mu\text{mol/L}$), PT ($36 \text{ s} \pm 15 \text{ s}$), and PTT ($75 \text{ s} \pm 18 \text{ s}$). Twelve of 17 responded rapidly with a decrease in AST from $1540 \text{ U/L} \pm 833 \text{ U/L}$ to $188 \text{ U/L} \pm 324 \text{ U/L}$. Improvement in hepatic synthetic function was indicated by a decrease in PT from $27 \text{ s} \pm 7 \text{ s}$ to $12 \text{ s} \pm 1 \text{ s}$ and PTT from $61 \text{ s} \pm 10 \text{ s}$ to $31 \text{ s} \pm 2 \text{ s}$, and an increase in Factor V from $9\% \pm 4\%$ to $69\% \pm 18\%$ and Factor VII from $11\% \pm 5\%$ to $71\% \pm 20\%$. Five responders with NANB hepatitis relapsed upon discontinuation of therapy, with recurrence of HE and increases in AST and PT, and improvement was observed upon retreatment. After 4 wk of intravenous therapy oral PGE2 was substituted. Two patients with NANB hepatitis recovered completely and remained in remission 6 mos and 12 mos after cessation of therapy. Two additional patients maintained in remission after 2 mos and 6 mos of PGE2. No relapses were seen in the patients with hepatitis A virus and hepatitis B virus infection. Liver biopsies in all 12 surviving patients restored to normal. In the five non-responders an improvement in hepatic function was indicated by a fall in AST ($3767 \text{ U/L} \pm 2611 \text{ U/L}$ to $2142 \text{ U/L} \pm 2040 \text{ U/L}$), PT ($52 \text{ s} \pm 25 \text{ s}$ to $33 \text{ s} \pm 18 \text{ s}$), and PTT ($103 \text{ s} \pm 29 \text{ s}$ to $77 \text{ s} \pm 44 \text{ s}$), but all deteriorated and died of cerebral edema ($n = 3$) or liver transplantation ($n = 2$). These results suggest that PGE has beneficial effect on FHF.

According to the severity, hepatic failure was divided into early stage, typical symptom stage and late stage. A treatment group of 55 cases received PGE1 therapy and a control group received basic support therapy only. The results showed that difference of the total effective rate was not significant between these two groups, but in the early stage of hepatic failure, the effective rate in the treatment group was markedly higher than that in the control group. In addition, incidence of hepato-renal syndrome was lower in the treatment group^[2]. This study indicates that division of severe viral hepatitis into three stages for evaluation of therapeutic effect is rational and useful and early use of PGE1 may certainly show some efficacy.

While orthotopic liver transplantation (OLT) has become the treatment of choice for most

irreversible end-stage liver diseases, its role in patients with hepatitis B (HBV) infection is controversial. A high risk of reinfection of the transplanted graft, associated with significant morbidity and mortality, has been reported. Although passive and active immunization can delay the reappearance of virus in the allograft, there is not yet an effective therapy for recurrent HBV infection in liver transplant recipients. Twenty-eight OLT in 25 patients with acute and chronic HBV infections were performed^[5]. Twelve of the patients were HBV DNA-negative, six were HBV DNA-positive, and seven were not tested prior to transplantation. Only 19 patients surviving more than 100 days after transplantation were considered to have sufficient duration of follow-up (mean 734 days) to include in the analysis of recurrence. Five (26%) were free of recurrent disease at the time of last follow-up (mean 1031 days). Recurrent HBV in the allograft, as defined by positive immunoperoxidase stains of biopsy sections for viral antigens, was detected in 74% at a mean of 134 d posttransplantation. Histological changes of viral hepatitis were evident in 13 of 14 with positive immunostaining. Twelve of the 14 patients were treated, on an open trial basis, with intravenous and oral prostaglandin E (PGE) because of deteriorating clinical condition. Eleven of the twelve responded to PGE with an initial drop in serum transaminases, improvement in coagulopathy and resolution of encephalopathy. One patient failed to respond and died of myocardial infarction within 9 d of institution of therapy. Three of the eleven patients with an initial response relapsed and died of liver failure as a direct result of recurrent HBV after 13 d, 16 d and 37 d of treatment in association with generalized sepsis. Eight of the 12 patients (67%) had a sustained favorable response to PGE therapy (mean follow-up 737 days). All patients with a sustained response had accompanying improvement in histology and reduction in viral antigen staining in hepatocytes. Treatment with PGE appeared to be of benefit in recurrent HBV infection of the transplanted liver with an initial response rate of 92% and a sustained response rate of 67%.

The efficacy of PGE1 was demonstrated in the treatment of another 4 patients with subfulminant hepatitis of viral hepatitis B^[6]. Three patients suffered from hepatic encephalopathy of the first degree, and the remaining one of the second degree. In three patients the clinical and biochemical improvement came relatively quickly, followed by recovery. In one patient, due to drug intolerance, the treatment was discontinued on the third day. The recurrence of illness was noted with the moderate increase of serum aminotransferase activities without clinical deterioration, necessitating no further use of prostaglandin E1.

Bojic suggested that prostaglandin E1, applied in the treatment of patients with subfulminant form of hepatitis, has favorable effect on the course of illness.

In a rare case of severe acute hepatitis A complicated by pure red cell aplasia (PRCA), plasma exchange transfusion and glucagon-insulin (GI) therapy improved the consciousness, but bilirubin, transaminase levels, and IgM anti-HAV titer remained high. Intravenous administration of lipophilized PGE1 (lipo-PGE1) was added to the GI therapy. Bilirubin and transaminase levels were normalized in the wk 8 after the initiation of this combination therapy (17 wk after admission). The combined use of lipo-PGE1 with plasma exchange and GI therapy appeared to be useful for the severe hepatitis in this patient^[7].

Two patients with HIV infection developed acute hepatitis B with liver insufficiency and hepatic encephalopathy. After alprostadil infusion was begun, they improved quickly and got a full recovery^[8].

MECHANISMS OF HEPATIC CYTOPROTECTION OF PGE1

Indocyanine green disappearance enhanced by PGE1

Indocyanine green (ICG) is a reliable indicator reflecting hepatocyte function and hepatic blood flow. PGE1 has been indicated to increase hepatic blood flow and protect the hepatocyte. Tsukada^[9] found that PGE1 administration increased ICG-K in the liver cirrhosis (LC) and chronic hepatitis (CH) groups with normal liver function, and the ICG-K response was dose dependent when the dosage of PGE1 ranged from $0.01 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ to $0.05 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$.

Inhibitory effects of PGE1 on T-cell mediated cytotoxicity

The effects of PGE1 on cell-mediated cytotoxicity against hepatocytes were investigated using *in vitro* cytotoxic assay system by Ogawa^[10]. Isolated liver cells from normal C57BL/6 mice were used as the target cells, and effector cells were obtained from spleens of C57BL/6 mice in which experimental hepatitis had been induced by immunization with syngeneic liver antigens. In this assay system, spleen T cells adhering to nylon wool demonstrated a high cytotoxic activity against target liver cells. The cytotoxicity was markedly reduced by PGE1 at concentrations greater than 10^{-7}mol/L . Maximum suppressive activity was obtained when PGE1 was continuously present during the assay period. By contrast, indomethacin, a specific inhibitor of prostaglandin synthesis, enhanced the cytotoxic activity of effector cells. These data seem to indicate that exogenously added PGE1 has an inhibitory effect on cell-mediated cytotoxicity of effector spleen cells against target hepatocytes.

PGE1 enhance DNA synthesis of injured liver after partial hepatectomy by stimulating cyclic AMP production and increasing ATP level in hepatic tissue

D-galactosamine (D-gal) damaged rats were infused with PGE1 through peripheral vein for 40 min. before and after partial hepatectomy. DNA synthesis following 68% partial hepatectomy was severely inhibited by the pretreatment of D-galactosamine. PGE1 infusion ($0.5 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$, $1.0 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) enhanced the DNA synthesis inhibited by D-gal 600 mg/kg significantly ($P < 0.01$). After 20 min of PGE1 infusion cyclic AMP levels of liver tissue was increased as compared with saline infusion in D-gal (600 mg/kg) damaged rat ($P < 0.05$). Twenty min and 3 h after partial hepatectomy, ATP levels of liver tissue was enhanced in PGE1 treated group ($P < 0.05$). These results suggest that PGE1 enhances DNA synthesis of injured liver after partial hepatectomy by the mechanism of stimulating cyclic AMP production and increasing ATP level in hepatic tissue^[11].

PGE1 could accelerate the recovery of mitochondrial respiratory function after reperfusion, stabilization of membrane microviscosity

PGE1 has been indicated to increase hepatic blood flow and protect the hepatocyte. Kurokawa *et al*^[12] found that PGE1 could accelerate the recovery of mitochondrial respiratory function after reperfusion. When PGE1 was continuously administered to rats from 24 h before giving a dose of carbon tetrachloride, deranged serum glutamic pyruvic transaminase levels and prothrombin time were significantly reduced 12 h after intoxication compared with controls. A similar effect of PGE1 was seen at 24 h in D-galactosamine-intoxicated rats. Liver histology showed a comparable attenuation of injury in these rats. These results were consistent with reported effects of PGE2, suggesting that both prostaglandins may share a common pathway in protection against liver injury. When PGE1 or 16,16'-dimethyl PGE2 was added to the medium of primary cultured rat hepatocytes, lipid peroxidation-dependent killing of the cells by tert-butyl hydroperoxide was significantly attenuated without affecting the extent of malondialdehyde accumulation compared with controls. Both prostaglandins significantly reduced the extent of increased plasma membrane microviscosity of these cells. Masaki *et al*^[13] concluded that PGE1 and PGE2 may possess cytoprotective effects on liver parenchymal cells through stabilization of membrane microviscosity, which may contribute to protection against liver injury.

While the mechanisms of prostaglandin on protecting liver injury are not well understood, it has been demonstrated that dimethyl PGE2

abrogates the induction of tumour necrosis factor, leukotriene B4 (LTB4) and procoagulant activity by macrophages as well as attenuating the expression of major histocompatibility class antigens on the surface of hepatocytes, and may inhibit viral replication. From the present research, we came to a conclusion that increasing hepatic blood flow, accelerating the recovery of mitochondrial respiratory function after reperfusion, stabilizing the membrane microviscosity, decreasing the cell-mediated cytotoxicity against hepatocytes, enhancing DNA synthesis by stimulating cyclic AMP production and increasing ATP level in hepatic tissue made PGE1 as a hepatic cytoprotective agent.

TOXIC EFFECTS OF INTRAVENOUS AND ORAL PGE THERAPY ON PATIENTS WITH LIVER DISEASE

Prostaglandins are cytoprotective agents that have been shown to benefit patients with a variety of acute and chronic liver diseases. Few data exist on the frequency of adverse effects of prostaglandins in these patients. Catral *et al.*^[14] retrospectively studied 105 patients with liver disease who were treated with either i.v. or oral PGE. Forty-four patients with primary nonfunction after liver transplantation and 36 patients with fulminant hepatic failure received i.v. PGE1 for 4.5 d \pm 2.6 d and 12.6 d \pm 10.9 d, respectively. Twenty-five patients with recurrent hepatitis B viral infection after liver transplantation received oral PGE1 for 105 d \pm 94 d or PGE2 for 464 d \pm 399 d. Twenty-six of 80 patients (33%) receiving i.v. PGE1 developed gastrointestinal and/or cardiovascular side effects and 8% developed arthritis. Twenty-three (92%) of 25 patients who received high-dose oral PGE1 or PGE2 incurred arthritis and/or gastrointestinal adverse effects. Twenty-five patients received prolonged PGE therapy (oral >60d; i.v. >28d). Of this group, 23 (92%) developed clubbing and cortical hyperostosis resembling hypertrophic osteoarthropathy. All adverse effects were dose related and resolved with reduction or cessation of therapy. PGE therapy resulted in a wide spectrum of multisystem adverse effects which were reversible with reduction or cessation of therapy. Although the administration of PGE was safe and generally well tolerated, close medical supervision is necessary to avoid serious side effects.

RECENT ADVANCES IN LIPID MICROSPHERE TECHNOLOGY FOR TARGETING PROSTAGLANDIN DELIVERY

Although PGE1 exhibits pharmacological activities in free form, it has been hypothesized and experimentally verified that carrier can target them more effectively at lower doses, thus causing fewer

side effects. Lipid microspheres (LM) with a diameter of 0.2 μ m are drug carriers prepared from soybean oil and lecithin, and the drug is incorporated within the LM. Lipo-PGE1 is LM preparations of PGE1 that are designed to accumulate at the vascular lesions. The newly developed lipo-PGE1 (lipo-AS013) could overcome the disadvantages of the preparation currently available^[15]. Lipo-AS013, a precursor of PGE1, is considered superior to free PGE1 in terms of its chemical stability and the retention ratio in LM in the body.

Abstract

AIM To investigate the interaction of Zot with microtubule.

METHODS Zot affinity column was applied to purify Zot-binding protein(s) from crude intestinal cell lysates. After incubation at room temperature, the column was washed and the proteins bound to the Zot affinity column were eluted by step gradient with NaCl ($0.3 \text{ mol} \cdot \text{L}^{-1}$ – $0.5 \text{ mol} \cdot \text{L}^{-1}$). The fractions were subjected to 6.0%–15.0% (w/v) gradient SDS-PAGE and then transferred to PVDF membrane for N-terminal sequencing. Purified Zot and tau protein were blotted by using anti-Zot or anti-tau antibodies. Finally, purified Zot was tested in an *in vitro* tubulin binding assay.

RESULTS Fractions from Zot affinity column yielded two protein bands with a M_r of 60kU and 45kU respectively. The N-terminal sequence of the 60kU band resulted identical to β -tubulin. Zot also cross-reacts with anti-tau antibodies. In the *in vitro* tubulin binding assay, Zot co-precipitate with Mt, further suggesting that Zot possesses tubulin-binding properties.

CONCLUSION Taken together, these results suggest that Zot regulates the permeability of intestinal tight junctions by binding to intracellular Mt, with the subsequent activation of the intracellular signaling leading to the permeabilization of intercellular tight junctions.

INTRODUCTION

Vibrio cholerae, the human intestinal pathogen responsible for the diarrhoeal disease cholera, elaborates a large number of extracellular proteins, including several virulence factors. The severe dehydrating diarrhoea characteristic of cholera is induced by cholera toxin (CT). A number of epidemiological studies^[1-4] have shown a concurrent occurrence of the CT genes (ctx-A and ctx-B) and the genes for two other virulence factors elaborated by *V. cholerae*, zonula occludens toxin (Zot)^[5] and accessory cholera toxin (Ace)^[6]. Zot increases the intestinal permeability by rearranging the intestinal cell cytoskeleton strategically located to modulate intercellular tight junctions^[7]. However, the first step of Zot signaling after the protein internalization remains to be established.

Microtubules (MT) are intracellular structures functionally and anatomically related to the cell cytoskeleton. MTs are composed of α -tubulin and β -tubulin. Factors known to regulate microtubule dynamic include microtubule-associated proteins (MAPs). Neuronal MAPs, the most abundant of which are MAP2 and tau, stimulate MT assembly^[8,9]. The best characterized function of MT network polymers is the bi-directional movement of membrane vesicles driven by the MT-based motor proteins, kinesin and cytoplasmic dynein. Different cargoes can be transported via MT-dependent vesicles, including various types of endocytic and exocytic vesicles^[10,11]. Connection of actin filament network has been found^[12]. In eukaryotic organisms, various cell functions, including cell shape and mobility require coordinational interaction between actin and MT cytoskeleton^[13].

In our study, we found that when cell lysates from mammalian tissues passed through a Zot affinity column, two proteins bound to Zot, the N-terminal sequence of one of these two proteins revealed that it corresponded to tubulin; Zot cross-reacted with antibody against Tau, another well described MAP isolated from mammalian brain; by using a microtubule binding assay, Zot was found co-precipitated with MT. Taken together, these results suggest that Zot is a new member of MAPs family. This Zot property may be involved in the Zot signaling leading to the regulation of intercellular TJ.

MATERIAL AND METHODS

Purification of 6-his Zot

Plasmid pSU111, containing the clone Zot gene in a pQE-30 vector with a 6-histidine tag at its N-terminal, was grown in LB medium with 20 g/L glucose, 25 $\mu\text{g/L}$ kanamycin and 200 $\mu\text{g/L}$ ampicillin at 37°C with vigorous mixing until the A_{600} reached 0.7–0.9. Cultures were then induced with 2 $\text{mmol}\cdot\text{L}^{-1}$ isopropylthio- β -D-galactoside (IPTG, Fisher), followed by an additional 2 h culture period at 37°C with vigorous shaking. The cells were harvested by centrifugation at 4 000 $\times g$ for 20 min and resuspended in buffer A (6 $\text{mol}\cdot\text{L}^{-1}$ Guanidine-HCl, 0.1 $\text{mol}\cdot\text{L}^{-1}$ Na-phosphate, 0.01 $\text{mol}\cdot\text{L}^{-1}$ Tris-HCl, pH 8.0; 5 mL/g wet cell weight). After stirring for 1 h at room temperature, the mixture was centrifuged at 10 000 $\times g$ for 30 min at 4°C. A 50% slurry of Superflow (QIAGEN, 1 mL/g wet cell) was added to the supernatant and stirred for 1 h at room temperature. The mixture was loaded onto a 5 cm \times 1.5 cm column and washed sequentially with buffer A, buffer B (8 $\text{mol}\cdot\text{L}^{-1}$ urea, 0.1 $\text{mol}\cdot\text{L}^{-1}$ Na-phosphate, 0.01 $\text{mol}\cdot\text{L}^{-1}$ Tris-HCl, pH 8.0) and buffer C (8 $\text{mol}\cdot\text{L}^{-1}$ urea, 0.1 $\text{mol}\cdot\text{L}^{-1}$ Na-phosphate, 0.01 $\text{mol}\cdot\text{L}^{-1}$ Tris-HCl, pH 6.3). Each wash step was continued until the A_{280} of the flow-through was less than 0.01. His-Zot was eluted by addition of 250 $\text{mmol}\cdot\text{L}^{-1}$ imidazole (1,3-diaza-2,4-cyclopentadiene) to buffer C. After dialysis against urea, the eluate was diluted 200–500 times in PBS, stirred with 50% slurry Superflow (1 mL/g wet cell weight) for 2 h at room temperature, loaded onto another 5 cm \times 1.5 cm column, washed with phosphate-buffered saline (PBS) and eluted with 250 $\text{mmol}\cdot\text{L}^{-1}$ imidazole in PBS. Purity of the His-Zot protein was established by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis and Western blot using polyclonal anti-Zot antibodies.

Analytical procedures

SDS-PAGE It was carried out on a 50 $\text{g}\cdot\text{L}^{-1}$ –150 $\text{g}\cdot\text{L}^{-1}$ gradient gel, stained with Coomassie brilliant blue dye, destained by 75 $\text{mL}\cdot\text{L}^{-1}$ acetic acid with 100 $\text{mL}\cdot\text{L}^{-1}$ methanol and dried with Gel Drying Film (Promega).

Western blot analysis Following SDS-PAGE, proteins were transferred onto polyvinylidene difluoride (PVDF) membrane (MILLIPORE). Non-specific binding sites were blocked by PBS with 50 $\text{mL}\cdot\text{L}^{-1}$ milk plus 1 $\text{g}\cdot\text{L}^{-1}$ Tween-20. Primary and secondary antibodies were rabbit polyclonal anti-Zot antibody and anti-rabbit IgG (peroxidase conjugate, Sigma), respectively. Films were exposed with ECL detection reagent (Amersham) for 1 min, and developed by Konica SRX-101 developer.

Immobilization of his-Zot to AminoLink plus column

One mg of his-Zot in 4 mL coupling buffer (0.1 $\text{mol}\cdot\text{L}^{-1}$ sodium phosphate, 0.15 $\text{mol}\cdot\text{L}^{-1}$ NaCl, pH 7.2) and 40 μL of 5 $\text{mol}\cdot\text{L}^{-1}$ sodium cyanoborohydride, were added to an equilibrated AminoLink plus column (Pierce) and gently mixed overnight at 4°C. After washing with coupling buffer, 4 mL of 1 $\text{mol}\cdot\text{L}^{-1}$ Tris-HCl (pH 7.4) and 40 μL of 5 $\text{mol}\cdot\text{L}^{-1}$ sodium cyanoborohydride were added to the column followed by gently mixing for 30 minutes at room temperature to block the remaining active sites. The column was washed with 1 $\text{mol}\cdot\text{L}^{-1}$ NaCl and stored in PBS containing 0.5 $\text{g}\cdot\text{L}^{-1}$ sodium azide.

Preparation of human tissue plasma membranes

Adult human brain tissues were obtained from the Brain and Tissue Banks for Developmental Disorders at the University of Maryland and used under the approval of the University's Institutional Review Board. Adult human heart and intestinal tissues were utilized for comparative analysis. Tissues were washed with buffer D (20 $\text{mmol}\cdot\text{L}^{-1}$ Tris-HCl, 20 $\text{mmol}\cdot\text{L}^{-1}$ EDTA, 250 $\text{mmol}\cdot\text{L}^{-1}$ sucrose, pH 7.5), homogenized in buffer E (buffer D containing 5 $\text{mg}\cdot\text{L}^{-1}$ leupeptin, 2 $\text{mg}\cdot\text{L}^{-1}$ aprotinin, 1 $\text{mg}\cdot\text{L}^{-1}$ pepstatin, 10 $\text{mg}\cdot\text{L}^{-1}$ phenylmethanesulfonyl fluoride (PMSF), and centrifuged at 5 000 $\times g$, 4°C for 10 min. Supernatants were centrifuged at 12 000 $\times g$, 4°C for 45 min. Precipitates were discarded and supernatants were centrifuged at 30 000 $\times g$, 4°C for an additional 90 min. Precipitates were dissolved in buffer E with 5 $\text{g}\cdot\text{L}^{-1}$ 3[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate (CHAPS), sitting on ice for 60 min with gentle mixing every five minutes.

Affinity purification of his-Zot binding proteins

Membrane preparations obtained from human brain were loaded on an AminoLink plus -Zot affinity column, washed, and equilibrated with PBS at room temperature containing 1 $\text{g}\cdot\text{L}^{-1}$ Triton X-100. The columns were incubated for 90 min at room temperature, washed with 8 volumes of PBS containing 1 $\text{g}\cdot\text{L}^{-1}$ Triton X-100, and eluted with PBS containing 1 $\text{g}\cdot\text{L}^{-1}$ Triton X-100 with 0.1 $\text{mol}\cdot\text{L}^{-1}$ NaCl, 0.3 $\text{mol}\cdot\text{L}^{-1}$ NaCl, 0.5 $\text{mol}\cdot\text{L}^{-1}$ NaCl, 0.8 $\text{mol}\cdot\text{L}^{-1}$ NaCl and 1.0 $\text{mol}\cdot\text{L}^{-1}$ NaCl, respectively. Fractions were collected and subjected to SDS-PAGE. N-terminal amino acid sequence analysis.

N-terminal amino acid sequence analysis

The fractions of human tissue lysates containing Zot binding proteins were resolved by 50 $\text{g}\cdot\text{L}^{-1}$

150 g·L⁻¹ gradient SDS-PAGE and transferred onto PVDF membranes using CAPS buffer [10mmol·L⁻¹ 3-(cyclohexylamino)-1 propanesulfonic acid and 100 mL·L⁻¹ methanol]. The protein bands were excised and subjected to N-terminal sequencing using a Perkin-Elmer Applied Biosystems Apparatus Model 494.

Microtubule binding assay

Spin-Down assay kit (Cytoskeleton) was used in the experiments according to the *manufacturer's* recommendations. MT (20 nmol·L⁻¹ final concentration) were obtained by mixing an aliquate of tubulin (20 µL, 5 g/L) and 2 µL, 200 mmol·L⁻¹ taxol in G-PEM buffer (80mmol·L⁻¹ Pipes pH 6.8, 1mmol·L⁻¹ MgCl₂, 1mmol·L⁻¹ EGTA and 1mmol·L⁻¹ GTP). One µg of Zot was incubated with 20 nmol·L⁻¹ microtubule at room temperature for 20 min, while MT-associated protein MAP2 and bovine serum albumin (BSA) were used as positive and negative control, respectively. Proteins attached to MT and unbound proteins were separated by centrifugation. Each reaction product was carefully placed on the top of a cushion (G-PEM buffer plus 400 g·L⁻¹ glycerol) in Ultraclear TM ultracentrifuge tube. Following centrifugation, supernants and pellets were carefully removed and supernants were mixed with 1/20th volum of 500 g·L⁻¹ TCA solution for precipitation protein using centrifuge. Both supernants and pellets of the preparations containing the tested proteins were analyzed by either SDS-PAGE (MAP2 and BSA) or western blotting (Zot).

RESULTS

Isolation of Zot binding proteins from human brain

His-Zot was successfully immobilized to AminoLink Plus gel with immobilization yields of 89%-95%, as established by the protein assay (Bio-Rad detergent-compatible protein assay). Plasma membrane preparations from human brain loaded on the Zot affinity column contained two major Zot-binding proteins with apparent molecular masses of approximately 45kU and 55kU, respectively (Figure 1, lane 2).

N-terminal sequencing of the Zot binding proteins from human brain

The N-terminal sequences of the two Zot/zonulin binding proteins are shown in Table 1. The two proteins were also compared to other protein sequences by Blast search analysis. The N-terminal sequence of the 55kU protein was 100% identical to the N-terminal sequence of tubulin (Table 1) whereas the -45kU protein band resulted 72% identical to the N-terminus of calprotectin, a

calcium binding protein associated to chronic inflammatory processes^[14] and the cystic fibrosis antigen (CFA)^[15]. This second protein resulted to be the Zot/zonulin brain receptor^[16].

Western immunoblotting experiments

To investigate whether Zot and tau (a well characterized MAP) are immunologically related, cross immunoscreening experiments were performed. As shown in Figure 2, both proteins were recognized by either anti-Zot antibodies (left panel) or anti-tau antibodies (right panel). These results suggest that Zot and tau are immunologically related.

Microtubule binding assay

To confirm that Zot possesses MT binding properties, an *in vitro* binding assay was performed. As shown in Figure 3, we observed that Zot co-precipitated with MT as shown by Western immunoblotting analysis, while no Zot was found unbound. BSA lacking MT-binding properties was present only in the supernant. MAP2, a well defined MT associated protein, co-precipitated with MT and was not present in the supernant. These results confirmed the Zot ability to bind to MT.

Table 1 N-terminal amino acid sequences of Zot binding protein (55kU), β -tubulin, Zot binding protein (45kU), calprotectin (MRP-8), and cystic fibrosis antigen

Sample	N-terminus	Identity(%)
Zot binding protein-55kU	MREIVHIQAGQAGNQIGAKF	100
β -tubulin	MREIVHIQAGQAGNQIGAKF	
Zot binding protein-45kU	LTELEKALNXGGGVGHKY	77
Calprotectin (MRP-8)	LTELEKALNSIIDVYHKY	
Cystic fibrosis antigen	LTELEKALNSIIDVYHKY	77

Figure 1 SDS-PAGE of Zot binding proteins isolated by affinity column chromatography from human brain cortex plasma membrane preparations. Lane 1, molecular mass standards; Lane 2, whole-plasma membrane lysate; lane 3, eluate with 0.5 mol·L⁻¹ NaCl in PBS containing 1 g·L⁻¹ Triton X-100.

Figure 2 Western immunoblotting of Zot and tau using either anti-Zot antibodies (left panel) or anti-tau antibodies (right panel). Zot and tau were recognized by both antibodies.

Figure 3 Microtubule binding assay. BSA (negative control) and MAP2 (positive control) were visualized by Coomassie staining (left panel) while Zot was visualized by immunoblotting (right panel). The bottom protein bands in the left panel are tubulins. As anticipated, BSA remained in the supernatant (S), while MAP2 was entirely precipitated in the pellet (P). Zot also appeared confined in the pellet, confirming that it bound to MT.

DISCUSSION

Tj is the hallmark of absorptive and secretory epithelia. As a barrier between apical and basolateral compartments, the tj selectively controls the paracellular passage of water, solutes and immune cells between epithelial and endothelial cells. Variations in transepithelial conductance can usually be attributed to changes in the permeability of the paracellular pathway, since the resistances of eukaryotic cells plasma membrane are relatively high^[17]. Tj represent the major barrier in this paracellular pathway and the electrical resistance of epithelial and endothelial tissues seems to depend on the number of transmembrane protein strands and their complexity as observed by freeze-fracture electron microscopy^[18]. It has become abundantly clear that, in the presence of Ca^{2+} , assembly of the tj is the result of cellular interactions that trigger a complex cascade of biochemical events that ultimately lead to the formation and modulation of an organized network of tj elements, the composition of which has been only partially characterized^[19].

Identification and characterization of Zot, a toxin produced by *Vibrio cholerae*, has provided

new information on the regulation of intercellular tj [5,7,20-22]. After binding to its surface receptor, Zot is internalized^[23], and subsequently triggers a series of intracellular events including phospholipase C and PKC α -dependent actin polymerization which leads to the opening of tj^[7]. However, the complete cascade of the intracellular events activated by Zot, particularly concerning the early steps, remains undefined. There is now a large body of evidence that protein phosphorylation plays a major role in tj development^[24] and cytoskeleton rearrangement^[25]. In eukaryotic cells, junctional complex proteins, actin filaments, microtubules, and intermediate filaments interact to form the cytoskeleton network involved in determination of cell architecture, intracellular transport, modulation of surface receptors, paracellular permeability, mitosis, cell motility, and differentiation^[26]. We have previously demonstrated that there are two Zot binding proteins in the cell lysates of Zot-sensitive tissues^[16]. One has been characterized as the Zot/zonulin receptor. With this paper we showed that tubulin is the second Zot-binding protein. Based on these results, it is possible to hypothesize that Zot affects the actin filament network by binding to MT. The association of Zot to MT could be responsible of the effects of Zot on cell uptake and intracellular trafficking of molecules^[10,11] as well as the changes of tj structure and permeability. Alterations of intestinal tj occur in a variety of clinical conditions affecting the gastrointestinal system, including food allergies, malabsorption syndromes, and inflammatory bowel diseases. The knowledge that can eventually be acquired by studying the regulation of tj may have a tremendous impact on our understanding of the pathogenesis of these disease. It would not be surprising if the modification of tj structure and function by these pathological conditions would be an extension of normal physiologic regulation of tj.

However, several questions remain unanswered: what is the role of Zot-MT interaction on rearrangement of actin filament? Does this interaction affect the permeability of tj? Are MT-dependent cell functions, such as redistribution of organelles and the polarized distribution of membrane proteins, influenced by the MT-Zot binding? Experiments aimed at addressing these questions are presently in progress in our laboratory.

Subject headings familial adenomatous apolyposis (FAP); anticipation phenomenon; intergenerational bias; child generations; hereditary disorder; mortality

Iwama T, Utsunomiya J. Anticipation phenomenon in familial adenomatous polyposis: an analysis of its origin. *World J Gastroentero*, 2000;6(3):335-338

Abstract

AIM To analyze the origin of the anticipation phenomenon, which means earlier death in successive generation in familial adenomatous polyposis.

METHODS The study subjects were 2161 patients with familial adenomatous polyposis and their 7465 first-degree relatives who were members of 750 families registered at our Polyposis Registry. The ages at death and cumulative mortality rates in the parent, the proband, and the child generations were compared for both all subjects and the patients alone.

RESULTS In the patients over 5 years of age, the mean age at death was 50.9 years for the parent, 42.3 years for the proband, and 33.3 years for the child generations, respectively ($P < 0.001$). The deceased rates in the three generations were 90.7%, 51.3% and 23.1% of the patients, respectively, and this difference was the main cause of the anticipation measured by parent-child pairing method. The cumulative mortality rates for all subjects failed to show anticipation, however the cumulative mortality rates for the patients showed the anticipation. The anticipation phenomenon was shown by any parent-child pairing methods for the deceased patients. Other important causes of the anticipation were different proportion of causes of death between generations ($P < 0.001$), and a low proportion of detected or deceased patients

($P < 0.001$) in the child generation.

CONCLUSION Anticipation in familial adenomatous polyposis may be caused by parent-child pairing methods as well as several intergenerational biases.

INTRODUCTION

The earlier onset of a hereditary disorder in successive generations, often with increased severity or early death, is known as anticipation^[1,2]. Despite the development of medical care over generations, this phenomenon is commonly encountered in human dominant type hereditary disorders including familial adenomatous polyposis (FAP) clinically. The anticipation was evaluated by Penrose^[1] in myotonic dystrophy and by Veale^[2] in FAP using parent-child pairs. They attributed the apparent anticipation to ascertainment biases and the general variability in age of onset in the parent-child pairs. They assumed that the modifying allelic gene might be the cause of the lack of the parent-child correlation. Of these two conditions, the cause of the anticipation in myotonic dystrophy was proved to expand trinucleotide repeats in the causative gene^[3-9].

However, a mutation of the APC gene is stable, and the site of mutation determines the severity or associated features of FAP with strong parent-child correlation^[10-13]. If the anticipation is the biological phenomenon in FAP, not only we need to investigate the cause of the anticipation in the APC gene, but also it has a considerable clinical meaning because colorectal cancer must be prevented by an early detection and treatment. Consequently, it has aroused our interest to study whether the anticipation phenomenon in FAP is a biological fact.

MATERIALS AND METHODS

Between January 1975 and December 1995, data were collected from 750 families from 1198 FAP patients registered at our Polyposis Registry^[14]. These FAP cases fulfilled the diagnostic criteria by Bussey^[15]. Turcot syndrome was excluded. Histories of their family members were obtained from their doctors who registered patients, death

Received 2000-04-03 Accepted 2000-04-28

certificates and the National Family Registry^[16]. All first-degree relatives of proved FAP patients were recruited and no selection was made in these collections. Among the families of 9626 members (4991 men, and 4635 women), 2161 were FAP patients with colorectal cancer, and 7465 were their first-degree family members. Their births and deaths were certified by the National Family Registry or from the documents of the registry, and causes of death were ascertained by death certificates or by inquiring the doctors. The 9626 members were divided into three generations. They were 2958 individuals in the generation of the index patients (the proband generation), 4273 in the generation of their parents (the parent generation), and 2395 in the child generation of the indicated patients (the child generation). The ages at death, causes of death, and cumulative mortality rates of the three generations were compared to evaluate the features of anticipation. The cumulative mortality rates were calculated for both the entire group and the FAP patients by the Kaplan-Meier method. Chi-square test was used for comparison of occurrence rate in pairs of groups, and *t* test was used for the comparison of age.

RESULTS

There were a total of 3891 deceased individuals in the entire group. The proportion of deceased individuals in each generation was 66.0% in the parent generation, 39.5% in the proband generation, and only 10.5% in the child generation ($P<0.001$, Table 1). The mean age at death was 41.6 ± 26.2 years in the parent generation, 26.3 ± 22.3 years in the proband generation, and 15.8 ± 16.8 years in the child generation. These low age and large standard deviation in the age at death were the result of early childhood death occurring before five years of age, accounting for 18.4% of all deaths in the parent generation, 33.4% in the proband generation, and 47.2% in the child generation (Table 1). We examined the causes of death in each generation and their age at death (Table 2). The death from unknown causes in the parent generation (0.84 to FAP deaths) was almost five times higher than that in the other two generations ($P<0.001$). In this generation, the mean age at death (36.7 ± 19.8 years) from unknown causes was significantly lower than that at death from other causes ($P<0.05$).

The number of FAP patients was 508 (17.2%) in the parent generation, 1316 (30.8%) in the proband generation, and 337 (14.1%) in the child generation (Table 3). Among them, the number of deceased FAP patients was 460 (90.6% of 508) in the parent generation, 675 (51.3% of 1316) in the proband generation, and 78 (23.1% of 337) in the

child generation. There were significant differences among the groups in the FAP death rate ($P<0.001$). The age at death of FAP patients in each generation was 50.9 ± 12.4 years, 42.3 ± 12.3 years, and 33.3 ± 8.8 years, respectively, and the differences among the generations were significant ($P<0.001$). These results showed that any random selection of deceased intergenerational pairing in FAP patients would produce anticipation caused by these differences between the generations.

The cumulative mortality rates of the FAP patients gave us a few clues to the anticipation (Figure 1). The generation included less young FAP patients, and the start of death was delayed as compared to other generations. It may be said pseudo-anticipation. Between the child and proband generations, the acceleration of death was observed in the age between 22 and 40 years. Both a low detection rate of FAP patients (14.1%, Table 3) in the child generation, and a low portion of deceased FAP patients (23.1%) among them may cause this situation because many FAP patients were remained undiagnosed. This suggests a comparatively short observation period in the child generation. The incidence of colorectal cancer increased rapidly between 20 to 40 years of age, and this period might be overestimated in this generation.

In order to minimize these intergenerational biases in FAP patients, we calculated the cumulative mortality rates for the entire members as well as for the FAP patients to evaluate the anticipation. The cumulative mortality rates for the all subjects were plotted on Weibull's probability paper according to each generation (Figure 2). If the mortality curve of a descendant shifts to the left, it means earlier death or anticipation, and if a mortality curve shifts downside, it means the improvement of the general health condition of the group. The cumulative mortalities for both the parent and the proband generations were almost the same and parallel, while there was a slight vertical shift in these two curves, no horizontal shift was observed. This calculation method revealed no anticipation between the parent and the proband generations. The mortality rate of the child generation differed from those of the other generations; the overall cumulative mortality rate was low because of the lower infantile mortality in this generation. Although the mortality curve for the child generation showed a steeper slope line than those for the other two generations, the starting point of the steep slope, just after 20 years of age, was common to all the generations.

DISCUSSION

The anticipation phenomenon is so powerful that it surmounts the improvement of medical standards over years, and it is easily detected in hereditary diseases^[1,2,17-19]. Comparison of the age at death or onset in affected parent-child pairs is a conventional method in the study of the anticipation phenomenon^[1,2,17,18]. McInnis *et al*^[18] and Imamura *et al*^[19] applied the life-table analysis or random pairs method only to diagnosed patients and excluded other family members. If this method was applied to our FAP patients, the mean age at death in the proband generation was 8.5 years lower than that in the parent generation, and that in the child generation was 9 years lower than that in the proband generation. These figures exceed a standard period of 5 years to calculate postoperative survival of patients with colorectal cancer. This apparent anticipation was well correlated to the proportion of deceased cases in these three generations. This indicates that any fair pairing method will produce the anticipation. Veale^[2] estimated that a lack of parent-child correlation in onset of FAP was a major cause of sampling bias in his study over a limited period of time. He also concluded that the lack of correlation was due to the allele of the APC gene. Although his suggestions have not been denied as a contributor to the anticipation, some recent reports^[10-12] have suggested an apparent relationship between the site of the APC gene mutation and colorectal polyp density and retinal pigments in FAP patients. In addition, the comparison of the age at onset or death in parent-child pairs inevitably has two selection biases besides the intergenerational biases. One is that the parent has already been selected because he or she has already had at least one child, and this child must necessarily have already developed a symptom or died in order to make a parent-child pair. The other one is that a patient with a severe condition is difficult to gain a child, and this patient cannot be treated as a parent. We

confirmed the effect of selection bias in analysis of our 339 deceased parent-child pairs with FAP (Table 4). When the pairs were classified according to whether the child of the pair had become a parent or not, the childless group showed a significantly higher incidence of the anticipation phenomenon.

