RESULTS

Changes of the contents of MDA, SOD, GSH-PX in the empty intestinal tissues of burned rats

The content of MDA in the empty intestinal tissues gradually rose with the time of burns; compared with the SBC, the contents in each group increased significantly ($P<0.01$). But the activity of SOD and GSH-PX decreased markedly the difference being significant as compared with SBC ($P<0.01$).

Active change of myenteric plexus NOS in the empty intestine of burned rats

Observation under light microscope In the control group, most ganglion cells in myenteric plexus and their scabrosity appeared strongly positive in NOS, while a small number had moderate staining, most being distributed around myenteric plexus and the cell being comparatively large and various in shape, i.e., ovate, triangle or irregular. There were NOS positive products in dark blue in the cytoplasm and the nucleus was negative. Most of intersegment bind fiber contained bulge, and some had division and intersect with varying size (Figure 1). In the group

of 8 hours post-burn, the cell NOS stain appeared obviously lighter but intersegment bind fiber had no obvious change (Figure 2). In the 24 hours post-burn group, ganglion cell NOS staining was intensified obviously with clear cell outline and larger size. Intersegment bind fiber and bulge became markedly dense (Figure 3). In the 48 to 72 hour post-burn groups, ganglion cell and intersegment bind fiber staining gradually became lighter, especially in those of 72 hour group (Figure 4), perikaryon and OD change of myenteric plexus NOS in the empty intestine of burned rats. In burned rats after 8 hours the OD of myenteric plexus and intersegment bind fiber NOS were significantly lower than that in the control group ($P<0.01$) and in those after 24 hours, the OD of ganglion cells and intersegment bind fiber NOS was significantly higher than that in the control ($P<0.01$); while in those after 48 to 72 hours, OD of ganglion cells and intersegment bind fiber NOS decreased gradually, being significantly different from the control group and those of 24 hours post-burn ($P<0.01$).

DISCUSSION

NO, a newly discovered active biosubstance in recent years, is a dual-functional messenger and venosity molecule with short half-life and instable nature. The *in vivo* NO, in the form of L-Arg as primer, exists through the catalyza tion of NOS, which indicates that the distribution of NOS is closely related to the physiological functions of NO. It is reasonable to infer bioeffects of NO through the research of NOS, Nathan *et al*^[8] divided NOS into two types, i.e. cNOS and iNOS. cNOS is mainly distributed in neurocyte and endothelium and catalyzes NO which acts chiefly as neurotransmitter and secondary messenger, while iNOS, mainly distributed in macrophage and endothelium cell, catalyzes NO, which has cytotoxic effect. However, the physiological effect of NO to the body depends chiefly on the quality and strength of stimulat ive elements, the dosage and reactive sites. Thus we can presume that after serious burns bad perfusion of intestinal blood, disorder of motor functions and damaged enteromycoderm may be related to the abnormal intestinal NOS activit y. It was suggested that MDA content in the jejunal tissues of the burned rats increased, the result was consistent with that of Peng *et al*^[9]. At the same time, SOD and GSH-PX antioxidase activities in jejunal tissues decreased after being burned, indicating that lipoperoxidation reactions participate in the pathophysiological course of the mucosal damage of burned rats. Some studies demonstrated that cNOS was distributed extensively in plexuses of GI wall, and its output NO was inhibitory neurotransmitter of NANC nerves in GI tract, which may cause angiectasis of intestinal tract and laxation of smooth muscles^[10]. Eight hours after serious burns myenteric plexus NOS activity decreased obviously in our experiment suggesting burn stress caused adrenergic nerve excitation, and inhibited NANC nerves, leading to the decrease of cNOS activity and the catalyzed NO, causing excessive contrac tion of smooth muscles. These may be the main causes in bad perfusion of intesti nal blood and disorder of motor functions. In this experiment, 24 hours post-burn, myenteric plexus NOS activity increased significantly, possibly because the enterogenous infection after serious burn, activated the endotoxin on macrophage cell of intestine to release a series of such body fluid agents as TNT IL-1, etc, leading to increased iNOS

activity. A large amount of high-concentr ation NO produced in this way had cytotoxic effects which further damaged the intestinal tissues. Excessive amounts of NO and O₂ free radicals produced more toxic ONOO⁻ free radicals which further react to produce HO[·], NO₂, NO₃⁻, etc. while HO[·] and NO₂ are catalyst of biomembrane lipid peroxidat ion and can cause a succession of peroxidation of high unsaturation and adipoaci d occurring on the membrane, thus producing a large amount of metabolin MDA wors ening the damage of intestinal tissues. Therefore 48-72 hours post-burn, we fou nd that intestinal myenteric plexus ganglion cell and perikaryon reduced obviously, and changes caused by the lowered NOS activity and other delayed neuronal damage. It can be inferred that NO in the intestine of seriously burned rats and ONOO⁻ reacted by O₂ are important mechanisms that NO damages intestin al structure and functions. It suggests that the damaged structure and functi ons in seriously burned rats are related to the increase of NOS activity. It is concluded that using the inhibitor of NOS to lower NOS activity level may be beneficial to lessening the degree of post-burn intestinal damage.

INTRODUCTION

Gastric mucosal injury is one of the common disorders, there are many reports subjected to its pathogenesis treatment and prevention^[1-4]. We investigated the protective effect of electroacupuncture and moxibustion of Zusanli point on gastric mucosal damage and its relation with nitric oxide (NO) on the animal model with acute gastric mucosal damage induced by ethanol. The detected indexes include the content of NO, gastric mucosal blood flow (GMBF), gastric mucosal lesion index (LI) and transmucosal potential difference (PD).

MATERIAL AND METHODS

Drugs L-arginine (L-arg)—the precursor of NO (purchased from Huamei Biological Engineering Corporation); Natrii Nitroprussidum (SNP)—the donor of NO (provided by Experimental Drug Plant of the Beijing Institute of Pharmaceutical Industry), diluted with distilled water prior to use, Nw-nitro- L-arginine (L-NNA), an inhibitor of NOS (produced by Sigma), and diluted with 0.2 mol·L⁻¹ PBS; 200 g·L⁻¹ pentobarbital sodium was prepared with distilled water immediately before use.

Animal grouping

Wistar rats weighing 180 g-250 g (provided by the Institute of Acupuncture and Moxibustion, Anhui College of Traditional Chinese Medicine) were

fasted for 12 h and allowed free access to water. The animals were divided into 16 groups randomly, including: control group (c), model (m), m+electroacupuncture (EA), m+moxibustion (M), L-arg+m, SNP+m, L-NNA+m, L-NNA+L-arg+m, L-arg+m+EA, L-arg+m+M, SNP+m+EA, SNP+m+M, L-NNA+m+EA, L-NNA+m+M, L-NNA+L-arg+m+EA, L-NNA+L-arg+m+M.

Preparation of acute gastric mucosal damage model^[5]

The rats fasted for 12 h were injected with pentobarbital intraperitoneally at a dose of (30-40) mg·Kg⁻¹. The middle line incision below xiphoid process after anesthesia was performed, then stomach was exposed and injected with 2 mL 700 mL/L ethanol, and the abdomen closed, 30 min later the preparation of model was fulfilled.

Experimental procedure

Different procedures were used for different groups. In groups injected drugs or equivalent amount of physiological saline, these were injected respectively into blood flow slowly through the great saphenous vein of the anesthetized rats 15 min before the preparation of the model. In groups which required electroacupuncture or moxibustion, were treated with electroacupuncture or moxibustion on bilateral Zusanli points after the model was successfully prepared. The electroacupuncture was performed with PCE₂ electroacupuncture therapy device on the condition of frequency 20Hz, voltage 5v-8v for 30 min (produced by the Institute of Acupuncture and Moxibustion of Anhui College of Traditional Chinese Medicine). During moxibustion, the lighted pure moxa-cigar was maintained 1 cm from the bilateral Zusanli points. The GMBF and PD values were measured for all rats. Then the blood was obtained through decapitation or from retro-ocular vessel for the NO assay. Subsequently the rat stomach was resected for the analysis of LI, and the mucosa from gastric antrum and the body for assaying NO contents.

Index detection

GMBF was assayed by analyzing hydrogen gas clearance curves^[6]; PD was assayed with direct Ag-

AgCl. Electrode measurement technique^[7] with few alterations, i.e. the efficient electrode was put on the mucosa while the reference one on the serosa. The electric potential difference between two membranes was recorded. For the detection of LI, the stomach was resected and incised along the greater curvature, washed with physiological saline. Guth index assessment^[8] (slightly modified) was used to compute the damage, on a scale of grades 1-5 as follows: Grade 1, the petechia or ecchymosis, Grade 2, 3, 4 and 5, pathological focus of 1 mm; 1 mm-2 mm, 2 mm-4 mm, and over 4 mm, respectively. The NO content in blood and mucosa of gastric antrum and body were assayed based on the method from Green *et al*^[9]. The Kit for NO assay was provided by the Department of Biochemistry, Institute of Radiology, Academy of Medical Science of PLA. The analysis was based on the protocol, but the mucosa were homogenized before the assay.

Statistical analysis

All data were expressed as $\bar{x} \pm s$, and the Student's *t* test was used for the comparison between groups.

RESULTS

The effect of acupuncture and moxibustion of Zusanli point on GMBF, PD and LI in rats with the gastric mucosal damage (Table 1)

The mean of GMBF, PD in group m showed statistically significant difference compared with the control group ($P < 0.01$), demonstrating marked decrease of GMBF and PD after gastric mucosal damage, the integrity of gastric mucosa was depended on adequate blood flow. GMBF and PD in group m+M was obviously increased ($P < 0.01$) compared with group m, suggesting the electroacupuncture and moxibustion of Zusanli point may relieve and cure the gastric mucosal damage induced by ethanol.

Changes of NO content in blood and gastric mucosa and their relation with LI after electroacupuncture and moxibustion on the Zusanli point of rat models

From Table 1 we can find, NO contents in group m showed significant difference compared with normal control ($P < 0.01$); LI in group m+EA and group m+M was markedly lower than that in group m ($P < 0.01$). The results showed that the gastric mucosal damage aggravated as NO content decreased while NO content increased and the gastric mucosal damage relieved, which suggests that NO content is associated with the integrity of gastric mucosa.

Effect of L-NNA, L-arg and SNP on the response of electroacupuncture and moxibustion (Table 1)

The L-Arg (150 mg·Kg⁻¹), SNP (200 µg·Kg⁻¹) and L-NNA (3 mg·Kg⁻¹) were administered through the great saphenous vein respectively 15 min before administration of 700 mL/L ethanol in different groups. After that the electroacupuncture and moxibustion of Zusanli point were performed for 30 min. Subsequently, the GMBF, PD and LI as well as NO content in blood and gastric mucosa were assayed and detected respectively in each group. It was found that there was little difference in the indexes when group L-arg +m and group SNP+m were compared with group m+EA or group m+M ($P < 0.05$), indicating the function of electroacupuncture and moxibustion on gastric mucosal damage was similar to that of L-arg or SNP. Comparing group L-Arg+m+EA (or M) and group SNP+m+EA (or M) with group m+EA (or M), and group SNP+m+EA (or M) with group m+EA (or M), NO content, GMBF and PD values were markedly increased, and LI value was obviously decreased ($P < 0.01$ or $P < 0.05$), which suggested that electroacupuncture and moxibustion of Zusanli point had the effect of strengthening NO pathway and protecting gastric mucosa.

In comparison of group L-NNA+m with group m, NO content, GMBF and PD value decreased, and LI value increased ($P < 0.01$ or $P < 0.05$), showing that L-NNA aggravated ethanol induced gastric mucosal damage. When we compared group L-NNA+m+EA (or M) with group m+EA (or M), NO content, GMBF and PD value also decreased, but LI value increased ($P < 0.01$ or $P < 0.05$), which suggests L-NNA decreased the protective action of electroacupuncture and moxibustion on gastric damage. While we compared group L-NNA +L-arg +m+EA (or M) with group L-NNA+m+EA (or M), NO contents, GMBF and PD value increased and LI value decreased ($P < 0.01$ or $P < 0.05$), demonstrating L-arg may reverse the inhibitory function of L-NNA. In conclusion, the above mentioned results further suggest that the protective action on gastric mucosa by the electroacupuncture and moxibustion of Zusanli point is NO mediated.

Effect of electroacupuncture of Zusanli point on pH value of gastric fluid (Figure 1)

pH in group c was 4.33 ± 0.40 and that in Group m 2.92 ± 0.37 , decreasing significantly in the latter group ($P < 0.01$). The pH value in Group m+EA, 3.84 ± 0.69 was much higher than that in Group m indicating 700 mL/L ethanol promotes the stomach to secrete acids while electroacupuncture inhibits the secretion.

DISCUSSION

Acupuncture and moxibustion may treat and prevent gastrointestinal disorders, the mechanism of which is being further investigated. The acupuncture and moxibustion on Zusanli points show the two-way regulation of gastrointestinal function. In recent years, it is frequently reported that they may relieve symptom and promote the ulcer healing to certain extent^[1-4]. There is relative point specificity, the first choice is the Zusanli point in stomach channel of foot yangming. Our study investigated the therapeutic and protective effect of the acupuncture and moxibustion on acute gastric mucosal damage induced by 700 mL/L ethanol. It is found that

GMBF and PD value as well as NO content, pH value in rat gastric mucosa of model group with acupuncture and moxibustion increased more markedly than those without any therapy (*P*<0.01), while the gastric mucosal damage alleviated (*P*<0.01) which denotes the therapeutic and protective effect of acupuncture and moxibustion on the damage and suggests that the protective action is related with the level of NO content.

NO is a small molecular gas produced from the precursor L-Arg under the NOS catalysis. The process is called as L-Arg-NO pathway, NOS activity plays a key role in NO synthesis. NOS is existed in many kinds of tissues including vascular endothelial cell, thrombocyte, brain cell, renal epithelial cell, macrophage, neutrophil, hepatocyte, etc. Some factors can induce the expression of NOS and increase the NO synthesis. As a special bioinformational molecule, the neurotransmitter or the humoral factor, NO involves in the functional regulation and pathophysiology of many diseases. Our study investigates the protective effect of acupuncture and moxibustion on acute gastric mucosal damage and in the meantime measures NO content in blood and gastric mucosa and finds that NO content is negatively correlated with the severity of gastric mucosal damage, which proves that the protective action of acupuncture and moxibustion of Zusanli point is NO mediated; and in other words NO involves in the regulative effect of acupuncture and

moxibustion on gastrointestinal function.

The good balance between NO and ET keeps the endothelium intact. If the unbalance is developed, the gastric mucosal damage will be formed and the gastric dysfunction presented. Our study showed^[1] that when NO content decreased ET content increased and gastric mucosal damage aggravated, and on the contrary, the damage alleviated. Our results have verified it. When L-arg or SNP was administered 15 min before establishing the model with 700 mL/L ethanol; NO content was higher than that in the model group and concurrently GMBF and PD value increased, and LI value decreased; if NOS inhibitor -L-NNA was given, NO content, GMBF and PD value were lower than those in the model group while LI value increased, which indicates that NO plays an important role in maintaining the intact gastric mucosa. GMBF decrease may prominently respond to the gastric mucosal damage after ethanol induction. It is thought that NO is an EDRF, which is capable of relaxing the vascular smooth muscle obviously. Our research further confirmed that the vascular relaxing action of NO can protect gastric mucosa from damage.

NO initiates the protective effect of acupuncture and moxibustion on gastric mucosa, which has been proved in our work. During experiment, in the model rats, the NO content in their blood and gastric mucosa increased after acupuncture and moxibustion were performed, and GMBF and PD values were also increased while LI value decreased. If L-NNA was preliminarily given, the above effect of acupuncture and moxibustion of Zusanli point disappeared, but concurrently given L-arg, the action of L-NNA could be reversed. In addition, if L-arg or SNP was preliminarily administered and then the model established, NO content in the group with the acupuncture and moxibustion of Zusanli point increased more than that in the corresponding groups without acupuncture and moxibustion, moreover, GMBF and PD values increased and LI decreased correspondingly, showing the synergetic action between them. The above phenomena further confirm that the acupuncture and moxibustion of Zusanli points alleviate gastric mucosal damage, which is NO mediated, and this illustrates that the acupuncture and moxibustion of Zusanli point can activate endogenous NOS.

As far as the possible mechanism why Zusanli point can initiate NO system is concerned, we consider that the main nerves regulating gastric function are vagus nerves, the dorsal vagus nucleus (DMV) being the major motor nucleus. The efficient stimulus transmitted to DMV by the somatic sensory nerves through the spinal cord. DMV also receives afferent information from gastrointestinal tract and integrates other information from central nervous system (CNS), and transfers to the stomach by efferent vagus nerves, resulting in the increase of NO synthesis and release.

The possible mechanism about how NO can protect gastric mucosa from damage is as follows: NO acts as one of endothelial diastolic factors which can cause the dilatation of vascular smooth muscles, resulting in GMBF increase, improvement of blood supply of gastric mucosa, maintaining the integrity of gastric mucosal epithelium, protecting the gastric mucosa from the stimulation of gastric contents and from damage, preventing from H⁺ invasion and keeping normal ionic concentration gradient across gastric mucosa as well as maintaining appropriate PD value, while acupuncture and moxibustion may activate NOS to increase the synthesis and release of NO. Further research remains to be done as how does the acupuncture and moxibustion activate NOS.

Research of *Helicobacter pylori* infection in precancerous gastric lesions

Xiao Qiang Zhuang¹ and San Ren Lin²

Subject headings *Helicobacter pylori*; precancerous gastric lesions

Zhuang XQ, Lin SR. Research of *Helicobacter pylori* infection in precancerous gastric lesions. *World J Gastroentero*, 2000;6(3):428-429

INTRODUCTION

Helicobacter pylori (*Hp*) infection has been considered to play significant roles in pathogenesis of peptic ulcer. Additionally *Hp* is associated with the development of gastric epithelial hyperplasia and lymphoid malignancies. The International Agency for Research on Cancer has classified *Hp* as a class I carcinogen and a definite cause of gastric cancer in humans. *Hp* infection first causes chronic active gastritis and may slowly lead to infection of whole stomach. In the late stages of infection, mucosal atrophy and intestinal metaplasia (IM), and even dysplasia (DYS) occur^[1]. Chronic atrophic gastritis (CAG), IM and DYS are considered markers for development of gastric cancer in high-risk individuals. In our study we analyzed *Hp* infection prevalence in 486 patients with precancerous gastric lesions.

MATERIALS AND METHODS

The mucosal biopsy specimens were collected from 486 patients subjected to routine gastroscopy, including 163 cases of CSG, 207 cases of CAG, 71 cases of IM and 45 cases of DYS. Biopsies were taken from five sites in the stomach: one from the antrum, four from the lesser and greater curvature of gastric body and gastric antrum. Each biopsy was classified according to the presence or absence of CSG, CAG, IM and DYS, and scanned by Warthin-Starry method.

Data analysis was made with *Chi-square* test. Statistical significance was defined as $P < 0.05$.

RESULTS

Table 1 Relation between precancerous gastric lesions and age and sex

Variables	n	CSG		CAG		IM		DYS	
		n	%	n	%	n	%	n	%
Sex									
Male	314	96	30.6	142	45.2	43	13.7	33	10.5
Female	172	67	38.9	65	37.8	28	16.3	12	7
Age (yrs)									
≤40	184	64	34.9	98	53.5	13	7.0 ^a	9	4.6 ^b
41-55	171	52	30.3	70	41.2	30	17.3	19	10.8
≥56	131	40	30.5	46	35.4	28	21.1 ^a	17	13.0 ^b

^a $P < 0.05$, ^b $P < 0.05$.

Gastric pathology data was available for 486 cases. As shown in Table 1, there was no significant difference between the two sexes ($P > 0.05$), but the prevalence rates increased with age, being significantly higher in ≥56 age group than ≤40 group for IM and DYS ($P < 0.05$).

Table 2 *Hp* infection rate in precancerous gastric lesions

Variables	n	Hp(+)		Hp(-)	
		n	%	n	%
CSG	163	39	23.9	124	76.1
CAG	207	88	42.5 ^a	119	57.5
IM	71	54	76.1 ^b	17	23.9
DYS	45	40	88.9 ^c	5	11.1

^a $P < 0.05$, CAG vs CSG; ^b $P < 0.01$, IM vs CSG; ^c $P < 0.01$, DYS vs CSG.

The prevalence of *Hp* increased steadily with increasing severity of gastric histopathology (Table 2). The detection rates of *Hp* in IM (76.1%) and DYS (88.9%) were significantly higher than that in CSG (23.9%, $P < 0.01$), and in CAG than in CSG ($P < 0.05$).

Table 3 *Hp* infection distribution in precancerous gastric lesions by biopsy sites

Variables	n	ALC		AGC		A		BLC		BGC	
		n	%	n	%	n	%	n	%	n	%
CSG	39	37	94.9	36	92.3	32	82.1	18	46.2	10	25.6
CAG	88	84	95.4	80	90.9	78	88.6	53	59.9	41	46.2
IM	54	49	90.7	46	85.2	40	74.1	34	62.7 ^a	32	58.8 ^a
DYS	40	36	90.0	33	82.5	30	75.0	28	70.0 ^b	26	63.9 ^b

ALC:antral lesser curvature; AGC:antral greater curvature; A: angulus; BLC:body, lesser curvature; BGC:body, greater curvature

^a $P < 0.05$, IM vs CSG; ^b $P < 0.05$, DYS vs CSG.

As shown in Table 3, the prevalence of *Hp* positivity tended to increase from BLC to BGC, *Hp* positive rates in IM and DYS were significantly higher than that in CSG in both BLC and BGC ($P < 0.05$).

DISCUSSION

The first compelling evidence linking *Hp* infection to gastric carcinoma was generated by seroepidemiologic studies^[2,3], bacterial seropositivity was significantly more common in those with gastric adenocarcinoma, with an odds ratio ranging from 2.8 to 6.0, suggesting a strong association between *Hp* and gastric malignancy.

Hp infection was related to both the intestinal and diffuse types of cancer as well as the precancerous lesion of IM or DYS^[4], and greater than 70% of gastric carcinomas are linked to IM, although DYS may also be seen without neoplastic disease.

Our study demonstrated that the prevalence rates of precancerous lesions varied with age, for IM and DYS, it had an upward trend with aging, while for CSG, it had a downward trend with aging, but were not different between the two sexes. The prevalence

rose steadily with increasing severity of gastric histopathology, the detection rates of *Hp* in CAG (42.5%), IM (76.1%) and DYS (88.9%) were significantly higher than that in CSG (23.9%), suggesting that *Hp* may play a role in late as well as early stages of carcinogenesis.

Our study also showed that *Hp* positive rates in IM and DYS were significantly higher than that in CSG in the lesser and greater curvature of gastric body, suggesting the more serious the gastric histopathology, the higher the *Hp* infection rate, furthermore, the higher level of *Hp* infection site. The study suggests we should take multiple site biopsy for histopathology and *Hp* examination.

Zhang FX, Zhang XY, Fan DM, Deng ZY, Yan Y, Wu HP, Fan JJ. Antisense telomerase RNA induced human gastric cancer cell apoptosis. *World J Gastroentero*, 2000;6(3):430-432

INTRODUCTION

Human tissue homeostasis is precisely regulated by cellular division, differentiation and death. Normal human somatic cells progressively lose telomere restriction fragment (TRF) length with each successive cell division, eventually leading to cellular quiescence, chromosomal end-degradation and apoptosis^[1]. On the contrary, stabilization of telomere lengths by expressing telomerase, an RNA-dependent DNA polymerase, may be involved in cellular immortality and carcinogenesis^[2-4]. Changes of telomerase activity and telomere lengths have been found in almost all human cancers^[4-10], but the evidence of their relationship with immortalization of cancers cell remain to be directly demonstrated. Since shortened telomere was first discovered in Hela cells with antisense RNA techniques in 1995^[11], anticancer agents based on inhibition of telomerase RNA have been reported^[12,13]. However, the relationship between telomerase inhibition and cell apoptosis has not been fully understood. In this study, we investigated the effect of blocking telomerase activity on apoptosis of human gastric cancer cells *in vitro* using an antisense vector for human telomerase RNA component (hTR) into human gastric cancer cells.

MATERIALS AND METHODS

Reagents

EcoRI, *BaI* I, *SaI* I, SP6 or T7 polymerases (Promega), hygromycin (Boehringer Mannheim) and lipofectamine (Gibco BRL) were commercially obtained. Antisense hTR expression construct vector (pBBS212) and hTR recombinant plasmid (pGRN83) were kindly donated by Dr Villeponteau (Geron Corporation, USA).

Cell line

The human gastric cancer cell line SGC7901 (Fourth Military Medical University, China) was cultured in RPMI1640 (Gibco BRL) containing 100 mL/L fetal bovine serum.

Transfection of antisense hTR expression vector

The TRC₃ piece (hTR) was flanked by 2 *EcoRI* sites and was inserted into *EcoRI* site of pBBS212 to make the plasmids pBBS-hTR, which can express the antisense of hTR under the MPSV promoter^[11,14]. Cells at density of 2×10^5 /well (2 mL) in 6 well plates were transfected with purified plasmids (pBBS-hTR) and a selectable marker, hygromycin, by lipofectin procedure as described^[15]. As a control, cells were transfected either with an hTR-free plasmid (pBBS212) containing hygromycin marker or with hygromycin alone. Four clonal cells from each group were used for a series of experiments.

hTR expression by blot hybridization

Total RNA was prepared from each group cells by RNA isolation kit (Promega). PGR N83 was lined with *BaI* I or *SaI* I and transcribed *in vitro* using T7 RNA polymerase and SP6 RNA polymerase respectively. The transcription was carried out according to the manufacturer's instructions in the presence of 370GBg [α -³²P]UTP (Beijing Huri Co, China). Then a sense hTR or antisense hTR probe synthesized was used for RNA blot hybridization^[15].

Telomerase assay

Cell extracts were prepared by detergent CHAPS (Pierce), and telomerase activity was measured by telomeric repeat amplification protocol (TRAP) methods as described by Kim *et al*^[5,16]. The TRAP reaction products were separated by 100 g/L polyacrylamide gel electrophoresis and autoradiographed. The basal level of telomerase activity was measured by serial dilution of the protein extracts.

Determination of TRF length

Genomic DNA extracted from the gene transfected cells and the control cells were digested with *HinfI* and *RsaI*. DNA samples (8 μ g each) were loaded onto a 8 g/L agarose gel and electrophoresed for bromophenol blue to the bottom of gel at 90V. The gel was dried, denatured, neutralized and hybridized to a 5'-[³²P](TTAGGG)₄ probe (T₄ polynucleotide kinase, Promega) and *autoradi-*

ographed 48 h at -20°C ^[2,17].

Cell cycle analysis

Cells in log phase growth were collected, washed twice with phosphate buffered saline (PBS) and fixed in 70 mL/L ethanol at 4°C overnight. Cells were washed with PBS, digested with 20 mg/L RNase A at room temperature for 1 h, and then resuspended in 50 mg/L propidium iodide solution. Cell cycle was analyzed on the FAC/Scan (ELITEESP, Coulter Co) using a computer program interfaced with the integrator.

Ultrastructural observation

Ultrastructure in the gene transfected cells was observed under a transmissive electron microscope (JEM-2000EX, Japan).

RESULTS

Antisense telomerase RNA inhibited the sense telomerase RNA expression in the gene transfected cells. Antisense hTR expression was high and sense hTR expression was weak in RNA blot hybridization analysis (Figure 1). Sense hTR suppression rate analyzed by thin layer scanning reached 60% (Figure 1). Antisense RNA to hTR mediating telomerase activity was down-regulated in the gene transfected cells but not in the control plasmids transfected cells (Figure 2). Mean TRF length of

the gene transfected cells (11.0 ± 5.6) was also shorter than that of the control plasmids transfected cells (Figure 3). Compared with the control plasmids transfected cells, G1 phase decreased by 25% in the gene transfected cells and its apoptotic peak reached in 46.2% of cell cycle in a computer apoptotic program analysis (Figure 4). Either denaturation and necrosis or chromatin compaction and apoptotic body appeared in the gene transfected cells while the non-gene transfected cells showed no changes of this kind (Figure 5).

DISCUSSION

Cell apoptosis is closely associated with tumorigenesis, tumor growth and tumor metastasis. Changes of telomere lengths may play an important role in maintaining cell division, proliferation, apoptosis and immortalization^[2,4]. Normal human somatic cells progressively lose their telomeric sequence with replicative senescence till cell "crisis" or apoptosis occurred^[4,18,19]. In contrast, almost all tumor cells and tissues express telomerase and maintain telomere length through an indefinite number of cell divisions^[4-10,19-24]. Antisense hTR, hammerhead ribozyme TeloRZ and antisense oligonucleotide against hTR could suppress tumor cell growth by inhibiting telomerase activity or shortening TRF length^[11-13]. Therefore, it has been proposed that antisense RNA based on telomerase inhibition may potentially reverse uncontrolled proliferation of tumor cells and induce apoptosis of cancer cells^[25,26]. The present study is undertaken to investigate the possible relationship between the antisense hTR expression and apoptosis of human gastric cancer cells.

Our study has demonstrated that the antisense hTR expression level of SGC7901 cells was high. Based on the histogram of flow cytometry, G1 phase was arrested and there was a typical apoptotic peak in the antisense hTR expression vector transfected cells. Meanwhile, compaction of nuclear chromatin and apoptotic body were observed under a transmissive electron microscope. These results suggest that antisense hTR may mediate apoptosis of human gastric cells. Also, we have found that the antisense hTR expression of SGC7901 cell could down-regulate telomerase activity and shorten telomere length. This supports the changes of telomere length and telomerase activity in antisense hTR transfected tumor cells^[11,12], indicating that telomerase can mediate telomeric sequence replication in gastric cancer cells

and that shortening of telomere length by the antisense hTR may be associated with apoptosis of human gastric cancer. Thus, the induction of cell apoptosis in SGC7901 cells expressing antisense hTR demonstrates the potential of telomerase inhibition as a therapeutic target for human cancer.

INTRODUCTION

The efficacy of chemotherapy in the treatment of cancer patients is often hampered by the presence or appearance of multidrug resistance (MDR) of tumor cells. One of the most important mechanisms of MDR is overexpression of P-glycoprotein (Pgp) which is encoded by *mdr1* gene^[1]. Recently, another MDR-related protein, lung resistance protein (LRP), has been identified^[2]. Our primary study indicated that LRP overexpressed in gastrointestinal carcinoma^[3]. In this paper, the expression of LRP in human gastric carcinoma and its significance were studied.

MATERIALS AND METHODS

Patients

All the 36 patients (21 men, 15 women; aged 32-78 years, mean age 54.6 years) were in-patients of our hospital admitted between September 1997-August 1998 and surgically resected specimens were diagnosed as adenocarcinoma by pathologists. No patients received chemotherapy before operation.

Methods

The expression of LRP in tumor tissues was detected by SABC (streptavidin-biotin complex) immunohistochemical staining as described before^[4], and in 14 of 36 specimens, the LRP was also analysed by flow cytometry (FCM), the matched mucosas served as normal controls, and peripheral blood lymphocytes as negative controls. The specific LRP monoclonal antibody LRP-56 was kindly supplied by Dr. R.J. Scheper

(Department of Pathology, Free University Hospital, Amsterdam, the Netherlands), and the SABC immunohisto-chemical kit was purchased from Boster Biotechnology Company (Wuhan).

RESULTS

Expression of LRP in gastric carcinoma tissues

The LRP positive rate was 72.2% (26/36). LRP immunoreactivity was cytoplasmic, and in some specimens, the interstitial cells were also LRP immunostained. The intensity of the reactions was frequently strong and, in general, most of the cancer cells were LRP-positive in LRP-positive tissues.

Expression of LRP and pathologic parameters

The relationship between LRP expression and pathologic parameters is shown in Table 1. The LRP expression in highly and moderately differentiated carcinoma (9/9) was higher than that in mucoid carcinoma (6/11). There was no association between LRP expression and tumor size, lymphodal involvement, serosal invasion, or TNM stages.

Expression of LRP detected by FCM

LRP expression was at low to moderate levels in gastric cancer tissues (0%-20% in 10 patients, 21%-40% in 2 patients, and 41%-60% in 2 patients), and the mean LRP positivity rate was $29.9\% \pm 9.8\%$, significantly higher than that in normal ($16.9\% \pm 7.5\%$, $t = 3.94$, $P < 0.01$) and negative controls ($1.72\% \pm 0.23\%$, $t = 5.63$, $P < 0.01$).

DISCUSSION

LRP is the human major vault transporter protein and is suggested to confer anticancer drug resistance. The mechanism that LRP confers MDR is unknown, but concerning the reduced nuclear accumulation of daunorubicin in the LRP-overexpressing MDR cell line 2R120 and the evidence supporting a role of vaults as transporter unit of the nuclear pore complexes, it is tempting to hypothesize that LRP can mediate drug resistance by regulating both the cytoplasmic redistribution and the nucleocytoplasmic transport of drugs^[5]. LRP was overexpressed in ovarian cancer, leukemia, and several cancer cell lines of MDR phenotype, and LRP is of high predictive value for response to chemotherapy and prognosis^[6,7]. Ikeda *et al*^[8] quantitated the level of LRP mRNA expression in 10 gastric cancer cell lines by RT-PCR, and examined the relationship between its level in these cells and their sensitivities to anticancer drugs. LRP mRNA was expressed in all cell lines, and LRP correlated with the resistance to cisplatin. But up to now, there has been no study about LRP expression in specimens of gastric cancer and the relationship between LRP expression and pathologic parameters. Our study revealed that LRP was frequently overexpressed in untreated gastric cancer, suggesting that gastric carcinoma holds high intrinsic resistance. Analysis of LRP can help evaluate the chemosensitivity of patients to anticancer drugs, and choose more effective drugs.

Meanwhile, our results disclosed that LRP positivity rates in well and moderately differentiated carcinomas were 100%, in poorly differentiated cancer was 11/16, and in mucoid carcinoma was 6/11, showing the descending tendency, and LRP positivity rate in patients with well and moderately differentiated adenocarcinoma was higher than that in mucoid carcinoma, which was consistent with the clinical observation that well-differentiated cancer cells have less satisfactory chemosensitivity than poorly differentiated. LRP expression was independent on tumor size, lymph nodal

involvement, serosal invasion, and TNM stage, indicating that these parameters represent the progression of the tumor only, and have no correlation to chemotherapy drug sensitivity. Our previous studies showed that *mdr1* mRNA and MRP were overexpressed in gastric carcinoma^[9,3], and the present study demonstrated that LRP overexpressed in gastric cancer, suggesting that MDR can be mediated by all of them simultaneously, and combined administration of different MDR reversing agents, which can overcome MDR by increasing the intracellular drug accumulation of cancer cells, could achieve a better effect.

A study on arsenic trioxide inducing *in vitro* apoptosis of gastric cancer cell lines

Qin Long Gu¹, Ning Li Li², Zheng Gang Zhu¹, Hao Ran Yin¹ and Yan Zhen Lin¹

Subject headings Arsenic Trioxide (As₂O₃); gastric cancer cell; apoptosis

Gu QL, Li NL, Zhu ZG, Yin HR, Lin YZ. A study on arsenic trioxide inducing *in vitro* apoptosis of gastric cancer cell lines. *World J Gastroentero*, 2000;6(3):435-437

INTRODUCTION

Cell apoptosis, which involves the biologic regulation of the numbers and vital activity of cells, is an important metabolic process in both normal cells and tumor cells. Delayed process of cell apoptosis will probably lead to a disturbance of metabolism, and occurrence and development of neoplasms. Song *et al* have proved the relationship between apoptosis delay and tumor development through inhibition of cell apoptosis induced by tumor promotor^[1]. Thus, induction of cell apoptosis could be a new strategic measure against tumor. In this paper, we studied whether arsenic oxide will induce apoptosis of gastric cancer cell lines (GCCL) to explore the use of such chemical agent against gastric cancer in clinic.

MATERIALS AND METHODS

Target cells

Human gastric cancer cell lines, MKN45 and SGC7901 (provided by Chinese Academy of Sciences) were used as target cells. Human leukemia cell line K562 and human peripheral blood lymphocytes (PBL) were used as controls. All of cells were cultured in RPMI 1640 medium (GIBICO-BRL), supplemented with 10% heat-inactivated fetal calf serum, 100U/mL penicillin and 100mg/mL streptomycin, in a humidified atmosphere of 95% air/5% CO₂ at 37°C. The numbers of four kinds of cells were maintained at 1 × 10⁶/mL by daily adjusting cell concentration.

Product of arsenic trioxide (As₂O₃)

Ai-Lin No.1 containing As₂O₃ was prepared by pharmacy of our hospital. Stock solution was made at the concentration of 1mmol/L with phosphate-buffered saline (PBS) and diluted with RPMI 1640 to working concentration before use.

Cytocide test

MTT[3-(4,5-dimethylthiazoyl-2-yl)2,5-diphenyltetrazoliumbromide]colorimetric analysis was used to measure the cytocide rate of As₂O₃. Well grown cells were collected and were put into 96 well culture plate at 1 × 10⁴/well. As₂O₃ was added to culture plate at the concentration of 5 μmol/well, while cells stuck on wall, 6 duplicate wells were set up in each sample in both experimental and control groups. Cells were cultured for 24 h, 48 h and 72 h separately, MTT(5 mg/mL) was added at 10 μL/well. Acidulated isopropanol was finally added at 100 μL/well-after 2 h culture; values of OD570 were obtained on autocolorimeter. Cytocide rate was calculated by the following formula:

$$\text{Cytocide rate(\%)} = \frac{\text{Control OD} - \text{Experimental OD}}{\text{Control OD}} \times 100\%$$

Apoptosis detection

Cell treatment MKN45 and SGC7901 cells of 10⁶ were treated with As₂O₃ of the concentration of 5 μmol and 10 μmol, or with 5-Fu (0.5 g/L), or without any treatment as control. Cells were harvested after 24 h, 48 h and 72 h culture for apoptosis detection.

TDTlabel Consulting Gregory modified method^[2]: PBS containing 1% formalin was added to cells at 4°C. Thirty min later, it was washed twice with PBS, then reacted with 0.5 μg terminal deoxynucleotidyl transferase (TDT) and 0.5 μmol biotinylated dUTP at 37°C for 30 min. Afterwards it was washed again with PBS, finally labelled by affinitin-fluorescein isothiocyanate (FITC) at room temperature for 30 min. DNA strand will be broken off during apoptosis, which can be labelled by dUTP and the positive observable fluorescences were seen under fluorescent microscope.

Flow cytometry(FCM) assays and fluorescent photographing The stimulating wave length of FCM (Becton Dickson FAC Scan) is 488 nm, FITC detection spectrum is between 80 and 630 nm. A total of 2000 cells were counted. Results were recorded and analyzed automatically.

Preparation of specimen for electronic microscopy
MKN45 cells treated with As_2O_3 of concentration of $10\ \mu\text{mol}$ for 72 h were washed with PBS and fetal calf serum; 25% glutaraldehyde was added to fix the cell specimens for 12 h. Then it was washed twice with $0.1\ \text{mol/L}$ phosphoric buffer solution; the specimens were fixed with 1% osmic acid, and were dehydrated step by step with alcohol and acetone; then covered up with Epon 812 epoxy resin. Sections were made by ultramicrotome and dyed with uranium acetate and citric acid, and finally observed under transmission electronic microscope.

RESULTS

Cytocidal rate of As_2O_3 on GCCL

Our results showed that As_2O_3 had higher cytotoxicity on GCCL than on K562 ($P < 0.05$). The effect of cytocidal was observed at 24 h after reaction, and it increased with time (Table 1).

Table 1 Cytocidal effects of As_2O_3 ($5\ \mu\text{mol}$) on various cell categories (% $\bar{x} \pm s$)

Group	MKN45	7901	K562	PBL
24 h	69.45 ± 11.12	68.27 ± 8.27	51.36 ± 10.25^a	30.31 ± 5.12^b
48 h	71.40 ± 10.15	69.04 ± 11.31	57.11 ± 7.45^a	35.67 ± 4.37^b
72 h	80.53 ± 10.18	82.74 ± 9.14	65.33 ± 8.24^a	39.74 ± 8.27^b

Comparison of cytocidal rate between GCCL and controls by As_2O_3 , $^aP < 0.05$ ($t > 2.2262$), $^bP < 0.01$ ($t > 3.250$).

Table 2 Apoptosis rate (%) of MKN45 by different treatment methods ($\bar{x} \pm s$)

Group	Controls	5-Fu	As_2O_3 1	As_2O_3 2
24 h	4.71 ± 0.36	18.04 ± 1.50	32.33 ± 3.75^a	60.02 ± 7.41^b
48 h	14.90 ± 0.94	24.39 ± 3.45	90.59 ± 10.35^b	97.05 ± 8.24^b
72 h	28.98 ± 3.12	41.47 ± 2.24	98.10 ± 13.24^b	98.75 ± 11.53^b

Comparison of apoptosis rate between As_2O_3 and 5-Fu group, $^aP < 0.05$ ($t > 2.2262$), $^bP < 0.01$ ($t > 3.250$).

GCCL apoptosis rate induced by As_2O_3

As shown in Table 2, apoptosis rates of 2 kinds of GCCL induced by 5-Fu were also obviously higher than natural cell apoptosis rate, of controls, which suggested that antitumor drug can kill tumor cells by inducing cell apoptosis. Nevertheless, a more significant cytocidal effect of As_2O_3 on GCCL was demonstrated in our study compared with that of 5-Fu. We found that apoptosis rate of GCCL induced by As_2O_3 is correlated with the concentration and reaction time of As_2O_3 (Table 3).

Table 3 Apoptosis rate (%) of SGC7901 by different treatment methods ($\bar{x} \pm s$)

Group	Controls	5-Fu	As_2O_3 1	As_2O_3 2
48 h	7.44 ± 0.60	34.28 ± 4.15	51.33 ± 5.16^a	78.31 ± 9.14^b
72 h	30.90 ± 2.54	56.32 ± 4.56	78.15 ± 6.78^a	89.28 ± 10.26^b

Comparison of apoptosis rate between As_2O_3 and 5-Fu group, $^aP < 0.05$ ($t > 2.2262$), $^bP < 0.01$ ($t > 3.250$).

The morphology of GCCL apoptosis under fluorescent microscope:

Under fluorescent microscope, the apoptosis cell can be seen after being terminally labelled (positive), but nonapoptotic cells were not labelled by fluorescein isothiocyanate (negative). The positive staining showed bright green fluorescence. Fluorescent spots appeared in early stage, and these fluorescent bodies gathered like a bunch of grapes in late stage. The cellular volume can be seen shrunken under the microscope.

The morphology of GCCL apoptosis under electronic microscope:

Under the transmission electronic microscope, typical morphologic changes of apoptotic GCCL (mainly cell nucleus) took place after treatment of As_2O_3 . These changes included cell nucleus fixation and shrinkage of GCCL, chromatin condensation, and fragmentation of apoptotic bodies. These changes coexisted.

DISCUSSION

Some researchers have proposed that the uncontrolled growth of neoplasms would be due to the loss of the nature of autoapoptosis rather than over proliferation. Previous studies have proved that there existed autoapoptosis blockage in tumor cells. Lauwers *et al* [3] examined bcl-2 gene in 46 cases of gastric adenocarcinoma by immunochemical method, revealing 75% positivity. Of bcl-2 gene in tumor tissues, which indicated that apoptosis was blocked in gastric cancer. Bcl-2 has been considered as one of survival genes which plays an important role in the specific-inhibition of tumor cell apoptosis [4]. Based on these findings, a new proposal of inducing apoptosis to inhibit tumor growth was introduced [5]. Many factors such as high temperature, cytokine, radiations and all kinds of anti-tumor chemotherapy drugs have a certain effect on inducing tumor cells apoptosis. But some of these are not satisfactory. Our aim is to find a specific-agent which can induce apoptosis of tumor cells. Vollmers *et al* [6] reported the suppressive effects of monoclonal antibody (SC-1) on both *in vitro* proliferation of gastric cancer cell line and growth of a tumor inoculated on nude mice. The inhibition of proliferation of tumor cells was produced through the induction of autoapoptosis, which has been proved by the observation of ultrastructure.

Arsenic is a major composition of traditional Chinese medicine, white arsenic. White arsenic has been considered as a carcinogen. It can inactivate some important enzymes in cells, change the metabolic process and induce chromosome aberration [7]. Zhang *et al* [8] reported a satisfactory result by using As_2O_3 for the treatment of early acute promyelocytic leukemia (APL). Complete remission was 73.3% in patients after the first therapeutic course, and 52.83% in recurrent

patients. The longest remission period of APL patient was over 10 years. No obvious toxic reactions were found when As₂O₃ was given by iv drip, which is appropriate. Similar result has also been obtained by researchers at Shanghai Institute of Hematology of Shanghai Ruijin Hospital^[9,10]. Recently, Zhang *et al*^[11] demonstrated that Arsenic Oxide can inhibit growth of lymphosarcoma cells and induce apoptosis to these cells.

Based on the above studies, we applied As₂O₃ for the treatment of GI solid tumor. The results from *in vitro* study are impressive. Proliferation of MKN45 and SGC7901 was inhibited by As₂O₃ through apoptosis induction. Results also showed that As₂O₃ has a stronger effect of apoptosis induction than 5-Fu. Induction of apoptosis was enhanced with increase of concentration and time of As₂O₃. The question is what the optimal dosage is for clinical use so as to produce maximal effect with no toxicity. Further comprehensive researches are needed to clarify the significance of As₂O₃ for the treatment of GI solid tumors.

Relationship between collagen IV expression and biological behavior of gastric cancer

Zhen Ning Wang and Hui Mian Xu

Subject headings stomach neoplasms; collagen IV; biological behavior; immunohistochemistry

Wang ZN, Xu HM. Relationship between collagen IV expression and biological behavior of gastric cancer. *World J Gastroentero*, 2000;6(3): 438-439

INTRODUCTION

Conceivably the presence of basement membrane (BM) in a neoplasm might be a result of interaction of tumor cells with the extracellular matrix. Collagen IV is one of the major intrinsic components of BM. Recent study^[1] has shown that collagen IV has cell adhesion function and is involved in the process of tumor invasion and metastasis, including colorectal cancer^[2] and breast cancer. But there are few systematic studies on gastric cancer and the results are equivocal. In this study we evaluated the expression of collagen IV immunohistochemically in 148 advanced gastric cancer cases in an attempt to clarify the relationship between the patterns of expression and the biological behavior of gastric cancer.

MATERIALS AND METHODS

Patients

Surgical specimens (148) of gastric carcinomas resected at the Oncology Department of China Medical University from 1988 to 1992 were studied. Routinely formalin-fixed and paraffin-embedded tissue blocks were sectioned at 5 μ m thickness. HE-stained slides were also collected and available.

Immunohistochemistry

The avidin-biotin-peroxidase complex (ABC) method by Hsu *et al*^[3] was applied. Briefly, paraffin sections were deparaffinized, dehydrated and pretreated with pepsin (0.1% in 0.1M- HCl for one hour at 37°C) to restore the immunoreactivity to type IV collagen. After blocking of endogenous peroxidase with 0.3% H₂O₂ in methanol and

washing in phosphate-buffered saline (PBS) for 3 \times 5 min, the sections were incubated with anti-collagen IV monoclonal antibody (Dako Putts Co., diluted 1:75) overnight at 4°C in a moist chamber. After washing in PBS the sections were incubated with secondary antibody for 30 min and ABC for 60 min at 37°C, then sections were stained with 0.05% DAB freshly prepared to visualize the immunoreactivity. Tumors were classified as "positive" with regard to the immunoreactivity for collagen IV when there was unequivocal immunostaining of the matrix components at least in one representative area of the tumor.

Statistical analysis

Statistical analysis was performed by χ^2 test.

RESULTS

Collagen IV stained the basement membrane of normal gastric glands and vessels and also the basement membrane of the smooth muscle cells in the muscular layers of the gastric wall.

Relationship between collagen IV expression and histological type, growth pattern of gastric cancer

Seventy patients (47%) has continuous or, more frequently, disrupted linear structures around cancerous gland ducts or solid nests of tumor cells. The positive rates in undifferentiated or signet ring cell cancers were much lower than those in other cancers ($P < 0.01$). Fifty-five percent of carcinomas with the nest-fashioned growth pattern showed collagen IV positive staining (Table 1), which was slightly lower than the percentage of collagen-IV positive carcinomas with mass-fashioned growth pattern, but significantly higher than that of diffuse-gastric carcinomas ($P < 0.01$).

Relationship between the distribution of collagen IV and liver metastasis of gastric cancer

The distribution patterns of collagen IV in cancer tissue in gastric wall are quite different. Collagen IV was seen less often in the deep layer than in the mucosa. Collagen IV positive BM was found in 70 (47%) of 148 patients in the mucosa and only 36 (24%) in the deep layer of stomach. Based on the difference of collagen IV distribution, we divided the cases into three groups as follow: Group A, tumors positive for collagen IV in both mucosa and deep layer; Group B, tumors positive for collagen IV in mucosa but negative in deep layer; Group C,

Received 2000-01-05 **Accepted** 2000-02-26

tumors negative for collagen IV. From Table 2, we can find that liver metastasis rate in Group A is much higher than that in Group B or C ($P < 0.01$).

Table 1 Relationship between collagen IV expression and histological type, growth pattern of gastric cancer

Type	Number	Collagen IV n(%)	
		(+)	(-)
Growth pattern			
Mass-like	56	43(77)	13(23)
Nest-like	38	21(55)	17(45)
Diffuse	54	7(13)	47(87)
Histological type			
Well differentiated	37	30(81)	7(19)
Moderately differentiated	22	13(59)	9(41)
Poorly differentiated	23	10(43)	13(57)
Undifferentiated	27	3(11)	24(89)
Signet-net cell	25	2(8)	23(92)
Mucoid	14	12(86)	2(14)

Table 2 Relationship between the distribution of collagen IV and liver metastasis of gastric cancer

Liver-metastasis	Group A n = 36(%)	Group B n = 34(%)	Group C n = 78(%)
(+)	10(28)	2(6)	1(1)
(-)	26(72)	32(94)	77(99)

The blood vessels BM in gastric wall are also positively stained

In differentiated carcinoma, a large number of blood vessels were observed in the vicinity of cancer glands and collagen IV was localized around the blood vessels and cancer glands. But in poorly differentiated carcinoma, only a small number of blood vessels were distributed sporadically in stroma. In addition, vasoinvasion of tumor cells were highlighted by collagen IV immunostaining of the blood vessels BM.

DISCUSSION

Normal basement membrane is one of the biological barriers to tumor invasion and metastasis. In carcinomas, a dynamic interaction occurs at the interface between tumor cells and the surrounding extracellular matrix components. Tumor cells not only destroyed the basement membrane by producing collagenase, including the specific type IV collagenase, but also synthesize the components of basement membrane^[4]. And also as a host reaction to the invading tumor, extracellular matrix components may be deposited around the tumor cells. The appearance of these components may symbolize the characteristic of the tumor and reflect its biological behavior. Collagen IV is one of the major components of the basement membrane, Burtin *et al*^[5] showed that expression of collagen IV was related to the differentiation of the colorectal cancer.

Histological growth pattern could be considered as the objective indicator of the biological behavior of gastric cancer. In this study, we found that the presence of collagen IV containing basement membrane was closely related to the growth

pattern. In mass or nest-fashioned growth pattern of gastric carcinomas, continuous or disrupted linear structures stained positively for collagen IV can be seen around cancerous glands or solid nests of tumor cells. But only a few scattered spots or patches were positively stained in diffuse gastric carcinomas, most of which were undifferentiated or signet ring cell carcinomas. Our study demonstrated that the attenuation or absence of collagen IV expression was frequently seen in poorly differentiated and diffusely infiltrating gastric cancers. That is, the loss and irregular distribution of collagen IV expression could be considered as a biological marker of cancer cells which had strong invading ability. This finding may be concerned with these tumor cells which could produce collagenase with higher activity or had poorer potential of collagen IV synthesis.

The prognosis of patients with advanced gastric cancer is poor because the likelihood of recurrence is high. The most common patterns of recurrence are peritoneal implantation and liver metastasis. According to our study, the distribution patterns of collagen IV are related to liver metastasis in gastric cancer. Positive expressions of collagen IV in mucosa and deep layer of gastric cancer are accompanied by much higher incidence of liver metastasis. Vascular spreading of gastric cancer, which is different from direct invasion, is a multi-step process in which cells must migrate from the primary tumor and invade blood vessels. David L *et al*^[6] found that the expression of collagen IV was related to invading potential of tumor cells to blood vessels. All these findings support the hypothesis that collagen IV may play an important role in the metastatic process after migration from the primary tumor. The principal mechanism is an interesting subject for further studies. In conclusion, collagen IV-positive basement membrane in the deep layer of gastric wall in cancer tissue might be a risk factor for liver metastasis. In addition, collagen IV immunostaining facilitates recognition of vasoinvasion by highlighting the basement membrane of vessels.

The effect of mast cell on the induction of *Helicobacter pylori* infection in Mongolian gerbils

Jing Chi¹, Miao Lu¹, Bao Yu Fu¹, S Nakajima² and T Hattori²

Subject headings diseases models, animal; Mongolian gerbils; *Helicobacter pylori*; mast cell; *Helicobacter* infections

Chi J, Lu M, Fu BY, Nakajima S, Hattori T. The effect of mast cell on the induction of *Helicobacter pylori* infection in Mongolian gerbils. *World J Gastroentero*, 2000;6(3):440-441

INTRODUCTION

Since 1982, *Helicobacter pylori* (Hp) has been successfully isolated and cultured^[1], and the fact many diseases such as gastritis, peptic ulcer, gastric carcinoma and gastric lymphoma were related to Hp, and Hp as an etiological organism, has attracted much attention. In 1991 Yokata *et al*^[2] first induced the Hp infection in Mongolian gerbils. From then on researches on Hp infection and its eradication exploded worldwide. Nakajima *et al*^[3] reported that mast cells were increased in gastric mucosa and submucosa of patients with Hp infection and found degranulated mast cells in these tissues. Now it is known that high affinity IgE and Fc segment receptors exist on the mast cell surface. When IgE bound to these receptors, mast cells degranulated and then many kinds of bioactive mediators were secreted so that the inflammatory process could be effected. Therefore it is extremely important to understand the relationship between degranulation of mast cells in the mucosa infected with Hp and the inflammatory response, and to conjecture of the effect of mast cells on the pathogenesis of Hp infection. This study observed the inflammation of gastric mucosa and the morphology, density, distribution and degranulation of mast cells in the infected gerbils using the histochemical or immunohistochemical methods and electron microscopy to elucidate the effect of mast cells on the pathogenesis of Hp infection.

MATERIALS AND METHODS

Animals

Thirteen male Mongolian gerbils infected with Hp for 1mo to 3 mos were allocated to the experimental group, while 5 male Mongolian gerbils with out Hp infection to the control group.

The induction of animal models

Six-week-old specific pathogen-free/sea male Mongolian gerbils and Hp ATCC 43504 were used. The gerbils were subjected to ATCC 43504 and ethanol treatment according to the method described by Hirayama *et al*^[4]. Normal subjects were treated with the same amount of Brucella Broth. The gerbils infected with Hp were injected with BrdU subcutaneously one hour before sacrifice. A portion of the stomach was fixed in MFAA^[5] and embedded in paraffin, and cut in sequential 3 µm-4 µm section for light microscopy; the remainder was fixed in 25 g/L Glutaldehyde, serially dehydrated in ethanol, postfixed in 10 g/L osmium acid, embedded in Epon, and cut in 60 nm ultrathin sections for electron microscopy.

Staining of mast cells

Alcian blue (AB1.0)/ PAS staining The immunohistochemical staining of anti-mast cell monoclonal antibody, MSRM4 (produced by Moredum Scientific Limited Co. Britain, diluted 200 folds) by LsAB method was applied.

Double-staining AB staining was followed by anti-BrdU Ab and anti-CD3 lymphatic Ab complex staining to observe the cellular marking rate of mast cells in S-phase and their relationship with T lymphocytes.

Staining for electron microscopy with uranyl acetate and lead citrate

Bactericidal treatment Positive group was defined at 6 mos after Hp infection and then was cured with triad treatment (Lansoprazole, Ampicillin, Clarithromycin) for 2 wks continuously. At wk 4, wk 8 and wk 12 after withdrawal of medication, the gerbils were sacrificed to observe the changes in distribution, amount and degranulation of mast cells before and after bactericidal treatment.

Counting of mast cells At the magnification employed (× 400), the positive mast cells in the mucosa and the epithelial layer in gastric antrum and body in 5 consecutive areas were counted and

their mean values represented the density of positive cells in this particular area. All the data according to different areas were divided into different groups for further statistic treatment and analysis compared with the normal subjects.

RESULTS

Light microscopy

Mast cells appeared blue stained with AB/ PAS and brown when immunohistochemical staining was used. Positive mast cells, filled with granules in cytoplasm, dispersed in epithelium, lamina propria and submucosa and also commonly in muscular layer, having a close relationship with the vessels and nerves in submucosa and muscular layer. All of the above picture rarely appeared in the gastric tissues of normal gerbils. At 2 wk after *Hp* infection, the mast cells began to increase in amount with a tendency of inflammatory-dependence, significantly different from the normal group ($P < 0.001$). On the double staining section, there existed varied amounts of blue heterophilic granules in the cytoplasm and the nucleus was brown. The mast cells with these morphologic characteristics corresponded to the cells in S-phase. The increase of cells in S-phase signified the active hyperplasia in the progression of inflammation. The double staining of CD3 and mast cells indicated that a great deal of mast cells were around the lymphatic follicles in which CD3 existed. The amount of mast cells decreased 1 mo after bactericidal treatment and recovered to the normal level 3 mos after treatment.

Electron microscopy

Under the normal circumstances, the specific high-electron density granules in cells were stable and existed independently, while in inflammatory state the mast cells were activated to degranulate and form vacuoles and tended to be vacuolated after the fusion of vacuoles.

DISCUSSION

It is well known that mast cells exist widely in trachea, digestive tract, skin and many other organs and play an important role in the pathogenesis of allergic reaction characterized by bronchial asthma and urticaria. Recent studies on mast cells found direct or indirect evidences to reveal the close relationship between the mast cells and the injury of gastric mucosa^[6]. The mast cells located in human gastroenteral tract and induced by pathogen or some antigens, may secrete bioactive substances such as

histamine and prostaglandin, which increase the secretion of gastric acid, and then trigger a series of events: the injury of tissues and the inflammation of mucosa. The rapid development in recent years on the cell culture and molecular biology provides the possibility of explaining that various cytokines can cause the activation and proliferation of mast cells and mast cells can produce and secrete these cytokines. TNF α , GM-CSF, IL-6 and IL-8 can act as the precursor in the local inflammatory reaction which leads to the infiltration of inflammatory cells, and at the same time modulates the development and proliferation of themselves-the autoregulative process. The results of this study showed that the mast cells in gastric mucosa with infection of *Hp* increased significantly, the infiltration of lymphatic cells depended on the appearance of mast cells and the conspicuous increase of degranulation of mast cells in inflammatory areas was related to the degree of gastritis. All of the above supported the fact that mast cells play a role in the occurrence and development of the pathogenicity of *Hp*. It has been reported that some of the mast cells have the function of extending and movement so that the mast cells can penetrate the basal membrane and move toward the interepithelial space. During the moving process, degranulation appears gradually, which results in the phenomena of vacuolation. Therefore, some researchers believe that mast cells of mucosa-type are the active state of mast cells of conjugated-type. At present, the mechanism of the degranulation of mast cells remains unclear. The relationship between mast cells and *Hp* infection and the effect of the mediator secreted by mast cells on the pathophysiology of *Hp* infected gastric diseases need further investigation.

Effect of *Helicobacter pylori* infection on gastric epithelial cell proliferation

Hong Gao, Ji Yao Wang, Xi Zhong Shen and Jian Jun Liu

Subject headings *Helicobacter pylori*; cell proliferation; vacAs1a strain; gastric epithelial cell

Gao H, Wang JY, Shen XZ, Liu JJ. Effect of *Helicobacter pylori* infection on gastric epithelial cell proliferation. *World J Gastroentero*, 2000;6(3):442-444

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is one of the main pathogens of chronic gastritis and duodenal ulcer (DU), and it may be considered as a risk factor in the incidence of gastric cancer^[1]. *H. pylori* infection may lead to the anomaly of gastric epithelial cell proliferation which is closely related to the development of gastric cancer. Vacuolating cytotoxin (VacA) is an important virulence and vacA subtype determines the toxic activity^[2]. According to its signal sequence, it can be grouped into type s1a, s1b, s1c and s2^[3,4]. Strains harboring vacAs1a are more closely related with digestive diseases^[5] and may be the strains with high toxicity. The effect of *H. pylori* infection on gastric epithelial cell proliferation depends on the vacA subtype^[6]. The report of the effect of strains with vacAs1a on gastric epithelial cell proliferation has not been found in China. We particularly study the effect of this strain in order to reveal whether the patients suffering from *H. pylori* infection have accelerated proliferation of gastric epithelium compared with non-infected patients, and whether the strains harboring vacAs1a have more severe effect on it.

MATERIALS AND METHODS

Patients

Patients suffering from dyspepsia underwent diagnostic endoscopy and biopsy. Those taking H₂ antagonists, proton pump inhibitors, non-steroidal anti-inflammatory drugs, antibiotics or bismuth salts were excluded from the study. Patients with gastric ulcer or cancer were also excluded. Eighty-four patients with chronic gastritis (CSG) and 16 patients with duodenal ulcer (DU) with mean age of 46.45 years (22 years - 76 years) entered the

study. Biopsy specimens were taken from the site approximately 2 cm-5 cm from the pylori.

Histology and diagnosis of *H. pylori* infection

Two antral and one corpus biopsy specimens were routinely processed, and stained with haematoxylin and eosin. Examine *H. pylori* by fast urease test, modified Giemsa stain and culture. At least two positive results of test regarded as *H. pylori* infection.

Immunohistochemistry

An antral biopsy specimen was put immediately into RPMI containing bromodeoxyuridine (BrdU, 5 g/L). It was immersed in a waterbath for 60 min at 37°C and then fixed in Carnoy solution. Sections were stained with anti-BrdU antibody by ABC technique. The nuclei of proliferative cell were stained. Five hundred epithelial cells were counted and the number of positively stained epithelial cell nuclei expressed in percentage as labelling index (LI%). All sections were examined by the same person who was unaware of the subject's *H. pylori* status.

Polymerase chain reaction

H. pylori DNA was extracted routinely, vacAs1a amplified by PCR, 50 µL reaction solution contains the following: 1 × reaction buffer, dNTP mixture (0.2mM each), vacAs1a primers (0.2µM each), 1.25 unit Taq DNA polymerase and 4 µL template. PCR program comprises predenaturation at 94°C for 5 min, followed by 37 cycles of 1 min at 94°C, 90s at 52°C, 45s at 72°C, and a final incubation at 72°C for 7 min. PCR products were inspected by electrophoresis on 2% agarose gels stained by ethidium bromide. It is regarded as vacAs1a positive if a clear band can be seen at 190bp. Primers: 5'-GTCAGCATCACACCGCAAC-3', 5'-CTGCTTG-AATG CGCCAAAC-3'^[3].

Statistics

LI% is transformed to arcsin LI% 1/2, *t* test, Chisquare and multi variate linear-regression analysis were used to deal with the data.

RESULTS

The prevalence of *H. pylori* infection in CSG patients was 50%, and that of DU reached 93.75% (*P*<0.01), but the disparity of vacAs1a proportion between *H. pylori* positive CSG and DU was not significant (43.59% vs 58.33%, *P*>0.05).

There is significant difference on LI% between

Received 2000-01-07 **Accepted** 2000-02-29

CSG and DU ($P < 0.05$), but considering the different prevalence of *H. pylori* infection, we got negative result ($P > 0.05$) from comparing the LI% between positive cases of CSG and DU. The results (Table 1) of analyzing the effect of *H. pylori* infection and its different strains on proliferation, showed that patients with *H. pylori* had higher LI% ($6.14\% \pm 1.21\%$) than *H. pylori* negative ones ($2.43\% \pm 0.61\%$, $P < 0.001$). Patients harboring vacAs1a strains had significantly higher gastric epithelial cell proliferation LI% ($n = 24$, $8.00\% \pm 1.46\%$) than those with non-vacAs1a strains ($n = 27$, $4.51\% \pm 0.86\%$, $P < 0.02$) or noninfected patients ($P < 0.001$).

The sections were graded into mild, moderate and severe according to the extent of inflammation and intestinal metaplasia. Statistics shows a close relationship between inflammation and *H. pylori* status ($P < 0.005$), however it is negative on metaplasia ($P > 0.05$). No significant relationship was found between inflammation and vacAs1a genotype ($P > 0.05$).

The results show that inflammation and neutrophil infiltration were closely related to epithelial cell proliferation ($P < 0.001$), but not to metaplasia ($P > 0.05$). Multivariate linear-regression analysis shows that among the factors, such as age, sex, DU, inflammation, neutrophil infiltration, intestinal metaplasia, vacAs1a strains, non-vacAs1a strains and so on, vacAs1a strain and inflammation are the independent factors influencing the epithelial cell proliferation.

Table 1 BrdU LI% of the patients ($\bar{x} \pm s$)

	LI%	case number
H.pylori-positive	6.14 ± 1.21^a	57 [§]
vacAs1a positive	8.00 ± 1.46^{ae}	24
vacAs1a negative	4.51 ± 0.86^c	27
H.pylori-negative	2.43 ± 0.61	43

^a $P < 0.001$ vs *H. pylori* negative patients; ^c $P < 0.01$ vs *H. pylori* negative patients; ^e $P < 0.02$ vs non-vacAs1a *H. pylori* patients; [§]vacAs1a were not examined in 6 cases because of loss of specimens.

Table 2 Multivariate linear-regression analysis

LI%	coefficient	SD	t	P> t	95%confidence interval
vacAs1a	4.47	1.37	3.27	0.002	1.76 7.19
inflammatory coefficient	3.89	1.21	3.22	0.002	1.49 6.30
	4.50	1.89	2.38	0.019	0.75 8.26

DISCUSSION

The genesis of gastric cancer is the result of long-term effect of multiple factors of environment and host. Epidemiological investigation and histological evidences showed that *H. pylori* infection was related to gastric cancer independently. *H. pylori* infection induced gastric epithelial cell proliferation, increase of mitosis and mutation^[7]. Because of the unstability of the genome of the proliferative cell, hyperproliferation increases the

possibility of DNA damage and aneuploidy. Dysplasia may evolve into carcinoma if damaged DNA cannot be repaired on time or fail in promoting the apoptosis system. Accelerated cellular proliferation rate is the property of malignant tissue and has been confirmed in gastric carcinoma^[8].

The genesis of most gastric adenocarcinomas is believed to follow a series of defined histologic steps from normal gastric mucosa to chronic gastritis, atrophic gastritis, intestinal metaplasia, and neoplasia^[9]. It has been postulated that *H. pylori* plays a causative role at the early phases in this chain of malignant progression^[10]. Therefore, we studied CSG and DU patients (part of them had intestinal metaplasia).

The prevalence of *H. pylori* in DU patients (93.75%) was much higher than that in CSG (50%) which supports the conclusion that *H. pylori* is a closely associated pathogen of DU.

It is reported that gastric epithelial cell proliferation in *H. pylori* associated gastritis patients increased prominently compared with normal control subjects and patients with *H. pylori* negative chronic gastritis, and it reduced after *H. pylori* was eradicated^[11-16]. Our results are in agreement with these reports.

No significant difference was found on BrdU LI% between *H. pylori* positive DU and CSG patients which reveals that the existence of DU does not alter the status of proliferation, some factors other than hyperproliferation such as increased apoptosis may play an important role, in the genesis of DU by keeping the dynamic equilibrium of the epithelium^[17-20]. But some CSG patients cannot keep efficiently this equilibrium, in other words, the proliferation increases without corresponding apoptosis, DNA is prone to be attacked by other carcinogens, resulting in canceration.

About 50% population infected by *H. pylori*, gastric cancer or DU only occurred in a small portion of them. This may be associated with many factors, one of the determinants is the virulence of the strain infected.

Compared with the non-vacAs1a strains infected patients, epithelial cell proliferation of the vacAs1a strains infected patients was much higher. So vacAs1a *H. pylori* strains may be able to promote the epithelial cell proliferation. Multivariate linear-regression shows that vacAs1a strain is an independent influencing factor, which further supports the conclusion that vacAs1a strain is of high virulence. In view of the importance of hyperproliferation during the genesis of gastric cancer, vacAs1a strain may play a critical role in it.

There is much difference on the constitution of the vacA subtype of *H. pylori* according to the reports from different areas. The proportion of vacAs1a strains varied greatly^[3,21]. There have been few reports on the genotype of vacA in China. She *et al* reported the relationship between 60 *H. pylori* strains and the alimentary diseases. The relevance

ratios of vacAs1 in gastric cancer, peptic ulcer and chronic gastritis were 87.5%, 78.9% and 9.1% respectively^[22]. There was obvious geographical discrepancy in the distribution of *H. pylori* vacA subtype.

We found that intestinal metaplasia had nothing to do with *H. pylori* infection, this result corresponds with the report of Cahill *et al.* We also found that intestinal metaplasia was not correlated with proliferation, which differs with some other reports in its clinical importance, the relationship with gastric cancer and effect on cell proliferation. Therefore, we cannot draw conclusion that intestinal metaplasia is not associated with proliferation. Further studies will be conducted.

The mechanism that *H. pylori* and its different strains accelerate proliferation is not clear. Ricci *et al* found VacA can inhibit cell proliferation *in vitro*, while cytotoxin-associated gene (CagA) does not affect proliferation^[23]. *H. pylori* can induce proliferation *in vivo*, so *H. pylori* may act by this suggesting that *H. pylori* based on its ability of inciting inflammatory reaction, influencing the gastrin secretion, but not the direct action of virulences to exact the effect on cell proliferation.

Inflammation and neutrophil filtration are both associated with *H. pylori* infection. That means *H. pylori* infection can arouse acute and chronic inflammation. Accelerated proliferation is related to the extent of inflammation, and the latter is highly related to *H. pylori* infection. This points out that *H. pylori* infection may promote proliferation by inflammation, which was once reported by Lynch *et al*^[11,12]. It is also shown that inflammation acts on proliferation as an independent factor. *H. pylori* infection affects proliferation at least partly by inflammatory action. On the contrary patients harboring vacAs1a strains have similar inflammatory response to those with non-vacAs1a strains, but their ability of inducing proliferation differed. Thereby *H. pylori* may promote proliferation by inflammation, and vacAs1a strains may act by the mechanism other than inflammation, such as the increase of ammonia^[24], gastrin^[25], and the decrease of ascorbic acid concentration^[26,27].

We found that *H. pylori* infection was closely related to gastric epithelial cell proliferation, and the vacAs1a strains had higher activity. The vacAs1a strain and extent of inflammation affect proliferation independently. But the effect of *H. pylori* and its different strains on apoptosis is not clear and needs further studies. Besides, *H. pylori* can be typed into m1 and m2 strains according to vacA middle sequence, and positive or negative cagA. They may have different effects on proliferation and apoptosis, these may play important roles in the pathogenicity of *H. pylori*.

Effects of radical cholecystectomy on nutritional and immune status in patients with gallbladder carcinoma

Xing Yuan Jiao, Jing Sen Shi, Jian Sheng Wang, Yi Jun Yang and Ping He

Subject headings gallbladder neoplasms/immunology; cholecystectomy; nutritional status; immune status

Jiao XY, Shi JS, Wang JS, Yang YJ, He P. Effects of radical cholecystectomy on nutritional and immune status in patients with gallbladder carcinoma. *World J Gastroenterol*, 2000;6(3):445-447

INTRODUCTION

Carcinoma of the gallbladder is the most common neoplasm in biliary tract, and its incidence has been rising in recent years. The rate of correct diagnosis in early gallbladder carcinoma has been raised after the wide use of CT, ultrasound scans and frozen section examination. Now radical cholecystectomy is advocated as the best management for patients with early gallbladder carcinoma. In the present study, the diagnosis of 27 patients with gallbladder carcinoma was confirmed correct, and the patients underwent radical cholecystectomy, and their nutritional and immune assessments were performed pre- and post-operatively.

PATIENTS AND METHODS

Patients

From September 1993 to December 1997, 27 patients with gallbladder carcinoma who had undergone radical cholecystectomy were selected, and they were admitted to the First and Second Affiliated Hospitals of Xi'an Medical University. The patients included eight males, aged 46-65 years, with a mean of 57 years; nineteen females, aged 50-67 years, with the mean of 59 years. Four patients were diagnosed as having polyposis preoperatively, and diagnosed as carcinoma during the operation by the frozen section technique. In five patients with preoperative diagnosis of carcinoma, metastasis had not been found during the operation. No severe systemic disease was found, e.g. recent myocardial infarction, cerebral vascular accidents, uncontrollable diabetes mellitus or hypertension. Antibiotics were administered

postoperatively to prevent infection, intravenous infusion was routinely administered immediately after surgery and maintained at least for one week. The tumors were graded as stage I, II and III (Nevin stage) by histological examination. All of the resected specimens were sent for histological examination. No chemotherapy or radiotherapy was administered preoperatively.

Methods

The nutritional and immune status of the patients were assessed preoperatively (1 wk before surgery), and on d 3, d 7, d 14 and d 21 postoperatively.

Nutritional assessment Biochemical parameters evaluating the patient's nutritional status consisted of serum levels of albumin, cholesterol, iron, magnesium, zinc, and transferrin determined by an automated calorimetric technique (SMAC), and total iron binding capacity (TIBC) determined by radioimmunoassay.

Immune studies The immune status includes T lymphocyte subpopulation-CD₄, CD₈; immunoglobulins (IgG, IgA and IgM); complements (C₃ and C₄); and serum interleukin-2 and soluble interleukin-2 receptor were evaluated. T lymphocyte subpopulation assessment: blood samples were taken with venopuncture and anticoagulated by heparin. Mononuclear cells were isolated after the sample had been washed twice with Hank's balanced salt solution, and the concentration of the cells was regulated at 2×10^2 /mL with RPMI-1840 (Cow serum). Cell suspensions (0.2 mL) were placed in 24-well plates, and added cow serum 0.1 mL, PHA 0.05 mL, LPS 0.05 mL and 10% RPMI-1640 0.6 mL respectively. The plates were incubated at 37°C with 5% CO₂ for 72 h. Cultured supernatants were harvested and kept at -30°C. The cell suspension was assigned equally into three parts, which was washed once, added with CD₄ and CD₈ monoclonal antibody (monoclonal antibody was provided by Luo Yang Hua Mei Co.), stand for 2 h at 4°C; then each was washed twice again; a sheep-anti-mouse IgG fluorescent antibody 50 µL was added into each tube, stand for 2 h at 4°C, and washed twice again. After harvesting, cell suspension was studied under the fluorescence microscopy and the scintillation cells were quantitated as percentage of 100 or 200 lymphocytes.

Received 2000-01-18 Accepted 2000-03-14

Assay of IgA, IgG, IgM and complements Serum IgG, IgA, IgM, C₃ and C₄ were quantitated by nephelometric immunoassay.

Assay of serum IL-2, sIL-2R Serum IL-2 and sIL-2 levels were measured by a "Sandwich" enzyme-linked immunosorbent assay with two antibodies, the diagnostic reagents were supplied by Norman Bethune Medical University.

Statistical analysis

For each variable, multiple analysis of variance for repeated measurements was used to compare the values measured before operation with those measured at four subsequent time points. The results were presented as mean and standard error ($\bar{x} \pm s$) based on the mixed model of repeated measurement analysis. Statistical analysis was performed with SAS software. *P* values <0.05 were considered statistically significant.

RESULTS

The results of the nutritional and immunological assessment at various time points are demonstrated in Table 1.

Preoperation

As shown in Table 1, in patients with gallbladder carcinoma, the preoperative nutritional and immune status was all within the assigned normal ranges.

Third postoperative day

All the nutritional parameters decreased greatly after surgery, especially the serum iron, transferrin, cholesterol, TIBC, magnesium, and zinc ($P<0.01$, respectively).

The serum levels of immunoglobulins (IgA, IgG, IgM) and C₃, C₄ complements decreased significantly ($P<0.01$), serum IL-2 levels, CD₄ and CD₈ levels also reduced greatly ($P<0.01$), and CD₈ and sIL-2R levels increased significantly ($P<0.01$).

First postoperative week

Compared with the third postoperative day, all the nutritional parameters increased slightly, particularly the serum albumin, magnesium. Serum cholesterol, TIBC, transferrin, iron and zinc were still lower than their preoperative levels ($P<0.01$). CD₄, CD₈, CD₄/CD₈, IL-2, sIL-2 values differed significantly from those of the preoperative stage ($P<0.01$). The serum levels of immunoglobulins (IgG, IgA, IgM) and complements (C₃ and C₄) were significantly higher than those of the third postoperative day, but they were still lower than those of the preoperative day.

Second postoperative week

Compared with the third postoperative day and the first postoperative week, albumin, magnesium and zinc recovered to the preoperative levels ($P>0.05$), however, the levels of TIBC, transferrin and iron were still significantly lower than those of the preoperative ones ($P<0.01$). Compared with the third postoperative day and the first postoperative week, the serum levels of immunoglobulins (IgG, IgA, IgM) and complements (C₃ and C₄) gradually recovered, and IL-2, CD₄, CD₈, sIL-2R levels and CD₄/CD₈ ratio were not statistically different from the preoperative levels.

Third postoperative week

The nutritional evaluation showed continuous improvement in the third postoperative week, most of the nutritional parameters returned to the preoperative levels, except for the serum levels of iron, transferrin and TIBC. The immune parameters IL-2, sIL-2R, CD₄, CD₈, CD₄/CD₈ ratio, C₃, C₄ immunoglobulin levels (IgG, IgA, IgM) also returned to the preoperative levels, with no statistical difference ($P>0.05$).

Table 1 Nutritional and immunity status in patients with gallbladder carcinoma ($\bar{x} \pm s$)

Parameters	Preoperative	Postoperative			
		3rd day	1st week	2nd week	3rd week
Nutrition					
Albumin(g/mL)	3.6 \pm 0.07	3.01 \pm 0.14 ^b	3.49 \pm 0.13 ^a	3.50 \pm 0.12	3.58 \pm 0.15
Cholesterol(mg/dL)	215 \pm 7.81	78.16 \pm 7.22 ^b	85.23 \pm 7.41 ^b	131.45 \pm 6.85 ^b	148.62 \pm 8.41 ^b
TIBC(μ g/dL)	251.15 \pm 12.95	129.18 \pm 8.15 ^b	162.67 \pm 9.83 ^b	194.15 \pm 10.15 ^b	199.34 \pm 9.68 ^b
Transferrin(mg/dL)	221.07 \pm 12.11	99.77 \pm 8.98 ^b	131.29 \pm 9.01 ^b	175.25 \pm 9.31 ^b	186.21 \pm 10.18 ^b

IL-2(IU/mL)	9.95 \pm 2.95	4.81 \pm 1.81 ^b	5.99 \pm 2.30 ^b	8.41 \pm 2.93 ^a	9.89 \pm 3.01
sIL-2R(U/mL)	754.2 \pm 141.5	478.3 \pm 87.57 ^b	597.4 \pm 96.81 ^b	692.1 \pm 112.6	748.9 \pm 138.8

For each variable, multiple repeated measurements analysis of variance and *t* test were used to compare the values before operation with those measured after operation, ^a $P<0.05$, ^b $P<0.01$, vs before operation.

DISCUSSION

Carcinoma of the gallbladder is one of the most common neoplasms in biliary tract, and 40%-100% cases are complicated with gallstones^[1,2], but correct diagnosis of gallbladder carcinoma in its early stage accounted for only 19.1%, and 53.3% cases are always diagnosed as cholecystitis and gallstone^[3-5]. More and more clinical experiences indicate that radical cholecystectomy for early carcinoma is the most effective treatment^[6-8]. In the present study, though all patients with gallbladder carcinoma were well prepared to receive the radical cholecystectomy, their nutritional and immune status still deteriorated remarkably immediately after the extensive surgical resection. The reasons might be that: ① Large volume of body fluid lost during and after the surgery; ② the radical cholecystectomy is a complex operation needing long time and wide scope of resection. Sumiyoshi^[9] and Wang *et al.*^[10] studied the effect of surgery as an injury factor on nutritional and immune status in patients with carcinoma, it is coincident with our findings in this report. Our investigation showed that all of the nutritional parameters but the serum levels of iron, TIBC and transferrin recovered within 3 wk after operation. Hickey *et al.*^[11] advocated that supplemental vitamins and minerals, e.g. iron should be given postoperatively when deficiencies are suspected. Our conclusion is that adequate iron should be supplemented after the radical cholecystectomy for gallbladder carcinoma in the third postoperative week, and the serum levels of minerals should be monitored routinely after surgery.

The immune study showed remarkable decrease of serum IgA, IgM, IgG and C₃, C₄ complement, IL-2, CD₄, CD₄/CD₈ ratio, and the remarkable increase of serum sIL-2R and CD₈ ($P < 0.01$) on d3 after operation. IL-2 is a T-cell derived soluble lymphokine whose main bioactivity is to stimulate the activated T cell (Th, Ts, Tc) to reproduce continually, proliferate and is the key mediator in cell and humoral immunity and immune regulation. The balance between IL-2 and its receptor regulates the immune status. T cell serves as the center in controlling cellular immune status which can affect directly the occurrence, development and progression of tumor^[12]. T cell's regulating function is mainly performed by CD₄ and CD₈ T cells. CD₄⁺ T cells can help B cell produce antibody and CD₈⁺ T cells can suppress B cell to produce antibody. The stable balance between them keeps normal immune response of the organism. Surgery, as an injurious factor, broke the balance between CD₄ and CD₈, however T cell's immune regulating function is demanded finally by the organism. In gallbladder carcinoma in an early stage, the serum IL-2, CD₄, CD₈, CD₄/CD₈ ratio, sIL-2R recovered remarkably in the first postoperative week. In early

postoperative stage, the serum levels of immunoglobulins and complement reduced remarkably. This evidence suggests the results are possibly influenced by surgical stress and the diluting effect of the postoperative massive fluid therapy. The immune parameters returned to the preoperative levels within 2 wk-3 wk after surgery, suggesting that T cell plays a more important role in the immune regulating system.

The present study suggests that radical cholecystectomy for early gallbladder carcinoma might have a mild and transient adverse effect on the cell-mediated immune response during the early postoperative period. Because of tumor's own direct products, tumor cell's metabolites and immuno-complex in body circulation, which depress the anti-tumor action of the immune cells^[13,14], patients' immune status deteriorated remarkably in the middle and late stage. For gallbladder carcinoma, radical cholecystectomy in its early stage with complete resection of the tumor and removal of lymphnodes should be performed, thus the immune inhibitors in the tumor mass can be excluded. These factors played important roles in the recovery of immune function.

INTRODUCTION

The advent of laparoscopic cholecystectomy (LC) in the late 1980s gained widespread acceptance within a short period of time and has become the preferred treatment for symptomatic gallstones^[1-7], but the management of coexisting gallbladder and common bile duct (CBD) stones has remained controversial because the various strategies proposed have their limitations^[8-12]. In fact, choledocholithiasis is found in 10%-15% of patients with cholecystolithiasis, and most authors agree that at least 90% of CBD stones are secondary to those of the gallbladder, and that CBD stones must be extracted in a timely manner in order to avoid consequent complications which would otherwise occur in at least 90% of patients^[1-4]. This paper will introduce and evaluate a new approach of management of coexisting gallbladder and CBD stones-intraoperative endoscopic sphincterotomy (IOES).

MATERIALS AND METHODS

From December 1997 to August 1999, twenty-seven patients with cholelithiasis and CBD stones were treated by LC and IOES. Choledocholithiasis was detected in 9 patients by preoperative ultrasonography and 18 routine intraoperative cholangiography (IOC). They were 5 males and 22 females. The youngest patient was 23 years old, the oldest being 74 years, averaging 50.3 years. The preoperative diagnoses are summarized in Table 1. All patients were treated according to a standard

protocol (Figure 1).

Table 1 Preoperative diagnosis of 27 cases

Preoperative diagnosis	No. of patients
Acute cholecystitis with multiple gallstones	3
Chronic cholecystitis with multiple gallstones	15
Acute cholecystitis with multiple gallstones and CBDs	3
Chronic cholecystitis with multiple gallstones and CBDs	6

Figure 1 Protocol of treatment of 27 cases. LF: liver function; US: ultrasonography; LC: laparoscopic cholecystectomy; IOC: intraoperative fluorocholangiography; CBD: common bile duct; IOES: intraoperative endoscopic sphincterotomy.

LC was undertaken by the four trocar technique and IOC was performed according to the technique described by Alfred Cuschieri and Hong^[1,2]. As soon as the CBD stones were confirmed, the endoscopist was expected on call. The patient lay in supine position, after deflating abdominal CO₂, the endoscope (Olympus JF100 or a side-view JF100, JF140) was advanced into the duodenum. Once the position of ampulla of Vater was determined, EST was undertaken routinely. The size of sphincterotomy was about 0.8 cm-1.5 cm. The CBD stones were extracted in different ways according to their size, shape and number. The small stones (less than 8 mm) were expelled into the duodenum with the help of surgeons by injecting normal saline through the cholangiogram catheter, medium sized stones (8 mm-15 mm) were extracted with the basket (Olympus FG-23Q-1) or by a balloon (Wilson-cook EBL-12-200, EBL-8.5-200) monitored under fluoroscopy, large stones (more than 15 mm in diameter) were eliminated by basket or balloon after mechanical lithotripsy. After IOES and removal of CBD stones, the repeated IOC was performed to make sure that there were no retained CBD stones. The endoscope was withdrawn while aspirating the residual air. The LC was then completed.

RESULTS

The IOES was technically successful in 26 of 27 patients (96.30%) and the CBD stones were removed in all of these cases (100%). In 5 cases, the stones were expelled into the intestinal tract spontaneously, in 17 cases, extracted by basket or balloon and in 4 cases, removed after mechanical lithotripsy. The number of CBD stones ranged from 1 to 15, and the size of the stones varied from 3 mm to 16 mm. In one case, IOES failed because the sphincterome could not cannulate the ampulla of Vater due to stones impacted tightly the distal portion of CBD. Two cases were complicated with mild acute pancreatitis (7.69%) which resolved within 3 d and 7 d being fasted and intravenously supplemented fluid. No other complications occurred. There were no operative mortalities. The average operation time of LC combined with IOES was about 160 min (from 80 min to 210 min). All but 3 cases recovered uneventfully leaving bed and resuming food 8 h-24 h after LC and IOES. One patient developed pneumothorax after LC procedure. In the other two cases recovery was delayed due to the complication of mild acute pancreatitis (mentioned above). The mean duration of hospital stay was 1 d to 26 d ($3 \text{ d} \pm 1 \text{ d}$). The patient who had the pneumothorax was discharged on the 26 th postoperative day.

DISCUSSION

It is well known that LC has become the primary method of treatment of symptomatic gallstones. Of the 500 000 cholecystectomies performed annually in the United States, 85% of them are estimated now to be performed laparoscopically^[13]. In China LC is also rapidly accepted. Likewise, the introduction of ERCP and EST in the 1970s rapidly revolutionized the management of CBD stones. Numerous series of cases have shown successful endoscopic clearance of the CBD stones in approximately 90% of patients, complications of EST occur in 5%-15%, most of these are minor, and the mortality is less than 1%. New instrumentation is being developed and improved continuously enabling the endoscopist-surgeon to deal more and more successfully and creatively with a variety of intra-abdominal conditions^[4-6]. But the management of coexisting gallbladder and CBD stones is now more controversial than before, because many approaches to resolve this problem have their limitations besides the expense and time (Table 2)^[8-12].

From May 1994 to November 1997, 1794 cases of LC and IOC were performed in our hospital. In about 7%-8% of patients with cholecystolithiasis^[2,3], CBD stones were also found, we removed them by various methods such as converting to open choledochostomy, laparoscopic choledochostomy, laparoscopic choledochoscopy via

cystic duct and postoperative EST. The results revealed that there was no best procedure for the patients, some shortcomings existed as shown in Table 2. Therefore, we employed a new approach of IOES from December 1997 to August 1999 to remove CBD stones identified at the time of LC.

Table 2 Alternatives of management of coexisting gallbladder and CBD stones

Methods	Shortcomings
Convert to open choledochostomy	loss of all advantages of minimally invasive surgery
Laparoscopic transcystic duct choledochoscopy	limited by cystic duct anatomy and risk associated with cystic duct dilation
Laparoscopic choledochostomy	Installation of T-tube and high technical demand
Preoperative ERCP and EST	hard to precisely predict preoperative CBD stones; if failed, subsequent operation should be considered
Postoperative ERCP and EST	If failed, another operation should be performed

The major advantages of combining LC and EST into one procedure are encouraging. The obvious benefit is that the patients have both problems solved at one session. But our 27 cases treated by LC combined with IOES only represent some of the common bile duct explorations done at our hospital during this period due to the following reasons (among 1485 LC cases during this period). First, some surgeons in our department thought that IOES presents significant logistic difficulties in coordinating the necessary personnel and equipment. Second, it was thought that the supine position may increase the technical difficulty of EST^[8-12]. But in our experience it is easier to remove the CBD stones by a combination of LC with IOES than by pre- or postoperative EST. The endoscopist gets benefit from general anesthesia. The surgeons can help the endoscopist to locate the proper position of the ampulla of Vater and irrigate the CBD by injecting normal saline through the cholangiography catheter. Small or fragmented stones can be washed out with normal saline irrigation. Medium or large sized stones in CBD can be removed with the help of a basket or balloon and by lithotripsy. By deflating the peritoneal cavity of CO₂, the endoscopist was able to insufflate the duodenum adequately for performing IOES, after aspirating the gastrointestinal air, LC was more easily accomplished. From our study, IOES was successful in 26 (96.30%) of 27 patients and CBD stones were cleared in all of them (100%), only two cases were complicated with mild acute pancreatitis (7.69%) resolved within 3 d-7 d with intravenous fluid and fasting. No death occurred postoperatively. The case of pneumothorax after LC recovered by conservative management. The total operative time compares favorably with that of

standard LC with CBD exploration in our hos pital.

We recommend IOES as a valid alternative approach to the removal of CBD stones during LC. It has been safe and effective, and less traumatic to the patient than other intraoperative procedures or pre-or postoperative EST.

Pathogenetic effects of platelet activating factor on enterogenic endotoxemia after burn

Pei Wu Yu¹, Guang Xia Xiao², Wei Ling Fu², Jian Cheng Yuan², Li Xin Zhou² and Xiao Jian Qin²

Subject headings Platelet activating factor; burn; endotoxemia ; intestinal permeability

Yu PW, Xiao GX, Fu WL, Yuan JC, Zhou LX, Qin XJ. Pathogenetic effects of platelet activating factor on enterogenic endotoxemia after burn. *World J Gastroentero*, 2000;6(3):451-453

INTRODUCTION

Previous clinical and experimental studies have indicated that an early endotoxemia occurred after a major burn. It is unlikely that burn wound sepsis is the source of circulating endotoxin in less than 12 hour after burn. Increasing evidence demonstrates that the bacteria and endotoxin in the gastrointestinal tract can pass through the gut barrier into blood circulation to form enterogenic endotoxemia following burn^[1-3]. However, its pathogenesis remains poorly understood. Platelet activating factor (PAF), an endogenous phospholipid mediator, has recently been proposed as a critical mediator in shock, sepsis and multiple organ failure^[4,5]. In this study, the relationship between changes of PAF and enterogenic endotoxemia was observed on rat models with 30% TBSA III° burn. The purpose was to investigate the pathogenetic effects of PAF on the occurrence of enterogenic endotoxemia after burn.

MATERIALS AND METHODS

Animals

Wistar rats, male or female, weighing 220 g ± 30 g were used, they were provided by Laboratory of Animal Experiment, Institute of Burn Research, Third Military Medical University.

Experimental design

Animals were randomly divided into three groups. Group 1 (*n* = 10): normal rats served as control. Group 2 (*n* = 40): burned rats that had undergone

30% TBSA III° burn. Group 3 (*n* = 40): treated rats that received PAF antagonist WEB 2170 (5 mg/kg) by intraperitoneal injection after burn. WEB 2170 was provided by Boeringer Ingelheim *Pharmac-euticals* Inc, Germany.

Animals were killed on 6, 12, 24 and 48 hours postburn. Blood and terminal ileum were obtained from all animals for assay of PAF and endotoxin.

Burn model

Rats were anesthetized intraperitoneally with ketamine hydrochloride 80 mL/kg body weight, and their backs were shaved. They were placed in a mould that left approximately 30% area of their body surface exposed. These exposed surface s were immersed in 92°C water for 18s. This type of burn injury is a full-thick ness burn. Animals were resuscitated with 40 mL/kg of lactated Ringer's solution.

Measurement of PAF contents in blood and intestinal tissue

Blood (1mL) was collected into polypropylene tube containing 5 mL of methanol. The methanolic extract was separated by centrifugation. The supernata nts were collected and chloroform and water were added to effect phase separation. The lower chloroform-rich phase contained all PAF activity. Chloroform was evaporated under a stream of nitrogen. The samples were stored under -20°C. Segments of ileum tissue (200 mg) were added to 2 mL of 0.25% bovine serum albumin, and after homogenization, the mixture was added to 2 mL of cold acetone, and then centrifuged. Two mL of chloroform as added to the superna tants. After a further centrifugation, the thin layer chloroform containing PAF was collected and evaporated by nitrogen. PAF activity was bioassayed by the aggregation of rabbit washed platelets.

Measurement of intestinal mucosal permeability

After overnight fast, rats were anesthetized, a midline abdominal incision was made. Fifteen cm segments of ileum were isolated, cannulated proximally and distally, and perfused continuously with saline at rate of 1 mL/min-2 mL/min. ^{99m}Tc DTPA (5.55-7.4MBq/kg) was injected via the carotid ve in and allowed to equilibrate for 30 min. After that, a 10 min perfusion fluid and 1mL blood were collected for measurement of activity of ^{99m}Tc

¹Department of General Surgery, Southwest Hospital, Third Military Medical University, Chongqing 400038, China

DTPA. The animals were killed and the perfused ileal segment was excised and weighed. DTPA clearance was calculated using the following formula: DTPA clearance = (cpm perfusate \times Q)/(cpm plasma \times W), and was expressed as mL/min \cdot 100g. Where Q is the rate of perfusion; W, the weight of perfused ileum.

Measurement of plasma endotoxin

Plasma endotoxin was assayed with chromogenic limulus amoebocyte lysate technique.

Statistical analysis

All data were expressed as $\bar{x} \pm s$, and statistical analyses were made using Student's *t* test.

RESULTS

The changes of PAF content

PAF contents of blood and intestinal tissue in burn group were significantly higher than those in control group ($P < 0.01$). The peak level occurred at 12 h postburn. In PAF-antagonist treatment group, the PAF contents of blood and intestinal tissue were significantly decreased compared with burn group, but were higher than those in control group

(Table 1).

The changes of intestinal mucosal permeability

The intestinal mucosal permeability increased significantly at 6h postburn and kept increasing during 48 h postburn compared with control group. The intestinal mucosal permeability in treatment group was lower than those in burn group (Table 2).

The changes of plasma endotoxin

The levels of plasma endotoxin in burn group were significantly higher than those in control group. The levels of plasma endotoxin in treatment group were significantly lower than those in burn group (Table 3).

Correlation analysis

The correlations between intestinal PAF and intestinal mucosal permeability, blood PAF and plasma endotoxin, intestinal mucosal permeability and plasma endotoxin in burn group were analyzed. The results showed positive correlation among the above three pairs with $P < 0.01$, $r = 0.94$, 0.93 and 0.95 respectively.

Table 1 Levels of PAF in blood and intestinal tissue ($\bar{x} \pm s$)

DISCUSSION

The pathogenesis of enterogenic endotoxemia remains poorly understood. It is considered that the main cause is injury of intestinal mucosal barrier. Under physiological condition, the intestinal mucosa functions as a major local defense barrier preventing intestinal bacteria and endotoxin from invading distant organs and tissues. However, under the circumstances of trauma, shock and sepsis, the impairment of intestinal barrier may result from ischemic damage of the intestinal mucosa, the bacteria and endotoxin in gastrointestinal tract can pass through the intestinal barrier to mesenteric lymph nodes and systemic organs, resulting in enterogenic sepsis (endotoxemia)^[6,7]. There is increasing evidence that enterogenic sepsis may play an important role in the development of systemic infection as well as multiple organ failure^[8,9]. The present study results show that increased intestinal permeability after burn is an important cause of enterogenic endotoxemia.

PAF is a phospholipid mediator released from stimulated leukocytes, platelets, endothelial and mast cells^[10,11]. It has been regarded as an important endogenous mediator of shock, sepsis and multiple organ failure. Our study demonstrated that PAF contents in blood and intestinal tissue after burn were all significantly increased and were positively correlated with the increase of intestinal permeability and plasma endotoxin. Treatment with PAF antagonist can significantly decrease intestinal permeability and plasma endotoxin. These suggest that PAF is involved in the process of increasing the intestinal permeability after burn and is also an important factor leading to enterogenic endotoxemia.

Previous studies showed that endotoxin can stimulate directly or indirectly macrophages and endothelial cells to release PAF, which also

mediates some endotoxin-induced pathologic processes of multiple organ injury^[12,13]. It is suggested that a PAF-endotoxin positive feedback relationship existed in the body. Therefore, administration of PAF antagonists has an important effect on preventing and treating enterogenic endotoxemia.

Ultrastructural localization of glutathione S-transferase-pi in human colorectal cancer cells

Wen Jun Guo¹, Guang De Zhou¹, Hong Juan Wu¹, Yu Qing Liu¹, Rui Guang Wu² and Wei Dong Zhang¹

Subject headings colorectal neoplasms; GST-pi; immunoelectron microscope; colloid gold

Guo WJ, Zhou GD, Wu HJ, Liu YQ, Wu RG, Zhang WD. Glutathione S-transferase-pi in colorectal cancer cells. *World J Gastroenterol*, 2000;6(3):454-455

INTRODUCTION

Placental form glutathione S-transferase (GST-pi) is a group of isoenzymes with protein combining ability. Since the reports showing that GST-pi was significantly increased in proliferative hepatic nodule induced by chemical carcinogen and in well differentiated carcinoma^[1], more studies have shown^[2-4] that GST-pi expressed highly in neoplasm, and could be regarded as a tumor marker. GST-pi has the antimutagenesis and antitumor ability, and is related closely with the resistance of tumor to anticancer drugs. As the description about the immunoelectron microscopical localization of GST-pi in human colorectal cancer cells was not available, we have observed the ultrastructural localization of GST-pi in colorectal cancer cells, and explored the distribution of GST-pi in these cells and its relationship with colorectal carcinogenesis.

MATERIALS AND METHODS

Fresh colorectal cancer tissues ($n = 6$) were obtained from surgical specimens, and the colorectal mucosal tissues ($n = 3$) more than 10 cm away from the cancer served as controls.

Reagents Monoclonal mouse anti-GST-pi antibody (Dako Company); 10 nm colloid gold labeled goat anti-mouse IgG (Institute of Basic Medicine, Academy of Military Medical Science).

Tissue processing All fresh blocks of tissue were fixed with 2.5 mL/L glutaraldehyde and 40 mL/L

paraformaldehyde, routinely dehydrated and embedded in Epon 812. Ultrathin sections were placed on nickel grids, treated with 30 mL/L H₂O₂ (15 min), washed thoroughly with 0.05M, pH 7.4 TBS, blocked with 1% bovine serum (30 min), dropped mouse anti-GST-pi monoclonal antibody (1:20), and placed in refrigerator (4°C) overnight. Washed with 0.05M, pH 7.4 TBS, then with 0.02M, pH 8.2 TBS, dropped 10 nm colloid gold labeled goat anti-mouse IgG (1:10), stand in room temperature for 1 h, washed with TBS, and restained with uranyl acetate followed by lead citrate. The first antibody was replaced by TBS as control. These specimens were observed under electron microscope.

RESULTS

The most significant ultrastructural change of colorectal cancer cell occurred in the nucleus. It was large and irregular in shape, with peripheral aggregation of heterochromatin and plenty of ribosomes and large nucleoli. There were colloid gold labeled GST-pi positive particles in all of the six cancer specimens. The positive particles were round in shape, high and clear electron density, distributed as clusters or spots in cancer cells. The majority of positive particles were in mitochondria, lysosomes and some plasma, and some also presented in nuclei (Figure 1) or in the periphery of nuclei (Figure 2). The positive particles accumulated in lumps. Visible positive particles were never found in normal control cells.

DISCUSSION

Biological characters of GST-pi

Placental form of glutathione included rat and human forms named GST-p and GST- π respectively. Because they presented generally in placenta according to the new category, they were nominated as GST-placental isoenzyme (GST-pi) as a whole. GST-pi could detoxify chemical mutagenesis, cancer promoter, lipid and DNA hyperoxidase, and protect normal cells from the influence of cancerigenic materials, so that GST-pi played an important role in the anti-mutation and anti-cancer process. As an important enzyme of detoxification, GST-pi was controlled by the gene. The high expression of GST-pi gene occurred while the carcinogen acted on the cells to induce their mutation^[5]. The high expression of GST-pi in many neoplasms was related to the resistance of anticancer drugs. Katagiri *et al* reported that the expression of GST-pi negatively correlated to the sensitivity of anticancer drug in testicular tumor^[6]. Dong J suggested that the expression of GST-pi closely related to resistance of anticancer drug in ovarigenic neoplasm^[7]. GST-pi could be regarded as a marker in evaluating the effect of tumorectomy, or in predicting the drug resistance of tumor cells. High expression of GST-pi in precancer and cancer of liver, and the protein synthesis ability could be blocked by cyclohexamide, which showed that GST-pi was controlled in transcription level. This may be the molecular base of the cancer cells in

getting cytotoxic drug resistance. We found that GST-pi expressed only in cancer cells, but not in normal cells, suggesting that this might be related to the action of carcinogen. GST-pi specific expression in colorectal cancer cells may be used as a marker for diagnosis of colorectal carcinoma.

Ultrastructural localization of GST-pi

We found that GST-pi was located in cytoplasm, mitochondria, lysosomes and nucleus adjacent to nuclear membrane of colorectal cancer cells. These agreed with immunohistochemical studies^[8]. But normal mucosa occasionally showed slight positivity in immunohistochemical studies. This is different from our findings. It might be related to the weak expression in normal mucosa. There were few studies about the GST-pi ultrastructural localization. In our study, GST-pi positive particles were found not only in cytoplasm, but also in nucleus. Chen M reported the same result in bladder carcinoma^[9]. Why was GST-pi positive particles present in nucleus? We think this can be an atavism, and if so it could not be used as a marker indicating colorectal cancer. Whether it is a right concept or not needs further studies.

Case Reports

Life threatening vitamin B₁₂ deficiency: will timely screening make a difference?

T.S. Dharmarajan¹, S. Lakshmi Narayanan² and Rajiv D. Poduval³

Subject headings vitamin B₁₂ deficiency/therapy; anemia, sickle cell; gastric mucosa; biopsy; anemia, pernicious; toxicity

Dharmarajan TS, Narayanan SL, Poduval RD. Life threatening vitamin B₁₂ deficiency: will timely screening make a difference?. *World J Gastroentero*, 2000;6(3):456-457

INTRODUCTION

While Vit.B12 deficiency is common, with a prevalence of about 15% in the elderly^[1-3], and recommendations for treatment available, detection of deficiency at the pre-clinical stage by appropriate screening does not always take place. Our report is an example of life threatening Vit.B12 deficiency diagnosed at age 56, with the onset of Vit.B12 depletion likely to have begun in the previous decade. Further, the patient had sickle cell trait along with Vit.B12 deficiency, a combination only sporadically reported.

CASE REPORT

A 56 year old caucasian male with no significant past medical illness presented to our University hospital with a history of lethargy, weakness, anorexia, pallor and icteric sclera for a few months. He denied use of medications inclusive of acid lowering agents (H₂ blockers or proton pump inhibitors) and vitamins of any kind. Dietary habits were omnivorous. Physical examination confirmed marked pallor and jaundice. Vital signs were stable; rest of the examination including nervous system was unremarkable.

Hemoglobin: 24g • L⁻¹, Hematocrit: 6.9%, MCV: 75fl, Platelet: 64 × 10⁹ • L⁻¹, Corrected reticulocyte count: 0.004, Blood smear: anisocytosis, poikilocytosis and macroovalocytosis with hypersegmented neutrophils, Folate: 12.1 µg • L⁻¹, Iron: 1.57 µg • L⁻¹, TIBC: 59, Ferritin: 764 µg L⁻¹, LDH: 15500U/L, and Haptoglobin: 31 mg • L⁻¹. Hemoglobin electrophoresis: HbA 0.67, HbS 0.30. Direct

Coomb's test: negative. Vitamin B12: 57ng L⁻¹ (Normal 200-900ng L⁻¹), Intrinsic factor antibodies: positive. Bone marrow aspirate and biopsy: erythroid hyperplasia with megaloblastic features. Upper endoscopy and gastric biopsy revealed chronic gastritis with mucosal atrophy. Colonoscopy was normal except for hemorrhoids.

Therapy included a total of 6 units of packed red blood cells. Vitamin B12 therapy was initiated as daily intramuscular injections, 1 000 µg daily for 3 days. Clinical improvement was dramatic and the patient was discharged shortly.

DISCUSSION

Our patient presented with pancytopenia and a life-threatening drop in Hb to 24 g • L⁻¹. Though the hematologic manifestations were severe, interestingly, there was no evidence of peripheral neuropathy, myelopathy, dementia or any neuropsychiatric manifestations. In view of omnivorous dietary habits, a dietary deficiency from inadequate consumption of Vit. B12 was unlikely. Neither was the patient on any antacids or other acid lowering agents. Proton pump inhibitors and H₂ blockers, widely used as prescription and over the counter agents for upper gastrointestinal symptoms have been associated with Vit. B12 deficiency. Acid peptic activity is important in the initial step where Vit. B12 is separated from food protein; lack of acid may cause food-cobalamin malabsorption, a common cause of Vit.B12 deficiency^[4,5].

An average omnivorous American diet provides 5 µg-15µg of Vit.B12 per day. Animal products such as meat, poultry, fish, eggs and dairy products are rich sources of Vit.B12. Plant sources contain Vit.B12 only if they are contaminated with microorganisms^[6,7]. As a result, vegans are at a higher risk of becoming Vit. B12 deficient over a period of time. When consumed, Vit.B12 attaches to an 'R' binder (haptocorrin) present in saliva, after it is separated from food protein by acid in the stomach. The pancreas secretes proteases, which at an alkaline pH beyond the stomach digests the 'R' binder facilitating the attachment of intrinsic factor (IF) to B12. IF-B12 complex is absorbed via receptors in the distal ileum. An efficient enterohepatic circulation of Vit.B12, wherein most of the Vit.B12 secreted in the bile is reabsorbed, is the reason why it takes anywhere upto 20 years to become Vit.B12 deficient if one stops consuming

Vit.B12^[6,8].

PA was the most likely cause of Vit.B12 deficiency in our patient. The age of onset with advanced disease by mid fifties and absence of any other basis like gastric or small intestinal surgery, chronic pancreatitis, *Crohn's* disease and other causes of malabsorption makes PA the probable diagnosis. The presence of IF antibodies, which is more specific for PA than parietal cell antibodies and seen in about 40% of patients with PA, lends credence to our assumption^[9]. The additional finding of Vit.B12 deficiency with sickle cell trait in this patient is not common. Patients with severe sickle cell disease may have unrecognized Vit. B12 deficiency^[10]. Furthermore, routine folate supplementation in sickle cell anemia prior to determining Vit.B12 status has been considered risky, as it can mask the findings of Vit.B12 deficiency^[11].

The spectrum of Vit.B12 deficiency has been elaborately described in 4 stages^[8,12]. Stages 1 and 2 represent Vit.B12 depletion and stages 3 & 4 represent Vit.B12 deficiency with lab abnormalities and clinical manifestations. Our patient presented with full-blown stage 4 disease, suggesting that he would have been in the pre-clinical stage for many years prior to presentation. Screening for Vit.B12 deficiency would avert the morbidity associated with deficiency states. While in the past there have been no precise guidelines for screening, more recently several approaches have been described. Screening is aimed at reaching a diagnosis at the onset of depletion, i.e. at the pre-clinical stage. The literature suggests several options-from doing nothing until one is symptomatic, to screening all individuals, or an individualized approach^[4,13,14].

Our approach to screening and treatment of Vit. B12 deficiency has been described previously^[13]. Here initial screening is recommended for a select group of individuals at first contact. Included are patients with unexplained anemia, gastritis, acid lowering states from use of certain drugs, autoimmune diseases, HIV disease, *Crohn's* disease, multiple sclerosis, thyroid disease, malabsorption syndromes and vegans. In all other patients the initial screening is recommended at age 50, and thereafter every 5 years until age 65. Annual screening is suggested after age 65. Although normal Vit.B12 levels range from 200 to 900ng • L⁻¹, values between 200 and 400ng • L⁻¹ may need further evaluation including serum (or urine) homocysteine and methyl malonic acid to assess for presence of true deficiency^[13,14].

Treatment for Vit.B12 deficiency is generally initiated with intramuscular injections of Vit.B12, the usual dose being 1 000 µg daily for 3-5 days. Doses vary from 100 to 1 000 µg • d⁻¹ larger doses are accompanied by greater losses in the urine^[6]. Maintenance therapy may be by any of 3 routes intramuscular (IM), oral or intranasal. IM

injections are given every 1 to 3 months. Oral administration necessitates larger doses; 500 to 1 000 µg • d⁻¹ are needed to ensure absorption in PA where 1% maybe absorbed even in the absence of IF^[15]. However compliance with oral administration will always remain in question. Intranasal administration of Vit.B12 has been approved in 1998; this form of Vit.B12 is administered weekly (500 µg • wk⁻¹) and attains levels comparable to maintenance with IM route^[13,15].

CONCLUSION

The case illustrates the importance and need for timely screening for Vit.B12 deficiency. Delay in diagnosis and treatment resulted in a near fatal presentation of a common disease. The primary care physician should be aware that there is a window of opportunity for diagnosis and treatment; several complications of Vit.B12 deficiency are irreversible if early treatment is not provided. The treatment modalities are several and inexpensive, with no side effects. Selection of screening tests and choice of maintenance therapy may be individualized based on patient and physician preferences. Timely screening and treatment of Vit. B12 deficiency will make a difference.

Liver inflammatory pseudotumor or parasitic granuloma ?

Xiao Long Ji, Ming Shi Shen and Tong Yin

Subject headings inflammatory pseudotumor; parasitic granuloma; ascariasis larva; liver disease

Ji XL, Shen MS, Yin T. Liver inflammatory pseudotumor or parasitic granuloma. *World J Gastroenterol*, 2000;6(3):458-460

INTRODUCTION

Liver pseudotumor is a very rare benign lesion. Since the first case reported by Pack and Baker in 1953^[1], only 40 cases had been reported up to 1996. The diagnostic challenge of hepatic inflammatory pseudotumor is emphasized by the fact that most of the reported cases were diagnosed by surgical procedures.

Pathogenesis and etiology of hepatic inflammatory pseudotumor are uncertain. We report a case of hepatic pseudotumor that was suspected to be a well-differentiated hepatocellular carcinoma based on abdominal ultrasound, CT and MRI, but the final diagnosis is parasitic granuloma of ascariasis larva after hepatic lobectomy.

CASE REPORT

A soldierly multiple focal hepatic lesion was discovered in a 52-year-old man under the examination of ultrasonography when he was undergoing the regular physical examination in 1998-12. The ultrasonography showed that the nodule appeared as well defined, hypoechoic and hypovascular irregular solid mass without posterior acoustic enhancement on ultrasound (Figure 1). Subsequently, CT scan and MRI also demonstrated the existence of the lesion in the frontal segment of the right hepatic lobe (Figures 2, 3). In January 1999, a fine needle aspiration biopsy was performed on the lesion and the cytological examination showed the possibility of the well differentiated hepatocellular carcinoma. Therefore, the patient underwent the hepatectomy on January 12, 1999.

Pathological findings

Gross findings: The specimen of partial hepatic lobectomy measured 10 cm × 8 cm × 6 cm in size. The cut surface of the lesion contained several pale nodules, which were well-defined and slightly hardened. The center of the nodule was soft and pale-brownish in color, but the contour appearance of the surrounded liver was normal.

Figure 1 A nodule appeared as well-defined, hypoechoic and hypovascular irregular solid mass by ultrasonography.

Figure 2 Two nodules of low density without early enhancement detected on CT scans.

Figure 3 Two nodules of low signal intensity on T1WI and iso-signal intensity on T2WI by MRI.

Figure 11 Degenerated larva with Charcot-Leyden's crystals. HE $\times 400$

Microscopic findings

Histopathologic examination. The lesion contained a large area of necrosis with irregular border (Figure 4), around which there are fibrosis and infiltration of lymphocytes, plasma cells and eosinophils (Figures 5,6). In the center of the necrotic lesion, there are many Charcot-Leyden's crystals (Figure 7). The parasite infection was suspected and 26 pieces of tissues from the specimen were sectioned and embedded to find out the pathogen. Finally several parasites with certain morphologic architecture could be found in the sphacelus of the same section (Figures 8,9) only in one of the slides. Although the cells of the parasites were degenerated or necrosed, the viscus and somatic texture could still be recognized (Figures 10,11).

DISCUSSION

Inflammatory pseudotumors are rare benign lesions which may occur in anywhere of the body. They are usually associated with fever, pain and mass formation, and are frequently misdiagnosed as malignant neoplasm. Clinical manifestations and laboratory findings are similar in hepatic pseudotumor and hepatocellular carcinoma. The differential diagnosis between these two is difficult merely based on the images from ultrasonic and radiological examinations. The diagnostic challenge of hepatic inflammatory pseudotumor is emphasized by the fact that most of the reported cases were diagnosed after surgical procedures.

Liver pseudotumors are especially rare and the etiology and pathogenesis are uncertain. Infection was considered as a possible etiology^[2]. Only two cases with organisms were reported: *Escherichia coli* was detected in one case^[3], and Gram-positive cocci in the other^[4]. Other suggested mechanisms include an immune reaction, liver hemorrhage and necrosis,

occlusive phlebitis of hepatic veins, and local reaction to biliary tract^[5]. This is the first case in the literature which demonstrated that the ascariasis larva was found in the necrotic focus of the liver and it was primarily diagnosed as inflammatory pseudotumor. It was suggested that more sections should be taken when hepatic inflammatory pseudotumor was suspected.

The life cycle of ascariasis is complex but well understood. Adult male and female worms live in the small intestine, usually the jejunum, where each gravid female worm produces 200 000 to 250 000 eggs daily. Fertilized eggs pass in the feces and develop into infective eggs in 3 to 4 weeks. The eggs hatch in the small intestine, and the emerging larvae penetrate the intestinal wall, enter the portal vein or intestinal lymphatic vessels, migrate through the liver to the heart, and are pumped through the pulmonary arteries to the lungs. In the lungs, the larvae break out of capillaries into the air spaces. These larvae migrate up from the bronchi to the trachea and down to the esophagus. In the intestine, the larvae develop into sexually mature adults^[6]. From this life cycle, we postulate that the larvae are arrested in the liver during their migration through the liver and become a necrotic nodule.

INTRODUCTION

Secondary amyloidosis is a rare but serious complication of Crohn's disease (CD). The incidence of the association of secondary amyloidosis in patients with CD has been reported to be 0.5%-8% in Western countries [1-6]. However, in Japan, the number of patients with CD complicated by amyloidosis is limited. The characteristics of their clinical manifestations and the incidence of association are uncertain. Therefore, we report herein a patient with Crohn's disease who developed amyloidosis 13 years after the onset of CD. The diagnosis of renal amyloidosis was confirmed by renal biopsy. We also reviewed the literature concerning amyloidosis associated with CD in Japan.

CASE REPORT

The patient was a 29-year-old Japanese female. In May 1985, at the age of 14, she developed diarrhea. In March 1986, she developed fever and arthralgia. A diagnosis of CD was made by endoscopic and radiographic examinations. Thereafter, she received corticosteroids and sulfasalazine. However, hospitalization was required several times. In May 1993, severe stenosis of the ascending colon was found as shown in Figure 1. Therefore, subtotal colectomy, ileocecal resection, and ileosigmoid anastomosis were performed. As shown

in Figure 2, surgical specimen of the terminal ileum, cecum, and ascending colon (May 26, 1993) showed thickening of the bowel wall, cobblestone appearance, and longitudinal ulceration. Histological findings showed transmural inflammation and noncaseating epithelioid cell granuloma. In February, 1997, the patient was admitted because of fever, anemia, and hypoproteinemia. As shown in Figure 3, gastrografin enema examination performed on May 8, 1997 showed a stricture around the ileosigmoid anastomosis. The anastomosis and part of the remaining ileum were resected because of the stenosis. Cholecystectomy was also performed because of gallstones (the biggest stone measured 11 mm × 5 mm, five stones in total, pigmented). Immediately after surgery, right ureteral stricture due to retroperitoneal involvement was found and indwelling double J-catheter was placed. In August 1998, she was admitted because of anemia and hypoproteinemia. Her family history was unremarkable. Her height was 158 cm and body weight was 39.5 kg. Physical examination revealed marked pretibial edema. Laboratory findings included the followings: WBC $7.9 \times 10^9/L$, RBC $2.25 \times 10^{12}/L$, Hb-69 g/L, Ht 0.216, platelet $360 \times 10^9/L$, total protein 53 g/L, albumin 11 g/L, CRP 8.9 mg/dL (normal: less than 0.25 mg/dL), serum amyloid A protein (SAA) 235 $\mu g/dL$ (normal: less than 8 $\mu g/dL$), BUN 7.5 mmol/L, creatinine 145 $\mu mol/L$, creatinine clearance 0.38 mL/s, and urinary protein 9.3 g/day. Renal biopsy was performed in November 1998. As shown in Figure 4, amyloid deposition was found in the mesangial areas and blood vessels. The deposits were Congo red positive. The positive staining disappeared after pretreatment with potassium permanganate. The deposits immunoreacted with the antibody directed against amyloid A (AA)-amyloid. Colonoscopy revealed small discrete ulcerations around J-pouch. The amyloid deposition was not observed in the digestive tract. The electrocardiogram was normal. Ultrasonography did not show any abnormal findings in the heart. Thyroid was not swollen. Thyroid function tests were normal. Administration of prednisolone (40 mg/day) and 5-aminosalicylate (5-ASA) (2.25g/day) normalized serum levels of

acute phase protein such as CRP and SAA. However, massive proteinuria and hypoalbuminemia persisted. Then, when the dosage of prednisolone was reduced to 10 mg/day, serum CRP and amyloid A protein became positive. Thereafter, azathiopurine (50 mg/d ay) was administered in addition to 5-ASA (2.25 g/day) and prednisolone (10 mg/day).

The onset of CD in this patient was May 1985. Diagnosis was made in March 1986. Proteinuria developed in July 1997. Massive proteinuria developed in April 1998. Creatinine clearance was decreased in July 1997. Amyloid deposits were supposed to have already been present in mid 1997.

DISCUSSION

There is wide geographic variation in the incidence of secondary amyloidosis, occurring in 6%-8% of patients with CD in Northern Europe^[2,4,5], 2% in England^[3], but only 0.5%-0.9% in the United States^[1,6]. However, in Japan, the incidence of secondary amyloidosis in patients with CD remains uncertain. Only 18 Japanese patients with CD complicated by secondary amyloidosis have been reported in the literature from Japan (Table 1)^[7-22].

Secondary amyloidosis is caused by extracellular deposition of the N-terminal AA fragment of the circulating acute phase plasma protein SAA. Secondary amyloidosis can complicate any inflammatory condition in which there is a sustained acute-phase response including CD, rheumatoid arthritis, and chronic sepsis. It has been reported that the activity of the underlying inflammation is an important factor in the development and progression of secondary amyloidosis. In the 18 Japanese patients with CD complicated by

amyloidosis, there were no patients who maintained prolonged remission. Therefore, in CD as well, the disease activity is considered an important factor in the development of secondary amyloidosis. In the present patient, surgery had already been performed two times as the disease activity could not be controlled by medical treatment. Nevertheless, serum CRP remained positive. Moreover, in the present patient, the involvement of the retroperitoneum caused right ureteral stricture.

Inflammation is thought to precede the development of secondary amyloidosis. However, the time-course and progression of secondary amyloidosis are not understood well. In animal experiments, amyloid deposits were found 18h or a few weeks after inflammatory stimuli^[23-25]. Various factors have been reported to influence the susceptibility, onset, and progression of murine amyloidosis^[26,27]. It remains controversial whether amyloidosis is a late complication of CD. In the present patient, nephrotic syndrome developed and the diagnosis of secondary amyloidosis was made 13 years after the onset of CD. When proteinuria was initially detected, it had already been 12 years since the onset of CD. In the literature, the time lapse between the onset of CD and the diagnosis of amyloidosis has been reported to range from 3 to 15 years or from 1 to 21 years^[28,29]. In 11 of the 18 Japanese patients, more than 5 years had passed after the onset of CD. The longest period was 18 years. Conversely, in 2 patients, the diagnosis of amyloidosis preceded that of CD. When CD was diagnosed in these 2 patients, the lesion of CD had already become typical. These findings suggest that secondary amyloidosis usually occurs as a late complication of CD. However, as the onset of CD is usually gradual, CD and secondary amyloidosis may be diagnosed almost simultaneously.

[#]:The diagnosis of amyloidosis preceded that of Crohn's disease. CD: Crohn's disease, J: jejunum, I: ileum, C: colon, R: rectum, AA: amyloid A

Figure 1 Barium enema examination performed on March 18, 1993. Stricture associated with cobblestone appearance was seen in the ascending colon. Small inflammatory polyps were observed in the transverse colon and descending colon.

Figure 2 Surgical specimen of the terminal ileum, cecum, and ascending colon (May 26, 1993). Thickening of the bowel wall, cobblestone appearance, and longitudinal ulceration were found. Histologically, transmural inflammation and noncaseating epithelioid cell granuloma were found.

Figure 3 Gastrografen enema examination performed on May 8, 1997. A stricture was seen around the ileosigmoid anastomosis.

Figure 4 Findings of the renal biopsy.

A. Histological findings (hematoxylin and eosin). Amorphous, eosin-stained deposits were seen in the mesangial areas.

B. Histological findings (Congo red stain). The deposits were Congo red positive. Congo red stain showed reddish pink deposits that demonstrated apple-green birefringence when examined under polarized light.

C. Electron microscopic findings. Fine fibrils (8 to 10-nm in diameter) arranged randomly or in bundles were found in the mesangium.

The kidney is involved in the majority of patients with secondary amyloidosis. The resulting renal insufficiency caused a deterioration in the prognosis of the patient. Azathiopurine^[30], colchicine^[31,32], dimethylsulfoxide^[33], and elemental diet^[19] have been proposed as the treatment for secondary amyloidosis. However, the effectiveness of this regimen has not been established. Therefore, prevention or early diagnosis and treatment are important. In 15 of the

18 Japanese patients, the kidney was involved by amyloidosis. And in 13 of the 15 patients, renal involvement was the main clinical manifestation of amyloidosis. In only one of the 15 patients^[19], the amount of urinary protein decreased to less than 0.3 g/day since the initiation of elemental diet therapy. In the remaining 14 patients, however, neither proteinuria nor impaired renal function improved after various therapeutic attempts.

Therefore, regular urine test for proteinuria

would be useful for early diagnosis of amyloidosis regardless of the interval since onset of CD. To prevent the development and progression of secondary amyloidosis, it is probably important to maintain CD in the remission.

ACKNOWLEDGEMENT The authors thank the doctors of Osaka Medical College Hospital for their invaluable contributions to the study of this case.

Molecular biology of liver disorders: the hepatitis C virus and molecular targets for drug development

Howard J. Worman and Feng Lin

Subject headings hepatitis C; molecular biology; viral hepatitis; anti-viral agents

Worman HJ, Lin F. Molecular biology of liver disorders: the hepatitis C virus and molecular targets for drug development. *World J Gastroentero*, 2000;6(4):465-469

INTRODUCTION

Molecular biology has made a tremendous impact on the diagnosis and treatment of liver diseases^[1,2]. In particular, advances in molecular biology made possible the discovery of the virus that causes hepatitis C. In this review, we use hepatitis C as an example of the impact that molecular biology has made in the area of liver disorders. We emphasize how our growing understanding of the hepatitis C virus (HCV) has led to the identification of targets for development of new treatments.

THE HEPATITS C VIRUS (HCV)

Basic molecular virology of HCV

Investigators at Chiron Corporation were the first to discover HCV and reported this in a landmark paper published in 1989^[3]. The virus was identified by antibody screening of cDNA expression libraries made from DNA and RNA from the plasma of chimpanzees. These chimpanzees were inoculated with serum from humans with what was then called post-transfusion "non-A, non-B" hepatitis. The DNA expression library was screened with antibodies from sera of other patients with "non-A, non-B" hepatitis. This led to the isolation of clones that were derived from portions of the viral genome and encoded fragments of viral polypeptides. Treatment with RNase and DNase showed that HCV was a positive-stranded RNA virus^[3]. In an accompanying paper, the investigators who discovered HCV and their collaborators showed that the vast majority of individuals with chronic "non-A, non-B hepatitis" had antibodies against the newly identified viral

polypeptides^[4].

After the discovery of HCV, its entire genome was cloned and sequenced in several laboratories^[5-8]. HCV is a member of the Flaviviridae family. Once HCV infects cells, the positive, single stranded RNA genome is translated into a polypeptide of 3010 to 3033 amino acids, depending upon the strain (Figure 1). The viral RNA is not capped and translation occurs via an internal ribosome entry site (IRES) at the 5' end of the viral RNA^[9,10]. The mechanism of translation of uncapped viral RNA therefore differs from that used by virtually all cellular mRNAs which are capped at their 5' ends.

Both host cell and viral proteases cleave the HCV polypeptide into several smaller polypeptides (Figure 1). The major structural proteins are core protein and two envelope proteins called E1 and E2. Core protein forms the nucleocapsid of the mature virion and E1 and E2 are present in the viral envelope. A small polypeptide called P7 is also generated as a result of cleavage at the E2-NS2 junction but its function is not clear. Four major non-structural proteins called NS2, NS3, NS4, and NS5 are generated, two of which, NS4 and NS5, are further processed into smaller polypeptides called NS4A, NS4B, NS5A, and NS5B. The non-structural proteins have enzymatic functions that are critical for viral replication in cells, such as RNA helicase (NS3), protease (NS2, NS3-NS4A complex) and RNA polymerase (NS5B) activities. NS5A has been implicated in determining sensitivity to interferon alpha.

HCV replication and interactions with host cells

Little is known about the fundamental aspects of HCV replication, primarily because a robust cell culture has not been established. Although viral proteins and RNA components involved in critical steps in HCV replication are known, very little is understood about the mechanistic details or the role of accessory host cell factors. Some of the basic steps in HCV replication that occur in infected cells are outlined here.

After infection of cells, HCV RNA must be translated into protein. HCV RNA translation is initiated by internal ribosome binding, not by 5'-end dependent mechanisms^[9,10]. Internal initiation is specified by an IRES element. Such elements were first discovered in the genomes of picornaviruses^[11]. The IRES is believed to require the set of canonical translation initiation factors in order to function. In addition, IRES function is also thought to be dependent on other cell proteins. However,

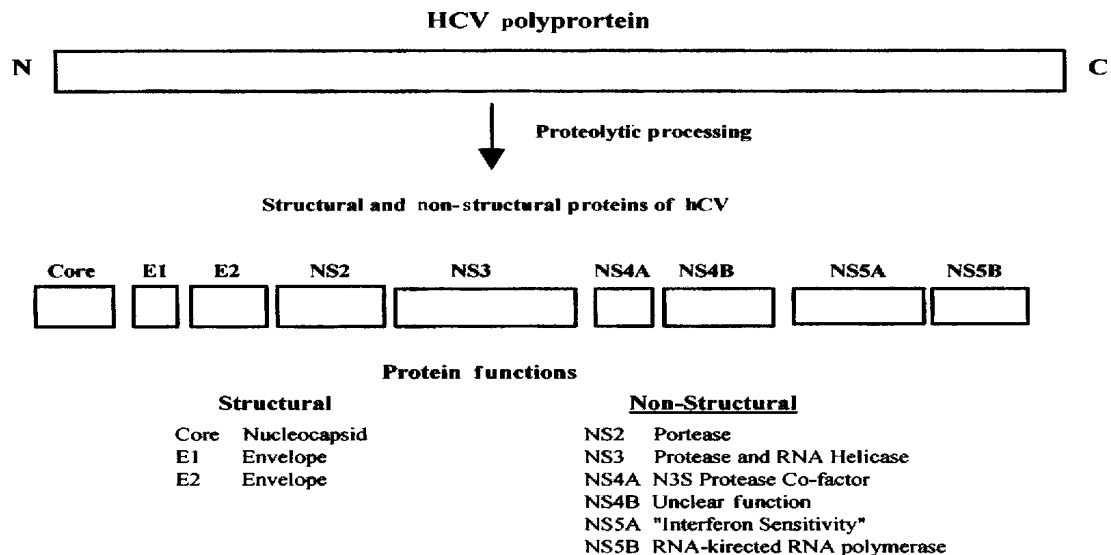

Figure 1 HCV proteins and their functions. The positive-stranded RNA of about 10,000 nucleotides is translated into a polyprotein of approximately 3000 amino acids. The polyprotein is proteolytically cleaved into several smaller proteins. Core, E1, and E2 are structural polypeptides. Core protein is the virus nucleocapsid and E1 and E2 are viral envelope proteins. A small polypeptide known as P7 (not shown) is also produced by additional cleavage between E2 and NS2. The major non-structural proteins are NS2, NS3, NS4, and NS5. NS4 is further processed into NS4A and NS4B and NS5 into NS5A and NS5B. NS2 and part of NS3 are proteases that process the viral polyprotein. NS3 also has RNA-helicase activity. NS4A is a cofactor for the NS3 protease and NS5B is an RNA-dependent, RNA polymerase. The functions of NS4B and NS5A are less well understood but NS5A is thought to play a role in determining sensitivity to interferon.

no single cell protein has been shown to be dispensable for the function of all IRESes.

HCV RNA must be unwound for efficient protein synthesis to occur. This process is catalyzed by a RNA helicase that is part of the viral NS3 protein. The three-dimensional structure of the HCV NS3 helicase domain has been determined and details about its function are emerging^[12-14]. At the present time, it is not known if host cell co-factors are necessary for optimal functioning of the NS3 helicase. Cellular RNA helicases have also been shown to bind to the HCV core protein^[15-17], however, it is not known if they also play a role in unwinding viral RNA.

After its synthesis, the HCV polyprotein is processed into the structural and nonstructural proteins. Proteolytic cleavages between structural polypeptides are catalyzed by signal peptidase in the endoplasmic reticulum. Two virally encoded proteases, NS2 and NS3, catalyze the other cleavages of the HCV polyprotein. The NS3 protease contains a trypsin-like fold and a zinc-binding site and is complexed with the viral protein NS4A^[18,19].

HCV RNA must be replicated to produce more virions. The viral protein NS5B is an RNA-dependent RNA polymerase. NS5B bears some similarity and motif organization to poliovirus polymerase and human immunodeficiency virus 1 (HIV-1) reverse transcriptase but adopts a unique shape due to extensive interactions between the fingers and thumb polymerase subdomains that encircle its active site^[20]. The precise mechanism of action of the

HCV NS5B polymerase is not known. Cellular or viral protein or RNA binding partners that function as subunits or initiation factors may be necessary for optimal activity.

The replication rate of HCV in human hosts is estimated to be extremely high. It appears that the estimated half-life of a viral particle is 2.7 h with production and clearance of about one trillion viral particles a day^[21]. This rate of virion production is approximately 1,000 times greater than that estimated for HIV-1. Factors responsible for the high rate of HCV replication are not entirely understood. This rapid rate of replication can explain the development of mutant strains or quasispecies that occur after HCV infection. It may also make development of an effective vaccine difficult.

DRUG TARGETS FOR THE TREATMENT OF HCV INFECTION

"Non-specific" anti-viral agents for HCV infection

The currently available drugs for the treatment of hepatitis C are anti-viral agents not specifically directed against HCV. The United States Food and Drug Administration (FDA) has approved several preparations of recombinant interferon alpha for the treatment of chronic hepatitis C. Interferon alpha is a suboptimal treatment in that only about 20% or less of patients who complete a one year course of treatment respond successfully as determined by the inability to detect HCV in serum 6 mo after the drug is stopped^[22]. Numerous adverse events are also associated with interferon alpha, most notably flu-like symptoms,

neutropenia, thrombocytopenia, and depression. Interferon alpha must be administered by injection 3 times a week. Newer preparations of interferon alpha-2b complexed with polyethylene glycol have been developed^[23]. These so-called “PEG-ylated” interferon alphas are released more slowly and evenly into the bloodstream and need only be administered by injection once a week. “PEG-ylated” interferon alphas will likely be approved for the treatment of chronic hepatitis C in the United States in the year 2000 or 2001.

The combination of interferon alpha-2b plus oral ribavirin is approved in many countries for the treatment of chronic hepatitis C. Combination treatment for 6 mo leads to no detectable virus in serum 6 mo after stopping therapy in approximately 40% of subjects^[24-26]. The major adverse event associated with ribavirin is hemolytic anemia, which in rare cases can be life threatening. VX-497 is a compound in development that inhibits inosine monophosphate dehydrogenase and may have antiviral effects similar to those of ribavirin^[27]. VX-497 is being studied in combination with interferon alpha to establish if it is as effective as ribavirin with a similar or preferable adverse events profile.

Other cytokines have also been tested in the treatment of HCV infection. A recent report of a pilot study suggests that interleukin-10 may slow the development of liver fibrosis in subjects with chronic hepatitis C^[28]. Interleukin-10, however, was not shown to have anti-viral activity against HCV.

Agents directed against HCV non-structural proteins

The next generation of drugs for the treatment of hepatitis C will likely be directed against non-structural HCV proteins with known enzymatic activities. Three major targets are the NS3 protease, NS3 helicase, and NS5B RNA-directed RNA polymerase. The fact that these proteins have enzymatic activities that can be measured *in vitro* make them amenable to high-throughput screening techniques favored by pharmaceutical chemists. This obviates the need to grow HCV in cell cultures or in small animals, tasks that have eluded investigators.

The three-dimensional structure of the HCV NS3 protease domain has been determined by X-ray crystallography^[18,19]. In addition, the structure of the NS3 protease domain complexed with an inhibitor has recently been established^[29]. Armed with this knowledge, chemists can use rationale drug design to synthesize compounds to inhibit protease activity. Rational drug design can be combined with combinatorial chemistry in which a library of thousands or more structurally similar molecules is tested against the target. By combining rational drug design and combinatorial chemistry with high throughput screening techniques that measure enzymatic activity, NS3 protease inhibitors can be identified, further developed and ultimately tested in infected chimpanzees and humans.

Similar methods can be used to identify inhibitors of the NS3 helicase domain and NS5B RNA

dependent RNA polymerase. The three-dimensional structures of these proteins are also known^[12-14]. Although human cells have RNA helicases, their mechanism of action is probably different than RNA helicases of viruses^[30]. Animal cells do not have RNA-dependent RNA polymerases, making NS5B an attractive target for an anti-viral agent.

Agents directed against HCV RNA

HCV RNA differs from cellular mRNA. First, it has a unique ribonucleotide sequence. Second, as outlined above, HCV RNA is uncapped and translation is initiated via an IRES. Third, the viral RNA must be efficiently packaged into the mature virions. These features make the HCV RNA a potential target for anti-viral drugs.

Ribozymes are catalytic RNA molecules that can be designed to cleave specific RNA sequences. Ribozymes therefore have potential utility as drugs against RNA viruses, including HCV. Investigators at Ribozyme Pharmaceuticals have developed ribozymes against conserved genomic sequences in HCV^[31]. These ribozymes cut the viral RNA at specific sequences and are able to inhibit HCV RNA-directed protein synthesis and HCV RNA replication in *in vitro* systems. It is anticipated that a ribozyme against HCV will be tested in human clinical trials in the next couple of years.

HCV RNA is translated by internal ribosome binding mediated by an IRES^[9,10]. The IRES adopts a tertiary structure that is necessary for function^[32,33]. Interference with IRES structure or function is a logical approach to attacking HCV replication. Antisense oligonucleotides targeted to a stem-loop structure within the IRES have been shown effective at inhibiting HCV gene expression^[34,35]. Other small molecule inhibitors can potentially be designed to inhibit HCV IRES function, which can be measured using *in vitro* assays adaptable to high throughput screening methods.

HCV RNA genomes must be packaged into newly synthesized virions. This is likely mediated by specific interactions between sequences in RNA and core protein. Synthetic oligonucleotides corresponding to sequences in the 5' region of the HCV genome have been shown to bind to core protein^[36]. Agents that block HCV RNA binding to core protein could be useful as inhibitors of virion production.

Agents directed against other targets of HCV

HCV presumably gains access to hepatocytes, and possibly other cells, by binding to a plasma membrane protein receptor or receptors. HCV envelope proteins E1 and E2 have been shown to interact with plasma membranes of hepatocytes and other cells^[37]. E1 and E2 may form a heteromeric complex^[38], however, it is not clear if their association is necessary for binding to cell membranes.

The receptors for HCV entry into liver cells are also not presently known. However, an interaction between HCV E2 and a plasma membrane protein CD81 has been described and characterized in some detail^[39,40]. It is difficult to establish if this interaction mediates HCV entry

into cells, primarily because a robust cell culture system for HCV is not currently available. Even if CD81 or other proteins that bind to HCV E1 and E2 are not receptors that mediate viral entry, knowledge of these interactions could lead to the development of drugs that inhibit the binding of HCV to cells. Additional experimental work that may lead to the definitive identification of HCV receptors could also lead to the development of viral entry inhibitors. Structural analysis of the interactions of viral envelope proteins with cellular receptors should be of tremendous value in the development of drugs as it will be in the case of HIV-1^[41,42].

The core protein of HCV is another potential target for the development of anti-viral drugs. In infected cells, HCV core protein is synthesized on the endoplasmic reticulum membrane with a large domain facing the cytoplasm^[43]. HCV core protein has been shown to form multimers^[44] and the self-interaction of core protein is likely important in the assembly of the virion nucleocapsid. HCV core protein expression may also influence critical processes that have implications for cellular pathophysiology. Core protein may play a role in transformation and oncogenesis^[45] or be involved in regulating apoptosis as it has been shown to bind to the cytoplasmic domain of lymphotoxin- β receptor, a member of the tumor necrosis receptor protein family^[46]. HCV core protein also binds to a cellular RNA helicase and this interaction may adversely affect host cell protein synthesis and provide the viral RNA with enhanced access to the cell's protein synthesis machinery^[15-17]. Inhibitors of core protein self-assembly or its interactions with other cellular proteins could therefore be useful in the treatment of hepatitis C.

CONCLUSIONS

The innovative application of standard technique in molecular biology led to the discovery of HCV. The development of treatments for HCV infection has lagged our understanding of the molecular biology of the virus because neither a small animal model of the disease nor a robust cell culture system for the virus currently exist. Recent advancements such as the development of "sub-genomic replicons"^[47] and an infectious viral RNA clone that can infect chimpanzees^[48] may partially overcome these limitations. Nonetheless, based on our present understanding of the molecular biology of HCV, several steps in the viral life cycle can currently be targeted for the development of anti-viral drugs.

INTRODUCTION

A major function of the intestinal epithelium is to control the amount of fluid entering into and being absorbed from the lumen^[1]. In healthy conditions, net fluid movement follows an absorptive vector, although significant secretion also takes place to subserve digestive function. Thus, the secretion of fluid, driven by the active secretion of electrolytes, is important for maintaining the fluidity of intestinal contents during various stages of digestion and thereby allowing for diffusion of enzymes and nutrients. In the setting of disease, dysregulation of intestinal transport mechanisms may alter the balance between absorptive and secretory processes such that secretion predominates, leading to the clinical consequence of diarrhea. However, under conditions of both health and disease, fluid secretion is driven largely by the active secretion of chloride ions. Thus, there are both basic and clinical reasons for wishing to gain a full understanding of the basis and regulation of this transport process. The goal of my article, therefore, will be to review our understanding of intestinal chloride secretion and the ways in which it is regulated. Recent insights in this are enhancing our ability to intervene in diseases where chloride secretion is over-expressed, such as infectious and inflammatory diarrheal illnesses will also be discussed. This article will also cover the implications of intestinal secretory mechanisms for a genetic disease where chloride secretion is under-expressed, namely cystic fibrosis, where significant intestinal dysfunction, including

obstruction and malabsorption, may also ensue.

MECHANISMS OF INTESTINAL CHLORIDE SECRETION

The secretory mechanism

The details of the ion transport pathways making up the intestinal chloride secretory mechanism have been quite well worked out at this point^[1,2]. The mechanism is predominantly expressed, at least as assessed functionally, in epithelial cells lining the crypts of both the small intestine and colon, although there may be a small degree of secretion derived from villus or surface epithelial cells in addition^[2]. Chloride is taken up from the bloodstream across the basolateral membrane of epithelial cells via a sodium/potassium/2 chloride cotransporter that has been cloned and designated as NKCC1^[3]. This cotransporter is driven secondarily by the low intracellular sodium concentration established by the active sodium/potassium ATPase, also localized to the basolateral membrane. This allows chloride to accumulate in the cell cytosol above its electrochemical equilibrium. When apical chloride channels are opened, this chloride is then free to flow out of the cell down this electrochemical gradient, resulting overall in net transepithelial transfer of the anion. Chloride exit occurs predominantly through a channel referred to as CFTR, which is the product of the gene that is defective in the setting of cystic fibrosis^[4]. More recently, in addition, it has been recognized that the apical membrane of intestinal epithelial cells may also contain calcium-activated chloride channels of the CLCA family, and perhaps other channels for these and/or other anions^[5,6]. The transport mechanism is also critically dependent on the presence of basolateral potassium channels which serve to recycle co-transported potassium back across the basolateral membrane, and thus prevent cell depolarization^[7,8].

Positive regulation of chloride secretion

Chloride secretion is stimulated in the intestine by a broad array of substances derived from local and more distant endocrine cells, enteric nerves, neighbouring cell types such as immune cells and subepithelial myofibroblasts, and exogenous factors such as bacterial enterotoxins^[2]. These regulatory pathways provide for minute-to-minute physiological increases in the extent of secretion (such as in response to ingestion of a meal) but also contribute to the marked upregulation of secretion that can occur in the setting of a disease^[1]. Despite many hormones, neurotransmitters and other mediators that have been identified and characterized to date as stimuli of chloride

Professor and Vice-Chair for Research, Department of Medicine, University of California, San Diego, School of Medicine, San Diego, CA 92103, USA. Professor Kim E. Barrett received her Ph.D. degree from University College London, England, in 1982, and postdoctoral training from the National Institutes of Health, USA. She is currently Professor and Vice-Chair for Research in the Department of Medicine, University of California, San Diego, School of Medicine, and directs an NIH-funded research program that focuses on the mechanisms and regulation of intestinal electrolyte transport. She has published over 140 original papers, book chapters and review articles, and is the current Editor-in-Chief of *American Journal of Physiology-Cell Physiology*.

Received 2000-05-25 **Accepted** 2000-06-15

secretion, however, appear to exert their effects through two main signaling pathways^[1]. The first of these is mediated by changes in intracellular cyclic nucleotides, and results in large magnitude, sustained secretory responses. At an intracellular level, the primary locus for regulation appears to be the cyclic-nucleotide mediated phosphorylation and opening of the CFTR chloride channel, particularly via cAMP and the cAMP-dependent protein kinase, PKA^[9,10]. It is increasingly recognized that at least one type of PKA is "scaffolded" in the proximity of CFTR via various interacting proteins, which likely contributes to the efficiency of signal transduction in response to cAMP-mobilizing agonists^[11,12]. Chloride secretion can also be evoked by agonists that increase intracellular levels of cGMP, the best physiological example of this pathway being the stimulation by the peptide agonist guanylin, which binds to an apical receptor also shared by the heat-stable toxin of *E.coli*^[13]. cGMP-dependent secretion involves a cGMP-dependent protein kinase and/or cross-activation of PKA, and is very similar to that induced by increases in cAMP in terms of its magnitude, kinetics and dependence on CFTR activation. Cyclic nucleotide-dependent secretion, in general, may also involve regulatory events at additional levels within the transport machinery. For example, there is evidence to suggest that sustained secretion requires the insertion of additional NKCC1 molecules into the basolateral membrane (or at least an alteration in their rate of endocytosis), and cAMP-activated potassium channels have also been postulated on functional grounds^[3,8,14].

Chloride secretion can also be evoked by agonists that are capable of causing an increase in cytosolic calcium concentrations. In contrast to the cyclic-nucleotide dependent chloride secretory responses discussed above, calcium-dependent responses are distinctive in that they are smaller and also considerably more transient^[2]. However, calcium-dependent secretion may nevertheless play a physiological role, particularly in the setting where only a brief, self-limited secretory response is called for. Moreover, synergism occurs between the secretory effects of cAMP- and calcium-dependent agents, allowing the host, to call on markedly upregulated rates of secretory function at times of threat (such as invasion by pathogenic microorganisms). Finally, calcium-dependent secretory responses may assume far greater significance in the setting of cystic fibrosis, where the cAMP-dependent chloride channel, CFTR, is lost or dysfunctional^[15]. At an intracellular level, at least part of the chloride secretory effect occurring in response to an increase in cytosolic calcium is secondary to the opening of basolateral, calcium-sensitive potassium channels. This, in turn, increases the driving force for chloride to exit across the apical membrane through the small proportion of CFTR channels that are hypothetically open even in resting cells^[16]. However, evidence is also accumulating to suggest that elevations in calcium, acting in concert with the calmodulin-dependent protein kinase CaMKII, open

additional apical chloride channels of the CLCA family^[17-20]. This view lends additional credence by the observation that calcium-dependent agonists can cause chloride secretion in at least some epithelial cells even in the absence of any measurable CFTR function^[17,21].

Negative regulation of chloride secretion

Work from our laboratory has also indicated that certain intracellular signaling pathways may lead to the inhibition of ongoing chloride secretion, and/or may result in its termination^[2]. Such negative signals appear to be particularly pertinent in the case of calcium-stimulated chloride secretion, with the transience of this secretory response implying that endogenous factors may serve to limit its extent. We have identified two main pathways whereby calcium-dependent chloride secretion is inhibited. The first of these, interestingly, is activated by substances that also serve to initiate calcium-dependent chloride secretion. An example is the muscarinic agonist carbachol, which evokes a transient chloride secretory response that renders intestinal epithelial cells refractory to re-stimulation by another calcium-dependent secretagogue^[22]. Both the stimulatory and inhibitory effects of carbachol are dependent on cytosolic calcium^[23]. The inhibitory pathway involves the generation of a novel inositol phosphate mediator, inositol 3,4,5,6 tetrakisphosphate [Ins (3,4,5,6) P₄], which reduces the open probability of calcium-activated chloride channels^[22,24]. The upstream pathways leading to generation of this messenger involve tyrosine-kinase dependent events, and the transactivation of the receptor for epidermal growth factor (EGF) and recruitment of the MAP kinase signaling cascade^[25]. Inhibitors of both the EGF receptor and MAP kinase pathway potentiate and prolong secretory responses to carbachol^[25].

A second inhibitory mechanism also centers around the EGF receptor, but the messengers and targets involved in the inhibition of chloride secretion are different^[26-28]. Thus, when the EGF receptor is activated by its cognate ligands, it heterodimerizes with another member of the ErbB receptor family, ErbB2, and thereby recruits alternative signaling events than those resulting from EGF receptor transactivation in response to carbachol^[29]. This signaling diversification, in turn, appears to activate phosphatidylinositol 3-kinase, an novel isoform of protein kinase C (PKC-), and ultimately leads to the inhibition of a basolateral potassium channel, thereby inhibiting the overall process of chloride secretion by preventing potassium recycling^[27,28,30]. It is of interest to note that EGF, and related growth factors, inhibit chloride secretion without themselves serving as agonists in the process. Since such growth factors and their receptors are known to be upregulated in the setting of mucosal injury, their ability to inhibit chloride secretory responses may represent an adaptive response that would limit diarrhea under these conditions.

ALTERATIONS IN CHLORIDE SECRETION IN THE SETTING OF DISEASE

Secretory diarrhea

An excess of chloride secretion into the intestine, above that which can be compensated for by the reserve capacity of intestinal absorptive mechanisms, manifests clinically as diarrhea^[1]. The classical example of this response is seen in cholera, where up to 20 liters of stool fluid can be lost per day^[1]. Cholera, in common with a number of other intestinal pathogens, elaborates enterotoxin that interact with epithelial cell signal transduction machinery to elicit profound and sustained chloride secretion due to an irreversible increase in intracellular cyclic nucleotide concentrations. Cholera toxin is internalized and induces a massive increase in intracellular cAMP, whereas the heat stable enterotoxin of *E.coli* bind to an apical receptor that contains an integral guanylyl cyclase activity, and thereby stimulates chloride secretion secondary to an increase in intracellular cGMP. The direct effects of enterotoxins on secretory epithelial cells are also amplified by a number of additional actions. For example, cholera toxin also activates enteric nerve endings, enterochromaffin cells and mast cells, all of which are capable of releasing neurotransmitters and other agonists that themselves can stimulate chloride secretion either directly or indirectly^[2].

Secretory diarrheal illness is also seen in the setting of infections with pathogens that are not known to elaborate enterotoxins activities. For example, *Salmonella* Dublin, an invasive bacterium, appears to activate a program of gene expression within the epithelial cell that predisposes to excessive fluid secretion. Thus, there is upregulation of cyclooxygenase-2 and nitric oxide synthase expression, and in cell culture models, both of these enzymes appear to contribute to an enhanced capacity of the epithelial cell to secrete chloride in response to a range of stimuli^[31]. Similarly, over-expression of cyclooxygenase-2 leads to an increased production of prostaglandins, particularly those of the E series that are known to be potent chloride secretagogues^[31]. *Salmonella* invasion also evokes the synthesis of a wide range of chemokines and other cytokines by intestinal epithelial cells, and the resulting inflammatory influx that is targeted to infected cells almost certainly further amplifies secretory responses in the intact tissue setting^[32]. Furthermore, some workers have shown that *Salmonella* infection is associated with the de novo expression of receptors for the neuropeptide galanin, a known secretory agonist^[33,34]. Antibodies that interrupt galanin signaling can significantly dampen intestinal fluid secretion in a murine model of salmonellosis^[33]. Thus, the host defense response of diarrhea can be generated even by pathogenic microorganisms that do not elaborate any known enterotoxins. Indeed, upregulation of the secretory capacity of intestinal epithelial cells can even occur in the setting of infection with a non-invasive parasite also associated with diarrheal illness, *Giardia lamblia*. These parasites adhere to, but do not penetrate, the intestinal epithelium. Co-culture of intestinal epithelial cells with *G. lamblia*

trophozoites results in enhanced chloride secretory responses, and a apparent upregulation of expression of membrane transport proteins involved in the chloride secretory mechanism such as CFTR and NKCC1 (Resta-Lenert *et al*, submitted). However, paradoxically, *Giardia* co-incubation appears to significantly reduce the ability of certain agonists to mobilize intracellular calcium. These data, in addition to being potentially significant for our understanding of infectious diarrhea, are also of interest because they underscore the concept that calcium-dependent secretagogues may exert negative as well as positive effects on secretion.

Diarrhea is also a common sequella of non-infectious, inflammatory conditions of the intestine, such as ulcerative colitis and Crohn's disease^[1]. A substantial body of evidence now suggests that cells of the immune system that presumably are activated in the course of such conditions can release a wide range of products capable of evoking chloride secretion. Conversely, inflammation and tissue injury is also often accompanied by upregulation of the expression of growth factors, such as EGF, and their receptors, which may serve ultimately to counteract excessive secretion associated with inflammatory conditions of the gut^[35]. Such mechanisms may underlie the efficacy of growth factors such as EGF and insulin-like growth factor that has been demonstrated in diarrheal conditions in various models of inflammation^[35].

Cystic fibrosis

The disease states discussed above are characterized by excessive chloride secretion. However, inadequate chloride secretion, as occurs in the setting of cystic fibrosis, can be equally or perhaps even more disadvantageous for the patient. Cystic fibrosis is characterized functionally by the absence of a cAMP-regulated chloride secretory pathway^[15]. This is due to a series of more than 800 known mutations although about 70% of cases are related to a single mutation, of the CFTR gene, $\Delta F508$, that results in a channel protein that fails to traffic normally to the apical plasma membrane of secretory epithelial cells. Much of the morbidity and mortality in cystic fibrosis relates to pulmonary manifestations^[36]. However, with advances in diagnosis and treatment, the median survival age for patients with cystic fibrosis has increased dramatically over the last several years. This means that disease manifestations in organs other than the lungs are becoming more recognized, and may carry a substantial burden in terms of morbidity.

There are a number of gastrointestinal manifestations of cystic fibrosis, as well as complications related to dysfunction of the biliary and pancreatic systems. A large proportion of newborns with the disease are born with a form of intestinal obstruction known as meconium ileus, assumed to result from inspissated intestinal secretions that are poorly hydrated and thus difficult to clear from the lumen. In some cases, prompt surgical intervention is necessary, and evidence suggests that children presenting

with this complication will go on to have poorer nutritional status and growth, even if treated successfully, than cystic fibrosis patients without this manifestation^[37,38]. Similarly, intestinal obstruction associated with cystic fibrosis may also be seen in older children and also in the increasing number of adults living with this disease^[39]. The role of CFTR in promoting biliary and pancreatic ductular secretion also means that the majority of patients suffer from pancreatic insufficiency, up to half experience biliary disorders, and approximately 5% may display Frank liver disease^[39]. In addition, it has recently been postulated that unsuspected cystic fibrosis (of genotypes other than those associated with pancreatic insufficiency, such as $\Delta F508$) may be the cause of at least some cases of idiopathic pancreatitis^[40]. In each of these cases of gastrointestinal complications of cystic fibrosis, the pathology suggests that any alternate chloride secretory mechanism that are present in intestinal, pancreatic or biliary epithelial cells are insufficient to compensate for the loss of cAMP-regulated chloride secretion. In this respect, the knowledge that intestinal epithelial cells, at least, express intrinsic negative signaling pathways that limit the extent of calcium-dependent chloride secretion may offer both an explanation for this situation, as well as a possible therapeutic target if such negative signaling events can be countermanded.

The prevalence of cystic fibrosis in, especially, Caucasian populations, where estimates suggest that more than 3% of the population are heterozygous carriers of the disease, raises questions about the evolutionary pressures that have driven the retention of mutant CFTR alleles in the gene pool. Hypothetically, such individuals might have thereby gained a heterozygote advantage in resistance to enterotoxin-mediated diarrheal illnesses, such as cholera, although this may be inconsistent with the relative prevalence of cystic fibrosis in Caucasian compared with other ethnic groups. Moreover, studies in mouse models of cystic fibrosis also fail to suggest that heterozygotes show any diminished intestinal secretory responses to cholera toxin^[41,42]. However, more recent studies suggest that tissues obtained from mice with one mutant CFTR allele do display an increased resistance to invasion by bacteria such as *Salmonella*, although the mechanism of this effect is unknown^[43]. This does provide an attractive hypothesis for cystic fibrosis prevalence, especially given that typhoid fever was common in Western Europe until relatively recent times.

CONCLUSION

Advances in our understanding of the molecular basis of intestinal chloride secretion, as well as its regulation, may offer significant insights into disease states where this transport mechanism is either over or under-expressed in the intestine, such as secretory diarrhea and cystic fibrosis. Ultimately, it is hoped that such insights will spawn new therapies for these conditions. Secretory diarrheal illness, in particular, still constitutes a major burden of morbidity

and mortality, particularly among children in developing countries. Moreover, in creased international travel, and the emergence of more highly pathogenic strains of certain bacteria, such as *E.coli*, will also increase the prevalence of diarrhea. Thus, improved therapies are urgently needed, in concert with the public health measures that will reduce exposure to the infectious agents that cause such disease.

ACKNOWLEDGEMENTS I thank Glenda Wheeler-Loessel for assistance with manuscript preparation. I am also grateful to the following former and present members of my laboratory who have contributed to some of the studies described herein: Lone Bertelsen, Ph.D., Sean Calandrella, Jimmy Yip Chuen Chow, Ph.D., Cornelia Gelbmann, M.D., Stephen Keely, Ph.D., Declan McCole, Ph.D., Silvia Resta-Lenert, M.D., Ph.D., Jrgen Ri es, M. D., Jane Smitham, Jrgen Stein, M.D., Ph.D., Jorge Uribe, Ph.D., M.D., and Mana Vajanaphanich, M.D. Studies from the author's laboratory have been supported by grants from the National Institutes of Health (USA): DK28305, DK53480 and DK35108 Unit 5.

INTRODUCTION

Helicobacter pylori is recognized as a cause of chronic active gastritis, gastric and duodenal ulcers, and gastric cancer, though the mechanisms of pathogenesis for *H. pylori*-associated diseases are not yet well understood [1-4]. The ecological niche to which *H. pylori* is well-adapted is the mucous layer of the human gastric antrum, which has mucin glycoproteins as major constituents. Mucins, high-molecular weight carbohydrate-rich glycoproteins that coat the surface of the stomach and are secreted into the lumen, function to protect the stomach and could be important in *H. pylori* colonization. For further understanding the pathogenesis of *H. pylori* related diseases, it is important to consider whether *H. pylori* colonization of the surface epithelium is associated, as cause or effect, with changes in the gastric mucin synthesized by surface mucous cells.

MUCINS PRODUCED IN NORMAL STOMACH

The entire gastrointestinal tract is coated with a protective mucous layer. The main components of the viscoelastic mucous are mucin glycoproteins. Mucins are thought to protect the surface of the gastrointestinal tract from mechanical damage, from dessication, and from chemical irritants. Gastric mucins are the major components of an unstirred mucous-bicarbonate layer that protects the gastric epithelium from the high concentrations of acid in the stomach lumen and from autodigestion by pepsin. The protective functions of the gastric mucous layer imposes rigid requirements on the structure of gastric mucins (Figure 1). They must be very high in molecular weight

and highly hydrated to provide the viscoelasticity necessary for protection from mechanical damage, and must also be acid-stable and have little non-glycosylated polypeptide exposed as a target for pepsin.

Figure 1 Models of gastric mucin structure. Lower bars represent cDNA sequences of MUC1 cell-surface mucin and MUC5AC secreted mucin, with different domains labeled. Resulting structures of the proteins with attached carbohydrate are schematically represented above.

Like mucins from a number of sources, human gastric mucins are very high in molecular weight and are heavily substituted with O-linked oligosaccharides. Human mucins are encoded by at least nine distinct mucin genes, of which three, MUC1, MUC5AC, and MUC6, are expressed at high levels in the normal stomach (Table 1).

MUC1 mucin is well characterized [5]. The protein encoded by the MUC1 gene has a large central domain (VNTR, Variable Number of Tandem Repeats) composed of a variable number (25 to 125) of tandem repeats of a 20-amino acid sequence with 25% threonine and serine and 7% proline. Unlike most other mucins, the MUC1-encoded protein has a transmembrane segment and a cytoplasmic tail that can interact with the cytoskeleton. The O-linked carbohydrates on MUC1 mucin are heterogeneous, differ between tumors and normal epithelial cells [6], and can influence the recognition of the mucin protein by different monoclonal antibodies. MUC1 mucin is produced to some extent by most epithelial cells, but has been studied most extensively in mammary, pancreatic, and colon cancer cells.

MUC5AC is expressed in the stomach and in tracheobronchial cells. Immunohistochemical studies indicate that MUC5AC apomucin is present in surface mucous cells of the gastric epithelium [7,8]. MUC5AC mucin has a small tandem repeat sequence of 8 amino acids, interspersed with cysteine-containing regions (Figure 1). The glycoprotein is very large with the bulk of the

molecule made up of heavily glycosylated tandem repeats of an 8-amino acid peptide sequence rich in threonine (to which O-linked oligosaccharides are attached) and proline. Interspersed irregularly within the tandem repeat region are cysteine-containing motifs. Like MUC2 intestinal mucin, both the N-terminal and the C-terminal have cysteine-rich globular domains^[9] with sequence similarity to the D domains of pre-pro-von Willebrand factor and an inferred cystine-knot motif, topologically similar to epidermal growth factor (EGF). The cysteine-rich globular domains of secreted mucins may be involved in the oligomerization of mucin or in binding to collagen of basement membranes^[10]. MUC5AC is expressed in the normal stomach, but not in normal colon. Aberrant expression of MUC5AC has been reported, however, in colorectal cancers and adenomas^[8,11,12] and may be related to the progression of colon cancers.

MUC6 is also expressed in the normal stomach, but in mucous glands rather than surface mucous cells^[7,8,13,14]. This mucin has a very large tandem repeat sequence of 169 amino acids, very high in amounts of Thr, Ser, and Pro^[13]. The high content of Thr and Ser likely accounts for the large amount of carbohydrate present on this molecule. Thus, there are (at least) two completely different secreted mucins produced by the normal stomach. How these mucins differ in carbohydrate (and whether they differ in function) is speculative. Genes for both MUC5AC and MUC6 have been assigned to a region of chromosome 11 that also codes for two other secretory mucins^[15], with a gene order of HRAS-MUC6-MUC2-MUC5AC-MUC5B-IGF2.

Like mucins from other sources, the carbohydrate portion of gastric mucin is heterogeneous. Several neutral oligosaccharide structures have been published^[16,17], but the overall complement of oligosaccharides is not known. The results of histochemical studies suggest that the carbohydrate portion of the mucin in surface mucous cells is different from that in mucous glands. The surface mucous cells are stained by PAS, while mucous glands (cardiac gland, mucous neck cells, and pyloric gland cells) are stained by alcian blue. The "neutral" mucins in surface mucous cells are also stained by galactose oxidase/Schiff, suggesting the presence of terminal Gal or GalNAc^[18]. The mucous gland cells uniquely show periodate-enhanced binding of concanavalin A, called paradoxical ConA staining. The structural basis for this is unclear, but it may detect terminal alpha-GlcNAc^[18]. The mucous gel layer covering the surface epithelium has been shown to have clearly demarcated layers of two distinct mucin types^[19]. On the basis of staining properties, these likely correspond to the surface-type neutral mucin (MUC5AC) reactive with galactose oxidase and to the gland-type acid mucin (MUC6), possibly sulfomucin, revealed by periodate-enhanced (paradoxical) ConA staining.

EFFECT OF *H.pylori* ON GASTRIC MUCIN IN VIVO

Though both the thickness and the hydrophobicity of the mucous gel layer is decreased in the gastric mucosa of ulcer patients^[20], it has not been established whether this is associated with increased mucin degradation, decreased mucin synthesis, or a change in mucin type. It has been postulated that one important pathogenic property of *H.pylori* is its ability to weaken the mucous gel that protects the gastric epithelium^[21,22], but the presence or absence of mucinase activities in *H.pylori* is controversial^[23-25]. Direct analysis of mucins from *H.pylori* infected and uninfected patients show no decrease in viscosity, arguing against *H.pylori* dependent mucin degradation^[26]. In spite of histochemical observations of mucous depletion accompanying *H.pylori* infection, qualitative alterations in the type of mucin produced have only recently been studied.

In order to determine the effect of *H.pylori* infection on mucin gene expression in the gastric epithelium^[7], biopsies from *H.pylori*-positive and *H.pylori* negative patients were examined by immunohistochemistry (Table 2). MUC6 was limited to mucous glands of *H.pylori*-negative patients, but 72% of *H.pylori* positive patients also expressed MUC6 on surface mucous cells. In contrast, MUC5AC mucin was seen in significantly fewer surface mucous cells of *H.pylori*-positive specimens. Overall, the percent of the surface epithelium stained by anti-MUC5 was significantly lower in *H.pylori*-positive specimens than in *H.pylori*-negative specimens ($P < 0.01$). Carbohydrates recognized by LeX and paradoxical ConA staining were aberrantly expressed in the surface mucous cells of 16/27 and 17/23 of *H.pylori*-positive tissues, respectively. There was a suggestive but non-significant decrease in staining for MUC1 mucin. Retrospective examination of clinical histories and histological findings showed that the mucin alterations occur in *H.pylori* infected individuals with and without ulcers, but not in patients with non-*H.pylori*-associated gastritis or gastric ulcers (Figure 2). This indicates that the mucin alterations are not simply a secondary effect of inflammation.

For more direct examination of mucin gene expression, the presence of MUC5AC and MUC6 message in antral biopsies were examined by in situ hybridization^[7]. In antral biopsy specimens from *H.pylori*-negative patients, MUC5AC mRNA was homogeneously expressed in surface epithelial cells. MUC5AC expression in the surface epithelial cells of *H.pylori*-positive patients was patchy, however, and often absent from large areas of the surface epithelium. Concordance between the pattern of MUC5AC expression as determined by in situ hybridization and immuno-histochemistry was 100%. MUC6 expression was limited to cells of the deep glands in *H.pylori*-negative patients, seen by both in situ hybridization and immunohistochemistry. In contrast, 6 of 8 *H.pylori*-positive specimens

Table 1 Human mucin genes

Gene	Locus	mRNA size	Tandem Repeats	Other structural features	Expression in normal tissues
MUC1	1q21-24	4-7 kb	20 AA	Transmembrane	Most epithelia
MUC2	11p15.5	14-16 kb	23 AA, -16 AA	D-domains, cystine knot	Colon>small intestine>respiratory tract
MUC3	7q22	16-17.5 kb	17 AA, 59 AA	Cystine knot	Small intestine>colon, gall bladder
MUC4	3q29	16.5-24 kb	16 AA		Respiratory tract, cervix>GI tract
MUC5AC	11p15.5	17-18 kb	8 AA	D-domains, cystine knot	Stomach (surface)>respiratory tract
MUC5B	11p15.5	17.5 kb	29 AA, interrupted	D-domains, cystine knot	Respiratory tract, salivary gland, cervix>GI tract
MUC6	11p15.5	16.5-18 kb	169 AA	Cystine knot	Stomach (glands), gall bladder
MUC7	4	2.4 kb	23 AA	No homology to large mucins	Salivary glands

^a% of surface epithelium stained; ^b% of patients with surface staining; ^a*P*<0.05, *H.pylori* positive vs *H.pylori* negative

Figure 2 Expression of MUC5AC in surface epithelium of normal human stomach and gastritis and gastric ulcer specimens. ^a*P*<0.05 vs corresponding *H. pylori* negative group.

(0/7 *H.pylori* negative specimens) had focal MUC6 mRNA expression in surface epithelial cells. MUC5AC and MUC6 gene expression were examined in antral biopsies obtained from patients with *H.pylori*-associated antral gastritis (biopsy-proven) before and after documented eradication of the bacterium. In 7 of 10 cases MUC5AC expression increased (*P* = 0.004) after *H.pylori* eradication (Figure 3). Eradication of *H.pylori* also resulted in reversal of MUC6 antigen expression toward normal patterns.

The effect of *H.pylori* on gastric mucin expression was further examined by purification and immunochemical analysis of mucins from gastric juice of *H. pylori*-positive and *H.pylori*-negative patients. For *H.pylori*-infected patients and uninfected patients that had been examined for immunohistochemical staining of biopsy tissues, gastric

Figure 3 MUC5 expression in patients before and after eradication of *H.pylori* infection. MUC5 gene expression was determined by in situ hybridization. Bars show mean percent of epithelial cells expressing MUC5. Lines show changes in MUC5AC expression in individual patients.

aspirates were used as a source for mucin purification by gel filtration and CsCl density gradient centrifugation. There was no significant difference in yield of mucin or carbohydrate content between *H.pylori*-positive and *H.pylori*-negative specimens (Figure 4). The purified mucins were examined by ELISA for MUC6 and Le^b antigenic activity. MUC6 activity was higher (*P* = 0.026) in mucins from the *H.pylori*-infected patients than in mucins from uninfected patients. Mucins from the *H.pylori*-infected patients also bound monoclonal antibody to Le^b antigen to a significantly greater extent (*P* = 0.014) than mucins from the uninfected patients (Figure 4). Subsequently, these purified mucins have been examined

by SDS-PAGE and Western analysis. Infection with *H. pylori* was associated with an increase in MUC6 (detected with anti-M6P and also with anti-Le-b and *Ulex europaea* agglutinin) and a decrease in MUC5AC (detected with anti-M5P and 45M1 antibodies and also with peanut agglutinin and *Vicia villosa* agglutinin) in these secreted mucins.

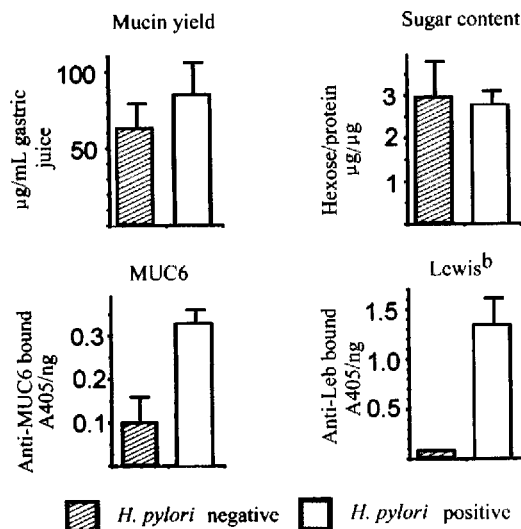

Figure 4 Purification and analysis of mucins from gastric juice. Upper left, yield of mucins purified from gastric aspirates of 5 *H. pylori*-negative and 5 *H. pylori*-positive patients. Upper right, carbohydrate content of purified mucins. Lower left, binding of antibody to MUC6 peptide in ELISA. Lower right, binding of antibody to Lewis-b antigen.

These results establish that there is aberrant surface expression of gland-type gastric mucin in surface mucous cells of *H. pylori* infected patients, accompanied by focally decreased MUC5AC mucin. This decrease in MUC5AC mucin and aberrant expression of MUC6 might be expected to disrupt the protective surface mucin layer. How or whether alterations in gastric mucins would influence processes that lead to disease is an important question which requires that the specificity and mechanisms of mucin depletion be better understood.

EFFECT OF *H. pylori* ON MUCIN SYNTHESIS IN VITRO

Analyses of tissue specimens and purified mucin glycoproteins indicate that gastric surface-type mucin expression is reversibly decreased in *H. pylori*-infected patients^[7] but do not allow direct examination of mucin synthesis. Gastric cells in culture were examined to determine the effect of *H. pylori* on mucin synthesis^[27]. KATO III gastric epithelial cells were incubated in the presence or absence of *H. pylori*, and the mucin produced was quantitated by labeling with [³H]glucosamine and size exclusion HPLC on Superose 6 columns. The ³H-labeled high-molecular weight glycoprotein was confirmed to be

mucin by CsCl density gradient centrifugation, chemical and enzymatic degradation treatments. *H. pylori* (type strain NCTC11637), under conditions that had little effect on viability, inhibited the synthesis of mucin by 82% (Figure 5). There was no inhibition of mucin synthesis by the non-gastric pathogen *Campylobacter jejuni*, and little inhibition by a strain (Tx30a) of *H. pylori* that is CagA-negative and non-toxigenic. Similar results were seen in five other gastric cell lines tested (Figure 5). Inhibition of mucin synthesis was detected as early as 4h after addition of bacteria, and was partially reversible, though with a slower time-course than the onset of inhibition. Inhibition of mucin labeling was concentration dependent (Figure 6) and did not require the presence of intact bacteria. There was no inhibition by a soluble extract of *H. pylori*, but the *H. pylori* pellet fraction gave inhibition equivalent to intact bacteria.

Figure 5 Effect of *H. pylori* on mucin synthesis in six gastric cell lines. Cells were labeled 22 h with [³H] glucosamine in the presence or absence of 1 OD600 *H. pylori*, and labeled glycoproteins were analyzed by size-exclusion HPLC.

In a pulse-chase analysis, *H. pylori* had no effect on mucin secretion. Furthermore, there was little or no degradation of mature mucin in the presence or absence of *H. pylori*. Further experiments, to examine the effects of *H. pylori* on mucin glycosylation, used benzyl-GalNAc, which specifically inhibits synthesis of peripheral carbohydrate on mucin-type glycoproteins^[28]. Incubation of KATO III with *H. pylori* decreased labeling of mucin to a similar extent in the presence or absence of benzyl-GalNAc (Figure 7), indicating that the effect of *H. pylori* is not due to inhibition of peripheral glycosylation per se, but results from inhibition of synthesis of mucin core structures.

Figure 6 Inhibition of mucin synthesis by subfractions of *H. pylori*. KATO III cells were labeled with [3 H]glucosamine in the presence of different concentrations of intact *H. pylori* (open circles), *H. pylori* lysate (filled circles), the 100,000 \times g pellet (open triangles), or the 100,000 \times g supernatant (open squares).

Figure 7 Effect of *H. pylori* on synthesis of peripheral and core carbohydrate structures of mucin. KATO III cells were incubated with or without 2 mmol/L benzyl-GalNAc, and labeled for 4 h in the presence or absence of 1 OD600 *H. pylori*. Bars show void volume (Vo) containing labeled mucin. Solid areas show labeling of the peripheral carbohydrate (inhibitable by benzyl-GalNAc). Open areas show residual labeling of core structures in the presence of benzyl-GalNAc.