Recent reports have revealed that the elongation of trinucleotide repeat sizes is correlated with the increased severity of several hereditary neurological diseases such as myotonic dystrophy^[4], fragile X syndrome^[5], Huntington's disease^[6,7], and spinal and bulbar muscular atrophy^[8]. Although it is proved that the meiotic elongation of trinucleotide repeats accelerates these diseases, it does not necessarily mean that the elongation is inevitable in the meiosis. If we take parent-child pairs, it may seem as if the meiosis in these diseases constantly increases the length of trinucleotide repeats as the cause of the anticipation. The anticipation is such a powerful phenomenon as Ashizawa *et al*^[20] noted in 48% of 56 parent-child pairs that showed contractions of CTG repeat. Because anticipation is commonly encountered in clinical practice, its mechanism must be rather general. It is necessary to approach the elucidation of this phenomenon using some methods other than parent-child pair comparisons^[21]. We studied not only the FAP patients but also their first-degree relatives in our calculations of life tables. In this kind of studies, the change of medical environment among generations may influence the pattern of mortality. Besides its difficulty in taking the recent improvement of medical care in count, we have several reasons for not calculating this influence. ① parent-child pairing method in this series showed an apparent anticipation phenomenon; ② overall improvement of mortality in colorectal cancer was not so substantial as the anticipation phenomenon was diminished; and ③ proportion of early detection and preventive treatment in FAP patients was comparably small^[14]. Bias was minimized by our method because the effect of deaths of undiagnosed FAP patients in the parent generation was taken into account. In the parent generation, inherent bias was present in the form of deceased but undiagnosed young FAP patients. In the child generation, the bias was present mainly in the form of premature observation period and unidentified FAP patients, picking up only young deaths.

As the anticipation phenomenon is observed only in the conditions that threat their life and reproductive ability, one of the methods to avoid these biases is to examine the anticipation phenomenon on the FAP specific phenotypes that do not affect the life of FAP patients. For example, congenital hypertrophy of the retinal pigment epithelium is specific to FAP, and it has no influence on optical function. Our experience did not show apparent anticipation phenomenon in number of the pigment areas^[22]. Despite these

results it will be wise to watch FAP patients for colorectal cancer before the age at which their parents had cancer.

ACKNOWLEDGEMENT We thank doctors who registered FAP cases that were the clue of this research. This work was supported by Foundation for Promotion of Cancer Research in Japan, Grant in Aid from the Ministry of Health and Welfare, and Japanese Society for Cancer of the Colon and Rectum. We are also grateful to Dr. Yoshiyuki Hashimoto for his important advice.

Subject headings hepatoma/therapy; biopsy; neoplasm staging; survival analysis; neoplasms metastasis; prognosis; drug therapy

Sithinamsuwan P, Piratvisuth T, Tanomkiat W, Apakupakul N, Tongyoo S. Review of 336 patients with hepatocellular carcinoma at Songklanagarind Hospital. *World J Gastroentero*, 2000;6(3):339-343

Abstract

AIM To determine the clinical presentations, survival and prognostic factors of hepatocellular carcinoma (HCC) in Southern Thailand.

METHODS Retrospective analysis was performed on the 336 hepatocellular carcinoma patients treated at Songklanagarind hospital between 1 January 1991 and 31 January 1999.

RESULTS Of these 336 patients, 276 were males and 60 were females. The mean age was 54.4 years. The common symptoms and signs were abdominal pain and hepatomegaly. The most common presentation of tumor was a dominant mass with daughter nodules. Portal vein involvement was found in 50% of total. Extra hepatic metastasis was found in 13%, and the lung was the most common site. There were 65.4% with evidence of cirrhosis and half of them were in *Child's* class B. HBsAg was positive in 72.6%. Regarding *Okuda's* tumor staging, 15%, 61% and 24% were stage I, II and III, respectively. Overall median survival was 2.1 months (11.5, 2.6 and 0.7 months for stage I, II and III respectively). Treatments of HCC improved patient survival (5.5 months vs 1.6 months for untreated patients). Most common causes of death were hepatic failure. Using multivariate analysis, the prognostic

factors identified were tumor staging, alpha-fetoprotein level above 10 000 $\mu\text{g}\cdot\text{L}^{-1}$, extrahepatic metastasis, portal vein thrombosis and treatment.

CONCLUSION HCC in Thailand is a fatal disease with poor outcome due to late presentation and high prevalence of liver cirrhosis. Early detection and proper management may improve outcome.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common form of primary liver cancer and is the leading cause of cancer death especially among males in South-East Asia including Thailand^[1,2]. This may be related to high prevalence of chronic hepatitis B infection (8%-15% in Asia and Africa, and 8%-12% in Thailand)^[3-7]. Though many types of treatment have been tried, HCC is still a fatal disease possibly associated with the advanced stage at which the disease is usually diagnosed^[2,8-11]. Thus, it remains a serious medical problem in this part of the world. There were many reports of the natural history of HCC in Japan, Mainland China, Southern Africa, Alaskan Eskimos, Taiwan, Italy, Spain and North America, but little information has been published from South-East Asia^[9-24]. Therefore, we reviewed 336 HCC patients at Songklanagarind Hospital to describe the clinical presentations and history of known risk factors and determine the survival rate, prognostic factors and the benefit of treatments.

MATERIALS AND METHODS

Patients

The medical records of 336 HCC patients admitted at Songklanagarind hospital between January 1, 1991 and January 31, 1999 were reviewed retrospectively. The diagnosis of HCC was made by liver biopsy or elevated serum alpha-fetoprotein level above 500 $\mu\text{g}\cdot\text{L}^{-1}$ with radiologic findings suggestive of HCC in patients whose liver biopsy was not available^[25]. Data from medical records, including patient demographic, known risk factors, clinical manifestation, abnormal physical findings, laboratory data (complete blood count, coagulogram, renal function test, liver function

tests, viral hepatitis serology, serum alpha-fetoprotein level, chest X-ray, ultrasonography, CT scan, liver biopsy and other tissue biopsy if suggested metastasis), survival and treatments modality, were used for analysis. The known risk factors include alcohol drinking, history of blood transfusion and history of jaundice or viral hepatitis infection or known cases of cirrhosis. Patients were classified into 6 groups based on their clinical presentation: group 1, mass-related symptoms (abdominal pain or fullness, dyspepsia, palpable mass); group 2, cirrhosis-related symptoms (jaundice, GI bleeding, edema, abdominal enlargement, hepatic encephalopathy); group 3, liver abscess-like symptoms (high fever with abdominal pain and tenderness); group 4, non-specific symptoms (anorexia, nausea, vomiting, malaise, weight loss and anemia); group 5, metastasis symptoms (dyspnea, cough, bone pain and palpable lymph node); and group 6, asymptomatic cases (accidental finding by routine check-up or complain of other unrelated disease). The abnormal physical findings included anemia, jaundice, fever, hepatomegaly, splenomegaly, ascites and sign of chronic liver stigmata such as palmar erythema, spider nevi, gynecomastia and superficial dilated vein. A test of viral marker for hepatitis B (HBsAg) was done in most of patients but that for hepatitis C (anti-HCV) was not available until 1996. Tumor volume was calculated from ultrasonography or CT scan of the liver by a radiologist. Tumor volume or sum of tumors in instances multiple nodules were expressed as fraction of total liver and subsequently classified into two groups (tumor size $\leq 50\%$, $>50\%$ of the whole liver). Staging of HCC was made according to Okuda's^[9]. Cirrhosis was confirmed by liver biopsy or ultrasonography or CT scan and classified by Child-Pugh's (Class A, B or C)^[26]. The extrahepatic metastasis was confirmed by histology (incisional biopsy, excisional biopsy, necropsy or autopsy).

Therapy

The treatment of HCC ranged from no treatment, transhepatic artery oily chemoembolization (TOCE), percutaneous ethanol intralesional injection (PEI), hepatectomy, systemic chemotherapy and multimodality combination chemotherapy.

For systemic chemotherapy before 1995, we used intravenous adriamycin and/or 5-FU injection. Later this was changed to PIAF regimen (cisplatin $80 \text{ mg} \cdot \text{m}^{-2}$ body surface area (BSA) and adriamycin $40 \text{ mg} \cdot \text{m}^{-2}$ BSA at d1, followed by 5-FU $500 \text{ mg} \cdot \text{m}^{-2}$ infusion over 24 h for the following 3 d, with alpha-Interferon $5 \text{ mU} \cdot \text{m}^{-2}$, iv, 3 h after cisplatin and 5-FU every day).

TOCE was performed monthly by super-selective insertion of catheter to the right or left hepatic artery branch feeding the tumor then injection adriamycin 50 mg, lipiodol 8 mL and gelfoam. PEI was performed by using 10 mL of absolute ethanol injected percutaneously under CT-scan guide.

Multimodality combination therapy comprised a combination of several treatments depending on the tumor staging and complication, such as the patients who presented with advanced HCC and had portal vein involvement with lung metastasis, the treatment was started with systemic chemotherapy (PIAF regimen) until no evidence of extrahepatic metastasis remained and was then followed by TOCE and/or intralesional ethanol injection (PEI). Because of the limitation of retrospective study, we were unable to determine the exact outcome or improvement of general condition after treatments, so we determined the outcome by survival analysis.

In patients who were lost to follow-up, we determined the date and cause of death from the population register and personal contact with the family. Patient status was unable to determine in 20% of the patients. For statistical analysis these patients were considered as censored at the date of last contact.

Survival profiles were constructed using the Kaplan-Meier method. Prognostic factors were identified using Cox proportional hazards regression. P value <0.05 was considered statistically significant.

RESULTS

Of the 336 patients, 276 (82%) were male with a male to female ratio of 4.6:1. The mean age was 54.4 (a range of 20-89) years (54.3 years in male and 55 years in female) (Table 1). Diagnosis was confirmed histologically in 273 (72.3%) cases and 63 (18.7%) cases were diagnosed by a combination of elevated serum alpha-fetoprotein level above $500 \mu\text{g} \cdot \text{L}^{-1}$ and imaging such as ultrasound or CT scan showing a lesion compatible with HCC.

The most common symptom was mass-related such as abdominal pain, abdominal discomfort, dyspepsia and palpable mass (Table 2). Mean duration of symptoms was 49 d (range <1 day -1 year). Among the abnormal physical findings hepatomegaly was the most common, followed by fever and jaundice (Table 2).

Elevation of alkaline phosphatase and serum aspartate aminotransferase (AST) was the most common abnormal finding in the liver function test. Serum bilirubin above $51.3 \mu\text{mol} \cdot \text{L}^{-1}$ was found in 30%. The most common radiologic finding was a solitary mass with or without daughter nodules (73%, Table 1). The tumor was located most frequently in the right lobe (53%) followed by both

lobes (37%) and left lobe (10%). Tumor volume larger than half of the total liver was found in 71% and portal vein thrombosis or portal vein involvement in 50%. Portal vein thrombosis or involvement was significantly associated with increased tumor volume ($P = 0.0005$). The mean serum alpha-fetoprotein level was 145 110 (range 2-7 990 000 $\mu\text{g}\cdot\text{L}^{-1}$) and values above 500 $\mu\text{g}\cdot\text{L}^{-1}$ (the cut point for diagnosing HCC) occurred in 64% (Table 1).

Table 1 HCC patient characteristics

Patient characters		<i>n</i>	%	Mean	Range
Age(years)	All			54.4	20-89
	Male			54.3	20-89
	Female			55.0	20-81
Sex	Male	276	82.0		
	Female	60	18.0		
Risk factors	Alcohol drinking	126	38.0		
	HBsAg positive (299 sample)	217	72.6		
	anti-HCV positive (135 sample)	10	7.4		
	Cirrhosis	219	65.2		
Liver function test	Total bilirubin ($\mu\text{mol}\cdot\text{L}^{-1}$)			63.8	3.4-752.4
	Direct bilirubin ($\mu\text{mol}\cdot\text{L}^{-1}$)			38.8	0.5-581.4
	Aspartate aminotransferase ($\text{U}\cdot\text{L}^{-1}$)			225	17-3890
	Alanine aminotransferase ($\text{U}\cdot\text{L}^{-1}$)			97	4-3370
	Alkaline phosphatase ($\text{U}\cdot\text{L}^{-1}$)			304	8-2080
	Albumin ($\text{g}\cdot\text{L}^{-1}$)			35.6	20-52
	Globulin ($\text{g}\cdot\text{L}^{-1}$)			38.2	18-78
Radiologic finding (<i>n</i> = 329)	Solitary type (total)	240	73.0		
	with daughter nodules	144	43.8		
	without daughter nodules	96	29.2		
	Multinodular type	47	14.3		
	Diffuse or infiltrative type	42	12.7		
Alpha fetoprotein ($\mu\text{g}\cdot\text{L}^{-1}$) (<i>n</i> = 295)				145 110	2-7990 000
	<10	38	13.0		
	10-99	36	12.0		
	100-499	33	11.0		
	≥ 500	188	64.0		
Okuda's staging	Stage I	51	15.0		
	Stage II	205	61.0		
	Stage III	80	24.0		

The most common risk factor was chronic hepatitis B infection (72.6%), and 65.2% showed evidences of liver cirrhosis (Table 1). Patients with cirrhosis were classified into Child A, B and C in 20%, 55.3% and 24.7% respectively. Cirrhosis was found in 76.2% of alcoholic patients, 66.4% of HBV infected patients and 90% of HCV infected patients. Okuda's staging distribution was 15%, 61% and 24% for stage I, II and III respectively (Table 1). Spontaneous rupture of HCC was found 11% (4%, 9.3% and 20% in stage I, II and III). At the time of diagnosis, extrahepatic metastasis occurred in 43 cases (13.1%), 13.7%, 10.7% and 18.8% of stage I, II and III respectively. The metastatic sites were lung (76%), lymph node (16%) and bone (7%).

Overall median survival was 2.1 months (Stage I, 11.5 months; Stage II, 2.6 months; and Stage III, 0.7 months) (Table 3, Figure 1). The 1 and 2-year survival rates were 15% and 8% respectively. Treatment of HCC was associated with improvement of patient survival (5.5 vs 1.6 months

in non-treated group; $P = 0.011$) (Table 3, Figure 2). In the non-treated group ($n = 245$) median survival was 1.6 months (7.7, 1.8 and 0.6 months for stages I, II and III respectively, Table 3, Figure 3). Regarding treatment, patients treated with TOCE, intravenous chemotherapy, multimodality combination therapy and Tamoxifen administration had median survival times of 6.3, 5.33, 17.1 and 3 months, respectively (Table 3). Compared to the non-treated group, patients treated with TOCE, intravenous chemotherapy or combination therapy had significantly better survival ($P = 0.0005$, 0.011 and 0.007 respectively) whereas survival of the patients treated with Tamoxifen was not significantly different from non-treated ($P = 0.86$) patients.

Table 2 Presenting symptoms and abnormal physical findings of patients

Presenting symptoms	<i>n</i>	%
Mass-related symptoms (Abdominal pain or fullness, dyspepsia, palpable mass)	188	56
Cirrhosis-related symptoms (Jaundice, GI bleeding, edema, abdominal enlargement, encephalopathy)	59	17.6
Liver abscess-like symptoms (High fever with acute abdominal pain and tenderness)	45	13.4
Non-specific symptoms (Anorexia, nausea, vomiting, malaise, weight loss, chronic anemia)	26	7.7
Metastasis symptoms (Dyspnea, cough, bone pain, palpable lymph node)	11	3.2
Asymptomatic (Routine checked up or other unrelated disease)	7	2.1
Abnormal physical findings		
Hepatomegaly	282	83.9
Fever	185	50.5
Jaundice	143	42.6
Anemia	138	41.1
Ascites	123	36.6
Cachexia	86	25.6
Chronic liver stigmata	86	25.6
Edema	59	17.6
Splenomegaly	42	12.5

Table 3 Median survival

Group of patients	<i>n</i>	Median survival (months)
All	336	2.1
Stage I	51	11.5
Stage II	205	2.6
Stage III	80	0.73
Untreated	245	1.6
Stage I	26	7.7
Stage II	146	1.8
Stage III	73	0.63
Treated	91	5.5
Stage I	25	13.7
Stage II	59	4.2
Stage III	7	1.7
TOCE	44	6.3
Stage I	11	24.3
Stage II	29	5.5
Stage III	4	1.4
Chemotherapy (adriamycin and/or 5-FU)	16	5.2
Multimodality therapy (PIAF/iv, chemotherapy \pm TOCE \pm PEI)	12	17.1
Tamoxifen	9	3.0
PIAF regimen chemotherapy	5	-
Hepatectomy	4	-
PEI	1	-

*Data of PIAF regimen chemotherapy is not completely finished. †It were too small number of patients to evaluated.

The most common causes of hospital death ($n = 54$) were hepatic failure, GI bleeding and rupture of tumor (59.2%, 20.4% and 20.4% respectively). Among cases with hepatic failure, sepsis was the most common complication leading to death. Cox proportional hazards model reviewed the following, prognostic factors: Okuda's stage II ($P = 0.014$, hazard ratio 2.05), stage III ($P = 0.001$, hazard ratio 3.79), AFP level above $10\,000\ \mu\text{g}\cdot\text{L}^{-1}$ ($P = 0.001$, hazard ratio 2.03), lung metastasis ($P = 0.01$, hazard ratio 1.93), lymph node metastasis ($P = 0.015$, hazard ratio 3.76), portal vein involvement or thrombosis ($P = 0.0005$, hazard ratio 1.79) and treatment ($P = 0.011$, hazard ratio 0.91).

Figure 1 Kaplan-Meier survival curve for overall patients. Total ($n = 336$) median survival of 2.1 months; Okuda's stage I ($n = 51$), median survival of 11.5 months; Okuda's stage II ($n = 205$), median survival of 2.6 months; Okuda's stage III ($n = 80$), median survival of 0.7 months ($P = 0.014$ and 0.001 respectively).

Figure 2 Kaplan-Meier survival curve in relation to treatment or non-treatment. Treated group ($n = 91$), median survival of 5.5 months; non-treated group ($n = 245$), median survival of 1.6 months ($P = 0.011$).

Figure 3 Kaplan-Meier survival curve in non-treated group. Total ($n = 245$), median survival of 1.6 months, Okuda's stage I ($n = 26$), median survival of 7.7 months; Okuda's stage II ($n = 146$), median survival of 1.8 months; Okuda's stage III ($n = 73$), median survival of 0.6 months.

DISCUSSION

Similar to other studies, we found that HCC was more common in males (a male to female ratio of 4.6:1) because the risk factors such as cirrhosis, chronic HBV infection and alcoholic are more frequently seen in males than females^[2,8,12-19,27,28]. In our study, the most common risk factor was chronic HBV infection (72.6%) as HBV is endemic in South-East Asia^[5]. The common symptoms were non-specific and included abdominal pain, dyspepsia, jaundice, hepatomegaly, anorexia and weight loss. Clinical jaundice was found in 42.6% and mainly caused by failure of hepatic function due to cirrhosis. The most common type of tumor in our patients was dominant mass with daughter nodules whereas multiple nodules or diffuse lesion are common in Western patients^[15,17,18]. The difference in risk factors may explain the variation in tumor characters as chronic HBV infection is the most important risk factors in our region while chronic HCV infection and alcohol drinking are the largest risk factors in Japan and Western countries^[3,8,13-18,27,29]. Cirrhosis was found in 65% of our patients and 80% of them were classified as Child's B or C. These may be associated with poor prognosis. In our study, hepatectomy and TOCE were not suitable in more than half of the patients due to portal vein involvement (50%) and advanced liver cirrhosis (24.7%). Extrahepatic metastasis was found in 13% and most of them were located in the lung, probably because of direct drainage into the right heart via the hepatic vein. Elevated serum alpha-fetoprotein above $500\ \mu\text{g}\cdot\text{L}^{-1}$ was found in only 64% of patients, so this tumor marker was not very sensitive for diagnosis of HCC in our country. Most our patients had advanced HCC (61% and 24% were stage II and III respectively). The overall median survival in our patients was 2.1 months because majority of our patients had advanced disease with significant liver cirrhosis. In treatment of HCC, hepatectomy and TOCE could improve survival^[9,13], but could not be performed because of liver cirrhosis and portal vein involvement. Systemic chemotherapy, arterial infusion and Tamoxifen administration could not improve survival^[9,20,24,30-32], whereas data of PIAF regimen chemotherapy showed complete pathological remission, but survival analysis did not^[33]. In our study, TOCE and multimodality therapy could improve survival, particularly in patients with stage I and stage II disease as compared with the non-treatment group (24.3% vs 7.7 months in stage I and 5.5 vs 1.8 months in stage II receiving TOCE and 17.1 months vs 0.63 months in patients receiving multimodality therapy). However, our study is only a retrospective study that had its limitation in comparing survival rate between different groups. The most of our patients died of hepatic failure (60%) as a majority of them had

advanced HCC and liver cirrhosis. By multivariate analysis, poor prognosis was associated with advanced stage of the tumor, serum alpha-fetoprotein level $>10\,000\,\mu\text{g}\cdot\text{L}^{-1}$, extrahepatic metastasis and portal vein involvement.

ACKNOWLEDGEMENTS The authors acknowledge the cooperation of the staff of the Registration Unit of Songklanagarind Hospital and of the Official Register of Population for providing patient data and Dr. Allan Geater for English advice.

Abstract

AIM To investigate the application of confocal laser scanning microscopy (CLSM) in tumor pathology and three-dimensional (3-D) reconstruction by CLSM in pathologic specimens of hepatocellular carcinoma (HCC).

METHODS The 30 μ m thick sections were cut from the paraffin-embedded tissues of HCC, hyperplasia and normal liver, stained with DNA fluorescent probe YOYO-1 iodide and examined by CLSM to collect optical sections of nuclei and 3-D images reconstructed.

RESULTS HCC displayed chaotic arrangement of carcinoma cell nuclei, marked pleomorphism, indented and irregular nuclear surface, and irregular and coarse chromatin texture.

CONCLUSION The serial optical tomograms of CLSM can be used to create 3-D reconstruction of cancer cell nuclei. Such 3-D impressions might be helpful or even essential in making an accurate diagnosis.

INTRODUCTION

Under conventional light microscope, *histopathologists* often use plane image to evaluate the three-dimensional (3-D) cellular characteristics. Three-D configuration may be reconstructed by using serial mechanical sectioning, but its axis definition is not good, image is blur and tiny structure can't be shown clearly, and the specimen might be damaged. Using the serial optical tomograms and 3-D reconstruction function, confocal laser scanning microscopy (CLSM) can provide a much better quality 3-D image than conventional light microscope, and lead the observer into a brand-new 3-D world. Although CLSM has been used extensively in cell biology^[1], few applications were reported in routine clinical pathology such as three-dimensional DNA image cytometry by CLSM in thick tissue blocks of prostatic lesions and 3-D reconstruction by CLSM in routine pathologic specimens of benign and malignant lesions of human breast^[2-4]. In this study, 3-D reconstruction was performed on routine formalin-fixed, paraffin-embedded tissues of normal, and hyperplastic tissues of liver and hepatocellular carcinoma by using computer-assisted CLSM together with 3-D reconstruction. The goals of our study were to present 3-D morphologic characteristics of benign and malignant specimens of the liver and to attempt to demonstrate the usefulness of CLSM in routinely obtained surgical pathologic tissues.

MATERIALS AND METHODS

Two cases of normal liver tissue were selected from autopsy specimens collected in the Department of Pathology of Shanghai Medical University, six cases of hepatocellular carcinoma including adjacent liver tissue were routine clinical specimens collected in 1996 from the Liver Cancer Institute of Zhongshan Hospital affiliated to Shanghai Medical University.

All tissues were fixed in 10% formalin, embedded in paraffin, serial sections were cut at 5 μ m and 30 μ m. The 5 μ m slices were stained with hematoxylin and eosin for conventional light microscopic observation. The 30 μ m slices were stained with DNA fluorescent probe, YOYO-1 iodide (Molecular Probes, Eugene, Ore., USA).

The sections were deparaffinized with xylene (10 min \times 2) and dehydrated with 100%, 95%, and 70% ethanol (5 min \times 2) and rinsed in distilled water for 2 min \times 5. The specimens were then fixed with 10% neutral buffered formalin for 30 min and washed with tap water. After rinsing with distilled water and 0.01M phosphate buffer 5 min \times 2, nuclear RNA was removed by incubating the sections for 30 min at 37°C in 200 μ L of ribonuclease A (RNAase; Sigma, USA) at a concentration of 160 g/L in PBS. DNA was next hydrolyzed with 2N HCl for 25 min at 27.5°C. After rinsing with distilled water for 2 min \times 5, the sections were covered with 200 μ L of YOYO-1 iodide diluted into 1:2000 with PBS. The PBS was diluted 1:5 with distilled water to reduce the salt concentration. To this 200 μ L working solution of YOYO-1 iodide, 20 μ L of 0.1N HCl was added and the final solution was stored in the dark at 4°C for use. Homogeneous fluorescence intensity of nuclei at different depths of the confocal slices was obtained by agitating the YOYO-1 iodide for 1 h in the dark. Afterwards, the sections were rinsed with distilled water, covered with buffered glycerol, and the glass cover slip were sealed with finger nail polish. Sections were stored at 4°C in the dark until CLSM examination.

A Leica TCS-NT confocal laser scanning microscope equipped with epifluorescence optics and an appropriate combination of filters to visualize and digitize the images of the different specimens. An argon laser with an excitation wavelength of 488 nm was used to activate the green fluorescence of the YOYO-1 iodide-stained nuclear DNA (maximal absorption 491 nm and emission 509 nm). A 16 \times objective (numerical aperture of 1.30) was used to observe the specificity of the staining, and a 100 \times water objective (numerical aperture of 1.30) was used to study the details of chromatin pattern. Optical sections were collected throughout the entire stained thickness of the paraffin sections with a Z-step interval of 0.3 μ m or 0.6 μ m. The 3-D image processing was performed on a Leica computer with the original 3-D interactive visualization software. The collected confocal optical sections and the 3-D reconstructed images were printed with a Panasonic color video dye-sublimation copy processor.

RESULTS

Three-D morphologic features of normal liver cells

A microscopic field of view was selected from the normal liver specimen and comparison of the images taken under transmission conventional light microscope and CLSM is illustrated in Figure 1. The transmission conventional light microscopic image

was shown on the right side and the out-of-focus signals were visible. The out-of-focus blur reduced the contrast and sharpness of the final image. In the confocal image (left) the out-of-focus signals were cut off and only signals in focus were clearly visible. Optical sections (planes 1-60) were taken from the surface to the bottom of normal liver specimen with a Z-step interval of 0.5 μ m. Figure 2 shows the 10th, 20th, 30th, 40th, 50th and 60th plane digital images of Z-series. The confocal images were taken at 5, 10, 15, 20, 25 and 30 μ m depths, respectively. In the confocal images some nuclei appeared or disappeared depending on their orientation in space. The 60 2-D optical sections were computer focused on a plane (deep-focusing) to analyze the fine structure of chromatin patterns inside the nucleus and reconstructed 3-D images to display the 3-D detailed arrangement of nucleus. Figure 3 shows normal liver cells with similar round or ovoid nuclei, homogeneous intensity of YOYO-1 iodide fluorescence as well. Three-dimensional view was shown in Figure 4. The nuclear surface appeared smooth with homogeneous fluorescence intensity.

Three-D morphologic features of atypical hyperplasia of liver cells

Optical sections (planes 1-50) were taken from the surface to the bottom of atypical hyperplasia of liver specimen with a Z-step interval of 0.6 μ m. The structure of chromatin patterns inside the nucleus with homogeneous fluorescence intensity is shown with deep-focusing in Figure 5. Three-dimensional view is shown in Figure 6. The nuclear surface appeared smooth with homogeneous fluorescence intensity. But the volume of nucleus of atypical hyperplasia liver cell was bigger than that of normal liver cell.

Three-D morphologic features of hepatocellular carcinoma cells

Optical sections (planes 1-50) were taken from the surface to the bottom of hepatocellular carcinoma specimen with a Z-step interval of 0.6 μ m. The deep-focusing images were shown in Figure 7 and Figure 8. The structure of chromatin patterns inside the nucleus with heterogeneous karyotheca thickness, irregular and coarse chromatin texture, chromatin underside the karyotheca mainly. Three-dimensional view is shown in Figure 9 and Figure 10. HCC displayed remarkably different features in 3-D morphology, including: indented, molding, and irregular nuclear surface; marked pleomorphism; chaotic arrangement of tumor cell nuclei.

Figure 1 The transmission conventional light microscopical image was shown on the right side. The out-of-focus blur reduced the contrast and sharpness of the image. In the confocal image (left) the out-of-focus signals were cut off and only signals in focus were clearly visible. $\times 160$

Figure 2 The 10th, 20th, 30th, 40th, 50th and 60th plane digital images of Z-series. In the normal liver tissues of the confocal images some nuclei appeared or disappeared depending on their orientation in space. $\times 1000$

Figure 3 Deep-focusing image showed the normal liver cells with similar round or ovoid nuclei, similar in size and homogeneous intensity of YOYO-1 iodide fluorescence as well. $\times 1000$

DISCUSSION

The area, volume, shape, DNA content, and chromatin pattern of nuclei may be important for the diagnosis and prognosis of cancer. *Histopathologists* often use $4\text{ }\mu\text{m}$ to $6\text{ }\mu\text{m}$ thick paraffin sections to obtain representative and diagnostically relevant images. Due to the very limited section thickness in comparison with the size of the tissue, and the images are nearly two-dimensional, focusing up and down at high magnification provides a rough idea of the 3-D cellular characteristics, and such 3-D impression may be helpful or even essential in arriving at a certain diagnosis, especially for borderline lesions or tumors. However, in spite of the usefulness of such 3-D information about nuclei, conventional light microscopy is not always the ideal tool for 3D evaluation due to the interference of out-of-focus structures with the images of the focus plane studied. Much of the light emitted from the regions of specimen above and below the focal plane contributes to the out-of-focus blur, which seriously reduces the contrast and sharpness of the final image. Confocal laser scanning microscope allows the acquisition of optical sections from a thick specimen and out-of-focus blur can be reduced considerably and thus much sharper and clearer images will be obtained. CLSM has become an exciting new instrument in biomedical research because of its increased resolution over conventional light microscope and its utility for subsequent 3-D-reconstruction analysis^[5,6].

In this paper, the 3-D reconstruction have demonstrated 3-D contour of representative characteristics of normal liver cells, atypical hyperplasia liver cells, and HCC cells and the spatial relationship of nuclei, as well as the subtle structure of chromatin texture inside nuclei. This

paper emphasized the practical feasibility of CLSM and 3-D reconstruction from routine surgical histopathologic materials. To obtain desirable quality 3-D image from formalin-fixed, paraffin-embedded specimens, YOYO-1 iodide, a highly specific and sensitive (picogram sensitivity)^[7] DNA probe was utilized. Intense and homogeneous fluorescence was obtained by incubating the YOYO-1 iodide for 1h with agitation in the dark. To reveal subtle details of nuclear structure, RNA was removed by RNase predigestion, since nuclear RNA was stained by YOYO-1 iodide as well.

CLSM combines the three most advanced and important elements of our era, the microscope, the laser and the computer in one, moreover it is non-invasive and can be used on archival paraffin blocks. We anticipate that, in the future, pathologists may utilize these new techniques to make more precise diagnosis.

Bian HJ, Chen ZN, Deng JL. Direct technetium-99m labeling of anti-hepatoma monoclonal antibody fragment: a radioimmunoconjugate for hepatocellular carcinoma imaging. *World J Gastroentero*, 2000;6(3):348-352

Abstract

AIM To directly radiolabel an anti-hepatoma mAb fragment HAb18 F(ab')₂ with ^{99m}Tc by stannous-reduced method, and assess the stability, biodistribution and radioimmunoimaging (RII). **METHODS** Immunoreactive fraction was determined according to Lindmo's method. Ellman's reagent was used to determine the number of thiols in the reduced F(ab')₂. Labeling efficiency and homogeneity were measured by paper chromatography, sodium dodecylsulphate polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography. Challenge assay involved the incubation of aliquots of labeled antibody in ethylenediaminetetraacetate (EDTA) and L-cysteine (L-cys) solutions with different molar ratio at 37°C for 1 h, respectively. Investigations *in vivo* utilized nude mice bearing human hepatocellular carcinoma (HHCC) xenografts with gamma camera imaging and tissue biodistribution studies at regular intervals. **RESULTS** The labeling procedure was finished within 1.5 h compared with the "pretinning" method which would take at least 21 h. *In vitro* studies demonstrated that the radiolabeled mAb fragment was homogeneous and retained its immunoreactivity. Challenge studies indicated that ^{99m}Tc-labeled HAb18 F(ab')₂ in EDTA is more stable than in L-cys. Imaging and biodistribution

showed a significant tumor uptake at 24 h post-injection of ^{99m}Tc-labeled HAb18 F(ab')₂. The blood, kidney, liver and tumor uptakes at 24 h were 0.56 ± 0.09, 56.45 ± 11.36, 1.43 ± 0.27 and 6.57 ± 3.01 (%ID/g), respectively. **CONCLUSION** ^{99m}Tc-HAb18 F(ab')₂ conjugate prepared by this direct method appears to be an effective way to detect hepatoma in nude mice model.

INTRODUCTION

The introduction of mAbs as targeting devices in nuclear medicine is well developed and many different antibodies which labeled with a variety of isotopes have been reported in cancer diagnosis. It seemed that ^{99m}Tc is the most popular radionuclide for nuclear medicine imaging because of its favorable physical characteristics, low cost, and ready availability. ^{99m}Tc labeled mAb fragments should be superior to other big molecule radioimmunoconjugates for use in tumor RII. A number of methods have been proposed for ^{99m}Tc labeling proteins, and mAbs in particular. In general, these methodologies can be divided into two categories: indirect and direct methods^[1]. In indirect method the protein was modified with a technetium binding ligand and then reacted with a technetium complex. Several bifunctional chelating agents have been synthesized and used, such as diethylenetriaminepentaacetic acid (DTPA)^[2], diamide dimercaptide N₂S₂ ligands, and hydrazino nicotinamide analog^[3]. Although it is said that the indirect method can lead to loss of immunoreactivity, Joiris *et al.* have tested that the derivatization of antibody or fragment by iminothiolane does not split the protein and keeps the immunoreactivity^[4]. By direct method, ^{99m}Tc metal ion binds directly to endogenous donor groups on the antibody. The method is simple to perform and compatible with practical clinical use. However, direct labeling of mAbs with ^{99m}Tc was reported to be unstable due to non-specific binding (low and high-affinity)^[5,6], but some reports suggest an improved labeling of proteins with ^{99m}Tc.

In the Schwarz and Steinstrasser procedure, as modified by Mather and Ellison^[7], disulfide bridges in the mAb are reduced with 2-mercaptoethanol (2-ME). After purification, the resulting reduced antibody can be stored frozen until required for use. Labeling is accomplished by addition of stannous ion from a bone-scanning kit and pertechnetate. In addition to using regular reducing agents, such as 2-ME, stannous ions^[8], borohydride^[9], ascorbic acid^[10], dithionite^[11], or glutathione^[12] to generate sulphhydryl groups, other peculiar approaches also appeared recently. Direct ^{99m}Tc labeling of mAbs were finished by reduction of antibodies using photoactivation and insoluble macromolecular Sn (II) complex^[13,14]. With the development of direct method, there have been a few reports of successful use of this technique in colorectal, breast, and ovarian cancer imaging^[15-17].

In this report, we describe a direct method for radiolabeling anti-hepatoma monoclonal antibody fragment HAb 18F (ab')₂ with ^{99m}Tc . The stability and homogeneity of ^{99m}Tc -HAb18 F(ab')₂ were evaluated. The biodistribution and tumor localization in nude mice bearing a HHCC xenograft were studied.

MATERIALS AND METHODS

Monoclonal antibody

The mAb HAb18 is of murine IgG₁ isotype and was developed by our laboratory^[18]. F(ab')₂ fragment of HAb18 was generated by papain digestion with a molecular weight of 96 000 dalton^[19].

Tumors

Hepatocellular carcinoma grown in Balb/c mice was used as a prototype tumor model. Approximately 10⁷ HHCC cells obtained from Shanghai Cell Institute of Chinese Academy of Sciences were implanted in the left thigh of the animals and the tumors were allowed to grow for 8-10 days to approximately 1cm in diameter.

Antibody reduction

The antibody concentrated to 8 g/L in neutral PBS was reduced by reaction with a molar excess of stannous/glucoseheptonate (Sn/GH) ranging from 10:1 to 50:1 (Sn/GH: MAb) at 37°C for 15 min-30 min. The Sn/GH with a mass ratio of 1:100 was dissolved in 50mM acetate-buffered saline (ABS), pH 5.3 purged with nitrogen. The reduced antibody was isolated from reductant through a PD-10 column (Pharmacia) equilibrated with 0.05 mol/L ABS. The number of resulting free sulphhydryl groups was assayed with Ellman's reagent 5, 5'-dithio-bis (2-nitrobenzoic acid), (DTNB, Sigma Chemical Co., USA)^[20]. One hundred μL of sample was mixed with 20 μL of 0.01 mol/L-DTNB and diluted to

3 mL with 0.05 mol/L Tris-HCl buffer pH 8.4. The mixture was incubated at room temperature for 15 min and coloration measured with an UV/VIS spectrophotometer at 412 nm. The number of thiols was obtained by comparison with a series of L-cysteine (L-cys) standards ranging from 0.312 mg/L to 10 mg/L.

The integrity of the reduced F(ab')₂ was determined by non-reduced SDS-PAGE with 100 g/L gel using Vertical Gel Electrophoresis System (Bio-Rad). The gel was stained with Coomassie brilliant blue R250. Control experiments were run using unreduced mAb F(ab')₂.

Radiolabeling

For labeling, 160 μg of reduced HAb18 F(ab')₂ was mixed with a 10 μL -20 μL of diluted Sn/GH solution (0.2 g/L), and pertechnetium solution (0.2 mL, 74MBq), (Chinese Academy of Atomic Energy) was injected into the mixture. The Sn/GH solution was freshly prepared each time by dissolving 100 mg GH and 1mg SnCl₂·2H₂O in 5 mL of saline purged with nitrogen. The reaction mixture was incubated for 0.5 h-1 h at 37°C before it was analyzed by Whatman 3MM paper chromatography which was then developed in acetone or 100 g/L trichloroacetic acid (TCA). R-f values for acetone are: mAb 0.0, ^{99m}Tc -GH 0.0, and $^{99m}\text{TcO}_4$ -0.9-1.0. R-f values for 100 g/L TCA are: mAb 0.0, ^{99m}Tc GH 0, and $^{99m}\text{TcO}_4$ - 0.7. Labeled mAb was differentiated from ^{99m}Tc colloid by the method of Thrall *et al*^[21]. The same strips impregnated with 10g/L-20g/L human serum albumin before development with 5:2:1, water: ethanol: 5N NH₄OH. Colloid remained on the bottom of the strip while mAb-bound isotope migrated with the solvent front.

The integrity of the labeled F(ab')₂ was assayed using the same non-reduced SDS-PAGE as described above. The gel was autoradiographed on x-ray film before stained with Coomassie brilliant blue R250.