KATO III produces MUC5AC and MUC1 mucins, and the amount of both mucin proteins is decreased by co-incubation with *H. pylori* (Figure 8). Expression of another high molecular weight glycoprotein, CEA, and another control protein, galectin-3, was unaffected by *H. pylori*. *H. pylori* also decreased the amount of MUC5AC protein in BGC-823 gastric cells and the amount of MUC1 protein in the BGC-823, AGS, and MGC 80-3 cell lines. The inhibition of synthesis of both MUC5AC and MUC1 protein was concentration dependent and associated with the insoluble fraction of *H. pylori* lysates. Kinetically, the onset of inhibition of MUC1 expression was more rapid than inhibition of MUC5AC expression. MUC1 inhibition was seen within 4 h while MUC5AC inhibition was slower. MUC1 recovery was also more rapid than recovery of

Figure 8 Effect of *H. pylori* on expression of MUC1 and MUC5AC in KATO III gastric epithelial cells in vitro. KATO III cells were incubated with or without *H. pylori*, and cell lysates were subjected to Western analysis. Content of MUC1 antigen, detected with monoclonal antibody HMFG2, and of MUC5AC antigen, detected with monoclonal antibody CLH2, is expressed as percentage of untreated cells.

MUC5AC.

These experiments^[27] demonstrate that *H. pylori* decreases the amount of total mucin, and MUC5AC and MUC1 proteins in gastric epithelial cells. Indirect evidence indicates that this is due to a decrease in the synthesis of mucin protein rather than changes in glycosylation, secretion, or degradation of mucins. These results may help to explain the mucin depletion associated with *H. pylori* infection *in vivo*^[7,29].

INFLUENCE OF MUCINS ON *H. pylori* ADHESION

Most of the *H. pylori* in the stomach are present in the mucus gel layer, and appear to cause little harm to the host; adhesion of *H. pylori* to the gastric epithelial cell surface may be required for causing disease. For example, induction of the proinflammatory chemokine interleukin-8, requires that bacteria be in contact with the epithelial cell surface^[30,31]. Mucin glycoproteins produced by the gastric epithelial surface could influence the process of *H. pylori* adhesion in two ways: First, secreted glycoproteins could bind to bacterial adhesins and help to keep the bacteria in the mucous gel layer, preventing their approach to the epithelium. Although *H. pylori* has several different adhesins which could be involved in binding to mucins^[32-35] and human gastric mucin has been shown to inhibit bacterial binding to other cell types, e.g., erythrocytes and HEp-2 cells^[36,37], it is not known whether secreted gastric mucin can inhibit the adhesion of *H. pylori* to gastric epithelial cells. Second, cell-surface mucin glycoproteins could shield the epithelial cell surface from exposure to contact-dependent virulence factors, preventing adhesion-dependent synthesis of pro-

inflammatory chemokines. In MUC1-expressing cells, the highly glycosylated tandem repeat domain extending out from the cell surface can interfere with cell-cell interactions, for example, integrin-mediated aggregation^[38]. Since adhesion of *H. pylori* to gastric epithelial cells requires their close proximity to the cell surface where they can interact with integrins or other cell-surface receptors, cell-surface mucins might be expected to block adhesion of *H. pylori* to gastric epithelial cells.

Since previous results indicated that gastric surface-type mucins are decreased by *H. pylori* both in vivo^[7] and in vitro^[27], we sought to determine the influence of mucin on adhesion of *H. pylori* to cultured gastric epithelial cells. For measurement of the adhesion of *H. pylori* to gastric epithelial cells, an assay was established using biotinylated *H. pylori*, with bacteria attached to the BGC-823 gastric epithelial cells quantitated with avidin-biotin-peroxidase complex and ABTS as chromogen. The binding of bacteria was characterized with regard to time dependence, temperature dependence, and bacterial strain dependence. Optimal conditions for adhesion were found to be 30 min incubation at 37°C. Under conditions where the CagA/cytotoxin positive type strain of *H. pylori*, NCTC 16137, bound well to BGC-823 cells, there was little binding of the CagA-negative, cytotoxin-negative strain of *H. pylori*, Tx30a or of the non-human pathogen *Helicobacter mustelae*. As further validation, the standard binding assay was compared to colony counts for detection of viable *H. pylori* bound to BGC-823 cells (Figure 9). Binding of biotinylated bacteria was equivalent to binding of viable bacteria.

Figure 9 Assay of adhesion of *H. pylori* to gastric epithelial cells. Biotin-labeled *H. pylori* were incubated with BGC-823 cells for 30 min at 37°C, and attached bacteria were quantitated using the avidin-biotin-complex assay (A, left panel) or by colony counts (B, right panel).

BGC-823 cells are well differentiated, attach well to tissue culture plastic, and are susceptible to *H. pylori*-dependent inhibition of mucin synthesis^[27,39]. In comparison to other gastric epithelial cell lines, there was more binding of *H. pylori* to BGC-823 cells (which produces MUC5AC mucin and has relatively low levels of MUC1 cell-surface mucin) than to two cell lines (AGS and MGC-803) which do not produce MUC5AC mucin but

produce high levels of MUC1 mucin^[27,40]. This inverse correlation between MUC1 expression and *H. pylori* adhesion in gastric epithelial cell lines suggests that MUC1 mucin could interfere with *H. pylori* adhesion.

In order to test the role of mucin in *H. pylori* adhesion, we sought to inhibit mucin synthesis in BGC-823 gastric epithelial cells and examine the effect on binding of bacteria. It was initially confirmed that treatment of BGC-823 cells with the mucin-specific glycosylation inhibitor benzyl-GalNAc inhibits total mucin synthesis (measured by labeling with [³H] glucosamine and size-exclusion chromatography) by approximately 80% (Figure 10). Treatment of 823 cells with benzyl-GalNAc significantly increased the adhesion of *H. pylori* (treated/control = 1.43 ± 0.14 , $n = 6$). These results indicate that inhibition of mucin glycosylation is associated with an increase (rather than a decrease) in *H. pylori* adhesion, suggesting that mucins protect against (rather than facilitate) binding of the bacterium to the gastric epithelial surface.

Figure 10 Effect of inhibitors of mucin synthesis on *H. pylori* adhesion. BGC-823 cells were treated with 2 mmol/L benzyl-GalNAc, with 5 μ mol/L MUC1 antisense (5'-GGG-CTG-GGG-GGG-CGG-TGG-3'), or with 5 μ mol/L MUC5AC antisense (5'-AGA-GGT-TGT-GCT-GGT-TGT-3'). Solid bars show, as percent of control, amounts of total mucin (left), MUC1 mucin (middle), and MUC5AC mucin (right). Open bars show binding of biotinylated *H. pylori*, expressed as percent of control.

In order to specifically decrease the synthesis of MUC1 and MUC5AC phosphorothiolate antisense oligodeoxynucleotides were designed and targeted against the VNTR regions (M1TR) of MUC1 and MUC5AC genes. By Western analysis (Figure 10), MUC1 antisense treatment decreased MUC1 protein (treated/control = 0.39 ± 0.15 , $n = 6$), and MUC5AC antisense treatment decreased MUC5AC protein (treated/control = 0.27 ± 0.13 , $n = 3$). MUC1 antisense oligodeoxynucleotide treatment of BGC-823 cells significantly increased the adhesion of biotinylated *H. pylori*, (treated/control = 1.43 ± 0.18 , $n = 4$). MUC5AC oligodeoxynucleotide treatment had no significant effect on adhesion (treated/control = 1.23 ± 0.22 , $n = 5$), but it should be noted that the culture medium, which would contain most of the secreted (MUC5AC) mucins, was removed before the

adhesion assay was performed.

These results indicate that cell-surface mucin glycoprotein decreases adhesion of *H. pylori* to gastric epithelial cells. Since inhibition of mucin synthesis *in vitro* is associated with an increase in *H. pylori* adhesion, *H. pylori*-dependent mucin depletion *in vivo* would be expected to facilitate further binding of the bacterium to the gastric epithelial surface.

CONCLUSION AND WORKING HYPOTHESIS

Our working hypothesis (Figure 11) is that *H. pylori* alters the synthesis of gastric mucin in surface mucous cells and that the resultant alteration in the surface mucous gel layer facilitates adhesion of *H. pylori* to the epithelial cell surface, which could lead to increased inflammation. Based on *in vitro* results, *H. pylori* adhesion decreases mucin synthesis, and decreased mucin synthesis increases *H. pylori* adhesion. If a similar cycle applies *in vivo*, the pathogenetic effects of *H. pylori* infection could be mechanistically tied to the mucin depletion observed histologically.

Figure 11 Working hypothesis: interaction of *H. pylori* and gastric mucins.

The diseases caused by *H. pylori*, gastroduodenal ulcers and gastric cancer, take years to develop, but only short-term effects can be studied *in vitro*. *H. pylori* infection causes little overt damage to the gastric epithelium in most of the host population. *H. pylori* may, therefore, cause ulcers through a subtle disturbance in the interaction between the bacteria and the host, rather than acute damage to one critical component of the host cell. Non-physiological conditions are necessary for observable effects in cultured cell systems. Caution must therefore be exercised in extrapolating these data to the *in vivo* interactions between *H. pylori* adhesion and mucin expression. Nevertheless, if, as we hypothesize, *H. pylori* adhesion to gastric epithelial cells decreases mucin synthesis, and decreased mucin synthesis further increases *H. pylori* adhesion, even small effects on both processes could eventually lead to disease.

INTRODUCTION

The 1990's have brought a significant promise and the hope for a better and brighter future in the new millennium for patients with inflammatory bowel disease (IBD). A better understanding of the pathophysiology of IBD symptoms has led to newer treatment modalities and streamlining of therapy for specific subsets of patients.

ULCERATIVE COLITIS

The treatment for ulcerative colitis (UC) is aimed at modulating the inflammatory response. The drugs which are found to be effective are sulfasalazine (Azulfidine, Salazopyrin) and its 5ASA derivatives, glucocorticosteroids, immunomodulators/immunosuppressants, and other new potential drugs (Table 1).

Table 1 Medical therapy in IBD

Sulfasalazine and 5-amino salicylates	Azulfidine Olsalazine, Asacol, Pentasa, Balsalazide
Corticosteroids	Hydrocortisone, ACTH, Prednisone, Budesonide
Immunosuppressive/Immunomodulators	Immunan/6MP, Cyclosporin A, Methotrexate, Anti-TNF α Antibody, (Remicade, CD P571) FK506, IL-10, IL-11

sulfasalazine was quickly recognized as being effective in the treatment of colitis. Consisting of a molecule of 5-aminosalicylic acid (5-ASA) joined by an azo bond to a molecule of sulfapyridine (Figure 1), sulfasalazine has been a mainstay in the treatment of UC for more than 50 years^[1].

Figure 1 Structure of salicyl-azo-sulfapyridine or sulfasalazine (azulfidine, salazopyrin).

The active moiety in sulfasalazine is 5-ASA, with the sulfapyridine acting as a carrier to prevent absorption of 5-ASA in the small bowel. In the distal ileum and colon, bacteria that possess azo reductase split the molecule, releasing free 5-ASA and sulfapyridine (Figures 1,2). Almost all colonic bacteria have azoreductase enzyme. The sulfapyridine is readily absorbed from the colon, acetylated in the liver, and conjugated with glucuronic acid, and excreted in the urine^[1]. The 5-ASA is only minimally absorbed, with the majority being excreted in the feces unchanged (Figure 2). 5-ASA's mechanism of action is by direct contact with colonic mucosa to suppress various pro-inflammatory pathways including both cyclooxygenase and lipoxygenase derived products such as prostaglandins and leukotrienes from arachidonic acid and from suppression of superoxide dismutase and possibly by other mechanisms.

Sulfasalazine has been well studied in UC and has proven efficacy in inducing remission in patients with mild-to-moderate disease, as well as in maintaining remission. Its use has not been studied in a controlled manner for severe UC, but it is commonly used as an adjunct to approximately 80% of patients with mild-to-moderate disease, compared with 30% to 35% of those receiving placebo. Studies examining maintenance of remission have shown that sulfasalazine's effect is dose-dependent, with relapse rates of 33% with 1 g/day, 14% with 2 g/day, and 9% with 4 g/day^[2].

The toxic effects of sulfapyridine are the limiting factor in using sulfasalazine. Common adverse reactions include headache, nausea, anorexia, and dyspepsia. These

symptoms relate to plasma levels of sulfapyridine and usually occur at doses greater than 3 g/day [3]. Because of sulfasalazine's substantial toxicity and the limitation of dosing due to side effects, efforts were made to develop 5-ASA products with other delivery systems to prevent proximal small-bowel absorption. Three such oral preparations are now available in the United States: two products containing mesalamine (Asacol, Pentasa), olsalazine sodium (Dipentum) and balsalazide. Each uses a different mechanism to deliver the 5-ASA moiety to the sites of inflammation such as distal small bowel and colon, bypassing the absorption by jejunum.

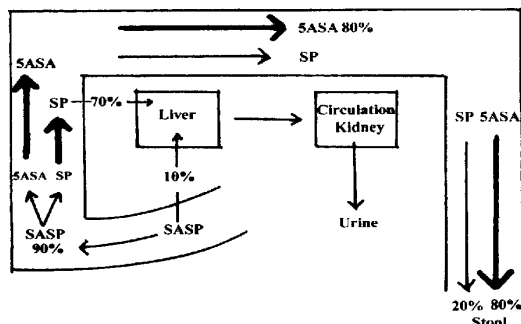

Figure 2 Metabolism and pharmacokinetics of salicylazosulfapyridine. Adopted from the Ph.D. thesis entitled, "Salicylazosulfapyridine Metabolism in Clinical Practice" submitted by Das KM to the University of Edinburgh, U.K., January 1973.

Asacol (mesalamine) contains 5-ASA coated with an acrylic-based resin. It releases 5-ASA in a pH-dependent manner at pH 6 or above. This causes release of 5-ASA in the distal small bowel and colon, making this drug ideal for the treatment of UC. Another mesalamine product, Pentasa, is 5-ASA encapsulated in ethylcellulose microgranules. This time-release formulation allows for release of 5-ASA throughout the small and large intestines. Thus, this drug appears to be superior for small bowel Crohn's disease (CD) in addition to its use in UC. While these products are effective and safe, there have been rare reports of granulomatous hepatitis, interstitial nephritis and recurrent thrombocytopenia on rechallenge with mesalamine/mesalazine^[4,5,6].

Olsalazine sodium consists of two molecules of 5-ASA linked by a diazo bond. Balsalazide consists of 5-ASA linked with 4-amino-benzoyl-β-alanine (an inert compound) by a diazo bond. The presence of the azo bond in both of these compounds, similar to sulfasalazine's, prevents small-bowel absorption and allows for delivery of the drug mainly in the colon, where bacterial azo reductase liberates the 5-ASA. These drugs would therefore be useful in the same circumstances as sulfasalazine. However, the 5-ASA products may cause diarrhea due to decreased water absorption in the small bowel, and this side effect occurs most frequently with olsalazine. Since the diseases these

drugs are used to treat are diarrheal illnesses, their use may be limited by this untoward effect. In a recent study^[7] balsalazide was found to be more effective and better tolerated than mesalamine as treatment for UC.

In the treatment of distal colitis, enema preparation of 5-ASA (Rowasa enema) is efficacious. In the initial study to identify the active moiety in sulfasalazine, patients with distal UC were treated with sulfasalazine, 5-ASA, or sulfapyridine enemas^[8]. Three quarters of the patients in the sulfasalazine and 5-ASA groups showed improvement, while only about one third of patients in the sulfapyridine group improved. These data supported the hypothesis that 5-ASA was the active therapeutic moiety, and subsequent studies confirmed the efficacy of 5-ASA enemas in distal colitis^[9]. 5-ASA is also available in suppository form (Rowasa) that is beneficial for the treatment of proctitis.

Distal ulcerative colitis

About two thirds of the patients with proctitis and proctosigmoiditis respond to hydrocortisone enema (Cortenema) or 5-ASA enemas (Rowasa). However, in the patients with proctitis and/or proctosigmoiditis that do not respond to this conventional treatment of hydrocortisone enema or 5-ASA enemas, several maneuvers are helpful. A clinical trial that compared the efficacy of nightly 4 g 5-ASA retention enemas with continued administration of 100-mg hydrocortisone enemas in distal UC after failure of a 3-week trial of the latter, with or without oral sulfasalazine, demonstrated that a significantly greater number of refractory patients responded to 5-ASA enemas than to continuation of standard therapy^[10].

Several studies show that mesalamine enemas 4 g/day along with oral mesalamine 2.4-4 g/day are useful in inducing and maintaining remission. The data also suggest that a higher dosage (such as 4 g/day orally) of all but one 5-ASA agent offers an important therapeutic advantage in some of the patients who are apparently "refractory" to conventional dosage. The exception to this is olsalazine, which, because of dimer-induced intestinal secretion, delivers more fluid to the colon and may cause diarrhea. Other data suggest that daily or every-other-day administration of 5-ASA enemas is sufficient to maintain remission, but that this effect is lost if administration is reduced to every third day.

A recent 6-week multi-center, randomized, double-blind comparative study of oral mesalamine versus rectal mesalamine versus combination therapy in the treatment of mild-to-moderate distal UC evaluated the differences among these regimens. A total of 60 patients were enrolled in the study; patient demographics, including UC history, did not differ significantly among treatment groups^[11]. This study suggests that a combination of oral and rectal mesalamine in patients with mild-to-moderate UC produces earlier relief of rectal bleeding than either therapy alone and more complete relief of rectal bleeding than oral therapy alone. 5-ASA by the oral route and intermittently by topical route was found to be more effective than oral

therapy alone in maintaining remission^[12].

Glucocorticoids

Like sulfasalazine, glucocorticoids and adrenocorticotrophic hormone (ACTH) have been used in the treatment of UC for more than 40 years. The first controlled trial was done in 1955 by Truelove and Witts^[13], and this, and other subsequent studies, clearly established the efficacy of glucocorticoids. Several studies have established that for mild-to-moderate disease, a daily dose of 40 mg of prednisolone is optimal, while for severe disease the optimal dosage is 60 mg of prednisolone or equivalent in divided doses. Even in severe disease, intravenous glucocorticoids have been shown to induce remission in up to 80% of patients. While ACTH is effective, studies have shown that it has no significant benefit over glucocorticoids, and it is now rarely used due to its expense and the fact that it must be used intravenously. For distal colitis, local therapy with glucocorticoid enemas is effective. However, unlike sulfasalazine and 5-ASA compounds, glucocorticoids have not been found to have any benefit as long-term maintenance therapy in UC.

Because of the numerous systemic side effects of glucocorticoid therapy, attempts have been made to develop poorly absorbed, topically active steroids and glucocorticoids with high topical activity and high rate of metabolism in the liver. The most promising of these agents appears to be budesonide. It is readily absorbed from the gut and rapidly degraded to metabolites with low glucocorticoid systemic activity during the first passage through the liver. It is not yet available in the United States, but several recent studies with oral administration suggest its efficacy in treating UC^[14], and ileal Crohn's disease^[15,16], as well as distal UC in the form of enemas^[17,18].

In a randomized trial of Budesonide 8 mg/day vs prednisone 40 mg/day for 8 wk in patients with CD, there was equivalent remission by CDAI < 150 in both groups. However, twice as many responders in the Budesonide groups responded to treatment with no side effects as compared to the prednisone group^[19].

Immunosuppressive/immunomodulatory agents

The first immunosuppressive agents used in the treatment of IBD were 6-mercaptopurine (6-MP) and its *S*-imidazole precursor, azathioprine. Azathioprine was developed with the intent of allowing delayed release of 6-MP, which is the active metabolite. In clinical practice, azathioprine and 6-MP have similar efficacy and toxicity, and their use is usually based on personal preference and experience.

Several controlled and uncontrolled trials have been conducted to evaluate the efficacy of 6-MP (1-2 mg/kg body weight per day) and azathioprine which is metabolized in the liver and releases 6-MP. The overall results show a response rate of about 70%, with a significant steroid-sparing effect in most patients. In patients who stop taking these agents after remission is

induced, the relapse rate is about two thirds^[20,21].

The main impediment to use these agents by many gastroenterologists is the concern of toxicity. While many patients receiving either agent may develop a decreased white blood cell (WBC) count, few develop marked leukopenia. Because of the potential for bone marrow suppression, blood counts must be checked frequently (e.g. initially bi-weekly and then once a month), but at the dosages used problems are rare. In one of the largest series reviewing the toxicity of 6-MP in inflammatory bowel disease, the authors found marked bone marrow suppression in 2% of patients (WBC < 2500/mm³ + 3), infections in 7.4%, and severe infections in 1.8%. Of note, however, many patients were receiving concomitant corticosteroids, and it is unclear what role this may have played in the infections. Pancreatitis can be seen in 3.3% of patients^[22]. This is believed to be an allergic reaction and usually occurs within 1 month of onset of therapy and abates on withdrawal of the agent. Pancreatitis precludes further use of these drugs, while leukopenia may be supported with low-dose corticosteroids or by using a smaller dosage of 6-MP. Rarely, patients may develop a cholestatic hepatitis-like picture even after long term use. Therefore, periodic check-ups (about every 6 months) for liver function tests are necessary. Abnormal results are reversible after cessation of therapy.

A theoretical risk with the use of purine analogues is teratogenicity and the development of malignancy, particularly lymphoma. Although there have been occasional reports of malignancy in patients receiving 6-MP or azathioprine, little data support a causative effect in patients with IBD^[23]. In reviews looking at teratogenicity, no difference in premature births or congenital anomalies was found in patients taking 6-MP compared with the general population^[24].

Cyclosporine is an immunomodulatory agent that has shown some promise in refractory IBD. It acts by inhibiting T-lymphocyte function, does not have the myelosuppressive effects of the purine analogues, and produces an effect quickly, usually within 1 wk. The first report of cyclosporine use in IBD was in 1984, and multiple open trials for use in UC have been conducted since then.

Several recent trials have investigated the efficacy of cyclosporine. These studies, although with small patient numbers, indicate that cyclosporine, at least temporarily, induced remission in up to 80% of patients with severe UC unresponsive to corticosteroid therapy^[25]. However, the majority of these patients do not sustain clinical remission with oral cyclosporine and eventually required colectomy before one year^[26]. Recently, a study showed lower relapse rate with azathioprine maintenance therapy after remission was induced with intravenous cyclosporine^[27].

Antibiotics

Antibiotics are not generally useful as a primary therapy for

UC. Although antibiotics do have a clear role in treating complications of UC, such as abscesses, they have never been shown to be efficacious as a direct treatment for the underlying disease^[28].

A recent double blind, placebo controlled trial found that ciprofloxacin treatment was slightly better than placebo at 3 months but approached placebo without significant difference in response at 6 months in UC patients^[29].

Nicotine

While UC is more common among the previous smokers, the efficacy of nicotine as a therapeutic agent in UC remains controversial^[30,31]. Given the addictive property of nicotine and significant adverse effects on cardiovascular system and the lack of clear benefit in UC, nicotine cannot be recommended at this time^[32].

Nutrition

Since UC is a condition of bowel inflammation, several investigators have studied bowel rest as therapy. Total parenteral nutrition (TPN) allows for bowel rest, eliminates dietary macromolecules and, thus, reduces mucosal immune response, and helps to correct the malnutrition associated with UC. Several randomized controlled trials have looked at the benefit of TPN in active UC. They found that TPN offered no benefit over the control group with regard to UC^[33]. Patients with distal colitis/proctitis should be on a high roughage diet^[34] and those with anemia refractory to iron and vitamin supplements may benefit from treatment with oral iron and recombinant erythropoietin^[35].

Other agents

Heparin was found to paradoxically induce remission in 9 of 10 patients with UC refractory to standard therapy^[36]. It may act as an anti-thrombotic agent or may be directly anti-inflammatory. Further multicenter studies are currently in progress to examine the efficacy of heparin in patients with active UC.

Deficiency of short-chain fatty acid (SCFA) is associated with diversion colitis, and studies with SCFA enemas in patients with distal UC showed good response in an initial study^[37] although a subsequent study could not reproduce these data^[38]. Further studies are warranted to explore this simplified treatment.

CROHN'S DISEASE

The management of CD is similar in many respects to the management of UC since the two diseases share many common features. However, there are differences.

Sulfasalazine and 5-ASA products

Being a transmural disease, the medical management of the inflammatory process in CD is often more difficult than it is in UC. Pharmacologically active compounds that exert their effect from the luminal side of the intestine as a local anti-inflammatory agent have limited response because of the

lack of transmural availability of the drug. Oral sulfasalazine or 5-ASA derivatives are commonly employed initially for the colonic manifestations of the disease. A multicenter study that evaluated the role of Pentasa in active CD demonstrated that a dose of 4 g/day was more effective in inducing remission than placebo^[39].

Glucocorticoids

Corticosteroids are often used on a short-term basis to manage acute exacerbations of the disease. However, intra-abdominal and perineal sepsis, common complicating factors, must be ruled out before corticosteroids are administered. Oral budesonide (9 mg daily) treatment has been found to be useful to induce remission with less steroid-related side effects^[40]. The efficacy was lower than prednisone^[41]. Recently, budesonide (9 mg daily) was also found to be superior in inducing remission than mesalamine (2 g twice daily) over 16 wk of therapy in active ileocolonic CD^[42]. However, on a long term basis, (over 12 months), the use of budesonide (6 mg/day) did not sustain clinical remission^[43]. Further studies are currently in progress to ascertain the dosage, duration and clinical response.

Immunosuppressive/immunomodulatory agents

In a double-blind placebo controlled study, 6-mercaptopurine (6-MP) was found to induce remission or significant clinical improvement in about two-thirds of patients with symptomatic CD^[44]. If symptoms cannot be controlled with corticosteroids or if it is not possible to taper steroid dosage while maintaining symptom control, then immunomodulatory agents such as azathioprine or 6-MP may be used in conjunction with reduced doses of steroids to induce and maintain remission. 6-MP may be used in conjunction with reduced doses of steroids to induce and maintain remission. 6-MP has also been demonstrated to be effective in closing fistulas and reducing steroid requirements in patients with CD. Unfortunately, fistulas frequently recur upon cessation of immunosuppressive treatment^[44]. IV loading of 6-MP has not been shown to decrease the time to respond in patients requiring ongoing steroid therapy for Crohn's disease. However, Casson has a report of a rare response of IV 6-MP in patients with fulminant colitis who failed steroid management and refused to have surgery^[45,46]. Cyclosporine and methotrexate have been found to be beneficial in subgroup of patients with chronically active CD^[47,48]. Tacrolimus (FK506) has a mechanism similar to cyclosporine and preliminary results have shown some benefits to proximal small bowel or fistulizing CD^[49]. In a recent small study, 7 of 11 patients with steroid refractory Crohn's disease and UC, tacrolimus with azathioprine and mesalamine achieved rapid remission and allowed for tapering of steroids^[50]. However, the data related to the use of these drugs is very limited, and at this time, these drugs may be considered in a subgroup of patients who are refractory to more conventional treatment.

Nutrition

Low residue diets have been found to be beneficial in patients with CD^[51]. In patients with proximal CD there was a significantly increased incidence of lactose malabsorption^[52]. A defined formula diet can induce remission, probably through a decrease in immunostimulation by luminal contents^[53]. This treatment is controversial because remission lasts only as long as the diet is continued. Because fish oil has anti-inflammatory actions, studies have shown a reduction in relapse rates in CD, but its use is limited by the unpleasant taste and smell^[54].

Antibiotics

Antibiotics (metronidazole, ciprofloxacin, and clarithromycin and trimethoprim-sulfamethoxazole) can be useful in treatment of CD^[55,56]. Antibiotics are also used to treat complications such as intra-abdominal sepsis and perineal fistulas. Although long-term use of antibiotics for treatment of CD has been advocated by some physicians, there is no convincing support for this strategy.

Maintenance of remission in CD

One of the most vexing issues in the treatment of CD is maintaining remission. The recent data come from trials that compare maintenance regimens following surgical resection. Both mesalamine and metronidazole have been useful in prolonging the time from surgery to symptomatic relapse^[57,58,59].

A meta-analysis of sulfasalazine and 5-ASA for maintenance therapy of CD demonstrated that 5-ASA was more likely to maintain remission than sulfasalazine and that it demonstrated greater efficacy for patients with ileal disease than for those with combined ileocolonic disease; ileocolonic disease responded better than colonic disease^[60].

Although oral mesalamines have demonstrated some benefit in maintaining remission, there are many unresolved issues, e.g. which mesalamine preparation is preferable, in which clinical group such as phlegmonous type, stricture type or perforating type of CD, what dose should be used, and whether drugs are equally effective in maintaining remissions induced initially by medical and/or surgical interventions. A recent study suggested that 6-MP is also effective in preventing post-operative recurrence of CD and may be more effective than 5-ASA preparations^[61].

Newer agents

Tumor necrosis factor (TNF- α) is a proinflammatory cytokine present in excess in the mucosa of patients with active CD. A chimeric mouse/human anti-TNF- α monoclonal antibody (cA2, infliximab, Remicade; Centocor, Malvern, PA) was developed and its efficacy was assessed in patients with severe CD^[62]. There was no apparent dose relation between 5 mg per kg to 20 mg per kg body weight given as intravenous infusion as a single

dose over a 2 h period. After a single dose of infusion 5 mg/kg clinical response was achieved in 65% of the patients. About half of these patients in the treatment group (compared with 4% in the placebo group) went into remission by wk 4. However, by wk 12, the number of patients maintaining their clinical response after the single dose infusion had decreased to 41% (compared to 12% in the placebo group). Repeated doses in initial responders appear to maintain remission at least in the short term study reported so far. The patients with no response to the first infusion of cA2 were less likely to have a response to a second infusion. Thus, this group of patients may clinically differ from the responder group. Preliminary results from another anti-TNF antibody (CD P571) also showed promising results^[63]. The adverse effects of cA2 therapy were mostly transient and not serious and they included headache, nausea, upper respiratory tract infection, fatigue, myalgia, rhinitis, pain, pruritus and dyspnea^[62]. Of the 29 patients who received two cA2 infusions, two had a reaction with chest pain, dyspnea and nausea necessitating discontinuation of the infusion. At least 6% of the patients developed anti-cA2 antibody by 12 wk. This percentage may be higher because cA2 was still detectable in serum samples in two-thirds of the patients and the presence of cA2 may have interfered with the anti-cA2 assay. As use of infliximab has increased, reports of hypersensitivity have been published. In our experience, this can be avoided by premedication with benadryl and glucocorticoids^[64]. It is unknown at this time whether the presence of anti-cA2 will influence the efficacy of the therapy, particularly after subsequent infusions. Remicade has recently been approved by the FDA for use in moderate and severe Crohn's disease, with or without fistula since closure of fistula has also been reported with this therapy. In another review, infliximab was effective in achieving fistula closure 68% vs 26% placebo^[64].

Interleukin-10 (IL-10) is a cytokine with both anti-inflammatory as well as immunosuppressive properties. In a recent study in patients with steroid-refractory active CD, daily administration of IL-10 for one week resulted in 50% of patients achieving complete remission within 3 wk (compared to 23% in the placebo group)^[65].

IL-11 has been known to have a mucosal protective effect. Besides its anti-inflammatory effects, it also has a trophic effect on intestinal villi. Sands *et al* are currently investigating dosing strategies for possible use of this cytokine in the treatment of active Crohn's disease^[66,67].

Intercellular adhesion molecule-1 (ICAM-1) is an inducible transmembrane glycoprotein involved in the activation of leukocytes and is upregulated in inflamed mucosa in CD. ISIS 2302 is a 20-base phosphorothioate oligodeoxynucleotide which selectively inhibits cytokine-induced ICAM-1 expression. In patients with steroid-resistant active CD, it was found to achieve remission in 7 of 15 patients immediately after treatment and 5 of 7 patients were still in remission at the end of six months^[68]. This modality of treatment opens up yet another novel

approach of administering antisense therapy for IBD.

It is recognized that NSAIDs may be harmful in patients with inflammatory bowel disease. Since the arrival of COX₂ inhibitors on the market, only one study has attempted to evaluate their safety in IBD. The results do not point to any advantage or safety of COX₂ drugs over NSAIDs^[69].

Probiotics

There has been recent investigation into the bacterial makeup and possible association of intestinal bacteria with inflammation. Investigators have focused on use of nonpathogenic *E.coli* and other probiotic preparations in maintaining remission of UC. In one study by Rembacken *et al* at 12 months there was a statistically significant difference between two groups, one taking mesalamine, the other taking nonpathogenic *E.coli*^[70,71].

Pitchumoni CS. Pathogenesis and management of pain in chronic pancreatitis. *World J Gastroentero*, 2000;6(4):490-496

INTRODUCTION

Of the three cardinal manifestations of chronic pancreatitis—pain, diabetes mellitus and steatorrhea, it is pain that brings the patient to the physician and is the most difficult to manage. The intractable pain that is quite debilitating disrupts lifestyle and leads to functional incapacity, drug and alcohol dependency, and a drug-seeking behavior that occasionally might push the desperate patient to suicidal tendency. Painless CP is an exception that has been observed in nearly 5% to 10% of patients with all forms of chronic pancreatitis. Lack of pain is also a feature of the late onset idiopathic CP.

CHARACTERISTICS OF PANCREATIC PAIN

The pain of pancreatitis is steady and agonizing, is felt in the epigastrium, sometimes in the left upper quadrant with radiation to the back between T12 and L2 or to the left shoulder. Typically pain is postprandial in nature suggesting a gastric lesion. Colicky pain is unusual in CP. Associated nausea and persistent vomiting that does not relieve the pain are in contrast to the pain of gastritis or pyloric obstruction. The pain may be accompanied by flushing and shortness of breath. The severity of pain varies greatly in different patients and indeed in the same individual in different episodes, for no obvious reason. The onset of the persistent abdominal pain 12 to 48 h after a drinking bout or “on the afternoon after the night before” is said to be characteristic of alcoholic pancreatitis, but exacerbation of pain may occur even during abstinence from alcohol with no identifiable cause. At times of pain patients bend forward to the so-called “pancreatic position” or lie in the knee-chest position on their right or left side.

The duration of pain-free intervals is unpredictable and may last from weeks to many months, making it difficult to assess the value of different modalities of pain therapy. As the disease advances, the postprandial relationship is lost and pain becomes steady and unrelenting^[1].

Recently Ammann *et al* reported characteristics of pancreatic pain in 207 patients with alcoholic chronic pancreatitis^[2]. They identified two patterns of pain Type A and B based on natural history. In Type A pain in nearly 44% of patients, who never, who never needed surgery for pain relief the duration of pain was short usually less than 10 days. In contrast Type B pain occurred in 56% of patients who had episodes of constant pain defined as prolonged periods of daily persistent pain, occurring 2 or more days per week for at least 2 months. All these patients underwent surgery. The two types of pain noted by Ammann in Switzerland has not been observed in other series^[3]. What Ammann has noted in his Zurich patients based on the natural history of pain in chronic pancreatitis as “burning out of the pancreas” and pain relief after 10 or more years is also not seen in many other countries^[4-6]. Although it is not clear why geographical differences occur in the natural history of chronic pancreatitis, one observation is that the different studies quoted include patients with a alcoholic and non-alcoholic pancreatitis while Ammann’s group is exclusively of alcoholic pancreatitis.

PATHOGENESIS OF PAIN IN CP

Pain in CP is multifactorial in pathogenesis^[1]. The current thoughts include (a) increased intraductal pressure, (b) increased pancreatic tissue pressure (interstitial-hypertension), (c) pancreatitis-associated neuritis, (d) pancreatic ischemia, and (e) ongoing pancreatic injury. Complications of CP, such as pseudocyst, common bile duct obstruction, and associated gastroduodenal diseases (e.g., peptic ulcer), may contribute to the pain. Pancreatic cancer may mimic CP and may be a complication in some patients with CP.

Intraductal hypertension

Increased intraductal pressure is the most important cause of pain. Intraoperative ductal pressure measurements, direct measurements through endoscopic approach, and studies on surgical and autopsy specimens of pancreas have substantiated the concept.

The normal intraductal pressure, depending on the

methodology used in the unstimulated pancreas, is about 7 mmHg, and it is markedly increased in CP. DuVal in 1958 measured the pancreatic duct pressures in nine patients with CP using a small-caliber Foley catheter inserted into the distal pancreatic duct at pancreaticojejunostomy and in four patients with cutaneous pancreatic fistulae who served as controls^[1]. In those with CP the intraductal pressure was invariably higher. Histopathological studies reveal that strictures of the ducts and ductules, obstruction by calculi in major ducts or its branches are the essential features of CP and could all cause pre-stenotic intraductal hypertension.

Interstitial hypertension

The pathogenesis of interstitial or tissue hypertension is the same as intraductal hypertension^[7]. Even minimal obstruction to the ductules can lead to tissue fluid hypertension. Indeed, interstitial hypertension can theoretically occur much before intraductal hypertension and ERCP changes of ductal morphology are detectable. In the so-called minimal change chronic pancreatitis, the severe pain cannot be explained with the above^[8].

Pancreatic pain maybe ischemic in nature analogous to the pain in compartment syndromes. High interstitial pressure could greatly increase vascular resistance and reduce pancreatic blood flow. Karanjia *et al* have shown in their cat model of CP that the blood flow to the pancreas was 40% lower than in normal pancreas, whereas secretory stimulation of the pancreas further decreased the blood flow^[9]. Decompression of the obstructed pancreatic duct reversed all these changes. Increase in ductal or interstitial pressure has been questioned in a few studies and no correlation has been found between ductal morphology and pain^[10]. In those with normal ERCP findings, one cannot rule out the possibility of interstitial hypertension.

Ongoing pancreatic injury

Kloppel hypothesizes that the dynamics of the disease rather than the end result are possible factors for pain^[11]. During progressive scarring the pancreatic nerves and ducts become irregularly entrapped in fibrotic tissue. Recurrent tissue necrosis causes pain in early stages, whereas the persistent pain in an advanced CP is a result of incomplete obstruction of the ducts.

The role of pancreatic stellate cells in this regard is notable. Pancreatic stellate cells are perivascular and derived from Vitamin A-containing cells. These cells because of their contractile potential and perivascular location could cause microvascular ischemia and pain^[12].

Inflammatory mass

Nearly 30% of patients with painful chronic pancreatitis have enlargement of the pancreatic head caused by inflammation^[13]. The inflammatory mass caused pain by involving pancreatic nerves and producing obstruction of

bile duct, pancreatic duct or duodenum^[14,15]. Operations have been devised to remove inflammatory masses^[16,17]. The studies of Ammann *et al* did not find these inflammatory masses in the head of the pancreas^[2].

Neuronal changes

Keith *et al* (1985) studied pancreatic tissue obtained from 50 patients who underwent pancreatic resection or decompression^[18]. They found perineural accumulation of inflammatory cells, predominantly eosinophils correlating with severity of pain and alcoholism-scores, but not with ductal morphology, indicating a role of these inflammatory cells in the causation of pain.

It is well known that eosinophils are toxic to nerve tissue. The mean diameter of nerves in the pancreas of CP patients is significantly greater than in controls^[19]. The perineural sheath is altered such that it no longer provides a barrier between the surrounding connective tissue and the internal neural components. The absence of the normal barrier provided by the perineurium exposes the nerves to activated enzymes, plasma components, and bioactive materials released from inflammatory cells. Increased mean diameters of nerves argue against an old thought that pain is caused by strangulation of nerves by fibrosis. The weakness of the neuronal theory of pain lies in its failure to explain the relief of pain with the cessation of pancreatic function when it shows the same histologic changes in nerves, as in painful pancreatitis. It also does not explain the relief of pain with surgical procedures that reduce intraductal pressure but do not alter the neuronal changes.

NATURAL HISTORY OF PAIN IN CP

Pain in CP as the disease progresses to pancreatic exocrine and endocrine insufficiency is unpredictable in an individual case. Levra *et al* (1970) reporting on a longitudinal study of 113 patients followed for 4 years, observed that the pain decreased in 42%, was stable in 32%, and worsened in 26%^[20]. The often quoted study of Ammann *et al* (1984) from Switzerland concluded that 85% of patients obtained lasting relief from pain at a median of 4.5 years from the onset of disease accompanied by a marked increase in pancreatic dysfunction and calcifications suggesting a relation between pain and the onset of pancreatic insufficiency.

Although there seems to be no consensus with regard to the percentage of patients who get spontaneous relief, some observers have confirmed a final pain-free stage in the natural history of CP in 30% to 50% of patients. However, in an individual case no one can predict how long it will take to reach a pain-free stage of CP or whether that individual will ever get a "burned out pancreas". Surgical management cannot be delayed hoping that spontaneous relief would ever occur.

The study of Ammann *et al* quoted earlier is relevant here^[2]. Nearly 44% of patients had only intermittent pain

and had a favorable course without invasive therapy. In evaluating various treatment modalities the group of patients who underwent the therapy has to be clarified. An endoscopic therapy of clearing stones from the pancreatic duct by a group claimed that the best predictor of pain-free interval after therapy was infrequent attacks before therapy^[22]. One might criticize studies with similar results as expected response even without the therapy.

MANAGEMENT OF PAIN IN CP

Management of pain in CP is to be approached by a team of physicians that includes a gastroenterologist, surgeon, radiologist, and a psychiatrist. It is difficult to assess the severity of pain in patients with CP since many of them are addicted to alcohol and/or narcotics. Equally important is to recognize that in patients with alcoholic pancreatitis it is not uncommon to see malingering or a drug-seeking behavior in the form of exaggerated complaints of pain. The available modes of therapy in the management of pain are tabulated. Before the initiation of therapy, treatable complications such as pseudocysts, bile duct obstructions, and peptic ulcer disease should be ruled out.

Table 1 Management of pain in chronic pancreatitis

Medical (conservative)	Abstinence from alcohol
	Analgesics (nonopioid and opioid NSAIDs)
	Tricyclics
	Pancreatic enzyme supplements
	Parenteral nutrition
Endoscopic therapy	Octreotide
	Sphincterotomy, stone extraction, extracorporeal shock wave
	Lithotripsy (ESWL) of pancreatic calculi
	Septotomy+
	Stent placement
Neurolytic therapy	Drainage procedures
	Surgical therapy
	Resections
Experimental	Denervation procedures
	Dissolution of calculi with oral medications
	Direct chemical dissolution of calculi
	Duct injection to cause complete obstruction (prolamin, acrylate, latex)

Abstinence from alcohol

The help of a psychiatrist or an alcoholics anonymous group is often necessary. The rate of pain relief is usually higher in abstinent patients, and deterioration of pancreatic function is slower. The importance of alcohol abstinence thus cannot be overemphasized. Considerable time should be spent in discussing with the patient and making him or her understand the inevitable progression of disease if alcohol use is continued.

It is difficult to interpret the results of studies showing no correlation between abstinence from alcohol and abdominal pain. It is likely that the clinical stage of the disease alters the effect of alcohol on pain. In the early stages, with well-preserved pancreatic function, secretagogues such as alcohol may exaggerate pain, whereas in advanced stages they may have very little

stimulatory effect on the fibrotic pancreas^[21].

Diet

The goal is to provide rest to the pancreas or avoid excessive stimulation while maintaining adequate nutrition. The conventional diet is one that is low in fat and small in quantity. In some patients hospitalization, total cessation of oral intake of food, and short-term use of partial or total parenteral nutrition may be needed for urgent management of severe pain. The diet is also determined by the fact whether there is associated diabetes and/or steatorrhea. Supplementation with oral antioxidants is reported to reduce the intensity and frequency of pain.

Antioxidant supplementation

The basis of antioxidant therapy was the hypothesis that CP is a disease caused by unopposed free radical (FR) injury^[23,24]. Banks and colleagues in their attempt to prevent generations of FR used allopurinol 300 mg/d. There was no significant reduction in pain. Despite a definite proof for FR injury in relation to CP or clinical trials confirming the use of antioxidants, there is widespread enthusiasm for the therapy. Antioxidant therapy is inexpensive and harmless. For a disease with no better substitute for treatment the simplicity of antioxidant therapy is attractive.

Cigarette smoking is noted to be an associated factor in the pathogenesis of CP, it is prudent to advise against smoking^[25,26]. Most alcoholics who develop CP are heavy cigarette smokers.

Analgesics

The first step is to try nonopioid analgesics, such as acetaminophen, salicylates and nonsteroidal anti-inflammatory drugs (NSAIDs) with or without antidepressants. However, most patients need opioid analgesics for symptomatic relief, and the initial doses should be low and administered less frequently. Small doses of codeine derivatives with acetaminophen are the usual drugs of choice. The use of an H₂ receptor antagonist or a proton pump inhibitor to suppress gastric acid production, reduce destruction of orally administered pancreatic enzymes and theoretically reduce pancreatic stimulation is advocated. As an adjunct to the therapy, a small dose of an antidepressant may be helpful. If a potent narcotic is needed to offer pain relief, surgery should be considered as early as possible before the development of narcotic addiction.

Pancreatic enzyme therapy

The basis for oral enzyme therapy for pancreatic pain is as follows. Secretory status of exocrine tissues and obstruction to outflow determine intraductal pressure. Deficiency of proteases (trypsin, chymotrypsin) within the duodenal lumen causes release of cholecystokinin from the mucosa,

leading to enhanced stimulation of the exocrine tissues [27-29]. Experimental evidence indicates that the presence of intraluminal proteases in the proximal small intestine inhibits the release of cholecystokinin and thereby stimulation of the exocrine parenchyma.

To effect feedback inhibition of pancreatic secretion, it is important to administer large doses of commercially available pancreatic enzymes. One should choose the type of preparation that increases the intraduodenal proteases [28]. The ideal patient for enzyme therapy is a female with idiopathic pancreatitis with normal fecal fat excretion. Individuals with large dilated ducts tend not to respond to enzyme therapy. Enzyme therapy is simple, easy to initiate, but somewhat expensive. However the cost of enzyme therapy cannot be considered high when the alternative is major pancreatic surgery. The selection of an enzyme preparation is to be based on the protease concentration within the preparation, the stability of the enzyme in withstanding gastric acidity, and the timely release of the enzyme from capsules in the proximal intestine. The inconvenience of taking large doses of enzyme preparations is justified if the preparations relieve pain or reduce the need for analgesics. Hence, it is worth trying enzyme therapy in all patients with painful CP for at least 6 to 8 weeks.

If there is no pain relief with a nonenteric coated preparation, addition of an H₂ receptor antagonist or sodium bicarbonate (650 mg) before and after each dose of pancreatic enzymes to protect them from gastric acid is a consideration.

The side effects of enzyme therapy are few. Pancreatic extracts from insoluble complexes with folic acid, as a result folic acid deficiency can develop. Hyperuricemia and hyperuricosuria are described in cystic fibrosis patients treated with large doses of pancreatic extracts. Allergic reactions to the porcine proteins in extracts may occur. There is a valid criticism that studies supporting response to enzyme therapy are few and have used only a small number of patients.

The vast majority of patients with CP are those with longstanding history of alcoholism, more often men, with large duct disease. Even the protagonists of enzyme therapy do not consider the above group as ideal patients to obtain relief with oral pancreatic enzymes. It appears that at this time the majority of gastroenterologists are not quite enthusiastic about enzyme therapy for pancreatic pain [30]. The role of enzyme therapy is limited despite its wide popularity which is solely based on its simplicity and the fact that it appears to be a non-invasive form of therapy compared to endoscopic therapy or surgery.

Somatostatin and octreotide

Somatostatin is a naturally occurring hormone that inhibits pancreatic secretion. Octreotide is a synthetic long-acting analogue of somatostatin that inhibits cholecystokinin

release and both basal and oral stimulated pancreatic secretion. The duration of action of octreotide is longer than that of somatostatin, but it increases the contractability of the Sphincter of Oddi while somatostatin decreases it. One multi-center randomized study of 91 patients with CP showed promising results [31]. At a dose of 200 mg TID octreotide offered good pain relief especially in those with constant pain. Another recent study by Malfertheiner *et al* however did not show any benefit [32].

Endoscopic therapy in CP

Endoscopic therapies are based on the premise that the most important mechanism of pain in CP is impairment of outflow of pancreatic secretion by strictures or calculi in the main pancreatic duct [33-36]. The attractive feature of endoscopic drainage procedures is that it offers an alternative to surgical forms of drainage. The optimistic belief that these methods may achieve the same results as surgical drainage but without its operative morbidity (20% to 40%) or mortality (2% to 5%) rates is attractive.

The forms of endoscopic procedures currently available include sphincterotomy, internal drainage of pancreatic cysts, extraction of stones from the pancreatic duct, guidewire-catheter dilation of strictures, and placement of pancreatic stents. Endoscopic intervention can be considered in the following situations: (1) biliary strictures, (2) pain or recurrent pancreatitis associated with a dominant stricture at the proximal end (head), (3) recurrent pancreatitis with pancreas divisum, (4) pancreatic cysts, (5) pancreatic stones, and (6) Sphincter of Oddi dysfunction.

Lithotripsy

Although it is controversial whether stones or calculi directly cause pain it is logical to assume that removal of stones would relieve intraductal hypertension. Although endoscopically it is possible to remove one or two stones in the head end of the pancreas, it is only after fragmentation by shock wave or laser lithotripsy that the more proximal innumerable stones can be drained. Some studies have noted excellent pain relief [35-38]. In a series of 123 patients with pancreatic calculi ESWL was helpful in 122. After ESWL the pancreatic duct could be completely cleared with endoscopic papillotomy in 595 of patients [37]. Adamack and group recently (1999) studied 43 patients who were successfully treated with ESWL [38]. The only feature associated with treatment success was the presence of a single stone rather than multiple stones. Successfully treated patients achieved some degree of reduction in pain. The factors favoring stone removal and clinical response include three or less stones, absence of multiple strictures, stones confined to the head of the pancreas, stone diameter of <10 mm and absence of impacted stones [35]. Lithotripsy with stone removal is not yet a well accepted form of therapy for pain relief in chronic pancreatitis. Lack

of expertise, a skepticism generated by lack of adequate well controlled trials and the theoretical opinion that removal of stones is only cosmetic to the total histology of the pancreas have dampened the enthusiasm for this form of therapy in the U.S. among academicians.

Sphincterotomy

The best indication for endoscopic sphincterotomy is when the patient has a solitary ductal stone in the head of the pancreas without any evidence of proximal stricture. Relief of pain can be predicted if a postsphincterotomy pancreatogram demonstrates immediate reduction in size of the main pancreatic duct.

Stenting

Another procedure used in the treatment of pain is endoscopic stenting of the main pancreatic duct after sphincterotomy. The stents have side holes at approximately 1-cm intervals that permit better drainage of pancreatic juice from side branches. Plastic stents have been noted to be inferior to self-expandable metallic stents (Wallstent), which provide better dilation of the stricture and do not clog as often. Cremer's group noted that in addition to pain relief marked improvement in nutritional status of patients occurred as a result of better delivery of bile and pancreatic secretions in the duodenum helping digestion^[37]. Excellent improvement in pain has been reported. Prolonged symptomatic improvement even after the stent has been removed is observed. This unexpected result may be explained by the fact that before or during stenting, many small calculi are removed, eliminating small ductular obstructions.

The risk of pancreatic stenting is beginning to be appreciated^[33,39,40,41]. A number of complications are reported after stent placement: (1) clogging of the endoprosthesis is frequent, and it must be changed every 4 to 6 months; (2) migration of the prosthesis may be a serious problem (3) the stent can be passed spontaneously without any adverse effect; (4) migration, clogging, and occlusion of the stent may lead to pancreatic abscess formation or infect a pseudocyst that is in communication with the main pancreatic duct; (5) duodenal erosion may be caused by improper positioning of the stent; (6) pancreatitis may be induced by stent placement but is usually mild and self-limiting; and (7) ductal changes mimicking CP may develop even after stent placement.

Celiac ganglion blocking

It is reasonable to expect that pharmacologic denervation of the celiac plexus will result in pain relief. Celiac plexus blocking is technically difficult; the pain relief is transient and sometimes lasts only a few days. It is also associated with complications such as hypotension, epidural or intraperitoneal hematomas, and sexual dysfunction. Neurolytic block is thus considered a last resort therapy.^[41]

Recent reports on celiac ganglion blocking using endoscopic ultrasound guidance offer much hope^[42,43].

A variant of celiac block is intrapleural analgesia achieved by instilling local anesthetic into the pleural space^[44]. Dramatic pain relief lasting for 4 months has been reported. Diffusion within the interpleural space seems to block several intercostal nerves. The scientific explanation is that pancreatic pain is transmitted along afferent fibers from the pancreas to the splanchnic nerves and also by the lower intercostal nerves, which innervate the peritoneum.

Acupuncture and transcutaneous nerve stimulation (TENS)

A pilot study showed that 3 patients with chronic pain responded well to both electroacupuncture and TENS^[45]. In 23 patients with chronic pancreatitis with daily pain for 3 months the efficacy of TENS was studied. In two prospective studies with cross over design active acupuncture was compared with sham acupuncture and TENS of the segmental points of the pancreas with sham treatment. Neither acupuncture nor TENS brought about pain relief that could substitute for or supplement medical treatment (Ballegaard, et al. 1985). This small study conducted in an institution not specializing in acupuncture should not discourage experts in the field from trying it. In the absence of an effective therapy for pain in CP, there is a great need to look at alternate medicine for possible answers. The expertise of the Chinese is greatly needed here.

Surgery for pain in CP

Surgery is a consideration when pain is severe enough to interfere with day-to-day life and when it cannot be managed safely with medical treatment alone. Recent review articles well describe the surgical aspects of CP^[46,47]. Evaluation for surgery must be individualized and the following should take into consideration: frequent hospitalizations, disruption of employment and social life, nutritional status, depression of other psychiatric manifestations, and drug dependence. Preoperative assessment should include abdominal computed tomography, ERCP, and if appropriate, psychiatric evaluation.

The operative candidates can be divided into two broad groups: those with dilated pancreatic ducts (who more likely benefit from ductal drainage) and those with normal size ducts (who may need pancreatic resection or a denervation procedure).

Drainage procedures Many authors recommend longitudinal pancreaticojejunostomy or lateral pancreaticojejunostomy (modified Puestow procedure) when the pancreatic ducts are large enough for anastomosis^[46]. Long-term pain relief is achieved in more

than two thirds of patients with CP and a dilated (more than 7 mm diameter) pancreatic duct. Pain relief is immediate in 80% to 90% of patients, although there is an unpredictable recurrence rate in some of them. Some 60% to 75% of patients are pain free for 5 to 6 years. Recurrence of pain after an initially successful longitudinal pancreaticojejunostomy suggests stricture formation and may indicate the need for reoperation.

The operative mortality rate averages about 4%, and diabetes, does not result from the procedure. However, many patients may go on to become insulin-requiring diabetics because of continual destruction of the pancreas as a result of CP.

Pancreatic resection Resection is the procedure of choice in a pancreas whose ducts are not dilated, when a previous drainage procedure has failed, or if pathologic changes predominantly involve a particular area of the gland. Resection offers good pain relief that tends to be more permanent than that after pancreaticojejunostomy. Resections generally involve one of the following procedures: (1) pancreaticoduodenectomy, (2) local resection of the head of the pancreas, and (3) subtotal or distal pancreatectomy. However, exocrine and endocrine insufficiency is a major drawback with resections.

Therapeutic methods for diarrhea in children

S.K. Bhattacharya

Subject headings diarrhea, infantile/therapy; dehydration; antibiotics; infusion, intravenous; water-electrolyte balance; antidiarrheals; nutritional requirements

Bhattacharya SK. Therapeutic methods for diarrhoea in children. *World J Gastroentero*, 2000;6(4):497-500

DEFINITION

Acute diarrhoea is defined as passage of loose or watery stools at least three times in a 24 h period. When loose stools contain blood, it is called bloody diarrhoea (dysentery). It is the consistency of the stools which is most important rather than the frequency. Breast-fed babies often pass "pasty" stools frequently which is not diarrhoea. The mother can often tell accurately whether child has diarrhoea or not.

MAGNITUDE OF THE PROBLEM

Acute diarrhoea is an important cause of mortality and morbidity particularly in young children in the developing countries. Of the 11.6 million deaths among children less than five years old in all developing countries (1995) due to infectious diseases, 19% deaths are attributed to diarrhoea^[1]. In 1993, an estimated 3.2 million children below five years of age died from diarrhoea alone; 80% of these deaths occurred in the first two years of life^[2].

AETIOLOGY

Acute diarrhoea is usually caused by different infectious agents. The microbial agents causing diarrhoea may be classified as bacterial (*Vibrio cholerae* O1 and O139, *Vibrio parahaemolyticus*, enterotoxigenic *E.coli*, *Shigella*, *Salmonella*, *Campylobacter jejuni*, *Aeromonas* etc.), viral (Rotavirus, Norwalk virus etc.), parasites (*E. histolytica*, *Giardia lamblia*, *Cryptosporidium* etc.). The various agents produce diarrhoea either by production of toxin(s) or by invasion of the gut mucosa. Those organisms which produce diarrhoea by production of toxin(s) produce watery diarrhoea. *Vibrio cholerae* and enterotoxigenic *E.coli* are the prototype organisms producing watery (also called

secretory) diarrhoea. Those organisms which invade the gut mucosa usually produce bloody diarrhoea (dysentery). *Shigella* and *E.histolytica* are the prototype organisms producing bloody diarrhoea (also called invasive diarrhoea).

In watery diarrhoea usually there is loss of lots of fluid and electrolytes from the body which results in dehydration which is a conspicuous clinical feature in watery diarrhoea. In contrast, in invasive diarrhoea not much fluid and electrolytes are lost in the stool. Therefore, dehydration is not a major feature. It is most practical to base treatment of acute diarrhoea on the clinical type of illness (watery or bloody). Laboratory studies are usually not needed.

DEHYDRATION

Management of acute watery diarrhoea includes replacement of fluid and electrolytes losses, proper feeding and use of appropriate antibiotic in selected cases. It has been mentioned that dehydration occurs due to loss of fluid and electrolytes from the body. Dehydration is now clinically assessed as diarrhoea with "no signs of dehydration", diarrhoea with "some dehydration" and diarrhoea with "severe dehydration". Table 1 describes how to determine the degree of dehydration clinically. The signs typical of children with no signs of dehydration are shown in column A, signs of some dehydration in column B and those with severe dehydration in column C. The sign in bold print with asterisks (*) are the most valuable signs for assessing dehydration and are called "key signs". If two or more of the signs in column C are present including at least one key sign the child has severe dehydration. If this is not the case, but two or more signs from column B (and C) are present, including at least one key sign, the child has some dehydration. If this also is not the case, the child is classified as having no signs of dehydration.

PREVENTION OF DEHYDRATION (PLAN A)

Diarrhoea with no signs of dehydration may be managed safely and effectively at home with the administration of extra fluid, proper feeding and watching for danger signs. The mother may be educated to give her child extra fluid in the form of coconut water, salt and sugar solution, rice water with salt, mild tea (these fluids are called "home available fluid"-HAF) or oral dehydration salt solution (ORS). At any stage if the child becomes either very thirsty, passes many watery stools, vomits repeatedly, or has fever, or blood in stool, the mother should be alerted to take the child to a doctor for further management.

Table 1 Assessment of diarrhoea patients for dehydration

1. Look at:	Condition ^a	Well, alert	Restless, irritable	'Lethargic or unconscious; floppy'
	Eyes ^b	Normal	Sunken	Very sunken and dry
	Tears	Present	Absent	Absent
	Mouth and tongue ^c	Moist	Dry	Very dry
	Thirst	Drinks normally, not thirsty	*Thirsty, drinks eagerly'	'Drinks poorly, or not able to drink'
2. Feel:	Skin pinch ^d	Goes back quickly	'Goes back slowly	'Goes back very slowly'
3. Decide:		The patient has no signs of dehydration	If the patient has two or more signs, including at least one 'sign', there is some dehydration	If the patient has two or more signs, including at least one 'sign', there is severe dehydration
4. Treat:		Use Treatment Plan A	Weigh the patient, if possible, and use Treatment Plan B	Weigh the patient and use Treatment Plan C urgently

^a Being lethargic and sleepy are not the same. A lethargic child is not simply asleep: the child's mental state is dull and the child cannot be fully awakened; the child may appear to be drifting into unconsciousness.

^b In some infants and children the eyes normally appear somewhat sunken. It is helpful to ask the mother if the child's eyes are normal or more sunken than usual.

^c It is necessary to look inside the child's mouth. The mouth may be dry in a child who habitually breathes through the mouth. The mouth may be wet in a dehydrated child owing to recent vomiting or drinking.

^d The skin pinch is less useful in infants or children with marasmus or kwashiorkor, or obese children.

TREATMENT OF DEHYDRATION (PLAN B & C)

Studies have shown that 90% of cases of watery diarrhoea with some dehydration can be safely and effectively managed with ORS solution alone^[3]. WHO/UNICEF recommended ORS contains sodium chloride 3.5 g, 85 mm potassium chloride 1.5 g, sodium bicarbonate 2.5 g, or trisodium citrate, dihydrate 2.9 g and glucose 20 g dissolved in 1 L of water. For the treatment of some dehydration ORS should be administered (50-100 mL per kg). Table 2 gives the guidelines for treating children and adults with some dehydration. The mother should be taught to prepare and give ORS solution. The solution should be given to infants and young children using a clean spoon or cup. Use of a feeding bottle is strongly discouraged. If vomiting occurs (usually during the first hour of treatment) the mother should wait for 5-10 minutes and then start giving ORS solution again but more slowly. The disadvantages of WHO/UNICEF ORS are that it does not reduce the stool volume or duration of diarrhoea and thus are sometimes not acceptable to the mothers. Several clinical trials have shown that an ORS solution containing cooked rice powder in place of glucose substantially reduces the rate of stool loss due to acute diarrhoea. Rice based ORS solution significantly reduces the rate of stool output during the first 24 hours of treatment by 36% in adults with cholera and by 32% in children with cholera. In contrast, the rate of stool loss in infants and children with acute non-cholera diarrhoea treated with rice ORS solution was only reduced by 18%^[4]. A small but significant proportion of dehydrated patients might benefit from using a low osmolarity solution in which glucose concentration has been slightly reduced^[5]. However, the real benefit of using such a solution as well as their exact composition remains to be determined.

The preferred treatment for children with severe dehydration is rapid intravenous rehydration. Such treatment should preferably be carried out by admitting the patient to the hospital. Guidelines for intravenous

rehydration are given in Table 3. The preferred solution is Ringer's Lactate.

FEEDING DURING DIARRHOEA

During diarrhoea the child should be fed properly. Previously it was thought that during diarrhoea, nutrients are not absorbed adequately and hence the bowel should be given a rest. Recent studies indicate that during and after diarrhoea most of the nutrients are sufficiently absorbed. In fact, proper feeding during diarrhoea has been shown to be beneficial and prevents malnutrition. Breast feeding should be continued throughout the duration of diarrhoea. Easily digestible, energy-rich, high potassium containing, non-fibrous food should be given to the child. During convalescence at least one extra feed daily for several weeks is recommended. Locally available and culturally acceptable foods are preferred.

ROLE OF DRUGS

All cases of bloody diarrhoea where dehydration is present should be managed with rehydration therapy as detailed for the acute watery diarrhoea. In addition, all the cases of bloody diarrhoea in children below 5 years of age should be treated with an appropriate antibiotic assuming that the child is suffering from shigellosis. Studies have shown that antibiotic therapy definitely hastens recovery^[6]. The drug of choice for shigellosis is nalidixic acid^[7]. Other drugs (ampicillin^[8] or cotrimoxazole^[9]) may be used depending upon the drug resistance pattern of the circulating shigella strains in the area. It has been shown that norfloxacin^[10] or ciprofloxacin^[11] are also highly effective in the treatment of shigellosis. These drugs are contraindicated for young children because of the potential cartilage toxicity reported in experimental animals^[12]. However, more and more information is coming that these drugs may turn out to be safe even in children for such short term use^[13]. Amebiasis rarely occurs in children below 5 years of age and therefore random use of antiamoebic drugs for childhood diarrhoea is

Table 2 Guidelines for treating children and adults with some dehydration

	Approximate amount of ORS solution to give in the first 4 hours					
Age ^a	Less than 4 months	4-11 months	12-23 months	2-4 years	5-14 years	15 years or older
Weight:	Less than 5 kg	5-7.9 kg	8-10.9 kg	11-15.9 kg	16-29.9 kg	30 kg or more
In mL	200-400	400-600	600-800	800-1200	1200-2200	2200-4000
In local measure						

^a Use the patient's age only when you do not know the weight. The approximate amount of ORS required (in mL) can also be calculated by multiplying the patient's weight in kg by 75.

- If the patient wants more ORS than shown, give more.
 - Encourage the mother to continue breastfeeding her child.
 - For infants under 6 months who are not breast fed, also give 100-200 mL clean water during this period.
- NOTE: During the initial stages of therapy, while still dehydrated, adults can consume up to 750 mL per hour, if necessary, and children up to 20 mL per kg body weight per hour.

Table 3 Guidelines for intravenous treatment of children and adults with severe dehydration

• Start IV fluids immediately. If the patient can drink, give ORS by mouth until the drip is set up. Give 100 mL/kg Ringer's Lactate Solution ^a divided as follows:			
	Age	First give 30 mL/kg in:	Then give 70 mL/kg in:
	Infants (under 12 months)	1 hour ^b	5 hours
	Older	30 minutes ^b	2.5 hours

• Reassess the patient every hour. If hydration is not improving, give the IV drip more rapidly.

• After six hours (infants) or three hours (older patients), evaluate the patient using the assessment chart. Then choose the appropriate Treatment Plan (A, B or C) to continue treatment.

^a If Ringer's Lactate Solution is not available, normal saline may be used.

^b Repeat once if radial pulse is still very weak or not detectable.

not recommended. However, if antibiotic therapy fails and *E. histolytica* trophozoites are seen by microscopic examination of stool, metronidazole or tinidazole may be used in the recommended doses.

Routine use of antibiotic(s) in acute watery diarrhoea is not recommended and is actually harmful. The only indication for use of antibiotics is for the treatment of suspected severe cholera cases as an adjunct to rehydration therapy. Cholera should be suspected when a child of more than two years of age suffers from acute watery diarrhoea with severe dehydration in an endemic area. The drugs of choice for the treatment of cholera are tetracycline and doxycycline. Norfloxacin^[14] and ciprofloxacin^[15] have been shown to be also highly effective. Antibiotic therapy shortens the volume and duration of diarrhoea thereby reducing the fluid requirement, and duration of hospitalisation and excretion of *Vibrio cholerae* in stool. Other drugs, as for example, antiemetics, anticholinergics, antidiarrhoeals like opium, charcoal, kaoline and pectin, steroid and cariotonics are not required for the treatment of diarrhoea. In fact some of them are not only useless but may also be harmful. Antiemetics produce sedation and therefore, interfere with oral rehydration therapy and may produce or aggravate hypotension thereby interfering with the renal circulation. Anti-cholinergics may produce paralytic ileus.

Recently, supplementation with micronutrients especially zinc as an adjunct to rehydration therapy for the treatment of acute diarrhoea has been suggested^[16].

A study on relationship of nitric oxide, oxidation, peroxidation, lipoperoxidation with chronic cholecystitis

Jun Fu Zhou¹, Dong Cai¹, You Gen Zhu², Jin Lu Yang², Cheng Hong Peng¹ and Yang Hai Yu¹

Subject headings nitric oxide; oxidation; peroxidation; lipoperoxidation; chronic cholecystitis

Zhou JF, Cai D, Zhu YG, Yang JL, Peng CH, Yu YH. A study on relationship of nitric oxide, oxidation, peroxidation, lipoperoxidation with chronic cholecystitis. *World J Gastroentero*, 2000;6(4):501-507

Abstract

AIM To study relationship of injury induced by nitric oxide, oxidation, peroxidation, lipoperoxidation with chronic cholecystitis. **METHODS** The values of plasma nitric oxide (P-NO), plasma vitamin C (P-VC), plasma vitamin E (P-VE), plasma β -carotene (P- β -CAR), plasma lipoperoxides (P-LPO), erythrocyte superoxide dismutase (E-SOD), erythrocyte catalase (E-CAT), erythrocyte glutathione peroxidase (E-GSH-Px) activities and erythrocyte lipoperoxides (E-LPO) level in 77 patients with chronic cholecystitis and 80 healthy control subjects were determined, differences of the above average values between the patient group and the control group and differences of the average values between preoperative and postoperative patients were analyzed and compared, linear regression and correlation of the disease course with the above determination values as well as the stepwise regression and correlation of the course with the values were analyzed.

RESULTS Compared with the control group, the average values of P-NO, P-LPO, E-LPO were significantly increased ($P < 0.01$), and of P-VC,

P-VE, P- β -CAR, E-SOD, E-CAT and E-GSH-Px decreased ($P < 0.01$) in the patient group. The analysis of the linear regression and correlation showed that with prolonging of the course, the values of P-NO, P-LPO and E-LPO in the patients were gradually ascended and the values of P-VC, P-VE, P- β -CAR, E-SOD, E-CAT and E-GSH-Px descended ($P < 0.01$). The analysis of the stepwise regression and correlation indicated that the correlation of the course with P-NO, P-VE and P- β -CAR values was the closest. Compared with the preoperative patients, the average values of P-NO, P-LPO and E-LPO were significantly decreased ($P < 0.01$) and the average values of P-VC, E-SOD, E-CAT and E-GSH-Px in postoperative patients increased ($P < 0.01$) in postoperative patients. But there was no significant difference in the average values of P-VE, P- β -CAR preoperative and postoperative patients. **CONCLUSION** Chronic cholecystitis could induce the increase of nitric oxide, oxidation, peroxidation and lipoperoxidation.

INTRODUCTION

Chronic cholecystitis is a frequently encountered disease of the digestive system. Some studies point out that in blood of patients with acute cholecystitis the levels of inducible nitric oxide (iNO) and lipoperoxides are markedly increased, while the level of vitamin C, the activities of superoxide dismutase and glutathione enzyme are significantly decreased^[1-5]. However, up to now, there has been no reports on the above in patients with chronic cholecystitis. In order to observe the metabolic state of nitric oxide and other free radicals in patients with chronic cholecystitis, and the degree of injury induced by oxidation, peroxidation, lipoperoxidation due to the chronicity of cholecystitis, we determined nitric oxide (P-NO), vitamin C (P-VC), vitamin E (P-VE), β -carotene (P- β -CAR) and lipoperoxides (P-LPO) levels in the plasma as well as superoxide dismutase (E-SOD), catalase (E-CAT), glutathione peroxidase (E-GSH-Px) activity and lipoperoxides (E-LPO) level in the erythrocytes in 77 patients with chronic cholecystitis and 80 healthy controls.

We also analyzed and compared differences of the above average determination values between the patient and the control group, and between preoperative and postoperative patients. Additionally, we analyzed the relationship between the course of the disease and the above values in the patients by the linear regression and correlation as well as the stepwise regression and correlation.

SUBJECTS AND METHODS

Subjects

Patients Seventy-seven patients suffering from chronic cholecystitis with gallstones who were confirmed diagnostically through abdominoscopy and biopsy in the People's Hospital of Jinhua City were randomly sampled. Their ages ranged from 31 to 69 years (52.4 ± 10.3 a), and their courses of disease were from 2 to 20 years (5.2 ± 5.6 a). Of them, 32 were male and 45 were female. No patients had abnormality in the routine examination of blood, urine, feces, ECG and X-rays, and medical history about heart, brain, lung, liver, kidney, diabetes, autoimmune disease, peripheral vascular disease, cataract, tumor, and so on. The gallbladders of all the patients with chronic cholecystitis were removed by abdominoscopy.

Control Eighty healthy adults confirmed through the comprehensive health examination by the 2nd Affiliated Hospital of Zhejiang University were randomly sampled, their ages were from 31 to 70 years (52.7 ± 9.6 a), and 40 were male and 40 were female. The healthy adults were all normal in the routine examination of blood, urine, feces, ECG and X-rays, with no medical history regarding heart, brain, lung, liver, kidney, cholecystic disease, diabetes, autoimmune disease, peripheral vascular disease, cataract, tumor, etc.

All the patients and the healthy adults had neither exposure to kind of radiation, nor contacted any kind of pesticide and poison. Within a month prior to the study they had not taken any antioxidants such as vitamin C, vitamin E, ginkgo leaf agents, tea-polyphenol etc. There was neither any significant difference ($P > 0.05$) between the average age of the patient and the control group as determined by t test, and nor any significant difference ($P > 0.05$) between the gender proportion of the patient and the control group as determined by χ^2 test.

Methods

Blood samples Fasting venous blood samples were collected in the morning for all the subjects with heparin sodium as an anticoagulant. The separated plasma and erythrocytes were stored immediately at 4°C [6].

Plasma NO (P-NO) level Colloidal aluminium hydroxide without nitrite was used to absorb yellow pigments and to cause protein sedimentation in the plasma. The nitrite in the supernatant, which contained sodium acetate (0.20 mol/L) and disulphanilic acid (3.30 mmol/L), reacted with β -Naphthylamine and formed a

colored product, which was detected spectrophotometrically, using sodium nitrite ($2.50 \text{ } \mu\text{mol/L}$) as the standard and at a wavelength of 520 nm . The P-NO concentration was expressed in nmol/L [6,7].

Plasma LPO (P-LPO) level Trichloroacetic acid (TCA) solution (20.0 g\%, w/v) was used to cause protein sedimentation in the plasma. The protein sediment reacted with thiobarbituric acid (TBA) solution (0.67 g\%, w/v) and produced red colored compounds following incubation in a water bath at 100°C . This was detected spectrophotometrically at 532 nm , using tetraethoxypropane (TEP, $5.0 \text{ } \mu\text{mol/L}$) as the standard. The P-LPO concentration was expressed as $\mu\text{mol/L}$ [6,8].

Plasma VC (P-VC) level TCA (5.0 g\%, w/v) was used to cause protein sedimentation in the plasma, and ferric trichloride was added to the supernatant. Vitamin C in the supernatant reduced Fe^{3+} in ferric trichloride to Fe^{2+} . Fe^{2+} , on reacting with ferrocene, produced a colored product which was detected spectrophotometrically at 563 nm , using vitamin C as the standard. The P-VC concentration was expressed as $\mu\text{mol/L}$ [6,9].

Plasma VE (P-VE) level Absolute ethyl alcohol was used to cause protein sedimentation in the plasma and to extract vitamin E. Vitamin E in the supernatant reduced Fe^{3+} in ferric trichloride to Fe^{2+} . Fe^{2+} reacted with ferrocene to form a colored product that was detected spectrophotometrically at 563 nm , using vitamin E as the standard. The P-VE concentration was expressed as $\mu\text{mol/L}$ [6,10].

Plasma β -CAR(P- β -CAR) level A mixture of absolute ethyl alcohol and petroleum ether was used to cause protein sedimentation in the plasma and to extract β -carotene. The petroleum ether extract containing β -carotene was analyzed colorimetrically, using β -carotene as the standard at a wavelength setting of 440 nm . The P- β -CAR concentration was expressed as $\mu\text{mol/L}$ [6,11].

Erythrocyte LPO (E-LPO) level A mixture of absolute ethyl alcohol and trichloromethane ($5:3$) was used to precipitate hemoglobin (Hb) from a hemolytic solution (HS) of RBC without WBC and platelets. Hb level was determined in the HS. LPO in the extracted solution reacted with TBA-glacial acetic acid solution (1.0 g\%, w/v) in a water bath at 100°C and produced red colored compounds. These were detected using TEP ($5.0 \text{ } \mu\text{mol/L}$) as the standard at 532 nm . The E-LPO concentration was expressed as nmol/g Hb [6,12].

Erythrocyte SOD (E-SOD) activity A mixture of absolute ethyl alcohol and trichloromethane ($5:3$) was used to precipitate Hb from the HS of RBC without WBC and platelets. Hb level was determined in the HS. Pyrogallol (6.0 mmol/L) auto-oxidized in Tris-HCl buffer (50

mmol/L, pH 8.20), SOD was added to the buffer to inhibit its auto-oxidation and SOD activity was calculated according to the auto-oxidation rate of pyrogallol and the rate of SOD-inhibited pyrogallol auto-oxidation. The WL of 420 nm was used and the E-SOD activity was indicated as U/g Hb^[6,13].

Erythrocyte CAT (E-CAT) activity H₂O₂ (0.20 mol/L) was added to phosphate buffer (10 mmol/L, pH 7.0) containing HS of RBC without WBC and platelets. The Hb level was determined in the HS. After a reaction time of 60 s, a solution of potassium dichromate (0.169 mol/L) and glacial acetic acid (1 : 3) was added to the reacting mixture to stop the reaction, and the reacting mixture was heated for 10 min at 100°C. Colorimetry was done at 570 nm. The E-CAT activity was indicated as K/g Hb^[6,14].

Erythrocyte GSH-Px (E-GSH-Px) activity A mixture of absolute ethyl alcohol and trichloromethane (5 : 3) was used to precipitate Hb from the HS of RBC without WBC and platelets. Hb level was determined in the HS. GSH-Px in the extract catalyzed the reaction of glutathione and 5, 5'-Dithiobis-*p*-nitrobenzoic acid (DTNB) and produced yellow colored compounds which were detected at 422 nm, using glutathione (1.0 mmol/L) as the standard. The E-GSH-Px activity was expressed as U/g Hb^[6,15].

Major analytical reagents such as Vitamin C, Vitamin E, β -Carotene, Superoxide dismutase, Catalase, β -Naphthylamine, 1,2,3-Trihydroxybenzene (pyrogallol), 1, 1,3,3-Tetraethoxypropane, 2-Thiobarbituric acid were all purchased from SIGMA CHEMICAL COMPANY, USA; and the other analytical-grade reagents were all procured from China. The main analytical instruments were 721-spectrophotometer and UV-754-spectrophotometer.

Statistic analysis

All data were analyzed with SPSS/8.0 and Statistica/6.0

statistic software using Compaq Pentium III/600 computer. Statistical testing methods included unpaired and paired *t* test and chi square test (χ^2 test), linear regression and correlation analysis, stepwise regression and correlation analysis, and confidence interval (CI) of 95%. The level of significance of hypothesis testing was $P < 0.05$ and the power of test (power) > 0.75 .

Results

Comparison between the above mentioned determinations in the patient and the control group

The average values determined for P-NO, P-LPO and E-LPO in the patient group were significantly increased ($P < 0.01$) with respect to the control, whereas the average values of P-VC, P-VE, P- β -CAR, E-SOD, E-CAT and E-GSH-Px in the patient group were significantly decreased ($P < 0.01$) (Table 1).

Comparison between the above mentioned determinations in the preoperative and the postoperative patients

The average values of P-NO, P-LPO and E-LPO in the postoperative patients were significantly decreased ($P < 0.01$), whereas the average determination values of P-VC, E-SOD, E-CAT and E-GSH-Px in the postoperative patients were significantly increased ($P < 0.01$), but there was no significant difference between the average values of P-VE, P- β -CAR in the pre- and postoperative patients (Table 2).

Linear regression and correlation analysis between the course of disease and the above mentioned values determined in the patients

In pace with gradual prolonging of the course of disease in the patients, the values of P-NO, P-LPO, E-LPO in the patients were gradually increased ($P < 0.01$), the values of P-VC, P-VE, P- β -CAR, E-SOD, E-CAT, E-GSH-Px were gradually decreased ($P < 0.01$) (Table 3).

Stepwise regression and correlation analysis for the course of disease and the above-mentioned values determined in the patients

Supposing the course of disease in the patients to be y, the determination values of P-NO, P-VC, P-VE, P-β-CAR, E-SOD, E-CAT, E-GSH-Px, P-LPO and E-LPO in the patients to be $x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8$ and x_9 respectively, after stepwise regression and correlation, the stepwise regression equation was $y = -0.2706 + 0.0203x_1 + 0.6844x_3 - 11.3731x_4$, $r = 0.7902$, $F = 40.4440$, $P < 0.01$. The equation suggested that the correlation of the course of disease was the closest with the values determined for P-NO, P-VE and P-β-CAR.

DISCUSSION

The metabolic status of nitric oxide and functional status between oxidation and antioxidation systems in human body are in close relationship with health^[6-10,12-73]. If the metabolism of nitric oxide is abnormal and the dynamic balance between oxidation and antioxidation is disturbed, free radicals (FRs) concentration will unusually increase and a series of FRs chain reactions will pathologically aggravate in human body. This status can speed senility of human cells, and induce many diseases^[6-10,12-73]. Vitamin C (VC), vitamin E (VE) and β-carotene (β-CAR) are the most important antioxidants in human body, and they play an important role in scavenging superoxide anions ($O_2^{\cdot -}$), hydroxyl radical ($\cdot OH$), hydroperoxyl radical (HO_2^{\cdot}), lipid FRs, lipoxyl FRs, alkyl FRs, alkoxyl FRs, singlet oxygen (1O_2), hydrogen peroxide (H_2O_2) and others, thereby protecting biological membranes against oxidation, peroxidation and lipoperoxidation^[6,9,10,44-54, 56-69] injury. And they can promote synthesis and stabilization of immunoglobulin in human body and obstruct formation of carcinogens such as nitrosamine^[6,9,10,44-54,56-69]. Superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GSH-Px) are the most important specific antioxidases in human body, SOD is able to clean $O_2^{\cdot -}$, obstruct and prevent the pathological aggravation of a series of FRs chain reactions induced by $O_2^{\cdot -}$, CAT enables toxic active mass H_2O_2 to degrade into non-toxic O_2 and H_2O , GSH-Px may decompose toxic active mass LPO^[6,13-15,29-39,41,42,46-54,56-69]. LPO and its metabolic products such as malondialdehyde (MDA), conjugated

diene (CD) and others are important poisonous residual products that enable biological membranes to be injured by lipoperoxidation. Marked increase in LPO level in human body can strongly attack DNA, proteins, enzymes, biological membranes and so on, which leads to the lipoperoxidation injury of the biological membranes, etc^[5-8,39-43,48-53,62-71]. Nitric oxide (NO) is a neurotransmitter and endothelium-derived factor that reduces tone of vascular smooth muscle, and disorder of NO metabolism can induce many diseases^[6,7,16-28,46-49,55,62-66].

In this study the results that the average values of P-NO, P-LPO and E-LPO in the patient group were significantly higher than those in the control group ($P < 0.01$), and that the average values of P-VC, P-VE, P-β-CAR, E-SOD, E-CAT and E-GSH-Px in the patient group were significantly lower than those of the control group ($P < 0.01$) showed that there was a severe disorder of the NO metabolism and imbalance between oxidation and antioxidation, and there was the pathological aggravation of the oxidation, peroxidation, lipoperoxidation reactions in the bodies of the patients with chronic cholecystitis and gallstones. The causes probably were as follows. The cytokines, particularly interleukin -1 (IL-1), which were released out by inflammatory cells such as phagocytes namely lymphocytes, neutrophilic granulocytes, macrophages in the cholecystic inflammatory reaction, can activate inducible nitric oxide synthase (iNOS). The iNOS enables NO to be produced excessively in the body of patients, thereby resulting in a significant increase in the P-NO value in the patients^[6,7,16-28,46-49, 55,62-66]. Excessive NO was diffused into nearby tissues and cells, thus further leading to injury of the tissues and cells^[6,7,16-28,46-49,55,62-66]. The excess NO can combine with iron ions in heme group, with activated guanylate cyclase and lipoperoxidation reaction. The excess NO also inactivated antioxidases such as SOD, CAT, GSH-Px by means of the reaction of NO and hydrosulfide group (-SH) in the enzymes, which further resulted in marked decrease in SOD, CAT, GSH-Px activities and further injured cells and biologic membranes. Excessive NO in the body was able to be speedily oxidated into nitrogen dioxide (NO_2). Both NO and NO_2 themselves are extremely active FRs, NO_2 was still able to react with the organic molecules in cystic bile, and activate the neutrophils and phagocytes in the cholecystic focus, thereby releasing out a vast amount of $O_2^{\cdot -}$, $\cdot OH$, HO_2^{\cdot} , and H_2O_2 etc. Meanwhile, the phagocytes such as polymorphonuclear leukocyte were speedily activated, and a large number of $O_2^{\cdot -}$, $\cdot OH$, HO_2^{\cdot} etc were released out, and continuously got into the blood stream in the patients, thereby inducing the pathological aggravation of a series of FRs chain reactions^[6,7,16-28,46-49,55,62-66].

It must be stressed that excessive NO was capable of reacting speedily with $O_2^{\cdot -}$, thereby forming another kind of free radical, i.e. superoxide nitroso free radical ($ONOO^{\cdot}$) which possessed still more strong oxidative

properties. ONOO^- can further attack and injure the various cells in the body, and deactivate the antioxidases such as SOD, CAT and GSH-Px. Excess NO and NO_2 in human body injured DNA by way of the deamination of the base and the chain scission^[6,7,46-49,55,62-66]. So, on one hand the P-NO level in the body of patients was significantly increased, and on the other hand the body had no choice but to put to good use a great quantity of antioxidants and antioxidases in the body so as to catch and clear these excess $\text{O} \cdot$, $\text{OH} \cdot$, $\text{HO}_2 \cdot$ and others^[6-10,12-73], which resulted in significant decrease of the levels of P-VC, P-VE, P- β -CAR and the activities of E-SOD, E-CAT, E-GSH-Px in the patients. Besides the gallbladder calculi such as bilirubin, cholesterol and other organic substances themselves also produce a large number of FRs^[2-5,29,34,35,70-78].

NO_2 is a very active catalyst, and NO_2 can aggravate lipoperoxidation of the polyunsaturated fatty acids (PUFAs) through hydrogen-extractive process. The excess NO, NO_2 , $\text{O} \cdot$, $\text{OH} \cdot$, $\text{HO}_2 \cdot$ also can attack upon directly PUFAs, aggravate significantly the lipoperoxidation, thereby resulting in a large number of PUFAs which get lipoperoxidated, and subsequently form LPO. With the addition of the significant reduction in the synthesis or regeneration of GSH-Px decomposing LPO, and the marked loss of the GSH-Px activity, it goes without saying that finally this status resulted in significant increase of P-LPO and E-LPO levels^[6,7,46-49,51,52,55,62-66].

In general most anti-oxidative vitamins such as VC, VE, β -CAR, etc, must be acquired from dietary sources because they cannot be synthesized in the body. It is generally recognized that the chronic cholecystitis patients have poor appetite because their diets are controlled, and digestion of VC, specially digestion of fat-soluble vitamins such as VE and β -CAR, markedly reduced. And the anti-oxidative vitamin-poor diets cannot provide sufficient free radical scavengers to keep the balance between oxidation and antioxidation. For this reason, the values of P-VC, P-VE, P- β -CAR in the bodies of the patients were further significantly decreased^[6,9,10,47-54,56-68].

In this study the average values of P-NO, P-LPO and E-LPO in the postoperative patients were significantly decreased, the average values of P-VC, E-SOD, E-CAT, E-GSH-Px were significantly increased, but there was no significant difference in the average values of P-VE and P- β -CAR between the preoperative and postoperative patients. The findings showed that the series of FRs chain reactions in the body of patients were marked lysis, and the dynamic balance between oxidation and antioxidation, obtained resumption to a very marked degree because of the elimination of inflammatory focus after operation. However, before the compensation of common bile was established the absorption of fats and lipids was still limited, thus the absorption of fat-soluble VE and β -CAR obviously reduced^[6,9,10,47-54,56-68]. Therefore, the normal levels of P-VE, P- β -CAR in the patients were

difficult to be resumed shortly after operation.

In this study there was the linear correlation between the course of disease and the above determined values, specially the stepwise correlation with the course with P-NO, P-VE, P- β -CAR values was the closest. This status suggested that in chronic cholecystitis, a large amount of NO produced by iNOS induced and activated by the long-time infection and stimulation of the calculi in gallbladder provoked the pathological aggravation of a series of FRs chain reactions^[2-5,16-29,34,35,46-54,56-78]. As a result, the patients with chronic cholecystitis over a long time were in the state of serious imbalance between oxidation and antioxidation as well as injuries induced by oxidation, peroxidation and lipoperoxidation^[2-5,29,34,35,70-78]. The findings also showed that the metabolic status of nitric oxide and the changes in vitamin E and β -carotene levels in the body played an important part in chronic cholecystitis. Therefore, the above values, particularly the dynamic determination of P-NO, P-VE and P- β -CAR values, to a great degree, contribute to wards monitoring the condition and course in patients with chronic cholecystitis.

We think that in treating preoperative and postoperative patients with chronic cholecystitis with suitable dosage of antioxidants such as vitamin C, vitamin E, β -carotene, ginkgo leaf agents, tea-polyphenol daily to the patients may alleviate the injuries induced by oxidation, peroxidation and lipoperoxidation.

Abstract

AIM To compare the effects of intravenous route and peritoneal route on liver targeted uptake and expression of plasmid delivered by galactose-terminal glyco-poly-L-lysine (G-PLL). **METHODS** The plasmid pTM/MMP-1 which could be expressed in eukaryotic cells was bound to G-PLL, and was then transferred into Wistar rats by intravenous and intraperitoneal injection. The expression and distribution of the plasmid were observed at different time periods by *in situ* hybridization and immunohistochemistry. **RESULTS** The plasmid could be expressed significantly within 24 h after being transferred *in vivo* by both intravenous and intraperitoneal routes. One week later the expression began to decrease, and could still be observed three weeks later. Although both the intravenous and intraperitoneal route could target-specifically deliver the plasmid to the liver, the effect of the former was better as compared to that of the latter.

CONCLUSION Intravenous route is better for liver targeted uptake and expression of G-PLL-bound plasmids than the peritoneal route.

INTRODUCTION

The efficient transference and the high expression of exogenous genes in specific cells or tissues are critical steps

for both *in vitro* and *in vivo* gene therapy^[1-12]. Gene transference mediated by receptors is carried out by high affinity linkage between the ligands (binding to the foreign gene) and specific receptors on the surface of different kinds of cells, and then the foreign gene can be delivered into the cells by phagocytosis^[13,14]. There also exist some specific receptors on the surface of hepatocytes such as asialoglycoprotein receptors (ASGP-R)^[15-19], which facilitate the researchers to deliver exogenous genes into hepatocytes specifically using the ligand-receptor interaction. Galactose-terminal glyco-poly-L-lysine (G-PLL) contains the saccharide group of galactosan that can be specifically ligated to the asialoglycoprotein receptor (ASGP-R) on the surface of hepatocytes. At the same time, the cationic poly-L-lysine can bind to nucleotides with high affinity, so it can serve as a good carrier to deliver exogenous DNA to liver specifically and steadily^[20-24].

Both peripheral veins and abdominal cavity can be used as the delivery route to target drug or nucleotide to liver^[25-28], but the comparison of their effects on the targeted liver uptake has seldom been reported.

Using rats as the experimental animals, we compared *in vivo* the difference in distribution and expression of the plasmid given through intravenous or intraperitoneal route.

MATERIALS AND METHODS

Preparation of the carriers

The original plasmid of rat interstitial collagenase was kindly provided by Prof. John J Jeffrey^[29], and we reconstructed it with the plasmid of pTarget (TM) (Promega Co., Madison, MI, USA), which could be expressed in eukaryotic cells. We also inserted a segment of nucleotides (GAC TAC AAG GAC GAC GAT GAT AAG) before the terminator codon (TAA) of the rat interstitial collagenase. The 'Flag Domain' peptide (DYKDDDDK) encoded by the segment of nucleotide above, which was usually called 'Tag', could be fused in the rat interstitial collagenase^[30] and could be specifically recognized by an M2 monoclonal antibody (Kodak, New Haven, CT, USA). This recombinant plasmid was named pTM/MMP-1. The plasmid of pTM/MMP-1 was extracted and purified using QIAGEN-Tip 500 kit (QIAGEN Inc., Valencia, CA, USA) according to the manufacturer's instructions. The plasmid was mixed with different amounts of galactose-terminal glyco-poly-L-lysine (kindly provided by Dr. Shou-Ming Wen of Air-Force General

Division of Gastroenterology, Zhongshan Hospital, Shanghai Medical University, Shanghai 200032, China

Chang-Qing Yang, male, 35 years old, got his M.D. in 1990 and Ph.D. in 1998 from Xiangya Hospital of Hunan Medical University, now is working as a postdoctoral fellow in Zhongshan Hospital of Shanghai Medical University, majoring in liver targeted uptake and hepatic fibrosis. This work was supported by National Natural Science Foundation of China (No39570336).

Hospital of PLA, China. The mean molecular weight of this GPLL was 8500 and the ratio of galactose to poly-L-lysine was 15:28. The optimal proportion of the plasmid pTM/MMP-1 binding to galactose-terminal glyco-poly-L-lysine was determined by electrophoresis in 1% agarose gel.

Animal experiments

Eighteen male Wistar rats, with body weight of 130–150 g, were randomly divided into three groups of six rats each. Poly-L-lysine intravenous (PI) group: 50 µg plasmid pTM/MMP-1 bound to galactose-terminal glyco-poly-L-lysine was administered through cauda vein; poly-L-lysine intra-peritoneal (PP) group: each rat was given the same amount of pTM/MMP-1 bound to galactose-terminal glyco-poly-L-lysine intraperitoneally; normal group: control animals. Twenty-four hours, 48 h, 72 h, 1 wk, 2 wk, 3 wk after the administration of the plasmid, one rat from each group was randomly selected and anaesthetized with 2% pentobarbital sodium intraperitoneally. Then 1 mL blood was obtained by cardiac puncture for the assay of alanine transaminase (ALT), aspartic transaminase (AST), and creatinine (Cr) to observe the functions of important organs. After perfusion of the whole body with 20 mL phosphate-buffered saline and 40 mL 4% paraformaldehyde through ventricular injection, the tissues of liver, spleen, lungs, and kidneys were collected and fixed in 4% paraformaldehyde, encapsulated in paraffin and cut into sections 4-µm thick. This procedure above was approved by the Laboratory Animal Committee of Shanghai Medical University.

Immunohistochemistry

Immunohistochemistry was performed according to the literature^[31,32]. The first antibody used was M2 monoclonal antibody which was specific for flag-domain tag (Kodak, New Haven, CT, USA) and the second antibody used was Horse anti-mouse IgG, labeled with biotin (Vecter, Burlingame, CA, USA). After the treatment with avidin and biotin (ABC kit, Vecter, Burlingame, CA, USA), color development was followed using dimethylaminoazobenzene (DAB) and counterstained with hematoxylin. Five fields were observed under high power from every immunostained section and the positive signals were counted.

In situ hybridization

The procedure of *in situ* hybridization was also described previously^[25,26]. To state briefly, the oligonucleotide probe (5'-TGG TGT GAC TAC AAG GAC GAC GAT GAT AAG-3') was synthesized in Cell Biology Institute of Chinese Academy of Sciences (Shanghai), which could hybridize with the (mRNA) of the flag-domain tag in the plasmid pTM/MMP-1, and the 5' end of the probe was labeled with biotin. After the hybridization of the target mRNA with the probe, the rest of the procedure was similar to that followed in immunohistochemistry excluding

the step of hematoxylin counterstaining.

Other biochemical assays

ALT, AST, and Cr were assayed using the 7170A Automatic Analyzer (HITACHI, Japan) to observe the changes in the important organs' function.

Data analysis

All of the data were analyzed by the software SPSS 7.0 for windows (one-way ANOVA).

RESULTS

Ratio of G-PLL to plasmid

According to the electrophoresis results, we found that 0.3 µg of galactose-terminal glyco-poly-L-lysine could thoroughly bind to 1 µg of the plasmid, which meant that about 72 molecules of G-PLL could carry one molecule of the plasmid pTM/MMP-1 (Figure 1).

Figure 1 Determination of optimal proportion of G-PLL bound to plasmid by 1% agarose electrophoresis. Lane 1–8 are respectively 0.05 µg, 0.1 µg, 0.2 µg, 0.3 µg, 0.4 µg, 0.5 µg, 1.0 µg, and 1.5 µg G-PLL mixed with 1 µg pTM/MMP-1 plasmid. pTM/MMP-1 1 µg plasmid could only be bound completely by more than 0.4 µg G-PLL.

The changes in the functioning of important organs

Compared with the normal group, there was no obvious elevation of the ALT, AST, and Cr levels in the PI and PP groups.

The distribution and expression of the plasmid in liver, spleen, lung and kidney

The results of the immunohistochemistry and *in situ* hybridization showed that the plasmid binding to G-PLL could be expressed *in vivo*, regardless of the introducing route and the results of immunohistochemistry were more sensitive and stable. In addition, the protein product of the plasmid could be secreted extracellularly (Figures 2 and 3), similar to the expression of interstitial collagenase in the physiological state^[30,33]. We found that both intravenous route and intraperitoneal route could make liver as the major distribution organ of the plasmid bound to G-PLL.

Figure 2 Immunostaining of flag-domain tag in the liver all hours after administration of the plasmid bound to G-PLL (galactose-terminal glyco-poly-L-lysine) via cauda vein. $\times 200$

Figure 3 *In situ* hybridization with biotin labeled oligonucleotide probe in the liver 3 wk after the administration of the plasmid bound to G-PLL (galactose-terminal glyco-poly-L-lysine) via abdominal cavity. $\times 100$

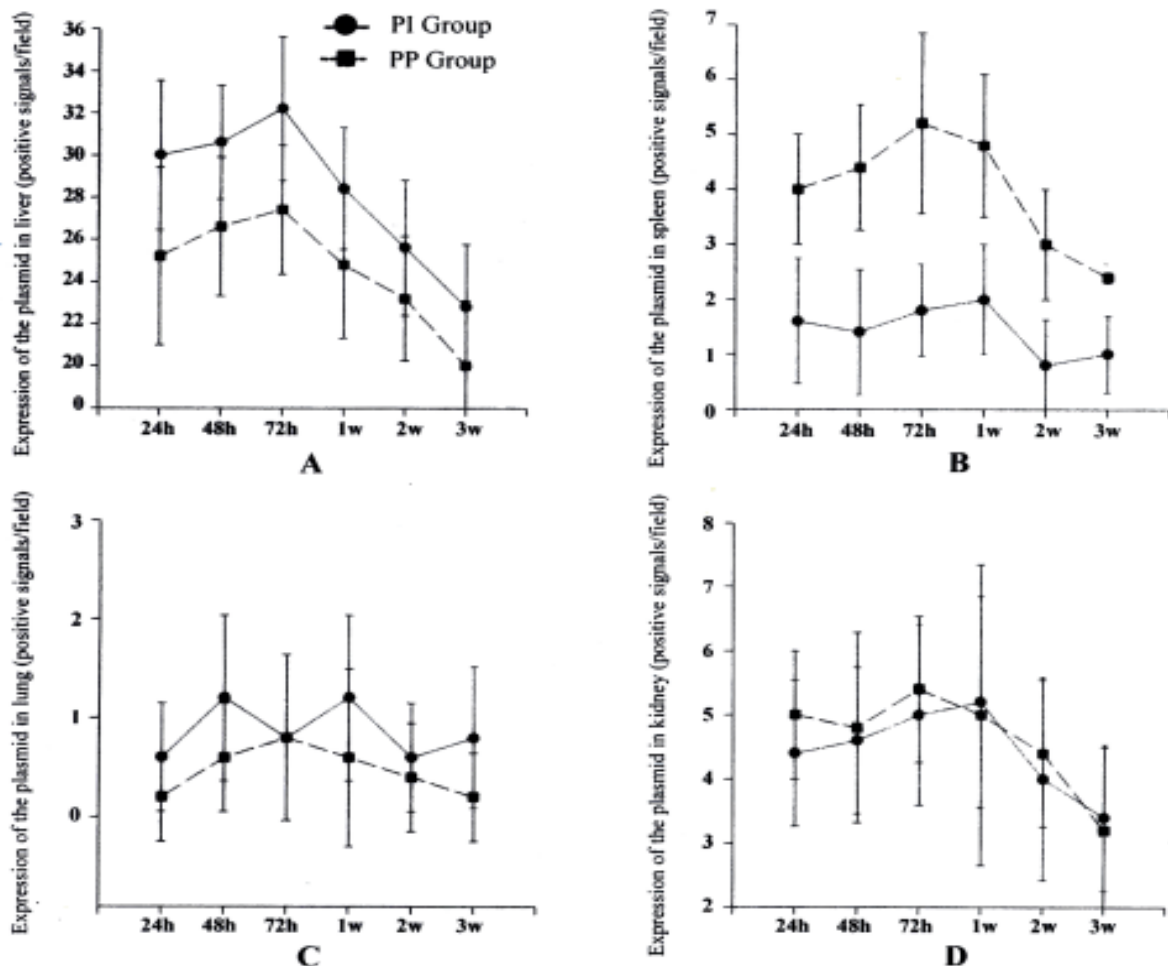

Figure 4 The distribution and expression of the plasmid bound to G-PLL (galactose-terminal glyco-poly-L-lysine) in different tissues and at different time period and administered intraperitoneally or intravenously. A: liver, B: spleen, C: lung, D: kidney. PI: plasmid bound to G-PLL introduced intravenously, PP: plasmid bound to G-PLL introduced intraperitoneally.

The obvious expression of the plasmid could be observed 24 h after the administration and began to decrease one

week later, although it could still be observed weakly even two or three weeks later. Among the two groups, we

observed that the expression and distribution of the plasmid in the liver of the PI group was significantly higher than that of the PP group. Besides the liver, the plasmid in PI group could also be expressed in lung at a lower level, and almost could not be expressed in spleen and kidney. As for the PP group, most of the distribution and expression was located in the liver and a relatively higher level could be seen in the spleen and kidney, whereas low expression could be observed in the lungs (Figure 4).

DISCUSSION

Regarding the gene therapy of hepatic diseases, efficient delivery of the exogenous genes to the liver and its high expression there could increase its local accumulation and minimize the side-effects on other tissues and organs as well^[34-36].

For the gene therapy of hepatic diseases in the animal experiments, exogenous genes were usually delivered to the liver through the portal vein, bile duct injection, or even by direct liver injection^[37-41]. From the viewpoint of clinical application these methods have limitations concerning its invasive trauma and possible risk. If the gene transference to liver could be accomplished by a peripheral vein or abdominal cavity, the limitations could then be avoided or decreased and it would also be easily accepted by the patients. So we observed the efficacy of liver targeted gene delivery using intravenous and intraperitoneal routes.

Receptor mediated gene transfer was carried out by high affinity linkage between the ligands (binding to the foreign gene) and specific receptors on the surface of different kinds of cells, such that the foreign gene could be delivered into the cells by phagocytosis^[24,42]. It has been reported that the ratio of the targeted uptake by the liver delivered by G-PLL could reach up to 70%-90% *in vivo*^[43,44]. In our experiments we found that in addition to its main location in the liver, the plasmid binding to G-PLL could be also expressed in kidneys, spleen, and lungs. It might be due to the existence of AS GP-R in the other extrahepatic tissues^[45,46].

Recently Zhang *et al*^[42] found that intravenous injection was an useful method for delivery to liver by a target carrier. We found that the peripheral vein route was better than abdominal cavity in the targeted delivery of the plasmid bound to G-PLL. We conjectured that although the majority of the DNA/cARRIER complex would reach the liver through portal vein after the absorption by the abundant capillary bed of peritoneum, quite a lot of the complex would possibly be absorbed or degraded by other organs in the abdominal cavity, thus leading to the decreased distribution and expression of the plasmid in the liver. In the same way, it might be one of the reasons that its distribution in the spleen reached to a relatively high level. In this experiment, we also observed whether G-PLL binding to the plasmid would induce some toxicity to the body. We did not find any detrimental effect on the functioning of important organs such as liver, heart, and

kidney, and this further indicated that G-PLL could be used safely *in vivo* as the delivery carriers for drug or nucleotides.

In conclusion, we found that the plasmid bound to GPLL could be delivered to the liver efficiently and safely, and the intravenous transference was better than peritoneal transference for the targeted uptake by the liver when G-PLL was used as a carrier. But whether G-PLL can be used to deliver drugs or nucleotides for the treatment of liver diseases in human beings by intravenous route deserves further investigations.

ACKNOWLEDGEMENT We express our thanks to Dr. Shou-Ming Wen of the Air-force General Hospital of PLA in P.R.China for kindly providing galactose-terminal glyco-poly-L-lysine. We also want to thank the Department of Pathology in Zhongshan Hospital for their technical assistance.

Li J, Yang XK, Yu XX, Ge ML, Wang WL, Zhang J, Hou YD. Overexpression of p27^{KIP1} induced cell cycle arrest in G₁ phase and subsequent apoptosis in HCC-9204 cell line. *World J Gastroentero*, 2000;6(4):513-521

CONCLUSION Bak may induce cell cycle arrest in G₁ phase through upregulating expression of p27^{KIP1} and subsequently lead to apoptosis in HCC-9204 cells. The p27^{KIP1}-GFP fusion protein can be transiently expressed in HCC-9204 cells. The inducible p27^{KIP1} expressing cell line provides a model to assess p27^{KIP1} function.

Abstract

AIM We have previously reported that inducible over-expression of Bak may prolong cell cycle in G₁ phase and lead to apoptosis in HCC-9204 cells. This study is to investigate whether p27^{KIP1} plays an important role in this process.

METHODS In order to elucidate the exact function of p27^{KIP1} in this process, a zinc inducible p27^{KIP1} stable transfectant and transient p27^{KIP1}-GFP fusion transfectant were constructed. The effects of inducible p27^{KIP1} on cell growth, cell cycle arrest and apoptosis were examined in the mock, control pMD vector, and pMD-KIP1 transfected HCC-9204 cells.

RESULTS This p27^{KIP1}-GFP transfectant may transiently express the fusion gene. The cell growth was reduced by 35% at 48 h of p27^{KIP1} induction with zinc treatment as determined by trypan blue exclusion assay. These differences remained the same after 72 h of p27^{KIP1} expression. p27^{KIP1} caused cell cycle arrest after 24 h of induction, with 40% increase in G₁ population. Prolonged p27^{KIP1} expression in this cell line induced apoptotic cell death reflected by TUNEL assay. Forty-eighth and 72 h of p27^{KIP1} expression showed a characteristic DNA ladder on agarose gelelectrophoresis.

INTRODUCTION

Cell cycle regulatory proteins play a critical role in both normal cell growth and tumorigenesis. The cyclin dependent kinases (CDKs) are the major regulators of cell cycle progression, and thus are important candidates for therapeutic tumor suppression^[1]. The CDKs, which are responsible for the phosphorylation of the retinoblastoma protein (pRb) and pRb related proteins, are in turn regulated by changes in cyclin levels, phosphorylation and the presence of cyclin kinase inhibitors (CKIs)^[2-3]. Two classes of CKIs are present within mammalian cells. One class, the INK4 (inhibitors of CDK4) family, is a group of ankyrin repeat protein whose members p16^{INK4A}, p15^{INK4b}, p18^{INK4c} and p19^{INK4d} are specific inhibitors of cyclin D1/CDK4 or CDK6 complexes^[4-6]. The second class of CKIs, the p21 family, consists of p21^{CIP/WAF1}, p27^{KIP1} and p57^{KIP2} which are general inhibitors of the G₁/S CDKs^[7-9]. Homology between the family members is limited to a conserved amino-terminal 60-residue domain responsible for kinase binding and inhibition^[10].

p27^{KIP1} regulates cell cycle progression by interacting with, and thereby inhibiting, various cyclin-CDK complexes. Physiologically, p27^{KIP1} is believed to act primarily to regulate progression of cells from late G₁ into S through its interaction with cyclin E-CDK2 complexes^[11]. p27^{KIP1} has been implicated as a mediator of growth arrest due to TGF- β , cAMP, and other extracellular factors^[12]. Moreover, elevated expression of p27^{KIP1} leads to G₁ arrest in many cell types and promotes neuronal differentiation in mouse neuroblastoma cells, while inhibition of p27^{KIP1} expression through use of antisense technology prevents G₁ arrest and/or suppresses entry of fibroblasts into a state of quiescence in response to mitogen depletion^[13-14]. The phenotype of mice null for the p27^{KIP1} gene includes increased body size, female sterility and a high incidence

of spontaneous pituitary tumors^[15].

We have previously shown that overexpression of Bak might prolong cell cycle in G₁ phase though this new property of Bak had never been reported before. We provided a hypothesis that Bak's translocated expression from the cytoplasm to the nuclei of HCC-9204 cells may trigger the expression of certain cell cycle regulators such as cyclins, CDKs, or CDK inhibitors through DNA-protein or protein-protein interaction. Since p27^{KIP1} is one of major cyclin-CDK regulators in G₁ phase, we currently executed an investigation of whether overexpression of Bak in HCC-9204 cells upregulates the expression of p27^{KIP1} and whether p27^{KIP1} itself may induce cell cycle arrest in G₁ phase and even apoptosis in HCC-9204 cells.

MATERIALS AND METHODS

Cell line and cell culture

HCC-9204 cell line derived from a human hepatocellular carcinoma and established in our laboratory was cultured in Eagle's medium containing phenol red, with 50 mL/L fetal bovine serum (FBS) (HyClone Laboratories, USA) in a humidified atmosphere of 950 mL/L air, 50 mL/L CO₂ at 37°C^[16]. All media were supplemented with 2 mmol/L L-glutamine, 100 mg/L penicillin and 100 kU/L streptomycin. Culture medium and supplements were obtained from GIBCO BRL. Of the HCC-9204 cell line, p53 was mutated. Medium was changed every 3 days. Cells were removed from culture flasks for passage by washing once with Hank's balanced salt solution, followed by a 5 min incubation with 0.5 mmol/L EDTA and 0.5 g/L trypsin at pH 7.4, RT.

RT-PCR analysis

Total RNA was extracted from HCC-9204 cells using an RNA extraction reagent, TRIzol (Life Technologies, USA), according to standard acid-guanidium-phenol-chloroform method^[17]. About five µg of total RNA were reverse transcribed at 42°C for 60 min in a total 20 µL reaction volume using a first-Strand cDNA synthesis kit (Boehringer Mannheim, Germany). cDNA was incubated at 95°C for 5 min to inactivate the reverse transcriptase, and was served as template DNA for 32 rounds of amplification using the GeneAmp PCR System 2400 (Perkin-Elmer Applied Biosystems, CA, USA). PCR was performed in a standard 50 µL reaction mixture consisting of 10 mmol/L Tris-HCl, 50 mmol/L potassium chloride, 1.5 mmol/L magnesium chloride (pH 8.3), 0.2 mmol/L dNTPs, 50 pmol of each sense and antisense primer and 2.5 U of Taq DNA polymerase (MBI, Canada). Amplification was performed for 30 s at 94°C, 45 s at 58°C and 45 s at 72°C after heat-start for 5 min. Finally, an additional extension step was carried out for 7 min. As negative control, the DNA template was omitted in the reaction. The amplification products were separated on 12 g/L agarose gels and visualized by ethidium bromide staining. PCR primers for p27^{KIP1} were as follows: forward primer, 5'-ggggtaccatgtcaaactgacgttc-3'; reverse

primer, 5'-gcgtcgacacgtttgacgtcttc-3': according to the p27^{KIP1} gene structure in Genebank. PCR product of 597 bp was obtained. Kpn-I and Sal-I sites were designed in the 5' and 3' end of cDNA encoding p27^{KIP1} and the terminal code for p27^{KIP1} was mutated so as to construct a fusion protein.

DNA sequencing

The PCR product was purified through Wizard Plus Minipreps DNA Purification System (Promega, USA). The pGEM-T Easy Vector Systems (Promega, USA) was applied for the cloning of the PCR product. Then the recombinant plasmid DNA was transformed into *E. coli* and was sequenced by dideoxy-mediated chain-termination method, using ABI PRISM-TM Dye Terminator Cycle Sequencing Ready Reaction Kit (Perkin Elmer, USA). This kit was developed specifically for the preparation of samples for sequence analysis on the ABI PRISM 377 DNA Sequencer. Cycle sequencing was performed on the GeneAmp PCR systems 2400 (Perkin Elmer, USA) according to the instructions.

Plasmid construction

Plasmids were constructed using standard molecular biology techniques^[18]. In order to construct a hybrid DNA encoding a chimerical p27^{KIP1}-GFP fusion protein, pGEM-T Easy KIP1 was digested with Kpn-I and Sal-I to yield a 0.6 kb fragment. The resulting fragment then ligated to Kpn-I and Sal-I digested pGREEN LANTERN-1 (Clontech, USA) containing the humanized Thyr⁶⁵ GFP cDNA under the control of CMV enhancer/promoter and the SV40 polyadenylation signal. Correct reading framework of the fusion gene was confirmed by DNA sequencing. Human p27^{KIP1} (pBluescript SK-p27) was a gift from Dr. Polyak^[19-20]. PCR primers for p27^{KIP1} were as follows: forward primer, 5'-ggggtaccatgtcaaactgacgttc-3'; reverse primer, T7 primer. PCR product of 1.0 kb was obtained and subsequently ligated into pGEM-T Easy Vector System. To construct pMD-KIP1, pGEM-T Easy KIP1 was digested with EcoR-I and Xho-I to yield a 1.0 kb fragment. The resulting fragment then ligated to EcoR-I and Xho-I digested pMD-neo. Plasmids for transfection were purified using a kit (Quiagen Inc., USA).

Transient and stable transfection

pKIP1-GFP and pMD-KIP1 were used for transient and stable transfections respectively. Clonfectin (Clontech, USA) was used to transfect plasmids into HCC-9204 cells. According to the instructions, Clonfectin transfection reagent was an effective liposome transfection reagent for many mammalian cell types with high transfection efficiencies and required only 1-4 hour incubation for optimal results, especially effective transfections in serum-containing media. Green fluorescence was detected 4, 24 and 48 h after transfection. For stable transfection, the transfected HCC-9204 cells were grown for 2 weeks in a

medium containing 0.5 g/L G418 (Life Technologies, Inc., USA), after which the G418 concentration was reduced to 0.2 g/L. Stable cell line of HCC-9204 transfected with pMD-KIP1 vector was treated by continuous exposure to 100 μ mol/L of ZnSO₄.

Cell viability

Cells were seeded at 10⁵ per dish. HCC-9204 cells viability was determined by Nikon Eclipse TE200 inverted microscopic examination of cells stained by 1 g/L trypan blue (trypan blue exclusion), counting cells on a hemocytometer at the time point indicated^[21].

Apoptosis analyzed by TUNEL assay

Cells were harvested for TUNEL staining. The proportion of cells showing DNA fragmentation was measured by incorporation of fluorescein isothiocyanate (FITC)-12-dUTP into DNA by using terminal deoxynucleotidyltransferase (TdT)^[22]. Briefly, a kit from Boehringer Mannheim (In Situ Cell Death Detection Kit, FITC) was used. After a 30 min (RT) incubation with 30 g/L BSA, 200 mL/L normal bovine serum in PBS, pH 7.4, slides were covered with the TUNEL mix (calf thymus TdT, FITC-12-dUTP and cobalt chloride in 1 \times reaction buffer) for 1.2 h at 37 °C. The morphologic features were visualized by fluorescence microscopy. Routine HE staining was also conducted. Negative control was performed by omitting TdT. We used paraffin-embedded sections of HCC as a positive control^[23].

DNA laddering

Laddering of DNA in extracts from untransfected and transfected cells was carried out. DNA was extracted from 5 \times 10⁶ cells 24 h post-induction. DNA fragmentation was assayed as described previously^[24]. Briefly, 24 h following addition of 100 μ mol/L ZnSO₄, 5 \times 10⁶ cells were lysed in buffer containing 5 mmol/L Tris (pH 8.0), 20 mmol/L EDTA and 5 g/L Triton X-100 on ice for 30 min. High molecular weight DNA was removed by centrifugation at 14 000 r/min for 15 min at 4 °C, and the supernatant was sequentially extracted with phenol:chloroform, and chloroform. The low molecular weight DNA was recovered by ethanol precipitation, resuspended in 30 μ L of TE buffer, and treated with RNase A for 3 h at 37 °C prior to electrophoresis on 12 g/L agarose gels.

Western blot analysis of transgene expression

Monolayers were rinsed with PBS and lysed with SDS-PAGE loading buffer (50 mmol/L Tris HCl pH 6.8, 100 mmol/L dithiothreitol, 20 g/L SDS). Mock and pMD-neo transfected cells served as a control. Samples were analyzed by SDS-PAGE and transferred into Hybond-C super membranes (Amersham, UK). The membranes were blocked with 50 mL/L skim milk, 1 g/L Tween-20 and then probed with primary antibody overnight according to manufacturer's instructions, washed in PBS, 2 g/L Tween-20 and then incubated with the appropriate horseradish-

peroxidase (HRP) conjugated secondary antibody. After washing, the membranes were developed by DAB detection reagents according to manufacturer's guide (Dako Co. USA). p27^{KIP1}, rabbit polyclonal antibody (Santa Cruz Biotechnology, USA) was detected followed by HRP-conjugated anti-rabbit IgG (Fc) was used. The level of β -actin was used as a control for equal loading of protein.

Immunohistochemistry analysis

HCC-9204 cells were harvested at different times of induction with ZnSO₄. Cell preparations were fixed with 700 mL/L ethanol for two hours, washed in PBS, and incubated with p27^{KIP1} antibody diluted 1 \times 100 in PBS containing 10 mL/L bovine serum albumin (BSA, Sigma, USA). Immunostaining was performed using LSAB1 kit (Dako, Peroxidase, USA), according to the instructions of the manufacturer.

Fluorescence microscopy and laser confocal microscope

Nikon Eclipse TE200 inverted fluorescence microscope was used to observe and photograph. Images were collected on a laser confocal microscope, model MRC-1024 (BioRad, UK) with a Plan-Neofluar 40 \times 1.3 NA Apochromat objective (Zeiss, Germany). The 488 nm line of a krypton/argon laser was used for fluorescence excitation of FITC. Images were processed using Adobe Photoshop 5.0 software (Adobe Systems Inc., USA).

RESULTS

RT-PCR for p27^{KIP1} in Bak transfected HCC 9204 cells

Bak transfected HCC-9204 cells were collected 0, 24 and 48 h post-induction as the previous study mentioned and were used to extract total RNA by TRIZOL reagent. The findings as shown in Figure 1 suggested that overexpression of Bak constantly induced expression of CDK inhibitor, p27^{KIP1}, at mRNA level in HCC-9204 cell line.

Figure 1 RT-PCR results of human p27^{KIP1} RNA in Bak transfected HCC-9204 cell line. Predicted PCR product size is about 600 bp. lane 1: Molecular weight Marker (Takara, DL 2000); lane 2: Bak (0 h); lane 3: Bak (24 h); lane 4: Bak (48 h)

Sequencing of p27^{KIP1} and p27^{KIP1}-GFP fusion genes

The purified p27^{KIP1}-PCR product was cloned into pGEM T-Easy vector and sequenced. Comparison of the sequences with published data in Genbank indicated only one base pair of disparity while the amino acid residue encoded was the same as what the Genbank indicated (Figure 2). pGEM-T Easy KIP1 was digested with Kpn-I and Sal-I to yield a 0.6 kb fragment. The resulting fragment then ligated to Kpn-I and Sal-I digested pGREEN LANTERN-under the control of CMV enhancer/promoter and the SV40 polyadenylation signal. Correct reading framework of the fusion gene was confirmed by restriction enzyme analysis or DNA sequencing.

Transient expression of p27^{KIP1}-GFP fusion proteins in HCC-9204 cell line

Green fluorescence was visible 8 h after transient transfection with pKIP1-GFP fusion constructs. The p27^{KIP1}-GFP fusion proteins localized primarily to cell nuclei, with some GFP presented in the cytoplasm (Figure 3). However, 24 h post transfection, the green fluorescence disappeared. Some cells exhibited typical active cell death including condensed and rounded cells, cell detachment under Nikon Eclipse TE200 inverted microscope as shown in Figure 4.

Figure 3 Cell slides under Nikon Eclipse TE200 fluorescence microscope using excitation light at either 488 nm to detect GFP (emission filter 522 nm). Distribution of GFP p27^{KIP1} fusion protein expressed in living HCC-9204 cells 8 after 100 μmol/L ZnSO₄ treatment, indicated by an arrow. × 200

pMD vectors direct the inducible expression of p27^{KIP1}

Inducible pMD-KIP1 vectors were constructed to express human cyclin kinase inhibitors, p27^{KIP1}, as shown in Materials and Methods. Transgene expression was under the control of the metallothionein-II (MT-II) promoter and the BGH polyadenylation signal. Previously it was found that MT-II promoter gave higher expression levels in HCC-9204 cells as compared with those obtained with the HCMV promoter. To study the effects of pMD-vector driven expression of p27^{KIP1}, HCC-9204 cells were left untreated (mock), or were transfected with control pMD-vector or pMD-KIP1, at 4, 24 and 48 h, respectively after addition of 100 μmol/L ZnSO₄. Western blot analysis showed a strong signal of Mr 27 000 protein appeared in HCC-9204 24 h post induction. However no band was detected in normal HCC-9204 cells as shown in Figure 5. Immunohistochemistry of p27^{KIP1} as shown in Figure 6 was consistent with Western blot analysis. Nuclear staining signals were observed in p27^{KIP1} stable transfectant 24 h post addition of ZnSO₄.

Figure 5 The results of Western blots of lysates from transfected HCC-9204 cells, probed with antibodies against human p27^{KIP1}. Excellent p27^{KIP1} expression was observed in HCC-9204 cells even 4 h after induction with zinc.

Figure 6 p27^{KIP1} detected by DAKO LABC kit in transfected HCC-9204 cells after 24 h of addition of ZnSO₄. p27^{KIP1} dark-brown granules are present in the nuclei of p27^{KIP1} transfected HCC-9204 cells, as indicated by an arrow. $\times 200$

Inhibition of tumor cell growth by exogenous p27^{KIP1}

p27^{KIP1} gave a very pronounced inhibition of growth. HCC-9204 cells viability was determined by microscopic examination of cells stained by 1 g/L trypan blue (trypan blue exclusion) (Figure 7). Time course effect of p27^{KIP1} on HCC-9204 cells growth was observed under Nikon Eclipse TE200 inverted microscope (Figure 8). Within one day post-induction, a block in cell growth was observed in HCC-9204 cells with a few cells staining positive with Trypan blue, indicating that the exogenous p27^{KIP1} was having a cytostatic effect on growth. More dramatic effects were observed 24 h after addition of zinc. Mock and control pMD vector transfected cells grew until confluent (day 3) and then entered a growth arrest following which significant numbers of trypan blue-staining cells were observed, indicative of cell death, accounting for the decline in the cell number, which was especially apparent in confluent HCC-9204 cells. By 3 days post-induction, cells staining positive with trypan blue-staining cells were observed in the cultures transfected with p27^{KIP1} even though the monolayers were not confluent, and this cell death accounted for the overall reduction in cell number that was observed during the remainder of the experiment. Cell death was greatest in HCC9204 cells transfected with pMD-KIP1.

From Figure 7, we could obviously figure out that the cell growth was reduced by 35% after 48 h of p27^{KIP1} induction with zinc treatment as determined by trypan blue exclusion assay. These differences remained the same at 72 h, and even at 96 h post addition of zinc.

pMD vector expression of p27^{KIP1} alters cell cycle distribution profiles

To see if the p27^{KIP1} had an ability to induce G₁ arrest, cell cycle analysis was performed on transfected HCC-9204 cells. At 24 h post-induction, HCC-9204 cells expressing exogenous p27^{KIP1} showed an accumulation of cells in G₁

compared to mock and control pMD transfected cells, consistent with p27^{KIP1} inhibiting tumor cell growth. (Figure 9)

Figure 7 Time course of growth of cells transfected with pMD-KIP1 expressing p27^{KIP1}. HCC-9204 cells were induced by 100 μ mol/L ZnSO₄. HCC-9204 cells viability was determined by microscopic examination of cells stained by 1 g/L trypan blue, counting cells on a hemocytometer at the time point indicated. Each treatment was triplicate.

Figure 8 Time course effect of p27^{KIP1} on HCC-9204 cells growth. Cells were seeded at $10^5 \pm 5$ per dish. HCC-9204 cells were induced by 100 μ mol/L ZnSO₄ at the time indicated. Cells morphology was observed under Nikon Eclipse TE 200 phase-contrast microscopic at 0, 24 and 48 h post addition of zinc. "Upper-row" represents pMD-neo transfected cells; "Lower-row" represents pMD-KIP1 transfected cells. $\times 200$

FACS analysis showed that overexpression of p27^{KIP1} resulted in an increase of G₁ population in HCC-9204 cells from 35.21% to 76.31%. Together, these data indicated that overexpression of p27^{KIP1} alone is sufficient to suppress the proliferation of human tumor cells. We are currently investigating the role of p27^{KIP1} in mediating cellular responses to a variety of external signals and the mechanism of inhibition.

Figure 9 Result of flow cytometric analysis. Cells were stably transfected with p27^{KIP1} and induced by 100 μ mol/L ZnSO₄. The percentage of each phase for each group (before or 24 h after addition of zinc) is indicated in each panel.

Induction of apoptosis in cells transfected with vectors expressing p27^{KIP1}

Since by day 3, a significant proportion of HCC-9204 cells transfected with the vectors expressing p27^{KIP1} stained positive with trypan blue, indicative of cell death, we attempted to ascertain whether p27^{KIP1} was inducing apoptosis. To confirm that over-expression of p27^{KIP1} induced cell death was apoptotic, a variety of apoptosis associated detection assays were applied. In stable transfectants after addition of 100 μ mol/L ZnSO₄, cell growth was significantly inhibited according to FACS analysis as shown in Figure 9. TUNEL analysis (Figure 10) and DNA laddering (Figure 11) confirmed that part of cells underwent apoptosis 48 h or 72 h after addition of 100 μ mol/L ZnSO₄.

Figure 10 TUNEL assay demonstrating obvious apoptotic changes in HCC-9204/p27^{KIP1} 24 h after addition of zinc under laser confocal microscope as indicated by an arrow. (Bar represents 10 μ m)

Taken together, p27^{KIP1} overexpression induced rapid morphological changes in HCC-9204 cells. p27^{KIP1} overexpression inhibited proliferation of HCC-9204 cells and subsequently induced apoptosis.

Figure 11 Analysis of DNA ladder formation at 0 (lane 1), 4 h (lane 2), 24 h (lane 3), 48 h (lane 4), 72 h (lane 5) post addition of zinc in HCC-9204 cell line. Each lane was loaded with 10 μ g DNA.

DISCUSSION

Since its introduction into cell biological research, the green fluorescent protein (GFP) of the jellyfish *Aequorea victoria* has become a versatile tool for the analysis of protein function and dynamics at the cellular level^[25]. GFP, which consists of 238 amino acids, has been used as a tag for localization of a broad range of proteins in a wide variety of eukaryotic cells^[26]. A mutant of GFP, S65T with an excitation peak of 489 nm and an emission peak of 511 nm, emits four to six times more fluorescence energy compared with wild-type GFP. GFP may be fused generically to a target protein, and the fluorophore of GFP forms spontaneously in the presence of oxygen, thus rendering it an ideal probe for *in vivo* applications. The *in vivo* expression of GFP obviates the fixation and permeabilization of cells for immunofluorescence or the microinjection of labeled proteins^[27].

GFP fusion proteins constitute a major advance in the study of the dynamics of intracellular processes in living cells^[28-32]. A major concern in the application of GFP as a fluorescent tag relates to whether the distribution of GFP fluorescence is identical to that of the protein to which it is fused. We have constructed GFP p27^{KIP1} fusion gene and transfected into HCC-9204 cells. The results indicated that the fusion protein was still expressed in the nuclei of HCC-9204 cells.

Previous studies indicated that cell survival following transfection with pGRE EN LANTERN-1 was similar to transfection with pCMV \cdot SPORT- β gal. No trypan blue-stained cells were seen to fluoresce green, and the fluorescence intensity of green fluorescent cells treated with trypan blue remained the same when judged by microscopic observation indicating that fluorescent cells were viable cells^[33]. A comparative study has been performed to determine whether apoptotic cells still can express GFP. A

GFP positive clone was chosen and co unstained with PI. The cells which had a property of apoptosis were stained with PI and no longer expressed GFP. We used PI counter-staining to show that the cells appearing as red fluorescence were not viable and only viable cells had a potential to express GFP. The fluorescence green vanished as soon as the cells become unviable (Figure 12). Therefore, transient expression of KIP1 - GFP fusion protein was disrupted when these cells underwent apoptosis.

The cell cycle progression is controlled by a family of cyclins and their specific catalytic partners, cyclin-dependent kinases (CDKs). D-type cyclins govern the G₁/S transition in association with their proper physiological partners, CDK4 or CDK6, and CDK2, respectively^[34-35]. For cells to complete the G₁/S transition, the activities of both D-type cyclins and cyclin E are essential. CDK inhibitors stop the cell cycle progression by negatively and stoichiometrically regulating cyclin/CDK activities and are the targets of various extracellular growth-modifiers. These inhibitors have similar N-terminal regions which are responsible for the blockade of CDK kinases. They can inhibit any G₁ cyclin/CDK activity. The CDK inhibitors also served as the common mediators of various biological processes including DNA-damages, cell differentiation, cell to cell contact inhibition and cell senescence^[36]. Recent studies indicate that oncogene signals converge to cyclin/CDK and CDK inhibitors^[37]. We have reported that overexpression of Bak may prolong cell cycle in G₁ phase in HCC-9204 cells. We postulated that translocated expression of Bak in this process transferred signals to the cell cycle regulators in the nuclei, and thus induced cell cycle arrest in G₁ phase.

p27^{KIP1}, as a member of CDKIs, is constitutively expressed in many cells, and the level of this protein is elevated in G₀ phase and declines as cells in culture enter the cell cycle^[38-40]. p27^{KIP1} may play an important role in governing the growth factor restriction point by ensuring that CDK activity is suppressed during G₀ and early G₁ phase^[41]. Interestingly, in many types of tumors including breast, colon, prostate and ovarian carcinomas, the expression of p27^{KIP1} gene was down-regulated^[42-43]. From the sequencing analysis, we could figure out that in some types of tumor, p27^{KIP1} gene was null or mutated, while in other types it was still intact. HCC-9204 cells, as a target cell line, has intact p27^{KIP1} which was confirmed by fluorescence *in situ* hybridization (FISH) as shown in Figure 13 and DNA sequencing. Researchers are attempting to discover the mechanism of controlling the expression of p27^{KIP1} and cyclin-CDK activation in these malignant cells.

The correct timing of cyclin-CDK activation is regulated at several levels, including the control of cyclin-encoding gene expression, cyclin stability and cellular localization, as well as CDK subunit phosphorylation and dephosphorylation^[44-46]. Another level of regulation is provided by the CDKIs which consist of two families. The

potential role of p27^{KIP1} in control of the hepatocyte cell cycle is suggested by the implication of mitogens and anti-mitogens known to control p27^{KIP1} levels in the regulation of liver cell proliferation^[47]. The discovery of p27^{KIP1} has facilitated the elucidation of these mechanisms. In addition, in all organs including the liver, p27/, but not p21/mice show an increased cell density without any obvious alteration in liver cells differentiation or structure^[48].

Figure 12 Comparative study of whether apoptotic cells can still express GFP. A GFP positive clone was chosen and counterstained with PI. Apoptotic cells were stained with PI and no longer expressed GFP. HCC-9204 cells were observed under Nikon Eclipse TE200 fluorescent phase-contrast microscopic. $\times 200$

Figure 13 In situ fluorescence hybridization with FITC labelled p27^{KIP1} probe. Two signals were observed in the chromosome under laser confocal microscopy. (Bar represents 5 μ m)

Most studies examining the function of p27^{KIP1} had been performed in tissue culture systems using transformed cell lines or embryonic cells. Previous studies suggested that p27^{KIP1} overexpression causes cell cycle arrest in G₁ phase and/or apoptotic death of mammalian cells and supported the potential utility of gene therapeutic approaches aimed at elevating p27^{KIP1} expression for

treatment of human cancers and inhibition of tumorigenicity^[49]. Recent evidences demonstrated that high levels of p27^{KIP1} protein, induced by adenovirus vector, led to growth arrest as well as enhancement of apoptosis in several cell lines from different species and tissues of various origins^[50]. However, as far as we know, no study has been conducted previously to examine the expression of p27^{KIP1} in human hepatocellular carcinoma tissue in relation to apoptosis. We obtained p27^{KIP1} gene fragment in Bak transfected HCC-9204 cells and constructed a transient or stable transfectant. The purpose of the study was to examine the potential role of p27^{KIP1} during Bak overexpression in HCC-9204 cells. The results suggest that overexpression of Bak may induce expression of p27^{KIP1} at least in mRNA level. p27^{KIP1} may exert its effect on G₁ phase elongation induced by Bak and p27^{KIP1} itself may play an important role in the regulation of cell cycle during this process. To our knowledge, this is the first time that a significant correlation between p27^{KIP1} expression and cell cycle arrest and apoptosis has been demonstrated in HCC-9204 cell line.

However, the mechanism of tumor growth suppression appears to include not only p27^{KIP1} but also various other proteins, such as p53 etc. As we know, p53 is mutated in HCC-9204 cell line and is often null in other cell lines^[51-53]. Therefore, how these cell types undergo cell death is of concern since the p53-dependent apoptosis pathway has been abolished. p53 serves as a major G₁ checkpoint regulator of the induction of p21-CIP1 but not of p27^{KIP1} and p57^{KIP2}, while it induces apoptosis^[54]. The p53-mediated CDK inhibitor p21^{CIP1} does not lead to significant apoptosis, though both p21^{CIP1} and p27^{KIP1} induce G₁ arrest through their potential abilities to inhibit CDK activity^[55-56]. These findings suggest that the inhibition of CDK activity may not be sufficient to induce apoptotic cell death. A possible explanation of these differences between p27^{KIP1} and p53-mediated p21^{CIP1} functions is that p27^{KIP1} may have other functions in addition to its notable function as a CDK inhibitor. It can also be speculated that p27^{KIP1}, which has the potential to induce growth arrest and apoptosis, may play a more important role in tumor growth suppression than p53-mediated p21^{CIP1}.

ACKNOWLEDGEMENTS Special thanks are extended to Mr. Dong Bo for technical assistance with fluorescence-activated cell sorter analysis; Ms. Zhang Fan for technical assistance with laser confocal microscope; Dr. Polyak SS for pBluescript SK-p27; Dr. Zhang Jie for pMD-neo plasmid and technical support; Ms. An Jianhua for photo processing; Dr. Zheng Jian-Yong for other cooperation.

Abstract

AIM To evaluate a culture system for bile acid formation in primary human hepatocytes in comparison with HepG2 cells. **METHODS** Hepatocytes were isolated from normal human liver tissue and were cultured in serum-free William's E medium. The medium was collected and renewed every 24 h. Bile acids and their precursors in media were finally analysed by gas chromatography-mass spectrometry.

RESULTS Cholic acid (CA) and chenodeoxycholic acid (CDCA) conjugated with glycine or taurine accounted for 70% and 25% of total steroids. A third of CDCA was also conjugated with sulphuric acid. Dexamethasone and thyroid hormone alone or in combination did not significantly effect bile acid formation. The addition of cyclosporin A (10 µmol/L) inhibited the synthesis of CA and CDCA by about 13% and 30%, respectively.

CONCLUSION Isolated human hepatocytes in primary culture behave as in the intact liver by converting cholesterol to conjugated CA and CDCA. This is in contrast to cultured HepG2 cells, which release large amounts of bile acid precursors and unconjugated bile acids into the medium.

INTRODUCTION

The degradation of cholesterol to bile acids is a major way for elimination of cholesterol from the body. Disturbances of bile acid formation may lead to clinical disorders in humans like atherosclerosis, cholesterol gallstone formation and liver diseases. Primary bile acids-cholic acid (CA) and chenodeoxycholic acid (CDCA) are formed from cholesterol in human liver and excreted via the bile as conjugates to the intestine. In the intestine, the bile acids are partly deconjugated and 7 α -dehydroxylated by microbial enzymes to the secondary bile acids deoxycholic acid (DCA) and lithocholic acid (LCA). The bile acids, with the exception of lithocholic acid, are efficiently absorbed from the intestine and return to the liver via the portal vein. In the liver (70-90)% of the bile acids are reextracted and resecreted to the bile. Thus, the main bile acids in human bile are CA, CDCA, and DCA. Small amounts of LCA and ursodeoxycholic acid (UDCA), a metabolite of CDCA are also found.

Two major pathways of bile acid synthesis from cholesterol have been described^[1-5]. The main pathway, also called the neutral pathway, is initiated by a 7 α -hydroxylation, catalyzed by the rate-limiting enzyme cholesterol 7 α -hydroxylase. This hydroxylation is followed by further transformations of the steroid nucleus and oxidative cleavage of the side chain. An alternative pathway, also called the acid pathway, is initiated by a 27-hydroxylation of cholesterol. The quantitative importance of the latter pathway is not yet clear. It may be of importance for the formation of particularly CDCA and as a "back-up" pathway in conditions in which the neutral pathway is repressed for some reasons.

Bile acid formation in humans has been studied by different in vivo and in vitro techniques. Also cultures of human hepatoblastoma cells (HepG2) have been employed. However, these cells have been found to be defective in CA formation and conjugation by some authors^[6-9]. The cells have also been found to produce large amounts of bile acid precursors.

More recently, techniques have been developed for preparation of primary cultures of normal human hepatocytes. These offer now possibilities to study bile acid synthesis in normal hepatocytes under various experimental conditions.

MATERIALS AND METHODS

Preparation and culture of human hepatocytes

Primary hepatocytes were prepared from normal donor liver tissue. The project was approved by the Ethics Committee at Huddinge University Hospital and by Human Ethics

Committees of the Western Sidney Area Health Service, Australia. Liver sections weighing 100-200 g and with only one cut-surface were used. Hepatocytes were isolated using a 2-step perfusion technique utilizing EGTA and collagenase type IX-S as recently described^[10]. They were seeded on 60-mm dishes at a density of 3.5×10^6 cells per dish. Dishes were precoated with 0.2 mL of matrigel, a laminine-rich extracellular matrix prepared from Engelbreth-Holm-Swarm mouse sarcomas^[11]. Hepatocyte viability was >85% as determined by trypan blue exclusion. The cells were then incubated in serum-free William's E medium (3 mL/dish), supplemented with glutamine (292 mg/L), Na_2SeO_3 (173 $\mu\text{g/L}$), insulin (2 mIU/mL), penicillin G sodium, streptomycin sulphate and gentamycin. In some experiments, triiodothyronine (T3) (0.1 $\mu\text{mol/L}$) and/or dexamethasone (0.1 $\mu\text{mol/L}$) were added. In some other experiments, on d 4, cyclosporin A (CsA), an inhibitor of the sterol 27-hydroxylase^[12,13], was added to the medium (0-10 $\mu\text{mol/L}$). The medium was collected and renewed every 24 h and frozen at -20°C for later analysis of bile acids. At the end of the incubation, the hepatocytes were harvested and stored at 20°C until extraction.

Analytical procedures

For determination of the primary bile acids CA and CDCA formed, deuterium-labeled bile acids were added to the collected culture medium. After alkaline hydrolysis and extraction, the bile acids were analysed by gas chromatography-mass spectrometry as described recently^[10]. For more detailed analysis of neutral and acidic steroids-unconjugated and conjugated with glycine or taurine and/or sulphuric acid-group separation was performed by anion exchange chromatography after addition of isotopically labeled steroids. Deconjugation was performed by an enzymatic method. Sulphate groups were cleaved by solvolysis in acidified tetrahydrofuran. The identification of steroids was performed by gas chromatography-mass spectrometry. Further details are given in a recent paper^[14].

RESULTS AND DISCUSSION

Formation of bile acids

CA and CDCA were the two dominating steroids formed, accounting for as much as 70% and 25% of total, respectively (Figure 1). CA and CDCA are the two bile acids normally synthesized in human liver but the ratio between the production rates of the two bile acids in the hepatocytes was higher (about 3:1) than that of normal subjects (about 2:1). However, the ratio is similar to that obtained in patients with complete biliary drainage^[15]. Small amounts of two other bile acids, 3 β -hydroxy-5-cholenoic acid and 3 β , 7 β -dihydroxy-5 β -cholanoic acid were also detected (about 1% of total of each).

Bile acid formation was lowest on d 1 and 2 and then increased several-fold on d 4 to 6, whereafter it declined slightly (Figure 2). The reason for this is not clear.

However, it has previously been observed that the activity and mRNA levels of cytochrome P450 enzymes involved in drug metabolism show a similar profile in human hepatocytes e.g., a sharp recovery followed by a steady decline (Liddle C *et al.*, unpublished observations).

About 3% of the total amount of the isolated steroids consisted of bile acid precursors. Among those, 7 α -hydroxy-cholesterol and 7 α -hydroxy-4-cholesten-3-one are established intermediates in the neutral pathway and 27-hydroxycholesterol is the first intermediate in the acidic pathway. Since 7 α -hydroxycholesterol can also be formed by autooxidation of cholesterol, 7 α -hydroxy-4-cholesten-3-one is a better marker for the neutral pathway. The daily release of 7 α -hydroxy-4-cholesten-3-one increases in parallel to those of CA and CDCA, whereas the release of 27-hydroxycholesterol decreases. Since the hepatocytes are incubated in serum-free medium devoid of lipoprotein cholesterol, the decrease in amounts of 27-hydroxycholesterol is consistent with the hypothesis that cholesterol utilized for the acidic pathway is mainly derived from plasma lipoproteins^[2,7].

Figure 1 Distribution of cholic acid, chenodeoxycholic acid and precursors formed in primary cultures of human hepatocytes.

Figure 2 Formation of cholic acid and chenodeoxycholic acid in primary cultures of human hepatocytes during d 2, 4, 6 and 8. Effects of adding T3 and dexamethasone (DEX) alone and in combination.

As can be seen in Figure 3, HepG2 cells release large amounts of bile acid precursors into the incubation medium. It cannot be excluded that the bile acid synthetic pathways also may be abnormal in cultured HepG2 cells.

Figure 3 Distribution of cholic acid, chenodeoxycholic acid and precursors formed in cultures of HepG2 cells (data from ref. 7).

Conjugation

CA and CDCA were conjugated with glycine or taurine to more than 99.5% (Figure 4). About one-third of CDCA was also conjugated with sulphuric acid (Figure 5). 3 β -Hydroxy-5 β -cholanoic acid and 3 β , 7 α -dihydroxy-5 β -cholanoic acid were also sulphated. 27-Hydroxycholesterol and other oxysterols were partly sulphated.

In contrast to primary human hepatocytes, HepG2 cells release large amounts of unconjugated bile acids into the medium (Figure 6).

Figure 4 Conjugation of bile acids and precursors formed in primary cultures of human hepatocytes.

Effect of cyclosporin A

Cyclosporin A (CsA) is a potent inhibitor of the sterol 27-hydroxylase activity, especially towards nonpolar substrates like cholesterol^[12,13]. When added to the culture medium, 1 μ mol/L and 5 μ mol/L CsA had little or no effect on the formation of bile acids, but 10 μ mol/L CsA decreased the formation of CA by about 13% and CDCA by about 30% (Figure 7). No accumulation of bile acids occurred in the hepatocytes. However, a significant accumulation of 7 α -

Figure 5 Distribution of free and conjugated bile acids and potential intermediates isolated from medium on the fifth day of incubating primary human hepatocytes. CDCA = chenodeoxycholic acid; CA = cholic acid.

Figure 6 Conjugation of bile acids and precursors formed in cultures of HepG2 cells (data from ref. 7).

Figure 7 Effect of cyclosporin A on bile acid formation in primary human hepatocytes.

hydroxy-4-cholestene-3-one and 7 α , 12 α -dihydroxy-4-cholestene-3-one, an intermediate in CA synthesis, was found indicating that not only the acidic pathway but also the neutral pathway of bile acid formation was affected by CyA. In agreement with these results, it has previously been reported that patients with cerebrotendinous xanthomatosis, who lack the sterol 27-hydroxylase^[16,17],

accumulate 7 α , 12 α -dihydroxy-4-cholestene-3-one more than other intermediates in the liver^[18]. However, the decreased formation of total bile acids (CA and CDCA) during CsA treatment may mainly be due to an inhibitory effect of CsA on the hepatic synthesis of cholesterol^[12].

Influence of hormones

Previous studies have shown that the combined addition of T3 and dexamethasone stimulates bile acid formation, cholesterol 7 α -hydroxylase activity and mRNA levels in rat hepatocytes, whereas the addition of T3 or dexamethasone alone has little or no stimulatory effect^[10,19]. The addition of T3 and dexamethasone alone or in combination to human hepatocytes did not increase bile acid synthesis (Figure 2). If anything, bile acid formation tended to decrease. The different effects of T3 and dexamethasone in rat and human hepatocytes agree well with recent studies of the hormonal regulation of the cholesterol 7 α -hydroxylase gene promoter^[20,21]. These studies showed that the rat cholesterol 7 α -hydroxylase gene promoter is stimulated by dexamethasone whereas thyroid hormone has no significant effect. The promoter of the human cholesterol 7 α -hydroxylase gene, on the other hand, is suppressed by both dexamethasone and thyroid hormone.

In conclusion, isolated human hepatocytes in culture behave as in the intact liver by almost quantitatively converting cholesterol to conjugated CA and CDCA. In contrast, cultured HepG2 cells release large amounts of bile acid precursors and unconjugated bile acids into the medium. Human hepatocytes in culture represent a useful model for further studies on the synthesis and regulation of bile acids.

Abstract

AIM To compare the effects of liposomes and glyco-poly-L-lysine on liver targeted uptake and expression of plasmid in rat liver.

METHODS After binding with lipofectamine or galactose-terminal glyco-poly-L-lysine, the plasmid could be expressed in eukaryotic cells when injected into Wistar rats by intravenous route. At different time intervals after the injection, the distribution and expression of the plasmid in liver of rats were observed and compared using *in situ* hybridization and immunohistochemistry.

RESULTS The expression of the plasmid binding to liposomes or G-PLL could be markedly observed 24 h later, and began to decrease one week later, but it still could be observed up to three weeks. Both liposomes and G-PLL could deliver the plasmid to the liver effectively, but the effect of the latter was better than the former concerning the distribution and expression of the plasmid targeted uptake in the liver.

CONCLUSION G-PLL is better than liposome as the targeted carrier for delivering exogenous genes to the liver.

INTRODUCTION

Liver is one of the important metabolizing organs, and is closely related to many kinds of diseases, such as hereditary disease, infectious disease, metabolic disease, tumors and so on. Since the development of chemical

drugs for the treatment of these diseases is comparatively slow, gene therapy has opened up a prospective way for them^[1-5].

The efficient delivery and the high expression of exogenous genes in specific cells or tissues are critical steps for gene therapy both *in vitro* and *in vivo*^[6-15]. As for the gene therapy of hepatic diseases, efficient delivery of the exogenous genes to the liver and its high expression could increase its local accumulation while minimize the side-effects on other tissues and organs as well.

Both liposome and glyco-poly-L-lysine (G-PLL) are often used as carriers to deliver exogenous genes to the liver in gene therapy experiment^[16-22]. Most of the liposomes are cationic when used as the carriers of gene transference. Both *in vitro* and *in vivo* studies have showed that liposomes could be applied to transfer exogenous genes to hepatocytes^[23,24], but its specificity varies in different studies^[24-26]. Poly-L-lysine is a kind of polycation which can be bound to DNA by interacting with the opposite electric charge on DNA. After binding with other specific ligands through covalent linkage, the resulting ligand-poly-L-lysine-DNA complex can be formed^[27] and can thus be used to deliver foreign DNA to specific cells or tissues. Similarly, after being saccharified by galactose, glyco-poly-L-lysine (G-PLL) formed is then capable of delivering exogenous genes to the liver specifically^[28-30].

Using rats as the experimental animal, we compared the *in vivo* potency of liposomes and glyco-poly-L-lysine on delivering the plasmid, which could be expressed in eucaryotic cells.

MATERIALS AND METHODS

Preparation of the carriers

The original plasmid of rat interstitial collagenase was kindly provided by Prof. John J Jeffrey^[31], and we reconstructed it with the plasmid of pTa rgetT (TM) (Promega Co., Madison, MI, USA), which could be expressed in eucaryotic cells. We also inserted a segment of nucleotides (GAC TAC AAG GAC GAC GAT GAT AAG) before the terminator codon (TAA) of the rat interstitial collagenase. The 'Flag Domain' peptide (DYKDDDDK) encoded by the segment of nucleotide above, which was usually called 'Tag', could be fused in the rat interstitial collagenase^[32-33] and could be specifically recognized by a M2 monoclonal antibody (Kodak, New Haven, CT, USA). This recombinant plasmid was named

pTM/MMP-1. The plasmid of pTM/MMP-1 was extracted and purified using QIAGEN-Tip 500 kit (QIAGEN Inc., Valencia, CA, USA) according to manufacturers of the instructions. The plasmid was mixed with different amounts of lipofectamine (GIBCO, Grand Island, NK, USA) or galactose-terminal glyco-poly-L-lysine (kindly provided by Dr. Shou-Ming Wen of Air-force General Hospital of PLA, China. The mean molecular weight of this kind of G-PLL was 8500 and the ratio of galactose to poly-L-lysine was 15:28). The optimal proportion of the plasmid pTM/MMP-1 to lipofectamine or galactose-terminal glyco-poly-L-lysine was determined by electrophoresis in 1% agarose gel.

Animal experiments

Eighteen male Wistar rats, with body weight 130-150 g, were randomly divided into three groups. Lipofectamine intravenous (LI) group: 50 µg of plasmid pTM/MMP-1 encapsulated by lipofectamine was given through cauda vein; Poly-L-lysine intravenous (PI) group: 50 µg plasmid pTM/MMP-1 binding to galactose-terminal glyco-poly-L-lysine was administered through cauda vein; Normal group: control animal. Twenty-four hours, 48 h, 72 h, 1 wk, 2 wk, 3 wk after the administration of the plasmid, one rat from each group was randomly selected and anaesthetized with 2% pentobarbital sodium intraperitoneally. Then 1 mL blood from each rat was obtained by cardiac puncture for the assay of alanine transaminase (ALT), aspartic transaminase (AST), and creatinine (Cr) to follow the functions of important organs. After perfusion of the whole body with 20 mL phosphate-buffered saline and 40 mL precold 4% paraformaldehyde through ventricular injection, the tissues of liver, spleen, lungs and kidneys were collected and fixed in 4% paraformaldehyde, encapsulated in paraffin and cut into sections of 4 µm thick. The animal experiments above were approved by the Laboratory Animal Committee of Shanghai Medical University.

Immunohistochemistry

Immunohistochemistry was performed according to the literature^[34,35]. The first antibody used was M2 monoclonal antibody which was specific for flag-domain tag (Kodak, New Haven, CT, USA) and the second antibody used was Horse anti-mouse IgG, labeled with biotin (Vector, Burlingame, CA, USA). After the treatment with avidin and biotin (ABC kit, Vector, Burlingame, CA, USA), color development was followed using dimethylaminoazobenzene (DAB) and counterstained with hematoxylin. Five fields were observed under high power from every immunostained section and the positive signals were counted.

In situ hybridization

The procedure of *in situ* hybridization was also described

previously^[34,35]. To state briefly, the oligonucleotide probe (5'-TGG TGT GAC TAC AAG GAC GAC GAT GAT AAG-3') was synthesized in Cell Biology Institute of Chinese Academy of Sciences (Shanghai), which could hybridize with the (mRNA) of the flag-domain tag in the plasmid pTM/MMP-1, and the 5' of the probe was labeled with biotin. After the hybridization of the target mRNA with the probe, the rest of the procedure was similar to that followed in immunohistochemistry excluding the step of hematoxylin counterstaining.

Other biochemical assays

ALT, AST, and Cr were assayed using the 7170A Automatic Analyzer (HITACHI, Japan) to observe the changes in the important organs' function.

Data analysis

The data was analysed using the software SPSS 7.0 for windows (One-way ANOVA).

RESULTS

Ratio of liposomes and G-PLL to plasmid

According to the electrophoresis results, we found that 5 µL of lipofectamine could encapsulate 1 µg of plasmid pTM/MMP-1 completely; While 0.3 µg of galactose-terminal glyco-poly-L-lysine thoroughly could bind to 1 µg of the plasmid, which meant that about 72 molecules of G-PLL could carry one molecule of the plasmid pTM/MMP-1 (Figures 1 and 2).

Figure 1 Determination of the optimal proportion of liposome bound to plasmid by 1% agarose electrophoresis. Lane 1-8 are respectively 1-8 µL lipofectamine mixed with 1 µg pTM/MMP-1 plasmid. Plasmid 1 µg could only be encapsulated completely by more than 5 µL lipofectamine.

The changes in the functioning of important organs

Compared with the normal group, there was no obvious elevation of the ALT, AST, and Cr levels in the LI, PI groups.

The distribution and expression of the plasmid in liver, spleen, lung and kidney

The results of the immunohistochemistry and *in situ* hybridization showed that the plasmid binding to liposomes or G-PLL could be expressed *in vivo*, and the results of immunohistochemistry were more sensitive and stable. In addition, the protein product of the plasmid could be secreted extracellularly (Figures 3 and 4), similar to the expression of interstitial collagenase in the physiological state^[36]. We found that both liposomes and G-PLL could deliver the plasmid to the liver very efficiently, making liver as its major distribution organ. The obvious expression of the plasmid could be observed 24 h after the administration and began to decrease one week later, although it could still be observed weakly even two or three weeks later (Figure 5). Among the three groups, we also observed that the expression and distribution of the plasmid in the liver was most in the PI group, followed by the LI group. Besides the liver, the exogenous gene could also be expressed highly in lungs, and expressed in kidney in a relatively lower level in the LI group; while for the PI group, a relatively lower level of the expression could be seen in the kidney, the spleen, and the lung.

DISCUSSION

Both liposomes and G-PLL can be used as the targeted carriers to deliver drugs or nucleotides to liver^[17-21,24-29], but the comparison of their effects on the liver targeted uptake have not been reported extensively.

Gene transfer mediated by receptors is carried out by high affinity linkage between the ligands (binding to the foreign gene) and specific receptors on the surface of different kinds of cells, and then the foreign gene can be delivered into the cells by phagocytosis^[37-40]. There also exist some specific receptors on the surface of hepatocytes such as asialoglycoprotein receptor (ASGP-R)^[41,42], which facilitate the delivery of exogenous genes into hepatocytes specifically using the ligand-receptor interaction. Galactose-terminal glyco-poly-L-lysine contains the saccharide group of galactosan that can be specifically ligated to the ASGP-R on the surface of hepatocytes. At the same time, the cationic poly-L-lysine can bind to nucleotides with high affinity, thus forming a good carrier to deliver exogenous DNA to liver specifically and steadily^[28-30]. It has been reported in the literature, that the ratio of the liver targeted delivery could reach up to 70%-90% *in vivo*^[27,43]. In our experiments we found that in addition to its main location in the liver, the plasmid binding to G-PLL could be expressed in kidney, spleen, and lung also. It may be due to the existence of ASGP-R in other extrahepatic tissues^[44,45].

Liposomes are a kind of annular closed vesicles made from double layers of lipid molecules^[46]. Having no toxicity and no immunogenicity^[47]. Gene transfer mediated by liposomes is achieved by the fusion between liposomes

Figure 2 Determination of the optimal proportion of G-PLL bound to plasmid by 1% agarose electrophoresis. Lane 1-8 are respectively 0.05 μ g, 0.1 μ g, 0.2 μ g, 0.3 μ g, 0.4 μ g, 0.5 μ g, 1.0 μ g, and 1.5 μ g G-PLL mixed with 1 μ g pTM/MMP-1 plasmid. Plasmid 1 μ g could only been bound completely by more than 0.4 μ g G-PLL.

and the membrane of the cells. Liposomes encapsulating the foreign DNA can be integrated with the membrane of

Figure 5 The distribution and expression of the plasmid bound to liposomes or G-PLL (galactose-terminal glyco-poly-L-lysine) in different tissues and at different time points. A: liver, B: spleen, C: lung, D: kidney. LI: plasmid encapsulated by liposomes given through cauda vein, PI: plasmid bound to G-PLL introduced intravenously.

the cells, and thus the foreign gene can be delivered inside the cells by phagocytosis^[24,48-50]. Because it contains lecithin and lactosylceramide that can bind to ASGP-R on the surface of hepatocytes specifically, liposome could also be used as targeted delivery carrier to the liver^[51,52]. Our experimental results demonstrated that the plasmid encapsulated by liposomes could also be expressed in lung and spleen to a certain extent despite its major expression in the liver, maybe due to the macrophage system which existed in the lung, spleen, and other tissues. This phenomenon demonstrates further that the efficacy of liver targeted delivery by liposomes is inferior to that of G-PLL.

In this study, we also observed whether liposomes and G-PLL, both binding to the plasmid, would induce some toxicity to the body or not. We did not find any detrimental effects on the functioning of important organs like liver, heart, and kidney and this indicated further that liposomes and G-PLL could be used *in vivo* safely as delivery carriers for drug or nucleotides.

In conclusion, we found that the plasmid binding to liposomes or G-PLL could be delivered to the liver efficiently and G-PLL was better than liposomes regarding the distribution and expression of the plasmid in the liver. Both liposomes and G-PLL can be used as carriers to deliver drugs or nucleotides to rat liver, but whether they can be used in human beings in the future deserves further investigation.

ACKNOWLEDGEMENT We express our thanks to Dr. Shou-Ming Wen of Air-Force General Hospital of PLA, China for kindly providing galactose-terminal glyco-poly-L-lysine. We also want to thank the Department of Pathology in Zhongshan Hospital for their technical assistance.

Abstract

AIM To study the effects of arsenic trioxide and HCPT on different degrees of differentiated gastric cancer cells (SGC-7901, MKN-45, MKN-28) with respect to both cytotoxicity and induction of apoptosis *in vitro*.

METHODS The cytotoxicity of As₂O₃ and HCPT on gastric cancer cells was determined by MTT assay. Morphologic changes of apoptosis of gastric cancer cells were observed by light microscopy and transmission electron microscopy. Apoptosis and cell cycle changes of gastric cancer cells induced by HCPT and As₂O₃ were investigated by TUNEL method and flow cytometry.

RESULTS As₂O₃ and HCPT had remarkable cytotoxic effects on different degrees of differentiated gastric cancer cells. The IC₅₀ of As₂O₃ on well differentiated gastric cancer cell MKN-28, moderately differentiated gastric cancer cell SGC-7901, and poorly differentiated gastric cancer cell MKN-28 were 8.91 μmol/L, 10.57 μmol/L, and 11.65 μmol/L, respectively. The IC₅₀ of HCPT on MKN-28, SGC-7901, and MKN-45 were 9.35 mg/L, 10.21 mg/L, and 12.63 mg/L respectively after 48 h treatment. After 12 h of exposure to both drugs, gastric cancer cells exhibited morphologic features of apoptosis, including cell shrinkage, nuclear condensation,

and formation of apoptotic bodies. A typical subdiploid peak before G₀/G₁ phase was observed by flow cytometry. The apoptotic rates of SGC-7901, MKN-45, and MKN-28 were 13.84%, 22.52%, and 9.68%, respectively after 48 h exposure to 10 μmol/L As₂O₃. The apoptotic rates of SGC-7901, MKN-45, and MKN-28 were 21.88%, 12.35%, and 30.26%, respectively after 48 h exposure to 10 mg/L HCPT. The apoptotic indices were 7%-15% as assessed by TUNEL method. The effect of As₂O₃ on SGC-7901 showed remarkable cell cycle specificity, which induced cell death in G₁ phase, and blocked G₂/M phase. HCPT also showed a remarkable cell cycle specificity, by inducing cell death and apoptosis in G₁ phase and arrest of proliferation at S phase.

CONCLUSION As₂O₃ and HCPT exhibit significant cytotoxicity on gastric cancer cells by induction of apoptosis. As₂O₃ and HCPT might have a promising prospect in the treatment of gastric cancer, which needs to be further studied.

INTRODUCTION

Gastric cancer is one of the most common malignant tumors in China. Evidences have demonstrated that stomach cancer is a disease caused not only by excessive cellular proliferation and poor differentiation, but also by decrease in apoptosis of the gastric cells^[1]. Though the disease in its early stage can be treated by surgical resection, in advanced stage its response to conventional chemotherapy or radiotherapy is usually not satisfactory. Therefore, we think, that induction of apoptosis of gastric cancer cells might be a new means in the treatment of gastric cancer. Arsenic trioxide (As₂O₃) and hydroxycamptothecin (HCPT) have long been used in China. The former was first reported by investigators in Harbin and Shanghai to be an effective drug in the treatment of patients with acute promyelocytic leukemia (APL)^[2,3]. It induces apoptosis of the leukemic cells at a concentration achieved in the plasma of treated patients (0.5 × 10⁻⁶ mol/L-1 × 10⁻⁶ mol/L), as demonstrated by studies on all-trans-retinoic acid (ATRA)-susceptible or resistant APL cell lines, on primary APL cell culture, and on patients' blood samples

obtained during treatment with arsenic^[4]. It is not known whether As₂O₃ is effective in the treatment of solid tumors such as gastric cancer or not.

HCPT is a unique antitumor drug that has been extracted and synthesized by Chinese scientists from *Camptotheca accuminata* which is a native plant in China^[5]. HCPT can act directly on topoisomerase I inhibiting its activity. HCPT possesses stronger cytotoxicity to tumor cells with less side effects, as compared to camptothecin^[6]. More recent studies have shown that camptothecin have strong apoptosis induction effects in human leukemia cell lines^[7]. However, there is yet no report about HCPT-induced apoptosis in stomach cells. Therefore, we studied the effects of HCPT and As₂O₃ on induction of apoptosis in gastric cancer cells.

MATERIALS AND METHODS

Cell culture and chemicals

Human moderately differentiated gastric adenocarcinoma cell line SGC-7901 was obtained from Shanghai Sixth People's Hospital, human poorly differentiated stomach adenocarcinoma cells line MKN-45 and well differentiated stomach adenocarcinoma cell line MKN-28 were kindly provided by Japanese Cancer Research Resources Bank Corp (Tokyo, Japan). SGC-7901, MKN-45 and MKN-28 were maintained in a humidified, 5% CO₂ atmosphere and cultured in RPMI 1640 (GIBCO) supplemented with 10% FCS, 2 μmol/L L-glutamine, 100 units/mL penicillin, and streptomycin. HCPT 1 g/L and 0.1% As₂O₃ preparation for iv administration were kindly provided by Hubei Huangshi Second Pharmaceutical Company, and Shanghai Institute of Hematology, respectively.

MTT method and cytotoxicity

One hundred μL cancer cells in exponential growth at 1×10^4 /mL were added into flat-bottomed 96-well plates (NUNC) 24 h prior to drug treatment. Cells were treated with 1 mg/L-100 mg/L HCPT, (0.5-10) μmol/L As₂O₃ and with no drugs (control) in triplicate for 24 h and 48 h, respectively. After washing the medium was replaced by 100 μL RPMI 1640 (GIBCO) medium containing 1 g/L 3-(4,5-dimethylthiazol)-2,5-diphenyltetrazolium (MTT, MERCH). After 4 h, plates were centrifuged at $800 \times g$ for 5 min, the MTT medium was removed, and the blue dye was dissolved in 200 μL of warm dimethylsulfoxide (DMSO). Absorbance was measured at 570 nm. The cytotoxicity rates were measured by the formula:

$$\text{The cytotoxicity rate} = \left(1 - \frac{\text{OD}_{570 \text{ test}}}{\text{OD}_{570 \text{ control}}}\right) \times 100\%$$

The IC₅₀ was evaluated from the cytotoxicity curve.

Apoptosis cell morphology

One hundred μL cancer cells at concentration of 5×10^6 /

mL were incubated into 6-well plates with previously placed glass slides. After 24 h, the medium was replaced with the drug containing medium. After incubation with drugs for 12 h, 24 h, 48 h, and 72 h, glass slides with cancer cell growth were fixed with 4% polyformalin, and stained with hematoxylin-eosin. Cell morphology was examined under light microscopy.

Transmission electron microscopy

Culture cells were fixed in 2% glutaraldehyde in 0.1 mol/L, pH 7.4 PBS at 4 °C and postfixed with 1% osmium tetroxide for 2 h, then the cells were embedded with Epon 812 and ultrathin sections were cut. Cells were observed under transmission electron microscope (H-500, Japan).

TUNEL assay

Apoptosis was assessed by dUTP labeling of DNA nicks with terminal deoxynucleotidyl transferase (TUNEL). One hundred μL cancer cells at concentration of 5×10^6 /mL were inoculated into 6-well plates with previously placed glass slides. After 24 h, the medium was replaced with the drug containing medium. After incubation with drugs for 24 h and 48 h, glass slides with cancer cells growth were fixed with 4% polyformalin. The TUNEL assay was performed according to the instructions in the *In Situ* Cell Death Detection Kit (Boehringer-Mannheim, Germany). Briefly, after washing twice with pH 7.4 PBS, 50 μL TUNEL reaction solution was added to the well, then incubated at 37 °C for 2 h. After substrate reaction, stained cells were examined under light microscopy. Apoptotic cells were scored and expressed as the number of positively stained cells per 500 cells ($n = 4-5$).

Flow cytometry

Apoptotic cells were also detected by flow cytometry which was performed as described previously. About 1×10^6 cells were treated with drugs for 24 h and 48 h. After trypsin digestion, the cells were collected by centrifugation, then fixed in 70% ethanol/phosphate buffered saline for at least 12 h at 4 °C. After 100 μL (1 g/L) RNase treatment, cells were stained with 50 mg/L propidium iodide. Cells were examined by flow cytometry using a FACScan (Becton-Dickinson, USA). The results were analyzed with Lysis II software (Becton-Dickinson).

RESULTS

As₂O₃ and HCPT cytotoxicity

HCPT and As₂O₃ had strong cytotoxic effect on gastric cancer cells (Figure 1). The IC₅₀ of As₂O₃ on MKN-28, SGC-7901, and MKN-45 was 8.91 μmol/L, 10.57 μmol/L, and 11.65 μmol/L, respectively. The IC₅₀ of HCPT on MKN-28, SGC-7901, MKN-45 was 9.35 mg/L, 10.21 mg/L, and 12.63 mg/L, respectively.

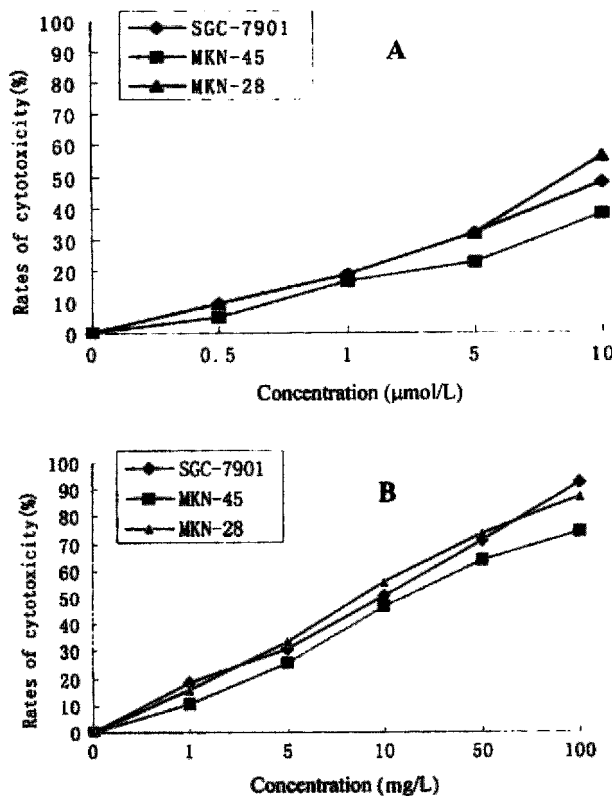

Figure 1 Cytotoxicity of As₂O₃ (A), and HCPT (B), on gastric cancer cells.

Figure 3 The index of apoptosis of gastric cancer cells induced by As₂O₃ (A) and by HCPT (B).

Induction of apoptosis by As₂O₃ and HCPT

After 12 h of exposure to As₂O₃ and HCPT, gastric cancer cells MKN-28 and SGC-7901, began to show morphologic features of apoptosis. The apoptotic cells increased on

prolongation of exposure time to drugs. The ultrastructural features of apoptosis was observed in MKN-45 and SGC-7901 by transmission electron microscopy, including cell shrinkage, cytoplasmic blebs, condensation of chromatin, nuclear condensation, fragmentation of nucleus, and formation of apoptotic bodies, and so on. The results are presented in Figure 2.

As₂O₃ and HCPT induced time- and dose-dependent apoptosis in three strains of gastric cancer cells. The indices of apoptosis were measured by TUNEL. The results are presented in Figure 3A and 3B.

To further study the inducing effect of As₂O₃ and HCPT on gastric cancer cells, we analysed the DNA fragment reflecting the endonuclease activity during apoptosis. (Figure 4). Examination of histogram related nuclear DNA contents on FACS showed a distinct region below G₁ phase, which is the typical profile of apoptotic cells in which DNA stainability is reduced due to degradation and subsequent leakage of DNA from cells. After 48 h exposure to 10 mg/L HCPT, the apoptotic rates of SGC-7901, MKN-45, and MKN-28 were 21.88%, 12.35%, and 30.26%, respectively. After 48 h of exposure to 10 μmol/L As₂O₃, the apoptotic rates of SGC-7901, MKN-45, and MKN-28 were 13.84%, 22.52%, and 9.68%, respectively (Figure 4).

Effect of As₂O₃ and HCPT on cell cycle of SGC-7901 cells

The effect of As₂O₃ and HCPT on SGC-7901 cells show remarkable cell cycle specificity. There was no significant change in cell cycle after 10 μmol/L As₂O₃ treatment for 24 h. The fraction of G₀/G₁ was decreased from 54.2% to 17.7%, while the fraction of G₂/M was significantly increased from 20.2% to 63.4% with 10 μmol/L As₂O₃ treatment in SGC-7901 cells for 48 h. The results showed that As₂O₃ induced gastric cancer cell death was in G₁ phase, blocked at G₂/M phase. The fraction of G₀/G₁ phase was decreased from 54.2% to 37.6%, while the fraction of S phase was increased from 25.6% to 38.6% with 10 mg/L HCPT treatment in SGC-7901 cells for 48 h. The results showed that HCPT-induced apoptosis was at G₁ phase, and arrested at S phase.

DISCUSSION

Since the first observation of the relationship between arsenic and skin cancer in 1820s, arsenic compounds have been generally recognized as potent environmental carcinogens, more likely as a co-mutagen and co-carcinogen for human skin and lungs^[8], although no animal model had been established^[9]. Biochemically, it is documented that arsenic can inactivate some important enzymes by binding their sulfhydryl groups. Arsenic can also interfere with the phosphorylation-dephosphorylation process by replacing the phosphorylation reaction. It has

Figure 2 Electron microscopic observation of ultrastructural changes in gastric cancer cells treated with 10 $\mu\text{mol/L}$ As_2O_3 for 48 h. The early change of apoptosis, nuclear chromatin condensation, looks like a new moon subjacent to the nuclear membranes (A). The intermediate stage of apoptosis presents cytoplasmic blebs, nuclear condensation, overflow of nuclear chromatin, and like-sprout (B). The late stage of apoptosis is characterized by splitting of nuclear membrane, nuclear chromatin condensation, overflow of some parts of nuclear chromatin, and fragmentation of nucleus (C), and formation of apoptotic bodies (C) (D).

also been shown that arsenic can induce chromosome aberrations, sister-chromatin exchanges, DNA-protein cross links and protein-associated DNA-strand breaks in mammalian cells^[10,11]. However, low concentration of some arsenic compounds also had some benefits to human physiologically, such as stimulation of human hematopoiesis. The use of arsenic compounds as drugs has a long history in Chinese traditional medicine. For example, it was recorded that arsenic had therapeutic effects on some human diseases such as psoriasis, syphilis, and rheumatism. Recently, it has been shown that two arsenic compounds As_2O_3 ^[2] and arsenic disulfide^[12], which were used in some traditional Chinese prescriptions, are very effective in APL treatment. For instance, a report from the northeastern region of China showed that As_2O_3 (10 g/L via intravenous infusion for 28 to 60 days) induced clinical complete remission (CR) in 65.6% of APL patients. More interestingly, 28.2% (9/32) of patients survived more than 10 years. A more recent clinical trial with As_2O_3 treatment also demonstrated that

CR was achieved in 15 of 16 APL patients who relapsed after ATRA-induced and chemotherapy-maintained CR^[4].