Immunoreactivity assessment

The *in vitro* immunoreactivity of the radiolabeled HAb18 F(ab')₂ was evaluated by a live cell assay^[22]. Briefly, HHCC cells 5 × 10⁹/L were centrifuged (1 000r/min) for 5 min and washed twice with 1% bovine serum albumin (BSA) in PBS, then 5 serial 1:2 dilutions were made in 10 g/L BSA in Eppendorf tubes precoated with BSA. Radiolabeled HAb18 F(ab')₂ at a concentration of 40 ng/mL in 10 g/L BSA was added using a volume equal to half the volume of cell suspension. The total volume of cell-binding assay solution was 0.3 mL. After incubation for 2 h at 37°C, the total as well as the cell-bound radioactivity were counted in a gamma counter.

In Vitro stability studies

The stability was analyzed by using two different challenging agents, EDTA and L-cys. An aliquot of 50 μL $^{99\text{m}}\text{Tc}$ -HAb 18 F(ab')₂ solution was incubated with EDTA or L-cys at 37°C for 1 h. The molar ratio of mAb to challenging agent was at a maximum of 10 000:1. Dissociation ratio was analyzed on paper chromatography.

Biodistribution and imaging

Balb/c mice bearing HHCC were divided into three groups. Each group consisted of three animals and each animal received approximately 15 μg antibody with about 7.4MBq through a lateral tail vein. At time intervals of 4, 10 and 24 h postinjection, three groups of mice were killed, and imaged on a SPECT (Starcam 3 000, UK). Data were collected 100 000 counts per image and peak energy settings at the 140 keV (20%) window for $^{99\text{m}}\text{Tc}$. The blood and other organs of interest were collected. Tissues were washed, blotted, weighed and counted in a gamma counter. For each mouse, data are expressed as percent of injected dose per gram of tissue (%ID/g) after physical decay corrected.

RESULTS

Figure 1 represents the calibration curve for the determination of sulphhydryl groups using L-cys standards over a range of 0.312 to 10 mg/L, by plotting optical density at 412 nm versus L-cys standard concentrations after subtraction of the background due to Ellman's reagent. Linear regression was used and correlation coefficient 0.999 was obtained. Table 1 shows the influence of the reduction conditions on the number of free sulphhydryl groups detected by this thiol assay. As expected, increasing the molar ratio of Sn/GH to antibody in the reaction mixture does increase the number of apparent -SH groups per antibody, and increase the labeling efficiency correspondingly, which results in the labeling efficiency at a maximum of 84.2%. The free $^{99\text{m}}\text{TcO}_4^-$ and colloid amounts determined by Whatman 3MM paper using different developing systems were also showed in Table 1. In control experiments, labeling efficiency was 2% when unreduced HAb18 F(ab')₂ was used. SDS-PAGE by both staining and autoradiography showed that the radioactivity co-migrated with the proteins and that there were almost no protein fragments present within the 60:1 of molar ratio of Sn/GH to mAb (Figure 2). However, another SDS-PAGE in Figure 3 illustrates that fragmentation occurred during the reduction procedure when the molar ratio of Sn/GH to mAb was at 500:1.

As shown in Figure 4, the immunoreactive fraction, 0.84 was determined by plotting the inverse of the bound fraction compared with the inverse of the cell concentration, which is based on

the assumption that the total antigen concentration (cell concentration) is a good enough approximation for the free antigen concentration.

Challenging with EDTA did not remove $^{99\text{m}}\text{Tc}$ from the labeling conjugate remarkably, while L-cys at a molar ratio of 625:1 remove approximately one-tenth of the label (Figure 5).

Biodistribution of radioactivity in blood and excised tissues are displayed in Table 2. The preparation localized at the tumors was more than at any organ examined at both 10 h and 24 h after injection, except the kidneys. The lower radioactivity in blood at 24 h suggested fast blood clearance. The imaging results in Figure 6 showed significant tumor uptake at 24 h post-injection.

DISCUSSION

Great efforts have been made to develop a method that can be used for the direct labeling of mAbs with ^{99m}Tc ^[16]. Earlier studies involved the incubation of mAbs with stannous phthalate tartrate solution for up to 21 h at room temperature, which was named “pretinning” method. Clinical success with this method has been claimed by the author^[23].

One aim of our study was to further evaluate the role of stannous as a reducing agent in the direct labeling of mAb F(ab')₂-2 with ^{99m}Tc . The difference between the “pretinning” method and this method is that we use GH instead of phthalate-tartrate as transfer ligand and stabilizer to avoid Sn or Tc-colloid formation. To do this, we investigated the effect of the quantity of Sn/GH on the labeling time and efficiency. When the molar ratio of Sn/GH to mAb F(ab')₂ was constant, we found that there was no obvious difference on the number of-SH between the reduction time of 20 min and 30 min or even longer^[24]. The whole labeling process can be accomplished within 1.5h. Hnatowich *et al.* reported that labeling efficiency in the case of the stannous ion-reduced antibodies was generally in excess of 70%^[12], however, in our method molar ratio of Sn/GH to mAb was an important parameter to obtain good labeling results, and molar ratio of 40:1 or higher were needed to get labeling

efficiency of more than 80% (Table 1). The low percentage of free $^{99m}\text{TcO}_4$ and radiocolloid in each sample implied that pH 5.3 and GH are the optimal pH value and transfer ligand. Under this condition, the labeled mAb HAb18 F(ab')₂ keeps its immunoreactivity. Autoradiography of SDS-PAGE had only one migration of component identical to that of native HAb18 F(ab')₂ determination by staining with Coomassie brilliant blue R250 (Figure 2), which demonstrated that Sn/GH reduction is mild and does not destroy interchain bridges in mAbs. Labeling efficiency of 2% in control experiments using unreduced HAb18 F(ab')₂ indicated that there was no exchange with the low affinity sites and also demonstrated that reduction of disulfides is a necessary initial step in ^{99m}Tc direct labeling of antibodies. The bond between ^{99m}Tc -SH and Tc is stronger than that of N-Tc or O-Tc which was verified by the challenge assay of ^{99m}Tc -HAb18 F(ab')₂ in the presence of EDTA. We found that EDTA even at a molar ratio of 10 000:1 failed to remove a significant amount of ^{99m}Tc , this is in agreement with the results of Rhodes *et al*^[8]. But L-cys at 625 Å remove one-tenth of the label (Figure 5). Despite such instability of the label, there was no *in vivo* evidence of release of pertechnetate due to no thyroid imaging observed in the whole imaging process (Figure 7). Tumor localization of ^{99m}Tc -HAb18 F(ab')₂ was successfully demonstrated in a human tumor/nude mouse xenograft model. Biodistribution and imaging results showed the highest tumor uptake at 24 h post-injection. Whereas kidney levels were found to be higher in the whole process. Accumulation of radioactivity in the kidney may be the result of retention of this metallic radionuclide by the kidney proximal tubule^[25], the possible release of ^{99m}Tc -labeled cysteine and glutathione^[26] stemming from the radioimmunoconjugate catabolism, and the relative amount of ^{99m}Tc -GH. A technique has been used in patients to block renal tubule uptake of ^{99m}Tc -anti-CEA Fab' fragments by amino acid infusion^[27].

In conclusion, a radioimmunoimaging conjugate for hepatoma detection was prepared by direct labeling mAb HAb18 F(ab')₂-with ^{99m}Tc using stannous/glucoheptonate as reducing agent. Although the labeling efficiency is not satisfactory to some degree, it has several advantages: simple, easy and quick, besides, the labeled mAb fragment retains its immunoreactivity. Biodistribution and imaging studies reveal that this conjugate is useful for the detection of hepatoma.

Abstract

AIM To study the changes of endogenous transforming growth factor β (TGF β) and basic fibroblast growth factor (bFGF) in lung following intestinal ischemia and reperfusion injury and their effects on lung injury and repair.

METHODS Sixty Wistar rats were divided into five groups, which underwent sham-operation, ischemia (45 minutes), and reperfusion (6, 24 and 48 hours, respectively) after ischemia (45 minutes). Immunohistochemical method was used to observe the localization and amounts of both growth factors.

RESULTS Positive signals of both growth factors could be found in normal lung, mainly in alveolar cells and endothelial cells of vein. After ischemia and reperfusion insult, expressions of both growth factors were increased and their amounts at 6 hours were larger than those of normal control or of 24 and 48 hours after insult.

CONCLUSION The endogenous bFGF and TGF β expression appears to be up-regulated in the lung following intestinal ischemia and reperfusion, suggesting that both growth factors may be involved in the process of lung injury and repair.

INTRODUCTION

Our previous investigations have shown that basic fibroblast growth factor (bFGF) and transforming growth factor β (TGF β) play important roles in organ injury and repair after ischemia and reperfusion insult, and that there was a significant relationship between gene expression of bFGF or TGF β and lung repair^[1,2]. Because many growth factors are involved in wound repair by their mitogenic and non-mitogenic effects, we have further investigated the alteration of endogenous bFGF and TGF β in the lung tissue following intestinal ischemia-reperfusion injury and explored their effects on lung repair as well.

MATERIALS AND METHODS

Animal model and tissue preparation

Sixty male, pathogen-free Wistar rats, weighing 250 g \pm 10 g were used in this study. They were divided into 5 groups, which underwent sham-operation, ischemia for 45 minutes, and reperfusion for 6 hours, 24 hours and 48 hours after ischemia for 45 minutes, respectively. Anesthesia was induced by administration of 30 mg/kg of pentobarbital sodium. Following midline laparotomy, intestinal ischemia was achieved by complete occlusion of the superior mesenteric artery (SMA) with a non-crushing microvascular clip. Reperfusion was performed by removal of the microvascular clip after 45 minutes SMA occlusion. All animals were killed by exsanguination at designated times. The samples from right base of lung were obtained immediately and fixed in 10% formalin for analysis. All procedures but SMA clip were done in animals of sham-operated control group.

Immunohistochemical detection for bFGF and TGF β

Immunohistochemical detection was made using polyclonal anti-bFGF or TGF β antibody (Santa Cruz Co. and Zymed Co., respectively) by an indirect streptavidin/peroxidase (SP) technique. Experiments were performed following the manufacturer's recommendation. Paraffin-embedded sections were incubated with polyclonal anti-rat bFGF or TGF β antibody for 12 hours at 4°C

after antigen repair. Biotinylated IgG was added as second antibody. Horseradish peroxidase labeled streptomycin-avidin complex was used to detect second antibody. Slides were stained with diaminobenzidine, and examined under light microscope. The brown or dark brown stained cytoplasm and/or cell membrane was considered as positive. The phosphate-buffered saline (PBS) solution was used as negative control.

Statistical analysis

The slides from 5 animals in each group were used for observation and statistical analysis. One visual field in each slide was randomly selected and observed under light microscope with 400-fold magnification. The percentage of positive immunohistochemical staining cells was expressed as mean \pm SD. Statistical analyses were performed using paired *Student's t* test. $P < 0.05$ was considered significant.

RESULTS

Pathological alternations of lung tissue

The histological structure of alveolar and mesenchymal cells was normal in healthy lungs, while the lung tissues from ischemia and reperfusion rats were significantly damaged, with pulmonary edema and inflammatory cell infiltration.

Expression of bFGF and TGF β

Both bFGF and TGF β were expressed in alveolar epithelial cells and microvascular endothelial cells of normal lung tissues. The positive signals were of immunohistochemical staining in brown or dark brown color and localized in cytoplasm and/or membrane when observed under light microscopy (Figure 1A and B). After ischemia, the expressions of both bFGF and TGF β were increased, especially in the area of alveolar epithelial cells and capillary endothelial cells (Figure 2A and B). At 6 hours postinjury, the expression of bFGF was the same as that in the early injury, while that of TGF β was increased significantly. Many positive cells were type I alveolar cells (Figure 3A and B). Up to 24 hours and 48 hours postinjury, the expression of both growth factors returned to basal levels. By quantitative analysis, the expressions of both bFGF and TGF β were quite different in the early injury when compared with those of control group ($P < 0.01$, Table 1).

Table 1 Expression of bFGF and TGF β in lung following ischemia-reperfusion injury ($\bar{x} \pm s$)

Groups	Animals	bFGF	TGF β
Sham-operated	5	15.4 \pm 3.4	20.0 \pm 5.1
Ischemia 45min	5	61.8 \pm 7.5 ^b	63.4 \pm 7.0 ^b
Reperfusion 6h	5	42.4 \pm 10.1 ^b	50.6 \pm 7.1 ^b
Reperfusion 24h	5	29.0 \pm 5.5 ^b	32.8 \pm 8.7 ^a
Reperfusion 48h	5	15.6 \pm 3.3	19.4 \pm 7.1

^a $P < 0.05$, ^b $P < 0.01$, vs sham-operated.

Figure 1 The expressions of bFGF and TGF β in normal lung. The weakly positive signal could be found in alveolar epithelial cells and microvascular endothelial cells. SP stain $\times 400$

Figure 2 The expressions of bFGF and TGF β in damaged lung following ischemia (45 minutes) and reperfusion (6 hours). Deep staining of both growth factors could be found in alveolar epithelial cells and microvascular endothelial cells. SP stain $\times 400$

The staining of both growth factors could be found in alveolar epithelial cells and microvascular endothelial cells and the expression returned to normal levels. SP stain $\times 400$

DISCUSSION

The lung is one of the very important target organs in multiple organ dysfunction syndrome (MODS) or multiple system organ failure (MOSF) caused by severe injury^[3]. It has been found that in addition to the direct trauma, the lung could also be damaged by indirect injury such as shock, gut ischemia, reperfusion insult, etc. Under the condition of an inadequate mucosal blood flow, the gut barrier function can be progressively impaired and invaded by bacteria or endogenous endotoxin. This process is associated with activation of systemic inflammatory mediators including bacteriotoxin, inflammatory mediators, such as tumor necrosis factor (TNF) and interleukin (IL) and immunocytokines. The tissue damage was manifested as increased inflammatory reaction, low content of ATP in tissue, alveolar endothelial cell damage, enhanced permeability of microcirculation, etc.^[4]. In severe cases, the animal would die of pulmonary failure. But most commonly, these changes are maintained brief because the lung has the ability of self-repair. Recent studies demonstrated that one of the important mechanisms of self-protection and self-repair was the effect of endogenous growth factor and/or nitric oxide synthetase^[2,5]. Therefore, the

localization and quantitation of endogenous growth factors play important roles in lung repair.

Both bFGF and TGF β are important growth factors involved in tissue repair. They are involved in dermal and epidermal wound healing via their chemotactic effects for inflammatory cells and mitogenic effects for tissue cells, such as epidermal cells, fibroblasts and endothelial cells. Normally, TGF β is stored and released from platelets and macrophages, while bFGF combined with heparin is stored in endothelial cells in an inactive form. Both the growth factors are involved in the process of capillary reconstruction and tissue regeneration by their mitogenic and non-mitogenic effects. At the same time, they can also be relieved from injured tissues^[6,7]. Our previous researches have indicated that severe trauma results in histological damage, further decreasing the endogenous growth factors. Thus, it is necessary to supply exogenous growth factors to promote internal organ repair. We have also found that slight ischemia can induce the expression of endogenous factors, and these growth factors participate in the process of wound healing^[8,9]. We also investigated the gene expression of both growth factors in the same animal model, and found that the changes of these gene expressions were consistent with the changes of their proteins. On the basis of these studies, we came to a conclusion that there is a positive relationship between growth factors and tissue repair, and induction of endogenous bFGF and TGF β by ischemia is necessary for tissue repair. By the end of tissue repair, they are restored in tissue again. This result demonstrates that growth factors are involved in organ repair by their increased synthesis or released from damage cells after ischemia-reperfusion insult.

Sun BH, Zhang J, Wang BJ, Zhao XP, Wang YK, Yu ZQ, Yang DL, Hao LJ. Analysis of *in vivo* patterns of caspase 3 gene expression in primary hepatocellular carcinoma and its relationship to *p21^{WAF1}* expression and hepatic apoptosis. *World J Gastroentero*, 2000;6(3): 356-360

Abstract

AIM To detect the expression of caspase 3 gene in primary human hepatocellular carcinoma (HCC) and investigate its relationship to *p21^{WAF1}* gene expression and HCC apoptosis.

METHODS *In situ* hybridization was employed to determine caspase 3 and *p21^{WAF1}* expression in HCC. *In situ* end-labeling was used to detect hepatocytic apoptosis in HCC.

RESULTS Twenty-one of 39 (53.8%) cases of HCC were found to express caspase 3 transcripts, while 46.2% of HCC failed to express caspase 3. Non-cancerous adjacent liver tissues showed more positive caspase 3 (87.5%, 7/8) as compared with HCC ($P < 0.05$). The expression of caspase 3 is correlated with HCC differentiation, 72.2% (13/18) of moderately to highly differentiated HCC showed caspase 3 transcripts positive, while only 38.1% of poorly differentiated HCC harbored caspase 3 transcripts ($P < 0.05$). No relationship was found between caspase 3 expression and tumor size or grade or metastasis, although 62.5% (5/8) of HCC with metastasis were caspase 3 positive and a little higher than that with no metastasis (51.6%, $P > 0.05$). Expression of

caspase 3 alone did not affect the apoptosis index (AI) of HCC. The AI was 7.12% in caspase 3-positive tumors ($n = 21$), while in caspase 3-negative cases ($n = 18$) 6.59% ($P > 0.05$). Expression of caspase 3 clearly segregated with *p21^{WAF1}* positive tumors as compared with *p21^{WAF1}* negative cases (16 of 23, 69.6% versus 5 of 16, 31.3%) with statistical significance ($P = 0.017$). In the cases with positive caspase 3 and negative *p21^{WAF1}*, the AI was found slightly higher, but with no statistical significance, than that with expression of *p21^{WAF1}* and caspase 3 (7.21% vs 6.98%, $P > 0.05$).

CONCLUSION Loss of caspase 3 expression may contribute to HCC carcinogenesis, although the expression of caspase 3 does not correlate well with cell apoptosis in HCC. *p21^{WAF1}* may be merely one of the inhibitors which can reduce caspase 3 mediated cell apoptosis in HCCs.

INTRODUCTION

Hepatocellular carcinoma (HCC), represent 80%-90% of the primary liver cancer, is one of the leading causes of cancer morbidity and mortality on a global scale. More than 80% of liver cancer cases occur in the developing world, especially in China, where HCC is the second cause of cancer death and responsible for 130 000 deaths every year^[1]. Despite dramatic advances in basic and clinical research in the past decades, the exact molecular mechanism for hepatocarcinogenesis is unclear. Gene expression changes have been demonstrated in accordance with cell growth, differentiation and carcinogenesis^[2]. Tumor formation can result from a decrease in cell death, as well as an increase in cell proliferation. In addition to altered expression of cell cycle-related gene, dysregulation of apoptosis (programmed cell death) is thought to contribute to cancer by aberrantly extending cell viability and favoring the accumulation of transforming mutations^[3].

Caspase is a large family which contains at least 14 members. It has been shown that caspase play an important role in regulating cancer cell death both induced by activated lymphocytes through Fas/FasL pathway and by chemotherapy agents^[4]. Caspase 3 or cpp32 is the key member of effector caspases. Caspase 3 had overexpression in B-cell chronic lymphocytic leukemia (B-CLL)^[5], acute myelogenous leukemia (AML)^[6], follicular small cleaved cell non-Hodgkin's B-cell lymphomas^[7,8], human breast cancer cell lines and primary breast tumors^[9] and neuroblastomas^[10]. Caspase 3 is a potent protease which can cleave a large scale of substrate, including cell-cycle related genes such as p21^{WAF1}^[4]. p21^{WAF1} is a cyclin-dependent kinase inhibitor and plays an important role in DNA damage-induced growth arrest. p21^{WAF1} overexpression can cause G₁ cell cycle arrest and further interrupt the apoptotic process at a point upstream from caspase 3 activation^[11]. In this study, we investigated the expression of caspase 3 in primary human HCC and its potential impact on tumor cell apoptosis and its relationship to p21^{WAF1} expression.

MATERIALS AND METHODS

Patients and samples

The surgically resected specimens employed in this study were obtained from consecutive patients with primary HCC who had undergone potentially curative tumor resection at the Department of General and Hepato-Biliary Surgery, Tongji Hospital during 1996-1997. A cohort of 39 cases was involved in this study. All cases were selected on the basis of availability of frozen material for study and on the absence of extensive chemotherapy-induced tumor necrosis. Materials were composed of 3 cases of grade I, 18 cases of grade II, 11 cases of grade III, the remaining 7 cases were grade IV according to TNM system (1987). The tumor lesions analyzed here included 21 poor, 9 moderate and 9 well differentiations. There were 34 males and 5 females, and the age ranged from 24 to 71 years with an average of 46.1 (SD, 12.5). Eight cases of non-cancerous adjacent liver tissues were also included in the study. Routinely processed 40 g/L paraformaldehyde-fixed, paraffin-embedded blocks containing principal tumor were selected. Serial sections of 5 μ m were prepared from the cut surface of blocks at the maximum cross-section of the tumor.

In situ hybridization staining for caspase 3 and p21^{WAF1} and scoring methods for its expression

The plasmid pET21b-cpp32 containing caspase 3 (cpp32) cDNA probe was kindly provided by Dr. JC. Reed (La Jolla, USA). After digestion with *Xho*I and *Nde*I, the fragment was separated by

electrophoresis through an agarose gel and recovered by QIA quick gel extraction kit (QIAGEN) using a micro-centrifuge according to the manufacturer's protocol. The p21^{WAF1} cDNA probe was kindly provided by Dr. SJ Elledge (Houston, USA). Preparation of p21^{WAF1} probe was described previously^[12]. The probes were labeled and detected using a Dig DNA labeling and detection kit (Boehringer Mannheim Biochemica, Germany). Briefly, 40g/L paraformaldehyde-fixed paraffin embedded samples were cut at 5 μ m and adhered to APES-treated slides. After deparaffinized and rehydrated through a graded series of ethanol, the sections were immersed in a 0.01 mol/L DEPC-treated PBS (pH 7.4) two times each for 5min, and then, in PBS containing 100 mmol/L glycine and PBS containing 3 mL/L Triton X-100 for 5 min in turns. Sections were permeabilized for 30 min at 37°C with TE buffer (100 mmol/L Tris-HCl, 50 mmol/L EDTA, pH 8.0) containing 10 mg/L RNase-free proteinase K and washed with DEPC-treated PBS, then incubated at 42°C for 2 h with pre-hybridization buffer. Hybridization solution (400 mL/L deionized formamide, 500 g/L dextra sulfate, 1 \times Dehardt's reagent, 4 \times SSC, 10 mmol/L DTT, 1 g/L yeast tRNA, 1 g/L denatured salmon sperm DNA) containing 2 mg/L probe overlay each section after deprive prehybridization buffer from slides and hybridize at 42°C for 36 h in a humid chamber. The sections were washed in a shaking water bath at 37°C in 2 \times SSC, 1 \times SSC, 0.1 \times SSC for 15 min each, then washed with buffer I (100mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl) for 20 min and with blocking solution (buffer I containing 20 mL/L normal sheep serum) for 30 min, and added sheep anti-Dig-alkaline phosphates (diluted at 1:800 in buffer I) and incubated for another 1h before development by NBT at 37°C for 3 h in the dark. Hybridization buffer containing no probe was used for negative control for each staining. Scoring method for caspase 3 and p21^{WAF1} expression was described by Kawasaki^[13]. Positive tumor cells were quantified by two independent observers, and the average percentage of positive tumor cells was determined in at least 5 areas at \times 400 and assigned to one of five categories: (a) 0, <1%; (b) 1, 1%-25%; (c) 2, 25%-50%; (d) 3, 50%-75% and (e) 4, >75%. The ISH staining intensity was scored as (a) weak 1+; (b) moderate, 2+; and intense, 3+. For tumors showing heterogeneous staining, the predominant pattern was taken into account for scoring. The percentage of positive tumor cells and staining intensity were multiplied to produce a weighted score for each case. Cases with weighted scores <1 were defined as negative, otherwise were defined as positive.

Histochemical detection of apoptosis and

determination of the AI

Tumor cell apoptosis was identified by DNA fragmentation detection kit (QIA33-kit, Calbiochem). Briefly, deparaffinized and rehydrated sections were permeated with proteinase K (20 mg/L in 10 mmol/L Tris, pH 8.0) for 20 min at room temperature and washed with $1 \times$ TBS (20 mmol/L Tris pH 7.6, 140 mmol/L NaCl). After endogenous peroxidases were inactivated by using 30 mL/L hydrogen peroxide for 5 min and washed with $1 \times$ TBS, equilibration buffer was added to each section and incubated at room temperature for 20 min. Terminal deoxynucleotidyl transferase (TDT) enzyme in TDT labeling reaction mix at a 1:20 dilution was pipetted onto the sections, followed by 1.5 h incubation at 37°C. After the reaction was terminated by immersing sections into stop solution and washed with blocking buffer for 10 min at room temperature, the anti-digoxigenin-peroxidase was added to the sections. DAB solution was used for color development. Sections were counterstained by methyl green. A positive control generated covering specimen with DNase I (1 mg/L) for the first procedure. Specific positive tissue sections were used for negative control by substituting distilled water for the TDT in the reaction mixture. The AI was expressed as the ratio of positively stained tumor cells and bodies to all tumor cells, given a percentage for each case. A minimum of 1 000 cells was counted under a 400-fold magnification. Positively staining tumor cells with morphological characteristics of apoptosis were identified using standard criteria, including chromatin condensation, nuclear disintegration and formation of crescentic caps of condensed chromatin at the nuclear periphery.

Statistical analysis

Variables associated with caspase 3 expression as well as the relationship between caspase 3 and p21^{WAF1} were analyzed by χ^2 test. Differences in the tumor cell AI for groups dichotomized according to caspase 3 expression were checked by independent *t* test.

RESULTS

Expression of caspase 3 gene in HCCs

By ISH staining, caspase 3 transcripts was detected predominantly in cytoplasm (Figure 1). Consistent with the presence of caspase 3 protein in human biopsy liver samples, expression of caspase 3 in non-cancerous adjacent liver tissue was also observed in 87.5% (7/8) of cases. The intensity of caspase 3 staining was heterogeneous within a case detected. The tumor cells positively stained by ISH range from 10% to 90%, depending on the cases

examined. After multiplying the weighted caspase 3 score, 21 cases of HCC in the present study were defined as positive (53.8%), with weighted caspase 3 score from 1 to 12.

The expression of caspase 3 and its association with clinicopathological variables

A clinicopathological analysis of caspase 3 positive cases is shown in Table 1. No statistical significance was observed in the prognostic parameters, including tumor size, metastasis, TNM grade, analyzed in the present study except for differentiation. The expression of caspase 3 is correlated with HCC differentiation. It was found that as high as 72.2% (13/18) of moderately to highly differentiated HCC showed caspase 3 transcripts positive, while only 38.1% of poorly differentiated HCC harbored caspase 3 transcripts ($P < 0.05$).

Relationship between caspase 3 and p21^{WAF1}

Twenty-three cases were detected expression p21^{WAF1} transcripts. Positive signal was predominantly located in cytoplasm with a heterogeneous distribution of positive tumor cells. The significance of p21^{WAF1} gene expression was discussed in our previous study^[12]. Expression of caspase 3 clearly segregated with p21^{WAF1} positive tumors as compared with p21^{WAF1} negative cases (16 of 23, 69.6% vs 5 of 16, 31.3%) with statistical significance ($P < 0.05$).

Relationship between tumor cell apoptosis and caspase 3 expression

Apoptotic cells and apoptotic bodies were found in all cases of HCCs examined by *in situ* end-labeling (Figure 2). The mean AI of all tumors cases was 6.82‰ (s, 3.36‰; range 0.87‰-17.3‰). No significant association was observed between AI and tumor stage. The mean AI for caspase 3-positive tumors ($n = 21$) was 7.12‰ (s, 3.75‰), while in caspase 3-negative cases ($n = 18$) the AI was 6.59‰ (s, 2.98‰), no statistical significance was found between the two groups ($P > 0.05$). In the cases with co-expression of p21^{WAF1} and caspase 3, the AI was found lower, but with no significance, than that of cases with positive caspase 3 and negative p21^{WAF1} (6.98‰ vs 7.21‰).

DISCUSSION

In this study, we have shown that caspase 3 was expressed in most of HCC cases. In our opinion, we are the first to describe the cyp32 expression in human primary HCCs. Like the result of human biopsy and autopsy liver materials^[14], the non-cancerous adjacent liver tissue showed strong caspase 3 expression. As high as 46.2% of human primary HCCs failed to show caspase 3 expression.

In the 21 cases which express caspase 3, the expression showed heterogeneous pattern with a weighted score from 1 to 12. Because caspase 3 is the effector caspase in the apoptosis pathways, we think that loss of caspase 3 expression may play an important role in HCC carcinogenesis. Caspase 3 expression had no relationship with clinicopathological features except for tumor differentiation (Table 1). The result suggests that the expression of caspase 3 is correlated with tumor differentiation in HCC. It was reported that 33.1% cases of gastric carcinoma were caspase 3 positive^[7]. Two of 3 breast carcinoma tissues expressed caspase 3, the immunointensity was generally higher in invasive cancers^[8]. It raised the possibility that expression of caspase 3 in tumors showed tissue specificity. It was observed in this study that the apoptosis index (AI) was not associated with the expression of caspase 3 in HCC (7.12‰ in cyp32-positive cases versus 6.59‰ in cyp32-negative group). In the non-cancerous adjacent liver tissues more than 50% of the cells showed positive caspase 3, the AI was not increased as compared with HCC, no matter caspase 3 was positive or negative. This suggests that other factor(s) may exist in regulating normal cell apoptosis.

p21^{WAF1} was first reported as a universal inhibitor of cyclin-dependent kinase, which is required for G₁ to S transition^[15]. Previous studies demonstrated that p21^{WAF1} can interrupt the apoptotic process at a point upstream from caspase-3 activation, because serum starvation, which also synchronized cells in G₁ but did not induce p21^{WAF1}, did not protect cells from apoptosis, while restoring a late G₁ checkpoint by inducing p21^{WAF1} expression can protect cells from DNA damage induced apoptosis^[16]. p21^{WAF1} can bind procaspase-3 but not activate caspase 3. On the other hand, activated caspase 3 can cleave p21^{WAF1}. P21 cleavage by the activated cyp32 specifically abolished its interaction with PCNA and may interfere with normal PCNA-dependent repair^[15]. The presence of p21^{WAF1} in human HCCs was reported previously in our paper^[12]. In this context, the expression of p21^{WAF1} was also determined together with caspase 3 in an attempt to find whether there is relationship between them. We found that expression of caspase 3 was strongly associated with p21^{WAF1} in 16 cases of HCC. There was no significant difference in AI between p21^{WAF1}(+)/cyp32(+) and p21^{WAF1}(-) / cyp32(+) (6.98‰ vs 7.21‰). The results indicated that p21^{WAF1} may be merely one of the inhibitors which can reduce caspase 3 mediated cell apoptosis in HCCs. In fact, some other caspase 3 inhibitors, for example survivin, were reported to have overexpression in human tumors, including gastric and colorectal cancer^[17,18]. Survivin is

believed to bind activated caspase 3 and further inhibit cell apoptosis. It was reported that XIAP can interrupt caspase 3 mediated apoptosis via the same way as p21^{WAF1}. So, further investigation on other caspase 3 regulating protein is needed to find the regulation mechanism of caspase 3 mediated apoptosis in human HCCs.

Effects of salvianolic acid-A on NIH/3T3 fibroblast proliferation, collagen synthesis and gene expression

Cheng Hai Liu, Yi Yang Hu, Xiao Ling Wang, Ping Liu and Lie Ming Xu

Subject headings salvianolic acid-A, NIH/3T3 fibroblast, cell viability, cell proliferation, collagen, gene expression

Liu CH, Hu YY, Wang XL, Liu P, Xu LM. Effects of salvianolic acid-A on NIH/3T3 fibroblast proliferation, collagen synthesis and gene expression. *World J Gastroentero*, 2000;6(3):361-364

Abstract

AIM To investigate the mechanisms of salvianolic acid A (SA-A) against liver fibrosis *in vitro*.

METHODS NIH/3T3 fibroblasts were cultured routinely, and incubated with 10^{-4} mol/L- 10^{-7} mol/L SA-A for 22 h. The cell viability was assayed by [3 H]proline incorporation, cell proliferation by [3 H]TdR incorporation, cell collagen synthetic rate was measured with [3 H]proline impulse and collagenase digestion method. The total RNA was prepared from the control cells and the drug treated cells respectively, and α (1) I pro-collagen mRNA expression was semi-quantitatively analyzed with RT-PCR.

RESULTS 10^{-4} mol/L SA-A decreased cell viability and exerted some cytotoxicity, while 10^{-5} mol/L- 10^{-7} mol/L SA-A did not affect cell viability, but inhibited cell proliferation significantly, and 10^{-6} mol/L SA-A had the best effect on cell viability among these concentrations of drugs. 10^{-5} mol/L- 10^{-6} mol/L SA-A inhibited intracellular collagen synthetic rate, but no significant influence on extracellular collagen secretion. Both 10^{-5} mol/L and 10^{-6} mol/L SA-A could decrease α (1) I pro-collagen mRNA expression remarkably.

CONCLUSION SA-A had potent action against liver fibrosis. It inhibited NIH/3T3 fibroblast proliferation, intracellular collagen synthetic rate and type I pro-collagen gene expression, which may be one of the main mechanisms of the drug.

INTRODUCTION

Radix salviae miltiorrhizae, one of the most frequently used Chinese herbs, is regarded to have effects on both blood production and circulation by traditional Chinese medicine, and is widely applied in clinical therapy for liver diseases, such as chronic hepatitis, hepatic cirrhosis, etc. Salvianolic Acid-A is one of the water soluble components from *Radix salviae miltiorrhizae*. It was reported to have good actions on peroxidation^[1]. Lipid peroxidation could stimulate hepatic stellate cell (HSC) transformed into myofibroblast like cell (MFBC) and collagen gene expression *in vivo* and *in vitro*, and played an important role in liver fibrogenesis^[2]. In our previous work^[3], it was found that SA-A could protect hepatic lipid peroxidation, and had marked effects against liver injury and fibrosis in carbon tetrachloride induced fibrotic rats. In order to investigate the mechanism by which SA-A protects against liver fibrosis, we observed the effects of SA-A on NIH/3T3 fibroblast proliferation, collagen protein production and procollagen gene expression.

MATERIALS AND METHODS

Drug

SA-A, molecular formula as $C_{26}H_{22}O_{10}$, molecular structure as shown in Figure 1, molecular weight 494, was extracted and identified by Shanghai Institute of Materia Medica, Chinese Academy of Sciences.

Figure 1 SA-A molecular structure.

Main reagents and solutions

PRMI-1640 Medium and Dubocal modified Eagle Medium (DMEM) were purchased from Gibco BRL

Co., new brown serum (NBS) from Shanghai Sino-American Co., purified type III collagenase (specific activity, 960U/mg), N-ethylmaleimide (NEM) and β -aminopropionitrile from Sigma Co. [^3H]proline ([^3H]Pro) from Amersham Co. methyl-[^3H] thymidine (TdR) from Shanghai Institute of Atomic Energy, guanidium thiocyanate from Serva Co. Access RT-PCR System Kit, PCR marker from Promega Co., Diethylpyrocarbonate, saturated phenol/chloroform mix and agarose from Shanghai Sangon Biotech Co. Other reagents all were of analytical grade.

The non-homogeneous scintillation liquid was dimethylbenzene solution containing 5 g/L 2,5-diphenyloxazol (PPO) and 0.5 g/L 1,4-bis[5-phenyloxazol-2]benzene (POPOP), the homogeneous scintillation liquid was dimethylbenzene solution containing 7 g/L PPO, 0.5 g/L POPOP, 100 g/L naphthalene and 400 mL/L₂-ethoxy-ethanol.

Cell line

Mouse NIH/3T3 fibroblasts were purchased from Shanghai Institute of Cell Biology, Chinese Academy of Sciences, and cultured with PRMI-1640 medium containing 100 g/L NBS, 100KU/L penicillin and 100 mg/L streptomycin. After the cell growth became confluent, they were digested with trypsin-EDTA and subcultured.

PCR Primers

The PCR primers for pro-collagen $\alpha 2(\text{I})$ and β -actin were designed according to the published sequences and references in Table 1^[4], and were synthesized by Gibco BRL Co.

Table 1 PCR primer sequences and expected size of amplified products

Primers	Sequence	Size
$\alpha 2(\text{I})$ collagen upstream	5'TGT TCG TGG TTC TCA GGG TAG3'	254 bp
$\alpha 2(\text{I})$ collagen downstream	5'TTG TCG TAG CAG GGT TCT TTC3'	
β -actin upstream	5'ACA TCT GCT GGA AGG TGG AC3'	163 bp
β -actin downstream	5'GGT ACC ACC ATG TAC CCA GG3'	

Cell proliferation assay

Confluent NIH/3T3 fibroblasts in 24 well plates were incubated with 10^{-4}mol/L - 10^{-7}mol/L SA-A diluted in PRMI-1640 medium containing 100 mL/L NBS for 22 h, and [^3H]TdR (55.5KBq/well) was impu lused in the last 16 h. Then cells were harvested with trypsin digestion and collected on the filtration membrane, then sample radioactivity (cpm) in the non-homogeneous scintillation liquid was measured by Backman Wallac 1410 Scintillator. All tests were repeated 3 times.

Cell viability assay

According to *Mallat's* method^[5], confluent

NIH/3T3 fibroblast s in 24-well plates were incubated with 10^{-4}mol/L - 10^{-7}mol/L SA-A dissolved in PRMI-1640 medium without NBS for 22 h, and [^3H]Pro (55.5KB q/well) was impu lused in the last 16 h. Then cells were collected and the cpm was measured as above.

Assay of cell collagen synthetic rate

According to Greets' method^[6], confluent NIH/3T3 fibroblasts in 6 well plates were incubated with 10^{-5}mol/L - 10^{-6}mol/L SA-A diluted in PRMI-1640 without NBS for 22 h, during the later 16h the culture media were changed to DMEM containing 185 KB q/mL [^3H]Pro, 100 mg/L- β -aminopropionitrile, 50 mg/L ascorbic acid as well as the same drugs. Then the culture media and cell layer extract were collected respectively, dialyzed thoroughly and reacted with collagenase, etc. The total radioactivity in the samples (cpm_t), radioactivity in the samples treated with collagenase (cpm_c) and not treated with collagenase (cpm_b) were counted in the homogeneous scintillation liquid by Backman Wallac 1410 Scintillator. The new collagen that cell produced, i.e. the fraction of collagenous protein expressed as percentage of total radiolabeled protein, was calculated using the formula:

$$\% \text{ of collagen} = 100 \div \left(5.4 \times \frac{\text{cpm}_t - \text{cpm}_c}{\text{cpm}_c - \text{cpm}_b} + 1 \right)$$

RNA extraction and RT-PCR (reverse transcription and polymerase chain reaction)

The total RNA was extracted from the control cells and SA-A incubated cells by the acid guanidium thiocyanate-phenol-chloroform method^[7]. The RNA quantity was determined by absorption at 260 nm, its purity was confirmed with A_{260}/A_{280} spectrophotometer readings that ranged from 1.6 to 1.9, and its integrity was checked by 9 g/L agarose gel electrophoresis with ethidium bromide (EB) staining of 18S and 28S ribosomal RNA (Figure 2). With Access RT-PCR system kit, the cDNA synthesis and amplification was done in one tube following the manufacturer's instructions. In brief, 1 μg RNA, 50 pmol/L primers for $\alpha (1)$ I pro-collagen or β -actin were added to each reaction mixture respectively, which included 10 mmol/L dNTPs 1 μL , 25 mmol/L MgSO_4 2 μL , AMV reverse transcriptase 5U, Tfl DNA polymerase 5U, AMV/Tfl-5 \times buffer 10 μL . The reaction final volume was 50 μL and was covered with 20 μL mineraloil. Then with PCR Touchdown thermal cycler (Hyaid, England), RT-PCR reaction was run in the following procedures: ① 48°C for 45 min, 1 circle. ② 94°C for 2 min, 1 circle. ③ 94°C for 30s, 60°C for 1 min, 38°C for 2 min, 30 circles. ④ 68°C for 7 min, 1 circle. Five μL PCR product was run on 15 g/L agarose gel and observed by EB

staining under UV light, the electrophoresis image was transformed into computer, and $\alpha 1$ (I) pro-collagen intensity was analyzed with MPIAS500 image system, while the β -actin band intensity was subtracted as an internal standard.