It has been suggested that As_2O_3 might induce apoptosis selectively in APL cells^[13]. Furthermore, at pharmacological concentrations, it has no effect on the growth and survival of the leukemia myeloid cells U937 and HL60^[3]. However, preliminary reports suggest that the apoptotic effect of As_2O_3 is not specific for APL cells but can be observed in various lines of either myeloid or lymphoid origin^[14-18] and in blast cells from patients with non-M3 acute myeloid leukemia^[19]. Another arsenic-containing compound, the melaminyl-phenyl-arsenoxide melarsoprol, which is used in the treatment of human African trypanosomiasis, has a broad efficacy against leukemia cells of both lymphoid and myeloid lineage^[20]. Both As_2O_3 and melarsoprol also markedly induce apoptosis in plasma cell lines and in plasma cells from multiple myeloma^[21]. Recent reports have demonstrated that As_2O_3 can induce apoptosis in various cell lines of solid tumor. As_2O_3 inhibited the growth and survival of solid tumor cell

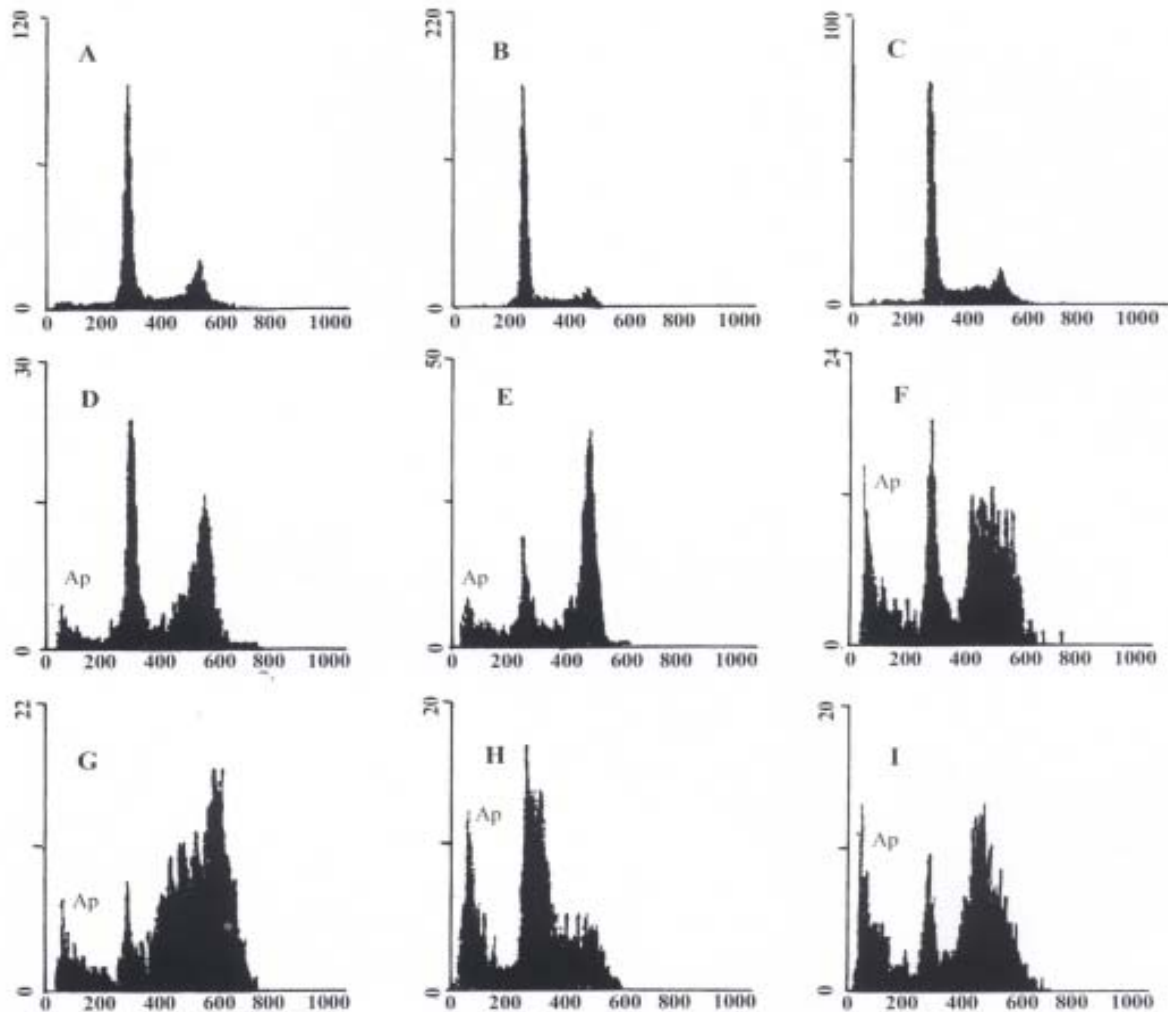

Figure 4 Nuclear DNA contents measured by flow cytometry in As_2O_3 and HCPT-induced apoptosis in gastric cancer cells at 48 h. Ap represents apoptotic cells. A: Untreated MKN-45 cells; B: Untreated SGC-7901 cells; C: Untreated MKN-28 cells; D: MKN-45 cells treated with 10 $\mu\text{mol/L}$ As_2O_3 ; E: SGC-7901 cells treated with 10 $\mu\text{mol/L}$ As_2O_3 ; F: MKN-28 cells treated with 10 $\mu\text{mol/L}$ As_2O_3 ; G: MKN-45 cells treated with 10 mg/L HCPT; H: SGC-7901 cells treated with 10 mg/L HCPT; I: MKN-28 cells treated with 10 mg/L HCPT.

lines in gastric^[22], esophageal^[23,24], lung^[24], cervix^[25], liver^[26] tumor and neuroblastoma^[27] by triggering programmed cell death. These results suggest that As_2O_3 may be an effective drug in treatment of solid tumors. As_2O_3 has been intensively investigated for the treatment of cancer.

There is growing evidence indicating that apoptosis plays a crucial role in both carcinogenesis and development of stomach tumors^[1,28-30]. Induction of apoptosis in gastric cancer cells might be a new means in the treatment of gastric cancer. It was reported that both radiation and chemotherapy (5-fluorouracil, cisplatin, mitomycin and trichostatin) can induce apoptosis in gastric cancer^[31-33]. Our previous study showed that As_2O_3 had an effect on inhibiting proliferation and inducing apoptosis in gastric cancer cell SGC-7901^[22]. In this study, we found that As_2O_3 exhibited a dose- and time-dependent cytotoxicity on gastric cancer cells at different

degrees of differentiation. The IC_{50} of As_2O_3 on MKN-28, SGC-7901, and MKN-45 were 8.9 $\mu\text{mol/L}$, 10.5 $\mu\text{mol/L}$, and 11.6 $\mu\text{mol/L}$, respectively. Toxicity of As_2O_3 was not significantly different among gastric cancer cells at different degrees of differentiation. As_2O_3 -treated gastric cancer cells presented characteristic morphological changes of apoptotic cells. Results showed DNA degradation into oligonucleosomal fragments and these changes occurred in a time- and dose-dependent manner. The apoptotic index was 7%-15% as assessed by TUNEL. A typical subdiploid peak before G_0/G_1 phase was observed by flow cytometry. After 48 h of exposure to As_2O_3 , the apoptotic rates of SGC-7901, MKN-45, and MKN-28 were 13.8%, 22.5%, and 9.68%, respectively. We concluded that one of the main effects of As_2O_3 on gastric cancer cells at the concentrations used is to induce cell death by apoptosis.

It was recently shown^[45] that the cell cycle time was prolonged in As_2O_3 treated malignant lymphocytes

Namalwa and Raji cells, and that no substantial increase in cell cycle time was found in Jurkat cells treated with As_2O_3 , as compared with untreated cells. This result suggests that As_2O_3 can inhibit proliferation of some malignant lymphocyte cell lines by prolonging the cell cycle instead of arresting cells in a specific phase. In the present study, we demonstrated that the effect of As_2O_3 on SGC-7901 showed remarkable cell cycle specificity in inducing cell death at G_1 phase, and blocking proliferation at G_2/M phase. This result is consistent with the report of Deng *et al.*^[46], in which As_2O_3 induced apoptosis in HeLa cells by arresting G_2/M phase of the cell cycle.

Camptothecin and its analogues are agents with a unique spectrum of antitumor activity mediated by a selective inhibition of eukaryotic DNA topoisomerase I (Topo I). The cytotoxicity of these compounds is predominantly exerted during S phase, and is associated with an inhibition of DNA replication. This inhibition is generally thought to be mediated by stabilization of the CPT-Topo I-DNA cleavable complex^[34]. Recent studies have shown that camptothecin and its analogues can strongly induce apoptosis in human leukemic cells^[35-36], prostate^[36-37], colon^[38] and breast^[39-40] cancer cells as well as glioma cells^[41].

HCPT has been used in the treatment of gastrointestinal tumor^[42,43], but its mechanism of anticancer action is still not completely understood. Recently, there were reports that HCPT can induce apoptosis of cancer cells of colon^[47], pancreas^[48], and bladder^[49]. Our previous study showed HCPT can induce apoptosis in gastric cancer cell SGC-701^[44]. In this study, we found that HCPT had a strong dose- and time-dependent cytotoxicity to gastric cancer cells at different degrees of differentiation. The IC_{50} of HCPT on MKN-28, SGC-7901, and MKN-45 was 9.35 mg/L, 10.21 mg/L, and 12.62 mg/L, respectively. There was no significant difference in toxicity of HCPT on gastric cancer cells at different degrees of differentiation. Gastric cancer cells treated with HCPT presented characteristic morphological changes of apoptosis. The effects of inducing apoptosis in gastric cancer cells could be correlated with time and dosage of HCPT treatment. A typical subdiploid peak before G_0/G_1 phase was observed by flow cytometry. After 48 h of exposure to 10 mg/L HCPT, the apoptotic rates of SGC-7901, MKN-45, and MKN-28 were 13.8%, 22.5%, and 9.68%, respectively. In this study, the fraction of G_0/G_1 phase was decreased from 54.2% to 37.6%, while the fraction of S phase was increased from 25.6% to 38.6% with 10 mg/L HCPT treatment of SGC-7901 cells for 48 h. The result suggested that HCPT also showed a remarkable cell cycle specificity, induced cell death and apoptosis at G_1 phase, and arrested proliferation at S phase.

The molecular mechanism of As_2O_3 on APL cells

showed that the inhibition of cell proliferation was due to a direct induction of apoptosis through downregulation of bcl-2 expression and modulation of PML/RAR α /PML protein *in vitro* studies^[3]. Furthermore, the activation of caspases was also involved in As_2O_3 -induced apoptosis in APL cells^[50]. Akao *et al.* also reported that As_2O_3 induced apoptosis through the down-regulation of Bcl-2 protein and activation of caspases in B-cell leukemia cell lines^[51]. It was also reported that As_2O_3 induced apoptosis in neuroblastoma cell lines through the activation of caspase-3^[27]. Litvak *et al.* reported that inhibition of gastric cancer by camptothecin involves apoptosis and multiple cellular pathways, and induction of apoptosis of gastric cancer cell was mediated by up-regulation of p53, p21Waf1/Cip1, and p27Kip1 and the down-regulation of Bcl-2 and Bcl-XL^[52]. Camptothecin induced apoptosis through activation of caspase in U-937 cells^[53]. Our results showed that HCPT and As_2O_3 exerted significant cytotoxicity on gastric cancer cells and induction of apoptosis *in vitro*. The molecular mechanism of apoptotic effect of HCPT and As_2O_3 on gastric cancer cells remains to be further investigated, and the effect of apoptosis must be confirmed by *in vivo* studies. However, the results of the present study suggest that HCPT and As_2O_3 might be candidate drugs to be used in the treatment of gastric cancer, thus needing further studies.

ACKNOWLEDGEMENTS We thank Professor Xu Jia Yu for revising this paper.

Wei HS, Li DG, Lu HM, Zhan YT, Wang ZR, Huang X, Zhang J, Cheng JL, Xu QF. Effects of AT1 receptor antagonist, losartan, on rat hepatic fibrosis induced by CCl₄. *World J Gastroentero*, 2000;6(4):540-545

Abstract

AIM To investigate effect of losartan, an AT1 receptor antagonist, on hepatic fibrosis induced by CCl₄; and to determine whether or not AT1 receptors are expressed on hepatic stellate cells. **METHODS AND RESULTS** Fifty male Sprague-Dawley rats, weighing (180 ± 20) g, were randomized into five groups (control group, model group, and three losartan treated groups), in which all rats were given the subcutaneous injection of 40% CCl₄ (every 3 days for 6 weeks) except for rats of control group. Rats of losartan-treated groups were treated with losartan (20mg/kg, 10mg/kg, 5mg/kg, daily gavage). After 6 weeks liver tissue and serum samples of all rats were examined. Serum hyaluronic acid (HA), procollagen type III (PC III) were detected by radioimmunoassays. van Gieson collagen staining was used to evaluate the extracellular matrix of rats with liver fibrosis. The expression of AT1 receptors, transforming growth factor-beta (TGF-β), and alpha-smooth muscle actin (α-SMA) in liver tissue were determined by immunohistochemical techniques. Compared with model group, serum ALT and AST of losartan-treated groups were significantly reduced ($t = 4.20$, $P < 0.01$ and $t = 4.57$, $P < 0.01$). Serum HA and PC III also had significant differences ($t = 3.53$, $P < 0.01$ and $t = 2.20$, $P < 0.05$). The degree of fibrosis was improved by losartan and

correlated with the expressions of AT1 receptors, TGF-β, and α-SMA in liver tissue.

CONCLUSION AT1 receptor antagonist, losartan, could limit the progression of the hepatic fibrosis induced by CCl₄. The mechanism may be related to the decrease in the expression of AT1 receptors and TGF-β, a meliorating the injury of hepatocytes; activation of local renin-angiotensin system might relate to hepatic fibrosis; and during progression of fibrosis, activated hepatic stellate cells might express AT1 receptors.

INTRODUCTION

Hepatic fibrosis, which may ultimately lead to cirrhosis, is associated with most chronic liver diseases, and is characterized by the net accumulation of extracellular matrix (ECM), including collagen, glycoproteins, and proteoglycans^[1,2]. Many reports have suggested that hepatic stellate cells (HSCs) are the major producers of ECM in liver injury, and play a prominent role in liver fibrosis^[3-7]. Tissue repair after acute liver damage involves "activation" of "quiescent" HSCs to myofibroblast-like cells^[8-12]. Transforming growth factor-beta (TGF-β) is a pleiotropic cytokine that has been assigned a key role in epithelial repair, and HSCs were shown to its main source^[13-16]. In cultured HSCs, TGF-β-mediated up-regulation of collagen and other ECM components mRNA was time and dose-dependent^[17,18]. In the past years, significant progress has been made in our understanding of this pathologic mechanism, however, few effective drugs can slow the progression of the fibrosis^[19,20].

Over the past decade, preventing the formation of angiotensin II by angiotensin-converting enzyme (ACE) inhibitors has revolutionized the therapy of hypertension and especially of congestive heart failure^[21]. Recently, a number of studies demonstrated that ACE inhibitors also effectively limited the progression of cardiac, renal and pulmonary interstitial fibrosis^[22-26]. Recent work has shown that angiotensin II type 1 (AT1) receptor antagonist, losartan, can also ameliorate the renal and cardiac fibrosis^[27,28]. The prevailing hypothesis for the main mechanism was suppressing the expression of TGF-β in kidney and heart, rather than its dynamic effects^[29-32].

Department of Gastroenterology, Xinhua Hospital, Shanghai Second Medical University, Shanghai 200092, China

Dr Hong Shan Wei, male, born on 1965-12-06 in Shandong Province, graduated from Jining Medical College and earned doctoral degree from Shanghai Second Medical University, majoring in hepatic fibrosis, having 15 papers published.

Based on this and other information, we hypothesized that the AT1 receptor antagonist, losartan, could also limit the progression of hepatic fibrosis. To explore our speculation, the present study was designed to investigate the effect of losartan on rat's hepatic fibrosis induced by CCl₄, and determine whether or not there was expression of AT1 receptor on hepatic stellate cells.

MATERIALS AND METHODS

Animals and reagents

Fifty male Sprague-Dawley rats, weighing 180 ± 20 g, were purchased from Animal Center of Shanghai Medical University (Shanghai, China). Losartan was obtained from MSD Co. (England). Polyclonal rabbit antibody to rat TGF- β was purchased from Boster Biotech Co. (Wuhan, China). Monoclonal antibody of α -smooth muscle actin (α -SMA) was purchased from Maixin Biotech Co. (Fuzhou, China). Hyaluronic acid (HA) and procollagen type III (PC III) radioimmunoassays kits were purchased from Navy Shanghai Medical Institute (Shanghai, China).

Serum function tests

Fifty rats were randomized into five groups (control group, model group and three losartan-treated groups) in which all rats were given subcutaneous injection of 40% CCl₄ (0.3 mL/100 g, every 3 days for 6 weeks) except for rats of control group (only given injection of same dose of olive oil). In an initial experiment, rats of losartan-treated groups were treated with losartan (20 mg/kg, 10 mg/kg, 5 mg/kg by daily gavage). After six weeks, all rats were sacrificed. Serum was collected and stored at -20°C for analysis of aspartate transaminase (AST) and alanine transaminase (ALT) activity by standard enzymatic methods. The serum levels of PC III and HA were determined by radioimmunoassays.

Immunohistochemical detections and histological data

The liver sections were fixed in a 10% solution of formaldehyde in 0.1 mol/L phosphate-buffered saline (pH 7.4), and embedded in paraffin. Five-micrometer slides were prepared. van Gieson collagen staining was used to evaluate the ECM of rats. According to van Gieson collagen staining, the degree of fibrosis was divided into five grades (0-5). Specimens were scored blindly by the histologist and were also ranked blindly for severity of fibrosis. The expression of AT1 receptor (anti-rat rabbit polyclonal antibody was the product of Santa Cruz Biotech Co), TGF- β and α -SMA were detected by immunohistochemical techniques.

Statistics

Data are presented as $\bar{x} \pm s_x$. Comparison between two groups was made using Student's *t* test. Difference of

fibrosis between model and losartan-treated groups was compared using Ridit analysis. The test was considered significant at $P < 0.05$.

RESULTS

Serum function tests

Compared with control group, ALT and AST increased significantly in fibrotic rats in the model group, but only marginally in losartan-treated rats. ALT and AST activities were significantly lower in 20 mg losartan-treated group than in model group of CCl₄ rats. The effects were associated with doses of losartan (Table 1).

Table 1 Serum function tests

	<i>n</i>	LT (U/L)	AST (U/L)
Control	10	99.50 ± 18.78	244.50 ± 46.52
Model	7	1863.29 ± 893.68^a	2680.00 ± 1039.12^a
Losartan (20 mg/kg)	7	432.14 ± 112.26^d	824.57 ± 265.41^d
Losartan (10 mg/kg)	7	535.25 ± 200.78^d	77.50 ± 270.32^d
Losartan (5 mg/kg)	6	771.71 ± 237.18^c	1643.00 ± 810.36

^a $P < 0.05$ vs control; ^c $P < 0.05$ vs model; ^d $P < 0.01$ vs model

Serum components of ECM

As expected, serum levels of HA and PCIII increased in rats of model group. Serum HA levels were approximately three times higher in rats of model group than rats of control group. There was a tendency towards a decrease in HA and PC III levels in losartan-treated group (Table 2).

Table 2 Serum component of ECM

^a $P < 0.05$ vs control; ^c $P < 0.05$ vs model; ^d $P < 0.01$ vs model

Histological data

Piecemeal and lobular necrosis was obvious in the CCl₄ model compared to rats in control group. The lobular necrosis was significantly decreased by losartan in three treated groups. There was an increase in the area of fibrosis in model rats compared with rats in control group. There was a significant decrease in the losartan-treated rats (Table 3, Figure 1).

Table 3 Degree of fibrosis

	<i>n</i>	0	I	II	III	IV	<i>U</i> -value

Figure 1 Collagen expression in liver section of model rat (van Gieson staining, $\times 200$) (A), and of losartan treated group (van Gieson staining, $\times 200$). Significantly less fibrosis can be noted compared to that in the model group (B).

Expression of AT1 receptors, TGF- β , and α -SMA

Compared with normal liver tissue, in which AT1 receptors mainly locate in vasculature, in the fibrotic liver tissue, the expression of AT1 receptors significantly enhanced, and scattered in fibrotic areas. The expression of AT1 receptors was markedly reduced by losartan (Figure 2). The expression of α -SMA was a marker of HSC activation. Immunohistochemical detection demonstrated that vascular smooth muscle cells and pericytes were positive for α -SMA in control livers, whereas HSCs strongly positive of α -SMA were observed in rats of model group, and they were scattered along the sinusoidal walls. Many α -SMA-positive HSCs were detected in the area of centrilobular and periportal fibrotic bands in rats of model group. Compared with model group, liver of rats treated with losartan, showed markedly reduced numbers of α -SMA-positive HSC. At same time, its serum levels of PC III and LN were also significantly decreased ($P < 0.05$).

Similar to the α -SMA, TGF- β was also strongly expressed in areas of periportal fibrotic bands in rats of model group. In contrast, livers of rats treated with losartan showed significantly reduced numbers of TGF- β -positive cells (Figure 3).

Figure 2 AT1 receptor expression in liver section of model rat (DAB staining, $\times 200$). AT1 receptor is seen mainly scattered in fibrotic areas and vascular wall (A), and of losartan treated group (DAB staining, $\times 200$). Note significantly less AT1 expression than that seen in the model group (B).

DISCUSSION

Our study firstly demonstrated that AT1 receptor antagonist, losartan, could slow the progression of hepatic fibrosis induced by CCl_4 . Activated HSC might express AT1 receptors in fibrotic liver tissue.

Over the last decade, many lines of evidence have demonstrated that local RAS activation was the major mechanism of cardiac and renal interstitial fibrosis^[33-37]. *In vivo* studies have shown that ACE inhibitors and AT1 receptors antagonists can limit the progression of cardiac, renal, and pulmonary fibrosis^[23,38-41], and the mechanism is independent of their dynamic effects. This is based on several *in vitro* and *in vivo* findings. First, all cardiac and renal fibroblasts express AT1 receptors; secondly, Ang II induces mitogenic response, increases protein synthesis, production of collagen, and TGF- β in fibroblasts in a dose-dependent manner^[29,42,43]. These results support the notion that Ang II can both directly act on fibroblasts and/or enhance the expression of TGF- β .

In the present study, the three different doses (20 mg/kg, 10 mg/kg, 5 mg/kg) of losartan were given to the rats. As the results shown, losartan could limit the progression of the hepatic fibrosis in a dose-dependent

Figure 3 TGF- β expression in liver section of model rat (DAB staining, $\times 200$). TGF- β expression is seen scattered in the fibrotic areas and vascular wall (A), and of losartan treated group (DAB staining, $\times 200$). Note significantly less TGF- β expression than that seen in the model group (B).

manner. At the dose not influencing systolic blood pressure (10 mg/kg) in the normotensive rats^[44], losartan could attenuate the fibrosis, but even at a very low dose (5 mg/kg), had a weak but significant effect. In agreement with this study, Boffa *et al*^[45] also reported that losartan completely prevented collagen I gene activation and attenuated the degree of fibrosis without influencing the systolic pressure in the kidneys of transgenic mice. This suggested that Ang II might act as an important regulator in the progression of hepatic fibrosis induced by CCl₄.

Using the immunohistochemical methods, we observed the expression of AT1 receptors in liver tissue. As the results shown, this is the first report that confirms that the liver tissue expresses AT1 receptors. Compared with normal rats, where AT1 receptors are mainly located in the vasculature, the expression of AT1 receptors were significantly enhanced in rats of model group, which were mainly located in fibrotic area, and correlated with the degree of fibrosis. The results suggested that the expression of AT1 receptors might relate to hepatic fibrogenesis. Furthermore, immunostaining indicated that the distribution of AT1 receptor correlated with the expression of TGF- β and α -SMA. As has been recently reported, in a model of chronic cyclosporine (CsA), TGF- β played a role in CsA-

induced tubulointerstitial fibrosis and arteriolopathy by stimulating ECM protein synthesis and inhibiting ECM degradation. Losartan resulted in decreasing expression of TGF- β and synthesis of ECM^[46]. Zhang *et al*^[28] have also reported that losartan is effective in reducing the increasing expression of AT1 receptors and ECM protein in infarcted heart tissue. Based on the above data, we postulated that expression of AT1 receptor might be related to the activation and ECM synthesis of HSCs.

Another interesting finding in our study was that losartan could ameliorate the hepatocyte injury, as reflected by the release of liver enzymes. The explanation for this observation is not known, but it might relate to protection of the hepatocyte from free radical-mediated damage. Recently, Anthuber *et al*^[47] demonstrated that non-thiol-containing ACE inhibitor, enalapril, could attenuate the hepatocyte injury induced by ischemia/reperfusion. The prevailing mechanism of action was considered to relate with modulation of the angiotensin, bradykinin, and prostacyclin metabolism. Whether losartan has some as-yet-unknown, specific, protective property, remains to be determined in future studies.

That transforming growth factor β (TGF- β) is a key molecule responsible for tissue fibrosis, provides a basis for targeting TGF- β as an antifibrotic agent^[48-50]. Recently, Sun *et al*^[31] found that the early induction of TGF- β 1 via the angiotensin II type 1 receptor played a major role in the development of cardiac fibrosis in infarcted heart. Shihab *et al*^[46] described that losartan reduced TGF- β overproduction in a dose-dependent manner, slowing the rate of renal interstitial fibrosis^[22].

Overproduction of TGF- β and activation of HSC are key processes in the progression of hepatic fibrosis. Our results demonstrated that losartan could reduce the expression of TGF- β and α -SMA in liver tissue and suppress fibrosis procession. It is suggested that RAS also participates in the progression of hepatic fibrosis induced by CCl₄ in rats.

In conclusion, our results demonstrated that (1) AT1 receptor antagonist, losartan, could limit the progression of the hepatic fibrosis induced by CCl₄. The mechanism may be related to the decrease in the expression of AT1 receptors and TGF- β , ameliorating the injury of hepatocyte; (2) activation of local renin-angiotensin system might relate to hepatic fibrogenesis; (3) in the progression of fibrosis, activated hepatic stellate cells might express AT1 receptor.

Luo DZ, Vermijlen D, Ahishali B, Triantis V, Vanderkerken K, Kuppen PJK, Wisse E. Participation of CD45, NKR-P1A and ANK61 antigen in rat hepatic NK cell (pit cell) mediated target cell cytotoxicity. *World J Gastroenterol*, 2000;6(4):546-552

Abstract

AIM Several triggering receptors have been described to be involved in natural killer (NK) cell-mediated target cytotoxicity. In these studies, NK cells derived from blood or spleen were used. Pit cells are liver-specific NK cells that possess a higher level of natural cytotoxicity and a different morphology when compared to blood NK cells. The aim of this study was to characterize the role of the NK-triggering molecules NKR-P1A, ANK61 antigen, and CD45 in pit cell-mediated killing of target cells.

METHODS ⁵¹Cr-release and DNA fragmentation were used to quantify target cell lysis and apoptosis, respectively.

RESULTS Flow cytometric analysis showed that pit cells expressed CD45, NKR-P1A, and ANK61 antigen. Treatment of pit cells with monoclonal antibody (mAb) to CD45 (ANK74) not only inhibited CC531s or YAC-1 target lysis but also apoptosis induced by pit cells. The mAbs to NKR-P1A (3.2.3) and ANK61 antigen (ANK61) had no

effect on pit cell-mediated CC531s or YAC-1 target cytolysis or apoptosis, while they did increase the Fcγ receptor positive (FcγR⁺) P815 cytolysis and apoptosis. This enhanced cytotoxicity could be inhibited by 3,4-dichloroisocoumarin, an inhibitor of granzymes.

CONCLUSION These results indicate that CD45 participates in pit cell-mediated CC531s and YAC-1 target cytolysis and apoptosis. NKR-P1A and ANK61 antigen on pit cells function as activation structures against FcγR⁺ P815 cells, which was mediated by the perforin/granzyme pathway.

INTRODUCTION

Natural killer (NK) cells can kill certain tumor cells or virus-infected cells without prior sensitization and thus play an important role in host anti-tumor defense^[1]. Cytotoxic activity of NK cells is achieved by two distinct mechanisms, i.e. necrosis (cytolysis) and apoptosis, and is believed to be regulated by triggering and inhibiting receptors on NK cells^[1-3]. Several candidate receptors involved in triggering a cytotoxic reaction, such as NKR-P1A (CD161A) and an NK-activation structure recognized by monoclonal antibody (mAb) ANK61 (ANK61 antigen), have been described on rat NK cells^[2,4,5].

NKR-P1A is a lectin-like surface molecule expressed on all rat NK cells^[4]. The ligands for NKR-P1A are oligosaccharides. Interactions of these oligosaccharides on target cells with NKR-P1A on NK cells are crucial for target cell recognition and for NK cytotoxicity^[6]. Monoclonal antibody to NKR-P1A (3.2.3) has been shown to stimulate NK cell phosphoinositide turnover, calcium mobilization, degranulation and NK cytotoxicity against certain Fcγ receptor positive (FcγR⁺) tumor target cells^[4,7]. These findings demonstrate that NKR-P1A is an activating molecule on rat NK cells that recognizes target cells and induces cytotoxicity.

Recently, a rat NK-activation structure (ANK61 antigen) recognized by mAb ANK61 has been described^[5]. Cross-linking of the ANK61 antigen and FcγR⁺ tumor targets with mAb ANK61 resulted in enhanced killing of the targets by NK cells^[5].

CD45, which is expressed by most leukocytes, including NK cells, has been shown to be involved in NK

cell-mediated target cell cytotoxicity^[8-10]. It is reported that mAbs against CD45 inhibit NK cell-mediated target cell killing^[8,9] and CD45-negative NK cells fail to lyse tumor targets^[10]. The cytoplasmic domain of CD45 has tyrosine phosphatase activity, which is believed to play an important role in the regulation of NK activity^[8,11].

Pit cells are liver-specific NK cells^[12]. Compared to blood NK cells, rat pit cells possess a higher level of cytolytic activity against a variety of tumor target cells, including NK resistant P815 cells, which is comparable to the cytotoxicity level of lymphokine-activated killer (LAK) cells^[13]. These data indicate that pit cells have different characteristics from blood NK cells. Although much is known about the NK receptors that participate in NK cell activation and target cell killing, the surface receptors involved in pit cell-mediated target cell killing have not yet been clarified. Moreover, involvement of the above mentioned antigens in NK cell-mediated target cell apoptosis has remained elusive, since ⁵¹Cr-release assay employed in the previous studies^[4,5,10] indicates only cytolysis, rather than apoptosis. In the present work, we used mAbs against CD45, NKR-P1A, and ANK61 antigen to evaluate their roles in pit cell-mediated target cell lysis and apoptosis.

MATERIALS AND METHODS

Isolation and purification of pit cells

Male Wistar rats (Proefdierencentrum, Leuven, Belgium) weighing (250–280) g were used at an age between 8 to 12 wk. Hepatic NK cells (pit cells) were isolated according to protocols described before^[14]. The purity of the recovered pit cells was at least 90%, as evaluated by morphology on May-Giemsa-stained cytospin preparations and by flow cytometric analysis using mAb 3.2.3. The viability of the recovered cells was more than 95%, as determined by Trypan blue exclusion. The procedures used in this study were approved by the local ethical committee (license No LA1230212).

Tumor cell line

CC531s, a dimethylhydrazine-induced colon carcinoma of Wag/Rij (inbred strain of Wistar) rats^[15], P815, a murine mastocytoma, and YAC-1, a mouse T cell lymphoma, were maintained in culture medium RPMI-1640 (Gibco, Life Technologies, Gent, Belgium), supplemented with 10% fetal calf serum (Eurobiochem, Bierges, Belgium), benzylpenicillin (100 kU/L), streptomycin (100 mg/L), and glutamine (0.2 mmol/L) (Gibco, Life Technologies, Gent, Belgium).

Reagents and antibodies

The following mouse anti-rat mAbs were used: 3.2.3 (anti-NKR-P1A, IgG_{2b} or IgG₁)^[4], ANK74 (anti-CD45, IgG₁)^[8], and ANK61 (anti-rat NK activation structure, IgG₁)^[5] were developed in Department of Surgery and Pathology, Leiden University Medical Center, the

Netherlands. 3,4-dichloroisocoumarin (DCI), a granzyme inhibitor^[16] was purchased from Sigma (Bornem, Belgium).

Flow cytometry

The expression of surface antigens on the cells was measured by one or two-color flow cytometric analyses as described previously^[17]. Briefly, a quantity of 0.5×10^6 cells per sample was incubated (30 min, 4°C) with the primary antibodies, 3.2.3, ANK74, and ANK61. Cells were then washed thrice with cold phosphate-buffered saline (PBS) containing 1% bovine serum albumin and 0.02% sodium azide. Subsequently, cells were incubated with fluorescein-conjugated anti-mouse IgG₁ and biotin-conjugated anti-mouse IgG_{2b} (Gilbertsville, PA). After incubation and washing, cells were incubated with streptavidin-phycoerythrin (Gilbertsville, PA). Then, cells were washed and fixed with 2% paraformaldehyde in PBS and analyzed (FACstar, Becton Dickinson, Mountain View, CA). Isotype-matched irrelevant antibodies were used as a control.

⁵¹Cr-release assay

Cytolysis was measured after 4 h incubation of P815 and YAC-1 cells, and 18 h for CC531s cells. ⁵¹Cr-release assay was performed using round-bottomed 96-well microplates as described previously^[18]. Briefly, 1×10^6 target cells/0.5 mL were labeled with 9.25 MBq Na ⁵¹CrO₄ (Amersham Belgium, Gent, Belgium) for 80 min at 37°C. Before the coincubation, freshly isolated pit cells were preincubated with either saturating amounts of the mAbs (final concentration for each mAb was 10 mg/L), 3.2.3, ANK61, ANK74, or irrelevant mouse IgG₁ for 15 minutes at room temperature. The mAbs were also present during the assay and the treatments with these mAbs did not affect the viability of the cells. The target cells were seeded at a concentration of 1×10^4 cells/well. Suspensions of effector cells were then added to the wells at effector to target (E:T) ratios of 10:1 in a final volume of 200 µL. All assays were done in triplicate. For the experiments using DCI, pit cells were preincubated with 50 µmol/L DCI for 30 min at 37°C. After washing twice with medium, the cells were coincubated with the target cells as mentioned above. After a coincubation at 37°C for 4 or 18 h, 100 µL of supernatant per well was aspirated and counted in a gamma counter to determine experimental release. Results were expressed as percentage of specific lysis according to the formula:

$$\% \text{ specific cytolysis} = \frac{\text{Experimental release} - \text{Spontaneous release}}{\text{Maximal release} - \text{Spontaneous release}} \times 100\%$$

Experimental release represents cpm (counts per minute) release from target cells in the presence of effector cell and mAbs. Spontaneous release was obtained from wells containing labeled target cells and medium only. Maximal release of ⁵¹Cr-labeled target cells was determined

after adding 20 μ L 10% sodium dodecyl sulfate (SDS) detergent to the labeled target cells.

Quantitative DNA fragmentation assay

DNA fragmentation in the target cells was determined as described previously^[19]. Briefly, to label the DNA of the target cells, 5×10^5 cells in 250 μ L medium were incubated with 0.37 MBq [methyl- 3 H] thymidine (3 H]-TdR) (Amersham, Buckinghamshire, U.K) for 3 h at 37°C. Before the coincubation, freshly isolated pit cells were preincubated with the mAbs as mentioned above. The pit cells (10^5 cells in 100 μ L) and the target cells (10^4 cells in 100 μ L) (E:T = 10:1) were placed in triplicate in 1.5 mL microcentrifuge tubes. The total volume per microcentrifuge tube was 200 μ L. For the experiments using DCI, pit cells were preincubated with 50 μ mol/L DCI for 30 min at 37°C. After washing twice with medium, the cells were coincubated with the target cells as mentioned above. After 3 h coincubation at 37°C and centrifugation at $300 \times g$ for 10 min, the incubation medium was removed from the tubes. Subsequently, the pelleted cells were lysed with 0.5 mL of cold lysis buffer (4°C) (5 mmol/L Tris, 2 mmol/L EDTA, 1% Triton X-100, pH 7.4) for 30 min at 4°C. Then, the lysates were ultracentrifuged ($10,000 \times g$ for 15 min at 4°C) to separate fragmented DNA from intact DNA. Radioactivity (cpm) in the incubation medium, in the $10,000 \times g$ supernatant and in the $10,000 \times g$ pellet was determined in a beta counter (Beckman, Fullerton, CA, USA). The percentage fragmented DNA was calculated using the following formula:

$$\% \text{ specific DNA fragmentation} = \frac{\text{cpm}_{\text{fr,exp}} - \text{cpm}_{\text{fr,spont}}}{\text{cpm}_{\text{total}} - \text{cpm}_{\text{fr,spont}}} \times 100\%$$

in which: cpm_{fr} = the radioactivity in the incubation medium plus the cpm in the $10,000 \times g$ supernatant; $\text{cpm}_{\text{total}} = \text{cpm}_{\text{fr}} + \text{radioactivity in the } 10,000 \times g \text{ pellet}$; exp = experimental (CC531s cells with pit cells); spont =

spontaneous (CC531s cells and medium only).

Hoechst 33342 (HO 342)/propidium iodide (PI) staining

The method of HO 342 and PI staining has been described previously^[19]. In short, target cells, at a concentration of 1×10^4 cells per well in a 96m multiwell plate, were coincubated with pit cells (E:T = 10:1). After 3 h coincubation, the cells were stained with HO 342, which stains DNA blue, and PI, which only penetrates necrotic cells through the damaged cell membrane and stains DNA red. Cells were viewed under a Leica DM IRB/E inverted fluorescence microscope (Leica, Heidelberg, Germany) with ultraviolet excitation at 340 to 380 nm. The apoptotic target cells were determined by their characteristic apoptotic morphological changes of the nucleus, i.e. condensation of chromatin and nuclear fragmentation. Target cells alone acted as spontaneous apoptosis control.

Statistical analysis

Results were given as the mean with the corresponding standard deviation. Statistical analysis was performed by Student's t test or one-way ANOVA with post-hoc multiple comparison analysis made by Duncan test, using SPSS statistical package (SPSS Inc., Chicago, IL, USA). Statistical significance between two groups was considered at the level of $P < 0.05$.

RESULTS

Expression of surface antigens on pit cells

Flow cytometric analysis was used to determine the expression of surface antigens on pit cells and target cells. In two-color flow cytometric analysis, mAb 3.2.3 was used to stain pit cells^[20]. Pit cells were shown to express CD45, which was recognized by mAb ANK74, and an NK activation structure, which was recognized by mAb ANK61 (Figure 1). CC531s, P815, and YAC-1 cells did not express these NK-associated antigens (data not shown).

Figure 1 Expression of CD45 and ANK61 antigen on hepatic NK cells (pit cells). The cells were washed out of the liver by sinusoidal lavage. After Ficoll-Paque gradient centrifugation and nylon-wool adherence to remove erythrocytes, granulocytes, monocytes and B lymphocytes, the cells were stained with anti-NKR-P1A mAb (3.2.3) (phycoerythrin) and anti-ANK61 antigen (ANK61), anti-CD45 mAb (ANK 74) (fluorescein) and analyzed by two-color flow cytometry. CD45 and ANK61 antigen were expressed on the x-axis (fluorescein), NKR-P1A on the y-axis (phycoerythrin).

Effect of CD45, NKR-P1A, and ANK61 antigen on pit cell-mediated target cell lysis

To investigate the function of these surface antigens in pit cell-mediated cytolysis of targets, the mAbs against these antigens were used in ^{51}Cr -release assays. In the presence of anti-CD45 mAb ANK74, the lysis of CC531s and YAC-1 cells by pit cells was significantly inhibited ($P < 0.01$, $P < 0.05$) (Figure 2A, 2B). The presence of mAbs 3.2.3 and ANK61 had no effect on pit cell-mediated lysis against-CC531s and YAC-1 targets (Figure 2A, 2B). These data indicate that CD45 is involved in pit cell-mediated cytolysis against CC531s and YAC-1 targets.

Figure 2 Effect of the mAbs on pit cell-mediated CC531s (A), YAC-1 (B) and P815 (C) target cell cytolysis. ^{51}Cr -labeled target cells were incubated at an E:T ratio of 10:1 with freshly isolated pit cells in the absence or presence of the mAbs. (A), Cytolysis of CC531s cells was measured in an 18h ^{51}Cr -release assay. (B), Cytolysis of YAC-1 cells was measured in a 4-h ^{51}Cr -release assay. (C), Cytolysis of P815 cells was measured in a 4-h ^{51}Cr -release assay. Values are mean \pm SD from four different experiments. ^a $P < 0.05$, ^b $P < 0.01$ vs the control.

It is reported that mAbs 3.2.3 or ANK61 can induce cytolysis in $\text{Fc}\gamma\text{R}^+$ target cells by NK cells by redirected antibody-dependent cellular cytotoxicity (rADCC)^[4,5]. In order to investigate whether these mAbs play a similar role in pit cells, cytolytic activity of pit cells was measured by a 4-h ^{51}Cr -release assay using the $\text{Fc}\gamma\text{R}^+$ P815 cell line^[21], a murine mast ocytoma, as target cells. As shown in Figure 2C, the mAbs 3.2.3 and ANK61 significantly increased the cytolysis of P815 cells by pit cells ($P < 0.01$). Anti-CD45 mAb ANK74 did not significantly increase the cytolysis (Figure 2C).

Effect of CD45, NKR-P1A, and ANK61 antigen on pit cell-mediated target apoptosis

When CC531s^[19], P815 (Vermijlen D, unpublished data) or YAC-1 targets (Figure 3) were coincubated with pit cells, these target cells showed typical morphological characteristics of apoptosis like nuclear fragmentation. To address the effect of the surface antigens in pit cell-mediated apoptosis of these targets, a quantitative DNA fragmentation assay was used. The results showed that the anti-CD45 mAb ANK74 significantly inhibited pit cell-mediated DNA fragmentation of CC531s and YAC-1 cells ($P < 0.05$, $P < 0.01$) (Figure 4A, 4B). The presence of mAbs 3.2.3, ANK61 had no effect on DNA fragmentation of CC531s and YAC-1 cells by pit cells (Figure 4A, 4B), but increased the DNA fragmentation of P815 cells induced by pit cells ($P < 0.01$) (Figure 4C). The anti-CD45 mAb ANK74 did not significantly affect the DNA fragmentation of P815 cells by pit cells (Figure 4C).

Inhibition of anti-NKR-P1A and ANK61 antigen mAb-enhanced P815 cell cytotoxicity by DCI

To address whether mAbs 3.2.3 and ANK61 enhanced $\text{Fc}\gamma\text{R}^+$ P815 cell killing by pit cells via the perforin/granzyme pathway, we used DCI, an inhibitor of granzymes in intact cells, to investigate the role of granzymes in the process. When pit cells were preincubated with 50 $\mu\text{mol/L}$ DCI, the mAb-enhanced P815 cytolysis and apoptosis by pit cells were completely inhibited ($P < 0.05$, $P < 0.01$) (Figure 5A, 5B). These results suggest that mAbs 3.2.3 or ANK61 induce cytotoxicity in $\text{Fc}\gamma\text{R}^+$ P815 cells by pit cells via the perforin/granzyme pathway.

DISCUSSION

Pit cells are liver-specific NK cells and, together with Kupffer cells, constitute the natural cellular defense against invading cancer cells in the liver^[12]. It has been shown that pit cells are four to eight times more cytotoxic against YAC-1 and CC531s cells than blood NK cells and are able to kill NK-resistant, LAK-sensitive P815 cells^[13]. However, the surface receptors involved in pit cell-mediated cytotoxicity against tumor targets have remained elusive. Present data show that the mAbs against the NK-triggering molecules NKR-P1A and ANK61 antigen increased not only cytolysis but also apoptosis of $\text{Fc}\gamma\text{R}^+$ P815 cells, but had no effect on $\text{Fc}\gamma\text{R}$ YAC-1 and

Figure 3 Fluorescence and light micrographs of YAC-1 cells coincubated with pit cells at an E:T ratio of 10:1 for 3 h. (A) Fluorescence micrograph showing the apoptotic YAC-1 cells with fragmented nuclei (thick arrows) and pit cells (thin arrows). Light micrograph shows the same field as (A). Bar = 5 μ m.

CC531s cytotoxicity induced by pit cells. These results indicate that NKR-P1A and ANK61 antigen on pit cells function as triggering molecules against $\text{Fc}\gamma\text{R}^+$ target cells, but not against $\text{Fc}\gamma\text{R}^-$ targets. It has been demonstrated that mAbs 3.2.3 and ANK61 enhance cytolytic activity of NK and LAK cells only against $\text{Fc}\gamma\text{R}^+$ tumor target cells by rADCC^[4,5,7]. Other evidence to support this observation was that, in our experiments, cross-linking of NKR-P1A on pit cells with mAb 3.2.3 did not induce granule exocytosis from pit cells, as observed in May-Giemsa-stained cytospin preparations (data not shown). This is in contradiction with a report describing that mAb 3.2.3 can induce degranulation and release of granzymes from NK and IL-2 activated NK cells^[22]. Furthermore, after incubation of pit cells with mAb 3.2.3, the medium and the pit cells were separated by centrifugation. The medium

Figure 4 Effect of the mAbs on pit cell-induced CC531s (A), YAC-1 (B) and P8 15 (C) target cell apoptosis. [^3H]-TdR labeled target cells were incubated at an E:T ratio of 10:1 with freshly isolated pit cells for 3 h in the absence or presence of the mAbs. Values are mean \pm SD from four different experiments. ^a $P < 0.05$, ^b $P < 0.01$ vs the control.

did not kill CC531s and YAC-1 cells, whereas the pit cells' cytotoxicity against these targets was comparable to freshly isolated pit cells (data not shown). Moreover, it has also been shown that NKR-P1A negative NK clones are able to lyse the same type of target cells as NKR-P1A positive NK clones^[23] and expression of NKR-P1A is not an absolute requirement for NK activity^[24]. These data suggest that NKR-P1A is not the sole activation molecule on NK cells. Actually, a diversity of activation molecules on NK cells has been described^[2,3,5,25]. NK cells might use these different activation molecules to lyse different target cells.

It is believed that mAbs 3.2.3 or ANK61-enhanced cytotoxicity in $\text{Fc}\gamma\text{R}^+$ target cells by NK cells is a rADCC reaction^[4,5]. The present data show further that these

Figure 5 Effect of DCI on mAbs 3.2.3 and ANK61-enhanced FcγR⁺ P815 cell cytotoxicity (A) and apoptosis (B) by pit cells. Pit cells were preincubated with 50 μmol/L DCI for 30 min at 37°C. After washing twice, the cells were coincubated with P815 cells as mentioned in materials and methods. Values are mean ± SD from three different experiments. ^a*P* < 0.05, ^b*P* < 0.01 vs the corresponding control.

mAb-enhanced cytotoxicity and apoptosis of P815 cells by pit cells are mediated by the perforin/granzyme pathway because this enhanced cytotoxicity can be completely inhibited by the granzyme inhibitor DCI.

Although the function of CD45 is well known in NK cells^[8-11], its role in pit cells has not yet been clarified. We showed here that CD45 was involved in the pit cell induced cytotoxicity and apoptosis of CC531s and YAC-1 cells but not of P815 cells. The reason that CD45 on pit cells had different effects on pit cell-mediated cytotoxicity against different targets is not clear. It has been reported that CD45 is not essential for FcγR-mediated function in NK cells, since NK cells in CD45^{-/-} mice have normal cytotoxic activities, comparable to normal mice (CD45^{+/+})^[26]. Another possible explanation is that CD45 plays a regulatory role in signal transduction through surface receptors on NK cells, such as NKR-P1A, LFA-1, and killer cell inhibitory receptors (KIR) in NK cell-mediated target killing^[8,10,11]. A diversity of receptors is found to be involved in NK cell activation^[2,3]. It could be that CD45 plays a different regulating role in different NK activation receptors. On the other hand, the regulatory role of CD45 in the inhibitory signal pathway via KIR is dependent on the expression level of MHC class I on target

cells^[8]. The anti-CD45 mAb inhibits only the lysis of target cells expressing low level of MHC class I, such as CC531s^[8] and YAC-1^[27], whereas the lysis of target cells expressing high level of MHC class I, such as P815^[27], is not inhibited^[8].

In summary, CD45 on pit cells participated in pit cell-mediated CC531s and YAC-1 but not P815 cytotoxicity and apoptosis. NKR-P1A and ANK61 antigen on pit cells were involved in pit cell-mediated FcγR⁺ P815 cell cytotoxicity and apoptosis, but not in FcγR⁻ CC531s and YAC-1 cell cytotoxicities. The mAbs 3.2.3 and ANK61-induced cytotoxicities of FcγR⁺ P815 cells by pit cells were mediated by the perforin/granzyme pathway. These findings provide evidence that the same molecules on pit cells and blood or spleen-derived NK cells regulate target cell lysis and apoptosis. The difference in cytotoxic capacity between these cell types therefore may be on a quantitative rather than a qualitative level.

ACKNOWLEDGEMENT We thank Carine Seynaeve and Marijke Baekeland for their technical help, Karen Crijts for her technical assistance in flow cytometry, Ronald De Zanger for his help with the statistical analysis, and Chris Derom for her photographic support.

Jiang BJ, Sun RX, Lin H, Gao YF. Study on the risk factors of lymphatic metastasis and the indications of less invasive operations in early gastric cancer. *World J Gastroentero*, 2000;6(4):553-556

INTRODUCTION

The principle of surgical treatment for gastric cancer is the radical resection although the suitable resecting range for different cases of gastric cancer is still being argued upon^[1-9]. However, the diagnostic accuracy of early gastric cancer (EGC) without lymphatic metastasis has obviously improved with an improvement in the diagnostic technique and due to the accumulation of knowledge on the biological profiles of EGC^[10-17]. The D₂ lymph node excision was used as a regular operation to treat the EGC previously. But the concept for the EGC without lymphatic metastasis has gradually changed and the less invasive resections has been applied in some cases^[18-20]. This study aimed at investigating the risk factors of lymphatic metastasis in EGC in order to find out the proofs for the suitable indications for less invasive operations such as endoscopic mucosal resectioning (EMR), laparoscopic and laparotomic resectioning.

MATERIALS AND METHODS

From 1978 to 1999, 520 cases of EGC with operative and pathological analyses were studied. Among them, 287 were male and 233 female, with an average age of 62 years (32-81). The samples from the primary tumor and the

metastatic lymph nodes were collected and examined as previous reports distinguishing the tumor was limited in mucosal layer (m Ca) or submucosal layer (sm Ca) of stomach^[10] were scanty. According to the gross differences of the following groups were constituted of II_c+III, II_c, II_b, II_a and I.

Sixty-six cases diagnosed by the ultrasound endoscopic examination received the less invasive operative technique. This resection retained the partial omentum and resected the 1st station and No 7 of lymph nodes. In this operation, the dissection was made and the omentum was cut off in (3-4) cm places away from or along the blood vessels in greater and less curvature of the stomach. And the No 7 lymph nodes were resected and blocked or picked out. Hepatic branch of vagus had better to be protected possibly. Mouth margin and anal margin for gastrectomy was over 2 cm away from the tumor site. All of 259 cases received radical resectioning of N₂ lymph nodes or a more radical resection.

The rate of lymphatic metastasis and the morbidity of intestinal obstruction after operation and the expression of long-term survival were statistically analyzed by Check test or by log-rank test respectively. *P* value less than 0.05 was considered statistically significant.

RESULTS

In this study, the risk factors regarding the occurrence of lymphatic metastasis were investigated. The long-term survival analysis and the complications relating to the less invasive operation were studied at the same time.

Gross type

Lymphatic metastasis happened the most easily in II_c+III subgroups of both m Ca and sm Ca, and secondly in II_c subgroups. In II_c+III subgroups, the lymphatic metastasis could be identified in 2 cases of m Ca and 20 cases of sm Ca, and one n₂ lymphatic metastasis was observed in m Ca and 10 in sm Ca (Table 1). No n₂ lymphatic metastasis could be found in other subgroups of m Ca. However, this n₂ lymphatic metastasis could be observed in sm Ca in all groups except II_b.

Invading depth

Forty-four cases of n₁ lymphatic metastasis and 14 cases of n₂ lymphatic metastasis (58 cases of lymphatic metastasis in

Received 2000-02-28 Accepted 2000-06-02

total, 11.2%) could be demonstrated in all cases of EGC. Four (1.5%) of 275 cases suffering from the m Ca had lymphatic metastasis, of which one case shared n_2 lymphatic metastasis (Table 2). Lymphatic metastasis was identified in 54 (22.0%) out of 245 cases in sm Ca group, of which 13 cases were of n_2 lymphatic metastasis. This result showed that lymphatic metastasis was more frequent in sm Ca than in m Ca ($P < 0.05$).

Table 1 Lymphatic metastasis relating to gross types (%)

Gross types	m Ca (n = 275)	sm Ca (n = 245)
II _c +III	2.5 (2/85) ^{a,b}	25.3 (20/79)
II _c	1.7 (2/120) ^b	20.2 (17/84)
II _b	0 (0/3)	0 (0/4)
II _a +II _c	0 (0/29)	23.8 (10/42)
II _a	0 (0/34)	25.0 (2/8)
I	0 (0/4)	17.9 (5/28)

sm Ca (n = 245)	16.7 (41)	5.3 (13)	22.0 (54)
Total cases (n = 520)	8.5 (44)	2.7 (14)	11.2 (58)

^{*}Number of cases. ^b $P < 0.01$, vs sm Ca.

Tumor size with or without ulcer

With tumor size less than 20 mm in m Ca, there was no lymphatic metastasis in 122 of 275 cases regardless whether accompanied with ulcer or not. In 153 cases with tumor larger than 20 mm, there were 4 cases of lymphatic metastasis in m Ca ($P < 0.01$, Table 3). Among 164 cases with m Ca and without ulcer, the lymphatic metastasis could be observed only in one with 25 mm of tumor. On the other hand, 3 of 111 cases of lymphatic metastasis could be found in ulcer group, in which all tumors were larger than 30 mm. These findings indicated that lymphatic metastasis was more significantly in cases with tumor size larger than 20 mm subgroups, especially those with ulcer ($P < 0.05$).

Table 3 Lymphatic metastasis related to tumor size with or without ulcer (%)

Ulcer diameter- (cm)	m Ca (n = 275)		sm Ca (n = 245)	
	With ulcer (n = 111)	Without ulcer (n = 164)	With ulcer (n = 110)	Without ulcer (n = 135)
≤ 2	0 (0/43)	0 (0/79)	16.7 (3/18)	3.1 (1/32)
~ 3	0 (0/21)	2.4 (1/42)	20.8 (5/24)	21.1 (8/38)
~ 4	5.3 (1/19)	0 (0/15)	20.0 (4/20)	24.0 (6/25)
~ 5	6.7 (1/15)	0 (0/14)	18.8 (3/16)	18.2 (4/22)
≥ 6	1 (1/13)	0 (0/14)	43.8 (14/32)	33.3 (6/18)
Total No	2.7 (3/111) ^a	0.6 (1/164)	26.4 (29/110) ^a	18.5 (25/135)

^a $P < 0.05$, vs ulcer subgroup in each group.

In sm Ca, 4 out of 50 (8.0%) cases of lymphatic metastasis could be identified in cases with tumor size less

than 20 mm with or without ulcer, which showed that the radical resection with standard lymph node excision could be carried out even in small tumor sized sm Ca.

In 135 cases of sm Ca without ulcer, 25 (8.5%) cases were demonstrated to have lymphatic metastasis, out of which 12 (11.3%) cases belonged to n_2 lymphatic metastasis. But 29 out of 110 (26.4%) cases of sm Ca with lymphatic metastasis were proven to occur in the ulcer subgroup, in which 7 (6.4%, $P < 0.05$) cases had n_2 lymphatic metastasis. Therefore, the n_2 lymphatic metastasis happened more significantly in sm Ca than in m Ca.

Pathological classification

One hundred and forty-three out of 275 cases (52.0%) with m Ca had well-differentiated adenocarcinoma in which there was no lymphatic metastasis. Two out of 58 cases (3.4%) and 2 out of 57 cases (3.5%) sharing lymphatic metastasis were respectively identified in the poorly-differentiated group and the non-differentiated group of EGC. Fifty-four out of 245 (22.0%) cases with lymphatic metastasis were observed in sm Ca, out of which there were 21 (8.6%), 11 (4.5%), 15 (6.1%), and 7 (2.9%) cases respectively in each group of well-differentiated, poorly-differentiated, non-differentiated and ringed cells cancer. Difference in pathological classification could not significantly result in the increase of lymphatic metastasis, but n_2 lymphatic metastasis was more easily recognized in worst differentiated groups.

Comparison of D₂ and D₁₊₇

resections In a study regarding the less invasive D₁₊₇ resection, this resection and D₂ or more radical lymph node excision were separately carried out in 66 cases and 259 cases during 1988-1999. All cases resulted in the curable resection and the longest follow-up was of 10 years. In D₁₊₇ group, only one case was histopathologically demonstrated for the occurrence of lymphatic metastasis. Twelve cases diagnosed as m Ca preoperatively were sm Ca and others were m Ca. In investigating the postoperative complications, 1 out of 66 cases (1.5%) with D₁₊₇ resection and 39 out of 259 cases (15.1%) with D₂ resection suffered from the intestinal obstruction ($P < 0.01$). But no mortality occurred in D₁₊₇ resection group and 2 cases (0.8%) died within one month after D₂ operation.

The investigation of long-term survival showed that the survival rates of 1 and 5 years in D₁₊₇ and D₂ operation groups were respectively 98.3% vs 97.6% and 90.2% vs 92.1%, in which no significant differences could be observed.

DISCUSSION

As is well known, the degree and the range of lymphatic metastasis is dependant on the biological features of the primary tumor^[10,12-14]. This study showed that one of the main risk factors for the lymphatic metastasis was the tumor invading depth infiltrating through the mucosal layer and

the tumor size being larger than 20 mm. In sm Ca with tumor size larger than 20 mm, the morbidity of n_2 lymphatic metastasis happened with an increase in the tumor size. Therefore, correct determination of the invading depth and the tumor size are key points for the less invasive surgeries in EGC. The indications for endoscopical mucosal resection (EMR)^[20-21], laparoscopic resection^[22-31] and less invasive resection by laparotomy^[20,32-33] should be limited in the cases of EGC without lymphatic metastasis. Even for less invasive resection by laparotomy, it should be indicated only for n_1 lymphatic metastasis without ulcer, I, II_a and II_b gross types as II_c types with tumor size less than 20 mm although such indications have not been accepted ubiquitously^[10,20,32-33]. The less invasive surgery by laparotomy has become one of the main choices in surgical treatment of EGC currently. The range of less invasive operation includes the partial gastrectomy and regional lymph node excision as well as the retains of the omentum, vagus, pylorus and so on^[10,14,27]. The less invasive operations for m Ca or sm Ca have been proven to share the good results of long-term survival^[14,33], and at the same time, less invasive surgery is required.

Development of less invasive operations by laparotomy have made both MER and laparoscopic resection applicable in the treatment of EGC^[18-32]. The rate of complete resection for primary tumors and metastatic lymph nodes by EMR or laparoscopic resection was between 45%-85%. This resection rate was lower because most tumors were larger than 10 mm and some were located in the cardia, lesser curvature of gastric body as well as latter wall of stomach^[9,11,14]. Mucosal resectioning by laparoscopic surgery including lesion lefting resection^[31] and gastric mucosal resection^[20,23] comes in between EMR and less invasive laparotomy. Advantages of this laparoscopic surgery are to get more satisfactory resectioning of the entire layer of the gastric wall at the lesion site and the regional lymph nodes of n_1 around the tumor in comparison to EMR^[20,29-31]. If the tumor infiltrated to the sm Ca or the vessels in the gastric wall, the radical resectioning at the 2nd station of lymph nodes should be carried out as the first choice^[1,9,32,34].

Judgements for the invading depth of EGC before operation are mainly based on the gastric fiber examination with the ultrasound. On the application of the ultra sound endoscopy, especially at 20 MHz, correct diagnostic has been observed in over 80% cases and identification of m Ca or sm Ca was easier^[15-17,34]. At the same time, n_2 lymphatic metastasis happened more easily in sm Ca. Therefore, D₂ lymph node excision should be applied in sm Ca if the diagnosis is doubtful before or during operation. The investigations on the metastasis and the regional invasion of gastric cancer has the support of not only clinicopathological studies but the genetic and molecular biological studies also^[35-42]. At present, a very careful choice should be made for the less invasive operations,

especially for EMR and laparoscopic surgery, as making a correct judgement for the invading depth of tumor in stomach before operation^[16-17,34] is very difficult.

Li ZR, Chi YL, Ke RC. Sutureless end-to-end bowel anastomosis in rabbit using low power CO₂ laser. *World J Gastroenterol*, 2000;6(4):557-560

INTRODUCTION

The use of laser energy to weld biological tissues and produce sutureless anastomosis has its advantages over conventional silk-sutured anastomosis since it was reported in small vessels^[1] and fallopian tubes^[2], in the late 1970s. Since then, more investigators have welded a larger variety of tissues^[3-13] and have expanded its application to welding trials of enterotomies of rabbit and rat small intestine^[14-17]. Sauer *et al*^[18] reported results from Nd: YAG laser in reconstruction of end-to-end welding in rabbit small intestine. Recently, controlled temperature during YAG and argon laser-assisted welding of enterotomies of rabbit and rat was implemented to eliminate exponential increases in the rate of denaturation associated with rapidly increasing temperature^[19,20]. Yet there was no report of sutureless end-to-end bowel anastomosis using low-power CO₂ laser. This is a report of a circumferential end-to-end laser welding bowel anastomosis in rabbit by using 3 different CO₂ laser powers to explore the feasibility of CO₂ laser welding of a circumferential intestinal tissue and to determine the optimal laser-welding parameter. Then the appropriate CO₂ laser power was chosen to weld bowels in rabbit and its long-term healing effect was evaluated.

MATERIALS AND METHODS

Animals and equipment

Twenty-eight Japanese white rabbits weighing between 1.8 kg and 2.5 kg (6 for a cut and 22 for chronic phase of experiment) regardless of sex were supplied by Experimental Animal Center of Wenzhou Medical College.

A hand-held Model JZ-5, power 500 mW-5 W adjustable CO₂ laser made in Shanghai Optical Machinery Institute, which was modified to provide a 100 mW-1000 mW potentiometer, was used. The laser spot diameter was 0.4 mm. The laser power output was calibrated by a Model SD2490 CO₂ laser power meter produced by Subei Electronic Equipment. The pressure was measured by a PT-6B pressure transducer and PTM-6B physiological pressure meter, jointly produced by Shanghai Fudan University and Zhejiang Ouhai Electronic Equipment Factory, with normal saline intraluminal infusion at an average rate. The flow was monitored by a computed infusion pump (DYB-1) made in Jiangsu Haimeng Electronic Equipment Factory.

Acute phase

A rabbit was fasted for 24 h prior to surgery and sodium pentobarbital (30 mg/kg, im) was used for anesthesia. Using a 5-cm upper abdominal incision, the ileum was identified. At 10 cm proximal to the ileocecal junction, intestinal circumference was measured. Ileum was cut apart and then reconstructed. Each subsequent test was moved approximately 10 cm and a bowel anastomosis was welded by using 3 different CO₂ laser powers of 250, 500 and 1000 mW respectively. At two circumferential cut-edges of ileum, 3 silk stay sutures were placed to hold tissue together and allow for accurate approximation and inversion. Before and after each welding, the laser power output was calibrated and modified. Tissue blanching and constriction, and fusing of both edges of the anastomosis were marks of the completion of a tissue weld. The circumferential welding was completed in sequence.

One min after each laser welding, a 10-cm segment of bowel including the anastomosis was isolated between occlusive bowel ligature, and the bursting pressure of anastomosis was tested by the intraluminal infusion of normal saline at a rate of 16 mL/min. The pressure was recorded until the anastomosis burst which was visible both as leakage of infusate from the anastomosis and as a sharp drop of pressure. Each rabbit was welded 3 to 5 times and all subjects were sacrificed after the experiment.

Chronic phase

A rabbit was fasted for 24 h prior to surgery and sodium pentobarbital (30 mg/kg, im) was used for anesthesia. Using upper midline abdominal incision, ileum was circumferentially cut apart for a laser-welded anastomosis and a conventional one-layer silk sutured anastomosis. It was randomly determined which anastomosis was 10 cm or

35 cm proximal to ileocecal junction. Three silk stay sutures were placed to hold the cut intestinal edges in welded anastomosis, and 16-20 stitches of interrupted one-layer 0 silk suture were used in sutured anastomosis.

The laser power output 500 mW was used in the laser welding. Tissue blanching and constriction, and fusing of both edges of the anastomosis by naked-eye were marks of the completion of a tissue weld. The time used for laser welded anastomosis was about 5-7 min while sutured anastomosis needed 10-15 min.

Gentamycin (4 mg, im) was administered 12 h pre and post-operatively. All rabbits were sacrificed at d 3, wk 1, 3 and 5 and pathological study was done macroscopically and microscopically.

RESULTS

Acute phase

The intestinal circumference was 26-30 (28.2 ± 1.3) mm. The laser was delivered within 1 mm of both intestinal cut-edges. Based on this calculation, the laser delivery area of each anastomosis was $(26-30) \times 2$ mm. The delivery time for 250 mW group, 500 mW group and 1000 mW group was 92 s-153 s (average 123 s), 59 s-84 s (average 70 s) and 25 s-45 s (average 40 s) respectively. According to the above parameters, the laser power density and energy density of each anastomosis could be calculated. The number of bowel anastomosis using 3 different CO₂ laser powers and the bursting pressure are shown in Table 1.

Table 1 The bursting pressure of the welded and sutured anastomoses

Groups	Number of anastomosis	Bursting pressure ($\bar{x} \pm s$) kPa (mmHg)
Silk-sutured	5	6.1 ± 1.9 (46 ± 14)
250 mW-welded	7	1.1 ± 0.4 (8 ± 3)
500 mW-welded	6	2.7 ± 0.7 (20 ± 5) ^a
1000 mW-welded	6	1.7 ± 0.8 (13 ± 6)

^a $P < 0.05$ vs other three groups

Chronic phase

In chronic phase experiment, except that one animal died at 1 day and another at 3 days after operation from unknown causes without anastomotic disruption by autopsy, the remaining 20 rabbits, which were dissected at a different postoperative times, were divided into four groups, each consisting of 5 rabbits.

At d 3 after operation, both modes of anastomoses healed well without leaks. Loose fibrous adhesion, stiffness, and edema were found in the adjacent bowel including the anastomosis and mesentery. Suture was seen in the sutured anastomosis while the laser welded anastomosis was smooth. Microscopically, both anastomoses showed edema, acute inflammatory cell infiltration, consisting of mainly neutrophils, lymphocytes, and macrophages, but comparatively less in the laser-welded anastomosis. At 1 wk after operation, edema was markedly reduced but the cut-edge in the sutured

anastomosis was still swollen. Adhesion was observed surrounding both anastomoses, less fibrous adhesion was seen in all laser-welded anastomoses except in one that had a small walled-off leak surrounded by fibrous formation without pus or purulent fluid in the abdominal cavity. Some inflammatory cells infiltration, mainly lymphocytes and plasmacytes, was found in both groups. Broad gap of mucous due to excessive inversion was seen in the sutured anastomosis while the gap was much narrower in the laser-welded anastomosis.

At 3 wk after operation, anastomotic tissues were morphologically normal and soft. Linear scar along the cut-edge of sutured anastomosis was seen while laser anastomosis showed less scar formation. Fibrous adhesion was remarkably decreased in the sutured anastomosis than before. No adhesion in 2 cases and very little adhesion in 3 cases was found in the laser-welded group. Microscopically, inflammatory cell infiltration and fibrous proliferation still existed in both anastomoses. In the sutured anastomosis, there was more and thicker fibrous tissue than in the laser-welded anastomosis, especially at the sutured site. At 5 wk after operation, white linear seams were seen around the sutured anastomoses. Slightly sunken scar was found on one anastomosis and some fibrous adhesion in another. At both cut-edges of anastomosis dotted line of scars resulted from the silk suture were vaguely observed, but no residual black suture remained. Two laser-welded anastomoses were hardly distinguishable and the calibre of the other three anastomoses was identical to that of the normal bowel, though thread-like scarring was found at the cut-edges.

DISCUSSION

Laser which is used to weld living tissue differs from high energy laser for other medical purposes in that the former requires specific low power energy. Which type of laser is to be chosen depends on the structure of the target tissue and welding requirement as well. Sauer *et al*^[16] used CO₂ laser to weld a 0.5 cm longitudinal incision in rabbit bowel and acquired the bursting power of 5.4 kPa. In this experiment low-power CO₂ laser was used to weld circumferential bowel anastomosis, which attempted to make laser-welding more applicable to clinical practice. The bursting pressure of 500 mW group was 2.7 kPa. The bursting pressure was lower probably because the welded anastomoses in this group were circumferential instead of a small longitudinal incision and therefore greater tension was expected. Besides, the distance between each stay suture to be welded was as long as 1.0 cm, much longer than Sauer's 0.5 cm^[16]. This study shows that the 500 mW group produced remarkably higher bursting pressure than the other two groups. Group 250 mW cannot produce a desired welding effect due to much too low power and prolonged delivery while charring tissue occurs in the 1000 mW group so that the tensile strength of the welded anastomosis is affected. Furthermore, Cilesiz *et al*^[19,21] believed that temperature feedback control improved the

quality and stability of laser-assisted enterotomy closures in surviving animals, temperature (90-95) °C was considered optimal.

Though no information is available about the maximum bursting pressure of bowel of the conscious rabbit, Abbott *et al* reported that the basic pressure of the distal bowel was 0.83-1.03 kPa, and Fink reported that the pressure of normal ileum was no more than 0.92 kPa with the peak pressure less than 2.03 kPa in the human body. Therefore we infer that the bursting pressure produced in the anastomoses of the 500 mW group is adequate to avoid the anastomotic disruption caused by peak tensile strength.

The healing process of the welded bowel reveals that fibrous tissue or intestinal adhesion to various degree form around both kinds of anastomoses early after operation. Later, the laser-welded anastomosis is hardly distinguishable from the normal intestine, while suture remnant and white linear scar are found in the sutured anastomoses. Microscopically, compared with the sutured anastomosis, the laser-welded anastomosis has less inflammatory cells early after operation and less fibrous proliferation, less scar formation, and no suture granulation later postoperatively. We therefore conclude that the laser-welding in intestinal anastomosis, as a new type of sutureless surgical technique, has its potential clinical application value with the advantages including sutureless anastomosis, no foreign material, avoidance of needle trauma and suture remnant, minimal inflammatory response with reduction in stricture and infection. It is especially suitable for mini-bowel anastomosis in congenital intestinal atresia.

It is universally accepted that laser thermal effect is involved in the mechanism of laser-welding of biological tissue. It is also shown that adequate tissue seals occur in laser-welded wounds only when the tissue edges are directly opposed, whereas any blood in the interface selectively absorbs the laser energy and forms a fibrin seal which is too weak to tolerate increased intraluminal pressure^[14,22]. According to Jain^[1] in his study of YAG laser welding of the microvessels, it is the physical coherence of fibrous collagen that welded successfully the vascular walls, meanwhile laser does not result in degeneration, coagulation, and necrosis. In contrast, it is held by most scholars that, based on the observation that coagulation and necrosis exists at the welded site, strong weld is not the result of physical coherence of collagen, but rather the result of chemical bonding caused by laser thermal effect which can lead to collagenic degeneration and tissue necrosis^[23-26]. In our welding experiments, ideal bonds formed when the opposed cut edges of the bowel were directly and strongly held together and tissue blanching was seen during laser welding. Microscopically, slight tissue degeneration and necrosis could also be seen near the laser-welded anastomosis. However, recent studies show that solid protein used as solder can improve vascular welding effect^[27,28]. Meanwhile, it is reported that collagen

synthesis is stimulated during the healing process after laser welding^[29,30], therefore, further study on mechanism of laser-welding is needed.

Can the rat donor liver tolerate prolonged warm ischemia ?

Ji Qi Yan, Hong Wei Li, Wei Yao Cai, Ming Jun Zhang and Wei Ping Yang

Subject headings liver transplantation; cadaver; tissue donors; organ procurement; tissue survival; non-heart-beating donors; warm ischemia

Yan JQ, Li HW, Cai WY, Zhang MJ, Yang WP. Can the rat donor liver tolerate prolonged warm ischemia. *World J Gastroentero*, 2000;6(4):561-564

INTRODUCTION

The last two decades of the twentieth century have witnessed increasingly successful rates of liver transplantation. The number of liver transplantations has increased steadily while the number of organ donors has remained relatively constant. Thus a great disparity has developed between the demand and supply of donor organs and remains a major limiting factor for further expansion of liver transplantation. Although many procedures, such as split liver^[1], living-related transplantation^[2], and xenotransplantation^[3], have been attempted clinically to overcome the shortage, it is hoped that livers harvested from non-heart-beating donors (NHBDs) would alleviate the problem of organ shortage, which again becomes the focus of attention^[4-9]. However, sensitivity of the liver to warm ischemia remains a major worry for use of the NHBDs. The aim of this animal study was to assess if murine liver could tolerate prolonged period of warm ischemia and to determine the optimum timing of intervention in the cadaver donor in order to preserve liver viability.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats, weighing 180 to 220 g, were obtained from Shanghai BK Lab Animals Co. Ltd. Donor and recipient rats were matched for size. Rats were housed in the standard animal room without fast before the surgery and with free activity and standard diet after surgery.

Experimental design

Orthotopic liver transplantation was carried out in 5 groups with non-heart-beating time in the donor ranging from zero to 15, 30, 45 and 60 min respectively (Group 1-5). The period of non-heart-beating was counted from the donors cardiac arrest to the beginning of the cold perfusion of the liver. Each group consisted of 13 rats; 5 rats were sacrificed one hour after surgery for sample collection and graft biopsies; the other 8 rats were used to observe one-week survival rate; and rats that survived for more than 7 d after transplantation were considered as survivors. Except for 1 or 2 survivors that were randomly selected to observe the possibility of long-term survival, the others were also sacrificed 7 d after surgery.

Animal surgery

Both donor and recipient surgery was performed at room temperature of 21°C to 22°C under ether anesthesia. No immunosuppressive agents were given to either donor or recipient. Five min after the intravenous administration of 500 IU of heparin, donor cardiac arrest was induced by opening the chest and cross clamping the base of the heart with hemostats. Donor surgery began 15 min prior to the end of the designated warm ischemic time in each group. All livers were perfused with 10 mL of 4°C Ringer's lactate solution through the abdominal aorta, and stored in the same cold solution for an average cold ischemia of 60 min. The donor liver was implanted to the recipient according to the cuff technique of Kamada and Calne^[10] with an average anhepatic phase of 16 min. No heparin was administered to the recipient rat.

Sample collection and analysis

The blood samples were obtained one hour and seven days after hepatic implantation for measurement of serum ALT and AST, meanwhile liver tissues were also taken for histologic examination. Furthermore, one hour after reperfusion serum TNF level was detected by the bioassay using L-929 cell lines as described elsewhere. The graft tissues were fixed in 10% formaldehyde, and sections were stained with hematoxylin and eosin.

Statistics

Values are expressed as the $\bar{x} \pm s$. Statistical significance was compared with group 1 and tested by unpaired Student's *t* test. The survival rates in each group were compared with group 1 using Fisher's exact test. *P* values less than 0.05 were considered significant.

RESULTS

Survival

No recipient death was directly related to operative technical failure in this study. The one-week survival rate and the long-term survival period of rats that underwent liver transplantation are listed in Table 1. With a stepwise increase of the non-heart-beating period from zero to 15, 30, 45, and 60 min in donors, the survival rates in recipients were 100, 75, 62.5, 25, and 0 percent respectively. Moreover, rats that received grafts having suffered 15, 30, or 45 min warm ischemia before implantation showed the possibility to survive more than 60 d. The longest time for using NHBDs in our study was 45 min. A total of 19 recipient rats died within 7 d, among which 15 deaths were caused by primary graft nonfunction, with massive ascites and patchy liver necrosis at autopsy. Two rats died of biliary complications and 2 died of pulmonary infection. The survivor in Group 3 also died of pulmonary infection 18 d after surgery.

Table 1 Survival status

Group	Warm ischemia/min	One-week survival rate	Long-term survival/day
1	0	100% (8/8)	>60, >60
2	15	75% (6/8)	>60, >60
3	30	62.5% (5/8)	18, >60
4	45	25% (2/8) ^a	>60
5	60	0% (0/8) ^a	

^a*P*<0.01 vs Group 1

Hepatic function

The mean serum ALT and AST concentration one hour after reperfusion was significantly higher in Groups 2, 3, 4, 5 compared with Group 1, and the concentration of enzymes dropped markedly after 7 d. The postoperative increase in enzyme concentration appeared to be proportional to warm ischemia time.

Table 2 ALT and AST values after transplantation

Group	One hour after reperfusion		7 d after operation	
	ALT(u/L)	AST(u/L)	ALT(u/L)	AST(u/L)
1	362 ± 49	623 ± 75	38 ± 9	115 ± 19
2	546 ± 68 ^a	873 ± 95 ^a	64 ± 11 ^{a,b}	345 ± 66 ^{a,b}
3	1096 ± 195 ^a	1435 ± 238 ^a	124 ± 35 ^{a,b}	454 ± 120 ^{a,b}
4	1505 ± 326 ^a	2001 ± 376 ^a	184	732
5	2357 ± 534 ^a	2886 ± 590 ^a		

^a*P*<0.01 vs Group 1; ^b*P*<0.01 vs 1 h after RPF

Serum TNF

The mean serum TNF levels one hour after reperfusion in Group 1 to 5 were (1.84 ± 0.21) U/mL, (2.62 ± 0.29) U/mL, (4.0 ± 0.4) U/mL, (4.5 ± 0.4) U/mL and (7.4 ± 0.6) U/mL respectively. The degree of serum TNF elevation was associated with the severity of warm ischemia injury to donor liver.

Histological examination

One hour after reperfusion, the livers whether or not subjected to warm ischemia all showed basically well-preserved hepatic architecture without lymphocyte infiltration in the portal area. In Group 5, mild diffused hepatocyte vacuolization was identified, accompanied by dilatation of the sinusoids. One week after transplantation, the livers of the different groups manifested lymphocyte infiltration in the portal area and congestion in the sinusoids. Neutrophil infiltration in the portal area was also identified in Groups 3 and 4. Furthermore, mild lobular necrosis surrounding hepatic vein was found in Group 3; moderate lobular necrosis and ballooning degeneration were found in Group 4.

DISCUSSION

Ever since the guidelines for defining brain death have been established, brain dead donors with beating hearts have been the commonest source of transplant organs^[8]. However, the concept of utilizing organ allograft from non-heart-beating donors for transplantation is not new. During the early stage of transplantation, NHBDs were the only source of unpaired allograft, i.e. hearts and livers. With refinements of surgical techniques, improvements in immunosuppression and development of effective organ preservation, the increasing success of and widening indication for liver transplantation has exacerbated the shortage of donor organs, and resulted in an increasing number of potential allograft recipients dying on waiting list. To increase the number of livers available for liver transplantation, grafts procurement from NHBDs has again become the focus of attention. Furthermore, recent estimates indicate that an increase of 20% to 25% in organ donors could be realized if NHBDs were used routinely^[12].

During the past two decades, the belief in the extremely high sensitivity of hepatic parenchyma cells damage from warm ischemic injury has been challenged. In both clinical and experimental studies, it has been suggested that the liver can tolerate warm ischemia up to 60 min^[13-18]. Warm ischemia of graft is considered a risk factor for postoperative graft dysfunction after liver transplantation. However, in liver transplantation from NHBDs, the effect of warm ischemic damage is subsequently compounded by preservation (cold ischemia) and reperfusion injuries. The tolerance of the liver to warm ischemia in such situations is still controversial.

Generally liver allografts can be preserved at low temperatures safely for up to 24 h in University of Wisconsin solution. In transplantation setting, however, there are a few studies about the limit of the period of warm ischemia before transplantation. In rodents, Soejima *et al*^[19] reported that none of their control rats exposed to 30 min warm ischemia before transplantation survived more than 2 d, and also the similar result was seen in Sumimoto's study^[20]. However, Ikeda^[21] reported that all

the rats suffering 30 min warm ischemia before transplantation survived more than 3 wk. Moreover, in 1995 Xu and Jones reported 50 per cent of one-week survival rate after 100 min of non-heart-beating time^[22], and also Takada reported his successful pig liver transplantation from NHBDs exposed to 60 min warm ischemia^[23]. Our data were compatible with Ikeda's^[21] and Richter's^[24]. The present study unexpectedly found that rat livers harvested from NHBDs after 30 min of cardiac arrest could be successfully grafted to the recipients with a 62.5% one-week survival rate and have the possibility to survive more than 60 d. No statistical significance of one-week survival rates was found between Group 1 and 3. In Group 4, even the donor liver suffered 45 min of warm ischemia, two of eight (25%) rats survived more than a week, also with a chance of long-term survival. The results confirmed that the liver is less sensitive to warm ischemia than formerly believed.

Hepatic ischemia-reperfusion injury is characterized by sinusoidal perfusion failure, accumulation and adherence of leukocyte in sinusoids, loss of the endothelial integrity with concomitant extravasation of blood cells, and, finally, breakdown of the liver microcirculation^[25]. Under inflammatory conditions, there are several factors that would favor neutrophil trapping. First swelling of Kupffer cells and endothelial cells occurs during exposure to inflammatory mediators. Second, an imbalance of vasoconstrictor (e.g. endothelin-1) and vasodilator (e.g. nitric oxide) formation can further narrow the sinusoidal diameter^[26,27]. Moreover, inflammatory mediators such as activated complement factors reduce the deformability of neutrophil. The combination of these factors appears to be responsible for the microcirculation failure.

It is widely accepted that warm ischemia and cold ischemia represent two different and distinct types of injury to the liver. While cold ischemia mainly causes injury to the cells of the sinusoidal lining, hepatocytes are the most vulnerable to warm ischemia^[21,28,29]. The postoperative elevations in the serum liver enzyme concentration observed in the present study may reflect the extent of hepatocyte disruption, which was more severe in proportion to the duration of warm ischemia. TNF produced by Kupffer cells plays an important role in the pathogenesis of early graft failure^[30-33]. In this study, we demonstrated an elevation of serum TNF levels in association with increasing prolonged warm ischemia time. The degree of histological damage and serum ALT and AST value changes correlated positively with the TNF levels.

In conclusion, rat liver can tolerate a prolonged warm ischemia time up to 45 min for transplantation with a chance of recipient survival. Based on our experience, warm ischemia is not the only factor limiting the success of liver transplantation from NHBDs^[34]. More attention should be paid to other factors such as the mechanical injury during the harvest of cadaver donor liver and to the

cold preserve time and anhepatic phase. Actually, clinical experience with the use of liver allograft from NHBDs has been reported^[4,5,35]. The patients, who had irreversible neurologic damage but did not meet standard brain death criteria, were transported to the operating room where ventilation was discontinued, and rapid cold perfusion was performed after declaration of death. In such controlled circumstances, the warm ischemia time was less than 30 min in most cases. Some of the procured grafts were actually transplanted, exhibiting satisfactory initial function. However, in the patients who suffered a sudden cardiac arrest, in whom cardiopulmonary resuscitation was necessary before organ procurement (referred to as uncontrolled NHBDs), there was a high incidence of primary graft nonfunction. In this regard, the present study is a simulation of well-controlled NHBDs, and further intensive experimental studies are required to approach this goal, because human NHBDs have much more complicated clinical conditions than healthy rat donor. In clinical liver transplantation, unstable hemodynamic conditions before cardiac arrest may produce a warm ischemia injury. New strategies to attenuate ischemic liver injuries will be required to establish the safety and efficacy of liver transplantation from human NHBDs.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies in China. To date, surgery is still the best solution to it. However, metastatic recurrences after curative hepatic resections are very common. Tang *et al* have reported that recurrence rate within 5 years of curative hepatic resection is 61.5%^[1]. As curative hepatic resection has a high tendency for metastatic recurrence, therapeutic interventions such as transarterial embolization and antiangiogenesis have been tried to further improve prognosis of HCC patients. Therefore, establishing a dependable, sensitive, easy, and economical method to predict metastatic recurrence following curative hepatic resection is of clinical urgency.

Neovascularization has been shown to be essential for the growth and metastasis of solid tumors. Vascular endothelial growth factor (VEGF), a dimeric heparin-binding glycoprotein with a molecular weight of about Mr45000, is one of the most important angiogenic factors. In addition to increasing permeability of blood vessels, VEGF has potent mitogenic effect on vascular endothelial cells^[2-9]. Serum VEGF levels have previously been shown to be raised in patients with various tumors, including brain, renal, melanoma, breast, gastrointestinal,

and liver malignancies particularly in metastatic diseases^[10-15]. Because VEGF plays an essential role in tumor angiogenesis and hence the metastasis and recurrence of HCC, its elevation in serum may be a candidate biomarker of metastatic recurrence. Consequently, we set out to study whether preoperative serum VEGF could be used as a biomarker of metastatic recurrence following curative hepatic resection in HCC. Since 84.6% of HCC patients have accompanied cirrhosis to some extent we also examined serum concentrations of VEGF in cirrhotic patients and normal healthy controls^[16]. In addition, we studied the relationship between serum VEGF concentrations and immunohistological expressions of two known metastatic recurrence parameters-p53 and PCNA in tumor tissues.

MATERIALS AND METHODS

Subjects

The current study registered 12 normal healthy controls, 12 patients with cirrhosis, 8 patients with benign liver tumors including hemangioma and focal nodular hyperplasia, and 85 HCC patients who received curative resection. The healthy controls were selected randomly from people coming to our hospital for a medical checkup and found to be healthy. Cirrhotic patients were diagnosed clinically. HCC and benign liver tumor were diagnosed histologically. All HCC patients had underlying cirrhosis to some degree as confirmed by operations. Thrombi, intra- and extra-hepatic dissemination, were confirmed by operation, and/or ultrasonography, and computed tomography. According to generally recognized standards, we set HCC patients with thrombi, intra- and extra-hepatic dissemination, and tumor size larger than 5 cm as high-tendency metastatic recurrence (HTMR) group, and less than 5 cm as low-tendency metastatic recurrence (LTMR) group. Hepatic resection with no signs of tumor lesion within the liver, and no metastatic lesion outside the liver after operation as well as no tumor thrombi in major branches of portal, hepatic vein, and intrahepatic biliary ducts before operation was considered as curative hepatic resection.

Blood samples were taken from all subjects. The serum was separated after 20-30 min of coagulation at room temperature and was stored at -80°C until the assay. Repeated thawing and freezing of samples was avoided.

Liver Cancer Institute & Zhongshan Hospital, Shanghai Medical University, Shanghai 200032, China

Dr. Qi Niu was born on April 8, 1970 in Guoyang, Anhui Province. In 1994 he graduated from Bengbu Medical College as a Bachelor of Medicine and in 1997 as a Master of Science. From 1997 to 2000 he studied as a Ph. D. and M.D. student in Shanghai Medical University majoring in metastasis and recurrence after curative hepatic resection in HCC and published 4 papers.

VEGF assay

The VEGF determinations were performed in duplicate following the manufacturer's instructions using the R&D Systems Quantikine enzyme-linked immunosorbent assay (ELISA) kit. The VEGF concentration in a sample was determined by computer software-generated interpolation (Microsoft Origin software) from the standard curve. The internal VEGF standards ranged from 0 to 2000 ng/L, and the intensity of chromogen was measured at a wavelength of 450 nm with a reference wavelength of 595 nm using the dual wavelength mode on the BIO-RAD 450 Microplate Reader. Standard curve was generated and plotted using a log-log linear regression.