Figure 2 Total RNA gel electrophoresis photograph. 28S and 18S of total RNA run on 9 g/L agarose gel stained with EB.

Statistical analysis

Data were analyzed by *Student's t* test.

RESULTS

Effects on cell morphology and viability

10^{-5} mol/L- 10^{-7} mol/L SA-A had no marked effects on cell morphology, but 10^{-4} mol/L SA-A led to shrinkage and detachment of some cells, showing cytotoxicity to some degree. 10^{-4} mol/L- 10^{-7} mol/L SA-A did not decrease intercellular [3 H] Pro incorporation, while 10^{-6} mol/L SA-A could increase [3 H]Pro impulse ($P < 0.05$) and enhance cell viability (Table 2).

Effects on cell proliferation

10^{-4} mol/L- 10^{-6} mol/L SA-A remarkably decreased intercellular [3 H]TdR incorporation and inhibited cell proliferation ($P < 0.05$), 10^{-4} mol/L SA-A showed more significant effect ($P < 0.01$), but it induced some cell death, which may be associated with its cytotoxic action. 10^{-7} mol/L SA-A had no obvious effect on cell [3 H] TdR incorporation (Table 2).

Table 2 Effects of SA-A on cell intracellular [3 H]TdR and [3 H] Pro incorporation (cpm/well, $\bar{x} \pm s$, $n = 4$)

Group	[3 H]TdR	[3 H]Pro
Control	1482 \pm 486	21018 \pm 5473
10^{-4} mol/L SA-A	675 \pm 201 ^b	18659 \pm 2363
10^{-5} mol/L SA-A	969 \pm 183 ^a	23761 \pm 5430
10^{-6} mol/L SA-A	868 \pm 183 ^a	31408 \pm 4981 ^a
10^{-7} mol/L SA-A	1056 \pm 187	26080 \pm 4504

^a $P < 0.05$, ^b $P < 0.01$, vs control.

Effects on cell collagen synthetic rates

10^{-5} mol/L- 10^{-6} mol/L SA-A could inhibit intracellular collagen synthetic rate significantly ($P < 0.01$), but did not influence extracellular synthetic rate (Table 3).

Table 3 Effects of SA-A on NIH/3T3 fibroblast collagen synthetic rates (% , $\bar{x} \pm s$, $n = 4$)

Group	Intracellular	Extracellular
Control	0.78 \pm 0.03	2.57 \pm 0.37
10^{-5} mol/L	0.48 \pm 0.24 ^b	2.54 \pm 0.91
10^{-6} mol/L	0.43 \pm 0.26 ^b	3.02 \pm 0.69

^b $P < 0.01$, vs control.

Effects on procollagen $\alpha 2(I)$ mRNA expression

Both 10^{-5} mol/L and 10^{-6} mol/L SA-A decreased procollagen $\alpha 1(I)$ mRNA expression significantly ($P < 0.05$), but there was no difference between the two different concentration groups (Table 4, Figure 3).

Table 4 The relative expression amount of $\alpha 2(I)$ procollagen mRNA ($\bar{x} \pm s$, % of β -actin)

Group	<i>n</i>	Col $\alpha 1(I)$ mRNA
Control	3	98.71 \pm 9.96
10^{-5} mol/L SA-A	3	76.23 \pm 12.02 ^a
10^{-6} mol/L SA-A	3	68.44 \pm 8.06 ^a

^a $P < 0.05$, vs control.

Figure 3 RT-PCR product gel electrophoresis photograph. Five μ L RT-PCR products of procollagen $\alpha 2(I)$ and β -actin run on 1.5% agarose gel stained with EB. Lane 1 as PCR marker, lane 2 and 3 as the control for procollagen $\alpha 2(I)$ and β -actin respectively, lane 4 and 5 SA-A 10^{-6} mol/L for procollagen $\alpha 2(I)$ and β -actin respectively, lane 6 and 7 as SA-A 10^{-5} mol/L for procollagen $\alpha 2(I)$ and β -actin respectively.

DISCUSSION

Hepatic fibrosis, a precursor of cirrhosis, is a common and important pathological feature of chronic liver diseases, which involves the abnormal accumulation of extracellular matrix (ECM)

proteins, particularly collagen^[8]. In fibrotic liver, ECM components are mainly produced by HSC and fibroblasts. It is known that during fibrogenesis, HSC undergoes a process of activation, developing a myofibroblast-like phenotype associated with increased proliferation and ECM production, especially type I collagen synthesis. The mouse NIH/3T3 fibroblast also shared the features that active HSC (MFBC) presented, such as remarkable proliferation and substantial production of collagen, and stable cell line. In practice, NIH/3T3 fibroblast is often used as a desirable cell model for investigation of antifibrotic drugs.

In order to rule out the possibility of SA-A cytotoxic influence *in vitro*, the intracellular [³H] Pro incorporation was measured, and inverted microscopic observation was done. It was found that only 10⁻⁴ mol/L SA-A caused some cell detachment, decreased [³H] Pro incorporation, and showed cytotoxicity to some extents. 10⁻⁵ mol/L-10⁻⁷ mol/L SA-A did not influence cell morphology or inhibit cell viability. However, 10⁻⁶ mol/L SA-A enhanced cell viability. Both 10⁻⁵ mol/L-10⁻⁶ mol/L SA-A could inhibit intracellular [³H] TdR impulse that NBS stimulated. It is suggested that SA-A had an effective action against NIH/3T3 fibroblast proliferation.

Type I collagen is the predominant component of ECM during liver fibrosis. Its production involves two processes: the first is intracellular synthesis, including gene transcription, translation and modification to form procollagen, then procollagen alpha chains are secreted to the outside of the cell to form helix collagen by sorting and alignment etc. In the study, it was found that SA-A downregulated procollagen α 2(I) steady-state mRNA expression, and intracellular collagen synthetic rate, but exerted no effect on extracellular synthetic rate. It is suggested that SA-A influence on collagen production through the intracellular synthetic

process. The fibrogenic cells have two predominant features: one is active in cell proliferation, which led to increase in cell number, another is strong fibrogenic ability per cell, which led to accumulation of ECM. In the study, SA-A not only inhibited NIH/3T3 fibroblast proliferation, but also decreased collagen synthesis, showing a good action against liver fibrosis.

Salvianolic acid is widely used as an important component in Chinese herbal formulas for the treatment of chronic liver diseases. Salvianolic Acid-A, one of water-soluble ingredients from Salvianolic acid, had effective actions on hepatic peroxidation and fibrosis *in vivo*^[3]. In the paper, it is for the first time found that SA-A has the potential action against hepatic fibrosis *in vitro*, and its main mechanisms of antifibrotic action perhaps was associated with the inhibition of fibrogenic cell proliferation, collagen gene expression and protein synthesis.

Primary porcine hepatocytes with portal vein serum cultured on microcarriers or in spheroidal aggregates

Yi Gao, Huan Zhang Hu, Ke Chen and Ji Zhen Yang

Subject headings porcine hepatocytes; microcarriers; cell culture; spheroidal aggregate culture; portal vein serum

Gao Y, Hu HZ, Chen K, Yang JZ. Primary porcine hepatocytes with portal vein serum cultured on microcarriers or in spheroidal aggregates. *World J Gastroentero*, 2000;6(3):365-370

Abstract

AIM To develop a culture mode providing durable biomaterials with high yields and activities used in bioartificial liver.

METHODS Hepatocytes were isolated from a whole pig liver by Seglen's method of orthotopic perfusion with collagenase. In culture on microcarriers, primary porcine hepatocytes were inoculated at a concentration of $5 \times 10^7/\text{mL}$ into the static culture systems containing 2 g/L Cytodex-3, then supplemented with 100 mL/L fetal calf serum (FCS) or 100 mL/L porcine portal vein serum (PPVS) respectively. In spheroidal aggregate culture hepatocytes were inoculated into 100 mL siliconized flasks at a concentration of $5.0 \times 10^6/\text{mL}$.

RESULTS In culture on microcarriers hepatocytes tended to aggregate on Cytodex-3 obviously after being inoculated. Typical multicellular aggregated spheroids could be found in the two systems 24 h-48 h after hepatocytes were cultured. The morphological characteristics and synthetic functions were maintained for 5 wk in FCS culture system and 8 wk in PPVS culture system. In spheroidal aggregate culture about 80%-90% isolated hepatocytes became aggregated spheroids 24 h after cultured in suspension and mean diameter of the spheroids was 100 μm . The relationship among the hepatocytes resembled that in the liver *in vivo*. Synthetic functions of albumin and urea of the

spheroids were twice those of hepatocytes cultured on monolayers.

CONCLUSION As high-yields and high-activity modes of culture on microcarriers or in spheroidal aggregate culture with portal vein serum are promising to provide biomaterials for bioartificial liver (BAL) efficiently.

INTRODUCTION

Great attention was paid world-wide to the bioartificial liver (BAL) aiming to release the clinical symptoms of severe acute liver diseases or liver injuries and act as a transitional bridge for liver transplantation. Modern BAL is mainly characterized by its multiple biofunctions resembling those of liver *in vivo* and such functions may be completely derived from the biomaterials in BAL. Years of researches at home and abroad showed that primary hepatocytes were the most ideal biomaterial of BAL. But for the morphological and functional changes of primary hepatocytes cultivated *in vitro* occurred obviously in short time, it was deadly restrained to use them as the biomaterial in BAL. To probe into this question, together with our proceeding researches on this subject^[1], we took the method of two-step orthotopic collagenase perfusion to isolate hepatocytes and cultured them on microcarriers Cytodex-3 statically in flasks in the systems supplemented with FCS or PPVS respectively, and also cultured them in the matrix DMEM containing porcine portal vein serum at a concentration of 100 mL/L through the way of spheroidal aggregating, then estimated the possibility of such hepatocytes acting as the biomaterial in BAL in view of their morphology and biofunctions.

MATERIALS AND METHODS

Materials

The experimental animals were five native sex-unlimited pigs aged 1 mo-2 mo and weighed 10 kg-15 kg from the experiment animal center of SUN Yat-Sen Medical University. Insulin, glucagon, transferrin, collagenase IV, tyran and microcarrier Cytodex-3 were purchased from Sigma (USA). Solution of 50 g/L methyl silicon resin ethyl acetate

was confected by ourselves. Ten g/L osmic acid, 20 g/L pentanal and gradient acetone solutions were provided by the Department of Electron microscope of First Military Medical University. S-450 electron scanning microscope was from Japan. PPVS was collected in the experiment. The liver perfusion solution was prepared according to Table 1.

Methods

Isolation of porcine hepatocytes The experimental pig was kept fasting for 12 h preoperatively and anaesthetized with 30 g/L sodium barbiturate ip. After the abdominal skin being prepared and disinfected, celiotomy was performed, then portal vein and inferior caval vein below the liver exposed and 0.25 mg (125 IU) heparin injected into the inferior caval vein. After being dissected, the portal vein and the inferior caval vein were ligated at the distal end and intubated at the proximal end respectively. When the inferior caval vein above the liver ligated at the superior end of liver vein, successive perfusing solutions I and II pre-warmed in 37°C water bath were perfused along the circuit via portal vein to inferior caval vein. Perfusing speed was about 50 mL/min-60 mL/min for 20 min. Perfusion was ended until the liver became pallor or yellow in color. Then the well digested liver were taken out, tore off the liver sheath and the isolated hepatocytes delivered into solution III pre-warmed in 37°C water bath. After being filtered by 150 µm, 100 µm and 80 µm sieve, the hepatocytes were suspended in solution and centrifuged at a speed of 1 000r/min for 3 min-5 min repeated three times. The deposited hepatocytes were added into solution IV to prepare the hepatocyte suspension for use. Portal vein blood was gathered from the distal end of the ligated portal vein and in a total amount of 1 300 mL from 5 pigs. It was centrifuged at a 2 000r/min to isolate the portal vein serum, and the very serum centrifuged three times more to prepare the refined serum which finally amounted to 714 mL. The refined serum was filtered to be excluded from bacteria and preserved separately for use. Sample from the suspension was observed under light microscope to calculate the yielding rate of hepatocytes and stained by typran for determination of their activity.

Static culture of hepatocytes on microcarriers in flasks

Porcine hepatocyte suspension was divided randomly into two halves, then one half was cultured on microcarriers in FCS system and the other in PPVS system. Five pigs were done separately and by the same method. ① Culture of hepatocytes in FCS system: five flasks were prepared and each one added with 2 mL-3 mL 50 g/L sterile methyl silicon resin ethyl acetate solution. After the flasks being shaken mildly and equably, the remained

solution was discarded. The flasks were parched in 60°C electric oven for use. 20 mg-30 mg Cytodex-3 was deposited into the siliconized flasks and rinsed with 40 mL Ca^{2+} and Mg^{2+} free phosphate buffer solution (PBS) for three times, then dipped in PBS over night. After being sterilized at 15 pounds for 30 min, the microcarriers were dipped in DMEM matrix over 10 h for use. Hepatocytes were inoculated into the flasks at the concentration of $5 \times 10^6/\text{mL}$ and DMEM matrix containing 100 mL/L FCS, 100 µg/L glucagon, 100 µg/L transferrin, 200 µg/L hydrocortisone, 100 µg/L insulin and 200 µg/L fortum added up to the total volume, 50 mL. Then the flasks were deposited into an incubator with 100% humidified atmosphere containing 5% CO_2 at 37°C and shaken reelingly once every 15 min-30 min at the first 4 h, once every 2 h after 4 h and laid quietly after 8 h without further shaking. Ten mL supernatant fluid of the culture matrix was changed after 24 h and once every 2 d from then on. The supernatant fluid was centrifuged at 1 000r/min for discarding the cell fragments. Synthesized albumin and urea were determined. ② Culture of hepatocytes in PPVS system: 100 mL/L refined PPVS was added into the culture system instead of FCS, and the other demands were the same as those of the FCS culture.

Spheroidal aggregate culture of primary porcine hepatocytes

Five flasks were prepared and each one added with 2 mL-3 mL 50 g/L sterile methyl silicon resin ethyl acetate solution. After the flasks being shaken mildly and equably, the residual solution was discarded. The flasks were parched in 60°C electric oven for use. Hepatocytes were inoculated into the flasks at the concentration of $5 \times 10^6/\text{mL}$ and DMEM matrix containing 100 mL/L porcine portal vein serum, 100 µg/L glucagon, 100 µg/L transferrin, 200 µg/L hydrocortisone, 100 µg/L insulin and 200 µg/L fortum added up to a total volume, 50 mL. Then the flasks were deposited into the incubator with 100% humidified atmosphere containing 5% CO_2 at 37°C and shaken reelingly once every 15 min-30 min at the first 4 h, once every 2 h after 4 h and laid quietly after 8 h without further shaking. 10 mL supernatant fluid of the culture matrix was changed after 24 h and once every 2 d from then on. The supernatant fluid was centrifuged at 1 000r/min for discarding the cell fragments. Syntheses of albumin and urea were determined.

Morphological observation and counting of hepatocytes

The porcine hepatocytes cultured on microcarriers and those cultured as aggregated spheroids were observed under phase-contrast light microscope and photographed on an automatic microscopic photographing device successively (Olympus, Japan). In culture on microcarriers 1 mL samples

were collected every day to calculate the amount of cells in the culture system by means of trypan blau. On d7, cell sample was taken at a well-distributed state, culture matrix discarded, rinsed with PBS, then fixed for 0.5 h with 2 mL 20 g/L pentanal, rinsed with PBS again, fixed for 0.5 h with 10 g/L osmic acid, and next dehydrated gradientially for 10 min each stage, exchanged with acetic isopental ester for 4 hours, dried by CO₂ drier (Hitachi HCP₂, Japan), and finally splashed with ionic platinum in vacuum. Growth of the cells was observed on S-450 electron scanning microscope (Japan). In spheroidal aggregate culture, 1 mL samples were taken well-distributedly from the matrix for cell calculation on the d7 and d12.

Determination of albumin and urea syntheses

When the culture matrix was changed, samples of supernatant fluid were obtained from the culture on microcarriers and spheroidal aggregate culture to determine the contents of albumin and urea through an automatic biochemical analyzer (Beckman, USA).

RESULTS

Isolation of porcine hepatocytes

We successfully took the improved *Seglen's* two-step orthotopic perfusion method with collagenase to isolate the porcine hepatocytes. About 2.82×10^{10} hepatocytes were obtained and the survival rate 91.2%. Each gram pig liver offered 7.01×10^7 hepatocytes.

Cultivation of porcine hepatocytes

In culture on microcarriers, the amount of hepatocytes on the d7 in the two systems is shown in Table 2. Hepatocytes growth curve (Figure 1) was drawn on the basis of Table 2. On d18 hepatocytes in FCS culture system amounted to $(1.1 \pm 0.53) \times 10^7$ and those in PPVS system $(3.1 \pm 0.71) \times 10^8$. In spheroidal aggregate culture the amount of hepatocytes on d7 was $(3.12 \pm 0.26) \times 10^7$ and that on d10 $(1.39 \pm 0.51) \times 10^8$.

Figure 1 Hepatocytes growth curve in different culture systems on microcarriers.

Morphological observation of hepatocytes cultured on microcarriers

Observation under phase-contrast light microscope Four hours after inoculation microcarriers were observed to be adhered with hepatocytes and the hepatocytes were beginning to expand. The phenomenon of bridge-link could be observed between microcarriers (Figure 2), i. e. the microcarriers were linked with each other through hepatocytes and arranged as slices or a string of beads (Figure 3). There was "snowball" effect between some microcarriers and hepatocytes. Twenty-four hours after culture over 1/3 microcarriers were covered with cells. The hepatocytes adhering to microcarriers was in irregular polygonal shape and thereafter these cells were observed to expand and grow. Forty-eight hours after culture most vivid hepatocytes were attached to microcarriers directly or indirectly. Growth of hepatocytes on microcarriers resembled that of monolayer growth in flasks. In FCS system hepatocytes began to adhere to microcarriers and expanded 2 h after inoculation. Double-nucleus hepatocytes could be observed and some linked to others in insular configuration. Twenty-four hours later about 60%-70% hepatocytes were attached. Three days after inoculation they began to proliferate and there were anile hepatocytes 6 days later. About 22 days later microcarriers were covered fully with hepatocytes. Five weeks after inoculation hepatocytes tended to become rough and blurry-edged. Granules and vacuoles could be observed in most of them. About 2 days later hepatocytes began to detach from microcarriers and died. Morphology of hepatocytes in PPVS system resembled that in FCS system at the first 24 h except that there were more double-nucleus hepatocytes in PPVS system. Three days after inoculation most microcarriers were covered with neonatal hepatocytes and they linked to others in spheroidal or trabecular conformation. Eighteen days later microcarriers were covered fully with hepatocytes and such condition could be maintained to the d52. Fifty-four days later hepatocytes could be observed to begin falling off from microcarriers and completed on the d56.

Observation under electron microscope On d18 of culture, the electron microscope showed that the hepatocytes adhering firmly to the microcarriers in semi-spherical form. The microvilli on the surfaces of hepatocytes could be observed clearly. The amount of hepatocytes adhering to the microcarriers varied and they were distributed unevenly. Some microcarriers aggregated with others through cell-bridge as shown in Figure 4.

Morphological observation of spheroidal aggregated hepatocytes

When successively observing the normal primary porcine hepatocytes cultured in spheroidal-aggregates under the phase-contrast microscope, we found that: about 80%-90% hepatocytes began to aggregate spheroidally 24 h after being inoculated and diameters of the spheroids ranged from 62 μm to 134 μm . Each spheroid contained 10-20 hepatocytes. The hepatocytes at this time linked with each other loosely and were likely to be

dispersed. When observed under light microscope, they looked like “cell flowers” (Figure 5). On the d7 they were hyperplastic and linked with others tightly and looked like “cell spheroids” (Figure 6). On d10 they took the shapes of spheroid and irregular column as “algoid plant” (Figure 7). On the d20, the algoid hepatocytes began to atrophy and vacuolous granules appeared in them, the nuclei began to lyse and the hepatocytes ended in falling off and dying. On the d23, all of the spheroidal aggregating hepatocytes died.

Figure 2 Four hours after inoculation cell-bridge could be observed between microcarriers (under phase-contrast microscope $\times 200$).

Figure 3 Microcarriers were arranged as a string of beads by adhered hepatocytes (under phase-contrast microscope $\times 400$).

Figure 4 Stringed microcarriers with adhered hepatocytes (under phase contrast microscope $\times 730$).

Figure 5 Hepatocytes looked like “cell flowers” 24 h after being cultivated in suspension and aggregated spheroids (under phase contrast microscope $\times 400$).

Figure 6 On the d7 hepatocytes aggregated into “cell spheroids” (under phase contrast microscope $\times 400$).

Figure 7 On the d10 hepatocytes in the forms of algoid plants (under phase contrast microscope $\times 200$).

^a $P < 0.05$ (compared with FCSs group)**Figure 8** Changes of albumin synthesis in hepatocytes from different culture systems on microcarriers.**Figure 9** Changes of urea secretion in hepatocytes from different culture systems on microcarriers.**Figure 10** Dynamic changes of albumin and urea in the supernatant fluid.

Determination of albumin and urea syntheses

By using the automatic biochemical analyzer (Beckman, U.S.A.) we determined the contents of albumin and urea in the supernatant fluid at different times successively. In the two culture systems on microcarriers the values were kept in high levels from the d7 to d14 and got the summit on the d11 to d12 (Figures 8 and 9). As Figures 8 and 9 showed, functions of hepatocytes in PPVS system 3-5 days after inoculation were obviously higher than those in FCS system. Hepatocytes in PPVS can maintain their activity for about 50 days. In spheroidal aggregate culture the values were kept in high levels from d7 to d14 and got the summit on d10. From then on, the values degraded gradually and finally the hepatocytes lost their biofunctions on d23 (Figure 10).

DISCUSSION

Years of researches at home and abroad showed that primary hepatocytes were the most ideal biomaterial for BAL. But for the morphological and functional changes of primary hepatocytes cultivated *in vitro* occurred obviously in short time, it was deadly restrained to use them as biomaterial in BAL. The specific functions of hepatocytes lost in *in vitro* culture accounted for the lack of some *in vivo* elements. Then it was proposed that syntheses of albumin and urea could be promoted by adding some nutritional factors and hormones into the monolayer culture system. By now some improvements has been achieved in searching for a new effective system to cultivate primary hepatocytes *in vitro* by the following methods: ① adding hormonal agents such as insulin, glucagon, transferrin and hydrocortisone into the basal culture medium^[1]; ② adding extracellular biological matrix into the culture system^[2-4]; ③ enriching the culture system with hepatocytes growth stimulating factors such as hepatocytes growth factor and epithelial cell growth factor etc^[5,6]; ④ co-culturing with other endodermal and mesodermal cells; ⑤ three-

dimensional cultivation such as microcapsular and macrocapsular culture, spheroid aggregate, microcarrier culture and hollow fiber culture^[7,8]; ⑥ adding several amino acids and nutritional substances into the culture system; and ⑦ adding penetrating-inducer such as pentobarbiturate to the culture system^[9]. The above measures all aimed to make a circumstance mimic to the *in vivo* environment for the hepatocytes.

It is well-known that about 70% blood supply of liver comes from portal vein system. The growth of liver and maintenance of its functions depend mainly on the nutritional circumstance provided by the portal vein system, that is, hepatocytes *in vivo* are nourished by the contents of portal vein blood. The later provides various amino acids, energy substances and several growth factors. Our experiments were based on this very point and PPVS was added into the culture matrix. The results showed that hepatocytes in this system could durably survive and maintain their biofunctions. This fluid was the ideal circumstance to cultivate the biomaterial for BAL.

Microcarriers Cytodex-3 were used to provide three-dimensional space for adhering and suspending hepatocytes so as to bring benefit from fully utilizing of the nutritional components in the culture system. Our proceeding studies had proved that Cytodex-3 was the best microcarrier for primary hepatocytes^[3]. Hepatocytes on Cytodex-3 were readily to shape the microstructure similar to that of liver so they could grow and function well.

Landry^[10] *et al* found that when no adhering agent in the spheroidal-aggregate culture system the isolated hepatocytes tended to be changed less in morphology and could survive and maintain their activities for 4 wk-6 wk due to the resemblance of the structure between the aggregating spheroids and normal liver. Clayton^[11,12] *et al* found that the specific transcription gene of hepatocyte in little masses of liver could be kept well than that of isolated hepatocytes and obviously the three-dimension structure of hepatocytes is of great importance in maintaining their specific functions. Relationship between cell skeleton and specific proteins reflected the influences of morphology to functions, that is, cell functions directly related with levels of mRNA and specific proteins, and inversely related with levels of actin and canalicular protein. Sakai^[13] *et al* found that the inoculation concentration was of great influence to the formation of hepatocyte spheroids in the

suspending spheroidal aggregate culture system. When hepatocytes being inoculated at a high concentration it often occurred that pH of culture matrix declined, cell-to-cell and spheroid to spheroid relationships changed and multiple necrotic foci could be observed in hepatocyte spheroids. When hepatocytes being inoculated at a low concentration they were difficult to aggregate into spheroids. Sakai *et al* considered $5.0 \times 10^6/\text{mL}$ to be the optimal inoculation concentration in suspending spheroid aggregate culture system of hepatocytes.

On view of the above factors, we concluded that primary porcine hepatocytes cultured on Cytodex-3 in PPVS system or in spheroidal-aggregate were promising to act as the biomaterial of BAL. Still there is much to be desired to promote the density, function and surviving time of hepatocytes for clinical use.

Subject headings insulin/chemistry; biological activities; A chain analogues

Yang SZ, Huang YD, Jie XF, Feng YM, Niu JY. Relationship between insulin A chain regions and insulin biological activities. *World J Gastroentero*, 2000;6(3):371-373

Abstract

AIM To study the relationship between insulin A chain regions and insulin biological activities, we designed a series of insulin analogues with changes at A21, A12-18 of C-terminal helical region and A8-10 located in the region of A6-A11 intra-chain disulphide bond. **METHODS** Insulin A-chain analogues were prepared by stepwise Fmoc solid-phase manual synthesis and then combined with natural B-chain of porcine insulin to yield corresponding insulin analogues. Their biological activities were tested by receptor binding, mouse convulsion and immunological assay.

RESULTS [A21Ala]Ins retains 70.3% receptor binding capacity and 60% *in vivo* biological activity. [DesA13-14, A21Ala]Ins and [DesA12-13-14-15, A21Ala]Ins still have definite biological activity, 7.9% and 4.0% receptor binding, and 6.2% and 3.3% *in vivo* biological activity respectively. [A15Asn, A17Pro, A21Ala]Ins maintains 10.4% receptor binding and 10% *in vivo* biological activity. [A8His, A9Arg, A10Pro, A21Ala]Ins, [A8His, A9Lys, A10Pro, A21Ala]Ins and [A8His, A9Lys, A10Arg, A21Ala]Ins have 51.9%, 44.3% and 32.1% receptor binding respectively, 50%, 40% and 30% *in vivo* biological activity respectively, and 28.8%, 29.6% and 15.4% immunological activity respectively.

CONCLUSION A21Asn can be replaced by simple amino acid residues. The A chains with gradually damaged structural integrity in A12-18 helical region and the demolition of the A12-18 helical region by the substitution of Pro and Asn for A17Glu and A15Gln respectively can combine with the B chain and the combination products show definite biological activity, the helical structure of A12-18 is essential for biological activities of insulin. A8-10 is not much concerned with biological activities, but is much more important antigenically in binding to its antibodies, these results may help us design a new type of insulin analogue molecule.

INTRODUCTION

To elucidate the multi-functions of insulin molecule, hundreds of insulin analogues with changes involving 90% of the constituting 51 amino acid residues at various parts of insulin molecule have been prepared by either chemical modification or synthesis during the past two decades. In this communication we report the influences of three different regions of insulin A chain, especially the secondary structure region, i.e. A12-18 helical region, on insulin biological activities. Recently, thorough studies of insulin analogues with deletion of fragments of the molecule were also undertaken, but restricted mostly to changes in the C-terminal part of the B chain^[1,2], presumably due to its location outside the disulfide linkage and therefore ease of splitting off a tryptic or peptic fragment and recombining with a modified or shortened fragment by chemical or enzymatic semi-synthesis. No such enzymatic site was found in A chain, and most of its amino acid residues are confined inside disulfide linkages. Chemical synthesis might be a better choice for making analogues with modification or deletion in part of the A chain, which constitutes the main feature of this communication.

To obtain insulin analogues, we first set up the semisynthesis strategy of insulin. Insulin A chain was synthesized by the Fmoc solid phase synthesis strategy, and then synthetic A chain S-sulphonate was combined with porcine insulin B chain S-sulphonate forming crystalline insulin^[3]. Based on these experiences, the following insulin analogues

were semisynthesized. They are [A21Ala]Ins^[4], where A21Asn is replaced by Ala, and its derivatives with deletions in the A12-18 helical region, [DesA13-14, A21Ala] Ins^[4] and [DesA12-13-14-15, A21Ala]Ins^[4], and [A15Asn, A17Pro, A21Ala]Ins, where the helical structure of A12-18 was also demolished by the substitutions of Pro for A17Glu and Asn for A15Gln predicted by Chou-Fasman method, and [A8His, A9Arg, A10Pro, A21Ala]Ins^[5], and [A8His, A9Lys, A10Pro, A21Ala]Ins^[5], and [A8His, A9Lys, A10Arg, A21Ala]Ins^[5], in which His reminiscent A8 of chicken insulin with high biological activity took the place of A8Thr and Arg, Lys, Pro replaced A9Ser and A10Ile to examine the influences of these alterations on receptor binding and antigenicity of insulin. The sequences of insulin A chain analogues are as follows (Figure 1).

Figure 1 Insulin A chain analogue sequence.

MATERIALS AND METHODS

Materials

Porcine insulin (26.4U/mg), Shanghai Biochem-ical Plant; Sephadex G-15, G-50, Sepharose CL-6B, Pharmacia; Fmoc amino acid, prepared in the laboratory; DCC, acetonitrile, trimethylsilyl trifluoromethane sulfonate (TMSOTf), thioanisole, Fluka Co. trifluoro- acetic acid (TFA) Merck Co.; DTT, Serva Co.

Methods

Peptide synthesis Base labile N-Fmoc protected amino acid was coupled by DCC-HOBt to the 2% cross linked α -alkoxybenzyl alcohol resin. The functional side chain groups were protected by tBu for Cys, Glu, Tyr and Ser. Scheme of manipulation was the same as reported^[6]. The peptide chain was detached from the resin support with simultaneous removal of all tBu protecting groups by TFA except S-tBu of cysteine. S-tBu was deprotected by M TMSOTf-t thioanisole-TFA system^[5] and transformed to S-sulphonate by tetrathionate and sulfite with the procedure as reported^[7].

Isolation and purification of ASSO₃⁻ Crude ASSO₃⁻ fractions were purified by HPLC with gradient elution (A: 0.1% TFA, B: 60% CH₃CN, 0.125%

TFA).

Recombination with the natural (porcine) BSSO₃⁻ and purification This was carried out according to modified Chance's procedure^[4]. The crude product was purified by HPLC using the same procedure as that for ASSO₃⁻.

Receptor binding, *in vivo* activities and RIA The receptor-binding of insulin and analogues was determined by the displacement of labelled insulin from the insulin receptor on the human placental membrane according to Feng's^[8] procedure. The *in vivo* activity was estimated semiquantitatively by mouse convulsion assay. RIA kit produced by the Shanghai Biological Product Institute was used for RIA of insulin and analogues.

RESULTS

Peptide synthesis

Insulin A chain analogues were prepared starting from 300 mg-500 mg each of Fmoc-alanyl resin and products obtained from each step and the final overall yield is given in Table 1.

Table 1 Data on the synthesis of A chain analogues

A Chain analogues	FmocAla-resin mg(mmol)	Target peptide-resin(mg)	After HPLC(mg)	Overall yield(%)
1	500(0.19)	769	62.1	12.3
2	500(0.19)	749	54.6	12.0
3	500(0.19)	724	45.4	12.4
4	500(0.32)	865	20.0	4.5
5	300(0.135)	657	39.6	10.6
6	300(0.135)	648	40.1	11.2
7	300(0.135)	660	41.3	11.1

Reconstitution of A and B chain and purification of the products

According to the modified Chance's procedure, insulin analogues were obtained by purification of the crude reconstituted products. The identifications of amino acid analysis and HPLC indicated homogeneous products of insulin analogues.

Biological activities

The receptor-binding capacities calculated from the receptor binding curve, *in vivo* activities and immunological activities are shown in Table 2.

Table 2 Biological activities of insulin analogues (%)

Sample	Receptor binding	Mouse convulsion	Immunological activity
Ins	100	100	100
1B	70.3	60	
2B	7.9	6.2	
3B	4.0	3.3	
4B	10.4	10	
5B	51.9	50	28.8
6B	44.3	40	29.6
7B	33.1	30	15.4

DISCUSSION

A21Asn was considered to be a key amino acid of the insulin molecule in regard to its receptor binding. It has been very conservative in the evolutionary process, and when replaced the analogues showed remarkable diminution of biological activity. Our results showed that the analogue with the A21 Asn replaced by Ala exhibited substantial activity *in vivo* and especially higher level of receptor binding, indicating the non-essentiality of A21Asn in receptor binding and biological activity as well. It could well be replaced by other amino acid residues with good retention of biological activities. Better results were observed when the side chain of the A21 amino acid is smaller or not present (Gly)^[9]. However, deletion of the A21 residue is fatal as the activity of desA21 insulin showed only less than 1% of the activity. Apparently, like some non-essential amino acid residues in the insulin molecule, A21 is important in maintaining the specified spatial configuration of insulin required for its biological activities.

It is generally accepted that during the reconstitution of A and B chain to insulin A6-11 disulfide bond formed first and this led to the formation of right natural conformation by self adjustment. When the B chain was getting in touch with the intrachain disulfide, A6-11, a hydrophobic nucleus was formed to enhance the proper pairing of two Cys in both ends of the B chain to corresponding Cys of the A chain^[10]. The success of our reconstitution with deleted A chain supports to a certain extent this suggestion. It showed that the C-terminal helical region in the A chain of insulin was not as important as the N-terminal helical region in reconstitution with the B chain. The biological activities of insulin analogues with gradually damaged structural integrity in A12-18 helical region were similar to that of insulin analogue with the demolition of the A12-18 helical region by the substitution of Pro and Asn for A17Glu and A15Gln respectively. The observations suggested that the helical structure of A12-18 is essential for biological activities of insulin.

It was generally suggested that the enhanced activities of [A8His]Ins^[11], chicken and turkey insulins were ascribed to the His at A8^[12-14], which should account for the higher affinity for insulin receptor. Our results showed that the presence of His at A8 apparently did not enhance the receptor binding. The receptor binding of [A8His] Ins should lie at the range of about 50%. The enhanced

potency of these insulins containing His at A8 may not result solely from an apparent and direct effect due to the presence of A8His. A8His and A10Arg signify a higher influence on insulin antigenicity. A8His will enhance the binding activity to the anti-insulin serum^[11], while A10Arg will decrease this binding, but amino acid at A9 had very little to do with antigenic activity. In addition to studies on how to elucidate the action of an insulin molecule to its receptor and express the physiological activity that follows such action, the purpose of studies on the structure activity relationship of insulin will rely more on how to get a better analogue with high potency but low antigenicity. We hope that the information provided in this study will be beneficial to the development of a new type insulin analogue with those qualities through design of an appropriate architecture of this important hormone.

Subject headings Helicobacter pylori; stomach neoplasm; risk factors; case control studies

Cai L, Yu SZ, Zhang ZF. Helicobacter pylori infection and risk of gastric cancer in Changle County, Fujian Province, China. *World J Gastroentero*, 2000;6(3):374-376

Abstract

AIM To evaluate the effects of *Helicobacter pylori* infection and other environmental factors on the development of gastric cancer.

METHODS A population-based case-control study was conducted in Changle County, Fujian Province. The primary gastric cancer cases were histologically confirmed or diagnosed by surgery between January 1996 and March 1998. Healthy controls were randomly selected and matched by age, sex, and neighborhood of residence. A total of 101 pairs were included in the study. Specially trained interviewers conducted face-to-face interviews with the subjects according to a standardized questionnaire. *Helicobacter pylori* infections were measured by serum IgG antibody to *Helicobacter pylori*. Conditional Logistic Regression analysis was used.

RESULTS The presence of IgG antibody to *Helicobacter pylori* was 63.7% in study subjects, 56.0% in patients with cardiac cancer, and 60.5% in patients with non-cardiac gastric cancer. The risk factors of gastric cancer in Changle County were identified such as low educational level [OR=3.864; 95% confidence interval (95%CI) 1.604-9.311], low consumption of fresh vegetables (OR=4.925; 95% CI 1.356-17.885), high intake of fish sauce (OR = 10.587; 95% CI 2.821-39.738), unscheduled meals (OR = 4.254; 95% CI 1.445-

12.552), and *Helicobacter pylori* infection (OR = 3.453; 95% CI 0.901-13.224).

CONCLUSION *Helicobacter pylori* infection may be important in the etiology of gastric cancer, but major risk factors other than *Helicobacter pylori* are responsible for the high gastric morbidity in Changle County.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is associated with gastric cancer^[1-4]. However, only a small proportion of individuals developed gastric cancer in comparison with the relatively high prevalence of *H. pylori* infection in the general population. In this study we evaluated the effects of *H. pylori* infection and other environmental risk factors on the development of gastric cancer in Changle County, one of the areas with highest morbidity of gastric cancer in the world.

MATERIALS AND METHODS

Study subjects

One hundred and one gastric cancer patients (87 males and 14 females) and the same number of normal controls, individually matched with region, sex and age (± 3 years) were included in the study. The studied subjects must have resided in Changle County for more than 20 years. The primary gastric cancer patients were histologically confirmed or diagnosed by operation during January 1996 - March 1998. Those who have ever been diagnosed as having gastric diseases in the past 3 years were not eligible as controls.

Data collection

Trained interviewers interviewed the patients and controls. A standardized questionnaire was used to obtain information on basic demographic characteristics (gender, race, year and place of birth, and education), dietary habits, personal habits (smoking and drinking), medical history and so on.

H. pylori assay

The presence of anti-*H. pylori* - IgG was assessed using the commercially available high-molecular-weight cell-associated protein *H. pylori* -immuno-

assay (Enteric Products Inc, Westbury, New York). The assay was done in 96-well microtiter plates. Sera diluted 1:101 were added, and peroxidase conjugated anti-human IgG was used as the detector. The absorbance of the solution was measured at 450 nm.

Statistical analysis

Data were handled by Epi-info. Odds ratios (OR) and 95% confidence intervals (95% CI) were calculated by Conditional Logistic Regression using STATA software

RESULTS

A total of 101 pairs were included in the study. They were all Han nationality. The age of the patients ranged from 32 years to 78 years, averaging 58.93 years. The educational level was higher in controls than in the patients. The serum samples of 101 patients and 100 controls were tested for antibodies against *H. pylori*. Among them, 128(63.68%) were *H. pylori* positive. The prevalence of *H. pylori* infection was not significantly different in different age (above 30 years) and sex groups. The demographic characteristics as well as the distributions of prevalence of *H. pylori* infection in different sex and age groups are presented in Table 1 and Table 2.

Table 1 Demographic characteristics as well as *Helicobacter pylori* infection in patients and controls

	Patients		Controls		P value
	n	%	n	%

<i>H. pylori</i> infection	1.2392	0.6852	3.453	0.901-13.224

DISCUSSION

Changle County is a hyperendemic area of gastric cancer^[5]. Chronic *H. pylori* infection has been identified as the most important risk factor of gastric cancer^[6]. The results of our study showed that residents in Changle County had a high prevalence of *H. pylori* infection. This coincided with the concept of high prevalence of *H. pylori* infection in the high risk area of gastric cancer. However, no statistical significant difference was found in respect to presence of *H. pylori* infection between patients and controls. The lack of association in this study may be due to the high prevalence of *H. pylori* in Changle County. *H. pylori* infection can initiate a sequence of histological alterations in the mucosa that may finally result in the development of gastric cancer,

but not all infected subjects will eventually develop gastric cancer. *H. pylori* alone cannot account for development of gastric cancer. Apart from *H. pylori* infection, other factors may play important roles in carcinogenesis.

The development of gastric cancer is believed to be a multistep and multifactorial process. In the Correa model of gastric carcinogenesis, environmental factors are related to the evolution from normal gastric tissue through superficial gastritis, atrophic gastritis, intestinal metaplasia and dysplasia to carcinoma^[7]. Environmental co-factors other than microbial agents may play roles in initiation, promotion or progression of gastric cancer.

The results of this study suggest that dietary factors, such as high intake of fish sauce and low consumption of fresh vegetables possibly increase the risk of gastric cancer. Fish sauce is a kind of traditional sauce consumed daily by Changle residents. It is usually produced from several kinds of sea fishes after long fermentation processes. The mutagenicity of fish sauce has been reported by several experimental studies^[8,9]. There was a large amount of important precursors of N-nitrosamines detected in fish sauce. High intake of fish sauce was an important risk factor involved in the etiology of gastric cancer. However, consumption of diets high in vegetables is the most effective means in preventing gastric cancer. Vegetables contain many biologically active compounds that may be responsible for an anticarcinogenic effect against gastric cancer^[10]. Additionally, unscheduled meals may cause injuries of gastric mucosa and potentiate the effects of carcinogens. Our study indicated that unscheduled meals might be one of the etiological factors for gastric cancer. In this study the educational level was higher in controls than in patients.

This supported the results of previous studies that socioeconomic status is a risk factor for gastric cancer, which in turn is related to diet and education.

These findings indicate that primary prevention should be focused in Changle County on reducing the etiological factors: fish sauce intake, deficiency in fresh vegetables, and *H. pylori* infection. Further elucidation of these risk factors for stomach cancer in Changle and assessment of the interaction between these risk factors and *H. pylori* infection are important for investigating the possible mechanisms of gastric carcinogenesis.

Construction of HBV-specific ribozyme and its recombinant with HDV and their cleavage activity *in vitro*

Shu Juan Wen¹, Kai Jun Xiang², Zhen Hua Huang¹, Rong Zhou¹ and Xue Zhong Qi¹

Subject headings hepatitis B virus; hepatitis D virus; ribozyme gene; recombinant DVRZ

Wen SJ, Xiang KJ, Huang ZH, Zhou R, Qi XZ. Construction of HBV-specific ribozyme and its recombinant with HDV and their cleavage activity *in vitro*. *World J Gastroentero*, 2000;6(3):377-380

Abstract

AIM To construct the recombinant of HDV cDNA and HBV-specific ribozyme gene by recombinant PCR in order to use HDV as a transporting vector carrying HBV-specific ribozyme into liver cells for inhibiting the replication of HBV.

METHODS We separately cloned the ribozyme (RZ) gene and recombinant DVRZ (comprising HDV cDNA and HBV-specific ribozyme gene) into the downstream of T7 promoter of pTAdv-T vector and studied the *in vitro* cleavage activity of their transcripts (rRZ, rDVRZ) on target RNA (rBVCF) from *in vitro* transcription of HBV C gene fragment (BVCF).

RESULTS Both the simple (rRZ) and the recombinant ribozyme rDVRZ could efficiently catalyze the cleavage of target RNA (rBVCF) under different temperatures (37°C, 42°C and 55°C) and Mg²⁺ concentrations (10 mmol/L, 15 mmol/L and 20 mmol/L) and their catalytic activity tended to increase as the temperature was rising. But the activity of rRZ was evidently higher than that of rDVRZ.

CONCLUSION The recombinant of HDV cDNA and ribozyme gene had the potential of being further explored and used in gene therapy of HBV infection.

INTRODUCTION

Hepatitis B virus (HBV) can cause acute and chronic B-type hepatitis in man. The conventional ways available for curing this disease have not been very efficient. This promotes people to explore novel genetic therapeutical ways. Hammerhead ribozyme is a kind of antisense RNA which can specifically cleave the target RNA^[1,2]. In the light of this, people have developed many effective genetic vectors containing ribozyme genes, the transcripts of which showed catalytic activity *in vitro* and *in vivo*^[3-5]. But how to improve the stability and efficiency of ribozyme and specifically carry ribozyme gene into only target cells or tissues has been a tackling problem. HDV, a human hepatitis agent, is a defective RNA virus, the replication cycle of which relies on the infection of HBV^[6]. So HDV can be developed as a specific transporting and replicating vector *in vivo* for ribozyme to reach liver^[7]. In this study, we constructed HBV-specific hammerhead ribozyme gene (RZ) and the recombinant (DVRZ) of HDV cDNA (DV) and ribozyme gene (RZ) and made a careful investigation of their *in vitro* catalytic activity under various conditions. The positive results encouraged us to further explore the feasibility of using HDV as a vector carrying ribozyme for inhibiting the replication of HBV *in vivo*.

MATERIALS AND METHODS

Plasmids

The plasmid pSVC-D3 (containing HDV cDNA) as one of two templates of recombinant PCR was kindly offered by Prof. Taylor of American. pTAdv-T vector used for cloning was purchased from Clontech Corporation.

Major reagents

RiboMax transcription kit, acrylamide, bisactylamide, dNTP, rNTP and Taq polymerase were purchased from Promega. [α -³²P]UTP from Beijing Yuhui Corporation. Advantage-TM PCR pure kit (gel purification kit) from Clontech. X-film from Kodak. DNA polymerase I from Biolabs. T7/Sp6 sequencing kit from Pharmacia.

PCR primers

Primers P1 and P2 covered the whole sequence of designed HBV-specific hammerhead ribozyme gene (RZ) and were used to amplify ribozyme gene (53bp) because of 9nt base-pairing of their 3' ends.

Received 2000-01-11 Accepted 2000-02-18

The sequence of HBV-specific hammerhead ribozyme was designed according to the requirement of domains of ribozyme^[1] and the sequence of HBV C gene fragment.

The ribozyme gene (RZ: 53bp) was also used as one of two templates for recombinant PCR to construct the recombinant (DVRZ) of HDV cDNA and ribozyme gene (mentioned below).

P3, P4 were both recombinant primers, each of which was composed of partial sequences of ribozyme and HDV in order to replace the sequence (17-67) of near 5'-end of HDV with ribozyme by recombinant PCR. P5 was the 3'-end sequence of HDV cDNA.

P3, P4, P5 were used to construct the recombinant (DVRZ) of HDV cDNA (DV) and HBV-specific ribozyme gene (RZ) by one-tube recombinant PCR^[8].

P6, P7 were used to amplify HBV C gene fragment (BVCF), which was the transcription template of target RNA (rBVCF). T7 was partial sequence of T7 promoter region of pTAdV-T vector and was used for sequencing (with Sp6) and identifying (with P2, P5, P7) whether 5'-end of foreign fragment forwardly inserted the downstream of T7 promoter.

The sequencing of all gene fragments was performed on ABI391 automatic sequencer (Pharmacia). The sequences and positions of these primers are listed in Table 1.

Table 1 The sequences and positions of primers

Primer name	Sequences	Positions
P1	5'-AACATTGACATAGCTCTGATGAGTCCGTGAG-3'	RZ:1-31
P2	5'-TCCAGGGAATTAGTACTTTTGCTCCTCACGGAC-3'	RZ:53-23
P3	5'-AGCAAGCTTGAGCCAAAACATTGACATAGCTCT-3'	HDV:1-16, RZ:53-37
P4	5'-CTCCGACGTTCCAATGCTCCAGGGAATTAGTACT-3'	HDV:84-68, RZ:53-37
P5	5'-GTCGAATTCGGGCTCGGGCGCGATCCAGCAGTC-3'	HDV:1680-1647
P6	5'-GATAAGCTTTTACATAGAGGACTCTTGG-3'	HBV:1650-1677
P7	5'-CTGGAATTCGGCGAGGGAGTTCTTCTTAG-3'	HBV:2480-2450

Construction and cloning of HBV-specific ribozyme gene(RZ)

Because of 9nt base-pairing between 3'ends of P1 and P2, direct PCR could produce complete 53bp ribozyme gene (Figure 1). After gel-purification (according to Advantage-TM PCR pure kit, Clontech Corporation), the PCR product (RZ) was directly cloned into the downstream of T7 promoter of pTAdV-T vector and so the resulting recombinant plasmid pTA-RZ was obtained. PCR with T7/P2 as primers and pTA-RZ as template could produce about 100 bp DNA fragment if 5'-end of ribozyme gene was forwardly inserted in to the downstream of T7 promoter of pTAdV-T vector and so could be used to identify the recombinant plasmid pTA-RZ of forward insert. The preparation of competent DH5 α cells and transformation of plasmids were performed according to the reference^[9]. The cloned ribozyme gene was finally verified by sequencing with T7/Sp6 primers.

Construction, cloning and sequencing of the recombinant (DVRZ) of HDV cDNA and HBV-specific ribozyme gene

Thirty μ L PCR reaction system was established^[8]: 20 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 2 mmol/L MgCl₂, each dNTP 200 μ mol/L; Primers P3, P4, P5 were separately 0.05 μ mol/L, 0.005 μ mol/L, 0.05 μ mol/L. The two templates were recombinant plasmids pTA-RZ (containing ribozyme gene) and pSVC-D3 (containing HDV cDNA), each 10 ng. Taq polymerase 2 μ L, denaturation at 92°C-50s; annealing at 53°C-50s; elongation at 70°C-120s; 33cycles; the final elongation at 70°C lasted 5 min. PCR product (DVRZ, 1.7kb) was identified by agarose-gel (1.5%) electrophoresis and then purified with Advantage-TM PCR pure kit. The obtained DNA fragment (DVRZ) was directly cloned into the downstream of T7 promoter of pTAdV-T vector. The resulting recombinant plasmid pTA-DVRZ (positive clones on Ampr & white-blue plate) was verified by PCR with primers T7/P5 and sequencing with Sp6/T7 primers. PCR with primers T7/P5 could produce about 1.7kb-1.8kb DNA fragment and was used to identify the forward insertion of 5'-end of DVRZ. Sequencing was performed on ABI 391 automatic sequencer (Pharmacia).

Cloning and isolation of target gene fragment (HBV C gene fragment-BVCF)

PCR with primers P6, P7 was performed to amplify HBV C gene fragment from serum of HBV. Extraction of sample DNA and PCR reaction were performed according to the reference^[10]. PCR product (BVCF) was directly cloned into the downstream of T7 promoter of pTAdV-T vector and the resulting recombinant plasmid pTA-BVCF (positive clones on Ampr & blue-white plate) was verified by PCR with T7/P7 and bidirectional sequencing with T7/Sp6 primers. PCR with primers T7/P7 was utilized to identify the forward-direction insertion of 5'-end of BVCF.

Linearization of recombinant plasmids pTA-RZ, pTA-DVRZ and pTA-BVCF

These plasmids were separately digested with BamHI and then filled with Klenow fragment for *in vitro* transcription of inserted gene fragments (RZ, DVRZ, BVCF).

In vitro transcription of linearized plasmids pTA-RZ and pTA-DVRZ

³²P-UTP-labeled transcription of the two plasmids was first carried out in order to test the effect of transcription. But the plasmids' transcripts (rRZ, rDVRZ) used for catalyzing the cleavage of target RNA (rBVCF-transcript of plasmid pTA-BVCF containing HBV C gene fragment-BVCF) were not ³²P-labeled. In vitro transcription was performed with T7 RNA polymerase according to RiboMax Transcription kit and the reference^[11]. The

transcripts (rRZ, rDVRZ) would additionally contain 100nt partial sequence of pTAdV-T vector at their both ends. rRZ and rDVRZ were extracted by phenol/chloroform/iso-propyl alcohol (25:24:1), precipitated with ethanol and resuspended with H₂O (RNase-free). The latter was the recombinant of HDV and ribozyme.

Preparation of ³²P-UTP-labeled target RNA (rBVCF)

Linearized plasmid pTA-BVCF (containing HBV C gene fragment) was *in vitro* transcribed and the target RNA (rBVCF) was produced. 20 µL transcription system was so established: ATP, CTP, GTP each 2.5 mmol/L and UTP 0.1 µmol/L, 0.5 µCi/µL[α-³²P]UTP, 2 µg linearized plasmid pTA-BVCF, T7 RNA polymerase 20U, RNasin 10U, 37°C-60 min. The product was loaded for 5% PAGE-7M urea autoradiographed electrophoresis. Gel-band of 1cm length and 0.5 cm breadth was cutted off from the position of target RNA and soaked overnight with NES buffer (0.5 mol/L NH₄Ac, 1 mmol/L EDTA, 0.1% SDS) and extracted with phenol/chloroform/iso-propyl alcohol (25:24:1). The supernate was precipitated with ethanol and then the pellet was harvested and resuspended with H₂O (RNase-free). rBVCF(831+100nt) contained also 100nt partial sequence of pTAdV-T vector at its two ends.

Cleavage reaction

Ten µL reaction system was established: 0.1 mol/L Tris-HCl (pH 8.0), 20 mmol/L MgCl₂, rRZ or rDVRZ and their target RNA (rBVCF) each 2 µL, mixed and incubated under different temperatures (37°C, 42°C, 55°C) for 1h. Negative control with ³²P-labeled rBVCF incubated at 55°C without rRZ & rDVRZ was performed. In the meantime, rRZ and rDVRZ were separately incubated with target RNA (rBVCF) at 37°C under different Mg²⁺ concentrations (10mmol/L, 15mmol/L). In the end, 10 µL ion-free formamide and 1 µL loading buffer (50% glycerol, 1mmol/L EDTA, 0.04% bromophenol blue) were added to terminate the reaction. Then after incubated at 65°C for 10 min, 5 µL reaction sample was loaded for 5% PAGE-7M urea electrophoresis.

RESULTS

Construction and cloning of ribozyme gene

53bp DNA fragment was obtained by PCR with primers P1/P2 (Figure 1). This was in accordance with the size of anticipated ribozyme gene. PCR using T7/P2 as primers and plasmid pTA-RZ as the template amplified a DNA fragment of about 100 bp, which identified forward-direction insertion of ribozyme gene into the downstream of T7 promoter of pTAdV-T vector. Sequencing verified the HBV-specific ribozyme gene. The sequence of ribozyme gene was as follows: 5'-AACATTGACATAGCTCTGATGAGTCCG-TGAGGACAACTACTAATTCCTGGA-3'

Construction, cloning and sequencing of the recombinant (DVRZ) of HDV cDNA(DV) and HBV-specific ribozyme gene(RZ)

About 1.7kb DNA was amplified by recombinant PCR, which indicated the anticipated recombinant DNA molecule DVRZ (Figure 1). After DVRZ's cloning into pTAdV-T vector and transforming into DH5α on Ampr & white-blue plate, PCR with primers T7/P5 produced about 1.8 kb-DNA fragment and identified the positive recombinant plasmid pTA-DVRZ of correct DVRZ's insertion direction. Sequencing of DVRZ with primers T7/Sp6 (pTA-DVRZ as template) confirmed the construct DVRZ.

Cloning and isolation of target gene fragment (HBV C gene fragment-BVCF)

Anticipated 831bp target DNA fragment was amplified by PCR from the serum of HBV (Figure 1). After its cloning into pTAdV-T vector and then transformed into DH5α, PCR with primers T7/P7 produced an about 0.9 kb DNA fragment and so identified the positive recombinant plasmid pTA-BVCF of BVCF's correct insertion direction. Finally, sequencing with primers T7/Sp6 confirmed the inserted BVCF.

Figure 1 Construction of HBV-specific ribozyme gene (RZ), its recombinant with HDV cDNA (DVRZ) and target DNA (BVCF) by PCR. a: Lane 1-PCR marker, Lane 2-ribozyme gene RZ (53bp). b: Lane 1-λ DNA/-Hind III+*Eco* RI marker, Lane 2-recombinant DVRZ (1682bp) Lane 3-target gene BVCF (831bp).

In vitro transcription of linearized recombinant plasmids pTA-BVCF, pTA-RZ and pTA-DVRZ

Target RNA (rBVCF) of 931nt was transcribed from pTA-BVCF. HBV-specific ribozyme (rRZ) of 153nt was transcribed from pTA-RZ.

HBV-specific recombinant ribozyme (rDVRZ, containing HDV) of 1782nt was transcribed from pTA-DVRZ (Figure 2). All these transcripts (rBVCF, rRZ, rDVRZ) contained the same partial sequence of pTAdV-T vector at their both ends after transcription with T7 RNA polymerase.

Cleavage reaction

Ribozymes rRZ and rDVRZ without ³²P-label were separately incubated with target RNA (³²P-labeled rBVCF) under different temperatures (37°C, 42°C, 55°C) and Mg²⁺ concentrations. The results from autoradiographed electrophoresis showed that under these temperatures and Mg²⁺ concentrations, both

rRZ and rDVRZ could catalyze the cleavage of target rBVCF into two RNA fragments (721nt, 210nt) and their catalytic activity tended to increase with the rising of temperature. Comparatively, the catalytic activity of rRZ was higher than that of rDVRZ. But it seemed that Mg^{2+} from 10 mmol/L to 20 mmol/L had no obvious effect on their cleavage activity (Figure 3).

Figure 2 *In vitro* transcription of linearized pTA-RZ, pTA-DVRZ and pTA-BVCF (Lane 1-rDVRZ,1782nt. Lane 2-rBVCF,931nt. Lane 3-rRZ,153nt).

DISCUSSION

Hammerhead ribozyme is a kind of antisense RNA with specific catalytic activity, which can catalyze the specific cleavage of target RNA^[1-3]. So far, many specific ribozyme constructs have demonstrated their catalytic activity both *in vitro* and *in vivo*^[12-15]. HDV, is a defective RNA virus, the replication cycle of which must be dependent on the infection of HBV^[6]. In view of the characteristics of hammerhead ribozyme and HDV, we constructed the recombinant(rDVRZ) of HDV and ribozyme by one-tube recombinant PCR with 3 primers and intended to have HBV-specific ribozyme carried into liver cells by using HDV as a transporting vector. As the first step, we studied the *in vitro* cleavage activity of HBV-specific ribozymes-rRZ and rDVRZ. The results showed that both rRZ and rDVRZ had the ability of catalyzing the specific cleavage of target RNA (rBVCF-*in vitro* transcript of HBV C gene fragment) into two RNA fragments (721nt, 210nt).

The activity of ribozyme rRZ (without containing HDV) was much higher than that of recombinant rDVRZ, which in part cleaved the target RNA. One possible reason is that rDVRZ has much longer two arms outside its base-pairing region and can easily form a complex secondary or tertiary structure, an obstacle to subsequent base-pairing with target RNA (rBVCF). Its three-dimensional structure simulated by computer (not presented here) supports this conclusion. However, we could conclude that the post-transcripted hammerhead ribozyme should not be too long though we are unsure how long ribozyme and its target RNA are optimal to their interaction.

We found that with the temperature rising, the ribozyme activity increased, possibly because higher temperature helped transit the complex tertiary structure into comparatively extended state and so partially delete the structural obstacle to base-pairing. We also found that the requirement of ribozyme for Mg^{2+} was not strict. It appeared that different Mg^{2+} concentrations from 10 mmol/L to 20 mmol/L could meet the ribozymes' activity. But overhigh Mg^{2+} seemed to cause the non-specific cleavage of target RNA (not presented). The reason for this was unclear. Presently, we are studying the activity of the recombinant ribozyme *in vivo* and its repressive effect on HBV replication.

Abstract

AIM To understand the anti-HBs persistence and the long-term preventive efficacy in rural newborns after vaccination with plasma-derived hepatitis B vaccine.

METHODS In the time of expanded program on immunization (EPI), the newborns were vaccinated with $10\ \mu\text{g} \times 3$ doses of hepatitis B vaccine and 762 newborns who were HBsAg negative after primary immunization were selected for cohort observation from 1986 to 1998. Their serum samples were detected qualitatively and quantitatively for hepatitis B infecting markers, including HBsAg, anti-HBs and anti-HBc by SPRIA Kits. The annual HBsAg positive conversion rate was counted by life-table method.

RESULTS ① The anti-HBs positive rate was 94.44% for the babies born to HBsAg negative mothers and 84.21% for those born to HBsAg positive mothers in the 1st year after immunization, and dropped to 51.31% and 52.50% in the 12th year respectively. GMT value was dropped from 31.62 to 3.13 and 23.99 to 3.65 in the 2nd to the 12th year respectively. There was a marked drop in GMT at the 3rd to the 5th year, and in anti-HBs positive rate at the 9th to the 10th year. ② In the period of 12 years observation, the person-year HBsAg positive

conversion rates were 0.12% (5/4150.0) in newborns born to HBsAg negative mothers and 0.20% (1/508.0) in those born to HBsAg positive mothers, and none of the HBsAg positive converted children became HBsAg chronic carriers. Compared with the baseline before immunization, the protective rates were 97.19% and 95.32% respectively.

CONCLUSION The protective efficacy of plasma-derived hepatitis B vaccine persisted at least 12 years, and a booster dose seems not necessary within at least 12 years after the primary three-doses immunization to newborns born to HBsAg negative mothers.

INTRODUCTION

In recent years, many studies on the efficacy of hepatitis B plasma-derived vaccine demonstrated that the anti-HBs antibodies were declined gradually, but the protective rate for children vaccinated with three-doses hepatitis B vaccine was still more than 80%^[1,2]. To understand the anti-HBs persistence and long-term efficacy in newborn, a 1-12 year experimental study on hepatitis B plasma-derived vaccine was carried out among newborns vaccinated with three doses 10 mg/L vaccine in rural area.

MATERIALS AND METHODS

Objects

Newborn infants from one township in Zhengding County, Hebei Province, were vaccinated during 1986-1989. A total of 762 infants who were HBsAg negative after primary vaccination were selected for cohort observation, of them 688 born to HBsAg-negative mothers, and 74 to HBsAg carrier mothers. The annual HBsAg positive conversion rate for newborn infants was 4.72% before immunization.

Vaccine and immunization

Hepatitis B plasma-derived vaccine was produced by Beijing Institute of Biological Product. The newborns were immunized with three doses vaccine at 0mo, 1mo and 6mos of age by well-trained

nurses between 1986-1989 under the rural area immunization program launched in 1986. The first dose was vaccinated at 2.7 mo-0.3 mo (95% CI). The coverage rate of vaccination with a complete course of 3-dose hepatitis B vaccine was 91.5%.

Blood collection and laboratory study

Blood samples were collected from infants by venipuncture at intervals of one or two years. Serum HBsAg, anti-HBs and anti-HBc were tested by RIAs from Beijing Institute of Biological Product. Those who showed HBsAg (S/N value ≥ 2.1), anti-HBc (CO/S value ≥ 2.0) or both were defined as HBV infection, and anti-HBs (S/N value ≥ 2.1) as immunity.

RESULTS

Persistence of anti-HBs after vaccination

The 688 new born babies were born to HBsAg negative mothers, and 74 were born to HBsAg positive mothers. Anti-HBs positive rate was gradually dropped from 94.44% to 51.31% and 84.21% to 52.50% in the 1st-12th year respectively. GMT value was dropped from 31.62 to

3.13 and 23.99 to 3.65 in the 2nd-12th year respectively. There was a marked drop in GMT value at the 3rd-5th year, and in anti-HBs positive rate at the 9th-10th year. Compared with infants born to HBsAg negative mothers, GMT value was lower in infants born to HBsAg positive mothers (Table 1).

HBsAg annual positive conversion rate for vaccinated children

In the period of 12 years follow-up, 5 children born to HBsAg-negative mothers became HBsAg positively converted. Two of them occurred at the 5th year and the rest occurred at the 9th-10th year. The person-year HBsAg positive conversion rate was 0.12% (5/4150.0). One child born to HBsAg positive mothers became HBsAg positively converted, and it occurred at the 5th year. The person-year HBsAg positive conversion rate was 0.20% (1/508.0). None of 6 HBsAg positive converted children became HBsAg chronic carriers (Table 2). Compared with the baseline before immunization, the protective rates were 97.19% and 95.32% respectively (Table 3).

DISCUSSION

The ultimate strategy for newborn vaccination with hepatitis B vaccine is controlling and eliminating hepatitis B. Many specialists think that newborns should be vaccinated within 24 hours which is more effective for preventing HBV mother-infant transmission. In recent studies, some reports say that the risk of HBV infection should increase with the decline of anti-HBs positive rate and GMT value after vaccination of hepatitis B vaccine^[2,3]. Thus, a booster of hepatitis B vaccine should be given. In this study, anti-HBs positive rate declined with age, so was GMT value. The anti-HBs positive rate declined markedly from the 9th to the 10th year, and maintained 50% or so at the 10th-12th year. GMT value declined markedly from the 3rd to the 5th year. Therefore, if we only analyze anti-HBs positive rate and GMT value, it is the best schedule to revaccinate at 3-5 years of age after the primary 3-doses regimen.

With the long-term observation of hepatitis B vaccine, more and more scholars think that the protective efficacy for immune responder could persist several years, even if anti-HBs may have declined to undetectable levels. This may be due to the good memory response to hepatitis B vaccination. The higher anti-HBs level after booster immunization dropped quickly with time, and at the end of 3-5 years dropped to the level of children who had not received booster immunization^[4,5]. The evaluation of the immune efficacy of hepatitis B vaccine should induce antibody level, but the dynamic of HBsAg and the chronic carrier rate during ten years of immunization. Cao *et al*^[6] reported that anti-HBs level declined with years after vaccination and HBsAg positive conversion had not been detected among children born to HBsAg negative mothers in Hunan. Our study indicated that none of children born to HBsAg negative mother became HBsAg chronic carrier within 12 years after vaccination with hepatitis B vaccine, although a few children were infected with HBV and positive for HBsAg. The protective rate

to those newborns born to HBsAg negative mother was still more than 95% within 12 years. We believed that long-term efficacy of hepatitis B vaccine was better and the children would have benefited from life-long hepatitis B vaccine. A booster dose seems unnecessary for children born to HBsAg negative mothers within 12 years after primary 3-dose regimen. It was reported by Cao *et al*^[7] that HBsAg positive conversion children born to HBsAg carrier mothers may become HBsAg chronic carriers after vaccination with hepatitis B vaccine, and most of them occurred at 2-3 years of age. In our study, only 1 of 74 children born to HBsAg carrier mother became HBsAg positively converted, but did not become HBsAg chronic carrier within 12 years after vaccination. In order to improve the immune efficacy for those children born to HBsAg positive mothers, the dynamic of HBsAg carrier rate should be observed further in vaccinated children on a large scale.

Subject headings traditional Chinese syndrome/recipe; Chinese medicine; pharmacokinetics; blood stasis; spleen deficiency; hypothesis

Huang X, Ren P, Wen AD, Wang LL, Zhang L, Gao F. Pharmacokinetics of traditional Chinese syndrome and recipe: a hypothesis and its verification (I). *World J Gastroentero*, 2000;6(3):384-391

Abstract

AIM To propose a hypothesis defining the absorption, distribution, metabolism and elimination of traditional Chinese recipe (TCR) component in blood of healthy subjects and patients, and estimate its correctness. **METHODS** The pharmacokinetics (PK) of same dose of drug was studied in the animal model of traditional Chinese syndrome (S) and healthy animals. The classification, terminology, concept and significance of the hypothesis were set forth with evidence provided in the present study. The hypotheses consisted of traditional Chinese syndrome PK (S-PK) and traditional Chinese recipe PK (R-PK). Firstly, the observed tetramethylpyrazine (TMP) PK in healthy, chronically reserpinized rats (rat model of spleen deficiency syndrome, RMSDS) and RMSDS treated with Sijunzi decoction (SJZD) for confirmation were used to verify S-PK; secondly, the ferulic acid (FA) PK in healthy and high molecular weight dextran (HMWD)-induced rabbit model with blood

stasis syndrome (RDBSS) was also used to verify S-PK; and lastly, TMP PK parameters in serum of healthy rats afterorally taken - *Ligusticum wallichii* (LW), LW and *Salvia miltiorrhiza* (LW&SM) decoctions were compared to verify R-PK.

RESULTS The apparent first-order absorption [K_a , $(13.61 \pm 2.56)h^{-1}$], area under the blood drug concentration-time curve [AUC, $(24.88 \pm 9.76) \mu g \cdot h^{-1} mL^{-1}$], maximum drug concentration [C_{max} , $(4.82 \pm 1.23) \mu g \cdot mL^{-1}$] of serum TMP in RMSDS were increased markedly ($P < 0.05$) compared with those [$K_a = (5.41 \pm 1.91)h^{-1}$, AUC = $(5.20 \pm 2.57) \mu g \cdot h^{-1} \cdot mL^{-1}$, $C_{max} = (2.33 \pm 1.77) \mu g \cdot mL^{-1}$] of healthy rats (HR). The apparent first-order rate constant for α and β distribution phase [$\alpha = (0.38 \pm 0.09)h^{-1}$, $\beta = (0.06 \pm 0.03)h^{-1}$], the apparent first-order intercom partmental transfer rate constants [$K_{10} = (0.24 \pm 0.07)h^{-1}$, $K_{12} = (0.11 \pm 0.02)h^{-1}$, $K_{21} = (0.11 \pm 0.02)h^{-1}$] of serum TMP in RMSDS were decreased significantly ($P < 0.01$) compared with those [$K_{10} = (0.88 \pm 0.20)h^{-1}$, $K_{12} = (1.45 \pm 0.47)h^{-1}$, $K_{21} = (0.72 \pm 0.22)h^{-1}$] of HR. However, no apparent differences occurred between HR and RMSDS treated with SJZD. The serum FA concentration and its AUC [$(5.6690 \pm 2.3541) \mu g \cdot h^{-1} \cdot mL^{-1}$] in RMBSS were also higher than those [AUC = $(2.7566 \pm 0.8232) \mu g \cdot h^{-1} \cdot mL^{-1}$] of healthy rabbits ($P < 0.05$). The K_a $(11.51 \pm 2.82)h^{-1}$, AUC $(0.84 \pm 0.17) \mu g \cdot h^{-1} \cdot mL^{-1}$ of LW & SM-derived TMP in serum were much lower ($P < 0.05$) than those [$K_a = (19.58 \pm 4.14)h^{-1}$, AUC = $(1.27 \pm 0.26) \mu g \cdot h^{-1} \cdot mL^{-1}$] of LW-derived TMP in serum after oral decoctions.

CONCLUSION The SDS and blood stasis syndrome state could affect significantly the pharmacokinetic parameters of drugs and the abnormal SDS pharmacokinetic parameters could be normalized by SJZD. The combination of Chinese medicine in TCR could reciprocally affect the pharmacokinetic parameters of other components absorbed into the systemic circulation. These results support the S and R-PK hypothesis.

INTRODUCTION

Three progresses in the related subjects arouse us to propose hypotheses defining the traditional Chinese syndrome (S) and recipe PK (S-PK and R-PK)^[1-6]. Firstly, in the field of traditional Chinese medicine (TCM), their characteristic PK has not developed as a consequence of what are the chemical components absorbed into the circulation after administering traditional Chinese recipe (TCR) is not clear yet. Then, the progresses in successful detection of TCR-derived component in serum from 1985 to 1989 supported the concept of above hypothesis^[7,8]. Finally, the theoretical and practical achievements of chronopharmacokinetics are not only an example but also enhanced our intention of presenting the hypothesis^[9-11].

The investigation of TCR-derived compound *in vivo* affords a sound basis for advancing the hypothesis of S and R-PK^[2-8,12,13] and the inspiration from the theory and practice of chronopharmacokinetics greatly encourages^[9-11]. The knowledge dealing with the rhythmic changes of pharmacokinetic phenomenon in living organisms is called chronopharmacokinetics^[14], in which, PK of administering drug at different time is not constant and is related to its therapeutic and toxic effects^[14]. Similarly, are there possible differences of serum drug concentration and its pharmacokinetic parameters between different TCS and different Chinese medicines of TCR? In other words, does TCS state and the drugs combination in TCR affect significantly the blood drug concentration and their pharmacokinetic parameters after oral administration? We have postulated the above positive differences in the previously published hypotheses^[11-6].

The four applications according to above concepts have been supported by National Natural Science Foundation of China since 1991. Under the support of grants, we choose *Ligusticum wallichii* (LW) prescriptions and its chemical components as the examples to verify the above hypotheses.

MATERIALS AND METHODS

Drugs, chemicals and reagents

Tetramethylpyrazine phosphorus (TMPP) intravenous infusion in 2 mL ampule (25 g/L, lot No. 90101) and sodium ferulate (SF) were purchased from Guangdong Limin Pharmaceutical Factory (Shaoguang, China); reserpine injection solution in 1 mL (1mg, lot No. 901008) was purchased from Red-Flag Pharmaceutical Factory of Shanghai Medical University (Shanghai, China).

LW was purchased from Dujiangyan City Pharmaceutical Company (Sichuan, China) which was identified by Professor Hu ZH (the Department of Botany, Northwest University, Xi'an, China). *Salvia miltiorrhiza* (SM), *Panax ginseng* C.A.Mey,

Atractylodes macrocephala Koidz, *Poria cocos* (Schw.) Wolf, *Glycyrrhiza uralensis* Fisch were purchased from Xi'an Pharmaceutical Company (Xi'an, China). All organic reagents were bought from Xi'an Chemical Reagent Factory. All chemicals were of analytical reagent grade unless otherwise stated. Methaqualonum (internal standard) was presented by Institute of Materia Medica, Beijing Medical University (Beijing, China). Coumarin (internal standard) was purchased from Sigma. High molecular weight dextran (HMWD) (M_w 500 000) was bought from Tianjin Air Force hospital (Tianjin, China).

Instruments

The following main instruments were used in the experiment: Shimadzu LC-6A HPLC system; SPD-6A ultraviolet detector; shimadzu QP-1000 gas chromatography-mass spectrometer. 7650 infrared spectrometer. RH-90 NMR meter.

Definitions of S and R-PK hypotheses^[1-6]

The S-PK hypothesis indicates that the pharmacokinetic differences between the different TCS have statistical significance and R-PK hypothesis means that one of TCM could influence markedly the pharmacokinetic parameters of other TCM-derived components in blood when administered together in same TCR. The above two pharmacokinetic characteristics are related to the therapeutic, toxic responses and theory of TCM.

The verification of S-PK

The preparation of SJZD (TCR): it consists of *Panax ginseng* C.A.Mey, *Atractylodes macrocephala* Koidz, *Poria cocos* (Schw.) Wolf and *Glycyrrhiza uralensis* Fisch (2:2:2:1). The 7000 g of SJZD drugs were divided into 7 parts. Each part of 1000g was macerated with 7000 mL of distilled water (drug: water=1:7, v/v) at room temperature for 1 h and then boiled for 40 min. The residues were boiled by same volume of water for 40 min once again. Firstly, the two boiled water extracts were mixed, then filtered through several layers of cotton gauze to remove the coarse particles and concentrated by evaporation, repeated preparation of the other parts of SJZD in the same way. The mixture of the seven parts of extraction gives the final concentration of 3 g·mL⁻¹.

Serum TMP and FA PK in healthy and modeled animals were studied to verify the hypotheses. Healthy animals and animal models were divided into five groups and the latter included rat model of spleen deficiency syndrome (RMSDS) treated with SJZD; and rabbit model with blood stasis syndrome (RMBSS). Group 1 (HR-1, *n* = 72): healthy male Wistar rats weighing 240 g ± 20 g afforded from the Experimental Animal Center, the Fourth Military Medical University were injected ip with normal

saline ($0.1 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{d}^{-1}$, 14d). Group 2 (RMSDS, $n = 72$): healthy Wistar rats were injected ip with reserpine ($0.5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{d}^{-1}$, 14d). Group 3 (RMSDS treated by SJZD, $n = 72$): healthy Wistar rats were prepared the same as Group 2 and treated with intragastric administration of SJZD ($30 \text{ g} \cdot \text{kg}^{-1} \cdot \text{d}^{-1}$, 14 d). The above three groups were given *po* $10 \text{ mg} \cdot \text{kg}^{-1}$ of TMPP 24 h after the final injection of normal saline or reserpine. Group 4 (HR-2, $n = 6$): healthy male New Zealand white rabbits afforded from the Animal Center of our university were injected intravenously with normal saline ($15 \text{ mL} \cdot \text{kg}^{-1}$). Group 5 (RMBS, $n = 6$): rabbits were prepared by intravenous injection of 100 g/L HMWD in normal saline ($15 \text{ mL} \cdot \text{kg}^{-1}$). FA was injected intravenously of $5 \text{ mg} \cdot \text{kg}^{-1}$ 30 min after the end of injection of normal saline or HMWD. Rats and rabbits were fasted 12 h before administration.

The 0.5 mL of serum samples of rats were obtained by decapitation after a single oral TMPP at 0.083 h , 0.5 h , 1.0 h , 3 h , 5 h , 8 h , 12 h and 24 h , respectively. At each time point, 6 samples were obtained. The rabbit blood sample of 0.5 mL was directly withdrawn and collected from the ear vein at 2 min , 5 min , 10 min , 20 min , 30 min , 45 min , 60 min , 90 min , 120 min , 150 min and 180 min after intravenous FA. The blood samples were centrifuged ($3000 \text{ r} \cdot \text{min}^{-1}$, 5 min), and 0.2 mL of the resulting serum was used.

Chromatographic condition

Determination of serum TMP concentration^[15-17]: the chromatographic system (Shimadzu LC-6A, Japan) consisted of two pumps (LC-6A), a sample injector (Rheodyne, model 7125), a SPD-6AV detector (Shimadzu) and a C-R3A data processor (Shimadzu). A Shim-Pach CLC-ODS column (particles $5 \mu\text{m}$, $150 \text{ mm} \times 4.6 \text{ mm ID}$) was used for quantitative analysis; AUFs was 0.04 , the flow rate was 1 mL/min , the paper speed was 3 mm/min , column temperature was 38°C , the detection wavelength was 280 nm , the mobile phase consisted of methanol and water ($72:28 \text{ v/v}$). The serum concentration data of HR-1 and RMSDS were analyzed by the 3P87 (Chinese Pharmacological Association) software.