Immunohistochemistry

For the immunohistochemical demonstration of p53 and PCNA protein, formalin fixed, paraffin embedded sections were deparaffinized in xylene and alcohol and placed for 15 min in alcohol-H₂O₂ for blocking endogenous peroxidase. The samples were processed in a microwave oven, placed in a thermoresistant plastic box with 10 mmol/L pH 6.0 citrate buffer. Tissue sections were treated in the oven twice for 5 min while the buffer was boiling. Tissue sections were left at room temperature in the buffer solution for 20 min without drying. Sections were treated with bovine serum albumin to prevent background staining and incubated for 1 h with a primary nondiluted ready-to-use murine anti-p53 antibody (Dako, Carpinteria, CA) or murine anti-PCNA antibody (Dako, Carpinteria, CA) diluted at 1:500 at room temperature in a humidified chamber. Slides were rinsed with phosphate buffered saline for 3 min and incubated first with the biotinylated linked goat anti-mouse antibody for 30 min and then with the labeling reagent, peroxidase conjugated streptavidine, for 30 min. After the slides were rinsed, the peroxidase label was demonstrated using 3-amino-9-ethylcarbazole (AEC) for 15 min, and counterstained with Mayer hematoxylin. AEC produced a red product which was soluble in alcohol and was used with an aqueous mounting media. Positive and negative controls were included in each experiment. Specifically, for the latter the primary antibody was substituted with nonspecific mouse IgG. p53 or PCNA immunopositivity was recorded when more than 15 carcinoma cell nuclei were stained in one or more fields^[10].

Statistics

Analyses were performed using SAS (Version 6.12; SAS Institute, Inc., Cary, NC). Student's *t* test and Oneway ANOVA were used to determine the differences between the means of different groups. Results were expressed as mean \pm SD. The level of significance was $P < 0.05$.

RESULTS

The VEGF concentrations in the normal controls and groups

of cirrhotic, benign liver tumor, and HCC patients were 158.46 ± 41.84 ng/L, 90.00 ± 22.42 ng/L, 156.34 ± 41.32 ng/L, 164.42 ± 76.07 ng/L, respectively (Table 1). Cirrhotic patients had the lowest levels of VEGF in the four groups. Compared with the cirrhotic group, HCC group had a significantly higher level of VEGF in the serum ($P < 0.01$). Yet, no significant differences could be found between serum levels of VEGF in HCC and benign liver tumor or normal healthy control group ($P > 0.05$) (Figure 1). Since large HCC has a high tendency to recur after hepatic resection, we next divided HCC patients into small HCC and large HCC group. The VEGF concentrations of large HCC group were a little higher than those of small HCC patients (173.52 ± 52.34 ng/L vs 154.46 ± 37.23 ng/L, $P > 0.05$). However, this difference was not significant. In patients with thrombi, VEGF levels were significantly higher than those in patients without (182.46 ± 35.61 ng/L vs 157.62 ± 53.42 ng/L, $P < 0.05$). On dividing the HCC patients into HTMR and LTMR groups, HTMR patients were observed to have significantly higher VEGF concentrations in the serum than LTMR patients (185.33 ± 92.88 ng/L vs 144.75 ± 51.37 ng/L, $P < 0.05$) (Figure 2). A notable case observed was that of a female patient having a tumor growth of just 1.8 cm diameter with no thrombi but with the highest levels of VEGF (819.37 ng/L), she was the first to metastasize (within three months). As p53 is reported to play a role in regulating the production of VEGF, we further divided HCC patients into p53 positive and p53 negative groups. We found that serum VEGF levels in p53 positive patients were significantly higher than those in p53 negative patients (176.56 ± 53.29 ng/L vs 149.26 ± 41.29 ng/L, $P < 0.05$). Despite PCNA being a commonly used clinical indicator of metastatic recurrence after curative hepatic resection in HCC, we did not find any significant difference in VEGF levels between PCNA positive and PCNA negative groups (176.56 ± 53.29 ng/L vs 165.26 ± 54.29 ng/L, $P > 0.05$).

Table 1 Serum VEGF levels in different HCC groups which received curative hepatic resection, benign liver tumor group, and normal control group ($\bar{x} \pm s$)

Group	Case (n)	VEGF concentrations (ng/L)
Normal control	12	158.46 ± 41.84
Liver cirrhosis	12	90.00 ± 22.42
Benign	8	156.34 ± 41.34
HCC	85	$164.42 \pm 76.07^{a,b}$
Small HCC	34	154.46 ± 37.23
Large HCC	51	173.52 ± 52.34^c
Without thrombi	71	157.62 ± 53.42
Thrombi	14	182.46 ± 35.61^d
p53 negative	34	149.26 ± 41.29
p53 positive	38	176.56 ± 53.29^e
PCNA negative	36	165.26 ± 54.29
PCNA positive	31	176.56 ± 53.29^f

^a $P < 0.01$, vs liver cirrhosis; ^b $P > 0.05$, vs benign; ^c $P < 0.05$, vs small HCC; ^d $P < 0.05$, without thrombi; ^e $P < 0.05$, vs p53 negative; ^f $P > 0.05$, vs PCNA negative.

Figure 1 Serum VEGF levels in benign liver tumor and HCC (hepatocellular carcinoma) groups.

Figure 2 Serum VEGF levels in HTMR and LTMR groups. HTMR: high-tendency metastatic recurrence group; LTMR: low tendency metastatic recurrence group.

DISCUSSION

VEGF is produced by a wide variety of tumor cells, helping the growth and dissemination of the solid tumor by making it more vascular. In HCC, it acts in a paracrine fashion and plays an essential role in tumor angiogenesis^[2-5, 17].

The prognostic value of VEGF has been shown in breast and gastric cancer based on VEGF expression in tumor tissue detected by immunohistochemistry, with VEGF concentrations being high in highly vascular rich breast tumors. The VEGF positivity in gastric cancer correlates with vessel involvement, lymph node metastasis as well as liver metastasis and is associated with an overall poor prognosis^[18-23]. Because local tumor invasion and metastatic spread are angiogenesis-dependent, it is hypothesized that metastatic recurrence after curative hepatic resection in HCC may be associated with up-regulation of angiogenic factors. Our present study showed that HTMR patients had significantly higher levels of VEGF than LTMR patients. This indicates that VEGF is a potential biomarker of metastatic recurrence in HCC patients after curative hepatic resection. The sensitive elevation of VEGF in one female patient further strengthens the hypothesis that raised VEGF levels may predict metastatic recurrence in HCC. The range of serum VEGF levels among healthy controls was from undetectable to

481.02 ng/L. The relevance of normal levels of VEGF is not clear at present and further studies are required to clarify it. As about 84.6% of Chinese HCC patients have some degrees of cirrhosis, it would be proper to compare VEGF levels between cirrhosis group and HCC group, rather than normal healthy controls and HCC patients^[16]. Compared with cirrhotic patients, HCC patients had significantly higher levels of VEGF in their serum. It indicates that VEGF could play an important role in transforming liver cirrhosis into HCC. Unexpectedly, the mean serum levels of VEGF in HCC and benign liver tumor patients were observed to be very close. This suggests that VEGF can not be used as a marker to distinguish benign liver tumor from malignant one (HCC). The main reason for this phenomenon may be that all of the benign liver patients in our study have noncirrhotic liver. Since tumor thrombi is a putative indicator of early metastatic recurrence following curative hepatic resection and poor prognosis^[24,25], we detected VEGF levels in HCC patients with thrombi and found that consistent high levels of VEGF reflected a high tendency towards metastatic recurrence in the thrombi group. Meanwhile, we found that there was no significant difference between small HCC group and large HCC group regarding VEGF concentrations although mean serum VEGF levels in big HCC patients were higher than those in small HCC patients. Despite the fact that tumor size is a commonly used prognostic indicator of HCC, our result does not sufficiently reflect its role as an important parameter of metastatic recurrence in HCC^[26,27]. Here the point to contemplate is that the ability of metastatic recurrence of HCC cannot be predicted by a single parameter alone, such as presence of tumor thrombi, intrahepatic dissemination or tumor size, rather all of them combined together can give a more precise indication.

p53 and PCNA have been reported to be indicators of HCC metastatic recurrence^[28-31]. Meanwhile, p53 also plays an important role in regulating the production of VEGF. Wild-type p53 down-regulates whereas mutated p53 up-regulates VEGF expression according to some studies^[32-35]. In the present study, p53 positive patients had significantly higher levels of VEGF than p53 negative counterparts, confirming previous reports^[25]. However, the difference in VEGF levels between PCNA positive and PCNA negative groups was not significant. The role of PCNA in the regulation of VEGF is currently being investigated in our lab.

In conclusion, this study demonstrates that serum VEGF is a potential biomarker of metastatic recurrence in HCC patients following curative hepatic resection. However, it can not distinguish HCC from benign liver tumor. p53 positive patients have a significantly higher VEGF level in the serum than their counterparts. Further follow-up studies are needed to delineate the ability of VEGF in predicting metastatic recurrence after curative hepatic resection in HCC.

ACKNOWLEDGEMENT We thank Professor Yin-Kun Liu and Dr. Li-Neng Zhang for their help and suggestions.

Comparative ultrastructural study of endoplasmic reticulum in colorectal carcinoma cell lines with different degrees of differentiation

Shu Feng¹ and Jin Dan Song²

Subject headings colorectal neoplasms; endoplasmic reticulum; ultrastructure; microscopy, electron; microscopy, electron, scanning; cell differentiation

Feng S, Song JD. Comparative ultrastructural study of endoplasmic reticulum in colorectal carcinoma cell lines with different degrees of differentiation. *World J Gastroentero*, 2000;6(4):569-571

INTRODUCTION

The endoplasmic reticulum (ER) consists of a complex system of tubules, lamellae, and flattened vesicles, and has a variety of morphologies in different cells. It is believed to play a central role in the biosynthesis of cholesterol, phospholipids, steroids, prostaglandins, membrane and secretory proteins^[1]. Cancer cells have different functions and ultrastructure from their original cells^[2-4]. The studies on ER membrane system of cancer cells are of great significance in understanding their malignant behavior. In the present work, the ultrastructural characteristics of ER in human colorectal carcinoma cell lines with different differentiation degrees were investigated.

MATERIALS AND METHODS

Materials

Well differentiated human colorectal carcinoma cell line CCL229 and poorly differentiated cell line CCL227 were generous gifts from Dana-Farber Cancer Institute of Harvard Medical School, USA.

Methods

Cell culture The human colorectal carcinoma cell lines

CCL229 and CCL227 were grown in Dulbecco's modified Eagle's medium (DMEM, GIBCO, BRL) supplemented with 10% calf serum and 2 kU/L gentamycin. Cell cultures were incubated at 37°C in a humidified atmosphere of 95% air and 5% carbon dioxide.

Transmission electron microscopy Exponential cells cultured in flasks were collected, washed thrice in phosphate buffer saline (PBS), and then fixed in 2.5% glutaraldehyde in a buffer containing 0.1 mol/L sucrose and 0.1 mol/L sodium cacodylate (cacodylate buffer, pH 7.4) for 2 h. After being washed in cacodylate buffer, the cells were post-fixed in 1% osmium tetroxide for 30 min, dehydrated through graded alcohol and acetone, and embedded in Epon 812. Ultrathin sections were cut with glass knives on LKB 2088 ultratome, stained with uranyl acetate and lead citrate and examined under a Hitachi H600 transmission electron microscope.

Scanning electron microscopy Cells grown on coverslips were rinsed thrice in a buffer containing 60 mmol/L sodium citric acid, 25 mmol/L KCl, and 35 mmol/L MgCl₂ (sodium citric acid buffer, pH 7.4), then fixed in 125 mmol/L potassium permanganate in sodium citric acid buffer for 7 min. Cells were rinsed in sodium citric acid buffer, dehydrated through graded alcohol, replaced with iso-amyl acetate, dried at CO₂ critical point in a Hitachi HCB-2 critical point drier, gilded on a BIKO TB-3 ion film-plating machine and then examined under a Hitachi S-450 scanning electron microscope.

RESULTS

Well differentiated colorectal carcinoma CCL229 cells appeared round or polygonal with many microvilli and pseudopodia and a large elliptic nucleus containing 1-2 dense nucleolus. The cytoplasm contained some mitochondria, Golgi apparatus, lysosomes, polyribosomes as well as abundant ER. The ER consisted of a complex system of tubules, lamellae, and flattened vesicles distributed throughout the cytosol. There was a great amount of vesicle-like and flattened cisternal ER in pseudopodia (Figures 1, 2).

More apparent heteromorphism was observed in poorly differentiated colorectal carcinoma CCL227 cell. There were less microvilli and pseudopodia on the cell surface. The ratio of nuclei to plasma was higher than that found in CCL229 cell. An abundance of free polyribosomes and less

DISCUSSION

Overlap with other compartments and limits of regular light and electron microscopy make it difficult to study the ultrastructure and cellular distribution of ER membrane system. Terasaki *et al*^[5] reported a rapid and simple technique for localizing the structure of whole-mount ER both in living and glutaraldehyde-fixed cells by fluorescent microscopy which can also be detected by phase-contrast microscopy and scanning electron microscopy in potassium permanganate-fixed cells. With this technique, the ultrastructure and distribution of ER in many normal and tumor cells have been studied^[6-11].

The ER is a highly specialized structure which performs many distinct functions. Hence a well developed ER may be looked upon as an expression of cell differentiation and functional activity. It is abundantly clear that immature or undifferentiated cells such as stem cells, embryonic cells, and cells in culture have, as a rule, a poor complement of ER as compared with their normal mature functioning counterparts, and this concept also applies to tumor cells. In general, there is a meaningful correlation between ultrastructural signs of anaplasia and malignancy. In this study, using regular transmission microscopy and whole-mount ER scanning electron microscopy of potassium permanganate fixation, the ultrastructure and distribution of ER in well and poorly differentiated colorectal carcinoma cell lines CCL229 and CCL227 was investigated comparatively. The results showed that well differentiated cell line CCL229 had abundant endoplasmic reticulum, which consisted of a complex system of tubules, lamellae, and flattened vesicles distributed throughout the cytoplasm. A great amount of vesicle-like and flattened cisternal endoplasmic reticulum were found in pseudopodia. Poorly differentiated cell line CCL227 had relatively less ER. This result is coincident with the above-mentioned concept.

In poorly differentiated CCL227 cell, the ER is not abundant, but free polyribosomes are very rich in the cytoplasm. This presumably reflects the active synthesis of endogenous proteins needed for cell growth and division.

Well differentiated cell CCL229 is a highly invasive colorectal carcinoma cell line, its high invasiveness correlates to its cell's ultrastructure^[12,13]. Pseudopodia of tumor cells play an important role in the invasion process^[14], tumor cells are supposed to secrete a great amount of proteolytic enzymes to cleave the basement membrane^[15-18]. In this work, cell CCL229 was found to have many microvilli and pseudopodia with abundant ER which presumably reflect its active synthesis of secretory proteins. This may be the ultrastructural basis of its high invasiveness.

Study on environmental etiology of high incidence areas of liver cancer in China

Nian Feng Lin¹, Jie Tang¹ and Hoteyi S. Mohamed Ismael²

Subject headings liver neoplasms; etiology; epidemiology; water pollution; environmental carcinogens; nitrosamines; china; geology

Lin NF, Tang J, Mohamed Ismael HS. Study on environmental etiology of high incidence areas of liver cancer in China. *World J Gastroentero*, 2000;6(4):572-576

INTRODUCTION

China is a country with a high incidence of liver cancer in some areas^[1]. Liver cancer has a wide distribution and threatens human health seriously. A rough estimation shows that out of a population of 1.2×10^8 in liver cancer areas patients are more than 1.0×10^5 . The environment of the liver cancer area is very complicated and has different characteristics in different regions. But the epidemic regularity of liver cancer is obvious, and the environment in the cancer areas has also distinct characteristics that contribute to the study on the environmental etiology of liver cancer^[2-5].

THE EPIDEMIOLOGICAL CHARACTERISTICS OF LIVER CANCER

The liver cancer discussed here has epidemiological characteristics like endemic, comparison and trend. The general investigation of liver cancer all over the country of China or local area shows that the high rate of liver cancer has been found in some provinces, counties, towns, and islands with the back-ground of the low death rate ($10/10^5$)^[1,6]. The main areas of high rate of liver cancer chiefly concentrate in the coastal areas such as Jiangsu, Guangxi, Fujian, Zhejiang, Guangdong Provinces, and Shanghai City^[7,8] (see Figure 1). Qidong in Jiangsu Province and Fusui in Guangxi Province are two counties of the highest death rate of liver cancer in China and the death rates are $47.76/10^5$ and $46.87/10^5$ ^[1,9]. As far as macroscopic environment is concerned, the risk area often

has focused distribution and has a strict and steady dividing line between light and non-liver cancer areas. The risk area has peculiar characteristics regarding landmark, geology, hydrogeology, and geochemistry^[9,10]. It is an important way to study the cause of high incidence of liver cancer from the angle of environmental etiology.

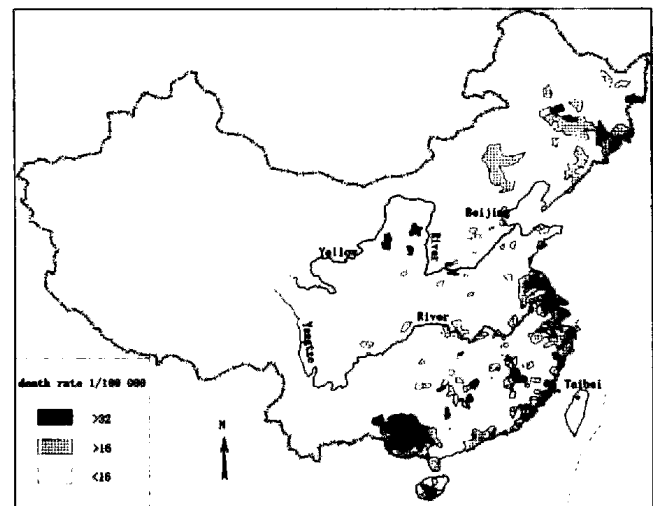

Figure 1 Sketch map of liver cancer in China.

The area of high incidence of liver cancer is adjacent to that of the low incidence area and the death rate has great disparity. For example, the death rate in Fusui is $46.87/10^5$ while that in Niming County is $7.47/10^5$, and the death rate in Qidong is $47.76/10^5$ while that of Rudong County adjacent to Qidong is $20.6/10^5$. The death rate in Tongxiang Town in Qidong County is $50.67/10^5$ while that in adjacent Xining Town is $17.28/10^5$. All these show that the carcinogens are distinctly different in the two adjacent environments^[9].

The three epidemic trends of liver cancer may be summarized as follows: the change in epidemic curve from low to high, parallel development or from high to low. The trend reflects the change in the intensity of carcinogenic factor with time, and the epidemic curve of many high incidence areas of liver cancer belongs to the first type. The curve rose in the 1970s, while it gently went down from the end of the 1980s to the beginning of the 1990s. We think that organic pollution of the drinking water may be the reason for the rising of the curve, while the downward trend of the curve may be the result of changed water.

THE ECO-ENVIRONMENTAL GEOLOGICAL TYPES IN LIVER CANCER AREAS

The cancer of digestive system in China has wide distribution and threatens human health seriously and liver cancer is the most serious one of all^[1,11]. Distinct environmental characteristics were discovered in the high incidence areas of liver cancer according to a survey and analysis on a large scale. It reflects comprehensively the climate, hydrology, landmark, geology, geochemistry, drinking water, the degree of pollution, economic condition, the food custom and so on. However, the organic and reduction environment and the drinking water polluted by organisms are the most obvious and common characteristics. The high incidence areas are classified into five geo-environmental types^[10,12-14].

(1) The denuded mountain environmental type: it is mainly distributed at the junction of three provinces of Hebei, Henan, and Shanxi in south Taihang Mountain. Esophagus, liver and stomach cancer are the common cancers. The climate is dry and the rainfall is about 500 mm-600 mm. The slopes are bare and are made up of carbonate and clastic rock. The ground has sparse plantation and the surface water and groundwater are very scarce. The drinking water condition is poor, and only a few residents drink stream and spring water, while most have to drink pool and pond water polluted with organic waste.

(2) The Karst mountain environmental type: it is mainly distributed in Fusui and Longan County in Guangxi Province, the main cancers are liver and stomach cancer. The rainfall is sufficient about 1100 mm-1300 mm. The carbonate rock layer distributes extensively in the cancer areas belonging to Karst geographical area. Underground rivers are developed while surface water is very scarce. People here mainly drink the water from dirty ponds or wells besides the ponds.

(3) The river network plain environmental type: it is mainly distributed in Jianhu and Huai'an in the north of Jiangsu Province, Yangzhong and Taixing in the middle and lower reaches of Yangzi River. Main cancers are of the esophagus and liver. The area belongs to the alluvial and lake plains of the lower reaches of Yangzi River, and most of the cancer areas are in the lake-marsh depression which is rich in humus sludge, peat, and biological deposition and CH₄ is easily found escaping from the earth's surface. The surface water and groundwater is rich but the runoff is stagnated.

(4) The delta type: it is distributed in Qidong, Haimen, Rudong, Chongming Island in Yangzi River Delta and Nanhui County belonging to Shanghai City, Shunde, Jiangmen, and Foshan in the Zhujiang delta. Liver and esophagus cancer are the main cancers. The climate is humid with plenty rainfall. Most of the areas are sea and land mutual depositions that are mainly made up of sand, humus, peat, and biological deposition. The surface

water and groundwater flow is sluggish and is severely polluted by organisms.

(5) Coastal plain and island type: stomach, liver, and esophagus cancer are the main diseases. The cancer areas of coastal plain type are mainly distributed in Changle and Putian in Fujian Province. Most of them are sea and land mutual depositions of coastal plains that are made up of clay, soil, and biological deposition. The groundwater and surface water are rich, but severely polluted by organisms. Dongshan Island in Fujian and Nan'ao Island in Guangdong Province belong to the island type which is a rocky hill and is covered by thin Quaternary deposition, and fresh water is scarce.

The classification of eco-environmental geology has contributed towards a deep study and contrast between the macroscopic and microscopic characteristics in disease areas, and searching for questionable carcinogenic factors of environment, and giving comprehensive protective measures.

DRINKING WATER TYPES AND LIVER CANCER

Comparing the high incidence areas of liver cancer in China, we discovered that there exists a common faction in cancer incidence in these areas although the natural environment is different. It is that the groundwater or surface water is rich in humus, the water flow is stagnant and is in an organic and reduction environment consisting of pools, ponds, cellars, trenches, channels, and the groundwater in the swampland. The people in non-cancerous areas mainly drink groundwater or surface water which is not polluted by organisms. The water flow is smooth and is in an oxidation environment such as springs, rivers, and shallow or deep well water^[9]. Taking Fusui and Qidong as examples, we have constructed a figure that reflects the relation between the type of drinking water source and the death rate due to liver cancer (Figure 2). The figure illustrates that the death rate due to drinking the pond and pool water is the highest and due to deep well water is lowest.

RELATIONSHIP BETWEEN DRINKING WATER AND LIVER CANCER

After affirming a close relationship between drinking water type and liver cancer, we tested the inorganic and organic compositions of all kinds of drinking water. We did not find any peculiar contents regarding common and trace elements, but some cancer areas were low in minerals and Se in water^[13-16]. However the organisms in water were different and the death rate due to liver cancer was found to have a very close relationship with drinking water type and the degree of water pollution^[17-18] (Table 1).

From Table 1, it can be observed that water pollution indicator such as nitrate, nitrite, COD, and humic acid have an obvious relation with the drinking water type and death rate from liver cancer increases with a rise in the

above indicators. In order to study the relationship between death rate and water quality, 29 water samples that corresponded to death rate due to liver cancer were chosen. The death rate and COD, DO, BOD, NO_2^- , and humic acid were used to make a correlation analysis to study the relationship between the death rate and the five factors. The regression equation is $y = a + bx$, y stands for the death rate due to liver cancer, x stands for the five factors. The results of the analysis are listed in Table 2.

Table 1 The organic pollution indicators of drinking water and death rate from cancer

The drinking water type	Qidong in Jiangsu					Fusui in Guangxi		
	Pond	Channel	River	Shallow well	Deep well	Pond	River	Deep well
Death rate	61.53	58.17	41.99	18.80	0.0	115.05	37.49	0.0
Number of samples	20	18	22	21	16	7	18	25
COD	4.66	3.85	3.55	3.20	1.28	48.27	0.75	0.197
Humic acid	0.43	0.36	0.28	0.18	0.08	0.58	0.18	0.042
NO_3^-	14.52	18.20	21.46	67.91	1.53	0.74	0.75	0.480
NO_2^-	0.54	0.48	0.38	0.28	0.04	0.061	0.008	0.0096

The death rate is $1/10^5$ and the unit of NO_3^- , NO_2^- is ppm.

Table 2 The analysis between various drinking water factors and death rate due to liver cancer

Content PPM	Regression a	Coefficient b	Interrelation coefficient r
Humic acid	29.4985	78.6384	0.5981 ^b
NO_2^-	53.1249	75.9767	0.4232 ^a
COD	43.8098	0.4280	0.4881 ^b
BOD	45.0576	0.6231	0.4872 ^b
DO	191.8340	-19.0087	-0.7285 ^b

^a $P < 0.05$, ^b $P < 0.01$, vs control.

The results shows that humic, COD and BOD have a very remarkable positive relation with the death rate ($P < 0.01$), NO_2^- has a significant positive correlation. While DO has a very marked negative correlation ($P < 0.01$). That is to say, the lower the DO is in the water, the higher is the death rate. Pond water is severely polluted by organisms and is in a strong reduction environment lacking of DO. We postulate that the five factors given above can be used as important signs to judge the water quality and the death rate due to liver cancer.

THE RELATION BETWEEN NITROSAMINE AND LIVER CANCER

It has been affirmed that nitrosamine is carcinogenic. Nitrosamine contents were observed in water from high incidence areas of liver cancer in the 1970s and 1980s in China, but the test method used was not very sensitive for semi-quantify^[18].

We collected 24 water samples from cancer-prone villages and non-cancer-prone villages in Fushui County to quantify the contents of nitrosamine compound in water. Nitrosamine was not found in sixteen water samples taken

from river, stream, and deep well water except in 8 samples of pond water. Dimethyl nitrosamine was the main compound in the pond water samples, only three pond water samples contained diethyl nitrosamine. The death rate seems to have positive relation with the contents of nitrosamine (Table 3).

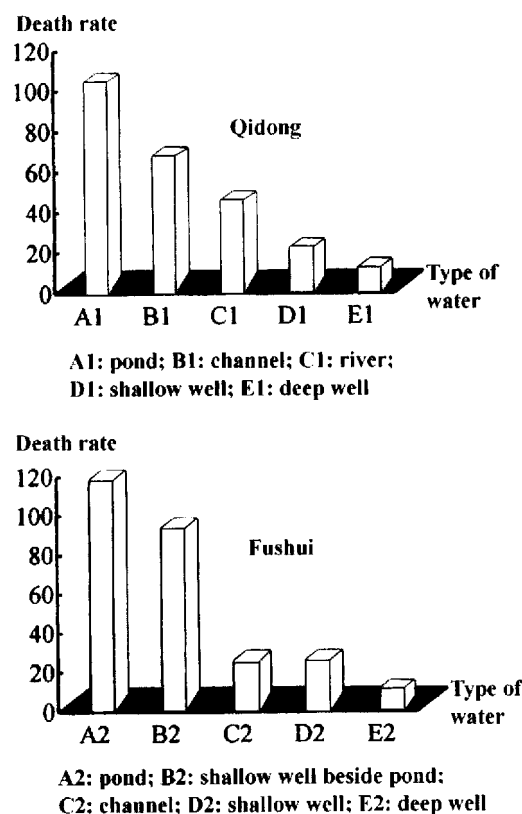

Figure 2 Relation between the types of drinking water source and the death rates from liver cancer.

Table 3 The content of nitrosamine in pond water and the death rate due to liver cancer in Fusui

Location of samples	Death rate of liver cancer $1/10^5$	Dimethyl nitrosamine ppb	Diethyl nitrosamine ppb
Sihe	74.96	3.8	
Jiuchen	35.42	3.2	
Yiliu	31.68	3.6	
Mumin	80.80	2.4	2.2
Qutun	112.59	5.6	
Zhongyuan	148.49	4.8	2.4
Lailu	95.36	4.2	
Jiuta	18.38	0.8	0.4

MUTATION TEST OF DRINKING WATER

Professor De Long Su^[11] holds that the high incidence of liver cancer has relation with water polluted by micro organisms. He carried out an Ames test on the drinking water in Qidong disease area and got a positive result. Li Sheng Zhang^[19] carried out a micronucleus test using Zilu Grass from America on pond water in Fusui disease area and extracted liquid from the pond mud. His results show

that high pollution degree corresponds to high micronucleus rate of plant cell and high death rate due to liver cancer. He also found that the micronuclei in clean deep well water in Karst area and corresponding water are very low.

Following some studies^[19-24], we decided to carry out an HHPL mutation test on pond water, shallow well water, and deep well water. Distilled water was used as a blank contrast.

The first test was the cell micronuclei test and the results showed that HHPL micronuclei rate found in the water that has been poisoned had a dose-effect relationship with the density of the samples and the higher the density of samples content was, the higher the micronuclei rate was. The micronuclei rate had a marked difference (pond water > shallow well water > deep well water ≥ blank). On evaluation by *t* test, the micronuclei rates of poisoned pond water and shallow well water were significantly different ($P < 0.001$).

The second test used was the mutation test of cell chromosome malformation test. The results showed that the mutation rate of chromosome aberration of HHPL has dose-effect with the density of each polluted water sample. Rates of chromosome aberration caused by polluted water are statistically significant and similar to micronuclei test as evaluated by *t* test, $P < 0.001$ (Table 4). This can be an important test for studying environmental etiology of liver cancer.

Table 4 Result of cell mutation test and polluted water samples

Water source type	Cell micronuclei rate %	Cell chromosomal aberration rate %
Pond water 1	63.34	6.42
Pond water 2	59.66	4.76
Shallow well water 1	48.32	3.76
Shallow well water 2	42.66	3.21
Deep well water	3.30	0.75
Blank contrast	2.43	0.17

STUDY ON THE WATER QUALITY BEFORE AND AFTER THE CHANGE IN WATER SOURCE

It has been accepted that liver cancer has close relations with the polluted drinking water. The changed water project has been made in many cancer prone areas since 1980's, especially in Fusui County, the changed water project has been implemented on a large scale, and the present water source is from the limestone layer. The depth of well is about 100 m-200 m. Most cancer prone villages have used this supply of water with beneficial results. We chose nine villages supplied with changed water and observed the change in the water quality and human health before and after. Before the water was changed, the pond water was severely polluted, and the color of water was brown and grey green, the water smelled terrible, and residents had many unhealthy symptoms such as pale cheeks, fatigue, distension of abdomen, menoxenia and liver cancer. After the water was

changed, the deep well water was clear and sweet, the symptoms noted above gradually disappeared, residents felt sound and the liver cancer death rate lowered. The results of water quality before and after the water was changed and mutation test are listed in Table 5.

Table 5 Contrast in water quality before and after the change in water

Test item (ppm)	NO ₂ ⁻	Humic acid	COD	DO	NH ₄
1	0.0224	0.53	44.24	6.10	0.34
2	0.0106	0.05	0.34	8.21	0.07
Test item (ppb)	Se	Fe	Mn	Zn	nitrosamine
1	0.56	1110.88	198.33	9.29	4.20
2	0.39	164.60	10.14	50.47	0
Test item	Plant cell micronuclei rate/%	HHPL			
		micronuclei rate/%	chromosome aberration rate/%		
1	10.34	59.61	4.76		
2	5.96	3.30	0.75		

Note: 1. pond water, 2. deep well water.

From Table 5 it can be observed that the water quality of deep well is better than that of pond water. Thus using a change in water source and additional treatments, an improvement in human health and prevention in the occurrence of liver cancer^[25-32] may be observed.

INTRODUCTION

The main reason for the death of the patient with acute hemorrhage necrosis pancreatitis (AHNP) is pancreatic infection and multi-organ failure caused by endotoxemia and intestinal bacterial translocation^[1-7]. However, the pathogenesis of endotoxemia and intestinal bacterial translocation remains a question^[8-10]; moreover, no effective method of prevention and cure for it has been found till now^[11-15]. In the present study, we infused low dose dopamine and low molecular weight dextran through the catheters to abdominal aorta and portal vein, and observed its influence on the endotoxin concentration in plasma and the rate of translocation of intestinal bacteria in AHNP rats.

MATERIALS AND METHODS

Animals

A total of 48 Sprague-Dawley rats weighing 295-320 g were divided into 4 groups (with 12 rats in each group): Group A (healthy rats), Group B (AHNP rats), Group C (femoral artery and femoral vein infused rats), and Group D (abdominal aorta and portal vein infused rats).

Experimental methods

Bacterial labeling Following the way previously described by Wells, we directly labeled O₅₅B₅ Escherichia coli (*E. coli*) with fluorescein isothiocyanate to prepare the solution of 5×10^6 cfu/L tracer.

Induction of AHNP model and blood vessels catheter insertion and infusion

Firstly, all rats were deprived of food 24 h before laparotomy, and were given a gavage of fluorescein-labeled *E. Coli* (0.7 mL/100 g) 12 h later, then they were kept for 12 h before being anesthetized ip with 2% pentobarbital sodium (0.15 mL/100 g). Secondly, after the abdominal hair was removed and the abdominal cavity was opened through a midline laparotomy, the pancreas was exposed and 5% taurodextran sodium solution (0.15 mL/100 g; Sigma) was slowly injected into the pancreatic duct with retrograde pressure. Five minutes later, hemorrhage, necrosis, swelling and exudation appeared in the pancreas. Thirdly, 2 h after the AHNP models were completed, the animals of group B were infused continuously with saline through the catheters which were connected to the femoral artery and femoral vein and portal vein (the catheter was inserted from the ileocolic vein to the main trunk of portal vein), the animals of group C were infused continuously and alternately with low dose dopamine ($5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) and low molecular weight dextran (1.5 mL through catheters inserted into femoral artery and femoral vein, while being infused continuously with saline through the portal vein. The animals of Group D were infused continuously and alternately with low dose dopamine and low molecular weight dextran through the portal vein and abdominal aorta (catheters were inserted from the femoral artery and above the junction between the abdominal aorta and abdominal cavity artery), while being infused continuously with saline through the femoral vein. The total amount of infusion (6 mL/100 g) was the same in each group. Lastly, after 4 h of sustained infusion, the abdominal cavity was found to be hemorrhagic on being re-opened, and it was more evident in both Group B and Group C than in Group D. The pancreas showed pathological changes such as hemorrhage, necrosis, swelling and exudation, while Group A (control group) had no pathological changes.

Indicators and methods

Plasma endotoxin One mL vein blood was put into the heparin-containing test tube under aseptic and non-pyrogenic conditions, and after being centrifuged 500 rpm at for 10 min, the plasma was absorbed and preserved in a refrigerator at -20°C . The content of plasma endotoxin was investigated by quantitative azostromatic coloration limulus test microassay (kit from Institute of Medicine in Shanghai).

Investigation of mesenteric lymph node (MLN) labeled-bacteria MLN of the ileocecum were excised, weighed, triturated and diluted into 10% tissue plasma and was observed under fluorescein microscope for the existence of labeled-bacteria. The bacterial translocation rate was also calculated.

The microcirculation of pancreas and mesentery

The diameter of pancreatic and mesenteric small vein at the ileocecum end was directly measured under the microscope and recorded on the video-camera.

Pathological changes in the intestinal mucosa:

Observed under light and transmission electron microscopy.

RESULTS

Changes in content of plasma endotoxin and rate of translocation of labeled-bacteria in MLN (Table 1)

Table 1 Changes in plasma endotoxin concentration ($\bar{x} \pm S_x$, EU/mL) and the rate of translocation of labeled-bacteria in MLN

Group	Plasma endotoxin (2 h)	Plasma endotoxin (6 h)	Rate of translocation of labeled-bacteria (%)
A	0.023 ± 0.004	0.033 ± 0.006	0
B	0.028 ± 0.002	0.340 ± 0.038	91
C	0.025 ± 0.007	0.270 ± 0.048	83
D	0.027 ± 0.001	0.103 ± 0.018	33

There was a significant statistical difference between group D and either group B or C ($P < 0.05$), regarding the content of plasma endotoxin and translocation rate of MLN labeled-bacteria. However, there is no statistical difference between group B and group C ($P > 0.05$), while a significant difference exists when group A is compared with either group B, C, or D ($P < 0.05$).

Microcirculatory changes in pancreas and mesentery (Table 2)

Table 2 Change in the mesenteric small vein diameter after 2 h and 4 h AHNP

Group	2 h MVD	6 h MVD
A	0.66 ± 0.04	0.63 ± 0.04
B	0.69 ± 0.05	1.03 ± 0.05
C	0.72 ± 0.03	1.09 ± 0.05
D	0.77 ± 0.07	0.68 ± 0.05

Between 2 h and 4 h after AHNP, in Group B and Group C, the diameter of pancreatic and mesenteric small vein increased significantly ($P < 0.05$), and the velocity of blood was observed to be retarded or even blocked, while there was no significant increase in the diameters of pancreatic and mesenteric small veins in group D ($P > 0.05$) and no statistical difference regarding the velocity of blood stream between group D and group A ($P > 0.05$).

Pathological changes in intestinal mucosa

Optical microscopic observation It was seen that a large-number of mucosal chorionic epithelium were exfoliated, the upper parts of villus intestina were in significant edema, the central chylectasia was expanded, the blood vessels congested, the proprietary membrane was in moderate edema and the inflammatory cells infiltrated in group B and group C. While the damage of mucosa in group D was alleviated as compared to group B or group C, it was seen that only the villus became shorter, the proprietary membrane was in edema and the inflammatory cells infiltrated.

Electronmicroscopic observation Rarefaction and exfoliation of the epithelium microvilli of intestinal mucosa, exudation of matrix vacuolar degeneration of mitochondria, swelling of endoplasmic reticulum, and break-down of epithelium bridges were observed in groups B and C; and in group D only slight derangement of intestinal mucosa epithelium and slight swelling of mitochondria and endoplasmic reticulum were seen.

DISCUSSION

An extensive amount of experimental and clinical work reveals that the disorder of pancreatic microcirculation, the production of many inflammatory mediators and cytokines and the translocation of intestinal bacteria are all thought to play a critical role in the pathogenesis of acute hemorrhage necrosis pancreatitis^[15-26]; furthermore, the disorder of splanchnic organic microcirculation, especially the disorder of pancreas microcirculation in AHNP is closely connected with the production of many inflammatory mediators and cytokines^[26-37]. Dopamine has been seen to possess complicate pharmacological functions^[38-40], in above $10 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, alpha adrenergic receptors are additionally activated, causing splanchnic vascular contraction. At a dose range of $1-4 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, the effect is predominantly on dopaminergic receptors, leading to splanchnic dilatation. At the $4-10 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, beta adrenergic receptors are increasingly stimulated, which stops the increase in microvascular permeability caused by histamine and bradykinin. It also activates dopaminergic receptors leading to an increase of blood flow in splanchnic organs. Low molecular weight dextran can lower blood viscosity and hemagglutination leading to a halt in microvascular thrombogenesis in portal vein system^[41-42]. Therefore, low dose dopamine and low molecular weight dextran can be used to improve splanchnic

microcirculation. With the aid of catheters inserted into the aorta and portal vein, we infused low dose dopamine and low molecular weight dextran continuously and alternatively, which enhances the drug concentration in pancreas, liver and intestinal tract. The results have revealed that by this method the microcirculation was improved, and the content of endotoxin and the rate of intestinal bacterial translocation were decreased with increasing blood supply to the pancreas and intestinal tract of AHNP rats. This effect can be related to the following factors: Firstly, low dose dopamine and low molecular weight dextran can directly improve the ischemic status of intestinal tract and inhibit the damage of the barrier function of intestinal mucosa. It can also inhibit the pancreatic hemorrhage, necrosis and decrease the production of inflammatory mediators by improving microcirculation of pancreas, liver, and intestinal tract. On the other hand they can lighten the damage of inflammatory mediators and endotoxin on intestinal tract by enhancing the ability of the liver in clearing from inflammatory mediators and endotoxin. Hence, the method can alleviate the injury of intestinal mucosa and protect its barrier function, and inhibit endotoxemia and translocation of the intestinal bacteria, and so indicate that the disorder of microcirculation of pancreas and intestinal tract and liver are critically important to endotoxemia and the bacterial translocation from the intestine. The study also shows that the infusion through catheter to femoral vein and artery has no obvious influence on the content of endotoxin in plasma and the bacterial translocation in AHNP rats, the reason of which may be related to the low concentration of drugs in pancreas, liver and intestinal tract.

To achieve clearance of inflammatory mediators in patients with AHNP, in addition to drainage and removing the necrotic tissues by operation, we can also infuse low dose dopamine and low molecular weight dextran into the abdominal cavity after operation through catheter inserted either from the right gastroduodenal vein to the portal vein or from the femoral artery, which can improve the microcirculation disorder of pancreas, liver and intestinal tract. Moreover, we can infuse enzyme inhibitors and other anti-inflammatory mediators through the catheter to the portal vein, so as to eliminate inflammatory mediators before they reach the liver.

Gao W, Huang YX, Chen H, Song DY, Wang QL. Regulatory effects of electro-acupuncture at Zusanli on ir-SP content in rats pituitary gland and peripheral blood and their immunity. *World J Gastroenterol*, 2000; 6(4):581-584

INTRODUCTION

It has been reported in many studies that electro-acupuncture (EA) can positively regulate erythrocytic immunity and T-lymphocytic subgroups^[1-8]. Nevertheless, its mechanism remains to be explored. In the present study, a multi-group, multi-stepped and multi-indexed observation was conducted on the effects of EA on erythrocytic immunity and T-lymphocytic subgroups. A simultaneous assay of the changes in immunoreactive substance-P (ir-SP) content in the pituitary gland and peripheral blood was also carried out. The objective of the study was to investigate the regulatory effects of the immune system and their possible mechanism in the treatment of relevant diseases with EA.

MATERIALS AND METHODS

Animals and groups

Forty healthy Shanghai SD white rats weighing 150 g-180 g, aged 12 wk-14 wk, provided by the Center for Laboratory Animals, 4th Military Medical University, Xi'an, were divided into 5 groups with 8 rats in each group: the normal control group, the Zusanli group, the immunosuppressive model group, the non-acupoint group, and the Zusanli + immunosuppressive group.

Instruments and agents

G6805-A EA Instrument was purchased from Shanghai Medical Instrument Factory, Shanghai, China. Radioimmunoassay kit was provided by Beijing Haikerui Biotech Co., Ltd., Beijing, China. Epics-profile II Flow Cytometer was product of Coulter, USA. Anti-rat CD4 FITC/CD8PE was provided by SEROTEC, Britain.

Methods

Rat model of immuno-suppression Rat model of immuno-suppression was established by injecting 100 mg/kg of newly-prepared cytoxan (CY) solution into the rats' abdominal cavity on the 1st and the 4th day. Same amounts of normal saline was injected into the abdominal cavity of the rats of the other 4 groups.

Electro-acupuncture All the rats were raised in a quiet place. The acupoint chosen for EA was Zusanli (He-Sea Point, St 36)^[9]; the non-acupoint for EA was 0.5 cm off Zusanli. EA parameters were intermittent waves at 2 Hz and 3 V. The visual parameter was the slight shivering of the hind limbs of the rats. After they were fixed on a wooden board, the rats of the Zusanli-group were electro-acupunctured at Zusanli continually for 30 min at a fixed time for 7 d on a daily basis. The immunosuppressive group and the Zusanli + immunosuppressive group were also established according to the above method. EA treatment for the Zusanli + immunosuppressive group was the same as that for the Zusanli group. Rats of the control and the immunosuppressive group were tied by the same method for 30 min at a fixed time on a daily basis but did not undertake EA stimulation.

Sampling and assay Thirty mg/kg of 1% pentobarbital sodium was injected into the abdominal cavity of all the rats on the 7th day of EA. Blood samples were taken by decapitation after anesthesia with 15 U/ml of heparin as an anticoagulant. Ir-SP content in the pituitary gland and peripheral blood was assayed by radioimmunoassay (RIA) according to the manufacturer's instructions. By micro-whole-blood direct immunofluorescence staining and flow cytometry, T-lymphocytic subgroups were assayed to reflect the cellular immunity. The rats' RBC-C₃bRR and RBC-ICR were assayed by immune adherence rosette^[10].

Statistical analysis SPSS 8.0 (a statistical analysis system) was applied for the data analysis. The methods included variance analysis and linear correlation.

RESULTS

In the Zusanli group, the values of CD4+, RBC-C₃bRR and RBC-ICR and the content of SP in pituitary gland and peripheral blood were all markedly higher than that of the control ($P < 0.01$). The values of CD8+ did not change significantly ($P > 0.05$), and the rate of CD4+ positively correlated with RBC-C₃bRR ($r = 0.719$, $P < 0.05$), and so did the content of SP. The values of CD4+ and RBC-C₃bRR and the content of SP in rats' pituitary gland and peripheral blood of the immunosuppressive group were significantly lower than that of the control ($P < 0.01$, $P < 0.05$). The values of CD8+ did not change significantly ($P < 0.05$). In contrast, after EA at Zusanli, there was significant improvement in the indexes of the immuno-suppressive group ($P < 0.01$) whereas there was no statistical difference between the non-point and the control group (Tables 1 and 2).

Table 1 Changes in the values of T-lymphocytic subgroups and erythrocytic immunity ($n = 8$, $\bar{x} \pm s$)

Group	CD4+	CD8+	RBC-C-3bRR	RBC-ICR
Control	43.1 \pm 3.1	23.6 \pm 2.6	8.6 \pm 2.1	6.8 \pm 2.3

DISCUSSION

Regulatory effects of EA at Zusanli on the neuroendocrine system

Zhao *et al*^[11] discovered the cubic structure of the microangium of Zusanli and Lin *et al*^[12] reported that there might be a nerve network in the colloid of the spine and brain stem that corresponds with the stomach channel of Foot Yangming, St, runs through the spine, and reaches the nucleus of spinal tract of trigeminal nerve. These studies have proved the regulatory effect of EA at

Zusanli on neuroendocrines. With the development of studies on the mechanism of acupuncture, the relation between acupuncture and endocrine hormone has become a focus of interest for many researchers. Many studies have indicated that acupuncture can regulate thyroid hormones, sex hormones, adrenocortical hormones, insulin, brain-gut peptide, etc^[13]. Substance P, an important cerebral and brain-gut peptide is widespread in the central nervous system and gastrointestinal tract. It exists not only in the endocrine and paracrine cells, playing the roles of hormones and the local transmitter, but also in the endogenous and exogenous neurons, playing the role of a neural transmitter. The present study has proved that EA at Zusanli can significantly increase the synthesis of substance P in the pituitary gland, and its content in the peripheral blood, thus bringing into play its unique physiological and pathophysiological regulatory functions.

The general regulatory effects of Zusanli EA and the theory of neuroendocrine-immune network

It has been reported that many hormones can modify the body's immunity by their intervention at macrophages, T-lymphocytes and B-lymphocytes^[14-20] receptor sites whereas immune cells can also secrete various neuropeptides and hormones as immune transmitters. What is more, some neuroendocrine cells can secrete cellular factors. These cells can influence both the neuroendocrine system and the immune system. The three systems of nerve, endocrine and immunity depend mainly on the peptidergic factors they generate and the receptors of the latter to communicate with each other. Therefore, immune cells can also be regarded as a kind of receptors in the body that receive stimulation from antigens, secrete immune transmitter, transmit information to the central nervous system before it regulates, as a feedback, the body's immunity by means of transmitting nerves and hormones. This is the so-called "theory of neuroendocrine-immune regulatory network". The regulatory effect of EA at Zusanli on the nervous, endocrine and immune systems cannot be separated from its internal association with the neuroendocrine-immune regulatory network. In addition to its direct regulation of the above systems, acupuncture can also indirectly act upon the systems through their internal association with each other. This is probably the theoretical basis of Traditional Chinese Medicine's general regulatory principle. It is also a point of collision between Traditional Chinese Medicine and modern medicine, namely the holistic medical mode^[21].

Role of SP in the mechanism of acupuncture's effects on the immunoregulation

SP is an important biologically active substance of information channel transmission^[22]. Modern immunological research has proved that cells of the immune system can release SP and contain SP conjugative sites of

high affinity^[23]. SP can affect the immune system in the following ways. It can 1) stimulate and proliferate lymphocytes *in vivo* and *in vitro*; 2) improve the proliferative reaction of the spleen, mesenteric lymph nodes and intestinal aggregated lymphatic follicles^[24]; 3) at milli-Molar level, it can induce interleukin-1 (IL-1), interleukin-6 (IL-6) and tumor necrosis factors (TNF) from monocytes^[25]; 4) increase lipopolysaccharide (LPS)-induced secretion of IL-10 from monocytes in human umbilical cord blood and reverse the inhibitory effect of INF- γ on LPS-induced secretion of IL-10^[26]; 5) stimulate the synthesis of PGE₂, which in turn stimulates the generation of cellular factors^[27]. The present study indicates that after electro-acupuncture at Zusanli, ir-SP in the rats' pituitary gland and peripheral blood increased significantly in comparison with that of the control and were positively correlated with the change in CD4⁺. This attests that electro-acupuncture can regulate cellular immunity by exciting organism synthesis and releasing SP and affect the neuroendocrine-immunoregulatory network through the indirect effect of SP on the change of various cellular factors. However, the change in SP after electro-acupuncture at Zusanli had nothing to do with the immune indexes of RBC, which indicates that electro-acupuncture probably does not depend on SP to influence RBC immune indexes.

The effects of EA at Zusanli on the mucosal immunity of gastrointestinal tract

Modern immunological studies have confirmed the significant regulatory effects of gastrointestinal hormone on the intestinal mucosal immunocytes^[28-30]. The intestinal mucosal immuno-tissues are controlled by peptidergic nerve fibres, which were located adjacent to lymphatic systems in the epithelial layer, lamina propria and immunocytes such as macrophages, mastocytes, etc. can directly regulate the intestinal immune system. In the intestine-associated lymphatic tissues, the existence of T-lymphocytes and SP receptors specific to B cells in dense SP teloneurons and aggregated lymphatic follicles indicates that SP might be acting as a nutritious factor for the intestinal immunocytes. It is by stimulating its organic synthesis and release that EA at Zusanli regulates the intestinal immunity, thus adjusting gastrointestinal diseases and functions. Furthermore, EA at Zusanli can also positively regulate the general immune system by the exchange between GALT and the general lymphatic tissues. According to Traditional Chinese Medicine, pathogenesis boils down to three factors, i.e., spiritual, exopathic and constitutional factors. The three factors constitute the gist of the theory of neuroendocrine-immunoregulation network.

The serological prevalence and risk factor analysis of hepatitis G virus infection in Hubei Province of China

De Ying Tian¹, Dao Feng Yang¹, Ning Shao Xia², Zheng Gang Zhang¹, Hong Bo Lei¹ and Yuan Cheng Huang¹

Subject headings hepatitis G virus; enzyme linked immunoabsorbent assay; risk factors; polymerase chain reaction; prevalence; transcription, genetic

Tian DY, Yang DF, Xia NS, Zhang ZG, Lei HB, Huang YC. The serological prevalence and risk factor analysis of hepatitis G virus infection in Hubei Province of China. *World J Gastroentero*, 2000;6(4):585-587

INTRODUCTION

Hepatitis G virus (HGV), also known as GB virus C, is a recently cloned virus which may be associated with human non A-E hepatitis^[1,2]. It is parenterally transmitted and usually coinfects or superinfects with hepatitis B or hepatitis C virus^[3-5]. Some investigations have been reported on the seroprevalence and molecular prevalence of HGV infection in different areas and different population^[6-15]. Current infection of HGV is diagnosed by detection of HGV RNA, and past infection with HGV is detectable by testing anti-HGV envelope protein (E2)^[16-17]. To investigate the prevalence of HGV in Hubei Province, a central area of the People's Republic of China, ELISA and RT-PCR were employed to detect serum anti-HGV and HGV RNA in 1516 patients who were divided into 16 groups.

MATERIALS AND METHODS

Samples

One thousand five hundred and sixteen serum samples were obtained from 16 groups in Hubei Province, including 299 drug users (19.72%), 98 prostitutes (6.46%), 504 blood donors (33.25%), 61 hemodialysis patients (4.02%), 351 cases with viral hepatitis (23.15%), 41 with primary hepatocellular carcinoma (PHC, 2.70%), 51 with hemopathy (3.36%), 53 renal transplant recipients

(3.49%) and 3 liver transplant recipients (0.20%). 55 freshmen, nurses and doctors (3.63%) were employed as healthy controls.

Reagents and detecting methods

Serum HBV markers, HAV IgM, HEV IgM, and anti-HCV were detected by enzyme linked immunoabsorbent assay (ELISA). Anti-HGV was also detected by ELISA and the test kits were procured from Wantai Biological Preparation Co Ltd, Beijing. HGV RNA was assayed by reverse transcript polymerase chain reaction (RT-PCR) with the primers of 5'-UTR, and the kits were purchased from the Center of Hepatitis Reagents, Beijing. Both anti-HGV and HGV RNA were simultaneously measured in the drug users, prostitutes, and healthy subjects. For other groups, HGV RNA was detected only when their anti-HGV was positive due to insufficient outlay.

Data statistics

All data were analyzed by means of the Chi-square test.

RESULTS

HGV infections in drug users and prostitutes

The positive rates of anti-HGV and HGV-RNA in drug users were 9.06% (34/375) and 27.20% (102/375); those in prostitutes were 38.77% (38/98) and 20.41% (20/98). The analysis of risk factors of HGV infections in drug users and prostitutes is listed in Tables 1 and 2.

Table 1 Positive rates of anti-HGV and HGV RNA in drug users and prostitutes

	n	Anti-HGV	HGV RNA
Drug users*			
po	211	6.63 (14)	27.96 (49)
iv	164	12.20 (20)	32.92 (54)
Prostitutes			
Non-addict	22	9.09 (2)	13.36 (3)
Addict	76	14.43 (36)	22.36 (17)
Healthy group	55	1.82 (1)	0 (0)

*Seventy-six prostitutes who were addicted to drugs were added to this group.

The positive rate of HGV RNA in intravenous drug users (IVDU) was higher than in oral users ($\chi^2 = 4.36$, $P < 0.05$). The positive rates of anti-HGV in the prostitutes who were addicted to drugs were higher than those who were not ($\chi^2 = 12.19$, $P < 0.01$).

Table 2 Risk factors of HGV infections in drug users

	Sex		Addiction duration		HBV infection	
	Male	Female	< 2 years	≥2 years	HBsAg (+)	HBsAg (-)
Anti-HGV	8.65	9.23	6.48	12.58	13.33	9.37
HGV RNA	3.46	32.84	9.72	52.56	16.67	22.78

The statistical difference of anti-HGV positive rate was tested between users addicted for more than 2 years and users for less than 2 years ($\chi^2 = 4.29$, $P < 0.05$). The positive rate of HGV-RNA in female users was higher than that in male users ($\chi^2 = 11.55$, $P < 0.01$), that in the patients who were addicted for more than 2 years was also higher than those addicted for less than 2 years ($\chi^2 = 79.06$, $P < 0.01$).

HGV infections in blood donors

Seven percent (29/417) of blood donors were found to be anti-HGV positive and 27.5% anti-HGV positive donors were detected to be HGV RNA positive.

HGV infections in the cases of PHC, hemodialysis, liver or kidney transplantation (Table 3)

Table 3 HGV infections in the cases of PHC, hemodialysis, liver or kidney transplantation

	n	Anti-HGV	HGV RNA in anti-HGV (+) cases
Hemodialysis	61	13.11 (8/61)	37.50 (3/8)
PHC	41	4.80 (2/41)	100.00 (2/2)
Liver transplantation	3	33.30 (1/3)	100.00 (1/1)
Kidney transplantation	53	1.82 (1/53)	0
Total	158	7.5 (12/158)	50.00 (6/12)

HGV infections in the patients with hemopathy

Anti-HGV was detected in 6 (11.7%) out of 51 cases with hemopathy, among them, 4 cases with acute or chronic leukemia, one with aplasia anaemia and one with leukopenia. No HGV RNA was assayed in six anti-HGV positive cases.

HGV infections in the patients with viral hepatitis (Table 4)

Table 4 Positive rates of anti-HGV and HGV RNA in patients with viral hepatitis

	n	Anti-HGV	HGV RNA in anti-HGV (+) cases
Hepatitis A	35	14.29 (5/35)	20.00 (1/5)
Hepatitis B	214	17.29 (37/214)	35.14 (13/37)
Hepatitis C	62	14.52 (9/62)	55.56 (5/9)
Hepatitis E	25	4.00 (1/25)	0
Hepatitis NA-E	15	26.67 (4/15)	50.00 (2/4)
Total	351	15.05 (56/351)	37.50 (21/56)

The positive rates of anti-HGV and HGV RNA did not correlate with the sex, age, duration, and severity of diseases. The mean levels of ALT and T-Bil in patients

with hepatitis B whose anti-HGV was positive were higher than those whose anti-HGV was negative.

DISCUSSION

HGV is a new pathogenic agent which was discovered in 1995, its genome structure resembles other flaviviruses containing a positive, single plus-strand RNA^[1,2]. It has been demonstrated that the distribution of HGV is global^[1,2,6-14]. The transmission route of HGV is similar to that of HBV and HCV^[1,3,4,11,12]. The investigation on HGV infection rates in Hubei Province of China showed that the infection rates of HGV in cases with viral hepatitis, hemodialysis, hemopathy, transplantation, intravenous drug users (IVDU) and prostitutes were 15.05%, 13.11%, 16.7%, 9.1% and 14.43%, higher than that in healthy controls (1.82%). The result indicates that HGV infection is common in China.

The infection rate of HGV in drug users varies widely on different documents with a range from 23.8% to 77.4%^[7,18-20]. However, there is no controversy regarding the fact that drug addiction is a high risk factor for HGV infection. We found that the positive rate of HGV RNA in IVDU was higher than that in oral drug users (12.82% vs 2.97%, $P < 0.05$). This suggests that the unsterilized injections contribute to HGV transmission among IVDU.

It is known that sexual contact is a common route for horizontal transmission of HBV, HCV and HDV. Recently, sexual transmission of HGV has been demonstrated^[18,21-25]. Our survey found that most of the prostitutes were also addicted to drugs, this may be one of reasons that they had a high HGV infection rate. HGV infection was found in 15.05% of patients with viral hepatitis. This is much higher among the blood donors in the same geographic area. However, there may be bias in this statistical inference, since blood donors who are found to be positive for HBsAg or for anti-HCV through screening programs are told not to donate blood. Thus, the low prevalence of HGV infection may represent a selection bias. This viewpoint was demonstrated by Handajani *et al*^[14].

No agreement has been reached on the pathogenicity of HGV. Most of the recent investigations show that HGV infection in patients with hepatitis B and hepatitis C is not associated with any changes in indices of liver diseases, including serum ALT level, Knodell score or histology activity index (HAI)^[25-28], and the consequences of hepatitis^[27,29]. However, some reports including this paper found that HGV infection was associated with liver damage, even fulminant hepatitis^[31,32]. So further prospective studies are needed to demonstrate its relative significance in causing hepatitis and other diseases.

High infection rates of HGV were also discovered in patients with hemodialysis, PHC, and transplantation. This result may be associated with the more transfusions received by these cases than healthy persons.

A conclusion which can thus be drawn from this study

is that HGV infection is common in this area, and the drug users, prostitutes, transplant recipients, blood donors, patients with hemopathy, hemodialysis, and liver diseases are high risk groups for HGV infection.

INTRODUCTION

Calmodulin (CaM), widely distributed in almost all eukaryotic cells, is a major intracellular calcium receptor responsible for mediating the Ca^{2+} signal to a multitude of different enzyme systems and is thought to play a vital role in the regulation of cell proliferative cycle^[1,2]. Recently, many studies showed that CaM is also present in extracellular fluid such as cell culture media and normal body fluid and has been reported to stimulate proliferation in a range of normal and neoplastic cells, apparently acting as an autocrine growth factor^[3-11]. In 1988, Crocker *et al* reported for the first time that addition of extracellular pure pig brain CaM could promote DNA synthesis and cell proliferation in K₅₆₂ human leukaemic lymphocytes^[7]. After that, more and more research was done on extracellular CaM and evidences demonstrated that extracellular CaM could also stimulate cell proliferation in normal human umbilical vein endothelial cells^[5], keratinocytes^[4], suspension-cultured cells of Angelica Dahurica, etc^[6]. CaM is a monomeric protein of 148 amino acids that contains four homologous Ca^{2+} binding domains. CaM has been highly conserved throughout the evolution. Only 1 out of 148 amino acids of human CaM is different from that of fish CaM. Complementary DNAs encoding rat, eel, chicken, human, and trypanosome CaM have been cloned.

In this paper, we describe the expression and purification of recombinant human CaM (rhCaM) and the

role of extracellular rhCaM in SP2/0 mouse myeloma cell proliferation.

MATERIALS AND METHODS

Construction of expression plasmid

PCR amplification was used for the insertion of the coding sequence of human CaM III (hCaM III) between BamHI and EcoRI sites of the expression vector pBV220 (constructed by Dr. Zhang^[12,13]). The primers for PCR based on the reported sequence of hCaM III were synthesized by DNA synthesizer (Sangon). Upper primer: 5'-CGGAATTCATATGGCTGACCAGCTGAC-3', containing EcoRI restriction site. Down primers: 5'-CGGGATCCTTACTTTGCAGTCATCA TC-3', containing BamHI restriction site. The vector pUC/hCaM III (a generous gift from Dr. Strehler EE^[14]) was used as template. PCR amplifications were performed on a thermocycler (PE 9600). The PCR conditions used were 95°C for 1 min, 58°C for 1 min, 72°C for 1 min, for 30 cycles. The product was a single band of about 400 bases detected by 1.2% agarose gel electrophoresis. After purifying the PCR product by High Pure PCR Product Purification Kit (Boehringer Mannheim) and isolating the vector pBV220 by the Wizard Plus Minipreps DNA Purification Kit (Promega), the amplified gene fragments of hCaM III digested with EcoRI and BamHI were ligated into the pBV220 vector that had been previously digested with the same enzymes. The recombinant construct (pBV220/hCaM III) was then used to transform *E.coli* DH5 α (a generous gift from Beijing Institute of Basic Medical Sciences) competent cells by the CaCl_2 method.

Expression and purification of rhCaM

A single colony from *E.coli* DH5 α cell harboring the pBV220/hCaM III construct was used to inoculate a 5-mL LB culture. After overnight growth at 30°C, the 5 mL culture was used to inoculate a 1-L culture in LB medium and grown at 30°C for 4-6 h until the absorbance reached 0.5 at 600 nm. The bacterial culture was then induced at 42°C for additional 5 h. Stable rhCaM-expressing recombinant *E.coli* was harvested by centrifugation at 5000 r/min for 5 min. The pellets were washed twice with PBS, resuspended in 0.05 mol/L Tris-HCl buffer (pH 7.5, containing 0.25 mmol/L PMSF, 2 mmol/L EGTA and 2 mmol/L β -mercaptoethanol) and disrupted by sonication (Cyclone/Tempest IQ₂) at 100 W for 30 min with 10 s of pulse and 10 s of pulse off time. Supernatant fractions were obtained by centrifugation at 12 000 r/min for 30 min. CaCl_2 solution 0.1 mol/L was added to the supernatant to

adjust to 5 mmol/L CaCl_2 final concentration. The supernatant was applied to a Phenyl-sepharose CL-4B affinity column (Pharmacia) equilibrated with buffer I (0.05 mol/L Tris-HCl buffer, pH 7.5, 0.1 mmol/L CaCl_2), then the column was washed with buffer I followed by another wash with buffer I containing 0.5 mol/L NaCl. CaM then was eluted from the column with buffer I containing 1 mmol/L EGTA. The solution containing purified rhCaM was dialysed against ddH₂O for 48 h. The protein concentration was determined by Bradford assay. RhCaM was filtered through micropore filter membrane (0.22 μm) to remove bacteria and stored at -20°C .

SDS-PAGE and immunoblot assay

Expression and purified protein were analyzed by 15% SDS-PAGE. Gels were stained with Coomassie brilliant blue G. For immunoblot analysis, protein were separated by 15% SDS-PAGE and electroblotted on to nitrocellulose (NC) membrane (BioRad). After blotting, nonspecific protein binding sites were blocked with 3 g/L BSA in 50 mmol/L Tris-HCl, pH 8, and 150 mmol/L NaCl, 0.5% Tween 20. The NC membrane were incubated with a 1:200 dilution of anti-CaM McAb (Sigma). After washing, the membrane were incubated for 1 h with HRP conjugated goat anti-mouse immunoglobulin antibody (1:200, Boehringer Mannheim). Color development was obtained by adding DAB substrate.

Amino acid composition

The amino acid composition of purified expression product was analyzed using an automatic amino acid analyzer, Hitachi 835-5Q.

DNA sequence analysis

The DNA sequence was determined with ABI PRISM™ 377 DNA sequencer.

NAD kinase assay

The activity of CaM-dependent NAD kinase (NADK) was detected as described by Harmon^[15].

Cell culture

SP2/0 cells were cultured in RPMI 1640 medium (GIBCO), supplemented with 20% neonatal calf serum (NCS) under 37°C , 5% CO_2 conditions.

Measurement of cell proliferative rate

Cell proliferative rate was determined by MTT colorimetric assay^[16,17]. SP2/0 cells were collected at the logarithmic growth phase by centrifugation. The cells were washed twice and seeded in 96-well plate and cultured for 48 h with rhCaM and CaM-antagonist trifluoperazine (TFP). MTT 10 μL (Sigma, 0.5 mg MTT in 1 mL PBS) was added to each well of 96-well plate and cultured for another 4 h. After the formazan was dissolved with 100 μL DMSO, absorbance value of each well at 490 nm ($A_{490\text{nm}}$)

was read on a BioRad Model 550 microplate reader.

Proliferative rate = $A_{490\text{nm}}$ value of experimental group / $A_{490\text{nm}}$ value of control group $\times 100\%$. Improved proliferative rate = Proliferative rate - 100%.

RESULTS

Expression of rhCaM in *E. coli*

The results of both restriction enzyme digestion of pBV220/hCaM III and PCR identification in which pBV220/hCaM III was used as template showed a specific single band with the same molecular weight as reported hCaM gene on agarose gel (Figure 1). DNA sequence analysis also indicated that the recombinant vector had been constructed successively. After heat induction, the total extract of the *E. coli* DH5 α cell harboring pBV220/hCaM III was analyzed by 15% SDS-PAGE under reducing conditions. As shown in Figure 2, a unique protein band with an apparent molecular weight (17 000) was similar to that of standard human brain CaM. This protein accounted for over 20% of the total cellular protein. The study on solubility of expression protein indicated that CaM protein was expressed predominantly in the soluble form. Western blot analysis showed that anti-CaM McAb specifically bound to the 17 000 band of expression product. The expression product purified by phenyl-sepharose CL-4B affinity chromatography was shown as a single band on agarose gel by SDS-PAGE. The protein concentration was determined by Bradford method and approximately 3-4 mg of the purified protein were obtained from 1 L of bacterial culture.

CaM. The acidic amino acid (such as Asp and Glu) composition was about 30% or more.

NAD kinase assay

The results of NAD kinase (NADK) assay showed that purified rhCaM was able to activate CaM-dependent NADK activity to the same extent as the standard human brain CaM (Sigma, Figure 3).

Figure 3 Activation of NADK by rhCaM.

Effect of extracellular rhCaM on cell proliferation

Cells were diluted with RPMI 1640 (containing 0.5% NCS) to $1-5 \times 10^5/\text{mL}$ and seeded in 96-well plates. rhCaM was added to the final concentration of 0.1-10 $\mu\text{g}/\text{mL}$ and each concentration was triplicated. Cells were incubated with different concentrations of rhCaM under 37°C, 5% CO_2 conditions for 48 h prior to MTT assay. The effect of extracellular rhCaM on cell proliferation was investigated (Figure 4). Evidence indicated that rhCaM within a certain concentration (0.1-7.5 mg/L) could stimulate cell proliferation. The stimulatory effect declined

when the rhCaM concentration was higher than 10 mg/L . Effect of a addition of pure rhCaM was also dependent in some degree upon the cell density of the initial culture. For a certain CaM concentration, the lower the cell density of the initial culture, the higher the promoting effect. Moreover, the effect of exogenous rhCaM was also influenced by the amount of NCS added to the culture medium. When NCS in medium accounted for 0.5%-1%, a significant stimulatory effect could be observed. However, when NCS in medium was increased to 2%-10%, no stimulatory effect was observed for rhCaM (data not supplied).

Figure 4 The effect of extracellular rhCaM on cultured SP2/0 cells.

Inhibitory effect of TFP on cell proliferation

Cells were seeded in 96-well plates as above. CaM-antagonist TFP (Sigma) was added to the final concentration of 0.025-250 $\mu\text{mol}/\text{L}$. Each concentration was done in triplicate. Cells were incubated with TFP under 37°C, 5% CO_2 conditions for 48 h and determined by MTT assay. Results indicated that addition of various concentrations of TFP to cell culture medium could significantly inhibit cell proliferation rate and the inhibitory effect strengthened with increase in the concentrations of TFP (Figure 5).

Effect of extracellular rhCaM on TFP-inhibited cells

TFP was added to the SP2/0 cell ($1 \times 10^5/\text{mL}$) culture medium until the final concentrations were 25 $\mu\text{mol}/\text{L}$. Cells were cultured in 5% CO_2 incubated under 37°C for 6h, washed twice with RPMI 1640, then seeded into 96-well plate at the density of $1 \times 10^5/\text{mL}$. Various concentrations of rhCaM were added and cells were cultured for 48 h. Results demonstrated that addition of rhCaM could alleviate the inhibitory effect of TFP. rhCaM 5 mg/L could offset the inhibition almost to normal (Figure 6).

DISCUSSION

CaM, a heat-stable, acidic and multifunctional calcium-binding protein, exists in almost all eukaryotic cells. On the gene level, a multigene family of three maximally

Figure 5 The inhibitory effect of CaM-antagonist TFP on cell proliferation.

Figure 6 The effect of extracellular rhCaM on TFP-inhibited cells.

divergent members is responsible—at least in mammals—for the generation of the single CaM protein with the same amino acid sequence. Three human CaM cDNAs called hCaM I, hCaM II, and hCaM III have been cloned^[14,18-23]. In this paper we described the construction of expression plasmid for human CaM III gene and expression of hCaM protein in *E. coli*. About 3-4 mg of purified rhCaM was obtained from 1 L of *E. coli* culture. This level of production is higher than that achieved by the classic purification method. If the genetic engineering techniques are used for a large scale expression, the product can be much higher.

It is well known that intracellular CaM plays an important role in the regulation of cell proliferation. The levels of intracellular CaM and CaM mRNA vary during cell cycle and accelerate cell proliferation. Moreover, CaM antagonists TFP, W₇, W₁₃ and anti-CaM antibodies can block the effect of CaM and arrest cell cycle at G₁/S boundary^[24-27]. In the last few years, extracellular CaM was detected and evidence accumulated that extracellular CaM could also affect cell proliferation.

In our study, effects of purified rhCaM and CaM antagonist TFP on SP2/0 proliferation rate were examined. The results revealed that certain concentrations of extracellular rhCaM (0.1-7.5 mg/L) could stimulate cell

proliferation in a dose-dependent manner and the stimulatory effect was dependent upon the cell density of the initial culture. The lower the cell density, the higher the stimulatory effect. The results are consistent with previous literature^[4-7]. TFP inhibited cell proliferation and the inhibition could be alleviated by addition of extracellular rhCaM, which further supports that extracellular CaM could accelerate cell proliferation. CaM was also detected in many extracellular body fluids such as breast milk, saliva and serum. Serum, which is necessary for the successful culture of many cell types, contains high levels of CaM which could amount to 0.9-8 mg/L^[28]. This might explain why the effect of CaM was influenced by NCS added to culture media. While CaM could facilitate cell proliferation, compared with NCS, the effect of CaM was less important.

So far, how extracellular calmodulin achieves its effects is yet unclear. Evidence indicates that the mechanisms may be as follow: (1) CaM can interact with some cell proliferation-related factors such as epidermal growth factor (EGF), transforming growth factor (TGF) and platelet derived growth factor (PDGF). It is possible that extracellular CaM exerts its effects by strengthening these factors' binding to their membrane receptors. It was reported that EGF receptor contained a CaM-binding domain^[29] and the binding of EGF to cells could be inhibited by CaM antagonist^[30]. Mac Neil *et al* showed that there was a significant positive correlation between CaM level and EGF concentrations in normal body fluids, indicating that CaM together with EGF, TGF, PDGF etc may be members of a functionally co-ordinated group of mitogens^[28]. (2) CaM may directly interact with CaM-binding proteins (CaMBPs) on cell membrane. CaMBPs were found to exist on cell wall of wheat coleoptiles^[31]. Extracellular CaMBPs were also detected in the suspension-cultured cells of *Angelica Dahurica* and carrot^[32]. CaMBP is a kind of glycoprotein which can bind with CaM and may function as a bridge between CaM and intracellular metabolic processes.

INTRODUCTION

Site-specific delivery of therapeutic drugs to their target cells is a major scientific challenge for the pharmaceutical sciences. It offers a number of advantages over conventional drug administration. With drug targeting, high local concentrations of the drug can be achieved, thus circumventing many unwanted side effects. Various carriers have been suggested for the delivery of drugs, including liposomes^[1-5] and (neo) glycoproteins^[6-8]. The asialoglycoprotein receptor (ASGP-R) has frequently been utilized for targeting drugs to the parenchymal liver cell^[6-12]. Liposomes have several advantageous characteristics as drug carrier, and particularly, ligand-tacked liposomes achieve a highly effective targeting^[13]. Hara *et al* reported that asialofetuin (AF)-tacked liposomes distributed to rat hepatocytes selectively *in vivo*^[14], and ASGP-R mediated the uptake of AF-liposomes encapsulating IFN- γ by isolated rat hepatocytes *in vitro*^[15]. Lactosaminated human serum albumin (L-HSA) is a neoglycoprotein taking number of galactose residue as terminal sugar^[6].

In this paper, we studied the preparation and rat hepatocyte uptake of the conjugate of L-HSA and liposomes, and the inhibitory effect of L-HSA-liposomes containing IFN- α on replication of hepatitis B virus (HBV) on 2.2.15 cells line.

MATERIALS AND METHODS

Materials

Sodium cyanoborohydride was purchased from Aldrich, Chemical Co., Milwaukee, WI, USA, α -lactose,

phosphatidylcholine (PC), cholesterol (Chol), and N-succinimidyl-S-acetylthioacetate (SATA) were obtained from Sigma, St. Louis, MO, U.S.A. Maleimido-4-(p-phenylbutyryl) phosphatidylethanolamine (MPB-PE) was purchased from Avanti Polar lipids, Birmingham, AL, USA. Dulbecco's modified eagle medium, penicillin and streptomycin were obtained from GIBCO, Grand Island, NY, USA. MTT was from Boehringer Mannheim, Germany. Fetal calf serum was a product of Hyclone, USA. Other reagents were of analytical grade.

Methods

Lactosamination of human serum albumin

Lactosamination was performed according to Schwartz & Gray^[16]; human serum albumin (HSA) 500 mg was allowed to react at 37°C with 1.0 g α -lactose and 1.0 g NaBH₃CN in 20 ml 0.05 mol/L potassium phosphate buffer solution (PBS), pH 8.0. The reaction was continued for 144 h. And the mixture was dialysed against double distilled water. The lactose content of lactosaminated human serum albumin (L-HSA) was determined by the phenol-sulphuric acid method of Dubois *et al*^[17].

Liposomes preparation PC, Chol, and MPB-PE were mixed in a molar ratio of 23:16:1 and dissolved in ether, dried by a rotary evaporator, dissolved in HN-buffer (10 mmol/L HEPES, 135 mmol/L NaCl, pH 6.7) and lyophilized. Phospholipid phosphorus of liposome preparation was measured by phosphate assay after perchloric acid destruction. Conventional liposomes were prepared with PC and Chol in a molar ratio of 23:16.

Coupling of L-HSA to MPB-PE containing liposomes (MPB-liposomes)

L-HSA was coupled to MPB-liposomes by a sulfhydryl-maleimide coupling technique according to Derksen *et al*^[18]. Using SATA as a heterobifunctional reagent, free sulfhydryl groups were introduced in L-HSA^[19]. After separation of SATA from the protein by Sephadex G-25 gel permeation chromatography, the acetylthioacetate-L-HSA was deacetylated by a freshly prepared solution of 0.5 mol/L hydroxylamine-HCl, 0.5 mol/L HEPES, 25 mmol/L EDTA, pH 7.0. After deacetylation, the thioacetyl-L-HSA was allowed to react with the MPB-PE containing liposomes for 4 hours at room temperature, in a ratio of 3 mg of protein per mg liposomes. N-ethylmaleimide was added to cap un-reacted sulfhydryl groups. Liposomes were separated from unconjugated protein by Sepharose 4B

infiltration. The L-HSA- liposomes conjugates were characterized by determining protein and phospholipid phosphorus content, lyophilized, and stored at 4°C.

Tissue distribution of L-HSA-liposomes L-HSA-liposomes were labeled with ^{131}I by Iodogen's method. Male Sprague-Dawley rats weighing 200-250 g were anaesthetized by intraperitoneal injection of 20-25 mg sodium pentobarbital. Radiolabeled liposomes were injected via the penile vein and the abdomen was opened. At the end of the experiment, liver lobules and other tissues were removed and weighed. Radioactivity was determined by γ -counter. And the results were registered as cpm per gram tissue.

Inhibitory effect of L-HSA-liposomes encapsulating interferon- α on HBV replication To assess the effects of L-HSA- liposomes encapsulating interferon- α on HBV replication, 2.2.15 cells were plated at a density of 2×10^5 per 17 mm culture dish and pre-incubated in Dulbecco's modified eagle medium containing 10% fetal calf serum for 24 h. After being washed with phosphate -buffered saline, they were cultured at 37°C for 12 d, with fresh medium changed every 3 d supplemented with L-HSA-liposomes encapsulating interferon- α (LL-IFN), conventional liposomes encapsulating interferon- α (CL-IFN), and free interferon- α (IFN) at an appropriate concentration. The culture medium was collected every 3 days and the cells were used in subsequent experiments. The viability of cells was examined spectrophotometrically by the MTT methods, and the cytotoxicity of the compounds was also monitored by the MTT assay.

RESULTS

Synthesis and characterization of L-HSA-liposomes

Having reacted with lactose, the HSA and lactose mixture was dialysed against water for 3 days. There was no lactose in the final dialysis solution, suggesting the L-HSA had been purified completely. Each HSA molecule was modified with about 17 molecules of lactose. When L-HSA was coupled to MPB-liposomes, the amount of L-HSA that could be coupled to 1 μmol MPB-liposomes was 538.7 μg . A number of about 107 000 L-HSA molecules per liposome particle were calculated, assuming that the molecular weight of L-HSA was 7 600 and the average diameter of MPB-liposomes was 400 nm. The liposomes conjugate was stored at 4°C for at least 8 weeks and filtered by Sepharose 4B. The infiltration figure showed as a single absorbing peak, suggesting that the liposomal conjugate was stable at 4°C.

Tissue distribution of L-HSA-liposomes

Forty minutes after i.v. injection of ^{131}I labeled L-HSA-liposomes, radioactivity in liver was higher than the other organs ($P \leq 7.84 \times 10^{-6}$) (Table 1). Spleen uptake of L-HSA-liposomes was less than half of that of liver, and the uptake by kidney, heart, and lung was 1/4 to 1/9.

When L-HSA was pre-injected, the liver uptake decreased significantly, showing no statistic difference with spleen ($P = 0.38$) (Table 2). However, ^{131}I labeled L-HSA-liposomes uptake was also observed in the other organs.

Table 1 Tissue distribution of ^{131}I -labeled L-HSA-liposomes in rat

Rat No.	Tissue distribution <i>in vivo</i> (cpm per gram tissue)

LL-IFN 0.01 MU	0	4.8	15.4	5.2

IFN: interferon; CL-IFN: interferon entrapped in conventional liposomes; LL-IFN : interferon entrapped in L-HSA-liposomes.

Compared with LL-IFN 0.08 MU: ^a $P = 0.003$, ^b $P = 0.015$

Anti-HBV activity of L-HSA-liposomes encapsulating interferon- α

Table 3 shows the antiviral activity of L-HSA-liposomes encapsulating interferon- α tested against HBV *in vitro*. The liposomes and L-HSA-liposomes did not show any anti-

HBV effect. However, when entrapped in L-HSA-liposomes, interferon was 3 to 5 times more effective against HBV replication in 2.2.15 cells than CL-IFN and IFN (*P* value was 0.015 and 0.003, respectively). To achieve similar antiviral effects, the dose of LL-IFN was only 1/4, 1/8 of CL-IFN and IFN, respectively. The treatments did not appear to be cytotoxic to 2.2.15 cells at the concentrations used in the anti-HBV assay.

DISCUSSION

Worldwide, HBV infection is the main cause of chronic liver disease. HBV carriers are at risk for chronic hepatitis, cirrhosis, and hepatocyte carcinoma. Previous studies have indicated the correlation of HBVX gene to hepatocyte carcinoma^[20]. An effective treatment for HBV infection is therefore urgently needed. Interferon- α , nucleotide analogs, Chinese medicinal herbs, and other immunological approaches have shown promising results in a subset of patients treated for prolonged periods^[21-24]. But overall response rates have been unsatisfactory. Selective drug delivery to the parenchymal liver cell by drug conjugation to a carrier would improve curative effect, reduce therapeutic dosage and side effects of drugs. In this report we describe the preparation of a liposomal drug carrier system, which could target the therapeutic drug to liver via the asialoglycoprotein receptor. Lactose was coupled to human serum albumin by reductive lactosamination in the presence of sodium cyanoborohydride. Then L-HSA was covalently coupled with liposomes using the heterobifunctional reagent N-Succinimidyl-S-acetylthioacetate. This is a well established method for coupling proteins to liposomes, based on the reaction of thiolated proteins and liposomal maleimido-4-(*p*-phenylbutyryl)phosphatidylethanolamine^[10]. Thiolation of L-HSA, in which about 17 of the free ϵ -amino groups of lysine were derivatized with lactose, still allowed the introduction of several sulfhydryl molecules in this protein. This indicates that SATA is suitable for coupling derivatized protein to liposomes.

Mammalian liver contains a unique asialoglycoprotein receptor responsible for the rapid serum clearance and lysosomal catabolism of desialylated glycoproteins bearing terminal, non-reducing galactose residues. Previous studies demonstrated that, for bovine serum albumin, at least 13 lactosyl groups were needed for high affinity recognition by the ASGP-R^[25]. In our study, about 107 000 molecules L-HSA per liposome were coupled, and each HSA molecule was modified with 17 lactose molecules, hence the liposomal conjugate had a high affinity to ASGP-R. The *in vivo* study indicated that the liver uptake of liposomal conjugate was higher than other organs, which was about 2 times higher than that of spleen, and 4 to 9 times higher than kidney, heart, and lung. L-HSA pre-injection almost prevented the selective liver delivery of liposomal conjugate, suggesting that the galactose-specific nature of hepatic uptake. Modified with 17 lactose molecules, L-HSA was capable of inhibiting the hepatic uptake of

liposomal conjugate, owing to the high affinity for the hepatic galactose-recognizing receptor. Another study also showed that liposomes modified with several galactose residues had a similar liver targeting^[26].

2.2.15 cell is a stable expression system of transfected HBV DNA, which could produce HBV particle, and is often taken as a cell model for screening anti-hepatitis B virus drugs^[27,28]. Interferon had the inhibitory effect on HBV replication in this system^[29]. Wu *et al.*^[30] proved that this system contained ASGP-R. *In vitro*, interferon- α entrapped in liposomal conjugate had a higher activity against HBV free than interferon and than interferon entrapped in conventional liposomes. To achieve similar antiviral effects, the doses of LL-IFN capable of inhibiting virus growth were 4 to 8 times less than that of CL-IFN and IFN.

In conclusion, the results obtained in this study indicated that the conjugate of lactosaminated human serum albumin and liposomes achieved good liver targeting, and allowed the development of a potent liver-targeting drug carrier system.

Intestinal acariasis in Anhui Province

Chao Pin Li and Jian Wang

Subject headings mite infestation; intestinal diseases, parasitic; epidemiology; data collection; tick control; leukocytes count

Li CP, Wang J. Intestinal acariasis in Anhui Province. *World J Gastroentero*, 2000;6(4):597-600

INTRODUCTION

The mites found in stored food and house comprise a large group of subclass Acari, belonging to the suborder Acaridida of the order Acariformes. They can be found in dust and vacuum samples from floors, furniture, mattresses, Chinese herbal medicine, dry fruit, grain, flour, sugar, and bedding. These mites are nidicolous and feed on organic debris, including sloughed human skin, fungi, spilled food, pollen, etc. These mites are particularly prevalent in Chinese herbal medicine, dry fruit, grain, flour, sugar, beds, though carpeted floors near beds or couches may also have large numbers. The most common species are *Acarus siro*, *Tyrophagus putrescentiae*, *Dermatophagoides farinae*, *D. pteronyssinus*, *Glycyphagus domesticus*, *G. Ornatus*, *Carpoglyphus lactis* and *Tarsonemus granarius*, etc. The viability of mites in storage is quite strong and they can invade and parasitize the intestines of humans^[1-15]. They can cause pulmonary acariasis^[16-25], urinary acariasis^[26-33] and so on. The dejecta of mites is a quite strong allergen and can cause different allergic diseases^[34-44]. Intestinal acariasis can be caused by some mites related to the way of diet intake and invading against intestinal mucosa, intestinal muscle^[45-58]. The first report of intestinal acariasis caused by these mites was made by Hinman *et al* (1934)^[45]. From then on, all kinds of studies on the disease have been reported gradually. In order to make an epidemiological survey of intestinal acariasis the investigation of the disease was taken in some areas of Anhui Province from 1989 to 1996.

MATERIALS AND METHODS

Materials

The site of investigation was in the Chinese traditional medicine storehouses, factories and rice storehouses, rice mills, primary schools and so on, the subjects of investigation were sellers of the traditional Chinese medicine, workers of granary and processing, primary school pupils in grades 1-6 and 152 patients with diarrhea who sought medical advice and workers in certain processing factories.