Determination of serum FA concentration^[18]: the detector was set at 320 nm (AUFs: 0.01); the mobile phase was acetonitrile $0.1 \text{ mL} \cdot \text{min}^{-1}$ phosphoric acid ($\text{pH } 2.5$) ($3:7, \text{ v/v}$); the other chromatographic conditions were the same as those in determining serum TMP concentration.

Sample preparation

Serum sample contained TMP: internal standard of Methaqualonum (428 ng) was added to 5 mL of

ground conical centrifuge tube containing $100 \mu\text{L}$ of methanol. The mixture was oscillated on vortex mixer and evaporated to dryness at 48°C on water bath under the stream of nitrogen. Successively added 0.2 mL of blank rat serum, the different amount of TMPP ($0.044 \mu\text{g} \cdot \text{mL}^{-1}$, $0.087 \mu\text{g} \cdot \text{mL}^{-1}$, $0.168 \mu\text{g} \cdot \text{mL}^{-1}$, $0.336 \mu\text{g} \cdot \text{mL}^{-1}$, $0.671 \mu\text{g} \cdot \text{mL}^{-1}$ and $1.342 \mu\text{g} \cdot \text{mL}^{-1}$), $0.2 \text{ mL } 0.05 \text{ mol/L}$ of NaOH solution and 2 mL of trichloromethane to the above centrifugate. After the mixture was vortex mixed again for 15 s , it was centrifuged at $3000 \text{ r} \cdot \text{min}^{-1}$ for 10 min . The organic layer was transferred into another 5 mL ground conical centrifuge tube contained $100 \mu\text{L}$ of 1 mol/L hydrochloric acid-methanol solution (50 mL/L) and evaporated again to dryness on water bath at 48°C under a stream of nitrogen. The residue was dissolved with $100 \mu\text{L}$ of methanol solution and then $20 \mu\text{L}$ was determined by HPLC each time^[15].

Serum sample contained FA: to 0.2 mL of rabbit serum added 0.4 mL of acetonitrile contained $1.5 \mu\text{g}$ of coumarin internal standard. The mixture was vortex mixed and then the deproteinized precipitate was separated by centrifugation ($3000 \text{ r} \cdot \text{min}^{-1}$, 5 min). The supernatant was evaporated at 60°C water bath under a stream of nitrogen. The residue was dissolved in $60 \mu\text{L}$ acetonitrile and $20 \mu\text{L}$ of solution was directly injected into HPLC system for determination. To each 0.2 mL of rabbit blank sera 20 to $800 \mu\text{g} \cdot \text{L}^{-1}$ of FA were added respectively. Their serum samples were analyzed separately by the corresponding method described above^[18].

The verification of R-PK

The preparation of LW decoction, LW&SM (LW: SM=3:1) decoction: the dried roots of them were pounded to about $2 \text{ mm} \times 4 \text{ mm} \times 4 \text{ mm}$ pieces. The other procedure was the same as those for preparing SJZD. The final concentration of LW decoction and LW&SM decoction were $3 \text{ g} \cdot \text{mL}^{-1}$ and $4 \text{ g} \cdot \text{mL}^{-1}$, respectively. TMP content of LW and LW&SM decoctions were determined before administration^[17].

Only healthy rats were used to verify R-PK. Twelve Wistar rats were divided into two groups. LW decoction ($30 \text{ g} \cdot \text{kg}^{-1}$) was given intragastrically to one group ($n = 6$) and LW&SM decoction ($40 \text{ g} \cdot \text{kg}^{-1}$) was given to another group ($n = 6$). The blood samples of 0.2 mL each were obtained by cutting the animal tails at 0.083 h , 0.25 h , 0.50 h , 0.75 h , 1.00 h , 1.50 h , 2.00 h , 3.00 h and 5.00 h after oral TCR.

Analytical method: all quantitative but qualitative detections of TMP were the same as those described above. Chromatographic

conditions: Shim-Pach CLC-ODS column (particles 5 μm , 150 mm \times 4.6 mm ID) was also used for quantitative analysis; the half-preparative column (particles 10 μm , 250 mm \times 10 mm ID) was used for the separation and purification of LW decoction components in serum; Nebulizer and vaporizer temperatures were 250 $^{\circ}\text{C}$. The drift voltage was 70eV.

The identification of LW-derived component in serum^[17]: the related component was firstly separated, purified, enriched and then identified by 3-dimensional HPLC, mass spectrum, and NMR. Calibration curve and statistical analysis were the same as the correspondings described above.

Statistical analysis

The results are expressed as $\bar{x} \pm s$. Comparison of serum drug concentration and pharmacokinetic parameters between controls and studied model of LW and LW&SM decoctions were made by *t* test for paired samples. Differences were considered significant when $P < 0.05$.

RESULTS

The methodological results

One of the chemical components in serum after oral administration of LW extract to rats was identified as TMP by three-dimensional HPLC, UV, IR, MS and NMR (data not shown)^[17].

The chromatographic retention time of TMP, methaqualone (internal standard), FA and coumarin (internal standard) were 3.992 min, 6.223 min, 3.82 min and 7.68 min, respectively (Figure 1, A-B)^[17,18]. They were separated well under their own chromatographic conditions. The ratios between the peak areas of the TMP and methaqualone (internal standard) in serum of rat, and of the FA and coumarin (internal standard) in serum of rabbit were calculated to make the calibration curves and the good linearity over the range (220-6710) $\mu\text{g} \cdot \text{mL}^{-1}$ (TMP, $r = 0.9990$, $n = 6$) and (20-800) $\mu\text{g} \cdot \text{mL}^{-1}$ (FA, $r = 0.9986$, $n = 6$) were obtained. Their equation of the curves were $Y = 0.1889 + 0.0440X$ (TMP) and $Y = 0.5826X + 0.1718$ (FA). If the concentration of FA was above 800 $\mu\text{g} \cdot \text{mL}^{-1}$, the sample was diluted. The detection limit of TMP and FA in sera were 68 $\text{mg} \cdot \text{L}^{-1}$ and 15 $\text{mg} \cdot \text{L}^{-1}$ respectively with a signal-to-noise ratio at 3.

The recoveries of TMP and FA contents from sera of rat and rabbit were determined. Their results are shown in Table 1.

The precision in sera with three levels (0.22 $\mu\text{g} \cdot \text{mL}^{-1}$, 0.8388 $\mu\text{g} \cdot \text{mL}^{-1}$ and 6.7100 $\mu\text{g} \cdot \text{mL}^{-1}$) of TMP and (0.030 $\mu\text{g} \cdot \text{mL}^{-1}$, 0.450 $\mu\text{g} \cdot \text{mL}^{-1}$ and 0.700 $\mu\text{g} \cdot \text{mL}^{-1}$) of FA was detected (Table 2).

FA	0.030	5.5	6.1
FA	0.450	3.2	4.3
FA	0.700	2.1	3.8

The results of verifying S-PK

RMSDS: Four days after ip injection of reserpine, RMSDS showed decrease in activity, severe muscular hypotonia, palpebral ptosis and diarrhea, which were similar to those reported in our previously paper^[15] and accorded with the published diagnostic standard of spleen deficiency syndrome by Chinese Association of Integrated Traditional and Western Medicine^[19]. In RMSDS, the body weights of rats were reduced by 40% (242 g ± 22 g vs 145 g ± 20 g), and in RMSDS treated with SJZD, they had not shown any significant changes (results not shown).

The above analytical method of TMP was used to study TMP PK following oral TMPP. The pharmacokinetic profiles of oral TMPP in HR-1, RMSDS and SJZD treated RMSDS were the 2-compartment models according to the calculation of serum TMPP concentration-time data (Figure 2), which was in agreement with the results obtained from human and rats^[20,21]. The serum concentrations of TMP in RMSDS were higher than those in HR-1 ($P < 0.01$, Figure 2). The pharmacokinetic parameters of TMPP in RMSDS (Table 3) with the exception of $V/F(C)$ and T peak were significantly different from those in HR-1 ($P < 0.01$); k_a , $T_{1/2\alpha}$, AUC , absorption of TMPP; α , β , $T_{1/2\beta}$, $T_{1/2\alpha}$, CLs , K_{12} , and K_{10} demonstrated that RMSDS decreased the rate of the distribution, transportation and clearance of TMPP ($P < 0.01$). The state of the syndrome in RMSDS affected obviously the absorption, distribution, metabolism and excretion of TMPP.

^a $P < 0.01$ vs healthy rabbit.

RMBSS: the above method of detecting FA used to study PK in healthy rabbit and FA serum concentration in RMBSS compartment model was fitted and then pharmacokinetic parameters were calculated with a MCPKP program on a COMPAQ 80-386 computer. Compartmental analysis yielded a two-compartment open model. A rapid distribution phase followed by a slower elimination phase was observed. The mean pharmacokinetic parameters are given in Table 4 and serum concentration-time data in Figure 3.

The results of verifying R-PK

The results of detecting TMP concentrations in LW and LW&SM decoctions were 574.50 g·kg⁻¹·L⁻¹ and 463.02 g·kg⁻¹·L⁻¹, respectively.

The chromatograms of TMP and methaqualonum, the latter was added into serum, and then extracted, were the same as shown in Figure 1A, 1B. The serum TMP chromatogram after administration of LW or LW&SM decoctions was different from that of TMP and of IS added to blank serum (Figure 1A) as well as that of post-administrative TMPP injection solution (Figure 1D). There were two more peaks of unknown significance in Figure 1C than that in Figure 1A and one more unknown peak than that in Figure 1D. The serum TCR-derived component parameters of 4 spectra of UV, IR, MS and NMR (data not shown) are similar to that of TMP standard substance and the reference value. Thus it gives an evidence to reveal that this TCR-derived component is undoubtedly TMP. The TMP PK were calculated by 3P87 program (Chinese Pharmacological Association). The fitted figures from two compartment open model and their parameters are indicated in Table 5.

DISCUSSION

Hypothesis

The concept, terminology, essentials and significance, especially scientific evidences, of S- and R-PK hypothesis were firstly reported and theoretically elaborated in our previous papers^[1-6]. These ideas were exclusively cited^[22-26]. Besides the definition described in above method, we summarized the main elements as follows: ① TCR-derived components *in vivo* are possibly to be detected; ② their number are relatively restricted; ③ they could represent the therapeutic effect of the parent recipe; ④ their concentration and PK could be affected by the combination of TCM in TCR; ⑤ effects of new bioactive components related with those of their parent TCR; and ⑥ the syndrome state could affect their PK significantly. All the ideas of S- and R-PK exhibited the characteristics of combination of TCM theory and PK. The other two published papers only concerned the element 1^[1-6]. So far, over 20 evidences in the available published literatures^[2-8,12,13] supported the element 1.

Methodology

It is necessary to develop scientific analytical method, mainly chromatography, for verifying the hypothesis of S- and R-PK. In general, western drug component (single chemical substance) in blood is only identified by the consistency of retention time of peak in chromatograms as compared with its standard substance derived from the national and international authorized unit^[27-29]. However, this method is not sufficient in analysing the serum TCR-derived component because the coherence of retention time may result from two possibilities, i.e., only a single component peak or an overlap of two or more component peaks according to the theory of chromatography^[17].

We developed the above HPLC method, to determine the serum TMP PK after the administration of TMPP or TCR-LW. When TMPP

solution (Figure 1D) was administered, determination of TMP qualitatively and quantitatively by HPLC is enough corresponding to the method for determining ordinary western drug^[27-29]. As orally administering LW or LW&SM decoctions, the structure of TMP was firstly identified by HPLC in combining with UV, IR, MS and NMR (Figure 1C) and then its concentration and pharmacokinetic value were determined by HPLC. Thus, it is likely to avoid the analytical errors in serum TMP derived from LW or LW & SM in our present experiments^[15-17]. Tables 1 and 2 indicated that these methods for the determinations of serum TMP and FA concentrations were simple, rapid, sensitive, accurate, specific and reduplicable, with high recoveries. All these indexes were sufficient in studying S- and R-PK.

The verification of S-PK

S-PK hypothesis was advanced according to the theories of TCM and PK^[1-6]. To verify this hypothesis, the animal models of spleen deficiency and blood stasis were chosen and their pharmacokinetic characteristics of TMP and FA were studied. One of these models, RMSDS, was induced by injecting reserpine, which had been used as an animal model for "spleen deficiency syndrome" (SDS) in TCM^[30,31] because its physical signs were similar to those seen in the SDS.

The "spleen" digests food, transports, distributes and transforms nutrients and replenishes qi^[32]. We inferred from the above "spleen theory" that the "spleen" should be also responsible for the absorption and disposal of drugs. So, syndrome state of "spleen" is likely to affect the PK. The aim described in the S-PK hypothesis is to demonstrate the pharmacokinetic differences between syndrome and non-syndrome. Our experimental design from S-PK hypothesis is that the poor absorption of drug in SDS state would decrease its blood concentration and bioavailability. On the contrary, Figure 2 and Table 3 show the results of the increases in TMP serum concentration and AUC in RMSDS. Moreover, the parameters of the distribution and elimination of TMP in RMSDS (Table 3) were slowish. The SDS state could markedly affect the absorption, distribution, metabolism and elimination of TMPP in rat, and the observed results from Figure 2 and Table 3 show that SJZD could restore the above abnormal PK of TMPP in SDS model rats. All these TMP pharmacokinetic characteristics in RMSDS and the normalizing effect of SJZD on PK of TMP in RMSDS provided evidences for S-PK.

The mechanism of forming TMP pharmacokinetic characteristics in RMSDS is unknown. It was reported that the gastric and intestinal motility^[33] and the absorptivity of D-xylose^[34] were all decreased in reserpine-induced RMSDS and the patients with SDS. These

observations are paradoxical to the increased serum TMP concentration in RMSDS. This confusion should be settled by further studies. Figure 3 shows that at corresponding time points the FA concentration in RMBSS increased markedly ($P<0.05$) as compared with normal rabbits. From Table 4 we also found that in RMBSS both the total volume of distribution (V_B) and total elimination rate (CL_B) decreased significantly while FA elimination half-life time ($t_{1/2\beta}$) and AUC increased significantly. This phenomenon may be due to the impairment of microcirculation induced by HMWD infusion. HMWD can lead to abnormal blood rheology (dense, sticky, aggregative, coagulative). So, it is impossible for FA to be metabolized quickly and distributed widely. In conclusion, through this experiment we found a significant difference in the pharmacokinetic parameters between healthy rabbits and RMBSS. This result coincides with S-PK hypothesis^[18].

The verification of R-PK hypothesis

So far, the orthodox academic society has thought that TCR-derived chemical components *in vivo* and their PK are not detectable and enable to study because they or their components are too complicated, trace in quantity or unable to represent curative effect of their parent TCR^[35-38]. Therefore, the article related to above problem is rarely seen in recent years, and resulted in hard to explore the basic pharmacodynamic substance of TCR. The R-PK hypothesis emerged in literature since 1991 holds the idea that TCR-derived chemical components *in vivo* and their PK are possibly to be determined^[1-6]. However, the qualitative and quantitative analysis of LW and LW&SM-derived TMP *in vivo* from Figure 1(C) and its PK from Figure 4 and Table 5 supported the R-PK hypothesis. Similarly, the determinations of over 20 TCR-derived chemical components in blood/urine and their PK^[2-8,12,13,39] in published papers are consistent with the viewpoint of R-PK hypothesis. All these achievements help elucidate the pharmacology of TCM and TCR^[39].

From the results provided in Figure 4 and Table 5 we found that the absorption (K_a), transport (K_{21}) and distribution (V_c/F) of LW&SM-derived TMP in rat serum were decreased significantly compared with those of LW-derived TMP. In Figure 4 and Table 5 it also shows that the concentration and AUC of LW&SM-derived TMP in rat serum were lower than those of LW-derived TMP, which could explain why LW and SM are rarely used alone in a TCR. This viewpoint supported the hypothesis that the combination of drugs in TCR could affect pharmacokinetic parameters of TCR-derived component *in vivo*. It is extremely urgent to explore which component play an important role in the field of interaction of LW or LW&SM derived components *in vivo*.

INTRODUCTION

At present hepatitis B vaccine immunization is an unique effective measure for controlling hepatitis B. It is important to determine optimal immunization strategy for controlling HB and to rationally allocate health resources. From the angle of health economics, cost-effective analysis (CBA) is used for the evaluation of economic benefit of the immunization strategies implemented in different endemic areas of HB in China in order to provide the evidences for decision-making and revision of the current HB immunization strategy.

MATERIALS AND METHODS

Basic data

The data for low and medium endemic areas of HB, involving morbidity and mortality of HB and liver cancer, cost of HB vaccine administration, overage personal income, GNP, and expenses for medical treatment of patients with acute, chronic hepatitis B and hepatocellular carcinoma, were collected from the medical literature^[1,2]. The corresponding data related to heavy endemic area were obtained from the survey.

Definition of immunization strategies and protective effectiveness

The principal immunization strategies currently

implemented in China and their effectiveness, which were used as the basis for evaluation, were selected from the related literature^[3,4] for the sake of fair comparison between the different endemic areas. The definition of these strategies is as follows: ① Low-dose immunization strategy is defined as without maternal predelivery HBeAg and HBsAg screening, and infancy vaccination with three or four doses (one dose of booster) of 10 µg plasma-derived hepatitis B vaccine, and yielding a protective effectiveness of 85%. ② Based on maternal predelivery HBeAg and HBsAg screening, high-dose immunization strategy is known as infancy vaccination with one of the following regimens: infant with maternal HBeAg- and HBsAg-negative only receives three doses of 10 µg plasma-derived hepatitis B vaccine; infant with maternal HBeAg and/or HBsAg-positive receives one dose of 30 µg and two doses of 10 µg plasma-derived hepatitis B vaccine; or three doses of 20 µg plasma-derived hepatitis B vaccine and one dose of hepatitis B immune globulin (HBIG); or three doses of 20 µg and one dose of 10 µg (for booster) plasma-derived hepatitis B vaccine. All provided a protective effectiveness of 90%.

Definition of heavy, medium and low endemic areas

The range of HBsAg-positive rate for heavy, medium and low endemic areas of HB is defined as over 11%, from 5% to 10%, and less than 4% respectively. Longan County, Jinan City and Beijing were selected as the representative areas for the heavy, medium and low endemic levels of HB in China, respectively. The HBsAg- positive rate for the whole population and pregnant women was 18.0% and 11.9% in Longan County, 7.59% and 5.40% in Jinan City, and 2.0% and 1.4% in Beijing, respectively. The data collected from these three places were used for CBA.

Study methods

CBA method was used to compare the data of economic benefit between the different places. Comprehensive weighted score analysis (CWSA) was made for determining the optimal immunization strategy. Definition and calculation formula relative to four scales for evaluation of the strategies are as follows: (a) proportion of individuals with HBsAg

carriage prevented among immunized population: HBsAg-positive rate before immunization-HBsAg-positive rate after immunization = HBsAg-positive rate before immunization \times protective effectiveness; (b) net benefit (NB) = total benefit-total cost; (c) benefit cost

ratio (BCR) =

here, the signal B, denotes benefit; C, cost; r , discount rate; t , time; n , lifetime saved. (d) Direct BCR (DBCR) was known as a BCR which only involved the expenses of medical treatment in hospital. The basic principle and procedure of CWSA: First, four kinds of standards, A,B,C,D, used for assessment of every strategy to endemic areas of HB were defined in terms of different weight score (from 0 to 4) of 4 scales. Standard A was designated as comprehensive effectiveness in four scales: 4 scores (very important) to scale I (HBsAg) which denoted the reduced proportion of HBsAg-positive rate between pre- and post-vaccination; 1 score (less important) to scale II (NB); 3 scores (important) to scale III (BCR), and 2 scores (fairly important) to scale IV (DBCR). Standard B: 4 scores to scale HBsAg; 3 scores to scale NB; 2 scores to scale BCR; and 1 score to scale DBCR. Standard C: 4 scores to scale HBsAg; 3 scores to scale NB; 3 scores to scale BCR; and 0 score (not important) to scale DBCR. Standard D: 0 score to scale HBsAg; 4 scores to scale NB; 4 scores to scale BCR; and 3 scores to scale DBCR. Then, the score rank for four scales was calculated according to their corresponding value in each strategy, the maximal score of any scale in all strategies was 10. The calculation of the score rank was that a measured or estimated value of the scale in each strategy was divided by the greatest measured or estimated value of this scale among all strategies being compared, then multiplied by 10. The total comprehensive scores for each strategy was calculated by the following formula: score rank for each strategy \times weighted score for each scale. Finally, based on the same standard, for example, B, the total comprehensive scores for all strategies were compared to screen a strategy with maximal scores. The strategy possessing greatest total comprehensive scores in all standards evaluated was considered as the optimal one.

Data analysis

All data was analyzed with the software of version SAS 6.0 and Excel 5.0.

RESULTS

Benefit from hepatitis B vaccination of different strategies in different endemic areas

Benefit of the low-dose strategy in three places CBA was conducted based on the actual epidemiologic data of Longan County, Shanghai and Jinan City,

and assuming that after the implementation of the infancy low-dose strategy same protective effectiveness of 85% and coverage of 100% could be yielded in these places. The results indicated that the outstanding benefit was obtained for all places in spite of their different economic development level and different endemicity. Longan had a lower value of benefit scales compared with Shanghai and Jinan except the DBCR scale. The greatest value of difference between BCR and BCR excluding the cost of liver cancer was found in Longan (Table 1).

Table 1 Benefit of HB vaccination of the low-dose strategy for three places with different economic development level and different endemicity

	Place		
	Longan	Shanghai	Jinan
HBsAg-positive rate before vaccination (%)	18.0	10.2	7.6
No. of neonates in 1987	7666	12 000	18 519
Direct benefit*	286	345	562
Indirect benefit*	683	1571	1852
Total benefit*	969	1916	2414
Total cost*	18	22	42
Net benefit*	951	1893	2372
BCR	52.7	85.8	57.9
DBCR	15.5	15.4	13.5
BCR excluding cost of liver cancer	23.6	67.9	34.8
DBCR excluding cost of liver cancer	9.2	14.2	10.1
HBsAg-positive rate after vaccination (%)	3.1	2.2	1.5

*10 000 Yuan RMB.

Comparison of benefit from different strategies in three places Assuming that different immunization strategies had been implemented in each place, the results of CBA for three places showed that the low-dose strategy in Longan and Shanghai would provide the highest values in both scales, BCR and DBCR; the high-dose strategy (30 μ g + 10 μ g \times 2 regimens) in Jinan would yield a slightly higher BCR value compared with the low-dose strategy, 55.35 vs 54.52; and if excluding the influence of difference of economic level between the places (assuming that average personal income for three places was the same i.e. 10 000 in 1998), Longan would have a greater economic benefit, BCR, than Shanghai and Jinan.

Determination of the optimal immunization strategy in different endemic areas of HB

Analysis of sensitivity Based on the assuming parameters involving birth number (10 000), coverage (100%), screening proportion (90%), and sensitivity for screening (90%), the influence of changing endemicity level and strategies on benefit was determined. The results indicated that if the same immunization regimen and strategy was adopted, rank of NB value for every strategy would be seen in order of medium, heavy and low endemic

areas; if BCR of the changing immunization strategies in same endemic area was compared, the low-dose strategy for all endemic areas would yield the greatest BCR and DBCR compared with other strategy, leading to BCR value of 49.91, 54.53 and 37.68 for heavy medium and low endemic area respectively; and DBCR of 14.63, 12.69 and 5.61 for corresponding three endemic areas. No matter which strategy was taken, the greatest difference between DBCR and the BCR excluding liver cancer might be seen certainly in the heavy endemic area; the high-dose strategy would yield the greatest NB compared with other strategy in any endemic area.

Comprehensive weighted score analysis Total comprehensive score for each strategy of different endemic areas were calculated according to four scales of standard, A, B, C, D. The results indicated that when the goal of expectation (representative of standards A, B, C) was to decrease HBsAg-positive rate in general population, the low-dose strategy yielded the highest total comprehensive score. Even through ignoring the decrease of HBsAg-carriage, i.e. only concerning the economic benefit (representative of standard D), the low-dose strategy still yielded the highest total comprehensive score in different endemic areas. But whichever the four standards, the regimen of $10\text{ }\mu\text{g} \times 3 + \text{HBIG}$ classified into the low-dose strategy always had the least comprehensive score, compared with any regimen of both low and high-dose strategies. The details are shown in Table 2.

Table 2 Comprehensive weighted score analysis of the immunization strategies in different endemic areas

Endemic-area	Immunization strategy	Standard			
		A	B	C	D
Heavy	$10\text{ }\mu\text{g} \times 3$	97.3	96.2	96.2	107.9
	$10\text{ }\mu\text{g} \times 4$	84.7	88.5	88.5	90.2
	$10\text{ }\mu\text{g} \times 3 + \text{HBIG}$	83.4	89.9	89.9	86.5
	$30\text{ }\mu\text{g} + 10\text{ }\mu\text{g} \times 2^*$	93.1	95.9	95.9	100.4
	$20\text{ }\mu\text{g} \times 3 + 10\text{ }\mu\text{g}^*$	90.6	94.3	94.3	96.8
	$20\text{ }\mu\text{g} \times 3 + \text{HBIG}^*$	91.4	94.8	94.8	97.9
Medium	$10\text{ }\mu\text{g} \times 3$	97.3	96.2	96.2	107.9
	$10\text{ }\mu\text{g} \times 4$	84.7	88.5	88.5	90.2
	$10\text{ }\mu\text{g} \times 3 + \text{HBIG}$	80.5	88.1	88.1	82.4
	$30\text{ }\mu\text{g} + 10\text{ }\mu\text{g} \times 2^*$	92.6	95.6	95.6	99.6
	$20\text{ }\mu\text{g} \times 3 + 10\text{ }\mu\text{g}^*$	90.2	94.1	94.1	96.3
	$20\text{ }\mu\text{g} \times 3 + \text{HBIG}^*$	91.2	94.7	94.7	97.7
Low	$10\text{ }\mu\text{g} \times 3$	97.3	96.3	96.3	108.0
	$10\text{ }\mu\text{g} \times 4$	84.7	88.5	88.5	90.2
	$10\text{ }\mu\text{g} \times 3 + \text{HBIG}$	78.1	86.6	86.6	79.0
	$30\text{ }\mu\text{g} + 10\text{ }\mu\text{g} \times 2^*$	90.8	94.5	94.5	97.1
	$20\text{ }\mu\text{g} \times 3 + 10\text{ }\mu\text{g}^*$	88.3	92.9	92.9	93.6
	$20\text{ }\mu\text{g} \times 3 + \text{HBIG}^*$	89.6	93.7	93.7	95.4

*High dose strategy.

DISCUSSION

The results of CBA and sensitivity analysis on the actual data from Longan, Shanghai and Jinan indicated that the low-dose strategy yielded higher NB and BCR in Shanghai and Jinan with higher level of economic development; and DBCR in Longan was slightly higher than that in Shanghai and Jinan after excluding indirect benefit; and the distribution of HBsAg-positive rate in these three places was positively correlated with their DBCR, suggesting that the higher the endemicity level was, the bigger the DBCR obtained; the difference between BCR and BCR excluding expenses of liver cancer in Longan was the greatest compared with that in other two places, and the half of total expenses was used for the treatment of liver cancer in Longan, revealing that a significant economic benefit would be obtained in hyperendemic area of liver cancer assuming that the morbidity of liver cancer could be prevented through the HB vaccination. It is demonstrated from the results mentioned above that the low-dose regimen is an optimal strategy in economic benefit and hepatitis B control for areas with different endemic and economic levels/ However, the strategy, i.e., the maternal HBVMs screening before delivery and high dosage vaccination ($30\text{ }\mu\text{g} + 10\text{ }\mu\text{g} \times 2$), should be adopted to improve the protective effectiveness of HB vaccine. Also, the results of CWSA used for determining an optimal strategy demonstrated that for any endemicity level the low-dose strategy yielded the maximal comprehensive score compared with other strategies, providing same conclusion with CBA based on the actual data.

It is recommended that in different endemic areas of hepatitis B in China, the high-dose strategy is suitable for the economically developed areas in obtaining better protective effectiveness in decreasing HBsAg-positive rate. However, the low-dose strategy is optimally used for poor rural areas based on its outstanding economic benefit and better protection against HBV.

Wang Y, Liu H, Zhou Q, Li X. Analysis of point mutation in site 1896 of HBV precore and its detection in the tissues and serum of HCC patients. *World J Gastroenterol*, 2000;6(3):395-397

INTRODUCTION

Hepatitis B is one of the common infectious diseases, which severely impairs the health of the people in our country and has close relationship to the initiation and progression of chronic hepatitis, cirrhosis, and liver cancer. The recent researches indicate that the mutation of HBV precore exists in the patients with these diseases as stated above^[1-5]. According to the recent publications, the mutation of HBV attracts great interests of investigators. The major mutation points in HBV precore are the point in sites 1896 (A1893) and 83 (A83), which are both of G→A point mutations^[6]. Based on the DNA sequence of precore region of HBV, the method of 3'-base specific polymerase chain reaction (3'-BS-PCR) is applied to analyze the 1896 site mutation of HBV^[7] in 126 clinical serum samples and 23 patients' tissues and sera whose tumors have been surgically excised and pathologically diagnosed.

analytical purity and made in China. Hema Thermocycler was the product from Zhuhai Hema Medical Instruments Company.

Specimens

The 126 serum samples were collected from outpatients and inpatients of Department of Infectious Disease, the First Affiliated Hospital of Anhui Medical University from November 1996 to August 1997. Seventy-two patients were infected by HBV, and 14 by HAV. Forty were HBsAg negative diagnosed by the method of RPHA. The 23 samples of liver cancer tissues were the surgical specimens from HCC patients in Department of Surgery, the First Affiliated Hospital of Anhui Medical University who were corroborated by pathological diagnosis. The corresponding serum was obtained before operation. These patients are diagnosed according to the diagnostic criteria stipulated by the Sixth National Meeting of Hepatitis, 1990.

DNA extraction from serum

Into 125 µL of the serum to be examined, add 125 µL HBV DNA extraction buffer (200 mmol·L⁻¹ NaCl, 2 mmol·L⁻¹ EDTA, 1% SDS, 100 mmol·L⁻¹ Tris-HCl, pH 8.0) and 6.25 µL Proteinase K (2 g·L⁻¹). Incubate in 37°C water bath for 6 hours. Extract with phenol and chloroform, precipitate the HBV DNA with ethanol, dissolve in 20 µL sterile re-distilled water and store at -20°C.

DNA extraction from the liver cancer tissues

Into the 200 µg HCC tissue, add 500 µL of DNA extract buffer (100 mmol·L⁻¹ NaCl, 1 mmol·L⁻¹ EDTA, 0.5% SDS, 50 mmol·L⁻¹ Tris-HCl, pH 8.0). Homogenize on ice. Add 50 µL of Proteinase K (2 g·L⁻¹). Incubate in 37°C water bath for 6 hours. Extract with phenol and chloroform, precipitate the HBV DNA with ethanol, dissolve in 20 µL sterile re-distilled water and store at -20°C.

PCR

The primers are designed according to the recorded HBV-DNA sequence, the principle of 3'-BS-PCR, and the papers published by Goergen^[6] i.e. 3' primer (GW-1-1d) TCC ACA CTC CAA AAG ACA

(2287-2270), wild type 5' primer (GW-1-1a) GTG CCT TGG GTG GCT TTG (1879-1896) and mutant type 5' primer (GW-1-1b) GTG CCT TGG GTG GCT TTA (1879-1896). Into the 10 μL DNA extracted from serum or tissue diluted into $5\text{ ng} \cdot \mu\text{L}^{-1}$, add PCR reaction buffer [$10\text{ mmol} \cdot \text{L}^{-1}$ Tris, $50\text{ mmol} \cdot \text{L}^{-1}$ KCl, $2\text{ mmol} \cdot \text{L}^{-1}$ MgCl_2 , 0.001% Gelatin, $200\text{ } \mu\text{mol} \cdot \text{L}^{-1}$ dNTPs, $0.5\text{ } \mu\text{mol} \cdot \text{L}^{-1}$ primers (wild type: GW-1-1a+GW-1-1d; mutant type: GW-1-1a+GW-1-1b) and $0.5\text{ } \mu\text{L}$ Taq DNA polymerase ($3\text{ U} \cdot \mu\text{L}^{-1}$)], covered with mineral oil, run PCR: 93°C 1min, 64°C 1min, 72°C 1min, 30 cycles, 72°C 5min. Aspirate $8\text{ } \mu\text{L}$ of PCR products, check the results with 1.5% agarose gel electrophoresis. The positive band is of 408bp.

RESULTS

3'-BS-PCR of HBV DNA

Using the specific oligonucleotides designed according to the DNA sequences of mutant and wild types the results showed that the amplified specific DNA of wild and mutant types of HBV in precode C were both of 408 bp. Figure 1 shows the PCR results of the DNA extracted from 126 patients' serum obtained at different stages, which demonstrates that constant results can be achieved when repeated. The PCR results of the 14 patients infected by HAV were all negative.

Figure 1 PCR results of HCC patients' point mutation in site 1896 of HBV precore.

1. 100bp DNA Marker; 2. positive control; 3. negative control; 4, 5. sample numbers

Analysis of the 126 patients' point mutation in site 1896 of HBV precore

Of the 72 patients with chronic hepatitis examined with the 3'-BS-PCR of HBV DNA, 58 were positive in wild type, 13 were positive in mutant type only, 21 were positive in both types. The positive rate of mutant type was 47.2% ($34/72$); the positive rate of mutant type only was 18.1%, the positive rate of both types was 29.1% ($21/72$). Neither of these types were detected in the 40 patients with negative HBsAg.

Detection of HBV precore gene in the 23 HCC patients (Table 1).

Table 1 The HBV precore and its mutant type detection in 23 HCC Patients n (%)

	Total	HBV precore positive	HBV precore negative	HBV precore positive		
				Mutant type	Wild type	Mixed type
Tissue	23(100%)	12(52.2)	6(26.1)	5(21.7)	12(52.2)	5(21.7)
Serum	23(100%)	7(30.4)	16(69.6)	6(26.1)	4(17.4)	3(13.0)

The positive rate of the 23 HCC patients' surgically excised tissues and pre-operational serum was 52.2% ($12/23$) and 30.4% ($7/23$) respectively. In order to exclude the possibility of contamination, negative controls and positive controls were performed each time.

DISCUSSION

The establishment of 3'-BS-PCR method for the analysis of point mutation in site 1896 of HBV precore

The mutation of HBV may have a close relationship to the continuous HBV infection and the deterioration of liver after the infection. The research on the mutation of HBV will greatly promote the clinical analysis of HBV infection and its subsequent diseases. The common methods to detect point mutation are DNA sequencing and SSCP, which are expensive, time-consuming and unsuitable for clinical practice. In order to fulfill the requirements of further researches on HBV mutation and its application to the clinic, we established the 3'-BS-PCR method for the analysis of point mutation in site 1896 of HBV precore.

According to the principle of primer design that only when the last base of primer's 3' end must strictly match its corresponding template could PCR be accomplished, the reports of Georgen^[6] and the phenomenon that the nucleotide of site 1896 of HBV precore mutates from G to A, the corresponding 5' primers of wild and mutant types whose 3' terminal base are G and A respectively were designed to amplify the wild or mutant type DNA of the HBV precore region. Georgen^[6] has successfully applied this kind of method to detect the point mutation of site 1896 in the HBV precore in the patients with positive anti-HBe results, which have been confirmed by DNA sequencing. The positive rates of this site's point mutation were slightly higher than the other reports^[9]. It may be because most patients investigated were inpatients from the Department of Infectious Diseases whose liver damages were more severe than those from outpatients. This explanation is supported by the recorded reports that the positive rates of mutant type are unanimous with the conditions of the liver

damages. The establishment of this method provides a new approach to study the HBV infection and analyze the liver damage.

The study on the integration of HBV precore gene in HCC

Many researches have shown that the infection of HBV has a close relationship with the carcinogenesis of liver cancer and is one of important factors inducing the liver cancer. With the research progresses in molecular oncology, two kinds of genes, oncogenes and anti-oncogenes, that have close relationship to carcinogenesis have been discovered. In the development of HCC, the activation of oncogene and the inactivation of anti-oncogene are frequent events, which cause the changes of the qualities or quantities of the important proteins that they are encoded and eventually lead to the carcinogenesis of normal cells. The integration of HBV DNA in the genome of the cells infected by the HBV is an important factor that brings the instability of chromosomes in liver cells^[8].

Therefore, it is meaningful to investigate the HBV-DNA fragments' integration and its effect on the activation of oncogene and inactivation of anti-oncogene. Our research shows that 12 of 23 primary HCC patients were found to have the HBV precore in the cancer tissues whose positive rate was 52.2%. Among these patients, the HBV precore DNA were detected in 7 patients' sera whose positive rate was 30.4%. The results indicate that the HBV precore gene widely exists in liver cancer tissues and the replication of HBV is accompanied by the development of HCC. HCC patients (21.8%,

5/23) had negative results in serum but positive results in cancer tissues, which indicates that these patients had HBV precore DNA fragments integrated in their liver cells and there was no virus replication. We plan to study whether there is an integration in the genome of liver cells using Southern Blot. Among these HBV precore positive patients, the patients with mutant type detected in the tissues were all wild type. Only half of the patients with mutant type detected in the serum were also wild type. A hypothesis could be made that the HBV precore may mutate during long host in the liver cell and may play an important role in the transformation of normal liver cells.

Orthotopic liver transplantation for fulminant hepatitis B

Xiao Shun He, Jie Fu Huang, Gui Hua Chen, Qian Fu, Xiao Feng Zhu, Min Qiang Lu, Guo Dong Wang and Xiang Dong Guan

Subject headings hepatitis B; liver transplantation; lamivudine

He XS, Huang JF, Chen GH, Fu Q, Zhu XF, Lu MQ, Wang GD, Guan XD. Orthotopic liver transplantation for fulminant hepatitis B. *World J Gastroentero*, 2000;6(3):398-399

INTRODUCTION

When fulminant hepatitis progresses to deep encephalopathy, with stage III or IV coma, it is commonly irreversible with a high mortality rate (80%-100%)^[1]. Liver transplantation may be the sole treatment of choice in such circumstances. However, the early results have been disappointing, largely due to the frequency of posttransplant HBV infection^[2,3]. This recurrent disease often develops in an aggressive manner characterized by high levels of HBV replication and rapidly progressive liver graft damage. In recent years, however, as new antiviral agents, such as lamivudine came into being, the patient's survival has much been improved. The purpose of this study is to assess the effect of OLTx in a series of 7 patients with fulminant hepatitis B, and to evaluate the efficiency of lamivudine on preventing patients from HBV reinfection.

MATERIALS AND METHODS

Between October 1993 and August 1999, 7 adult male patients with hepatitis B were referred for liver transplantation. Their age at the time of operation ranged from 32 years to 49 years (median age 42.9 years). All patients were positive for HBV surface antigen (HBsAg), and 2 had evidence of viral replication. The latter was demonstrated by positive hepatitis B e antigen or/and HBV-DNA. Patient profiles are shown in Table 1.

All patients received orthotopic liver

transplantation 1 to 10 days after admission. Initial immunosuppression with cyclosporine A (CsA), and methylprednisolone was used in all cases. In the latter 3 cases, tacrolimus (FK506) was given orally when the patients resumed oral intake. Doses were adjusted in the first month to maintain 12 h trough levels of 10 g/L to 15 g/L. Prophylaxis for cytomegalovirus infection was started immediately after surgery with acyclovir or ganciclovir for 2 weeks. Lamivudine was administered orally, 100 mg or 150 mg daily in 5 patients when it became commercially available, and the treatment was not interrupted in any patient.

RESULTS

All patients in this series recovered consciousness 24 h after OLTx. Of them, five recipients were still alive and well with normal liver function during a following up period of 3-7 months. One patient with grade III hepatic encephalopathy died due to HBV reinfection 36 days after liver transplant. Another patient with preoperative esophageal varicosis bleeding died of multi-organ failure 3 days after transplantation. Various medical and surgical complications occurred in two of the five survived patients. One developed recurrent onset of epilepsy necessitated continuous antiepileptic therapy. Another developed stenosis of inferior vena cava, which was successfully treated by balloon dilation and stent replacement.

No acute or chronic graft rejection occurred in any patient. In patient 1, viral replication disappeared within 1 month following OLTx and became positive thereafter. The other 6 patients had a negative HBsAg within 3 to 14 days after OLTx and all had a negative viral replication. No side effects were noted concerning lamivudine treatment.

DISCUSSION

Hepatitis B is a common disease in mainland China. It was estimated that HBsAg carriers accounted for 10% of the total population. However, the natural history of hepatitis B can be quite variable^[4]. Even once signs of portal hypertension develop, many patients can go years before complications develop that impair the quality of their lives. By contrast, others can have stable liver disease for quite some time and then deteriorate quickly, often related with bleeding or infection. Thus, it is difficult to make accurate decisions about the timing of liver transplantation. In general, once the patient's liver

Received 2000-01-13 **Accepted** 2000-03-02

disease begins to impair air quality of life, the physician should consider an evaluation for transplantation. Based on this understanding, fulminant or sub-fulminant hepatitis is justifiable for liver transplantation. According to the experience of King's College Hospital in London, the selection criteria for transplantation in hepatitis B are based on the occurrence of three of the followings: a prothrombin time greater than 50 seconds; a jaundice to encephalopathy time of more than 7 days; non-A, non-B hepatitis or drug-induced hepatitis; age younger than 10 years or older than 40 years; bilirubin greater than 300 $\mu\text{mol/L}$; or the finding of a prothrombin time of greater than 100 seconds in isolation^[5]. In the present series, all 7 patients met the above mentioned criteria. The overall survival rate of our series was 71.4% after a 3-7 month follow-up period. The mortality rate of those patients with fulminant hepatitis B was 29.6%. Of the two patients who died, one died 5 weeks following OLTx of recurrent fulminant hepatitis B, indicating the high risk of HBV reinfection when the serum HBeAg was positive. The other patient died of multi-system organ failure on postoperative day 3. Nevertheless, the overall outcomes were to our satisfaction and support the continued application of liver transplantation as a therapeutic measure for fulminant hepatitis B.

It has been found that nearly 100% of patients showing evidence of active viral replication, i.e. serum HBV-DNA or/and HBeAg positive, and 70%-80% of those with HBV DNA or HBeAg negative prior to OLTx and received no immunoprophylaxis, developed recurrent HBV infection of the graft following OLTx^[6]. The recurrent disease may manifest as rapidly progressive disease. In our series, patient 1

developed fulminant hepatic failure 5 weeks following OLTx. Interferon (IFN) has been used both prophylactically and therapeutically after OLTx in patients with recurrent HBV, but it has proved to be mostly ineffective and may lead to further complications^[7]. In recent years, perioperative administration of hepatitis B immunoglobulin (HBIG) has been reported to reduce the incidence of recurrence. But, it requires prolonged parenteral treatment and does not suppress viral replication. Additionally, availability of HBIG could be limited and the costs related to prolonged use of HBIG are very high^[8]. These disadvantages of HBIG prevent it from wide clinical use. Because high level viral replication seems to be important in the pathogenesis of HBV recurrence, there has been great interest in the potential role of nucleoside analogue with anti-HBV activity. The most promising are lamivudine and foscarnir. Both agents have been evaluated in both animal model of HBV and clinical trial and have been shown to rapidly suppress viral replication. Lamivudine prophylaxis after liver transplantation resulted in a complete and sustained suppression of viral replication in OLTx recipients^[9]. In our study, 5 patients received lamivudine treatment, no side effect has been identified, and the treatment was not interrupted in any patient. The doses of 100 mg daily suppressed HBV-DNA to undetectable levels in one patient. Serum HBsAg became negative and HBeAb became positive after transplantation in all the patients. No cases of HBV reinfection were noted in lamivudine-treated patients. The results indicated that lamivudine is a beneficial and well-tolerated therapy in OLTx with HBV infection. The long-term effects of lamivudine are being investigated.

Table 1 Details and results of 7 patients underwent OLTx for fulminant hepatitis B

Patients No.	Age/Sex	Medical history	Bilirubin ($\mu\text{mol/L}$)	Encephalopathy	ABO compatibility	Lamivudine regimen	Outcome	Cause of death

Dot immunogold filtration assay for rapid detection of anti-HAV IgM in Chinese

Feng Chan Han, Yu Hou, Xiao Jun Yan, Le Yi Xiao and Yan Hai Guo

Subject headings dot immunogold filtration assay; hepatitis A virus; immunoglobulin M/analysis

Han FC, Hou Y, Yan XJ, Xiao LY, Guo YH. Dot immunogold filtration assay for rapid detection of anti HAV IgM in Chinese. *World J Gastroentero*, 2000;6(3):400-401

INTRODUCTION

The hepatitis A virus specific immunoglobulin M(IgM) antibody is a specific serological marker for early diagnosis of hepatitis A. At present, the methods used at home or abroad for detecting anti-HAV IgM are RIA, ELISA and SPHAI. The dot immunogold combination assay that has been developed since 1989 is a new technique with the property of simple and rapid immunological detection, by using the red colloidal gold particles to label the antibodies as indicator, and the millipore filtering membrane coated with antigen as the carrier. Affected by filtration and condensation, the antigen antibody reaction is enabled to go on rapidly. When the reaction is positive, red dots appear on the membrane. It takes about 2 min to 4 min for the whole reaction to be carried out. With the above technique, we have established the dot immunogold filtration assay (DIGFA) for rapid detection of anti-HAV IgM with comparatively satisfactory results.

MATERIALS AND METHODS

Materials

The hepatitis A virus antigen (HAAG) was the cell-cultured antigen, some of which were purchased from the Reagent Factory of Chinese PLA 302 Hospital and the rest was prepared by our institute. The anti-human μ chain monoclonal antibody was purchased from the teaching and research group for immunology of our university. The sheep anti-human IgM antibody was purchased from the immunological room of Chinese PLA 302 Hospital. The chloroauric acid was the product of the Chendu Chemical Plant with the batch number of 93082. Part of the serum samples from hepatitis A patients was supplied by the Department of Epidemiology

and the rest was collected from the Xi'an Municipal Children Hospital and the Railroad Central Hospital with diagnosis in accordance with the standards revised by the Shanghai Conference held in 1990. The sera of the patients suffering from epidemic hemorrhagic fever were supplied by Professor Sun of the Department of Epidemiology. The remaining serum samples were obtained from the Xijing Hospital. The ELISA kits for anti-HAV IgM detection were purchased from the Nanjing Military Medical Research Institute.

Methods

Principle The serum to be tested was put on the millipore membrane previously coated with HAAG. If there was anti-HAV IgM, the HAAG-anti-HAV IgM colloidal gold complex was formed on the membrane as red dots which were visible to the naked eyes.

Preparation of colloidal gold It was prepared according to the methods by Dar *et al*^[1]. Fifty mL of 0.2 g/L chloroauric acid was heated to the boiling point with 1.2 mL of the 10 g/L sodium citrate added later. The boiling lasted 5 min. The preparation was well done and finished when it became dark red in color.

Anti-human μ chain antibody colloidal gold labelling It was prepared according to reference^[2] with the main procedures as follows: Using 0.1 mol/L K_2CO_3 , 1 mL colloidal gold was regulated to have the pH of 8.0 or 9.0. With the help of magnetic stirring, the F(ab')₂ anti-human μ chain monoclonal antibody or sheep anti-human IgM was added. After 10 min, the bovine serum albumin (BSA) was added to get the concentration of 10 g/L. After that, the mixture was centrifuged at $2\,500 \times g$ for 5 min. The supernatant was further centrifuged at $12\,000 \times g$ for 20 min. The supernatant was discarded and the precipitate was dissolved by 5 g/L BSA-PBS, thus forming the colloidal gold labelling reagent.

Millipore filtering membrane treatment and antigen immobilization The nitrocellulose membrane with millipore diameter of 0.65 μm produced by the attached factory of the Beijing Chemical School was soaked by triple-distilled water and then dried spontaneously. The disc, 1 cm in diameter was made from the prepared membrane with a punch, was soaked in 0.05 mol/L carbonate buffer and then dried in air. One μL HAAG solution was dripped onto the center of the disc. After dried at room temperature, the disc was enclosed with 5 g/L BSA, then rinsed with the PBS-T twice for 10 min each time. After being dried, it was put into the self-made immune filtration plate.

Testing methods The immune filtration plate was numbered with the corresponding serum numbers, to the center of the membrane, dripped a drop of 0.01 mol/L PBS-T to activate the surface of the membrane. After the PBS-T was filtered into the membrane, 10 μ L of the serum was dripped slowly to the center of the membrane. Then, the membrane center was flushed by 2-3 drops of washing solution. After that, 30 μ L of the colloidal gold labelling reagent was added. After the latter was filtered into the membrane, the center was flushed with 2-3 drops of washing solution. Red dots in the center denote positive results, while colorless means negative.

Blocking test A: Ten μ L of anti-HAV IgM positive serum was added to 10 μ L of anti-human IgM working solution. B: Ten μ L of the positive serum was added to 20 μ L of the HAAg original solution and mixed evenly. The solution was kept in the water bath at 37°C for 1 h. The sera treated in both ways were put on the membrane. The DIGFA was made following the steps depicted above.

2-ME destruction tests Ten μ L of 0.2 mL/L β -mercaptoethanol (2-ME) was added to 10 μ L of anti-HAV IgM positive serum and mixed evenly. The solution was kept in water bath at 37°C for 1 h. The treated sera were used to do the tests of DIGFA as described above.

ELISA tests The tests were performed according to the operative instructions in a strict way.

RESULTS

Comparison between DIGFA and ELISA Two hundred and seventy nine serum samples were tested in a contrast way with the DIGFA and ELISA. The result was that 148 samples were positive and 125 samples negative with both methods. If the ELISA was used as the reference standard, the specificity of the DIGFA was 98.4% and the sensitivity 97.3%. The coincidental rate of both methods was 97.8%.

Blocking tests and 2-ME destruction tests Ten samples of anti-HAV IgM positive sera tested by the DIGFA and ELISA were chosen at random, all changed to negative after undergoing the blocking affect. Besides, the 10 serum samples which were treated by the 2-ME also changed to negative. This testifies that what was detected by the DIGFA was surely the anti-HAV IgM.

Results of detection on non-hepatitis A sera Forty serum samples from epidemic hemorrhagic fever patients, 10 serum samples with positive anti-HBc IgM and 41 serum samples from the blood donors were all negative when tested by the DIGFA.

Rheumatoid factor interference tests Twenty samples with positive rheumatoid factor (RF) were all shown negative results by DIGFA.

Repetitive tests Ten anti-HAV IgM positive samples and 10 negative samples which were chosen at random were tested repeatedly for five time. They all showed the identical results.

DISCUSSION

The dot immunogold test is a new immunological technique which has been developed in recent years^[1,3,4]. Since the millipore filtering membrane not only absorbs protein, but also affords rapid filtration and acts as capillaries, the antigen or antibody in serum is able to combine rapidly with the counterpart on the membrane. Moreover, as the colloidal gold labelling reagent is red in color, red dots appear after the combination takes place. Therefore, no color developing reagent is needed. This method that has aroused our interest greatly not only keeps with the sensitivity and specificity of the ELISA and RIA, but also with the advantage of affording prompt result.

In China, to detect Anti-HAV IgM, the ELISA and RIA are mainly used^[5,6], but the successful employment of the solid-phase immunoabsorption hemagglutination inhibition test^[7] has been reported. However, the drawbacks of ELISA and RIA lie on their requirement of prolonged operation time, complicated procedures and instruments, and some reagents having carcinogenic or radionuclide effects may be harmful to the handlers or polluted the environment if not properly disposed. Furthermore, the activity of HAAg is unstable and may be likely influenced by temperature, so it is hard to obtain a reagent kits with reliable efficiency. As for the solid-phase immunoabsorption hemagglutination inhibition test, the operation time is also long and no kit is available. The advantages in using DIGFA to test the Anti-HAV IgM are as follows: The operation period is shortened from a few hours to 5 min and the results are reliable and visible to the naked eye. The specificity and sensitivity are approximately equal to those of the ELISA and not influenced by RF. The HAAg from cultured cells is coated on the nitrocellulose millipore filtering membrane in a solid phase, with durable activity; the colloidal gold labelling reagent can be preserved beyond one year; the manipulations are simple and no sophisticated testing instrument required; the operator can be trained in a simple way, and may become acquainted with whole operation technique in a short time.

Therefore DIGFA is an ideal method utilized in the early diagnosis and the epidemiological study of hepatitis A.

INTRODUCTION

Salvianolic radix, one of the most commonly used traditional Chinese herbs, was widely studied about its actions against liver injury and fibrosis, and was one of the focuses of recent research^[1,2]. Salvianolic acid-A (SA-A) was an aqueous soluble component of *Salvianolic radix*. In our previous work^[2], SA-A was found to have protective effects against liver injury and fibrosis induced by carbon tetrachloride (CCl₄) in rats. In order to investigate the effect of SA-A on peroxidation in hepatocytes, we induced the injured hepatocyte model by CCl₄ fumigation *in vitro*, treated the cell model with SA-A or aqueous soluble vitamin E (Vitamin E), the latter served as the control drug, and observed the influences of the drugs on the functions of the hepatocytes injured by peroxidation.

MATERIALS AND METHODS

Animals

Wistar rats, male, specific pathogens free (SPF), weighing 140 g-160 g, were provided by the Experimental Center of Animals, Shanghai University of Traditional Chinese Medicine.

Drug

SA-A, molecular formula C₂₆H₂₂O₁₀, molecular structure as Figure 1, weight 494, was extracted and

identified by Shanghai Institute of Materia Medica, Chinese Academy of Sciences. Vitamin E was purchased from Hoffman Co. USA.

Figure 1 SA-A molecular structure.

Main reagents

Purified type III collagenase (specific activity, 960 U/mg), insulin and dexamethasone were purchased from Sigma Co. USA. Soybean trypsin was from Institute of Biochemistry, Chinese Academy of Science; ficoll was from Shanghai Second Chemical Reagent Factory; medium 199 (M199) from Gibco Co., USA; carbon tetrachloride (CCl₄), analytical grade, from Yixin Third Chemical Reagent Factory, Jiangsu Province; and newborn bovine serum (NBS) from Shanghai Sino-American Co.

Isolation and culture of hepatocytes

According to a modified method^[3], hepatocytes were isolated and primarily cultured from rats. In brief, after anesthesia with ether, the rat liver was perfused *in situ* with Ca²⁺ and Mg²⁺-free Hank's solution via the portal vein for 5 min, followed by perfusion with Hank's solution containing 0.5 g/L collagenase for 20 min. The liver was then excised and minced with forceps to remove Glisson's capsule and the liver cells dispersed. The liver cell suspension was filtrated with double layers of gauze and was adjusted to 2 × 10¹⁰/L. Then 5 mL cell suspension was added onto the top of 20 mL 492 g/L Ficoll, and centrifuged at 50 × g, 4°C, 5 min to purify the hepatocytes. The cell recovery was about 1 × 10¹⁰ cells per liver, the purity was more than 95% identified by the cell typical appearance via phase contrast microscope, and the viability was more than 90% assessed by trypan blue exclusion. Hepatocytes were suspended with M199

containing 5% (v/v) NBS to adjust their density to 5×10^8 cells/L, seeded on plastic dishes (Nunc, Denmark) and primarily cultured at 37°C in a humidified atmosphere of 50 mL/L CO₂ and 950 mL/L air.

Induction of hepatocyte peroxidative injured model

According to David method^[4], the peroxidatic injury of hepatocytes was induced by CCl₄ fumigation. Briefly, after 48 h of isolation and culture, the cells were placed in sealed box, to which 1 mL/L CCl₄ was added, and the cells were fumigated with CCl₄ at 37°C for 24 h.

Drug treatment

Normal hepatocytes in dishes were divided into the following groups: the normal, the control, vitamin E (2×10^{-3} mol/L^[5]) and SA-A treated groups at different concentrations (10^{-4} mol/L- 10^{-8} mol/L). All but the normal group, were incubated with vitamin E or SA-A at different concentrations and fumigated with CCl₄ spontaneously for 24 h, then the culture medium was collected respectively and stored at -70°C until assay.

Biochemical index assay

The ALT and AST in culture medium were assayed with Riman and Frankle method, malondialdehyde (MDA) with Bacon's method^[6]. Superoxide dismutase (SOD), catalase (CAT), lactase dehydrogenase (LDH), glutathione peroxidase (GSH-PX), glutathione (GSH) were measured following the protocols provided by the manufacturer (Jianchueng Biochemical Technological Institute, Nanjing).

Statistics

Chi-square test and *q* test.

RESULTS

The cell morphological changes

After 48 h of isolation and culture, primary hepatocytes gathered, attached and grew very well. At 24 h after fumigation with CCl₄, the hepatocytes partially shrank, their plasma membrane became rough and organelles swollen. When the cell models were incubated with SA-A or Vitamin E, the plasma membrane became smoother and the organelles less smother than those of controlled model cells.

Effects of SA-A or Vitamin E on ALT, AST and LDH activity in hepatocytes injured by peroxidation

The activities of ALT and AST both increased, while the former increase more obviously. LDH activity enhanced approximately 20 folds. SA-A inhibited these pathological increase in dosage

dependent manner, and among all concentrations tested the 10^{-4} mol/L SA-A had the best effect on the cell structure and enzymes. The effect of SA-A was better than that of Vitamin E, but 10^{-7} mol/L- 10^{-8} mol/L SA-A was not effective compared with the control (Table 1).

Effects of SA-A or Vitamin E on MDA contents and the activities of SOD and CAT in hepatocytes injured by peroxidation

MDA content in the control nearly doubled that of the normal, and the activities of SOD and CAT increased remarkably. SA-A decreased these pathological changes, and 10^{-4} mol/L SA-A had a significant inhibitory action. Vitamin E also decreased the MDA content markedly, but had no obvious influence on SOD activity (Table 2).

Effects of SA-A or Vitamin E on GSH content and GSH-PX activity in hepatocytes injured by peroxidation

After the hepatocytes were injured by peroxidation, the GSH-PX activity increased but GSH content decreased remarkably. 10^{-4} mol/L SA-A or Vitamin E inhibited the increase of GSH-PX activity and the decrease of GSH. For the extent of inhibition in GSH lowering, SA-A 10^{-4} mol/L is superior to Vitamin E (Table 2).

DISCUSSION

In this study, 24 h after fumigation of hepatocytes with CCl₄, the ALT, AST and LDH all increased remarkably, the rate of elevation was in order of LDH, ALT and AST. It is suggested that the

hepatocytes were acutely injured, cell membrane integrity was broken and the enzymes in cell plasma leaked out. However, after the hepatocytes injured by peroxidation which were incubated with SA-A, the pathological increases of ALT, AST and LDH reduced markedly. It is indicated that SA-A had a potential effect against hepatocyte injury.

The free radicals and its triggered lipid peroxidation were involved in the main mechanisms by which carbon tetrachloride injured hepatocytes. MDA was one of main lipid peroxidatic products, its elevated levels could reflect the degrees of lipid peroxidatic injury in hepatocytes. GSH, a peroxide scavenger with a lower molecular weight, could eliminate superoxide anion and hydrogen peroxide. The content of GSH reflected the ability against peroxidation^[7]. In this study, GSH in hepatocytes of the model group was reduced remarkably, suggesting that the potency of antioxidation in injured cells was decreased. There were many other markers that could reflect lipid peroxidation, e.g. SOD, a scavenger of peroxide anion radicals, which could inhibit the initiation of lipid peroxidation by free radicals; GSH-PX, which could particularly catalyze the reductive action of GSH to H₂O₂ to protect the integrity of plasma membrane and functions; CAT etc. All the above-mentioned enzymes increased in the model cells. This may result from acute compensation after injury, and peroxidatic reaction stimulated by CCl₄ in

hepatocytes. SA-A markedly inhibits the increase of MDA level and the decrease of GSH, also reduced the activities of GSH-PX, CAT, SOD in different extents. Among these results, SA-A had better effect than vitamin E, which is a widely recognized antioxidation drug. It is indicated that SA-A had potential action against lipid peroxidation, this effect perhaps is the main mechanism of protection on liver injury. The results are also in accordance with the other reports^[8] and our previous work^[2].

Kupffer cell and apoptosis in experimental HCC

Hai Zhen Zhu, You Bing Ruan, Zhong Bi Wu and Chun Ming Zhang

Subject headings liver noplasm, experimental; diethylnitrosamine; apoptosis; protein P53; Kupffer's cell

Zhu HZ, Ruan YB, Wu ZB, Zhang CM. Kupffer cell and apoptosis in experimental HCC. *World J Gastroentero*, 2000;6(3):405-407

INTRODUCTION

Our previous study has proved that Kupffer cells may have an inhibitory effect on the process of hepatocarcinogenesis^[1], however, their inhibitory mechanism needs exploring deeply. We performed a comparative study on the expression of PCNA, Bax, P53 and apoptosis of liver cancer cells using immunohistochemical technology and terminal deoxynucleotidyl transferase (TdT)-mediated dUTP-digoxigenin nick end labeling (TUNEL) in the diethylnitrosamine-induced hepatocellular carcinoma (HCC) in rats with or without pretreatment with gadolinium chloride or zymosan which might effectively block or enhance the activity of Kupffer cells in order to know the role of Kupffer cells in apoptosis in the experimental HCC and explore further the inhibitory mechanism of Kupffer cells on the process of hepatocarcinogenesis.

MATERIALS AND METHODS

Establishment of animal models and pathological examination

One hundred and forty male Sprague-Dawley rats were divided into six groups. ① DENA group, 40 rats received diethylnitrosamine (DENA) at a dose of 70 mg/kg in distilled water once/wk till wk15. ② GC+DENA group, gadolinium chloride was injected iv at a dose of 10 mg/kg once 2 wk to suppress Kupffer cells in 40 rats till wk15 and these rats simultaneously received DENA just as DENA group. ③ ZM+DENA group, zymosan was injected iv at a dose of 20 mg/kg once 2 wk to activate Kupffer cells till wk15 and DENA was received just as DENA group. ④ GC group, gadolinium chloride was injected iv at a dose of 10 mg/kg in 0.85% NaCl once 2 wk till wk15. ⑤ ZM group, zymosan

was injected iv at a dose of 20 mg/kg in 0.85 % NaCl once 2 wk till wk15. ⑥ Control group, these rats were maintained on a standard laboratory diet and tap water. All rats were killed at the wk21 of hepatocarcinogenesis. The liver samples were taken, fixed in 40 mL/L paraformaldehyde and embedded in paraffin. Each specimen was cut into 5 µm serial slices, stained with hematoxylin-eosin and subjected to histopathological examination.

Immunohistochemical staining

The SP method was used, the 1st antibody was mouse-anti-human PCNA monoclonal antibody (Calbiochem Co., dilution 1 : 50), rabbit-anti-human Bax (Santa Cruz, dilution 1 : 50) and mouse-anti-human P53 monoclonal antibody (Novocastra Laboratories, dilution 1 : 50). The SP kit was purchased from Boehringer Mannheim, Germany. DAB staining was used. The dark brown staining of nuclei was taken as PCNA and P53-positive reaction. The dark brown granules in cytoplasm were taken as Bax-positive reaction. We used PBS to replace the 1st antibody as negative control.

Terminal deoxynucleotidyl transferase-mediated biotinylated-dutp nick end labeling method (TUNEL method)

In situ Cell Apoptosis Detection kit was purchased from Boehringer Mannheim, Germany. After deparaffinization and rehydration in ethanol, the sections were incubated with 0.2 mol/L HCl for 20 min at room temperature (RT). They were then deproteinized by incubation with 30mg/L proteinase (in 50mM Tris-HCl, pH 8.0; 5mM EDTA) for 30 min at RT. Terminal deoxynucleotidyl transferase (TdT) and biotinylated dUTP in TdT buffer (30mM Trizma base, pH 7.2; 140mM sodium cacodylate; 1mM cobalt chloride) were added to cover the sections, which were then incubated for 60 min in a humid atmosphere at 37°C. The sections then reacted with alkaline phosphatase (ALP) for 30 min at RT. Visualization was carried out with NBT/BCIP. Nuclei with clear blue staining were regarded as positive. TUNEL incubation solution without terminal deoxynucleotidyl transferase was used as negative control.

Proliferating index (PI) and apoptosis index (AI)
PI and AI were determined by Leitz ASM 68K image analyzing system purchased from Germany. Five visual fields (original magnification, 10 × 40)

Department of Ultrastructural Pathology, Tongji Medical University, Wuhan 430030, Hubei Province, China

Dr. Hai Zhen Zhu, graduated from Tongji Medical University in 1997, engaged in the researches of antitumor of Kupffer cell under the instruction of Professor You Bing Ruan, having four papers published.
Correspondence to: Hai Zhen Zhu, Department of Ultrastructural Pathology, Tongji Medical University, Wuhan 430030, Hubei Province, China

Received 2000-01-12 **Accepted** 2000-02-20

from every positive slide would be chosen and the TUNEL and PCNA-positive parenchymal cells as well as the total number of parenchymal cells in the same field would be counted. PI or AI was expressed as the percentage of the number of PCNA or TUNEL-positive parenchymal cells in the total parenchymal cells of the same field.

$$\text{Proliferating index (PI)} = \frac{\text{number of PCNA-positive cells}}{\text{number of total cells}} \times 100\%$$

$$\text{Apoptosis index (AI)} = \frac{\text{number of TUNEL-positive cells}}{\text{number of total cells}} \times 100\%$$

Statistical analysis

Fisher's exact test, Student's test and Spearman rank correlation were employed.

RESULTS

Macroscopic observation and histopathological examination (at wk 21 of hepatocarcinogenesis)

Neither the control group, nor the GC group and ZM group showed any changes macro and microscopically; on the contrary, the liver surface in DENA group and GC + DENA group were covered with a lot of white nodules. The diameter of the largest nodules was 0.5 cm in DENA group and 2.0 cm in GC+DENA group. These nodules were diagnosed as HCC histologically. Some white grey focal nodules scattered over the liver surface in ZM+DENA group, were also diagnosed as HCC with many apoptotic cells and apoptotic bodies.

Bax staining

Cytoplasm of cancer cells with clear brown staining was regarded as positive (Figure 1). The positive rates of Bax in ZM+DENA group, DENA group and GC+DENA group were 84.6% (11/13), 28.6% (2/7) and 27.3% (3/11) respectively. It was significantly higher in ZM+DENA group than that in DENA group (Fisher's exact test, $P < 0.05$).

P53 staining

A clear brown staining of the nuclei in cancer cells was regarded as positive (Figure 2). The positive rates of P53 in ZM+DENA group, DENA group and GC+DENA group were 76.9% (10/13), 14.3% (1/7) and 36.4% (4/11) respectively. It was markedly higher in ZM+DENA group than that in DENA group (Fisher's exact test, $P < 0.05$).

PCNA staining

Nuclei with clear brown staining were regarded as positive (Figure 3).

No expressions of Bax, P53 and PCNA in the control group, GC group and ZM group were found.

Apoptosis of cancer cells using TUNEL method

Apoptotic cells were observed in DENA group, GC+DENA group and ZM+DENA group by means of TUNEL method. The cells with clear nuclear labeling were defined as TUNEL-positive cells. Apoptotic cells were scattered in the cancer tissue (Figure 4).

GC+DENA group	3/11	0.74	<0.01	4/11	0.82	<0.05

Spearman rank correlation.

DISCUSSION

Gadolinium chloride is believed to be a specific suppressor of Kupffer cells^[1,2]. Zymosan is an immunopotentiator and may be used to activate Kupffer cells^[3]. We performed a comparative study on apoptosis in DENA-induced hepatocellular carcinoma in rats with or without pretreatment with gadolinium chloride or zymosan which might effectively block or enhance the activity of Kupffer cells in order to clarify whether the Kupffer cells play a role in apoptosis of the experimental hepatocarcinogenesis or not.

Proliferating cell nuclear antigen (PCNA) is an auxiliary protein of DNA polymerase- δ . It accumulates little in the resting stage cell, but prominently in the nuclei of proliferating cells during G₁-late phase and S-phase and decreases in G₂-phase and M-phase. It is associated with cell proliferation and regarded as a biological marker for cell proliferation^[4]. Bax is a 21 000 protein with extensive amino acid homology with Bcl-2. This protein has been shown to form heterodimers with apoptosis inhibiting protein, Bcl₂, so it can induce cell apoptosis^[5]. When DNA is injured by toxicant, wild-type p53 drives cell to G₁ and arrests or inhibits cell proliferation until DNA is repaired. When nuclear DNA is badly damaged or cannot be repaired, wild-type p53 induces transcription of apoptotic genes and drives the cell to be in apoptosis^[6]. Gottlieb *et al*^[7] thought that overexpression of P53 was related to cell apoptosis. Zhao *et al*^[8] observed that there was a positive correlation between apoptosis index and P53 protein, and supported the role of P53 in regulating apoptosis in human HCC. The positive correlation between apoptosis index and P53 protein immunoreactivity observed in our study also supports these findings. A new method to detect apoptosis *in situ*, terminal deoxynucleotidyl transferase-mediated (TdT) dUTP-digoxigenin nick end labeling (TUNEL) was recently developed by Gavrieli *et al*^[9], and was applied to detect cell apoptosis of human HCC and other tumors^[10].

Our results showed that the positive rates of Bax and P53 protein were markedly higher in ZM +

DENA group than in DENA group with significant differences. Proliferating index and apoptosis index respectively increased or decreased in ZM+DENA group, DENA group and GC+DENA group successively. These results demonstrated that the blockage of Kupffer cells with gadolinium chloride might suppress cell apoptosis and the activation of Kupffer cells with zymosan might promote cell apoptosis in the experimental hepatocarcinogenesis.

One of the characteristic features of cancer is the continuous growth and the ratio of cell proliferation and cell apoptosis determine the fate of tumor growth^[11-13]. In normal tissues, apoptosis is an efficient way of eliminating transformed cells. However, inability of cells to undergo apoptosis may advance their development, both by allowing the accumulation of dividing cells and by impairing the elimination of genetic mutants that may harbor malignant potential^[11,12]. Our results proved that Kupffer cells could promote apoptosis in the experimental hepatocarcinogenesis and revealed further that they played an inhibitory role in hepatocarcinogenesis through inducing apoptosis of tumor cells.

INTRODUCTION

Since the late 1980s, studies on the expression of intercellular adhesion molecule-1 (ICAM-1) in patients with malignancies have demonstrated that ICAM-1 may strongly express in two forms in such diseases: membranous one on the surface of tumor cells (membrane-bound ICAM-1) and soluble one in circulation (soluble ICAM-1, sICAM-1)^[1,2]. Furthermore, increased expression of sICAM-1 in various malignant diseases, such as gastric cancer, colonic and pancreatic cancer was reported by Tsujisaki *et al*^[3], who found that the incidence of positivity of sICAM-1 in the malignant diseases was significantly higher than that in benign diseases. Therefore, the diagnostic value of detecting sICAM-1 for some malignancies has been proposed^[3]. The recent studies on detecting serum sICAM-1 in patients with hepatocellular carcinoma (HCC) have revealed that serum levels of sICAM-1 were well correlated to progression and prognosis of the disease^[4-6], from which it has been considered that sICAM-1 may be useful for monitoring the response to treatment^[4]. However, whether sICAM-1 is a diagnostic marker is still controversial. Our recent study demonstrated that in HCC patients with normal or low levels of serum α -fetoprotein (AFP) measurement of sICAM-1 is of clinical value for detecting early HCC and its recurrence after hepatectomies^[7-9]. To further evaluate the clinical

significance of measuring sICAM-1 in HCC, the serum levels of sICAM-1 in 134 patients with HCC were examined and the results were analyzed.

MATERIALS AND METHODS

Patients

There were 134 patients with HCC, including 115 males and 19 females, aged from 12-80 years, median 49 years. The diagnosis of HCC for all patients was confirmed pathologically either by surgical resection of liver tumors or by liver biopsies. Tumor was less than 5 cm in diameter in 17 patients, less than 10 cm in 37 and more than 10 cm or with extrahepatic metastasis in 80 cases. Hepatitis B surface antigen (HBsAg) was positive in 112 cases and hepatitis C antibody positive in 10 patients. Surgical treatment was carried out in 68 patients, of whom 57 underwent tumor resection and 11 underwent laparotomy or selective catheterization of the hepatic artery. The rest of the patients were treated by transcatheter arterial embolization (TAE) or alcohol injection of tumors. As controls, serum levels of sICAM-1 were measured in 42 patients with chronic hepatitis B (CH), 40 with liver cirrhosis (LC) and 50 healthy blood donors.

Methods

Blood samples were collected early in the morning. The serum was immediately separated by centrifugation and frozen to -80°C. Concentrations of serum sICAM-1 were measured with an enzyme-linked immunosorbent assay kit (Biosource Europe, Fleurus, Belgium). The quantitative determinations of serum AFP in patients with HCC was done by radio-immunoassay (RIA), using an AFP kit (Jiuding Biological, Tianjin, China). The reference ranges of serum AFP concentration were classified as follows: above 200 µg/L, positive; 20 µg/L-200 µg/L, questionable positive; and below 20 µg/L, negative.

Statistical analysis

Data between groups were compared by Wilcoxon's Rank Sum test and Fisher test. $P < 0.05$ means significance statistically.

RESULTS

The median of sICAM-1 in 134 patients with HCC was 1801 µg/L, which was significantly higher than

those in patients with CH (median = 462 $\mu\text{g/L}$), LC (median = 587 $\mu\text{g/L}$) and the healthy subjects (median = 305 $\mu\text{g/L}$) (Table 1). The compared analysis of serum levels of sICAM-1 and AFP in the HCC patients was shown in Table 2. Serum AFP concentration was positive in 85 cases, negative in 22 and questionable positive in 27. The serum levels of sICAM-1, in the corresponding patients were 2018, 1370 and 1453 $\mu\text{g/L}$ respectively. A correlated analysis of serum concentrations of AFP and sICAM-1 demonstrated that there was a close correlation between the two parameters in patients with AFP positive ($r = 0.249$, $P < 0.05$). However, the correlation did not exist in patients with AFP negative or questionable positive. Although the serum concentrations of AFP in these two groups of patients were normal or in a low level, that of sICAM-1 in these patients all exceeded 1000 $\mu\text{g/L}$, the median values of which showed no significant difference compared with the median of the whole group of HCC patients ($P > 0.05$). The ranges of serum levels of sICAM-1 in the patients with HCC are shown in Table 3. One hundred and seven patients (80%) had a sICAM-1 level higher than 1000 $\mu\text{g/L}$ and 126 (94%) higher than 700 $\mu\text{g/L}$. There was no close correlation between the serum value of sICAM-1 and the tumor size among 134 patients with HCC (Table 4). The medians of serum levels of sICAM-1 in patients with different sizes of tumor showed no significant difference ($P > 0.05$).

Table 1 Concentrations of serum sICAM-1 in patients with HCC and control groups

Group	Number of patients	sICAM-1 ($\mu\text{g/L}$) ^a

DISCUSSION

One obvious phenomenon from the present study was that a much higher level of sICAM-1 was observed in our HCC patients than those reported by the others [4,6,12]. According to the following researches, we may explain the discrepancies: It has been known that ICAM-1 expression can be upregulated by several cytokines [10,11], of which interferon-gamma (INF-gamma) was the main cytokine trigger for ICAM-1 expression in a human hepatoplastoma cell line. In addition, hepatitis B virus-DNA-transfected cells expressed membranous ICAM-1, the triggering mechanisms of which may be gene activation by virus genome or autocrine virus-induced hepatocellular cytokine production. Furthermore, the clinical research of relationship between serum levels of sICAM-1 and HCC showed that the high levels of sICAM-1 were closely related to the progression and prognosis of HCC [4,6,12]. In this study, the rate of hepatitis B infection was 84% (112/134) and 87% of the patients were in the middle or late stage of HCC (117/134). Thus it can be seen from our study that a high infectious rate of hepatitis B and a delayed diagnosis of HCC in this group of patients may be the main reasons for the high expression of serum levels of sICAM-1.

However, with regards to the study on sICAM-1 and HCC, one more important point, which is still controversial and to be resolved is whether detecting sICAM-1 in patients with HCC is of clinical significance for early diagnosing the disease and detecting its recurrence after surgical resection. As the study results by Hyodo *et al.* [4] showed that there was no difference in serum levels of sICAM-1 between their patients with HCC and liver cirrhosis. Based on this they declared that sICAM-1 is only a marker for progression and prognosis of the disease, but not a diagnostic marker for HCC. However, this conclusion was at odds with the observations from other reports [6,8,12], in which significantly higher serum levels of sICAM-1 in patients with HCC than those with LC, HC and healthy controls were demonstrated. The results of present study by the authors further confirmed the observations.

Moreover, the following results from the literatures seem to be more useful to resolve the controversial problem: enhanced expression of ICAM-1 on HCC cell surface exists in most patients with HCC (ranged from 80% to 96.2%) [5,13], which did not exist in peritumor and normal liver tissues. Regarding the association between membranous and soluble ICAM-1 expression, a highly consistent expression rate of the two forms of ICAM-1 was reported by Momosaki *et al.* [5]. They found that in tumor lines, the consistent expression rate of the two forms ICAM-1 was 87.5% (present or absent concomitantly). There were two forms of sICAM-1 in HCC patients: inflammation-associated sICAM-1 and HCC-specific circulating form of sICAM-1. The latter mainly came from HCC cells,

from which the membranous ICAM-1 were shed into the circulation continuously and became the important source of sICAM-1^[14]. In addition, recent studies by the authors^[9] found that regardless of positive or negative serum AFP, after a radical resection of liver tumor, the sICAM-1 level would be decreased to the normal within 1-2 months postoperatively. However, in patients underwent non-radical resection due to vascular invasions of the liver or extrahepatic metastasis, the serum levels of sICAM-1 will maintain at a high level. It has been suggested from all of the studies mentioned above that the high level of serum sICAM-1 in HCC may originate mainly from tumor itself. Thus we believe sICAM-1 in HCC patients may be a useful marker for detecting HCC and a monitor of recurrence after hepatectomy.

As the strong correlation between serum levels of sICAM-1 and AFP in patients with positive AFP was disclosed (Table 2), the clinical significance of sICAM-1 detection for diagnosing HCC will be focused on patients with normal or low levels of serum AFP. Serum AFP is still the best diagnostic marker for HCC. But AFP levels may be normal in 20%-40% of patients with HCC, depending on the severity of the disease^[15]. In China about 30% of HCC patients can not be diagnosed by this serum marker, which results in delayed diagnosis and, consequently, hampers efforts to improve effective surgical treatment of the disease. Therefore, more sensitive serum markers are required for detecting HCC.