Methods

Case history Included the history of present illnesses, the history of past illnesses, the patients' occupation.

Feces examination First, the stool of the subject was collected in disposable feces boxes. Secondly, mites were separated by saturated saline flotation methods and identified with the help of microscope.

Blood examination Differential leukocyte counting was made in patients who had positive results of feces mite examination.

RESULTS

The rate of detection of mites in stool and clinical symptoms

The total number of samples of feces examination were 3416 (male 1879, female 1537), the positive number of mites in stool were 225 (male 128, female 97) and the detectable rate of mite was 6.59% (male 6.81%, female 6.31%). Among them, the samples of feces examined in the groups of age 5-14, 15-24, and >24 were 1829 (5.74%), 508 (3.54%), 927 (6.36%) respectively. There were 43 positive samples in 152 patients with diarrhea who were suspected to suffer from intestinal acariasis, the detectable rate was 28.29%. Of the 225 mite positive cases observed after stool examination, the detectable number of mite cases together with other intestinal parasites was 131, the number of cases with only mite symptoms was 94.

Results of analysis of digestive canal symptoms in 30 cases positive of mites: all one in stool showed that the number of patients with diarrhea, abdominal pain, abdomen discomfort, mucous stool, pus and blood stool, burning sensation of anus were 26 (86.67%), 20 (66.67%), 19 (63.33%), 15 (50.00%), 13 (43.33%), and 14 (46.67%) respectively. Besides, some of the patients were accompanied with the symptoms of hypodynamia, mager'sucht, lassitude, asthma, vomiting, anorexia, low fever, dysphoria, general

malaise, etc.

Mites seperated from stool

The detectable rates of adult mites, larval mites, both adult and larval nutes, both adult mites and eggs, adult and larval mites and eggs, both larvel mites and eggs, and both hypopus and eggs were 44.00% (99), 10.22% (23), 34.67% (78), 2.67% (6), 4.89% (11), 2.22% (5), and 1.33% (3) respectively. The population identification analysis showed that there were *Acarus siro*, *Tyrophagus putrescentiae*, *Dermatophagoides farinae*, *D. pteronyssinus*, *Glycyphagus domesticus*, *G. Ornatus*, *Carpoglyphus lactis* and *Tarsonemus granarius* in stool. Furthermore, the hypopus of mites could be found. The statistics of this investigation showed that the concentration of mites with a count of 1-2/cm³, 2-4/cm³, >5/cm³ was 11, 55, 159 respectively.

Blood examination

Among the 30 patients, differential leukocyte count in most cases was $(5.55-10.4) \times 10^9/L$ with the exception of 4 cases $[(11.0-12.9) \times 10^9/L]$. The eosinophilic granulocyte count was high $[(0.32-0.78) \times 10^9/L]$. The average value of constituent ratio of eosinophilic granulocyte was 0.09 (0.04-0.11) and was higher than that of normal control ($P < 0.01$).

The rate of detection in different occupations

The field investigation showed that different rate of invasion existed in different occupations. The detectable rates of mites in stool were 6.71% (20/298), 6.59% (89/1350), 6.14% (98/1596), 4.17% (5/120) and 25.00% (13/52) in herb stuff processors and sellers, food storage and processor workers, primary school pupils, machinery workers, and some others.

Anamnesis

Among the 30 patients with obvious symptoms, the total misdiagnosis rate was 63.33%. The patients who had been misdiagnosed for chronic colitis, allergic enteritis, intestinal neurosis, amebiasis, hookworm disease, ascariasis, chronic appendicitis, pelvic inflammation, metroendometritis, intestinal adhesion, and chronic diarrhea were 2, 5, 3, 1, 1, 1, 2, 1, 1, 1, and 1 respectively.

Mites seperated from work environment

Different breeding mites were separated from the samples of work environment and food. Collecting the samples of mill floor dust (30 shares), stores of traditional Chinese medicine, and traditional Chinese herbs (146 species) of wolfberry fruit, ophiopogon root, liquorice, boat-fruited sterculia seed, safflower, and so on. The results showed that the number of breeding mites per gram were 91-1862, 21-186, 0-483, 10-348, 51-712, and 311-1192, in mill floor dust, traditional Chinese medicine stores, traditional Chinese herbs such as candied fruit, dry

fruit, brown sugar, and expired cake. Twenty-six species of mites could be identified out of them (most of them were unidentifiable), and belonged to nine families of Acaridae, *Carpoglyphidae*, *Glycyphagidae*, *Pyroglyphidae*, *Histiostomidae*, *Chortoglyphidae*, *Lardoglyphidae*, *Tarsonemoidae* and *Cheyletidae*. The results of this study showed that the mites separated from work environment were identical to those from stored food.

DISCUSSION

The main pathogenic mites have been verified as *Acarus* and *Tarsonemidae* by Zuo Zuoxue (1951). However, most of the mites causing intestinal acariasis that have been confirmed by Li Yousong (1980), Zhou Hongfu (1986), Li Chaopin (1987)^[56] *et al*, belong to 6 families Astigmatid order like, *Acaridae*, *Carpoglyphidae*, *Glycyphagidae*, *Pyroglyphidae*, and *Tarsonemidae*. The results of our investigation are in basic agreement with the views that had been previously reported. With regard to the path of infection of intestinal acariasis, the general idea was that the infection of the disease was caused by the mites coming from stored and swallowed food^[50-58]. Our study has verified that mites separated from stool were identical to those from storage, and belonged to common species of mites in our living environment and stored food. With the help of dust sampler, eight sampling sites were set up in a traditional Chinese medicine plant. Thirteen mites (adult 9, larval 4) were separated from the 640 L volume of air in the work environment of the plant. Thus another path of infection may be through respiration and swallowing of the mites in the air. The results of our study also showed that intestinal acariasis was associated with the hobby of drinking of tea, including ophiopogon root, liquorice, boat-fruited sterculia seed; and eating dry fruit, including da teplum persimmon, preserved fruit, candied fruit, dried persimmon, and even dried flesh of fish. Previous reports^[45-58] and the conclusions of this study verify that the disease is associated with breeding of mites in the diet, work environment, and stored food; but unassociated with age or sex.

The vitality of some mites causing intestinal acariasis is quite strong. The study report of Kodama *et al*^[48] had confirmed that the mites could live in 10% formalin for 12 days and then oviposit after two weeks, they could live in stool for 83 days and then oviposit and hatch to larva. In our study, twenty mites were soaked in distilled water at the temperature of 20-25°C, and another twenty in running water at room temperature for 7 weeks. The results showed that the mites collected from the bottom of the test tubes were all alive. After the stool with *Acarus siro* had been stored in a sealed plastic bag for 7 weeks, active mites could still be found. Kampmeier's report verified that not all mites could be killed by gastric acid or digestive juices^[49]. Mites could be found alive by differential leukocyte count.

After mites came into the intestinal tract, mechanical stimulation and injuries of tissues were caused by the

gnathosoma, chelicera, feet, and so on^[59]. The dejecta, products of metabolism, and cleaved body parts of mites could cause different allergic reactions of the digestive system, such as abdominal pain, diarrhea, burning sensation of anus, and so on. The reports in past have shown that the dejecta, metabolites, cleaved body parts were all quite strong allergens and could result in high levels of eosinophilic granulocytes, total IgE, special IgE for mites in serum. The clinical manifestation of this was allergic urticaria, allergic rhinitis, allergic asthma *et al*^[34-44]. The results of our studies showed that the levels of eosinophilic granulocytes in patients with intestinal acariasis were high too. Its possible mechanism could be similar to that of the allergic reaction caused by other mites. The intestinal acariasis may not only cause injury of the intestinal mucosa and invade the intestinal muscle but also stimulate the immune system by the dejecta, metabolites, and cleaved body of the mite itself. The disease may be easily misdiagnosed for allergic enteritis, chronic colitis, intestinal neurosis, amebiasis, pelvic inflammation, or schistosomiasis japonica^[60]. As a result, proper treatment might be thus delayed.

Study of T-lymphocyte subsets, nitric oxide, hexosamine and *Helicobacter pylori* infection in patients with chronic gastric diseases

Hui Zhang¹, Shu Lin Jiang¹ and Xi Xian Yao¹

Subject headings stomach disease; T-lymphocyte; nitric oxide; *Helicobacter pylori*; hexosamine; Helicobacter infections; gastric mucosa

Zhang H, Jiang SL, Yao XX. Study of T-lymphocyte subsets, nitric oxide, hexosamine and *Helicobacter pylori* infection in patients with chronic gastric diseases. *World J Gastroentero*, 2000;6(4):601-604

INTRODUCTION

Chronic gastritis (CG) and peptic ulcer (PU) are frequently-occurring diseases. It is now well recognized that *Helicobacter pylori* (Hp) is a major factor that leads to CG and PU^[1-8]. In order to study the relationship among T lymphocyte subsets, NO, Hexosamine and Hp infection in patients with chronic gastric diseases, the levels of blood T lymphocyte subsets, plasma NO and hexosamine in gastric mucosa were measured respectively in 30 patients with CG and 32 patients of PU+CG.

MATERIALS AND METHODS

Clinical materials

Thirty-two patients with PU and CG (23 males and 9 females, aged 20 to 68 years, mean age 43.2) and 30 patients with CG (18 males and 12 females, aged 24 to 66 years, mean age 44.3) were enrolled in the study. Twenty healthy people with comparable ages acted as control. All subjects were excluded of hepatic and other diseases.

Methods

Vein blood 2 mL from each fasted patient was obtained for blood T lymphocyte subsets and NO determinations. Four gastric biopsies were taken from gastric antrum 3 cm from pylorus (2 from curvatura ventriculi minor and the other 2 from ante-wall) for Hp, pathology and hexosamine determinations. T-lymphocyte subsets were determined by FCM methods (FACS 420, by Becton-Dickinson

Company, U.S.A.). Laser light source was 2 Wargon ionic laser, wavelength 488 nm. The emerging green fluorescence by FITC was used for fluorimetry by 520 nm long filter disc. The data were processed by an HP-300 computer programme. Hp infection was diagnosed if any two of the following methods were positive: (1) rapid urase test (test kit procured from San Qiang Company); (2) gastric mucosa smear with gram's stain. The Hp density gradients were according to Monshoy staging grades: 0, free; I, a few; II, obvious (in all fields of microscopy); III, plenty or piled; (3) Warthin-Starry stain of gastric mucosa.

Pathology

HE stain was used for observing mucosal inflammation. The severity of gastritis was graded as: mild: infiltrated inflammatory cells only at gastric pit or intestinal villas; moderate: infiltrated cells in gland lamina propria; and heavy: infiltrated inflammatory cells in muscular layer of mucosa. Determination of hexosamine: two gastric biopsies were ground into 1 mL liquid, centrifuged it, and supernatant was kept at -20°C for measuring. Protein content in supernatant was measured by taking 20 µL sample and 500 µL Coomassie brilliant blue G250 reagent at the wavelength of 600 nm by automatic analysis apparatus. 0.5 mL of the supernatant and 0.5 mL enriched hydrochloric acid were mixed together at high pressure (147 KPa) for 30 min, put into 0.5 mL NaOH (8.3 mol/L) and acetyl acetone solution, boiled for 15 min and cooled, and then analyzed. The results were expressed as mg/mL. Hexosamine was calculated as following: hexosamine = supernatant hexosamine (mg/mL)/supernatant protein (g/L). NO measurement: (1) pre-measurement: Took 200 µL plasma and the same amount of a cetone nitrile, shook them, and centrifuged for 10 min (5000 r/min), repeating once again as above, taking 10 µL of supernatant overflow for measurement. Baseline 810 high effect liquid phase apparatus, made by Waters Company, U.S.A. and 486 outer purple detector were used. Conditions of chromatostrip included: mobile phase 2.5 mmol/L LiOH water solution +50 g/L acetonitrile, velocity of flow 1.2 mL/min, column temperature 40°C, detection wavelength 214 nm, analysis column IC-Pak Anion, 4.6 mm × 5 cm (Waters Company, U.S.A.), detection time 10 min.

RESULTS

T-lymphocyte subsets in CG patients

Total lymphocyte (CD_3^+), helper lymphocyte (CD_4^+), suppressor lymphocyte (CD_8^+), CD_4^+/CD_8^+ in CG patients were significantly lower than those of normal control ($P < 0.05-0.01$, Table 1). Eighteen out of 30 CG patients had *Hp* infection (60%). CD_3^+ , CD_4^+ in Hp^+ group were significantly decreased ($P < 0.01$, < 0.05), but CD_4^+/CD_8^+ was not significantly changed (Table 2). In addition, the study of the relationship between different pathological changes and T lymphocyte subsets indicated that: CD_3^+ , CD_4^+ , CD_4^+/CD_8^+ in severe CG were significantly decreased than those in mild to moderate CG ($P < 0.01$, < 0.05 , < 0.05 respectively, Table 3).

Table 1 T-lymphocyte subsets in CG patients ($\bar{x} \pm s$, %)

Lymphocyte	CG ($n = 30$)	Normal control ($n = 20$)
CD_3^+	60.7 ± 2.4^b	68.3 ± 3.9

^a $P < 0.05$, ^b $P < 0.01$, vs mild-moderate

Hexosamine levels

The hexosamine levels in patients with severe lesions ($38.0 \text{ mg/g} \pm 3.8 \text{ mg/g}$) were significantly lower than those with mild and moderate CG ($47.0 \text{ mg/g} \pm 7.6 \text{ mg/g}$, $P < 0.01$). The hexosamine levels in Hp^+ group were significantly lower than those in Hp^- group ($P < 0.05$, Table 4). In addition, 24 out of 32 PU+CG patients (75.0%) had *Hp* infection. The hexosamine levels in Hp^+ group were significantly lower than those in Hp^- group ($P < 0.01$, Table 4).

Table 4 Changes in hexosamine levels in CG, PU+CG patients with *Hp* infection ($\bar{x} \pm s$, mg/g)

	CG		PU + CG	
	<i>Hp</i> (+) $n = 18$	<i>Hp</i> (-) $n = 12$	<i>Hp</i> (+) $n = 24$	<i>Hp</i> (-) $n = 8$

^a $P < 0.05$, ^b $P < 0.01$, vs *Hp* (-)

Plasma NO levels

In CG, PU+CG patients, the levels of plasma NO ($2514 \mu\text{g/L} \pm 364 \mu\text{g/L}$, $2824 \mu\text{g/L} \pm 673 \mu\text{g/L}$) were significantly higher than those of normal control ($2228 \mu\text{g/L} \pm 214 \mu\text{g/L}$, $P < 0.05$, $P < 0.01$), and the level of plasma NO in PU+CG patients ($2824 \mu\text{g/L} \pm 673 \mu\text{g/L}$) was higher than those of CG patients ($2514 \mu\text{g/L} \pm 364 \mu\text{g/L}$, $P < 0.05$). The levels of NO in CG, PU+CG *Helicobacter pylori* positive group were significantly higher than in Hp^- group ($P < 0.01$, $P < 0.05$, Table 5). The study of the relationship between different pathological changes and NO levels indicates that the levels of NO in both groups with severe lesion were significantly higher than those in mild to moderate lesions ($P < 0.05$, Table 5).

Table 5 Changes in plasma NO, pathological stages and *Hp* infection in CG and PU+CG ($\bar{x} \pm s$, $\mu\text{g/L}$)

	CG	PU+CG
<i>Hp</i> (+)	2671 ± 258	3071 ± 398
<i>Hp</i> (-)	2282 ± 387	2579 ± 668
Mild-moderate	2328 ± 413	2403 ± 284
Severe	2656 ± 251	2880 ± 802

^a $P < 0.05$, ^b $P < 0.01$, vs *Hp* (-); ^c $P < 0.05$, vs severe.

DISCUSSION

As we all know, CG is closely related to *Hp* infection [9-12], but so far any report regarding the relationship between CG and T lymphocyte has not been observed. Our results showed that CD_3^+ , CD_4^+ , CD_8^+ , CD_4^+/CD_8^+ T cells in CG patients were observed to be significantly lower than in normal control. This indicated that the functioning of cellular immunity was impaired in CG patients. In order to explore the relationship between T lymphocyte subsets and *Hp* infection, this experiment divided CG patients into Hp^+ group and Hp^- group. The results showed that CD_3^+ , CD_4^+ T cells in Hp^+ group were significantly decreased showing that *Hp* infection is related to the decrease in the function of cellular immunity. In addition, the majority of the severe cases of CG (71%) had *Hp* infection, and the levels of CD_3^+ , CD_4^+ , CD_8^+ , CD_4^+/CD_8^+ T cells were significantly decreased than in mild to moderate CG patients. This implied that the impaired function of cellular immunity in CG patients especially in severe cases, may possibly be related to *Hp* infection.

Gastric mucin-bicarbonate barrier is one of main constituents of gastric mucosal barrier^[13,14]. Gastric mucin contains polymer glycoproteins, electrolytes, peptides, lipides, etc. The present study showed that: the orientation of *Hp* is related to pathogenic factors, such as lipopolysaccharide, urea enzyme^[15-18], vacuole toxin^[19-21] and adhesiveness. Hexosamine^[22] reflects the glycoprotein. So, the purpose of this study was to evaluate the lesion of gastric mucosal barrier by measuring the levels of hexosamine in gastric mucosa. The results showed that in CG, and PU+CG patients, the levels of hexosamine in *Hp*⁺ group were significantly decreased than in *Hp*⁻ group. The more severely the gastric mucosa was impaired, the higher the *Hp* infection rate was (moderate 60.7%, severe 74.2%). *Hp* infection leads to the decrease in hexosamine levels in gastric mucosa especially in severe cases. It is thus indicated that *Hp* is one of main pathogenic factors for endogastritis or severe gastritis.

NO is a multifunctional regulatory substance of the body^[23-30]. It has many biological activities. It participates in many physiological functions and pathogenesis in digestive tract. Endogenous NO is an important transmitter maintaining the blood flow of gastric mucosa, and has a role in inhibiting platelet aggregation in gastric mucosa microcirculation. The results in this study showed that the levels of plasma NO in CG and, PU+CG patients were increased to varying extents as compared to normal control, and the levels of plasma NO in PU+CG patients were significantly increased than those in CG patients. In addition, the plasma NO levels in *Hp*⁺ group in CG and PU+CG patients were significantly increased as compared to *Hp*⁻ group. According to the pathological stages, the more the gastric mucosa was impaired by *Hp* infection, the higher the levels of NO were. It is suggested by our results that *Hp* infection in gastric mucosa may induce an increase in NO production by inflammatory cells^[31]. It might be possibly an immune response of our body to resist *Hp* infection, but the exact pathogenesis needs to be further confirmed.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a major causative bacterium of chronic gastritis, peptic ulcer and mucosa-associated lymphoid tissue lymphoma in humans, and associated with an increased risk of gastric cancer^[1-8]. An important virulent factor of *H. pylori* is the vacuolating cytotoxin (VacA) encoded by vacA that induces cytoplasmic vacuolation in target cells both *in vitro* and *in vivo*^[9-11]. VacA is produced as a 140 kDa precursor which contains an N-terminal signal peptide and an approximately 33 kDa C-terminal outer membrane exporter. The precursor is cleaved at both N-terminal and C-terminal and secreted into the extracellular milieu as a 95 kDa mature protein. The mature protein further undergoes specific cleavage to yield 37 kDa and 58 kDa subunits^[12-14]. Although vacA is present in all *H. pylori* strains, only about 50% to 60% of strains can induce vacuolation of epithelial cells as assessed by the HeLa cell assay. vacA shows considerable genetic variation in *H. pylori* isolated from all over the world and contains at least two variable regions. The s region exists as s1 or s2 allelic types. Among type s1 strains, subtypes s1a and s1b have been identified. The m region occurs as m1 or m2 allelic types. Specific vacA genotype of *H. pylori* strains are associated with the production of the cytotoxin *in vitro*, epithelial damage *in vivo*, and clinical consequences^[15-27]. The other virulent factor is the cytotoxin-associated protein (CagA) encoded by the cytotoxin-associated gene (cagA). The cagA gene is present in about 60% to 70% of strains and all of these

strains express the cagA. The presence of cagA is also associated with the production of the cytotoxin *in vitro*, and clinical outcome^[24-30]. The aim of this study was (i) to identify vacA genotypes and cagA status of *H. pylori* isolated from Chinese patients; (ii) to evaluate the relationship between vacA genotypes, cagA status and related gastroenterological disorders.

MATERIALS AND METHODS

Patients

Seventy-four clinical isolates of *H. pylori* were obtained from patients which underwent gastroduodenoscopy in Changhai Hospital, Shanghai, China. *H. pylori* strain CCUG17874 and G50 obtained from IRIS, Italy were also used in this study. No patient had received nonsteroidal anti-inflammatory drugs or antacids. Of these, 31 patients (mean age 47 years) had peptic ulcer including 21 duodenal ulcers, 5 gastric ulcers and 5 complete ulcers; 39 patients (mean age 41 years) had gastritis including 18 suppur gastritis, 6 atrophic gastritis and 15 erosive gastritis; and 4 patients (mean age 56 years) had gastric adenocarcinoma.

Isolation and culture of H. pylori

Two gastric biopsies were obtained respectively from gastric antrum and corpus of each patient by using endoscopy. Each specimen was placed in a transport medium and sent to the laboratory within 3 h. The specimens were then incubated onto Campylobacter selective agar (MERCK) containing 10% sheep blood for 3 d at 37°C under microaerobic conditions (10% CO₂, 5% O₂, 85% N₂). All *H. pylori* strains were positive for urease, oxidase, catalase and were identified by Gram and Giemsa staining under light microscopy. Colonies directly harvested from the plates were used for RNA extraction.

Preparation of total RNA and RT-PCR amplification

The extraction of total RNA was performed using Promega's SV total RNA isolation system according to manufacturer's instructions. The DNA sequences of the primer oligonucleotides used for RT-PCR and the size of the corresponding PCR products are listed in Table 1. RT-PCR reactions were performed as follows: denaturation at 95°C for 2 min, followed by 30 cycles consisting of 95°C for 40 s, 55°C for 1 min, and 67°C for 2 min, and final extension at 67°C for 7 min. The RT-PCR products were electrophoretically separated on a 1.5% agarose gel and stained with ethidium bromide.

m2	5'GGAGCCCCAGGAAACATTG 3' 5'CATAACTAGCGCCTTGAC 3'	352 bp

RESULTS

vacA genotypes of *H.pylori* strains

Typing of the *vacA* gene of 74 clinical isolates and strain CCUG17874 and G50 was performed based on signal and middle sequences by RT-PCR as described in materials and methods. All of the 74 clinical isolates and strain CCUG17874 were s1a type whose fragment was 259 bp products as predicted by RT-PCR-amplification. Strain G50 was s1b type whose fragment was 286 bp products predicted by RT-PCR-amplification. No clinical isolates was of type s1b. Neither strain CCUG17874 and G50 nor clinical isolates was of type s2. Seven isolates (9.5%) and strain CCUG17874 were of m1 type whose fragment was 290 bp products. Sixty-seven isolates (90.5%) and strain G50 were of m2 type whose fragment was 352 bp products. Overall, 7 strains (9.5%) were type s1a/m1, 67 isolates (90.5%) were type s1a/m2. An s1a/m2 type strain was predominantly found in clinical isolates from Chinese patients living in Shanghai.

cagA positivity of *H.pylori* strains

The *cagA* gene was determined in 74 isolates by RT-PCR. Sixty-nine Chinese *H.pylori* strains (93.2%) were *cagA* positive. When the *vacA* genotype was compared with *cagA* status, all (100%) of 7 s1a/m1 type strains and 62 (92.5%) of 67 s1a/m2 type strains were *cagA* positive.

Relationship between *vacA* genotype, *cagA* status and related gastroenterological disorders

Infection with type s1a/m1 strain was found in 4 (12.9%) of 31 patients with peptic ulcers compared with 3 (7.7%) of 39 patients with gastritis. Infection with s1a/m2 strain was found in 27 (87.1%) of 31 patients with peptic ulcer compared with 36 (92.3%) of 39 patients with gastritis. There was no statistical significance between *vacA* genotype and the clinical outcome. ($P > 0.05$). *cagA* positivity was found in 29 (93.5%) of 31 patients with peptic ulcer compared with 37 (94.9%) of 39 patients

with gastritis. There was also no relationship between *cagA* status and related gastroenterological diseases ($P > 0.05$).

DISCUSSION

Based upon the methodology for typing *vacA* gene developed by Atherton *et al*^[19], we analysed and typed *vacA* genotype of clinical isolates from Chinese patients living in Shanghai by using RT-PCR. The product amplified by RT-PCR was obtained in all clinical isolates, CCUG17874 and G50 strains. The results suggested that *vacA* transcription occurred in each of *H.pylori* strains tested and was in agreement with previous reports^[19]. According to typing of *vacA* alleles, these Chinese patients infected prevalently with *H.pylori* contained the type s1a/m2 of *vacA* alleles. The finding reported here was different from that in United States, Germany, and Japan^[15-26]. The reason why the s1a/m2 strains have accumulated in Shanghai, China is unclear. It is known that genomic rearrangement may be associated with the uptake of DNA by natural transformation. Chinese have the same habits and customs, and little intermarriages with other nations. The high incidence of the s1a/m2 allele in Chinese population may indicate that it was first acquired in this population and the chance for genomic diversity may be little. Alternatively, the s1a/m2 allele may have a selective advantage in the Chinese population due to human polymorphism and ethnic background.

Recently, van Doorn *et al* found a novel subtype of *vacA* signal region from s1a subtype, designated as s1c. Type s1c allele was obtained exclusively in isolates from East Asia^[32]. We have done *vacA* gene sequencing from 5 clinical isolates (in press). The s region was considered as type s1a. Compared with s1c sequence, two of the five strains were of type s1c. These results indicated that s1c subtype could be identified as subtype s1a. Whether s1c strains are phenotypically different from s1a strains remains to be determined.

The findings here showed that all strains but five possessed the *cagA* gene and suggested that *cagA* positive strains were predominantly found in Shanghai also. The relationship between type s1a *vacA* allele and *cagA* positive has been described^[31]. All (100%) of Chinese (Shanghai) *H.pylori* strains were of type s1a *vacA* allele and 93.2% of strains were *cagA* positive and were highly prevalent in China.

Subtype analysis of *vacA* alleles and *cagA* positivity demonstrated that the *vacA* subtype and *cagA* status was not independently associated with the clinical outcome of *H.pylori* infection. The factors affecting the clinical consequences need further studies.

Zhong DR, Ji XL. Hepatic angiomyolipoma-misdiagnosis as hepatocellular carcinoma: A report of 14 cases. *World J Gastroenterol*, 2000;6(4):608-612

INTRODUCTION

Angiomyolipoma (AML) is a rare benign mesenchymal tumor of the liver, composed of a varying heterogeneous mixture of three tissue components: blood vessels, smooth muscle, and adipose cells. It has recently been proposed that the perivascular epithelial cell (PEC) is the common progenitor^[1,2]. Since its first description by Ishak in 1976^[3], there have been more than 100 cases reported in the English literature^[4-6]. With the advance of radiological techniques, many more tumors are being diagnosed by the means. But radiological findings of AML may only be suggestive of the lesion; its definitive diagnosis requires histological confirmation^[9-19]. Some authors regard renal and hepatic AMLs, pulmonary and soft tissue lymphangiomyomatosis^[2], pulmonary and pancreatic clear cell "sugar" tumor, and cardiac rhabdomyoma as closely related groups of tumors, based on their morphologic overlap and common immunoreactivity for HMB-45^[11]. They show different microscopic appearances, however, according to their organ of origin. The goals of this study were to highlight more subtle morphology and to gain possible insights into the differential diagnosis that could provide important information about this disease.

MATERIALS AND METHODS

Fourteen cases of AML were identified in the pathology files at the Department of Pathology, Chinese Military General Hospital, four of which were consulted cases. All the cases were independently reviewed by two pathologists, and the most important diagnostic criterion was the

presence of HMB-45-positive cells. The clinical data and follow-up information were obtained in each case (Table 1). All the tumor tissues had been fixed in neutral buffered formalin and were routinely embedded in paraffin. Hematoxylin and eosin-stained sections were examined. According to the morphological aspect, one block was selected for each of these cases. Immunohistochemical study was performed on representative blocks by using an avidin-biotin peroxidase complex technique. Selective cases were also examined with antibodies to CD68, CD31, CD34, factor VIII-related antigen.

RESULTS

Clinical findings

The clinical findings in all 14 patients are summarized in Table 1. There was marked female predominance (women: men = 9:5) and the average age of patients at diagnosis was 40.07 years (range 30-63 years). Only four cases (case 4, 7, 10, 13) had symptoms of space-occupying lesions while others were incidentally discovered on imaging studies (Figure 1). Two cases had two masses each (the other mass was diagnosed as a hemangioma by a pathologist) and one of them had calcified nodes (confirmed by a pathologist). None of 14 cases had tuberous sclerosis syndrome, angiomyolipoma of kidney, lymphangiomyoma or clear cell tumor of lung or other parts. For patients with complete follow-up data, all were well with no tumor recurrence and metastasis after excision.

Gross findings

Thirteen cases were solid and one was cystic (the content of cyst was a brown liquid). All tumors were well circumscribed, but not encapsulated (Figure 2). The average size of all thirteen cases was 9.4 cm (range 2.5 cm-26 cm). The surfaces of tumor sections were yellowish but not uniform and some parts of tumors were fish-like.

Histological features

The most common pattern was that of solid sheets of myoid cells intermixed with areas of adipose cells and vessels, most of which were thin-walled (Figure 3) and few of which were thick-walled but had to be carefully observed. In 12 out of 14 cases there were clusters of hematopoietic

cells and in 1 of 14 cases there were lots of multinucleated cells (Figure 4). The myoid cells usually predominated and their morphology varied from epithelioid to intermediate (ovoid or short spindle) spindle. The epithelioid cells in our 12 cases were main cell pattern, cytoplasm of which varied from clear to vacuolated and eosinophilic granular, nuclei of which were partly normal chromatic with moderate pleomorphism, with delicate chromatin, and a single distinct eosinophilic nucleolus. Furthermore, there were some large bizarre cells in 10 cases out of 14 cases but without nucleus mitoses

(Figure 5). Long spindle cells with elongated eosinophilic cytoplasm could be seen but very rarely lipoblast-like cells were observed in sheets in local areas. Only two cases had multiple local necrotic areas but their total size was smaller than 5 percent of the tumor (Figure 6).

Figure 5 Pleomorphic and large bizarre cells. HE $\times 200$

Figure 6 Local necrotic area of case 9. HE $\times 50$

Immunohistochemical findings (Summarized in Table 2) The tumor cells were positive for HMB-45, but negative for EMA and AFP in all cases. Local tumor cells were positive for Actin and S-100. HMB-45 staining was intense, granular, and concentrated in the perinuclear pink cytoplasm. Although the epithelioid cells were most consistently stained, the spindle cells were also weakly positive. Actin staining in spindle tumor cells was more intense than in other cells. The lipoblast-like cells were positive for both HMB-45 and S-100 protein. Lots of multinucleus cells presenting in 1 of 12 cases were positive for HMB45, Actin, S-100 and CD68. Furthermore, positive rate for Ki-67 of tumor cells in all 12 cases was no more than 1 percent.

Ultrastructural finding Six cases were examined under H-7000 electron microscopy. Neoplastic cells generally were polygonal and closely arranged with minimum intercellular material. In the cytoplasm, glycogen and round-to-oval mitochondria were common features,

together with a characteristic finding of lots of electron-dense, membrane-bound granules (these granules were 60-100 nm in diameter with some filament-like structures in them which could be seen under high magnification. These were deemed to be either premelanosomes or atypical lysosomal bodies) (Figure 7).

DISCUSSION

Angiomyolipoma, which occurs frequently in kidney but rarely in other sites^[7,8], previously considered as a hamartomatous growth rather than a true neoplasm, is a rare benign mixed mesenchymal clonal neoplasm of the liver. Since the first case described by Ishak^[3], AML has been diagnosed with increasing frequency with advances in MRI, CT, CD-SO and angiography. Despite the claim that the imaging features are highly characteristic^[9-19], the preoperative diagnoses are erroneous in more than half of the cases in the present series. None of our 14 cases were correctly diagnosed before operating, furthermore, 5 cases were misdiagnosed as hepatic cell carcinoma or sarcoma by pathologist even after operating.

The diagnosis of AML is usually made on recognition of three or four components of the tumor, namely blood vessels, smooth muscle, mature fat, and hematopoietic tissue^[4-6,20]. These elements, however, are variable in proportion and distribution. The adipose cells have no characteristic features in themselves to distinguish between various lipomatous tumors. Extramedullary hematopoiesis is not an integral part of AML and is seen in many primary benign and malignant hepatic tumors. Its occurrence is probably more closely related to the hepatic sinusoidal endothelium which plays an important part in hematopoiesis in the fetal liver. This also explains that hematopoietic cells are found only in hepatic but not renal AMLs. Blood vessels are present in all kinds of tumors which easily escape attention. The more distinctive features in AML are their tortuosity, thick walls (but rare in AML of liver) and perivascular muscle proliferation. It thus appears that the myoid component is the only specific and diagnostic

component in AML and it can exist in epithelioid, spindle, and intermediate forms. The essential component in this tumor appears to be PECs^[1-6]. It has been speculated that the distinctive epithelioid cells are primitive mesenchymal cells that have an ability to differentiate towards both myoid and fat cells. Spindle myoid cells and lipocytes probably represent the mature derivatives of the epithelioid cells. Immunohistochemistry is particularly useful for diagnosing, as many authors have found. HMB-45 has been shown to be a promising marker for renal and hepatic AMLs and can even be applied to minute samples such as fine-needle aspirates^[21,22].

Because of the rarity and the pleomorphism of histological features of hepatic AMLs, histological diagnosis may be difficult, especially with needle biopsy (one of our cases was diagnosed by this means). Many features in AML can mislead the unwary pathologist to a diagnosis of HCC: polygonal cells in trabecular arrangement, peliosis, nuclear pleomorphism, prominent eosinophilic nucleoli, deficient reticulin framework, presence of glycogen, eosinophilic globules, and tumor necrosis. Four of our cases were misdiagnosed by pathologists because of causes mentioned above. In AML with spindle cells and pleomorphic features, sarcoma is the most common incorrect diagnosis. For this reason, one case in our series was misdiagnosed as angiosarcoma. Lipomatous AML has to be differentiated from true lipoma and focal fatty change. Evidently, a careful histologic survey of the entire specimen usually reveals the presence of the classic mixed pattern of the tumor. Immunohistochemical result (positive for HMB45 and Actin but negative for AFP or EMA), ultrastructural structure and the low proliferation of tumor cells can further confirm the diagnosis^[25-35]. The histogenesis of AML is unclear, but immunohistochemical and ultrastructural studies provide important insights into its cell differentiation^[4-6,20,23,24]. The concept of "perivascular epithelioid cells" as the unified feature has been proposed^[1]. Presumably, the PECs are an aberrant type of mesenchymal cells proliferating to form tumorous lesions, possibly due to chromosomal aberrations in the tuberous sclerosis (TS) complex gene. Because they are capable of dual differentiation, the argument for a hamartomatous proliferation is unsound. Recent molecular studies have shown tumor clonality and 5q deletions with a common region of deletion spanning 5q33 to 5q34, indicating a clonal neoplastic process^[36-40].

Preoperative identification of AML is desirable because of differences in clinical course and treatment between this disease and other hepatic neoplasms^[41]. Although some imaging features may suggest hepatic AML, in such cases, histological analysis must be performed. No matter whether or not the liver biopsy contains fat component, the diagnosis can be established based on myoid component positive for HMB45.

INTRODUCTION

Stomach carcinoma is still the leading cause of cancer death in China and the second one in the world. Its possible causes include: A) chemical factors such as intragastric formation of *N*-nitroso compounds (NOC) and high salt intake; B) biological factors such as infection of *Helicobacter pylori* and biotoxins intake; and C) nutritional factors such as deficiency of vitamin C, selenium, and other antioxidants. Nitrogenous precursors of NOC, e.g. alkylamines, alkylureas, alkylguanidines, and alkylamides, occur widely in nature and potential nitrosating agents, e.g., nitrite (NO₂⁻) and NO_x (the gaseous oxides of nitrogen) are similarly widespread. Relationship between exposure to NOC and causes of human cancer was investigated extensively ten years ago. Results indicated that the exposures of NOC might contribute to the occurrences of malignancy in the upper digestive tracts including stomachs. It was also observed that both high salt intake and deficiency of some micronutrients enhanced NOC-induced carcinogenicity. Recent studies show that infection of *H. pylori* can lead to atrophic gastritis and achlorhydria, and promote endogenous formation of NOC indirectly^[1]. Much attention has been paid to stomach cancer and NOC regarding the characterization of natural *N*-nitrosamides in human environment in the 1990s.

N-nitrosamides, one kind of direct-acting NOC, can

be synthesized endogenously in stomach lumens and damaged DNA of gastric mucosal epithelium *in situ*. Most of epidemiological investigations showed that the occurrence of stomach cancers was correlated positively with exposure levels of nitrosating agents and nitrogenous precursors of NOC^[2]. Laboratory synthesized *N*-nitrosamides are strong animal stomach carcinogens. Intragastric *N*-nitrosamide formation may play an important role in the etiology of gastric carcinomas^[3]. However, most *N*-nitrosamides are chemically reactive, thermal, photo, and alkali-labile compounds. It is very difficult to detect *N*-nitrosamides in human environments chemically. Little was known about the existence of natural *N*-nitrosamides before the 1980s because of lack of a convenient sensitive method to detect them precisely^[4]. Several progresses have been made on the study of *N*-nitrosamides in the past ten years, including setup of detection methods for trace *N*-nitrosamides in the early 1990s^[5,6] resulting in recent discovery of natural *N*-nitrosoureas in human environments^[7-9].

This article will present and discuss results of studies on stomach cancer and *N*-nitrosamides in the past decade.

DEVELOPMENT OF SENSITIVE AND SELECTIVE METHODS TO DETECT *N*-NITROSAMIDES CHEMICALLY

Many *N*-nitrosamines can be analyzed sensitively (detection limit, less than 1 ng/injection) by a standard commercial Thermal Energy Analyzer Detector (TEA), relying on their thermal cleavage of the *N-N* bond to produce a nitrogen oxide (NO) radical. However, *N*-nitrosamides and related compounds, unlike *N*-nitrosamines, typically rearrange on pyrolysis to yield molecular nitrogen (N₂) instead of nitrogen oxide. Because of the possible etiological role of *N*-nitrosamides in human gastric carcinogenesis, it is necessary to setup a sensitive and selective method to detect *N*-nitrosamides in human environments.

A liquid chromatography (HPLC) with postcolumn photolysis device was assembled first at Shuker and Tannenbaum's laboratory, Massachusetts Institute of Technology in 1983 (Figure 1A)^[10]. In the device *N*-nitrosamides were cleaved photolytically by ultraviolet (UV) irradiation to produce nitrite ion in aqueous solution, which was determined colorimetrically with Griess reagent in a postcolumn reactor. However this method is not *N*-

nitrosamide-specific. It is of low sensitivity (detection limit, ng/injection): 20 for *N*-methyl-*N*-nitroso urea (NMU) and 8 for *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG). The polarity of *N*-nitrosamides ranges widely from strongly polar to non-polar. Non-polar *N*-nitrosamides do not undergo photohydrolysis because of their nondissolubility in aqueous solution. Though the device could not be used to detect trace amounts of *N*-nitrosamides in nature, it has been often used to further develop sensitive methods (Figure 1B and 1C)^[5,11]. Fine *et al*^[12] at New England Institute for Life Sciences have modified the pyrolysis chamber in a standard TEA such that *N*-nitrosamides release nitric oxide on pyrolysis (sensitivities for standards, less than 1 ng/injection) in 1987. However, details of the instrument were not provided and further development was needed.

An HPLC-photolytic interface-TEA method was reported to precisely detect *N*-nitrosamides and other non-volatile NOC at Hotchkiss's laboratory, Institute of Food Science, Cornell University in 1988 (Figure 1B)^[5]. A chromatographic effluent containing separated NOC is introduced into a glass coil with a purge stream of He and irradiated with UV in a photolysis device. Nitric oxide, cleaved by photolysis, is separated rapidly from the solvent through a series of cold traps and carried by the He into the reaction chamber in a standard TEA. The maximum sensitivity of the approach was approximately 8 ng for NMU and 16 ng for MNNG, and less than 1 ng for *N*-nitrosoamino acids and *N*-nitrosamines. The selectivity for *N*-nitrosamides was not mentioned.

A selective and sensitive HPLC-Photolysis/Pyrolysis-TEA method (Figure 1C) was set up for *N*-nitrosamides at Beijing Institute for Cancer Research, Beijing Medical University School of Oncology (Chen *et al*; Li and Deng)^[6,11]. In the photolysis device, *N*-nitrosamides are first cleaved photolytically by UV irradiation to produce nitrite ion in aqueous chromatographic effluent. Then nitrite ion in the effluent is introduced into a pyrolysis tube (made of Al_2O_3) at 550°C with carrying gas stream of He or N_2 , and releases nitric oxide on pyrolysis. Nitric oxide is separated rapidly from the solvent-spray through a series of cold traps, and is lead into the reaction chamber in TEA by the carrying gas. Detection limits (ng/injection) are: 5.2 for NMU, 8.5 for MNNG, about 1 for *N*-nitrosamines, and 16 for *N*-nitrosoproline. In addition, when UV lamp of the photolysis device is turned off, the responses decreased up to 90%-100% for *N*-nitrosamides, but only 0%-45% for other kinds of NOC. It indicates that the method is a selective one, which can be used to differentiate *N*-nitrosamides preliminarily from other kinds of NOC by comparing the difference in response UV when the lamp is on or off. This special feature can be useful for chemists to select the right chromatographic components for further identification of trace *N*-nitrosamides in human environments.

Figure 1 Diagrams of HPLC-Photolysis Device-UV Detector (A), HPLC-Photolytic Interface-TEA (B), and HPLC-Photolysis/Pyrolysis-TEA (C).

Zhang *et al*^[13] developed a method to detect the total amount of *N*-nitrosamides in biological samples with the Photolysis/Pyrolysis-TEA detector. It can be used only to roughly evaluate exposure levels of total *N*-nitrosamides, because calculation of the concentration of total *N*-nitrosamides is based on the difference in response when the UV lamp is on or off. Sample purification by extraction with organic reagents is required in the method. Therefore, *N*-nitrosamides with strong polarity in the samples will be lost during the process of extraction. Only medially polar ones can be detected by the method.

IDENTIFICATION OF *N*-NITROSAMIDES IN NATURE

There is an indispensable evidence to show existence of *N*-nitrosamides in human environments in order to prove etiological role of *N*-nitrosamides in gastric carcinogenesis. However, little is known about the detailed chemical structures of the natural *N*-nitrosamides except stre-

ptozotocin and therapeutic *N*-nitrosoureas^[14]. Establishment of above the sensitive methods to determine *N*-nitrosamides make it possible to detect the trace amounts of *N*-nitrosamides in nature.

Caffeine is a normal component of coffee. Kumar *et al*^[15] reported formation of caffenidine and caffenidine acid from pure caffeine treated under conditions similar to preparation of salted tea practised in Kashmir, which could result in two *N*-nitrosamides, dinitrosocaffenidine and *N*, *N'* dimethyl-*N*-nitrosourea by nitrosation. However, there is no report to show that these *N*-nitrosamides are detectable in the nitrosated-salted tea. Mende *et al*^[16] characterized the nitrosamide precursor pyrrolidin(2)one in food and tobacco. A volatile *N*-nitrosamide, *N*-nitrosopyrrolidin(2)one, was detectable in the nitrosated precursor by gas chromatography-TEA method. They also mentioned the existence of trace amounts of the *N*-nitrosamide in natural Indian nasal snuff. But no detailed supporting materials were provided.

Fish sauce is a liquid product of small marine fish and sodium chloride (7:3). The main species of fishes used are *Sardinella aurita* (Val.) and *Decaptes maruadsi* (T & S). The fishes are completely liquidized after being fermented for 1-2 years. The product is consumed daily (about 30 mL/capita) by residents as a traditional seasoning in the Chinese southeast coast, the highest risk area for stomach cancer in China (the male standard mortality of stomach cancer in Changle County, 134.44/10⁵ in 1986-1988). Epidemiological studies showed that the intake of fish sauce is a high risk factor for gastric carcinogenesis for the local residents^[17]. It was reported that extract of fish sauce samples is markedly and directly mutagenic toward *S. typhimurium* TA100 induced high sister chromatid exchanges and micronucleus in Chinese hamster V79 cells after nitrosation with sodium nitrite under the simulated gastric conditions. But the extract of non-nitrosated samples had no such effect. The nitrosated fish sauce also induced SOS in *E. coli* PQ37 and alkylation of calf thymus DNA. The potency of nitrosated fish sauce to induce unscheduled DNA synthesis in human normal gastric mucosal cells was increased about fivefold compared with fish sauce. When the extract of nitrosated fish sauce was given to newborn rats by gavage, dysplasia and adenocarcinoma were induced in the glandular stomach in the 4th and 16th experimental week, respectively^[13,18,19]. Because of the high exposure level of nitrosating agent nitrite for the local residents^[20], dietary fish sauce may contribute to the causes of the high mortality due to stomach cancer in the areas. It is necessary to identify chemical carcinogens in the nitrosated fish sauce.

Chen *et al*^[21] reported that 100% (*n* = 21) of fish sauce samples contained some kinds of volatile *N*-nitrosamines by HPLC-TEA and gas chromatography-TEA. Concentrations of total NOC in 49 fish sauce samples ranged from 0.2 to 16 µmol/L and rose by up to 4800-

and 100-fold after being nitrosated at pH 2 and pH 7, respectively^[19]. Deng *et al*^[7] characterized a chromatographic component of thermal-unstable *N*-nitroso compounds in nitrosated fish sauce by above HPLC-Photolysis/Pyrolysis-TEA method. A strong chromatographic peak with the same retention times as that for authentic NMU, was obtained under two different liquid chromatographic conditions after the sample was nitrosated by 5 mmol/L of sodium nitrite (final concentration) at 37 °C and pH 2.0 for 1 h. Like NMU, the chemical could not be detected by the method when UV lamp in the photolysis device was turned off. In a confirmation study, the chemical structure of the component was compared with authentic NMU by HPLC-electric spray ionization-mass spectrometer and HPLC-UV diode array detector. The chemical showed the same mass spectrum (*m/z* values 64, 102, 145) and spectrum of ultraviolet-absorbency (λ_{\max} = 230 nm) as those of NMU^[8]. These results indicated that the component was NMU. This was the first study reporting that there is *N*-nitrosamide, NMU, in nitrosated food. In addition, NMU could also be detected in the nitrosated human gastric juice sample spiked with fish sauce^[7]. The formation of NMU in the sample was pH- and nitrite-dependent (Table 1). These results provide direct evidences that NMU formation could occur in human gastric juice samples spiked by fish sauce during nitrosation under simulated gastric conditions *in vitro*. Another *N*-nitrosamide, one of *N*-nitrosodipeptides, was separated recently and confirmed in our laboratory.

Table 1 Comparison of formation of NMU at various doses of NaNO₂ in gastric lumen of pig model *in vivo* and control experiments *in vitro*^[9,22]

Amount of NaNO ₂ (µmol)	Formation of NMU			
	Concentration (µmol/L)		Total amount (µmole)	
	<i>in vivo</i>	<i>in vivo</i>	<i>in vivo</i>	<i>in vivo</i>
3480	25.40	29.20	4.27	1.75
870	7.97	6.48	1.91	0.38
220	ND	2.77	ND	0.17

ND, below detection limit; the value was the average of two independent experiments.

Furthermore, experimental mini-pig model and human volunteers were used to study the possibility of intragastric formation of NMU *in vivo*^[9,22]. Fish sauce sample (20-30 mL) and nitrite were administered into gastric lumen of experimental pigs by perfusion via pig stomach cannula, or taken orally by human volunteers. Gastric juice samples were taken out 30 min later. Concentration of NMU in condensed extracts of these samples was analyzed with HPLC-Photolysis / Pyrolysis-TEA. Results showed that NMU was formed in gastric lumens of both models *in vivo* and also that the formation of NMU was nitrite and pH-dependent (Tables 1 and 2).

Zhang *et al*^[20] reported that concentration of nitrite in

fasting gastric juice samples in China was up to 100 $\mu\text{mol/L}$. Pignatelli *et al*^[23] reported that the level of nitrite in fasting gastric juice in Columbia was up to 472 $\mu\text{mol/L}$. It was reported that NMU was still detectable in the condensed extract of 100 mL of mixture of pooled fasting human gastric juice samples and fish sauce sample (9 v:1 v) after treatment of 500 $\mu\text{mol/L}$ of nitrite *in vitro*, which is within the range reported in human gastric contents as reported by Deng *et al*^[9]. These results suggest that low micromolar amounts of *N*-nitrosoureas can be formed in the normal stomach when nitrite is consumed in amounts to which humans are commonly exposed.

Table 2 Status of gastric juice samples from four human volunteers and formation of NMU 30 min after taking 40 mL of diluted fish sauce and 500 μmol of nitrite^[9]

Sample's origin	Total volume of sample (mL)	pH of sample	Total amount of NMU detected in gastric lumen (nmol)
Male A	24	5.0	4
Male B	110	3.0	85
Female A	50	2.0	100
Female B	50	2.0	22

Fish sauce is rich in nitrosable amines, i.e. dipeptides, free amino acids, creatine, creatinine, and putrescine^[24]. It was reported that 16-31 mg/kg of methylurea could be detected in dried, salted bonito fish after nitrosation and denitrosation, though no methylurea could be detected in the fish directly^[25]. Further studies showed that methylurea was synthesized through 5-oxocreatinine 5-oxime and 1-methyl-5-oxohydrantoin 5-oxime during nitrosation of creatinine^[26,27]. NMU in the nitrosated fish sauce might be synthesized from creatinine.

POPULATION STUDY ON TOTAL *N*-NITROSAMIDES IN STOMACH

Previous knowledge on status of human exposure to *N*-nitrosamides is deduced indirectly from data obtained in studies to exposure of NOC precursors. The situation has been changed since the setup of chemical methods to detect total *N*-nitrosamides in biological specimens^[13]. To elucidate the correlation between exposure level of *N*-nitrosamides and causes of gastric carcinomas, a pilot cases-control study and a population study were reported by Zhang *et al* in 1991 and Deng *et al* in 1997^[13,28]. Total amount of natural *N*-nitrosamides was detected with the Photolysis/Pyrolysis-TEA method in fasting gastric juice samples from subjects in high and low risk areas for stomach cancer (Table 3, 4).

Gastric carcinogenesis is a multistage process. Its precancerous lesions include chronic atrophic gastritis, intestinal metaplasia, and dysplasia. In the case-control study, high levels of total *N*-nitrosamides were detected in the gastric juice samples from patients with chronic gastritis in Putian area, a county along the Chinese southeast coast (Table 3)^[13]. The positive rates and mean concentrations

Table 3 Relationship between presence of total *N*-nitrosamides in gastric juice samples from subjects with pathological changes in gastric mucosa

Gastric mucosal status	Positive rate of total <i>N</i> -nitrosamides in gastric juice samples (%)**		
	High risk areas		Low risk area
	Putian ^[13]	Linqu ^[28]	Cangshan ^[28]
*N and CSG	2/12 (16.7)	1/4 (25.0)	4/23 (17.4)
CAG	10/14 (71.4) ^b	38/76 (50.0) ^c	18/56 (32.1)
CAG and IM	12/13 (92.3)	17/56 (28.8) ^c	0/4 (0.0)
CAG and DYS	12/13 (92.3)	18/44 (40.9)	5/10 (50.0)

*N, normal mucosa; CSG, chronic superficial gastritis; CAG, chronic atrophic gastritis; IM, intestinal metaplasia; DYS, dysplasia; **sample was classified as *N*-nitrosamides-positive when more than 184 nmol/L (detection limit) of the chemicals was detected; ^bSignificantly different from N and CSG with $P < 0.01$; ^cSignificantly different from low risk area with $P < 0.05$; ^dSignificantly different from CAG with $P < 0.05$.

Table 4 Presence of total *N*-nitrosamides (NAD) in gastric juice samples (GJ) from low and high risk areas for stomach cancer

	High risk area (Linqu)	Low risk area (Chongshan)	P-value
No. of GJ samples	176	99	
Proportion, pH ≤ 3	48.0%	84.0%	<0.01
pH ≥ 5	45.3%	13.5%	<0.01
Positive rate, all	40.9%	30.3%	= 0.03*
GJ, pH ≤ 3	46.2%	27.4%	<0.01
GJ, pH ≥ 5	43.3%	53.9%	
Conc. ($\mu\text{mol/L}$)	0.91	0.73	

*after age-adjustment.

in the three groups of patients were positively correlated with the severity of pathological changes in the gastric mucosa. In the population study, the exposure status of total *N*-nitrosamides in stomach of subjects aged 35-68 years from high risk area for stomach cancer was further compared with that in low risk area under the same geographical and socioeconomic conditions in Shangdong Province, China (Table 3)^[28]. Similar relationship between presence of *N*-nitrosamides and pathological changes of gastric mucosa was obtained both in Linqu and Cangshan areas. However, the percentage of *N*-nitrosamides-positive samples was decreased in subjects with chronic atrophic gastritis when intestinal metaplasia was developed. The mechanism of decrease in concentration of NOC is not clear. *N*-Nitrosamides are alkali-labile compounds. It is a common step to adjust pH of sample-extractant mixture to 5.0 with 10% sodium hydroxide in order to accelerate stratification of aqueous phase and organic extractant during extraction of NOC. During extraction of NMU in sample (aqueous solution), it was observed that addition of even one-drop (about 50 μL) of sodium hydroxide solution would destroy all NMU in the sample (Deng *et al*, unpublished data). Gastric mucosa with intestinal metaplasia secretes alkali-mucus. It is necessary to study whether the alkali-mucus catalyzes decomposition (activation) of *N*-nitrosamides and contributes to the decrease of amount of total *N*-

nitrosamides in fasting gastric juice from patients with intestinal metaplasia of gastric mucosa. In addition, development of intestinal metaplasia of gastric mucosa is not suitable for colonization of *H. pylori* in the alkali-mucus closely adjacent to the surface of gastric epithelium and finally eradicates them from there. It is interesting to study the relationship between disappearance of *H. pylori* and the decrease in *N*-nitrosamides amounts in gastric juice.

In the population study, more *N*-nitrosamides-positive samples in the high risk area (Linqing) were observed than in the low risk area (Chongshan). The difference was significant after age-adjustment (Table 3)^[27].

Chemical formation of *N*-nitrosamides and other NOC occur mainly under acidic conditions. It had been observed that 84% of samples was pH ≤ 3 in Chongshan, whereas only 48% in Linqing (Table 4, $P < 0.001$). That *N*-nitrosamides-positive rate is higher in samples with pH ≥ 5 than with pH ≤ 3 in the low risk area indicates that there are some factors which could catalyze formation of *N*-nitrosamides in the achlorhydric stomach. Colonizations of microorganisms are common in the achlorhydric stomach. Some species of bacteria in stomach contain nitrate-reductase and could lead to high concentration of nitrite in gastric juice. It is well known that microorganisms catalyze formation of *N*-nitrosamines. Pan *et al*^[29] reported that synthesis of *N*-nitrosamides, NMU, could also be accelerated by *Pseudomonas aeruginosa* at pH of 6-7, simulating achlorhydric stomach conditions. He *et al*^[30] reported further that 6 out of 46 strains of bacteria, isolated from patients with gastritis in Linqing County, promoted formation of NMU at pH 6.0. Biological formation of *N*-nitrosamides mediated by microorganisms in the achlorhydric conditions might account for the high concentration of total *N*-nitrosamides in gastric juice sample with pH ≥ 5 .

High *N*-nitrosamides-positive rate was observed both in gastric juice samples with pH ≥ 5 and pH ≤ 3 from subjects in Linqing, the high risk area. The results suggest that there is a high chemical formation of *N*-nitrosamides in the acidic stomach. It is supported by the observation that *N*-nitrosamides-positive rate in the samples with pH ≤ 3 from Linqing is higher than that from Chongshan, the low risk area (Table 4).

Above results indicate that human intragastric exposure to *N*-nitrosamides is positively correlated to risk of stomach cancer. *N*-Nitrosamides may be synthesized chemically in the acidic stomach and biologically in the achlorhydric stomach.

PROSPECTS

Establishment of sensitive methods to detect trace *N*-nitrosamides enabled identification of this sort of NOC in human environments greatly. More natural *N*-nitrosamides

need to be discovered in order to understand aetiological role of *N*-nitrosamides in gastric carcinogenesis in populations. Rediscovery of *H. pylori* is an important event in the history of oncology of stomach. It causes atrophic gastritis, gastric ulcer, and correlates with the occurrence of mucosa-associated lymphoid tissue lymphoma closely. It might also contribute to the causes of gastric carcinoma. *H. pylori* mediated gastritis induces high levels of nitrogen oxide (NO) in gastric mucosa. Tissue nitrogen oxide could damage DNA directly if it penetrates into cytoplasm during S-phase and further into nucleus. When Fe²⁺ exists in the tissue simultaneously it also nitrosates nitrogenous precursors to form NOC. It is noted that *H. pylori* infection leads to an increase in concentration of nitrite in the stomach lumen, decrease in secretion of ascorbic acid from gastric mucosa, and might promote formation of *N*-nitrosamides in achlorhydric stomachs. However, relationship between occurrence of *N*-nitrosamides and *H. pylori* is not investigated extensively. Such investigation may bring to light the mechanism of carcinogenesis caused by *H. pylori*.

Because of the instability of *N*-nitrosamides, it is almost impossible for the chemicals to exist in diet. Most of the human exposure might originate from intragastric formation. That provides a good target to prevent stomach cancer by inhibition of nitrosation and elimination of nitrite in stomach. Garlic and related components are ideal candidates for such interventional study. They inhibit proliferation of microorganisms, combine nitrite, block nitrosation, and destroy formed NOC. An interventional study with garlic oil and other chemicals has been undertaken in Linqing area^[31].

Olbe L, Fändriks L, Hamlet A, Svennerholm AM, Thoreson AC. Mechanisms involved in *Helicobacter pylori* induced duodenal ulcer disease: an overview. *World J Gastroentero*, 2000;6(5):619-623

Duodenal ulcer (DU) can be developed via several different mechanisms. Hypersecretion of gastric acid is, however, a common denominator. A massive hypersecretion of acid can by itself evoke a DU, e.g. in the Zollinger-Ellison syndrome. Irrespective of the mechanism behind the development of a DU, powerful antisecretory treatment will heal the ulcer and prevent recurrence.

The hypersecretion of acid in DU patients is well characterized (Table 1). The maximal acid secretory capacity is increased in about half of the patients^[1], probably due to an enhanced trophic effect of gastrin on the oxyntic mucosa. Several mechanisms normally inhibiting gastric acid secretion, has been found defective in DU patients^[2-4], i.e. resulting in an increased release of gastrin^[2]. The final result is a raised and prolonged acid response to every meal^[5].

The most common cause of DU is *Helicobacter pylori* (*H. pylori*) infection. It is, however, only a minority (10% - 15%) of all *H. pylori* infected subjects, who will develop DU. The sequence of events leading to DU includes hypersecretion of acid, development of gastric metaplasia in the proximal duodenum with colonization of *H. pylori* in the duodenal bulb, progress towards a high density of virulent *H. pylori* bacteria in the bulb with a marked active and chronic inflammation, and a profoundly reduced bicarbonate secretion in the bulb. The overview is a short presentation of evidence supporting this concept.

Table 1 Gastric acid secretory characteristics of duodenal patients (all of which might be *Helicobacter pylori* induced)

Increased maximal acid secretory capacity
Increased parietal cell mass (trophic effect of gastrin?)
Increased basal acid secretion
Increased basal release of gastrin
Increased and prolonged acid response to meals
Increased release of gastrin
Defective inhibitory mechanisms
Antral acidification
Antral distension
Fat in the duodenum (<i>H. pylori</i> induced?)

H. PYLORI EFFECTS ON ACID SECRETION

A pronounced *H. pylori* induced inflammation of the antral mucosa in the presence of an intact oxyntic mucosa will result in acid hypersecretion, due to a blockade of mechanisms normally inhibiting gastric acid secretion^[6,7]. It should be emphasized that this acid hypersecretion does exist in all subjects with a *H. pylori* infection predominantly localized to the antrum, and is thus not a characteristic only for DU patients.

If, however, a pronounced *H. pylori* induced inflammation also includes the oxyntic mucosa, the acid secretion will instead be reduced due to inhibition induced by *H. pylori* inflammation on parietal cell level and a subsequent development of atrophic gastritis^[8].

Maximal acid secretory capacity

DU patients have a higher maximal acid secretory capacity than subjects without the ulcer disease, but there is a considerable overlapping between the two groups. *H. pylori* infection of the antrum results in a moderate increase of the release of gastrin from the antrum. Gastrin has a trophic effect on the acid secreting mucosa, that can produce a markedly increased maximal acid secretory capacity, e.g. in patients with the Zollinger-Ellison syndrome. Also moderately increased serum gastrin levels seem to be able to enhance the maximal acid secretory capacity^[9,10]. For instance, eradication of *H. pylori* has been followed by a reduced maximal acid secretory capacity^[9]. This conclusion is supported by the finding that resection of the antrum with retention of the whole acid secreting part of the

stomach in DU patients markedly reduced the maximal acid secretory capacity^[11].

The substantial overlapping of the maximal acid secretory capacity between DU patients and subjects without ulcer can be explained partly by the fact that many subjects without ulcer have *H. pylori* infection and consequently an increased release of gastrin, and partly by the possibility that the balance between the gastrins having acid stimulatory effect and those having only trophic effect^[12], might vary from subject to subject.

Defective inhibitory mechanisms

In subjects with a predominantly antral *H. pylori* infection the gastrin release is increased in the fasting condition, during meals, and by experimental administration of gastrin releasing peptide (GRP)^[6,13-17], which probably is a consequence of a reduction of the somatostatin in the antrum by the *H. pylori* infection^[18,19]. Antral somatostatin acts as a physiological inhibitor of the gastrin release. After eradication of *H. pylori* the gastrin release is normalized. During i.v. infusion of GRP the gastrin release and acid secretion was significantly higher in *H. pylori* infected subjects, and these responses were normalized after eradication of *H. pylori*^[20]. Interestingly the acid response to GRP in *H. pylori* infected DU patients was twice that in *H. pylori* infected subjects without ulcer despite similar gastrin responses in both groups. Whether this experimental situation reflects physiological conditions is open to question for several reasons, but the results indicate that DU patients may have a more pronounced hypersecretion of acid than *H. pylori* infected subjects without ulcer.

Antral *H. pylori* infection gives rise also to a blockade of an inhibitory nervous reflex from the antrum to the acid secreting mucosa^[7]. In subjects without *H. pylori* infection distension of the antrum provokes an inhibition of acid secretion via a reflex pathway, and this inhibition is completely absent in subjects with *H. pylori* infection. The blockade of the inhibitory reflex is probably a result of the inflammatory process in the *H. pylori* infected antrum, since the inhibitory reflex seems to turn up again only when the inflammatory reaction has ceased after eradication of *H. pylori*.

The defective inhibitory mechanisms caused by antral *H. pylori* infection results in acid hypersecretion under physiological conditions. The gastrin release during meals is increased in *H. pylori* infected subjects^[6,13-15], and contributes to an increased and prolonged acid response to meals^[15]. The well-known inhibition of gastrin release by acidification of the antrum is markedly impaired in *H. pylori* infected subjects^[14,15], contributing to the acid hypersecretion of the

infected subjects. The hypersecretion of acid obviously results in an increased acid load on the duodenal bulb^[15] both in *H. pylori* infected subjects without ulcer and DU patients. Thus, it seems reasonable that the explanation for the fact that only a minority of all *H. pylori* infected subjects will develop DU has to be searched for in the duodenal bulb, but with acid hypersecretion as necessary prerequisite.

GASTRIC METAPLASIA

Gastric metaplasia (GM) is islands of gastric mucosa in the duodenal bulb. GM develops as a result of an increased acid load on the bulb, and is e.g. rather extensive in patients with the Zollinger-Ellison syndrome^[21]. GM has been found in 90% of *H. pylori* infected DU patients, and in about 60% of *H. pylori* infected subjects without ulcer^[22,23], in accordance with the increased duodenal acid load in both these groups. GM is a prerequisite for colonization of *H. pylori* in the duodenal bulb. It is possible that the extension of GM is facilitated by the *H. pylori* induced inflammatory process in the bulb, since a combination of *H. pylori* eradication and antisecretory treatment reduced the GM area more effectively than either treatment alone^[25,26].

Hypersecretion of acid and development of GM exists in both DU patients and *H. pylori* infected subjects without ulcer, albeit somewhat more pronounced in DU patients. It therefore seems reasonable to assume that a critical factor in the development of DU could be a large number of *H. pylori* and/or particularly virulent *H. pylori* in the duodenal bulb of DU patients. The density and virulence of *H. pylori* in DU patients has previously been determined in several studies, but in biopsies taken from the antrum. In these studies of antral *H. pylori* density and virulence, only a marginal difference was found between DU patients and *H. pylori* infected subjects without ulcer. However, findings regarding *H. pylori* in the antrum does not necessarily reflect the situation in the duodenal bulb.

GM in the duodenal bulb is found in patches that cannot be visualized at ordinary gastroduodenoscopy. In a recent study^[24] the extent of GM in the duodenal bulb was therefore determined more systematically by taking 2 biopsies from each quadrant of the bulb. The area of GM in the multiple biopsies was 4 times larger in the DU patients than in the *H. pylori* infected subjects without ulcer^[24]. These biopsies were also used to determine the prevalence and density of virulent *H. pylori* as well as the type (active and chronic) and degree of the inflammatory reaction in both the antrum and the duodenal bulb of DU patients ($n = 20$) and *H. pylori* infected subjects without ulcer ($n = 21$).

BACTERIAL DENSITY AND *cagA* STATUS IN THE DUODENAL BULB

H. pylori colonization of GM in the duodenal bulb is very common. It was found in 95% of DU patients and in 80% of infected subjects without ulcer^[24], determined by quantitative culture^[27]. Rigorous precautions were taken at the endoscopy to avoid contamination of the duodenal biopsies with *H. pylori* from the stomach. Gastric epithelial cells express the blood group antigen Lewis-b, and *H. pylori* have the ability to bind to these antigens, thereby facilitating the colonization of the mucosa^[28]. *H. pylori* also has the ability to express various Lewis antigens, that might imply greater opportunity to escape the immune response of the host. It was recently shown^[29] that *H. pylori* expressing various Lewis antigens exist in a considerably higher frequency in the duodenal bulb of DU patients (90%) than in the bulb of infected subjects without ulcer (42%).

The density of *H. pylori* was much lower in the duodenal bulb than in the antrum, even after correction for the area of GM^[24], suggesting that the environment in the duodenal bulb is less favourable for colonization of *H. pylori*. The mean *H. pylori* density in the bulb was about 20 times higher in DU patients than in infected subjects without ulcer, despite the fact that the bacterial density in the antrum was similar for both groups^[24]. There was, however, a substantial overlap of the bacterial density in the bulb between DU patients and infected subjects without ulcer.

The clinically relevant virulence factors of *H. pylori* have not yet been identified. The presence of the *cagA* gene (cytotoxin associated gene A) is so far the best marker of virulence. *H. pylori* bacteria that are *cagA* positive can induce a more powerful release of proinflammatory cytokines with a subsequent potential of mucosal damage^[30]. The proportion of *cagA* positive bacteria might therefore be a significant factor determining the local mucosal damaging effect of colonized *H. pylori*. DU patients had a much higher prevalence of *cagA* positive bacteria in the duodenal bulb (81%) than *H. pylori* infected subjects without ulcer (30%), despite the fact that the prevalence of *cagA* positive bacteria in the antrum was of the same order for both groups (86% and 75%, respectively)^[24]. Furthermore, subjects with a predominance of *cagA* positive bacteria in the bulb had about 10 times higher bacterial density than subjects with *cagA* negative bacteria^[24].

H. PYLORI INDUCED INFLAMMATION IN THE DUODENAL BULB

The *H. pylori* bacteria are colonizing the GM in the duodenal bulb, and consequently the inflammatory cells are found in connection with the GM. The

chronic duodenitis, determined by the degree of infiltration of lymphocytes, was found more marked in DU patients than in *H. pylori* infected subjects without ulcer, but again with overlapping between the two groups^[24]. Active duodenitis, defined by the presence of neutrophil leucocytes, is an established and common finding in DU patients. Active duodenitis was found only in DU patients and almost exclusively in DU patients with *cagA* positive *H. pylori* in the bulb^[24]. Active duodenitis is thus a characteristic for DU patients. Activation of neutrophil leucocytes can result in tissue damage by release of proteolytic enzymes^[31] and by induction of reactive oxygen metabolites in the gastric epithelial cells^[32].

BICARBONATE SECRETION IN THE DUODENAL BULB

Hypersecretion of gastric acid with increased duodenal acid load can result in mucosal damage and development of ulcer. Under normal circumstances the acidification of the duodenal bulb will immediately activate bicarbonate secretion from the duodenal mucosa resulting in neutralization of the acid with the formation of carbon dioxide and water. The carbon dioxide will then stimulate the nitric oxide (NO) producing enzyme NO-synthase^[33], that has been demonstrated in the duodenal mucosa^[34]. NO will finally activate the bicarbonate secretion^[35].

DU patients have a markedly reduced bicarbonate secretion in response to acidification of the duodenal bulb^[36]. It has been shown more recently that the bicarbonate secretion is normalized after eradication of *H. pylori*^[37], implying that the reduced bicarbonate response to acidification of the bulb is a result of the *H. pylori* infection. Interestingly, the bicarbonate secretion was found normal in *H. pylori* infected subjects without ulcer^[37]. The *H. pylori* dependent reduction of the bicarbonate secretion is thus another characteristic of DU patients.

The mechanism by which the *H. pylori* infection is reducing the bicarbonate secretion has been studied recently. The bicarbonate secretion in response to acidification of the duodenal bulb in rats could be inhibited by local administration of a water extract of *H. pylori*^[38]. In these experiments a substantial increase of the NO synthase inhibitor asymmetrical dimethyl arginine (ADMA) was demonstrated in the duodenal mucosa. Separate administration of ADMA markedly reduced the bicarbonate response to acidification of the bulb. The presence of ADMA has not yet been determined in the bulb mucosa of humans. In the antrum, however, the ADMA concentration was 65 times higher in *H. pylori* infected subjects than in non-infected subjects^[39]. It is possible that *H. pylori* delivers peptides that are degraded by proteolysis in

the antrum-bulb region to for instance ADMA. It seems reasonable to assume that the high density of *cagA* positive *H. pylori* bacteria in the bulb of DU patients can produce high enough ADMA concentrations to explain the markedly reduced bicarbonate secretion that is a characteristic of DU patients.

WHY DOES ONLY A MINORITY OF *H. PYLORI*/INFECTED SUBJECTS DEVELOP DUODENAL ULCER?

A special series of events seem to result in the development of DU in *H. pylori* infected subjects. The first part of this series of events should be regarded more as a pre-/quisite for the development of DU, and is common for all subjects with an

antrum predominant *H. pylori* gastritis (Figure 1). The antrum gastritis results in hypersecretion of acid, the increased acid load to the duodenal bulb gives rise to formation of GM, and these islands of gastric mucosa can be colonized by *H. pylori*.

The most important factor for the development of DU seems to be a high density of virulent *H. pylori* bacteria in the duodenal bulb. When the density of virulent strains / with *cagA* positivity as a marker of virulence / reaches a high level, two effects are triggered that are characteristic for DU patients. Firstly, a high density of virulent *H. pylori* induces a pronounced release of proinflammatory cytokines, leading to a substantial chronic inflammation and an active duodenitis with its tissue damaging potential. Secondly, a high density of virulent *H. pylori* seems to produce enough amounts of NO synthase inhibitors to significantly reduce the bicarbonate secretion in response to acidification of the duodenal bulb. This entails a high acidity in the bulb leading to a potential increase of GM and tissue damage.

In summary the pivotal components in the conceptual development of DU are hypersecretion of acid and colonization of the duodenal bulb with a high density of virulent *H. pylori* strains resulting in an active duodenitis and reduced bicarbonate secretion (Figure 2).

PenañAS. Genetic factors determining the host response to *Helicobacter pylori*. *World J Gastroentero*, 2000;6(5):624-625

INTRODUCTION

The strongest evidence that *H. pylori* infection is the cause of peptic ulcer is that treatment with antibiotics as the only regimen, is not only effective for the clearance and eradication of the infection, but more importantly for the healing of the ulcer or the remission of gastric lymphoma. However, it is still a matter of controversy and research as to why only a minority of people develop gastric ulcer, gastric lymphoma, gastric cancer or duodenal ulcer when half of the world's population is infected by *H. pylori*. Since bacteria and host form an interactive unit, the pathogenesis of gastric pathology is determined and probably follows the same principles of any infectious disease.

First, the bacteria have to undergo evolutionary changes that are needed to survive the host response. This explains to a certain extent the highly diverse virulence of *H. pylori* strains which undoubtedly contribute to determining the development of disease^[1].

Second, host factors, such as the age at which the host acquires the infection, appear to determine the outcome of the interaction between *H. pylori* and the host. It is well known that gastric and duodenal ulcer rates increase with age. The presence of a genetic predisposition is also important. The relative risk of developing gastric, duodenal ulcer or duodenitis in patients with a family history of gastric pathology, is higher than in patients without familial occurrence. More convincingly still, several studies have established that the prevalence of peptic ulcer is higher in monozygotic twins than in dizygotic twins. Also, the concordance rates for *H. pylori* infection among pairs of twins reared apart is higher for monozygotic than for dizygotic twins^[2].

Experimental animal models have provided evidence that the host response is an important determinant in the severity of gastritis^[3].

THE BIOLOGICAL BASIS OF THE IMMUNE RESPONSE

Therefore, it is justifiable to look for the biological basis of the susceptibility to acquire the infection and which determines the pattern of disease and severity. The host response is important for the immune defense against a variety of infections and the protection of the organism against the invasion of foreign material.

It is important to recognize that immunity to infection is mediated by two systems, the innate and the acquired. Innate immunity provides a rapid antimicrobial host defense. Innate immunity is the bridge between the recognition of an invading microorganisms and the mounting of an efficient acquired and adaptive immune reaction that should overcome the infection. At the first contact of bacteria and host, *Helicobacter* Lipopolysaccharide (LPS) activate cells of the innate immune system. The host defense systems are mobilized to eliminate the infection. LPS of many *H. pylori* strains express Lewis antigens (Lex, Ley, Lea, Leb) which are similar to the antigens expressed by gastric epithelial cells of the host. Recent studies in *H. pylori* strains isolated from Asian peptic ulcer patients have shown to express more Lewis antigens than strains from non-ulcer dyspepsia patients^[4]. Since it is now known that Lewis antigens are involved in adhesion and colonization the increased adherence may lead to an increased bacterial burden. This will enhance the cross talk between the *H. pylori* and the host and leads to the activation of the transcription factor NF- κ B and host signal transduction pathways. IL-8 production is enhanced and results in the characteristic neutrophil infiltration and inflammation of *H. pylori* gastritis. *H. pylori* induces also IL-12 which in turn elicits interferon-gamma IFN γ production. During the induction of cell-mediated immunity, T lymphocytes expressing IFN γ and TNF α are generated. Macrophages are recruited and become activated. It is now known that IL-12 also facilitates the development of T helper type 1 (Th1) lymphocytes required for protection against the bacteria^[5]. In principle, the Th1 response is a normal adaptive immune response, however, when this response is too strong it will produce a severe chronic inflammation. In the stomach, locally produced IL-1 β is an important mediator of hypochlorhydria

Received 2000-07-05 Accepted 2000-08-01

since IL-1 β inhibits gastric acid and pepsinogen secretion. The levels of IL-1 β in cultured antral biopsy specimens are significantly higher in *H. pylori* positive patients than in individuals with negative cultures for *H. pylori* with normal antral mucosa. There is evidence that other cytokines, such as TNF, are also increased in *H. pylori* positive patients.

THE GENETIC CONTROL OF THE IMMUNE RESPONSE

During the inflammatory response a multitude of new genes encoding proinflammatory cytokines such as IL-1 α , IL-1 β , TNF α , and LT α as well as other proteins with pro-or anti-inflammatory properties are induced. Genetic control of the IL-1 family of cytokines and *TNF* appears to regulate the production and transcription of the respective cytokines. In healthy individuals, significant inter-individual variations were found in *in vitro* production of IL-1 proteins. This has been interpreted as inherited inter-individual differences.

The genes controlling the innate and the acquired immune response are different and probably work in a complementary way. Little is known of the genetic control of the innate immune response. With respect to the acquired immune response it is known that the *IL-1A*, *IL-1B* and *IL-1RN* genes are clustered on the long arm of human chromosome 2. Several functional polymorphisms have been described in these genes. This strongly suggests that individuals who produce high amounts of IL-1 β and lower amounts of the IL-1ra have difficulty in controlling inflammation. Preliminary results of IL-1 gene polymorphisms in duodenal ulcer patients have shown that the simultaneous carriage of *IL-1B* + 3953 allele 2 and *IL-1RN* allele 2, is an independent factor associated with reduced risk of bleeding duodenal ulcers^[6]. In a recent study supporting the role of the interleukin-1 gene cluster in the progression to disease, El-Omar and co-workers^[7] have reported the association of specific interleukin-1 gene polymorphisms with increased risk of gastric cancer. According to these authors, carriage of *IL-1B*-31 allele 2 and *IL-1RN** 2.2 homozygosity increase both the likelihood of a chronic hypochlorhydric response to *H. pylori* infection and the risk of gastric cancer, presumably by altering IL-1 β levels in the stomach. *IL-1B*+3953 allele 2 homozygotes seemed to play a protective role in gastric cancer, although the effect did not

reach statistical significance.

The localization of the tandemly arranged *TNF* and *LTA* genes, encoding respectively *TNF* and LT α in the central region of the MHC at the short arm of chromosome 6 (6p21.3) has prompted interest in the study of their contribution to diverse inflammatory processes. Recent studies have found that polymorphisms in the *TNF* and *LTA* genes are associated with peptic ulcers. Recently, the *TNF*-308 polymorphism located in the promoter region of the *TNFA* gene has been found associated with susceptibility to the development of duodenal ulcer^[8]. Thus, *H. pylori* positive individuals with the *TNFA*-308G/G genotype appeared to have a higher risk for the development of duodenal ulcer than individuals with the *TNFA*-308G/A or A/A genotypes.

CONCLUSION

The data suggest that the normal physiological control of the gastric secretory function and the control related to the pathogenesis of *H. pylori* associated diseases, to a certain extent are dependent on the genetic control of the inflammatory response. It is clear that more work needs to be done to clarify the role of the genetic control. Studies of the interaction between virulent *H. pylori* strains and the genetic factors as described above need to be addressed.

Caselmann WH, Serwe M, Lehmann T, Ludwig J, Sproat BS, Engels JW. Design, delivery and efficacy testing of therapeutic nucleic acids used to inhibit hepatitis C virus gene expression *in vitro* and *in vivo*. *World J Gastroentero*, 2000;6(5):626-629

Despite major achievements in the treatment of chronic hepatitis C with the combination of interferons and the nucleoside analog ribavirin^[1] the majority of patients with chronic hepatitis C virus (HCV) infection cannot be treated effectively. To improve this response rate we used antisense technologies to inhibit HCV translation as possible additional option for experimental treatment. Antisense oligodeoxynucleotides (ODN) are short nucleic acid oligomers, which bind complementary to the single-stranded HCV-RNA with plus (+) strand polarity and can induce hybrid arrest at the ribosome as well as cellular RNase H activity, which cleaves the RNA template in DNA-RNA hybrids. The 5'-non-coding region (NCR) is highly conserved among the 6 main genotypes and exerts the function of an internal ribosomal entry site (IRES), which is important for translation^[2] and possibly also for viral replication (Figure 1).

Various antisense oligodeoxynucleotides varying from 8 to 23-mers and covering stem-loop structures within the 5'-NCR and the adjacent core gene were synthesized^[3]. ODN₄ comprises HCV 5'-NCR nucleotides (nts.) 326-348 including the start AUG of the polyprotein coding sequence. Since easy-to-handle and generally a available infection or replication systems for HCV are lacking. We used model systems (Figure 2), in which the HCV 5'-NCR and 66 nts. Of the core gene were fused to the firefly luciferase gene for *in vitro* transcription/

translation from the bacteriophage T7 promoter. A similar construct with the cytomegalovirus(CMV) immediate early promoter was constructed for transfection experiments of hepatoma and non-liver cell lines^[4].

As compared to mismatch or sense controls completely phosphorothioate-modified ODN 4 showed the best inhibitory effect of luciferase activity in the rabbit reticulocyte lysate, which ranged in the order 96% ± 1% at about 4μM concentration. The effectiveness of ODN 4 is possibly due to its interference with a pseudonot structure (Figure 1) in HCV RNA which is disrupted, when ODN4 binds to the target RNA. In HepG2 tissue cultures comparable specific effects were obtained. However, fluorescence labeling of this ODN demonstrated that only a small percentage of transfected cells did take up the therapeutic ODN.

In order to improve the capability of membrane permeation by variation of their lipophilicity chemically modified ODN such as methylphosphonate and benzylphosphonate ODN 4 were compared with phosphorothioate ODN 4, which had been used in completely modified form in the previously described experiments. For the following experimental setting partially modified ODN4, which carried 6 modifications over a length of 23 nts. either in terminal localization or scattered along the molecule (Table 1). Toxicological testing revealed acceptable IC₅₀ concentrations between 0.2 and 5.8μM and the best therapeutic indices of 3.8 for terminally modified benzylphosphonate (tB-) ODN 4 and terminally modified phosphorothioates (tS-) ODN4. While both scattered (s) and terminal (t) modifications inhibited HCV gene expression in case of phosphorothioate (S-) ODN 4, only terminally modified methylphosphonate (tM)-ODN 4 and benzylphosphonate (tB)-ODN 4 showed specific and effective inhibition. This is possibly correlated to an induction of RNaseH activity and the steric hindrance of this enzyme by differently modified molecules^[5,6]. In cell culture, tB-ODN 4 showed the best inhibition of about 96%, leaving, however, 4% of reporter gene expression unaffected.

Therefore, katalytically active antisense RNAs, so-called hammerhead ribozymes (RZ), which cleave at NUH recognition sites (N: any nt., U: uridine, H: any nt. except guanosine) of a RNA template, were synthesized. Taking these recognition motifs into account, one of the RZ was directed towards similar stem-loop structures as the previously tested ODN. After purification of the RZ by denaturing polyacrylamide gel electro-

phoresis and reverse phase chromatography their katalytic activity was tested with short 14-mer substrates under defined cleaving conditions. Best cleavage was obtained for RZ A328-R which cleaves between HCV nts. positions 330 and 331. Its Michaelis Menton constant K_m was 69.1 ± 19.3 nM. The katalytic constant K_{cat} was $4,3 \text{ min}^{-1}$ indicating multiple turnover. The katalytic effectiveness K_{cat}/K_m was $6.4 \times 10^7 \text{ M}^{-1} \times \text{min}^{-1}$. The cleavage with longer (452 nts.) HCV-luciferase fusion RNA substrates was best effective, if a high molar excess of RZ were used. In direct comparison with antisense ODN or not katalytically active antisense RNAs targeting exactly identical HCV-RNA sequences RZ A328-R displayed the best about 90% inhibition of luciferase activity *in vitro*.

**Figure 1** HCV 5'-non-coding region.

The pseudoknot region and stem loop IV including the start AUG are indicated in bold font as optimum target sequences for ODN binding.

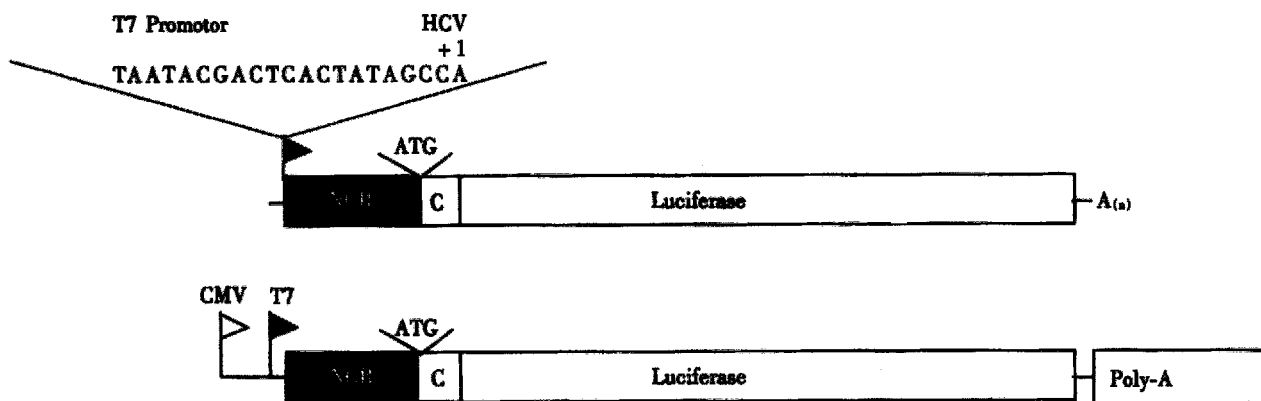

Figure 2 Plasmid constructs to analyze inhibition of HCV translation *in vitro* (upper) and *in vivo* (lower). Expression is directed either by the T7-promoter or the CMV immediate early promoter.

Figure 3 Modified hammerhead RZ and HCV target sequence. The $G_{16.2}C_{16.1}A_{17}$ recognition site (nts.346-348), in which cleavage occurs, is marked by an arrow. All nucleotides are 2'-O-allyl-ribose nucleotides except G_5 , A_6 , G_8 and G_{12} (light gray), which are unmodified ribonucleotides. The position of the A to I exchange (medium gray) and the start AUG of the HCV template are indicated.

Figure 4 Schematic representation of a taurocholic acid-coupled antisense oligodeoxynucleotide. R: oligodeoxynucleotide 5'-end.

To further extend the amount of possible target regions on the HCV genome a A \Rightarrow I exchange at nt. position 15.1 was introduced (Figure 3), which reverts the polarity of an important H-bond in the hammerhead structure and allows efficient cleavage at a non-natural NCH recognition site (N: any nt., C: cytidine, H: any nt. except guanosine). For stability reasons various 2'O-allyl or amino-ribonucleotide modifications had been introduced in these RZ^[7], which cleave between HCV nts. 346 and 347 (Figure 3). A inactive cleavage antisense RZ and an unspecific RNA completely unrelated to HCV were used as controls. Regardless of prehybridisation of the RNA molecules with their target sequence, the best inhibitions of luciferase activity were obtained with the NCH recognizing RZ. The inhibition was less pronounced, when inactive cleavage antisense RZ were used. This data could be reproduced in HCV-5'-NCR/core-luciferase-recombinant CCl13 cell lines, which stably express the HCV core-luciferase fusion protein above from the CMV immediate early promoter. *In vivo* testing using CMV-HCV 5'-NCR/core-luciferase-transgenic mice are presently going on.