From the study, one of the interesting results was that there were 22 (16.4%) and 27 (20.2%) patients with HCC, whose serum levels of AFP were negative (median = 11 µg/L) and questionable positive (median = 89 µg/L). However, that of sICAM-1 in those patients were 1370 and 1453 µg/L respectively (Table 2), which showed no significant difference compared with the median level of total group of HCC ($P > 0.05$). Furthermore, analysis of ranges of sICAM-1 levels in patients with HCC demonstrated that 80% of the patients had a high serum level of sICAM-1 exceeding 1000 µg/L. According to the study by Shimizu *et al*^[6], sICAM-1 level above 1000 µg/L is a determinant for prognosis and progression of HCC, the proportion of patients with high levels of sICAM-1 (> 1000 µg/L) in patients with HCC in our study was obviously higher than that of AFP (> 200 µg/L). As mentioned in our previous studies the diagnosis of HCC should be strongly suspected when a patient with an uncertain intrahepatic lesion had a serum level of sICAM-1 higher than 1000 µg/L^[7]. The results of the present study further confirm our previous conclusion.

Another interesting finding from the study was

that a significant correlation between serum level of sICAM-1 and tumor size of HCC was not observed (Table 4). The median of sICAM-1 concentration in 17 patients with tumor diameter less than 5 cm was 1518 µg/L, among them 4 being negative, 8 questionable positive and 5 positive for AFP. In addition, a tumor recurrence was diagnosed in 4 of the 17 patients after 1-3 hepatectomies during the postoperative follow-up. The median of tumor size in the 4 cases was only 2.8 cm when recurrence was confirmed, however, the median of serum level of sICAM-1 in the same patients was 1378 µg/L. It was strongly suggested by our observation that measurement of sICAM-1 is of clinical significance in detecting early HCC and monitoring its recurrence postoperatively when tumor is small in diameter, particularly for patients with normal or low serum concentrations of AFP.

ACKNOWLEDGMENTS We are grateful to Professor S. Meuer, and Dr. B. Schraven, Institute of Immunology, Ruprecht-Karls-University, Heidelberg, Germany, for their suggestions, advice, and cooperation in this study.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common cause of death from cancer in China. The mechanisms of hepatocarcinogenesis are not yet known clearly. p16INK4a gene, the multiple tumor suppressor gene 1 (MTS1), encodes P16 protein, which acts as an inhibitor by binding directly to CDK4 and CDK6 and preventing its association with a cyclin. It was supposed to exert negative control on cell proliferation. p15INK4b gene, multiple tumor suppressor gene 2 (MTS2), is a homologue of p16INK4a and has a similar role in control of cell proliferation. Both of them were mapped to chromosome 9p21 region^[1,2]. Although deletion or mutation of p16INK4a occurred in melanoma, biliary tract cancers, gastric carcinoma, hepatocarcinoma, and alterations of p15INK4b were shown in primary lung cancers, acute leukemia, biliary tract cancers and bladder tumors, there has been no report about whether p15INK4b gene altered in primary hepatocellular carcinoma^[3-9]. In the present study, exon 1, exon 2, exon 3 of p16INK4a and p15INK4b exon 2 in 35 HCC, 35 corresponding adjacent noncancerous liver

cirrhosis were analyzed for somatic mutation with PCR-SSCP and one case of aberrant SSCP DNA was cloned and sequenced.

MATERIALS AND METHODS

Specimens and extraction

Tissue specimens used in the study were paraffin embedded and stored in Department of Pathology, the First Affiliated Hospital, West China University of Medical Sciences from 1991-1993. The 35 samples of human primary hepatocarcinoma and 35 corresponding adjacent noncancerous liver cirrhosis were stained with HE and examined under microscope. More than 70% sections used in PCR were hepatocarcinoma sections. And more than 80% cirrhosis sections were the noncancerous liver cirrhosis sections. DNA was extracted from 1-3 sections (10 µm) of paraffin embedded tissue blocks with xylene, ethanol and phenol method, and dissolved in 50 µL of distilled water^[10]. Ten samples of normal human blood DNA were extracted with standard method. The concentration of DNA was determined with spectrophotometer.

PCR

The exons of p16INK4a gene and exon 2 of p15INK4b gene were amplified using the following primers (Table 1):

Table 1 Primers for p16INK4a and p15INK4b genes analysis

Gene	Primers	Fragment length (bp)	Ref
P16INK4a exon1	5'GGGAGCAGCATGGAGCCCC 3'(sense) 5'AGTCGCCCCGCCATCCCCT 3'(antisense)	204	[6]
p16INK4a intron1	5'GGAAATTGGAAGCTGGAAGC 3'(sense)	168	[1]
and exon2	5'GCTGCCCATCATCATGACCT 3'(antisense)		
p16INK4a exon2	5'GGCAGGTCATGATGATGGGC 3'(sense)	362	[1]
and exon3	5'TCTGAGCTTTGGAAGCTCT 3'(antisense)		
P15INK4b exon2	5'GGCCGGCATCTCCATACCTG 3'(sense) 5'TGTGGGGCGGTGGGAACCTG 3'(antisense)	345	[9]

The PCR reaction was performed as follows: 200 ng DNA from paraffin embedded tissue or 100 ng DNA from normal human blood cells, 200 µmol/L each dATP, dGTP, dCTP and dTTP, 20 pmol primers, 1.5 u of Taq DNA polymerase (Sino-American Biotechnology Company) with a buffer provided by the manufacturer, in a total

Received 2000-01-30 **Accepted** 2000-3-14

reaction volume of 25 μ L. The thermal cycle profile was 1min at 94°C, 1min at 66°C (p16 exon 1, 204 bp) or 57°C (p16 exon 2, 168 bp) or 55°C (p16 exon 2, exon 3, 362 bp) or 68°C (p15 exon 2), 2 min at 72°C, 40 cycles. The PCR reaction mixture for p16INK4a exon1 (204 bp) exon 2 and exon 3 (362 bp) contained 5% dimethyl sulfoxide.

SSCP

PCR products were directly subjected to silver-staining SSCP analysis according to the method of Peng *et al*^[11]. Ten μ L of PCR products were denatured in 30 μ L of 98% formamide, 10 mmol/L NaOH, 20 mmol/L EDTA, 0.05% (w/v) bromophenol blue and 0.05% (w/v) xylene cyanol, at 98°C for 5 min. The samples were immediately loaded on an 8% polyacrylamide gel and run at 1.25v/cm in 1 \times TBE in 4°C for approximately 14h. Ten μ L of PCR products of p16INK4a exon 2 and exon 3 (362 bp) was digested with Sma I. It generated two fragments (114 bp, 248 bp) which were then subjected to SSCP analysis. After electrophoresis, the gels were fixed, and stained with silver.

PCR cloning and sequencing

The gels were stained with silver. The staining was stopped by immersing the gel in 5% acetic acid, 16% methyl alcohol for 30 min. The gel was rinsed for 1 h in distilled water (changed each 5 min). The abnormal migration single strand DNA band of p15INK4b exon 2 was cut from gel and put into the same volume of distilled water. The gels were incubated in 37°C water bath for 4 h, centrifuged at 10 000r/min for 5 min, then the gel was discarded. The supernatant was extracted with phenol/chloroform, and chloroform. The DNA from approximately 90 mg gel was placed in the PCR mixture for amplification under the same conditions as the initial PCR.

Following reamplification by PCR, the PCR products were isolated on 1.8% agarose gel. The 345 bp DNA band was cut from the gel and purified with Glassmilk Isolation Kit (made in our Lab). The DNA was blunted and phosphorylated with E.coli- Klenow fragment and T₄ polynucleotide kinase, ligated to Sma I site of pUC118. The ligation reaction was transformed into *E.coli*- JM109. The recombinants were screened by minipreparation of plasmid and digesting with restriction endonuclease. The DNA from the clone was screened by PCR-SSCP to identify the clone containing the shift single strand and was sequenced on a ABI 377 DNA sequencer by CyberSyn B.J. Company.

RESULTS

Polymorphism of the p16INK4a gene intron 1 and exon 2

Mutation of p16INK4a gene was analyzed in 31 of

the 35 patients with HCC and 8 healthy blood donors. The PCR amplified 168 bp fragment of p16INK4a intron 1 and exon 2 containing 15 nucleotides within exon 2 and 153 nucleotides of its 5' flanking sequence within intron 1. Three patterns (A, B, B') of p16INK4a intron 1 and exon 2 (168 bp) at SSCP analysis were observed in hepatocellular carcinoma and corresponding adjacent noncancerous cirrhosis (Figure 1). The B pattern (48%, 15/31) outnumbered the B' pattern (26%, 8/31). A pattern was the least (13%, 3/31). Two patterns (B, B') at SSCP analysis were observed in healthy human blood cells. The B' pattern (62.5%, 5/8) outnumbered the B pattern (37.3%, 3/8). The PCR amplified 362 bp fragment covered exon 2, exon 3 and intron 2 sequences. The PCR products were cleaved into two fragments 114 bp and 248 bp by digesting with Sma I. Neither band shift nor polymorphism at SSCP analysis was observed. The PCR amplified 204 bp fragment containing exon 1 and 19 nucleotides of 5' flanking upstream sequence and 41 nucleotides of 3' flanking downstream sequence. No band shift was detected in all of the samples.

SSCP analysis of p15INK4b exon 2

A 345 bp fragment containing p15INK4 b gene exon 2 and 60 nucleotides of its 5' flanking sequence within intron 1 was amplified by PCR from all of the hepatocellular carcinomas, adjacent noncancerous cirrhosis and normal blood cells. No evidence of allele deletion was detected (Figure 2). On repeating SSCP analysis, one case of adjacent noncancerous cirrhosis showed an abnormal migration single strand (Figure 3). But no additional shift band was found in either the corresponding tumor tissue from the same patient or the other hepatocarcinoma and cirrhosis tissues. The identical migration single strand was detected in all of the 10 normal human blood cells. No evidence of polymorphism was found.

Cloning and sequencing of the abnormal single strand

The abnormal migration single strand DNA of C₅ (adjacent noncancerous cirrhosis) was purified and cloned in Sma I site of pUC118. The recombinant plasmid, pP15E₂, containing the p15INK4a exon 2 insert, was selected after minipreparation. The restriction endonuclease map analysis by Hind-III, EcoR I, BglI revealed that pP15E₂ plasmid contained a 345 bp insert (Figure 4) and the insert was placed in antisense orientation. PCR-SSCP analysis of the pP15E₂ showed an identical abnormal migration single strand with that of C₅ (Data not shown). Sequencing analysis of the insert of pP15E₂ indicated that its sequence was identical to that of p15INK4b exon 2 and its upstream 60 nucleotides reported by Kamb (Figure 5).

Figure 1 PCR-SSCP analysis of p16 gene intron 1 and exon 2. At the SSCP analysis T₂₀ and C₂₀ showed as A pattern; T₂₃ and C₂₃ showed as B pattern; T₂₁ and C₂₁ showed as B' and B pattern, respectively; T₂₂ and C₂₂ showed as B and B' pattern, respectively. T = Human hepatocarcinoma; C = Adjacent non-cancerous liver cirrhosis; N = Normal human leucocyte

DISCUSSION

The p16INK4a gene has been confirmed to be a tumor-suppressor gene by the analysis of p16 gene knock-out mice and its abnormalities have been reported in various kinds of primary cancers and cell lines, such as malignant melanomas, gliomas, glioblastomas, and esophageal squamous-cell carcinomas^[1,12-14]. But there have been relatively few studies concerning the alteration of p16INK4a gene in hepatocellular carcinoma. Kita *et al* reported only three (5%) intragenic mutations of p16INK4a in primary HCC^[15]. Chaubert *et al* found four patients carried hemizygous germ-line point mutations of the p16INK4a gene, suggesting the existence of familial HCC involving this gene^[6]. Hui *et al* found higher proportion of HCCs may fail to express p16INK4a at the protein level^[16]. The general conclusion is that alterations of p16INK4a gene are infrequent in HCC. Our study showed polymorphism of p16INK4a intron 1 and exon 2 at SSCP pattern. The A pattern was only presented in HCC patients, not in the healthy blood donors. It is worthy to study whether people with the A pattern has HCC susceptibility. Five patients showed different SSCP patterns in tumor and noncancerous cirrhosis, most of which (4/5) occurred in large HCC (no statistical significance was revealed). It suggested that intragenic mutation may occur during the progression of HCC, and advanced HCC, but not in the early stages of HCC.

There is argument on whether the inactivation of p15INK4b contributes to the carcinogenesis. Okamoto *et al* observed that non-small-cell lung cancer showed homozygous deletions of p15INK4b (23%), somatic mutation (12%) in exon 2, G→A and C→A polymorphism (8%) within the noncoding sequence of 23 nucleotides and 27 nucleotides of 5' of exon 2, respectively. The latter was named 15Int1-27A gene pattern^[7]. But Russin *et al* detected only the 15Int1-27A polymorphism (13%), no mutation in non-small-cell lung cancers^[17]. Sill *et al* reported 15Int1-27A polymorphism (13%), no somatic mutation in 80 acute leukemia^[8]. Orlow *et al* observed deletions of p15INK4b in primary bladder tumors (8%). Yoshida reported no somatic mutation of p15INK4b gene in biliary tract cancers^[4]. The general

consensus is that frequency of mutation of p15INK4b in progression of cancer is very uncommon. In the present study no intragenic mutation of p15INK4b exon 2 was detected. Although one case of adjacent non-cancerous liver cirrhosis showed abnormal migration single strand, the cloning and sequencing of the aberrant SSCP DNA showed the sequence is identical to wild type p15INK4b exon 2 and 60 nucleotides upstream of exon 2^[1]. It suggested that intragenic mutation of p15INK5b exon 2 was an uncommon event in progression of HCC. This result is in agreement to the infrequent mutation of p16INK4a occurring in HCC, and also similar to the studies in AML, bladder cancers and biliary tract cancers^[4,8,9]. Whether the high frequency of p15INK4b somatic mutation in non-small cell lung cancers is related to the different types of tumor deserves further investigation.

Computed morphometric analysis and expression of alpha fetoprotein in hepatocellular carcinoma and its related lesion

Li Juan Shen¹, Zong Ji Zhang¹, Yang Ming Ou², Hua Xian Zhang¹, Run Huang¹, Yun He², Min Jie Wang² and Guo Shu Xu²

Subject headings liver neoplasms; carcinoma, hepatocellular; alpha fetoprotein; morphometry

Shen LJ, Zhang ZJ, Ou YM, Zhang HX, Huang R, He Y, Wang MJ, Xu GS. Computed morphometric analysis and expression of alpha fetoprotein in hepatocellular carcinoma and its related lesion. *World J Gastroentero*, 2000;6(3):415-416

INTRODUCTION

Hepatocellular carcinoma (HCC) is closely related with hepatitis and cirrhosis. In order to investigate the pathogenesis and early pathologic diagnosis of HCC, HCC and related lesions were analyzed qualitatively and quantitatively by automatic image analyser and immunohistochemical assay.

MATERIALS AND METHODS

Materials

Specimens obtained from surgical resection, autopsy and needle aspiration biopsy of livers during 1966-1997 were fixed in 10% formalin, embedded in paraffin, made into serial sections, and stained with routine HE. They were divided into seven groups: I. normal liver tissues used as controls (10 cases); II. chronic hepatitis (10 cases); III. chronic hepatitis with early cirrhosis (10 cases); IV. micronodular cirrhosis (13 cases); V. micronodular and macronodular mixed cirrhosis (14 cases); VI. paracancerous cirrhosis (27 cases); VII. HCC (39 cases).

All of the specimens were examined and diagnosed by two pathologists. The diagnosis of hepatitis and cirrhosis was referred to the standard of the Beijing Conference in 1995 and WHO's criteria.

Morphometry

Thirteen morphometric parameters were determined by the automatic image analyser (Type Q-900, Cambridge Company). And the sections were

enlarged 1000 times under light microscope on the screen of monitor. The cells and nuclei in the sections were traced by light pen. The automatic image analyser was used to determine the nucleus area (NA), the coefficient of variation of NA (NACV), the nucleus perimeter (NP), the nucleus diameter (ND), the roundness of nucleus (NR), the average volume of nucleus (NAV), the cell area (CA), the cell perimeter (CP), the cell diameter (CD), the cell roundness (CR) the average volume of cell (CAV), the ratio of area of the nucleocytoplasm (A-N/C), the ratio of volume of the nucleocytoplasm (V-N/C). After 50-100 cells in each section were examined at random, of the data were analysed by variance (q-test) and stepwise discriminational analysis. Then the equation of discriminational function was set up, the results were compared based on the histopathological classification.

Immunohistochemical staining

Mouse monoclonal antibody against human AFP and Immunostain S-P Kit were purchased from Fuzhou Maxim Biotechnical Company. Immunostaining of AFP was performed by the S-P method in each case. The procedures of S-P staining were taken according to the manufacturer's recommendations. The color was developed with diaminobenzidine and hematoxylin. Positive and negative controls were simultaneously used to ensure specificity and reliability of the staining.

RESULTS

Morphometry

The values of nucleus parameters (NA, NP, ND, NAV, A-N/C and V-N/C) increased gradually and those of cell parameters (CA, CP, CD and CAV) decreased gradually in the sequence of chronic hepatitis, cirrhosis without tumor, paracancerous cirrhosis and HCC. The difference was statistically significant between the group of HCC and the other groups without tumor ($P < 0.05$). The values of NACV, NR and CR in all groups varied irregularly. The values of most parameters (NA, NP, ND, CA, CP, CD, CAV, A-N/C and V-N/C) of the paracancerous cirrhosis were in between those of the cirrhosis without tumor and HCC. The difference was statistically significant ($P < 0.05$). The difference of the value of most parameters was not significant among chronic hepatitis with early cirrhosis, micronodular cirrhosis, mixed

micronodular and macronodular cirrhosis ($P < 0.05$). Results of stepwise discriminational analysis: because the difference of most parameters was not statistically significant among chronic hepatitis with early cirrhosis, micronodular cirrhosis, micronodular and macronodular mixed cirrhosis, the three groups were merged into one cirrhosis group of as a whole. Six of 13 parameters processed by stepwise discriminational analysis were chosen in chronic hepatitis (Y_1), cirrhosis without tumor (Y_2), paracancerous cirrhosis (Y_3) and HCC (Y_4). The equation of discriminational function was setup.

$$Y_1 = -526.540 - 32.768(NP) + 631.477(NR) + 6.046(CP) + 1.887(CA) + 19.264(A-N/C) - 0.016(CAV)$$

$$Y_2 = -453.402 - 29.633(NP) + 590.223(NR) + 5.466(CP) + 1.636(CA) + 17.903(A-N/C) - 0.011(CAV)$$

$$Y_3 = -441.556 - 28.851(NP) + 603.816(NR) + 3.875(CP) + 1.854(CA) + 17.991(A-N/C) - 0.014(CAV)$$

$$Y_4 = -623.687 - 36.878(NP) + 698.493(NR) + 5.217(CP) + 2.074(CA) + 23.555(A-N/C) - 0.011(CAV)$$

Fifty-three specimens had been tested, only one of the chronic hepatitis with early cirrhosis was falsely classified into chronic hepatitis and the general conformation rate was 98.2% to pathologic diagnosis.

Expression of AFP

Immunostaining of AFP was seen in paracancerous cirrhosis and HCC cytoplasms. The positive rates were 33.3% (9/27) and 43.6% (17/39) respectively. The expression of AFP was negative in hepatitis and cirrhosis without tumor. The positive rate of AFP in the paracancerous cirrhosis (33.3%) was significantly higher than in the cirrhosis without tumor (0%, 0/27) ($P < 0.01$, $\chi^2 = 10.8$).

DISCUSSION

HCC which is related with hepatitis and cirrhosis, is one of the common malignant tumors in the world. Popper *et al* considered the occurrence of HCC was a multistep process: HBV infection → persistent inflammation → necrosis → regeneration and repair → hyperplasia → HCC. The course had been studied by morphometry and the results showed that the values of parameters of nucleus increased gradually and those of cells decreased gradually. These suggested that HCC was associated closely with hepatitis and cirrhosis, especially paracancerous cirrhosis.

Paracancerous cirrhosis differed essentially from cirrhosis without tumor. Ren *et al*^[1] considered the regenerative nodules in the paracancerous cirrhosis had regenerated more actively than those in the cirrhosis without tumor. Watanabe *et al*^[2] reported that the rate of dysplasia in the paracancerous cirrhosis (25.9%) was higher than that in the cirrhosis without tumor (12%). Dai

et al^[3] reported that some liver cells around the HCC triggered the closed gene to resynthesize AFP. Zhang^[4] reported that the re presented different degrees positive expression of AFP in the host hepatocytes around cancer and hepatocytes non-neoplastic animals in late stage experimental hepatocarcinoma in rats. All the results showed that the carcinogenesis in paracancerous cirrhosis was more liable to occur than in cirrhosis without tumor. We discovered that values of most parameters in the paracancerous cirrhosis were in between those of the cirrhosis without tumor and HCC by morphometry ($P < 0.05$). The expression of AFP was positive in the paracancerous cirrhosis and negative in the cirrhosis without tumor ($P < 0.01$). Evidently the paracancerous cirrhosis differed from the cirrhosis without tumor in the respect of function and morphology. It is more likely to be precancerous lesion than cirrhosis without tumor. The values of morphometric parameters in cirrhosis without tumor, regardless of early cirrhosis, micronodular cirrhosis or micronodular and macronodular mixed cirrhosis, were not different significantly. It suggested that the cirrhosis without tumor may be the result of regeneration and repair after HBV infection. Therefore, we inferred that the posthepatitis cirrhosis, the result of persistently affecting HBV, should be evolved into "precancerous cirrhosis" similar to paracancerous cirrhosis, and then some of liver cells were selectively developed into HCC in the circumstance suitable for carcinogenesis. The multisteps in the genesis of HCC may be HBV infection—chronic hepatitis—cirrhosis—"precancerous cirrhosis"—HCC. The paracancerous cirrhosis may be a sequential lesion of precancerous cirrhosis. This inference should be verified by further study. Now, since we can not differentiate the precancerous cirrhosis from the cirrhosis without tumor under light microscope, the precancerous cirrhosis was diagnosed merely by morphometry and immunohistochemical method, which suggested that the patient with precancerous cirrhosis would probably suffer from HCC in the near future or they had already suffered from HCC somewhere in the liver. It was significant to diagnose HCC as early as possible, especially by using needle aspiration biopsy of liver, thus to decrease the possibility of missing small HCC (SHCC, diameter ≤ 3 cm).

The new proof of neuro-endocrine-immune network—expression of islet amyloid polypeptide in plasma cells in gastric mucosa of peptic ulcer patients

Yan Huang¹, Shi Jun Lu², Jing Xia Dong³ and Feng Li³

Subject headings peptic ulcer; plasma cells; gastric mucosa; islet amyloid polypeptide (IAPP); neuro-endocrine-immune network

Huang Y, Lu SJ, Dong JX, Li F. The new proof of neuro-endocrine-immune network—expression of islet amyloid polypeptide in plasma cells in gastric mucosa of peptic ulcer patients. *World J Gastroentero*, 2000;6(3):417-418

INTRODUCTION

Peptic ulcer, as a common disease, seriously affected people's work and life. Its occurrence, development and change have close relationship with the change of people's moods. Animal experiment proved that significant changes occurred in the endocrine system of the gastric ulcer rats^[1]. Recent study also showed that the number of lymphocytes increased markedly in the gastric mucosa of peptic ulcer patients^[2]. All the above indicated that peptic ulcer is closely related neuro-endocrine-immune system. IAPP, a novel islet hormone, not only takes part in the regulation of blood glucose^[3], but also protects gastric mucosa^[4] and regulates gastrointestinal movements^[5]. On the basis of previous studies, we observed the expression change of IAPP and explored the relationship between the endocrine and the immune system in gastric mucosa of peptic ulcer patients, so as to provide morphologic data on the existence of neuro-endocrine-immune network and the changes in peptic ulcer.

MATERIALS AND METHODS

Twenty-one samples, including 6 cases from normal human stomach, 15 cases from gastrectomy of gastric ulcer patients, were collected. The paraffin

sections were prepared as usual. Immunohistochemical PAP method was used to show IAPP-IR cells. Briefly five-micron sections were placed on glass slides deparaffinized in xylene, rinsed in ethanol, and brought to PBS through a series of descending concentration of ethanol; endogenous peroxidase activity was blocked with methanol-H₂O₂ at room temperature for 30 min; rabbit anti-IAPP serum (peninsula, USA) was diluted 1/6000 with PBS, and the sections were incubated overnight at 4°C. Goat anti-rabbit IgG (Huamei, Beijing) (1/50), peroxidase-anti-peroxidase (Capital Medical University) (1/100) and DAB kit (Zhongshan, Beijing) were used for staining. As the negative control, the primary antiserum was replaced by PBS and other steps were the same as stated above. All the sections were counterstained with Mayer hematoxylin.

RESULTS

The IAPP-IR cell was not observed in the gastric mucosa of normal subject (Figure 1A). In comparison, a great number of plasma cells IAPP-IR were found in the gastric mucosa of peptic ulcer patients (Figure 1B,C). Most of IAPP-IR plasma cells were weak and only a few were strong for IAPP staining (Figure 1D). Of the negative control sections, no immunoreactive product to IAPP was found in plasma cells (Figure 1E).

DISCUSSION

The gastric mucosa, in which there are a lot of neurons, endocrine cells and immunocytes that may interact with each other, is an important field for the study of neuro-endocrine-immune network. It will undoubtedly provide valuable data for the study on this network by exploring the change of immune-endocrine of gastric mucosa of peptic ulcer patients. Based on the observation of T and B lymphocytes which increase obviously in the gastric mucosa of peptic ulcer patients^[2] and the action of IAPP, a novel islet hormone, which inhibits gastric acid secretion^[6] and protects gastric mucosa^[4], we further studied the expression change of IAPP in the gastric mucosa. Unexpectedly, it was found that the plasma cells of gastric mucosa increased in number, moreover most of them expressed IAPP to some degree.

Figure 1 Immunohistochemical PAP method, Mayer Hematoxylin counterstained showing IAPP-IR cells.

A. The gastric mucosa of normal human, no IAPP-IR cell was found. $\times 200$

B-E. The gastric mucosa of peptic ulcer patients.
B. The more IAPP-IR plasma cells (↑). $\times 1000$

C. The weak positive (↑) and negative (▲) plasma cells. $\times 1000$

D. The strong (↑) and weak (▲) positive IAPP-IR plasma cells. $\times 400$

E. The negative control section in which IAPP antiserum was replaced by PBS. (↑) showing plasma cell. $\times 1000$

Firstly, the specificity of the above findings should be confirmed because there was no IAPP expression in the plasma cells on the negative control sections; and there were also IAPP-IR negative plasma cells around the positive ones. Secondly, the significance of IAPP expression in plasma cells should be studied. IAPP is mainly secreted by islet B cells^[7]. Recent study indicated that besides regulating blood glucose, IAPP could inhibit gastric acid secretion^[4], and protect gastric mucosa^[5]. IAPP-IR cells of islet were markedly increased during the healing process of rat gastric ulcer^[8]. The above-mentioned studies all suggested that IAPP is beneficial to ulcer healing. As it is known, the plasma cells of gastric mucosa come from B lymphocytes and they respond by synthesizing and secreting IgA. It is observed, for the first time, that plasma cells in gastric mucosa of peptic ulcer patients not only increased in the number, but also expressed IAPP. Combined with our previous observation that T and B lymphocytes of gastric mucosa increased in peptic ulcer patients, it is reasonable to infer that some plasma cells in gastric mucosa of peptic ulcer patients may transform to ones expressing IAPP so as to maintain the high level of IAPP in the gastric mucosa and help promote ulcer healing just as a growth factor^[9].

CONCLUSION

It is found, for the first time, that IAPP was expressed in plasma cells of gastric mucosa of peptic ulcer patients, which provides morphologic evidence for the existence of neuro-endocrine-immune network.

Effect of gastrectomy on G-cell density and functional activity in dogs

Yu Qiang Chen¹, Wen Hu Guo², Zheng Ming Chen³, Lei Shi³ and Yan Xu Chen²

Subject headings gastrectomy; pylorus; G-cell; gastrin; peptic ulcer/surgery

Chen YQ, Guo WH, Chen ZM, Shi L, Chen YX. Effect of gastrectomy on G-cell density and functional activity in dogs. *World J Gastroentero*, 2000;6(3):419-420

INTRODUCTION

Billroth gastrectomy has some advantages of inhibiting acid secretion, low ulcer recurrence and low mortality. However, postoperative complications, such as dumping syndrome and reflux gastritis, often occurred as a result of pylorotomy^[1]. To minimize these complications, pylorus-preserving gastrectomy (PPG) had been performed for gastric ulcer with satisfied clinical results. Positive correlation was not found between ulcer recurrence and serum gastrin level^[2]. In this study, we performed distal partial gastrectomy with Billroth II anastomosis (DPG-BII), pylorus-preserving gastrectomy (PPG) and highly selective vagotomy (HSV) on dogs and investigated the relationship between different antrum disposal and gastric acid secretion, serum gastrin level and G-cell density and functional activity.

MATERIALS AND METHODS

Eighteen hybrid adult dogs, with body weight ranging from 10 kg to 20 kg, mean weight 13.9 kg, were randomly divided into 3 groups, and underwent PPG, DPG-BII or HSV respectively. In PPG group, antrum was strictly retained within 1.5 cm-2.0 cm and stomach was resected about 40%. DPG-BII, in which stomach was resected about 75%, and HSV were routinely done. After laparotomy biopsy was taken at antrum 2 cm beyond the pyloric sphincter, the first segmental duodenum and jejunum 4 cm beyond Treitz ligamenta, 3 mo after operation, biopsies were done again around the original biopsy sites. Gastric acid secretion was analyzed using neutralization method (subcutaneous injection of tetra-gastrin 4 µg/kg). Fasting and

postprandial serum gastrin levels were measured by radioimmunoassay. The G cell density and its functional activity were determined by immunohistochemical assay using an antigastrin antibody (Zymedco) at a dilution of 1:200 in PBS. G cell density was measured according to the method of Creutzfeldt^[3], in which G cell functional activity was divided into 4 grades, as follows: 1+, brown-red cytoplasm, without granule; 2+, minute brown granules, occupied within 1/3 cytoplasm area; 3+, brown granule or clusters occupied, 1/3-2/3 cytoplasm area; 4+, brown-black granules or clusters, above 2/3 cytoplasm area.

RESULTS

Effects of different operative procedures on gastric acid secretion

In DPG-BII, PPG and HSV groups, preoperative basal acid output (BAO) was 1.80 mmol/h, 2.25 mmol/h and 2.19 mmol/h; maximal acid output (MAO) was 5.19 mmol/h, 4.49 mmol/h and 5.30 mmol/h, respectively; 3 mo after operation, BAO decreased to 0.48 mmol/h, 0.98 mmol/h and 0.97 mmol/h; while MAO decreased to 1.04 mmol/h, 1.76 mmol/h and 1.29 mmol/h, respectively. Gastric acid secretion was significantly suppressed by 56%-80%, which showed that all of the three operations can effectively inhibit gastric acid secretion in dogs (Table 1).

Effects of different operative procedure on serum gastrin level

Pre and post-operative fasting and postprandial serum gastrin levels of DPG-BII, PPG and HSV groups are shown in Table 2. In DPG-BII, post-operative fasting and postprandial serum gastrin levels were significantly decreased ($P<0.05$), the inhibiting rate was 49.7% and 48.4% respectively; while in PPG, serum gastrin levels were slightly decreased with an inhibiting rate of 25.9% and 24.4%; in HSV, post-operative serum gastrin levels were increased by 65.2% and 54.1%, respectively.

Effects of different operative procedure on G cell density and functional activity

Postoperatively, G cell density increased in all sites checked. The increasing rate in duodenum was about 75.0% and 50.0% in antrum or residual antrum (Table 3). The increase in jejunum had no statistical significance.

Stained by immunohistochemical method, G cell was stained in brown color and there were brown-black granules in cytoplasm, which were the products of gastrin acted with its antibody and presented as the index of activity of G cell. If 1+

and 2+ grade cell was taken as normal- or hypofunction, while 3+ and 4+ as hyperfunction, the number of grade 3+ and 4+ G cells as a whole constituted 44% and 60% of the total G cells examined in pre and post-operative specimens respectively, and particularly in duodenum the corresponding postoperative rate was 63%. It reveals that no matter what procedure of gastrectomy was performed, the post-operative G cell functional activity, especially in duodenum was enhanced with statistical significance (Table 4).

Table 1 Effects of different operative procedures on gastric acid secretion

Operation	Group	Preoperation (mmol/h)	Postoperation (mmol/h)	Inhibiting rate (%)
DPG-BII	BAO	1.80 ± 0.25	0.48 ± 0.20 ^b	73.7
	MAO	5.19 ± 0.56	1.04 ± 0.19 ^b	80.0
PPG	BAO	2.25 ± 0.27	0.98 ± 0.26 ^a	56.4
	MAO	4.49 ± 0.34	1.76 ± 0.19 ^b	60.7
HSV	BAO	2.19 ± 0.21	0.97 ± 0.26 ^a	55.9
	MAO	5.30 ± 0.14	1.29 ± 0.47 ^b	75.7

DISCUSSION

According to the theory “no acid, no ulcer”, anti-acid secretion has been the dominant measure in treating peptic ulcer. For suppressing acid secretion, how to treat the antrum has been a much controversial question in general surgery^[4]. Total antrum excision would make the serum gastrin level and gastric acid output lowered, which was accompanied with relatively lower ulcer recurrence; on the other hand, damage of sphincter function resulted in dumping syndrome, reflux gastritis,

dyspepsia and even carcinogenesis of residual stomach^[1]. Under this condition PPG was presented, which not only removed the ulcer lesion and suppressed gastric acid secretion, but also preserved the sphincter function^[5]. Our results showed that all the three procedures can effectively inhibit gastric acid secretion in spite of the different postoperative serum gastrin levels. Clinically, similar results were observed that absolute serum gastrin value of patients were all kept within normal limits, regardless their gastrin level decreased or increased after DPG-BII, PPG or HSV^[2]. This implied that different disposal of antrum did not obviously affect the inhibition of gastric acid secretion.

Gastric acid secretion is a complex physiological process, which was regulated by several factors, such as vagus nerve, G cell, parietal cell and its receptor, some alimentary endocrine substances, gastric mucosal blood supply^[6]. Of them any change may inhibit the gastric and secretion and keep it at lower output level. In addition to regulating acid secretion, gastrin has important effects on nourishment of gastric mucosa and pancreas^[7]. Our results showed that there were many G cells in duodenum and jejunum besides antrum. After operation, the number of G cells in the nongastric tissue increased and their function enhanced, this was not only associated with the gastric acid depletion, but also was demanded by other physiological effects. Therefore it is evidently impossible and unnecessary to eliminate gastrin from serum by operation of peptic ulcer. To some extent, hypergastrinemia subsequent to treatment of peptic ulcer, such as HSV and antacid drugs, is the main determinant of ulcer healing^[8]. It is the key point that how to keep the whole function of sphincter. Fukushima *et al*^[5] has discovered that the length of preserved antrum was closely related to the residual stomach function. In our study, the length of preserved antrum was strictly limited within 1.5 cm to 2.0 cm, vomiting, decline of food intake and loss of body weight were not found postoperatively in the animals which suggested that the function of sphincter had been fairly maintained.

Wang QG, He LY, Chen YW, Hu SL. Enzymohistochemical study on burn effect on rat intestinal NOS. *World J Gastroentero*, 2000;6(3):421-423

INTRODUCTION

The blood irrigate flow obstruction, especially the gastrointestinal (GI) ischemia^[1], is the main factor of the damage to the digestive tract caused by serious burns. The effect of GI ischemia on the whole body is extensive and profound, which not only causes the increase of intestinal permeability and the movement of bacteria and toxin in the intestinal cavity, but releases a large quantity of inflammatory media. Neuroendocrine element after burns is closely related to intestinal damage^[2]. As is known at present, abundant nitric oxide synthase (NOS) is distributed in GI tract, whose product NO is a nonadrenergic and noncholinergic (NANC) restraining transmitter in enteric nervous system which participates extensively in various physiological functions in the intestinal tract^[3]. Few reports about the effects on intestinal NOS after serious burns are available. We used scalded rat model with degree III 40% of body surface area (TBSA), and enzymatic histological and biochemical methods to observe dynamically the active changes of empty myenteric plexus NOS and changes of jejunal tissue MDA SOD and GSH-PX and probe into the relationship between NOS and intestinal tissue and function damage as well as their mechanism so as to provide morphological experimental basis for clinical treatment.

MATERIALS AND METHODS

Materials

B-NADPH, TYPE, nitroblue tetrazolium (NBT) (Sigma); SOD reagent kit (Wuhan Xiehe Hospital Science and Technology Development Centre); thibarbiluric acid (Shanghai Reagent Factory); self-made phosphate buffer; and healthy SD rats weighing 250 g provided by the Animal Laboratory Centre of Tongji Medical University.

Methods

Eighty rats were randomly divided into five groups: sham-burn control (SBC) and 4 groups of 8, 24, 48

and 72 hours postburn, each group having 16 rats (40 were measured for biochemical indexes, and other 40 for morphological indexes). The rats, before being scalded, had their hair depilated on the neck and back with 80 g/L Na₂S under the anaesthesia with 100 g/L trichloroacetaldehy-demonohydrate after they became conscious, depilated parts were soaked into the 100°C boiling water for 16 sec and scalded to degree III 400g/L TBSA. They were then fed in different cages without treatment. And those in sham-burn control group were soaked into 37°C water.

Rats in different groups, after being scalded, were sacrificed at different time points, a 10 cm empty intestine was taken out and made into thick liquid. SOD activity was determined with modified pyrogallol auto-oxidation^[4]. GSH-PX activity by active DTNB^[5], and the content of MDA with modified thiobarbituric acid fluorescence analysis^[6].

The rats in each group were anaesthetized with 100 g/L trichloroacetaldehy demonohydrate (300 mg/kg), opened up to expose the heart, the blood was quickly rinsed away with 200 mL warm normal saline from left chamber through ascending aorta, and then 450 mL of 40 mL/L cold paraformaldehyde was instilled for one hour, a 10 cm empty intestine was taken out, the intestinal content was washed off and filled again with the same liquid to make the intestinal track full, both ends were ligated and fixed in the above-mentioned liquid (4°C) for 4 hours. The outer longitudinal tunica muscularis was peeled off carefully from the ring tunica muscularis and tela submucosa, and the specimens were made.

The specimens after being washed with 0.1 mol/L of PBS, was put into reduction type NADPH-d hatching liquid at 37°C for 50 min (consisting of 0.1 mol/L of PB (pH 8.0) which contained 30 g/L tritonx-100, 100 mol/L of nitroblue tetrazolium and 1 g/L of NADPH-d, and washed thoroughly with 0.1 mol/L of PBS. After reaction^[7], it was pasted onto a galative glass piece and conventionally dehydrated, made into transparency, sealed and observed under microscope. The staining result of NOS was achieved using IBAS automatic picture analyzer to determine semi-quantitatively the contents in myenteric plexus neuron NOS and internode bind NOS.

Statistical treatment

The data were expressed as $\bar{x} \pm s$, and *t* test was used to compare the results.