Coupling of effective antisense molecules to biomolecules such as bile acids which are specifically transported into the hepatocyte by bile acid transporters are in progress (Figure 4). The size of the antisense ODN coupled to cholic acid or taurocholic acid has been optimized with respect to efficient and specific inhibition of HCV-luciferase translation *in vitro*. Experiments with cell lines overexpressing the organic anion transporting polypeptide (OATP) and the sodium taurocholate cotransporting polypeptide (NTCP) are in progress.

SUMMARY

Antisense oligodeoxynucleotides, RNAs and ribozymes can effectively inhibit HCV translation in model systems *in vitro* and *in vivo*. Chemical modifications such as phosphorothioate or benzylphosphonate modifications of oligonucleotides as well as O-allyl or amino-ribonucleotide modifications of ribozymes guarantee sufficient stability towards nuclease degradation. The specific exchange of single ribonucleotides in synthetic ribozymes permits to extend the ribozyme cleavage specificity to non-natural NCH motifs. If problems of hepatocyte-directed delivery and sufficient intracellular effector concentration can be solved, therapeutic nucleic acids may turn out to be a safe and powerful treatment option in the multimodal therapy concept of chronic hepatitis C.

Hermon-Taylor J. Mycobacterium avium subspecies paratuberculosis in the causation of Crohn's disease. *World J Gastroentero*, 2000;6(5): 630-632

Mycobacterium avium subspecies paratuberculosis (MAP), originally called Johne's bacillus was first described from Germany in 1895 as the cause of a chronic inflammatory disease of the intestine in a cow. As the 20th century progressed, clinical and sub-clinical MAP infection in farm animals in Western Europe appeared to become more prevalent. Among the early reviews available are the excellent ones prepared by Doyle^[1] from the Veterinary Laboratory, Weybridge, UK, and Riemann and Abbas^[2] from the University of California, Davis. In general, the response on farms to the appearance of clinical Johne's disease was to cull infected animals. This practice over the course of the 20th century may have exerted a selection pressure on MAP favouring the emergence of strains which can infect animals for years without necessarily causing clinical disease. In the latter part of the 20th century the incidence of clinical disease due to MAP in some areas of Western Europe and North America appeared to decrease. The problem which confronts these regions now is subclinical MAP infection of domestic livestock throughout Western Europe and North America and the emergence of wildlife reservoirs including those in rabbits and their predators^[3]. In the United States and Canada the herd prevalence of MAP infection is reported in the range 21% - 54%^[4-8]. In Western Europe the herd prevalence lies in the same range, although a recent serological study of bulk-tanked milk from 900 dairy herds in Denmark reported that 70% of herds tested positive for MAP infection^[9]. What is beyond doubt is that MAP is widespread in our domestic animals.

Subclinically infected dairy cows secrete MAP in their milk. It is one of the ways the organism

passes from infected parent to offspring when the calf may be most susceptible. MAP is more robust than *M. bovis* or *M. tuberculosis* and the destruction of all viable MAP by exposure to current pasteurisation conditions of 72°C for 15 seconds is not assured. In on-going research in the Department of Food Science, University of Belfast, N. Ireland, small slow-growing, mycobactin-dependent, IS900 PCR positive colonies of MAP have been cultured from about 3% of retail units of pasteurised cows' milk, so far tested. In the U.K. what is also beyond doubt is that the human population is being exposed to MAP in retail milk supplies. These organisms accumulate particularly in the ileocolonic regions of the intestine where they may remain for years and not cause clinical disease. This situation is similar in principal to the widespread exposure of human populations in Europe, North America and elsewhere, to *M. bovis* before the introduction of milk pasteurisation and the tuberculin testing of dairy herds introduced in the middle third of the 20th century. With MAP, only those individuals with a particular inherited or acquired susceptibility may go on eventually to develop clinical disease.

Infected animals excrete MAP onto pastures. Wildlife reservoirs contribute to environmental contamination. The problems now being caused by MAP, differ from those previously caused by *M. bovis*, in that MAP can survive for long periods in the environment. Rains falling on contaminated land will wash MAP into ground and river waters. Although much research needs to be carried out in this area, it is probable that MAP in the environment is taken up into organisms such as amoebae in which they can survive. This may allow them to replicate, to increase their resistance to biocides and potentially acquire a phenotype which is more pathogenic for humans. Water abstracted from rivers and lakes contaminated with MAP may convey these organisms to human populations. MAP arriving at domestic outlets in high dilution may accumulate in biofilms lining household water systems. Either in the food chain therefore, or in water supplies, it is inevitable that humans sharing the same geographic areas with animals which are extensively infected, will be exposed to these pathogens.

The question as to whether MAP may also cause disease in humans has its origins in a proposition first published in 1913^[10]. We have recently prepared a detailed analysis of this complex issue which is in general poorly understood, even by

Received 2000-07-05 Accepted 2000-08-01

medical specialists in the field of chronic inflammatory diseases of the intestine^[11]. It is now known that MAP can cause chronic inflammation of the intestine in a very broad range of animals including large and small ruminants, monogastrics such as dogs and pigs, and so far at least four types of sub-human primates. MAP shows a well defined tissue tropism and will end up causing chronic inflammation of the intestine even if administered experimentally by subcutaneous, intravenous or intraperitoneal routes. The histopathological features of MAP disease in animals ranges from one in which millions of typical ZN-positive MAP are visible microscopically in the inflamed intestine to the other extreme where no MAP can be seen at all, but there is chronic granulomatous inflammation. This is just what leprosy does in humans. One of the properties of MAP which has retarded our understanding of the problems it is causing is that it may be very difficult to culture in the laboratory. Patient work in many laboratories has, however, shown that MAP can be grown in conventional culture from about 5% of people with Crohn's disease, but not from normal people. Cultures have had to be incubated for months or years before any growth identifiable by conventional means, becomes visible.

MAP is very similar to other organisms of the *M. avium* complex (MAC) to which we are all exposed, so that immunological tests for MAP infection in humans using crude extracts of laboratory cultured organisms usually report no difference between Crohn's disease and normal people. Recent studies have however shown that if specific targets on MAP are carefully selected, highly significant differences in immune recognition can be demonstrated between Crohn's disease and normal people. An important example of this has come from recent research at UCLA which showed that the blood of 9 out of 10 people with Crohn's disease contained IgA which recognised a mycobacterial protein richly expressed on MAP called HupB^[12]. HupB is identical to the laminin receptor used by *M. leprae* to enter Schwann cells round nerves causing the neural inflammation so characteristic of leprosy^[13]. Neural inflammation is long known to be a specific feature in the inflamed gut in Crohn's disease^[14] and antibodies to the chronic inflammatory disease associated autoantigen pANCA, cross-react with HupB.

In 1990, after spending 20 months carefully optimising sample processing and experimental procedures, we began a study which revealed the presence of MAP DNA in about two thirds of people with Crohn's disease using IS900 PCR^[15]. It was also present in the intestine of 12% of normal people, which is just what would be expected to occur in a totally exposed population. Since then there have been 18 peer reviewed publications using a variety of experimental methods, 9 of which reported the

presence of MAP in CD gut some or most of the time and 9 found MAP hardly ever or not at all^[11]. Similar inconsistencies have occurred in the results of DNA tests applied to other chronic inflammatory diseases such as TB. Apart from some obvious methodological errors, the reasons for the uncertainty are the low abundance of MAP in Crohn's disease intestine and its extraordinarily tough protease-resistant phenotype. Recent research by Dr Saleh Naser and colleagues from the University of Central Florida [cited in 11], using improved liquid cultures and IS900 PCR on their centrifugal pellets, has demonstrated MAP in 86% of surgically resected Crohn's disease gut. The same authors have also demonstrated MAP in the centrifugal pellets of breast milk from each of 2 mothers with Crohn's disease who had recently given birth, but not in the breast milk of 5 normal women. Work in our own lab by Jun Cheng and Tim Bull, using much improved methods, is currently reporting Chinese MAP in 69% of Chinese surgical path blocks from Crohn's disease patients in China, and in 14% of path blocks of normal intestine from Chinese people. In our view these studies clearly demonstrate the presence of this chronic enteric pathogen in a substantial majority proportion of humans with chronic inflammation of the intestine of the Crohn's disease type. Although the incidence of Crohn's disease in China is currently much lower than in Western Europe or North America, these recent studies in humans strongly suggest that Chinese people are exposed to these pathogens and that action may need to be considered at this early stage to limit the more extensive development of disease in humans.

It has long been known that infections due to non-tuberculous mycobacteria in immunocompetent people, particularly those caused by MAC, are usually resistant to standard anti-tuberculous drugs. These organisms can prevent the drugs penetrating the microbial cell and can rapidly develop mutations which confer drug resistance. Lasting resolution of MAP infections in animals using standard anti-mycobacterial treatment has never been convincingly demonstrated, and much the same outcomes have resulted from a similar treatment approach in humans with Crohn's disease^[11]. MAP are however more susceptible to some newer drugs which are man-made chemical modifications of natural streptomycetes antibiotics such as rifabutin and clarithromycin. These agents also have the advantage of being concentrated within macrophages where MAP in infected animals and in humans almost certainly resides. Our own studies from 1992^[16], supported by the work of Dr. Tom Borody in Sydney, Dr. Ira Shafran at the University of Central Florida, and by recent work from the North of England^[17] have shown that a substantial proportion of people with active Crohn's disease will go into remission with healing of the

intestine which is sometimes lasting, when treated with combinations of these drugs. A randomised controlled trial of this treatment was initiated in Australia in September 1999.

A question which is frequently asked is how can so few MAP cause so much chronic inflammatory disease? To answer this we must allow our thinking to escape from the immobilising presumption that it must be like TB, in which a major factor in the disease process is a direct immunological response to cell wall components. MAP in animals with the paucimicrobial form of the disease and in humans, does not have a classical mycobacterial cell wall. MAP colonising immunoregulatory cells like macrophages almost certainly causes an immune dysregulation. Together with defects in the integrity of the overlying mucosa, much of the disease itself is caused by an exaggerated immunological response to leakage into the gut wall of bacteria and food residues normally confined to the lumen. Clinical improvement can be achieved by suppressing or modulating the immune system, by reducing the allergic component and altering the enteric flora with elemental diets, and by treatment with antibiotics such as ciprofloxacin and metronidazole. Without killing the underlying causative pathogens however, the benefit which follows such treatments is rarely lasting.

The present analysis of the MAP problem suggests that particularly in Western Europe and North America, we are challenged by a public health issue of substantial proportions for which a range of remedial measures are needed. These measures include conditions of pasteurisation of retail milk which do ensure the destruction of all viable MAP. We need to use the improved culture systems available together with modern molecular methods to ensure our domestic livestock are free of sub-clinical infection. We need to test water supplies to make sure they are clean. In high incidence areas, we need to make Crohn's disease reportable so we have accurate data to monitor the effect of these measures on the overall problem. We need to make a rapid increase in the volume and intensity of research in the field, to sequence the

MAP genome and to develop preventative vaccines for animals and therapeutic vaccines for humans.

Treatment revisited and factors affecting prognosis of severe acute pancreatitis

Xie Ning Wu

Subject headings pancreatitis/therapy; prognostic factor analysis; inflammatory cytokines; necrosis; computed tomography; necrosectomy

Wu XN. Treatment revisited and factors affecting prognosis of severe acute pancreatitis. *World J Gastroentero*, 2000;6(5):633-635

INTRODUCTION

As stated in the author's previous articles^[1-5], severe acute pancreatitis is a multifaceted disease with rapid and sometimes fulminating onset and may result in many serious complications or even death if treatment is improper or delayed. Therapeutic measures must be directed against these multifacets simultaneously with a view to achieve the optimum results. The following regime has been practised many years since 1990 and verified repeatedly as proper and adequate.

THERAPEUTIC REGIME OF SEVERE ACUTE PANCREATITIS

Early diagnosis is based on history, symptoms and signs, elevation of serum and/or urinary amylase and computed tomography (CT) of pancreas. Once the diagnosis is verified, treatment is immediately instituted, the treatment regime is listed in Table 1.

Octreotide (Sandostatin) and the herbal medicine, Bulpleurum Peony Cheng Qi decoction have synergistic effects, their effects are depicted in Table 2.

In Balthazar's CT grading of D and E, there are always profuse exudation peripancreatically and sometimes massive into the peritoneal cavity and retroperitoneal space, plasma is always needed to improve the hypovolemia, and human albumin for hypoalbuminemia even when hypotension or shock is absent. When the hemodynamics become stabilized, intravenous hyperalimentation should be given. Octreotide and the herbal mixture are administered simultaneously at the start, the abdominal pain and abdominal distention usually subside within 1-3 days. Usually the patients run a smooth course without much fluctuation in one to one and a half months. Another important point is that food must be restricted until one month later after abatement of all symptoms and signs.

By the above regime, 20 cases of grade D and 10 cases of grade E recovered unequivocally with no mortality, almost no morbidity and no serious complications as ARDS, gastrointestinal failure and disseminated intravascular coagulopathy(DIC).

Table 1 Treatment regime of severe acute pancreatitis

CT grading	Treatment
Grade A-C	Octreotide 0.1mg q8h (H)×5-7d Bulpleurum Peony Cheng Qi decoction bid×5-7d
Grade D-E	Octreotide 0.1mg/25% glucose IV 0.5mg/5% glucose in saline 1000mL/24h thereafter 0.6mg/5% glucose in saline 1000mL/24h ×5-7d or more or Stilamin 6mg/5% glucose in saline 1000mL/24h×5-7d Bulpleurum Peony Cheng Qi decoction 150mL bid×5-7d Plasma 400mL-600mL stat, 200mL on 2nd and 3rd day each Human serum albumin 10-20g/d Low molecular weight dextran (-40)+Dan Shen liquid 16-20mL/ glucose water 250mL×1-2d, thereafter Dan Shen liquid in glucose in saline ×3-5d Ciprofloxacin 0.2g bid+Metronidazole 100mL bid×4 weeks or Imipenem 0.5g q8h×4 weeks Compound aminoacids 500-750mL qd, Intralipid 10% 500mL qd Fasting for food but not the herbal medicine Omeprazole 40mg IV qd×7d, and then 20mg per oral qd×2-3 weeks No atropine or gastric decompression Calcium, potassium salts supplement with occasional magnesium salt

Table 2 Effects of Octreotide and the herbal medicinals

Drug	Effects
Octreotide (Sandostatin) ^[5]	Inhibits release of CCK and pancreatic enzymes Stimulates and activates macrophages, lowering endotoxin level ^[6] Blocks release of inflammatory cytokines ^[7] Redistributes intrapancreatic blood flow Attenuates the interaction of neutrophils and endothelial cells ^[8] Inhibits eicosanoid and products as PGI ₂ , leucotrienes Relaxes Oddi's sphincter
Bulpleurum Peony Cheng Qi decoction ^[5]	Inhibits secretion and activities of pancreatic enzymes Stabilizes lysosomal membrane Inhibits inflammatory cytokines, IL-1, IL-6, IL-8, and TNF-α; Inhibits vascular permeability ^[9] Increase peristalsis with purgating effect, expelling bacterial flora and endotoxin Protects gut mucosal barrier, preventing bacteria dislocation ^[10,11] Relaxes Oddi's sphincter Reduces urea synthesis, promotes urinary excretion of urea and creatinine Has broad antibiotic spectrum, including <i>B. Fragilis</i> Stimulates secretion of endogenous glucocorticoids which can inhibit cytokines and inflammatory mediators Decreases blood lipids, inhibits lipid peroxidation Inhibits TXA ₂ synthase, promotes PGE ₁ , PGE ₂ levels, inhibits transformation of fibrinogen to fibrin and prevents endotoxin induced DIC
Dan Shen (Salvia Miltiorrhiza)	Inhibits platelet aggregation, decreases blood viscosity, improves blood rheology and microcirculation Inhibits lysosomal enzymes and chemotactic neutrophils Blockage of calcium ion influx Has antioxidation effect, ameliorates inflammation and tissue damage

FACTORS AFFECTING THE PROGNOSIS OF SEVERE ACUTE PANCREATITIS

Extent of necrosis and time of treatment after onset of the disease

The extent of necrosis can be categorized into ≤30%, 30% - 50% and >50% of the surface area

of pancreas shown in CT, which is relevant to the time of treatment given. The necrotic process is dynamic in nature, if diagnosed within 24h - 48h after disease onset, the extent of necrosis is usually $\leq 30\%$, if diagnosed after 72h, it may progress to 30%-50% or even $> 50\%$ even if the treatment is proper and adequate, the pathophysiologic changes can be more complicated, the rate of infection of intestinal origin is also higher with usher in of systemic inflammatory response syndrome (SIRS), then treatment can be more difficult with worser prognosis. In America, the mortality rate of this particular disease was around 17% - 20%, because the CT report usually took three days and this delay would enable progression of necrosis to the extent of 30%-50% or even $> 50\%$ with higher mortality rate.

Proper, improper and/or inadequate treatment at the beginning

The key element in determining the prognosis of the disease is the treatment given at the start, with idiopathic severe acute pancreatitis, treatment is mainly medical, if with presence of common duct stone obstruction, emergency endoscopic or surgical removal of stone is necessary.

The comprehensive medical treatment is listed in Table 1, continuous infusion of Octreotide gives better results than 0.1mg q8h given hypodermically, in the latter, sepsis occurred in 26%, and ARDS in 37%^[12]. Adequate plasma, albumin, low molecular weight dextran and Dan Shen restore the blood volume and improve the microcirculation of pancreas and other vital organs. Concomitantly, Blupleurum-Peony-Cheng Qi decoction is given which has seven constituents, including: Bulpleurum, White peony, Scutellaria, *Unripe bitter orange*, *Magnolia bark*, *Refined mirabilite* and *Rhubarb*, each 10g. It is prepared by adding 100-150 water to the first five constituents, and heated for 20min, at the 18th min, add Rhubarb (wrapped by cloth), heat only for two min, then decant the liquid and dissolve the refined Mirabilite (Na_2SO_4) crystals in it and drink. The mixture is taken twice a day by repetition of the same procedure. This herbal medicine should be taken orally for 5-7 days. No atropine, nor gastric decompression is allowed.

Combination of these measures can ameliorate the pancreatic autodigestion caused by release of pancreatic and lysosomal enzymes and ischemia-reperfusional damage significantly, it can also halt the exudation, and avoid the complications of the kidney, lung and GI tract. This herbal mixture can inhibit the excessive stimulation of macrophages; reduce the release of inflammatory cytokines, decrease the neutrophilic infiltration and its interaction with vascular endothelial cells, maintaining the gut barrier function, preventing the second attack which leads to SIRS.

Among the destructive enzymes, phospholipase A_2 (PLA_2) and lipase are most crucial, PLA_2 can destroy the phospholipid structure of cell membranes of GI tract, lung and brain. The lipase can degradate the fat which produce toxic free fatty

acids injuring the capillaries and increase lipoperoxidation^[13]. The cytokines damaging vital organs include IL-1, IL-6, IL-8, TNF- α , INF- γ and PAF. Among these, PAF and TNF- α increase vascular permeability which not only play important pathophysiological role in the pancreas itself but also cause complications in the lungs, brain and GI tract. By given Octreotide (Sandostatin) with concomitant herbal mixture, the damage caused by the above factors can be much reduced. Sandostatin and the herbal mixture have synergistic effects on inhibition of activated pancreatic enzymic activities and their secretion, also have complementary effect on interaction of the neutrophils and endothelial cells, and inhibition of neutrophilic infiltration in the pancreas and in the lung, thus is crucial in the treatment of severe acute pancreatitis.

When given Sandostatin or oral herb mixture singly and without given plasma, human serum albumin, but infuse large volume of balance solution or glucose in saline, these not only cannot act on simultaneously, but also may lead to cardiac and pulmonary failure, this may be one of the causes of high mortality rate and high complication rate as reported in the medical literature both domestically and abroad.

Whether preventive treatment has been instituted?

During admission, Omeprazole (Losec) should be given intravenously to prevent acute gastric mucosal bleeding; ciprofloxacin and metronidazole or imipenem to prevent infection, besides, the Rhubarb and Scutallaria have also antibiotic activities. Rhubarb also abolishes paralytic ileus, expel the bacteria flora together with endotoxin via the anus. The antibiotics shown above have penetrating abilities into the necrotic tissue or necrotic fluid, if other antibiotics are used instead or by rotation would not only be ineffective, but also lead to superinfection in these immunocompromized patients. Once the hemodynamic changes return to normal after correction of hypovolemia, total parenteral nutrition should be instituted to maintain positive nitrogen balance, in case with SIRS, more calories should be given regularly up to 2500-3000 Kal/d or more. Regular insulin should also be given to maintain normal blood sugar level. Supplements of calcium, potassium and magnesium salts are also required for hypocalcemia and hypopotassemia. Local fluid collection is best to be left alone without aspiration, this will be absorbed during convalescence.

During the early period, one should pay attention to avoid cardiac or renal failure, also the ARDS, in the middle period, one should notice and prevent the occurrence of pancreatic encephalopathy; late in the course, one should be aware of infection and residual infection. Food fasting but allow oral herb mixture only would take one month, early feeding can give rise to recrudescence. If one is not aware of the complicated and multifaceted nature of the disease

and has not paid great attention to the preventive measures, SIRS, multiple organ dysfunction syndrome (MODS) and eventually multiple organ failure (MOF) would be unavoidable. For SIRS, short-term hemofiltration had been adopted by the surgical pancreatology group of Shanghai Ruijin Hospital to downregulate the level of inflammatory cytokines and upregulate the antiinflammatory cytokines (IL-10) level which could shorten the course and hasten recovery^[14].

Can the precipitating factors be removed or not?

The precipitating factors as microlithiasis or cholesterol crystals from the gallbladder, the high fat, high protein diet and alcohol drinking were removed after treatment and fasting, the patient usually recovered clinically in 1-1.5 months, and the pancreas showed normal texture by CT by another 1-1.5 months. But when hyperlipidemia is the inducing factor, the lipoperoxidation and pancreatic ischemia are especially severe, the reason is stated above, the course is usually fulminating, because short-acting hypolipidemic agent for intravenous use is currently unavailable, especially in those with coexistent fatty liver, the oxidation of fatty acid by the mitochondria of the liver cells cannot be augmented, the severe ischemia and lipoperoxidation would result in extensive pancreatic necrosis, and because of the persistence of free fatty acid as the stimulus, numerous complications may set in, making treatment even more difficult, fortunately this precipitating factor is rare here.

Functional status of vital organs

Aged patients usually have degeneration and deteriorating function of many vital organs, diseases as ischemic heart, hypertension, diabetes, chronic bronchitis with emphysema, chronic liver disease, impaired kidney function or even lacunar infarction of brain are common, any one or two coexisted can add further embarrassment to the management, fortunately the severe acute pancreatitis among the aged is milder than that in the middle-aged and younger patients, they are mostly of grade C and B, whereas grade D is only occasional^[15]. One must be very careful throughout the course of treatment, detailed history, physical examination, blood chemistry, blood gas analysis, electrocardiogram should be performed on admission, fluid given must be concordant with the tolerability of patient's heart and circulation, the rate of fluid infusion should be slow to avoid the unnecessary occurrence of heart failure. In case when heart failure occurs, cedilanid and dobutamine should be given to increase myocardial contractility and phentolamine to diminish the pre-and afterload. At the same time, one should also pay attention to the renal function because cardiac and renal functions are interrelated, with both cardiac and renal incompetence, the condition is usually detrimental and may be fatal.

Whether necrosectomy is timely and thorough?

With stone obstructing the pancreatico-biliary common pathway, ERCP or endoscopic sphincterotomy should be tried first, or emergency surgery to relieve obstruction with common duct T-tube drainage, but leave the pancreatic necrosis aside, operation should be as simple as possible, afterwards, comprehensive medical therapy should be instituted immediately. With nonstone obstruction where necrosis is extensive and severe, patient should be placed in ICU, given energetic medical treatment and watched carefully by dynamic CT and other measures, in case of progression of the disease, necrosectomy should be performed with thorough removal of necrotic foci. Acute peritonitis occasionally requires laparotomy for drainage, followed by short-term peritoneal lavage when there is profuse exudation and fluid collection in the peritoneal cavity and retroperitoneal space. The peritoneal exudative fluid contains PLA₂, protease, bradykinin, PAF, prostaglandins and complement component which should be evacuated. Necrosis with infection if can be controlled by antibiotics, operation may be spared, but if it is uncontrollable, surgery should be performed to remove the infected necrotic foci within the pancreas, the peritoneal cavity and retroperitoneal space thoroughly. These are the surgical viewpoints of the expertised surgeon Zhang ZT of Ruijin Hospital^[16].

Riordan SM, Williams R. Transplantation of primary and reversibly immortalized human liver cells and other gene therapies in acute liver failure and decompensated chronic liver disease. *World J Gastroentero*, 2000;6(5):636-642

Studies performed in experimental small animals with hepatic-based metabolic disorders but no structural liver disease, including Gunn and analbuminaemic rats and rabbits with inherited low-density lipoprotein receptor deficiency, have shown that up to 95% of hepatocytes transplanted into the spleen or liver remain in these sites, with improvement in metabolic function of recipients^[1-4]. The feasibility of hepatocyte transplantation as a clinically-relevant therapeutic tool has subsequently been demonstrated in a small number of patients with disorders such as Crigler-Najjar syndrome type 1^[5], ornithine transcarbamoylase deficiency^[6] and familial hypercholesterolaemia^[7], in whom the delivery of numbers of primary hepatocytes approximately equivalent to only 5% or less of the normal liver cell mass led to satisfactory, if incomplete, correction of the metabolic defect. Hepatocyte transplantation has several real and potential advantages over conventional orthotopic liver transplantation (OLT). In addition to the relative simplicity, less invasive nature and lower associated cost of the former intervention, the ability to cryopreserve primary liver cells without substantial loss of viability or physiological function on subsequent thawing, provided that they are attached to microcarriers or gel-entrapped as spheroids^[8-10], offers the potential that, through liver cells stored in centralised banks, it will be possible one day to have them widely available for clinical use within a

few hours of a decision to institute such therapy.

A particularly important issue is whether liver cell transplantation has a role in the management of patients with severe liver damage resulting in acute liver failure (ALF), where only short-term support may be required given the potential for regeneration of the native liver^[11], or those with decompensated chronic liver disease, in whom on-going support over a longer period may be necessary. The availability of effective liver support "on demand" would constitute an important advance in the management of such patients, given the rapidity with which irreversible clinical deterioration often occurs in these settings. In this review we consider clinical experiences with hepatocyte transplantation in each of these liver failure syndromes reported to date, as well as discussing issues pertaining to the ideal cell type for clinical use. The potential applications of adjuvant and other gene therapies, as recently described experimentally, which may overcome two of the major limitations of liver cell transplantation at present, namely the relative unavailability of primary human hepatocytes and the requirement for pharmacological immunosuppression in the post-transplantation period, are also considered.

Liver cell transplantation in experimental animals with ALF due to chemically-induced hepatic necrosis or surgical models of hepatic ischaemia or resection has, to date, generally involved the use of primary hepatocytes. Such treatment has been associated with improved survival, even when small numbers of cells, in the order of only 0.5% to 3% of the normal hepatocyte mass, are used^[12-19]. These small numbers of cells may be sufficient to enhance hepatic regeneration, on which recovery ultimately depends, possibly due at least in part to reduction in levels of transforming growth factor (TGF) β 1, a potent inhibitor of this process^[20]. However, cell transplantation has been performed prior to the induction of ALF in some surgical models, a scenario clearly incongruous to the clinical setting. Furthermore, since mediators such as interleukin-6 and tumor necrosis factor- α produced by activated Kupffer cells in ALF contribute to both progressive liver damage and the development of multi-organ failure^[21-23], while the liver is also the source of TGF β 1 and other

inhibitors of liver regeneration^[24,25], the relevance of animal models in which the liver is removed to the clinical situation, in which it remains *in situ*, is uncertain.

Nevertheless, several preliminary studies have already been carried out on the clinical efficacy of hepatocyte transplantation in adult and paediatric patients with ALF. No randomised, controlled data is yet available and the impact of such treatment on clinical course is uncertain. Strom *et al.*^[26] reported their experience at the Medical College of Virginia with transplantation of small numbers (0.1% or less of the normal hepatocyte mass) of ABO-matched, freshly isolated or cryopreserved primary human hepatocytes via injection into the splenic artery in two adults with ALF due to hepatitis B virus infection and phenytoin hepatotoxicity, respectively. Both patients were in grade IV encephalopathy prior to the treatment. Immunosuppression was with methylprednisolone and cyclosporin. Reduced blood ammonia levels along with improvement in encephalopathy grade and reversal of haemodynamic instability were noted. Other evidence of metabolic function was unimpressive, with the serum bilirubin level increasing in both patients and the prothrombin time rising in one and falling only marginally in the other. Both patients underwent OLT after three and 10 days, respectively, with subsequent full recovery. None of three control patients, for whom either fresh or frozen hepatocytes were not available or consent for hepatocyte transplantation could not be obtained, survived. Of an additional five adult patients with ALF who underwent hepatocyte transplantation in this way at the same centre, three (60%) in grade III to IV encephalopathy (due to acetaminophen toxicity: $n = 1$; hepatitis B virus infection: $n = 1$ and idiopathic: $n = 1$) were successfully "bridged" to OLT between one and five days later. Another patient in grade IV coma (due to herpes simplex virus infection and/or sodium valproate hepatotoxicity) died of sepsis-related cardiovascular instability on day 5 before OLT could be performed, while the remaining patient with acute hepatitis B virus infection recovered without OLT but had only low-grade in grade I encephalopathy prior to the procedure^[27]. Bilir *et al.*^[28] from the University of Colorado subsequently transplanted by percutaneous injection larger numbers of cryopreserved primary human hepatocytes (in the order of 5% of the normal hepatocyte mass) in five adult patients with ALF and grade IV encephalopathy who were not candidates for OLT. Three (60%) patients survived more than 72 hours, with evidence of improved encephalopathy score, serum ammonia levels and prothrombin times. A delay in the order of 24 to 72 hours was apparent between hepatocyte transplantation and the first biochemical or clinical sign of improvement, possibly reflecting the time

required for effective engraftment, as demonstrated in experimental animals^[29]. However, no patient survived for more than seven weeks. The same group reported technical success in achieving engraftment via the transjugular route in an additional comatose patient with ALF, although no clinical benefit could be demonstrated^[30].

Transplantation of comparably small numbers of hepatocytes has been performed in six children with ALF, aged six months to 15 years, with aetiologies including acetaminophen hepatotoxicity ($n = 1$), other drug reactions ($n = 2$), idiopathic ($n = 2$) and sepsis/total parenteral nutrition ($n = 1$)^[26,27,31]. Five (83%) of these children were in grade IV encephalopathy at the time of treatment. Of these, four (80%) died within seven days, despite instances of reduction in serum ammonia levels and requirement for coagulation factor support, while the other patient recovered without OLT, having received multiple infusions of hepatocytes over a three day period. Another child, in whom hepatocyte transplantation was performed when in grade I encephalopathy, underwent OLT two days later.

In experimental animal models, successful hepatic engraftment of transplanted hepatocytes is associated with evidence of transient micro-circulatory damage to the host liver^[32]. This development of reversible portal hypertensi on precludes the transplantation of larger quantities of hepatocytes, at least in one session^[33]. However, transplantation of a relatively small number of cells can lead to substantial replacement of the recipient's liver mass in the experimental setting in the presence of various regenerative stimuli. The latter include the concurrent intravenous injection of hepatocyte growth factor (HGF)^[34], induction of ischemic atrophy of the contralateral liver lobe^[3,4] and in situations in which the recipient's own liver cells have a shortened life-span, as occurs with acute chemical injury^[35], transduction with a recombinant adenovirus vector expressing a non-secreted urokinase^[36] or anti-Fas antibody-induced apoptosis^[37].

The growth advantage of transplanted cells over native cells demonstrated in these circumstances may be maximised in the ALF setting by the use of purified hepatic stem cells able to replicate at least 100 times without loss of function or malignant transformation, as identified in adult rodent liver^[38,39]. Repopulation experiments using purified fractions of total liver cell suspensions will be required to identify any such cells in the adult human liver^[40]. Of note, a bone marrow-derived stem cell capable of repopulating the liver with mature hepatocytes following hepatic injury has recently been described in rodents. In the order of 1.0×10^6 hepatocytes (approximately 0.1% of the total hepatocyte mass) originated from transplanted

bone marrow cells by day 13 after liver injury^[41]. This finding raises the exciting possibility that bone marrow infusion may have therapeutic potential in liver failure, although, even if extrapolated from the animal to the human situation, the time required for engraftment and cell differentiation would be problematic in the acute setting.

On the premise that the fetal liver contains epithelial cells that are in different stages of lineage progression, some of which may exhibit the full regenerative potential of stem cells, transplantation of fetal hepatocytes has been suggested as the way forward, rather than use of adult cells. Clinical data so far are limited. Habibullah *et al*^[42] in India transplanted 6×10^7 blood group-matched, fetal hepatocytes per kilogram body weight by intraperitoneal injection in seven patients with ALF of unspecified aetiology and grade III to IV encephalopathy. Three (43%) transplanted patients survived. Those who survived each had a prothrombin index of 1.5 or less and were in grade III or IV a encephalopathy at the time of hepatocyte transplantation, while those who died had a more severe illness marked by prothrombin indices ranging from 2.6 to 3.0 and grade IVb encephalopathy at this time. Blood ammonia concentrations fell in 5/6 (83%) transplanted patients in whom serial levels were obtained. Survival in a control group, selected on the basis of inability to procure consent for the hepatocyte transplantation procedure, was 33%. Whether fetus-derived hepatocytes will prove superior to their adult counterparts in terms of regenerative capacity and functional characteristics, and whether any such superiority will translate into increased clinical efficacy in the ALF situation or with chronic liver damage, remain to be determined.

Irrespective of the fetal or adult nature of transplanted hepatocytes or even the use of bone marrow infusion as a source of stem cells capable of repopulating the liver, the potential role in the ALF setting of co-transplantation of non-parenchymal cells requires consideration. The co-transplantation of such cells may be advantageous to the viability and function of transplanted hepatocytes in terms of secretion of extracellular matrix, analogous to the beneficial effects in these regards documented in *ex-vivo* culture systems^[43-45]. However, the inclusion of non-parenchymal cells in suspensions for transplantation might also have deleterious effects if these cells become activated to produce cytokines such as TGF- β 1 and interleukin-1 which promote apoptosis of hepatocytes and inhibition of liver regeneration^[24,25].

Controlled studies in which liver cell transplantation in its various forms is compared to standard intensive care will be required in order to determine the efficacy or otherwise of this intervention in the ALF setting. These studies should be performed, at least in the first instance,

in the most severely affected groups fulfilling criteria for OLT but for whom this is unavailable or contraindicated by co-morbidity. Such studies will need to be conducted on a multicentre basis and using standardised outcome measures if sufficient numbers of patients are to be recruited and meaningful results obtained. If benefit is demonstrated in such groups, efficacy should then be addressed in patients with apparently lesser degrees of liver damage not fulfilling OLT criteria, as recent analyses showing poor negative predictive values of current selection criteria for OLT indicate that a substantial number of such patients nevertheless deteriorate with intensive medical care alone^[46-48].

Clinical experience to date with liver cell transplantation for decompensated chronic liver disease is similarly limited, uncontrolled and confined to the use of primary adult hepatocytes. The feasibility and apparent safety of hepatocyte transplantation in chronic liver disease was first reported by Mito and Kusano in Japan^[49], who injected small numbers of freshly isolated human cells into the spleens of 10 patients with cirrhosis or chronic viral hepatitis at laparotomy and under the influence of epidermal growth factor. Viable hepatocytes were detected in the spleen by scintigraphy in almost all patients up to 11 months later. Four patients with cirrhosis subsequently underwent hepatocyte transplantation via injection into the splenic artery at the Medical College of Virginia^[27]. One of two patients in grade IV encephalopathy survived until OLT was performed on day 2, while a third patient in grade II-III encephalopathy recovered to be discharged from hospital before relapsing and dying on day 33. Another patient in whom liver failure with grade IV encephalopathy was precipitated by trisegmentectomy died of cardiovascular instability within 2 days of the procedure. More recently, Bilir *et al*^[50] in Colorado treated five patients with Child's C cirrhosis who were not candidates for OLT with transplantation of 1×10^9 to 1×10^{10} cryopreserved primary human hepatocytes (in the order of 5% normal liver cell mass), with viability of 52% to 73% after thawing, via infusion into the splenic artery. Immunosuppression was with cyclosporin. Indications for hepatocyte transplantation were refractory encephalopathy with ascites ($n=4$) and hepatorenal syndrome ($n=1$). Improvements in encephalopathy grade and ascites and renal function, respectively were noted within days of the procedure. Improvements in serum albumin levels and prothrombin times also occurred, but only after a period of four to six months. Aside from one patient who stopped immunosuppression after five months, all patients were alive and well two to 15 months post-transplantation. There were no complications related to the procedure. In particular, no overt evidence of increased portal

venous pressure, as reported following hepatocyte transplantation in experimental animals with cirrhosis^[51], was recorded, although it is to be noted that transjugular intrahepatic portosystemic shunts had been placed prior to transplantation in the majority of patients. No instances of pulmonary vascular complications were clinically apparent, despite concerns of increased pulmonary sequestration of transplanted cells in the context of portal-systemic shunting. Results of a randomised trial of hepatocyte transplantation in cirrhosis, which is currently in progress, are awaited.

Even if the efficacy of primary human hepatocyte transplantation was to become firmly established in the ALF and decompensated chronic liver disease settings, the limited availability of these cells is likely to represent a severe, ongoing impediment to its widespread clinical application. Primary human hepatocytes are obtained from resected surgical specimens, unused segments or end-lobe wedges of donor organs for OLT and livers from apparently healthy donors which are ultimately rejected for OLT on account of overt steatosis, since these are often also fibrotic. Although approximately 10^9 hepatocytes are readily obtained from a segment of normal liver, the yield is substantially reduced when fibrosis is present^[52]. The high demand for whole organ OLT and the expertise to transplant portions of a single organ into more than one recipient mean that completely normal liver is increasingly in short supply for other uses. A satisfactory number of viable primary human hepatocytes cannot at present be obtained from needle biopsy-sized fragments of liver.

The *ex-vivo* expansion of hepatocytes recovered from surgical specimens represents a potential means of overcoming the problem of limited hepatocyte availability for transplantation. A number of proliferating human cell lines which have become immortalised by virtue of cultural conditions, without the use of oncogenes or carcinogens, have now been maintained in continuous culture for up to several years, although considerable limitations in their spectra of metabolic activity may inhibit their clinical utility were they to be used in the liver failure setting^[53-56]. An alternative approach to achieving population expansion of hepatocytes *ex-vivo*, without necessarily compromising their differentiated functional capability and the prospect of obtaining meaningful clinical support following their subsequent transplantation, is to transfect the cells with a replication-deficient retrovirus carrying a temperature-sensitive variant of the simian virus 40 large tumor (SV40 large-T) antigen gene. This gene binds to the cell cycle control protein, p53, and produces cell lines which proliferate at 33°C but cease proliferating and develop enhanced differentiated function, including upregulated synthesis of α -1-antitrypsin and inducible activity of some cytochrome P450 isoforms, at 39°C^[57,58].

Hepatocytes from Gunn rats immortalised by transfection with the SV40 large-T antigen have been used successfully for *ex-vivo* gene therapy, in which the cells were also transduced with the gene for bilirubin-uridine diphosphoglucuronate (UDP)-glucuronosyltransferase, expanded *in vitro* by culturing at 33°C and finally transplanted into syngeneic animals. Long-term reduction of serum bilirubin in association with the appearance of bilirubin glucuronides ensued^[59]. In addition, transplantation of SV40 large T-antigen-immortalised hepatocytes in porto-caval shunted rats and those with surgically-induced ALF has been shown to improve resultant hepatic encephalopathy and survival, respectively^[60,61]. Several non-clonal human hepatocyte cell lines successfully transfected with an amphotropic mouse retrovirus containing this gene have remained stable in long-term continuous culture^[58]. Nonetheless, the potential clinical applicability of such cell lines has been questioned following reports in experimental animals that hepatocellular carcinoma may develop in hepatocytes expressing the SV40 large-T antigen^[62].

Kobayashi *et al.*^[63] have recently investigated the feasibility of overcoming the otherwise unacceptable risk of tumorigenicity of SV40 large-T-immortalised cells, using a technique of reversible immortalisation in which cells are initially transduced to proliferate *in vitro* prior to the excision of the T-antigen-encoding DNA sequence before transplantation. Specifically, a highly differentiated cell line, NKNT-3, was generated by retroviral transfer to primary adult human hepatocytes of the SV40 large-T gene flanked by LoxP recombination targets, with concurrent expression of a fusion protein conferring sensitivity to gancyclovir. NKNT-3 cells became immortalised without an apparent growth crisis and double in numbers every 48 hours. The immortalising and gancyclovir sensitivity-conferring genes could subsequently be completely excised *in vitro* by transient transduction with a replication-deficient recombinant adenovirus expressing the Cre recombinase, which resulted in Cre/Lox site-specific recombination. After removal of the SV40 large-T gene in this way, NKNT-3 cells stopped proliferating and appeared more differentiated, with nucleus to cytoplasm ratios and cytogranules resembling those of normal primary hepatocytes. While mRNA's for bilirubin-UDP-glucuronosyltransferase and glutamine synthetase were each detectable in NKNT-3 cells before reversal of immortalisation, levels increased significantly after excision of the SV40 large-T gene by recombination, with mRNA's for albumin and coagulation factor X becoming detectable only in this latter circumstance.

The efficacy of transplantation of NKNT-3 cells, before or after recombination, was then

assessed in a rodent model of ALF in which 5×10^7 cells, equivalent to approximately 5% of the total number of hepatocytes in an adult rat, were delivered by intrasplenic injection one day prior to 90% hepatectomy under immunosuppression with tacrolimus^[63]. Transplanted animals showed substantial improvements in total bilirubin, prothrombin time and blood ammonia levels and survival compared to controls, with a trend towards a particular survival advantage in those animals which received the reverted NKNT-3 cells rather than immortalised counterparts. Taken together, these findings demonstrate the feasibility of controlling the *ex-vivo* expansion of primary human hepatocytes by transfection with the SV40 large-T antigen gene and Cre/Lox-based reversible immortalisation, with the removal of the oncogene prior to transplantation promoting a level of differentiated function adequate to sustain short-term survival in an experimental ALF setting. Future studies should assess the *in vivo* efficacy of reverted NKNT-3 cells when attached to microcarriers or gel-entrapped as hepatocyte spheroids, modifications which would render them amenable to cryopreservation and storage in cell banks for clinical use as required.

Adjuvant genetic manipulation of transplanted human liver cells may also be used to overcome the current necessity for pharmacological immunosuppression to prevent allograft rejection^[64]. This is an important issue since, although reduction or withdrawal of pharmacological immunosuppression in the post-OLT setting has been associated with lower incidences of metabolic, infective and neoplastic complications, side effects once developed such as chronic nephrotoxicity and hypertension may be irreversible^[65-69]. One approach to preventing rejection of transplanted cells without the need for immunosuppressive drugs relates to the use of cells previously transfected with the adenoviral E3 gene, which encodes several proteins that are known to inhibit host T cell reactivity^[70,71]. Preliminary data in rodents suggests that these proteins have the capacity to protect transplanted hepatocytes from rejection. In particular, Brown-Norway hepatocytes expressing E3 proteins persisted for up to 6 weeks following transplantation into allogeneic Gunn rats, as reflected by reduced serum bilirubin levels, while no reduction in this parameter, indicative of rapid allograft rejection, occurred in control Gunn rats receiving a comparable number of untreated Brown-Norway cells^[72]. It remains to be determined whether strategies designed to induce tolerance that are currently under investigation or consideration in the post-OLT situation, such as the adjunctive infusion of donor-derived bone marrow or soluble class I antigens, the use of anti-CD4, anti-CD25 and anti-CD54 monoclonal antibodies, blockade of the CD28-B7 T cell co-stimulatory pathway with

CTLA41g, pre-treatment of the recipient with IL-10 or even the withholding of all immunosuppression for the first 24 to 48 hours^[73-80], are of relevance when hepatocytes only, rather than with additional non-parenchymal cells and donor-derived leukocytes (as with OLT), are transplanted.

Another potential clinical application of gene therapy in the liver failure setting does not involve the transplantation of liver or other cells, but rather the repeated *in vivo* transfection of skeletal muscle with the gene for human HGF. Ueki *et al*^[81] recently reported that such an approach in a rodent model of cirrhosis, induced by repeated administration of dimethylnitrosamine, led to significantly increased plasma levels of human as well as endogenous rat HGF and increased tyrosine phosphorylation of the HGF receptor. Inhibition of fibrogenesis and hepatocellular apoptosis were noted, possibly consequent to reduction in levels of TGF- β 1. Gene transfer into the rats' skeletal muscle was achieved using weekly injections of liposomes containing the haemagglutinating virus of Japan and human HGF cDNA inserted into the EcoRI and NotI sites of the pUC-SRa expression vector. Survival of the animals was significantly improved compared to that in phosphate buffered saline-treated controls, with the cirrhotic lesion completely reversed in all transfected animals within 50 days of the toxic insult. Such HGF gene therapy would seem less likely to have substantial impact in ALF, since plasma HGF levels are already substantially elevated in this circumstance^[82, 83]. The prospect of maximising liver regeneration via gene therapy in this latter situation will likely depend, in the first instance, on a more comprehensive understanding of both the expression of cell surface receptors for stimulatory and inhibitory growth factors and the integrity of downstream effector and adaptor mechanisms, allowing targeted over-expression or inhibition, respectively, of key elements in these signalling pathways.

Metallic biliary stents for malignant obstructive jaundice: a review

Richard A. Kozarek

Subject headings pancreatic neoplasms; bile duct neoplasms; cholangiopancreatography, endoscopic retrograde; cholestasis; stents

Kozarek RA. Metallic biliary stents for malignant obstructive jaundice: a review. *World J Gastroentero*, 2000;6(5):643-646

Affecting 8-10 patients per 100 000 population, pancreatic cancer is the primary cause of malignant obstructive jaundice and is the presenting feature in over three quarters of these patients^[1]. Unfortunately, using modern imaging techniques, such as endoscopic ultrasound or pancreatic protocol computed tomography with vascular reconstruction, 80% - 90% prove unresectable for cure^[2,3]. Historically, this jaundice was treated surgically with biliary bypass. Over the past 10 years, however, multiple studies have shown comparable palliation (3-6 month survival) with percutaneous or endoscopic placement of a polyethylene prostheses^[4-6]. Moreover, our group, as well as others, have shown that despite comparable survivals, resource utilization (costs) to time of death for the endoscopic group are approximately one-half of those expended in surgically treated patients^[7].

Despite this palliative advance in an often aged and infirm group of patients, however, stent occlusion has proven problematic. A consequence of bacterial biofilm development, attempts to prolong patency with chronic antibiotic therapy, ursodeoxycholic acid, change in the type of polymer used or coating the inner lining with a variety of agents to preclude bacterial colonization have all proven unsuccessful^[8]. It was with this background that the first expandable metallic stent was introduced. This review will summarize the current state of our knowledge, new developments in self-expandable metal stent (SEMS) technology, and areas in which additional studies are needed.

WHAT DO WE KNOW ABOUT EXPANDABLE STENT TECHNOLOGY IN THE BILIARY TREE?

For one, we know that the vast majority of literature has utilized the open mesh stainless-steel Wallstents^[9-16] (Microvasive Inc. Natick, MA).

However, a number of additional SEMS (Table 1) have recently been introduced and variably studied. The latter included closed-weave prostheses fashioned from nitinol (Diamond stent, Microvasive Inc., Natick, MA; and Za stent, Wilson-Cook Inc., Winston-Salem, MA) or stainless steel (Spiral Z, Wilson-Cook Inc.)^[17-23]. They also included the Biliary Endocoil (Intratherapeutics, Eden, Prairie, MN), a tightly coiled nitinol spiral which ostensibly precludes tumor ingrowth^[24]. Not only these stents have different physical properties by virtue of wire material, gauge, and configuration, but also their delivery systems and their degree of foreshortening at time of delivery differ. For instance, neither Spiral Z nor Za stents foreshorten. Diamond and Wallstents shorten by a third and Endocoils by a half.

We also know that, to date, there has been no study which has randomized metallic stent placement against surgical bypass in the palliation of malignant obstructive jaundice. There are, however, numerous randomized and controlled studies randomizing Wallstents against plastic prostheses, all showing superior patency of the former^[4,10-13]. In a largest study, 182 patients with inoperable distal bile duct obstruction were randomized to plastic stent versus SEMS. At 30 days, one-quarter of the plastic prostheses were occluded compared with 5% of the Wallstents^[11]. Although survival was unchanged, there was a two-fold prolongation in patency rate compared to plastic stents. Comparable, albeit longer stent survival (Wallstent 273 days, plastic 126 days) was reported by Davids *et al* in a well-designed European trial^[10]. Additional, non-randomized studies have looked at the use of single or dual Wallstents in Klatskin-type tumor^[15-17]. Dual stenting was not only associated with a decreased risk of cholangitis, but a decreased need for reintervention, and, in one study, approximately a two-fold survival^[16].

Table 1 Commercially available self-expandable biliary stents for malignant obstructive jaundice

Stent	Wallstent	Endocoil	Diamond	Spiral Z	Za
Design	Mesh	Spiral coil	Mesh	Mesh	Mesh
Material	Stainless steel	Nitinol	Nitinol	Stainless steel	Nitinol
Length (cm)	4.2/6.8/8	6/7.5	4/6/8	5.7/7.5	4/6/8
Diameter(mm)	8/10	6/8	10	10	10
Stent foreshortening	Yes	Yes	Yes	No	No
Introducer diameter (Fr)	7.5/8	8/10	9	8.5	8.5

CAN THE ABOVE RESULTS BE GENERALIZED TO OTHER METALLIC PROSTHESES?

Probably not. Up to now there has been no study randomizing patients to Wallstents versus other SEMS. Dumonceau *et al*, however, reported 23 patients with malignant obstructive jaundice treated with Diamond stents and retrospectively compared them with an age and illness matched group treated with Wallstents^[18]. Technical insertion, incidence of recurrent jaundice, and life table analyses of bile duct patency were comparable with both types of prostheses. In contrast, Raijman *et al* placed Diamond stents in 21 patients noting delivery system kinking in 2 and stent distortion or displacement in 3^[22]. Moreover, mean patency was only 2.1 months compared to the 9.7 months of Wallstent patency in their historical controls. Seecoomar *et al* have also noted similar results^[23]. In one of the few comparative studies reported to date, Yoo *et al* placed Diamond stents in 75 patients, plastic prostheses in 58 and Spiral Z stents in 20. The success rate of insertion was comparable whereas the patency at 4 months was 63%, 24%, and 77%, respectively^[25]. They concluded that the patency rate of both SEMS was comparable and improved over plastic prostheses.

In addition to the above, there have been a few studies looking at biliary Endocoils but no comparative studies. In the latest series abstracted, 25 patients, including 6 with benign stenoses had Endocoil insertion and were followed for a mean of 13 months^[26]. Stents were successfully deployed in 23/25 (92%) and jaundice improved in 22/24 (92%). However, 50% of stents were dysfunctional at a mean of 7 months. Data are even sparser for the Spiral Zstent^[21] although a multi-center US trial is currently underway.

WHAT ELSE DO WE KNOW?

We recognize that in contrast to bacterial biofilm occlusion of plastic prostheses^[8], SEMS dysfunction is usually a consequence of tumor ingrowth or overgrowth or elicitation of mucosal hyperplasia at the site of individual metal stents^[27]. Whether all wire materials and gauges elicit comparable hyperplasia is unknown but common sense suggests that larger weave stents may allow more tumor ingrowth than tighter weaves. Wallstents may also become dysfunctional by local duct perforation at the proximal or distal ends, particularly if acutely angulated. Likewise, their exposed distal wires may cause prosthesis dysfunction by ulceration and impaction into the contralateral duodenal wall. Finally, Endocoils fail by virtue of migration or stent infolding. The latter may allow elicitation of granulation tissue or tumor ingrowth^[28].

Despite our knowledge about the mechanism of dysfunction, the ideal therapy of recurrent jaundice

in a patient with an imbedded SEMS remains controversial. Extraction of cholesterol and bile salt debris above a partially occluded stent is temporizing only and attempts to cauterize luminal tissue are usually unsuccessful. Most endoscopists will usually place one or two plastic stents through a SEMS although an additional SEMS may sometimes prove useful. This is currently my sole use of the biliary Endocoil^[9].

IN ADDITION TO WHAT WE DO KNOW, WHAT DO WE THINK WE KNOW?

We think that despite a 30 to 40-fold increase in cost of plastic stents as opposed to Wallstents, the latter are still cost-effective in patients with malignant obstructive jaundice^[10]. These data are derived from the incremental expense associated with repeat ERCP in patients who outlive their plastic stents. In an attempt to better define which patients with malignant jaundice would benefit from a SEMS, Prat *et al* reviewed a variety of clinical, biochemical, and imaging criteria. Patients with small tumors (<3cm) and normal albumen as well as those with good performance status were most likely to survive >6 months and were felt to benefit from a Wallstent^[13]. Those who survived <3 months were more likely to have larger tumors, metastases, low proteins, and poor performance status and should be considered for plastic prostheses. Unfortunately, this leaves a large number of patients in whom treatment remains uncertain. I would personally add that SEMS should be considered in patients who repeatedly occlude plastic prostheses or those who reside in geographically distant locations or those who do not have access to ERCP in their community.

We also think that covering a SEMS does not necessarily increase the patency rate^[29]. Not only is the migration rate increased if the stent is fully covered, but bacterial biofilms and mucosal hyperplasia are problematic in stents that are only partially covered. Recent studies, most using historical controls, have questioned this^[30-36]. For instance, Shim *et al* placed polyurethane-covered Z stents in 29 patients, following them for a mean of 15 months^[30]. Successfully inserting 32/34 (94%) prostheses, there were early complications related to sludge in 19% and tumor/tissue ingrowth or overgrowth in another 21%. Median patient survival was 15.8 months and the authors concluded that covered Z stents improved long-term palliation of malignant biliary strictures. Recent abstracts have also recently been published placing covered Wallstents and Diamond stents with variable results^[31-36].

WHAT DO WE NEED TO KNOW FOR THE FUTURE?

We desperately need comparative studies between different SEMS and need true prospective studies

randomizing covered versus uncovered SEMS. We need better algorithms using clinical data to predict survival and define who is likely to benefit from a SEMS as opposed to selecting patients who would be equally well palliated with a much cheaper plastic prosthesis. We need better knowledge about the elicitation of mucosal hyperplasia and mechanisms to prevent this. Ultimately, we will need new materials, perhaps expandable mesh plastic

polymers, cotton weaves impregnated with not only hardening agents but also antibiotics or chemotherapeutic agents, or metals that use a magnetic field or thermocouple to limit local tumor growth or treat ingrowth. If the precursor 10 years are any indication of the future 10, there will be new technologies that will be introduced and marketed before their advantages or disadvantages are fully known.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major cancers in the world with a mortality of more than 250 000 cases yearly. More than 137 000 cases of HCC were diagnosed each year in China, which account approximately for more than 40 percent of the total number in the world. HCC has become the second major cause of death for cancer in China since 1990, and its annual mortality is expected to be 21.2 cases per 100 000 population in the year 2000. Even though progresses have been achieved for HCC diagnosis and treatment, its 5-year mortality is still higher than 95 percent^[1-3].

The prevalence of HCC is quite different among different areas around the world^[4,5]. It is considerably high in South-East Asia and sub-Saharan Africa, particularly in some southern and eastern regions inside China such as Fusui County in Guangxi Zhuang Autonomous Region and Qidong City in Jiangsu Province^[6-9]. The standardized incidence of HCC in these high-risk regions may exceed 100 cases per 100 000 of population^[10]. The obvious difference in geographic distribution of HCC indicates that there must be environmental factors for its pathogenesis.

Aflatoxin B₁ (AFB₁), which is produced by some strains of *Aspergillus flavus*, is a potent hepatotoxin and hepatocarcinogen^[11,12], and is considered as a major cause of HCC in some regions^[13-18]. It has also been postulated that

chronic infection with hepatitis B virus (HBV) in combination with exposure to AFB₁ in the diet may contribute to the extraordinary high risk of human HCC in some areas. Actually, two case-control studies in Shanghai have demonstrated a strong interaction between HBV and AFB₁ for risk of HCC^[14,15]. A similar chemical-viral interaction has been observed in Taiwan^[18-20]. The synergism between virus and mycotoxic carcinogen for the development of human HCC suggests that reduction in both risk factors may bring important public health consequences.

The concept of chemoprevention of cancer is over 40 years old and a number of works have been done in this field^[21,22]. Looking for effective and safe reagents against AFB₁ and/or other HCC related risk factors is one of the most important chemopreventive strategies for HCC^[23-26]. Green tea was identified years ago as one of the effective chemopreventive reagents against HCC through a series of animal experiments as well as a clinical trial^[27,28]. Recently oltipraz, another preventive agent which was previously described as a potent inhibitor of AFB₁ induced hepatocarcinogenesis in rat^[29-33], has been shown to inhibit the bioactivation of aflatoxin and enhance its detoxification in a clinical trial^[34-37] as well as in human hepatocytes in primary culture^[38]. Meanwhile, a universal vaccination program against HBV that started a decade ago now results in lower rates of HCC in children^[39]. An experimental model to test the synergistic effect of these two agents and their prevention, therefore, is needed.

RESEARCH ON TREE SHREW MODEL OF HEPATOCARCINOGENESIS

Tree shrew (*Tupaia spp.*) is a kind of small, squirrel-like mammals. Formerly it was considered to belong to the Primate order; currently it is classified into a separate order Scandentia and is supposed to be more closely related to human being than rodents^[40,41]. They have been used in biomedical researches since as early as the 1960s. Many researches have been done on its visual and nervous systems. In 1976, however, Reddy *et al*^[42] successfully induced liver cancer in tree shrew by AFB₁. Yan *et al*^[43,44] reported that tree shrews can be infected with HBV and they successfully used this HBV-infected tree shrew model for liver cancer

research. Recently Walter *et al*^[45] reported their *in vivo* and *in vitro* study results from tree shrews infected with HBV. Yan and Li reported a significantly higher incidence of HCC in tree shrews both infected with human HBV and exposed to AFB₁ than with either agent alone^[46,47]. Thus, this tree shrew model appears to closely mirror the most common causative factors of human HCC in some prevalent regions. Furthermore, with the exception of the chimpanzee, tree shrew is the only known animal that can be infected with human HBV. Therefore, the application of tree shrew in research related to liver cancer and hepatitis is receiving increasing attentions and a number of works have been published^[48-52].

Because of the difficulties in raising tree shrews artificially, most of the tree shrews used so far for research in China are captured individually from Yunnan Province. The drawback of using tree shrews captured in the wild for animal experiments is that their age, health status and reproductive history are unknown. In an attempt to avoid this drawback, we have conducted a preliminary experiment on rearing tree shrews and a promising result was obtained^[53].

RESEARCH ON THE PREVENTIVE EFFECT OF OLTIPRAZ IN TREE SHREW

In order to study the preventive effect of oltipraz on AFB₁ by animal models other than rodents, a short-term experiment was conducted on tree shrews.

Male and female adult tree shrews (*Tupaia belangeri chinensis*) were purchased from the Kunming Institute of Zoology (Yunnan Province, P.R. China). Their body weights ranged from 100g to 160g. Upon arrival, 1mL blood was collected from each animal and tested for HBV markers (HBsAg, anti-HBsAg, anti-HBcAg) and ALT. The tree shrews that were negative for these markers of HBV infection and that had ALT value below 55 units were divided into 4 groups with 6 or 7 animals for each group. Group A: normal control; group B: AFB₁ alone; group C: AFB₁+oltipraz daily; group D: AFB₁+oltipraz weekly. All the tree shrews were allowed 1 week to acclimatize to the facilities prior to the experiment. They were housed in separate, suspended, stainless steel wire cages under controlled environmental conditions with a 12-hour light/dark photoperiod. They had free access to tap water and a natural ingredient diet.

The experimental design is presented schematically in Figure 1. Tree shrews in groups B, C and D were given AFB₁ (400μg/kg b.w./day in liquid milk) daily beginning at one week after the experiment started and continued for 4 weeks. One week before giving AFB₁, tree shrews in group C and D were respectively given oltipraz (0.5mmol/kg b.w.) daily or weekly, by gavage in a saturated solution of sucrose for 5 weeks. Blood

samples and 24-hour urine samples were collected once a week from each animal throughout the experiment. At the termination of the 9-week experiment, tree shrews were killed by cervical dislocation. Three blocks of liver tissue were taken from each animal. Serial sections from each block were stained histochemically for γ-glutamyl transpeptidase (γ-GT)^[54] and HE respectively. The γ-GT positive liver cells were counted with a nest-ruler under microscope. The results were analyzed by the medical statistics analyzing software PEMS that was designed by West China University of Medical Sciences. The levels of aflatoxin-albumin adducts in serum samples were determined by radioimmune assay^[35] and the levels of Aflatoxin-N⁷-guanine adducts in urine samples were assayed by HPLC^[29].

No γ-GT positive liver cell focus, a postulated precancerous marker^[54-56] was observed in any liver of the variously treated tree shrews in our study. However, different numbers of γ-GT positive liver cells, which scattered mainly around the portal spaces, were observed in each group. Even though the distribution patterns of these cells were similar among the 4 groups, the number was quite different. Groups B and D had obviously less γ-GT positive cells than groups A and C (Table 1).

γ-GT normally exists in embryonic liver cell in human being and rat. In adult rat, it exists only in some cells around portal spaces^[57] but can be re-expressed by mature hepatocytes during the recovery process after liver damage^[58]. In this study a number of γ-GT positive hepatocytes presented in periportal regions in the normal control group. On the contrary, the number of γ-GT positive hepatocytes of the same sites was markedly reduced in the AFB₁ treated B group. This phenomenon is fairly consistent with the findings on AFB₁ induced damage in rat, in which the periportal hepatocytes are the major targets of AFB₁. As shown in the same table, the number of γ-GT positive hepatocytes in group C was strikingly similar to the normal control group. This result indicates strongly the preventive action of oltipraz against AFB₁ toxicity. The apparent ineffectiveness of oltipraz in group D is most possibly due to its inadequate dose^[59]. These results might indicate that oltipraz has the preventive dose-related effect on AFB₁.

Insufficient duration and/or insufficient dosage of AFB₁ treatment may result in that no separate focus of γ-GT positive liver cell formed at the end of this 9-week experiment^[60]. However, the decrease of γ-GT positive hepatocytes in the periportal regions may be an early marker for the damage induced by AFB₁.

The levels of both aflatoxin-albumin adducts in serum samples and aflatoxin-N⁷-guanine adducts in urine samples of the tree shrews were also significantly affected by oltipraz. Following daily

exposures to AFB₁, the levels of serum aflatoxin-albumin adducts in group B increased rapidly over 2 weeks to reach a plateau that did not diminish until cessation of AFB₁ exposure. In group C however, oltipraz attenuated the aflatoxin-albumin adducts significantly ($P < 0.05$) with a median reduction of 80%. The mean levels of aflatoxin-N⁷-guanine (ng/mg creatinine) in the urine samples collected at week 5 were 6.34 ± 2.04 and 0.47 ± 0.13 in groups B and C respectively. This 93% decrease represented a statistically significant difference ($P < 0.05$). These results were reported in detail in another article^[61]. The major mechanism of oltipraz's chemopreventive effect is probably through inducing the activities of cytochrome P450 system and phase 2 enzymes such as glutathione transferases, epoxide hydrolase, etc, as reported by Langouet *et al.*^[38] and Fahey *et al.*^[62].

Figure 1 Experimental design for animal treatment. OLT: oltipraz; ↓: all the animals were sacrificed.

Table 1 The number and size of γ -GT positive hepatocyte-group ($\bar{x} \pm s_x$)

Group	Treatment	No./cm ²	mm ² /cm ²	mm ² /No.
A	Normal control	167.29 \pm 50.47	2.90 \pm 1.01	0.017 \pm 0.002

SUMMARY

Tree shrew is phylogenetically more closely related to human being than rodents. It is susceptible both to HBV infection and AFB₁ intoxication. It is a suitable experimental animal for hepatocarcinogenesis. Attempt for its rearing is promising.

Oltipraz is an effective reagent to protect AFB₁ intoxication. This effect is proved clearly not only by histological examination, but also by reduction of aflatoxin-albumin adducts in serum and aflatoxin-N⁷ guanine adducts in urine.

All of these studies mentioned above provide a foundation for further HCC chemoprevention study

by using tree shrews in the future.

ACKNOWLEDGEMENTS The authors express their appreciation to Drs. Guo-Hua Huang, Chao Ou, Xue-Lan Deng and Hua-Ping Huang for the contributions to the animal experiment. Preliminary accounts of this work were presented at the 1999 Annual Meeting of the American Association for Cancer Research^[63].

Takeuchi K, Kawauchi S, Araki H, Ueki S, Furukawa O. Stimulation by nizatidine, a histamine H₂-receptor antagonist, of duodenal HCO₃⁻ secretion in rats: relation to anti-cholinesterase activity. *World J Gastroentero*, 2000;6(5):651-658

Abstract

AIM To examine whether nizatidine stimulates duodenal HCO₃⁻ secretion in rats by inhibiting AChE activity.

METHODS Under pentobarbital anesthesia, a proximal duodenal loop was perfused with saline, and the HCO₃⁻ secretion was measured at pH 7.0 using a pH-stat method and by adding 10mM HCl. Nizatidine, neostigmine, carbachol or famotidine was administered i.v. as a single injection.

RESULTS Intravenous administration of nizatidine (3 - 30mg/kg) dose-dependently increased duodenal HCO₃⁻ secretion, and the effect at 10mg/kg was equivalent to that obtained by carbachol at 0.01mg/kg. This nizatidine action was observed at the same dose range that inhibited acid secretion and enhanced gastric motility, mimicked by i.v. injection of neostigmine (0.03mg/kg), and significantly attenuated by bilateral vagotomy and prior s.c. administration of atropine but not by indomethacin, a cyclooxygenase inhibitor, or N^G-nitro-L-arginine methyl ester, a NO synthase inhibitor. The HCO₃⁻ secretory response to acetylcholine (0.001mg/kg) was significantly potentiated by the concurrent administration of nizatidine (3mg/kg, i.v.). The IC₅₀ of

nizatidine for AChE of rat erythrocytes was 1.4×10⁻⁶M, about 12 times higher than that of neostigmine. Neither famotidine (>10⁻³M, 30mg/kg, i.v.) nor cisapride (>10⁻³M, 3mg/kg, i.v.) had any influence on AChE activity or duodenal HCO₃⁻ secretion. Duodenal damage induced by acid perfusion (100mM HCl for 4h) in the presence of indomethacin was significantly prevented by nizatidine and neostigmine, at the doses that increased the HCO₃⁻ secretion.

CONCLUSION Nizatidine stimulates duodenal HCO₃⁻ secretion, in both vagal-dependent and atropine-sensitive manners, and the action is associated with the anti-AChE activity of this agent.

INTRODUCTION

Nizatidine, a histamine H₂-receptor antagonist (N-[2-[[[2-[(dimethylamino) methyl]-4-thiazolyl]-methyl]thio]ethyl]-N"-methyl-2-nitro-1,1-ethenediamine), has been shown to have a potent antisecretory action and clinically ascertained to be effective for peptic ulcers as well as gastroesophageal reflux diseases^[1-3]. Of interest, an additional effect of H₂-antagonists on gastrointestinal motility has been reported, besides the antisecretory activities^[4,5]. Indeed, some H₂-antagonists including nizatidine exhibit a potent anti-acetylcholinesterase (AChE) activity^[6-9] and, as a result of this action, facilitate gastrointestinal motor activity in experimental animals and in humans^[10,11].

On the other hand, duodenal mucosal HCO₃⁻ secretion is a key process that aids in preventing acid-peptic injury^[12,13]. The mechanisms that govern mucosal HCO₃⁻ secretion include neuro-humoral factors and luminal acid^[12-14]. The ability of the mucosa to respond to acid seems especially important in the maintenance of the surface pH gradient and in the protection of mucosa. This process is also mediated by endogenous prostaglandins (PGs) as well as neuronal factors

Received 2000-08-08 Accepted 2000-08-25

including vagal-cholinergic mechanisms^[15-17]. Several investigators reported that cholinomimetic drugs increased duodenal HCO_3^- secretion, either directly or indirectly mediated by vasoactive intestinal polypeptide (VIP)^[17]. We also reported that both carbachol and bethanechol stimulated the HCO_3^- secretion, mediated by M_3 but not M_1 receptors^[18]. Because inhibition of AChE activity increases the availability of endogenous acetylcholine, it is possible that nizatidine might increase duodenal HCO_3^- secretion through inhibition of AChE activity. However, the effect of nizatidine on the HCO_3^- secretion has not been studied.

This study was undertaken to confirm the anti-AChE activity of nizatidine *in vitro*, and investigate the effect of this agent on HCO_3^- secretion in the rat duodenum, in comparison with the other H_2 -antagonist famotidine and the AChE inhibitor neostigmine. In addition, we also examined whether the doses sufficient to stimulate the HCO_3^- secretion are comparable to the gastroprokinetic and antisecretory doses.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats, weighing 200g-230g (Charles River, Shizuoka, Japan), were used in all experiments. The animals kept in individual cages with raised mesh bottoms were deprived of food but allowed free access to tap water for 18h before the experiments. Studies were carried out with 4-6 rats per group under anesthetized conditions induced by pentobarbital Na (30 mg/kg, i.v.), unless otherwise specified. All experimental procedures described here were approved by the Experimental Animal Research Committee of the Kyoto Pharmaceutical University.

Determination of duodenal HCO_3^- secretion

Duodenal HCO_3^- secretion was determined in the duodenal loop according to a previously published method^[16]. In brief, the abdomen was incised, and the stomach and duodenum were exposed. The duodenal loop (1.7cm) was made between the pylorus and the area just proximal to the outlet of the common bile duct, excluding the influences of bile acid and pancreatic juice. Then, the loop was perfused at a flow rate of 0.8mL/min with saline that was gassed with 100% O_2 and kept in a reservoir, and HCO_3^- secretion was measured at pH 7.0 using a pH-stat method and by adding 10mM HCl to the reservoir. Allowing 30-40min for stabilization of basal HCO_3^- secretion, the duodenal HCO_3^- secretory responses were examined for 2h after the following treatment; nizatidine (3-30 mg/kg), carbachol (0.003 mg/kg), neostigmine (0.03 mg/kg), famotidine (10 mg/kg) or

cisapride (3mg/kg). These drugs were administered i.v. as a single injection. In some cases, nizatidine (3 mg/kg) and acetylcholine (0.001 mg/kg) were administered i.v. simultaneously. In some cases, atropine (1mg/kg, s.c.), indomethacin (5 mg/kg, s.c.) or N-G-nitro-L-arginine methyl ester (L-NAME) the NO synthase inhibitor (5mg/kg, i.v.) was given 1h or 10min, respectively, before administration of nizatidine, carbachol or neostigmine. In a separate experiment, bilateral vagotomy was performed at the cervical portion 2h before administration of nizatidine, neostigmine or carbachol.

Determination of gastric acid secretion

Gastric acid secretion was measured in a chambered stomach, according to a previously published method^[19]. Briefly, the abdomen was incised, and both the stomach and duodenum were exposed. Then, the stomach was mounted in an *ex-vivo* chamber and perfused at a flow rate of 0.8mL/min with saline that was gassed with 100% O_2 , heated at 37°C and kept in a reservoir. The acid secretion was measured at pH 7.0 using a pH-stat method (Hiranuma Comtite-8, Tokyo, Japan) by adding 100mM NaOH to the reservoir. After basal acid secretion had well stabilized, the acid secretion was stimulated by continuous i.v. infusion of histamine (4mg/kg/h). Nizatidine (10 and 30mg/kg) and famotidine (10mg/kg) were administered i.v. as a single injection 1h after the onset of histamine infusion, when the acid secretory response to histamine had reached a plateau.

Measurement of gastric motility

Gastric motility was determined using a miniature balloon in conscious rats, according to a previously published method^[20]. Briefly, under ether anesthesia the balloon and the support catheter were placed in the stomach through an incision of the forestomach. The animals were kept in Bollman cages, and gastric motility was monitored on a Hitachi recorder (Model 056, Mito, Japan) using a pressure transducer (Narco Telecare, Model 151-T, Houston, TX., U.S.A.) and a polygraph device (San-ei, Model 6M-72, Tokyo, Japan) after complete recovery from anesthesia. After basal motility had well stabilized, the animals were administered i.v. with nizatidine (30 mg/kg), neostigmine (0.03mg/kg), cisapride (3mg/kg) or famotidine (10 mg/kg), and the motility was measured for 2h thereafter. In some cases, the effect of atropine (1mg/kg, s.c.) was examined on the enhanced gastric motility in response to nizatidine (30mg/kg, i.v.).

Induction of duodenal mucosal damage by acid perfusion

The increased HCO_3^- secretion caused by nizatidine might lead to decrease of the mucosal susceptibility

to acid injury. To test this possibility, we examined the effect of nizatidine on the mucosal ulcerogenic response by perfusing the duodenum with 100mM HCl at the flow rate of 1mL/h for 4h in the presence of indomethacin. The experiment was performed in the duodenal loop preparation, similar to that described for HCO_3^- secretion. Animals were first treated with indomethacin (5 mg/kg, s.c.), and 1h later the duodenum was perfused with acid for 4h. Nizatidine (10mg/kg) was administered i.v. 20min before the onset of acid perfusion. In comparison, the animals were treated i.v. with neostigmine (0.03mg/kg) or famotidine (10mg/kg). The duodenums were removed, inflated by injecting 0.5mL of 2% formalin, immersed in 2% formalin for 10min to fix the tissue wall, opened along the mesenteric artery, and examined for lesions under a dissecting microscope with a square grid ($\times 10$). The area (mm^2) of each lesion was measured, summed per duodenum, and used as a damage score. The person measuring the lesions did not know the treatment given to the animals.

Determination of anticholinesterase activity

Erythrocyte membranes and plasma each from rats were prepared to obtain both AChE and pseudocholinesterase (PChE), according to the method described by Hansen and Bert^[6]. Before the determination of anti-ChE activity, it was confirmed that PChE was not present in the erythrocyte membranes by using the PChE inhibitor, profenamine. The anti-ChE activity of H_2 -receptor antagonists and neostigmine was determined by the modified method of Ellman *et al.*^[21]. In brief, a reaction mixture was prepared to contain, in a total volume of 1mL, 0.1M sodium phosphate buffer (pH 8.0), 1mM acetylcholine, 0.3mM 5,5-dithio-bis (2-nitrobenzoic acid) and 1mU ChE. The enzyme activity was determined by tracing the changes in absorbance at 412nm at 30°C on a spectrophotometer (Model 320, Hitachi, Ibaragi, Japan) for a period of 70 sec after adding acetylthiocholine. The amount of enzyme required to convert 1 μmol of acetylthiocholine within 1min under the above conditions was taken as 1 unit. Anti-enzyme activity was measured by adding 10 μL of each test drug solution to the reaction mixture. The concentration of test drug required to inhibit 50% of the enzyme activity (IC_{50}) was calculated from the enzyme inhibition curve.

Preparation of drugs

Drugs used were pentobarbital Na, neostigmine bromide, histamine 2HCl, carbachol, acetylcholine (Nacalai tesque, Kyoto, Japan), nizatidine (Zeria Pharm. Co., Saitama, Japan), famotidine (Gaster R, Yamanouchi Pharm. Co. Tokyo, Japan), atropine, indomethacin, NG-nitro-L-arginine methyl ester (Sigma Chemicals, Saint Louis, Mo.,

USA) and cisapride (Synthesized by Zeria Pharm. Co.). For *in vivo* experiments, each drug except indomethacin was dissolved in or diluted with saline. Indomethacin was suspended in saline with a drop of Tween 80 (Wako, Osaka, Japan). Each drug was administered i.v. in a volume of 1mL/kg or s.c. in a volume of 5mL/kg, or by i.v. infusion in a volume of 1.2mL/h. For *in vitro* experiments, each drug was prepared in purified water or equimolar hydrochloric acid solution. In all experiments, solvents alone were used as controls.

Statistics

Data are presented as the means \pm SE from 4-6 rats per group. Statistical analyses were performed using a two-tailed Dunnett's multiple comparison test, and values of $P < 0.05$ were regarded as significant.

RESULTS

Effects of nizatidine on duodenal HCO_3^- secretion

Under the present experimental conditions, the rat duodenum spontaneously secreted HCO_3^- at a steady rate of 1.0 - 1.2 $\mu\text{Eq}/15$ min during a 3 h test period. Intravenous administration of nizatidine (3-30mg/kg) caused an increase of the HCO_3^- secretion in a dose-dependent manner (Figure 1). At 10 mg \cdot kg⁻¹, the H_2 antagonist nizatidine increased the HCO_3^- secretion from 1.2 $\mu\text{Eq}/15$ min to a plateau level of 1.8-2.0 $\mu\text{Eq}/15$ min within 30 min, remaining elevated for 2 h, the ΔHCO_3^- output being 5.6 ± 1.4 $\mu\text{Eq}/2\text{h}$. Likewise, duodenal HCO_3^- secretion was significantly increased in response to i.v. administration of carbachol (0.01mg/kg) and neostigmine (0.03 mg/kg), the ΔHCO_3^- output being 4.9 ± 1.1 $\mu\text{Eq}/2\text{h}$ and 5.2 ± 0.8 $\mu\text{Eq}/2\text{h}$, respectively, both of which were almost equivalent to that induced by nizatidine at 10mg/kg (Figure 2). By contrast, neither famotidine the H_2 -antagonist (10mg/kg, i.v.) nor cisapride the gastroprokinetic drug (3mg/kg, i.v.) had any influence on basal rates of duodenal HCO_3^- secretion (Figures 2 and 3).

The HCO_3^- secretory responses induced by both nizatidine (10 mg/kg, i.v.), neostigmine (0.03mg/kg, i.v.) and carbachol (0.01 mg/kg, i.v.). Were all significantly inhibited by prior s.c. administration of atropine (1 mg/kg) (Figure 4). This agent had a minimal effect on the basal HCO_3^- secretion without any treatment, but almost totally attenuated the increase of HCO_3^- secretion induced by either nizatidine, neostigmine or carbachol; the ΔHCO_3^- output remained unchanged before and at all time points after administration of these drugs. Likewise, bilateral vagotomy significantly reduced the HCO_3^- secretory response to nizatidine and neostigmine but not carbachol. On the other hand, the pretreatment of tie animals with neither

indomethacin (5mg/kg, s.c.) nor L-NAME (5mg/kg, i.v.) significantly affected the HCO_3^- secretory response induced by nizatidine (not shown).

Effect of the combined treatment of nizatidine and acetylcholine on duodenal HCO_3^- secretion

To further investigate the relation of anti-AChE activity of nizatidine with the HCO_3^- stimulatory action, we examined whether or not the acetylcholine-induced HCO_3^- response was potentiated by co-administration of nizatidine. As shown in Figure 5, acetylcholine (0.001 mg/kg) caused a slight but significant increase in duodenal HCO_3^- secretion, while nizatidine at 3 mg·kg⁻¹ tended to increase the secretion; the ΔHCO_3^- output was $1.8 \pm 0.1 \mu\text{Eq}/2\text{h}$ and $0.7 \pm 0.6 \mu\text{Eq}/2\text{h}$, respectively. However, when nizatidine was administered together with acetylcholine, the HCO_3^- secretion was markedly increased, reaching a peak of about 150% of basal values, the ΔHCO_3^- output being $4.1 \pm 0.7 \mu\text{Eq}/2\text{h}$, which is 2.4 fold greater than that induced by acetylcholine.

Effects of nizatidine on gastric acid secretion and motility

Acid secretion Following intravenous infusion of histamine (4mg/kg/h), gastric acid secretion was increased from $18.6 \pm 3.1 \mu\text{Eq}/10 \text{ min}$ to $39.5 \pm 3.2 \mu\text{Eq}/10 \text{ min}$ -within 60min, and remained elevated during a 2h test period. The acid secretory response to histamine was significantly reduced by i.v. injection of nizatidine (10 and 30mg/kg) in a dose-dependent manner, the inhibition of total acid output for 2h being 58.9 and 86.3%, respectively (Figure 6). A potent inhibition of histamine-induced acid secretion was also observed on i.v. administration of famotidine (10mg/kg), the inhibition of total acid output for 2h being 90.4%.

Gastric motility Normal rat stomachs spontaneously contracted at a frequency of 16-20/10min with an amplitude of $18.6 \pm 3.2 \text{ cm H}_2\text{O}$. Intravenous administration of nizatidine (30mg/kg) enhanced gastric motility, which reached a plateau level (about 2.5 times greater than basal values) within 40min and remained elevated thereafter, and this action was completely inhibited by atropine (1mg/kg, s.c.) (Figure 7). Both neostigmine (0.03mg/kg) and cisapride (3 mg/kg) increased gastric motility, similar to nizatidine, while famotidine (10mg/kg) did not have any effect on spontaneous contractile activity of the stomach (not shown).

Effects of nizatidine on duodenal damage caused by acid perfusion

Perfusion of the proximal duodenum with 100mM

HCl for 4h in indomethacin-treated rats caused severe damage in the mucosa, the lesion score being $49.1 \pm 7.4 \text{ mm}^2$ (Table 1). Pretreatment of animals with nizatidine (10 mg/kg, i.v.) or neostigmine (0.03mg/kg, i.v.) was effective in significantly reducing the severity of duodenal damage in response to acid perfusion, the inhibition being 56.6% or 64.0%, respectively. Famotidine (10mg/kg, i.v.) had no effect on the development of duodenal damage induced by acid perfusion.

Table 1 Effects of nizatidine, neostigmine and famotidine on duodenal damage induced by acid in rats

Group	Dose (mg/kg)	Number of Rats	Duodenal damage (mm ²)	Inhibition (%)
Control		5	49.1±7.4	
Nizatidine	10	5	21.3±5.1 ^a	56.6
Neostigmine	0.03	5	17.7±7.3 ^a	64.0
Famotidine	10	4	40.8±4.5	16.1

Duodenal damage was induced by perfusing a duodenal loop with 100mM HCl for 4h in the presence of indomethacin (5mg/kg, s.c.). Nizatidine (10mg/kg), neostigmine (0.03mg/kg) or famotidine (10mg/kg) was administered i.v. as a single injection 20min before the onset of acid perfusion. Data are presented as the means±SE from 5 rats.

^a Significant difference from control, $P < 0.05$.

Table 2 Inhibition by nizatidine, famotidine, neostigmine and cisapride of acetylcholinesterase activity in rat erythrocyte and plasma

Drugs	IC ₅₀ (M)	
	Rat erythrocytes	Plasma
Nizatidine	1.4×10^{-6}	5.7×10^{-4}
Neostigmine	1.1×10^{-7}	3.3×10^{-6}
Famotidine	$1.0 \times 10^{-3} <$	$1.0 \times 10^{-3} <$
Cisapride	$1.0 \times 10^{-3} <$	$1.0 \times 10^{-3} <$

Values represent the IC₅₀ of AChE activity for each drug. The experiments were performed in triplicate against AChE of rat erythrocyte and plasma.

Effects of nizatidine on acetylcholinesterase activity

Table 2 summarizes the activities of nizatidine for AChE and PChE, in comparison with neostigmine and famotidine. Nizatidine inhibited the AChE activity prepared from rat erythrocytes, and the IC₅₀ was $1.4 \times 10^{-6} \text{ M}$, about 12 times greater than that ($1.1 \times 10^{-7} \text{ M}$) of neostigmine. Likewise, both nizatidine and neostigmine inhibited the PChE activity prepared from rat plasma, the IC₅₀ being $5.7 \times 10^{-4} \text{ M}$ and $3.3 \times 10^{-6} \text{ M}$, respectively. However, neither famotidine nor cisapride had any effect on AChE or PChE activities, the IC₅₀ for these drugs being over $1 \times 10^{-3} \text{ M}$.

DISCUSSION

The present study showed for the first time that nizatidine, an histamine H₂-receptor antagonist, stimulates duodenal HCO_3^- secretion in rats, in both vagal-dependent and atropine-sensitive

manners, and this action is associated with the anti-AChE activity of this agent. Furthermore, the HCO_3^- stimulatory property of nizatidine was observed at the dose ranges for both gastric antisecretory and prokinetic actions. Since neither famotidine nor cimetidine had any effect on duodenal HCO_3^- secretion, it is unlikely that this action of nizatidine is simply resulted from the inhibition of gastric acid secretion due to H_2 receptor blockade or the increased luminal pressure due to enhanced duodenal motility.

It has been shown that several H_2 -receptor antagonists are endowed with anti-AChE

activity^[6-10]. This action results in facilitating gastrointestinal motor activity in experimental animals and in humans^[5,11]. Ueki *et al.*^[11] reported that nizatidine stimulates gastrointestinal motility and gastric emptying at antisecretory doses, mainly through its anti-AChE activity. In the present study, we confirmed that nizatidine potentially inhibited both AChE and PChE activities. On the basis of the K_i values, it was also noted that the anti-AChE activity of nizatidine was much potent as compared with the other H_2 -antagonist famotidine, although it was weaker than that of neostigmine, the authentic AChE inhibitor.

Figure 1 Effect of nizatidine on duodenal HCO_3^- secretion in rats. The HCO_3^- secretion was measured by perfusing a duodenal loop with saline and by adding 10mM HCl to the reservoir. Nizatidine (3-30mg/kg) was administered i.v. as a single injection after the basal secretion had well stabilized, and the HCO_3^- secretion was measured for 2h. Data are expressed as % of basal values and represent the means \pm SE of values determined every 15min from 6 rats. Lower panel shows Δ increase of HCO_3^- output for 2h. Data are presented as the means \pm SE from 6 rats. *Significant difference from controls, $P < 0.05$.

Figure 2 Effects of neostigmine, carbachol and famotidine on duodenal HCO_3^- secretion in rats. The HCO_3^- secretion was measured by perfusing a duodenal loop with saline and by adding 10mM HCl to the reservoir. Neostigmine (0.03mg/kg), carbachol (0.01mg/kg) or famotidine (10mg/kg) was administered i.v. as a single injection after the basal secretion had well stabilized, and the HCO_3^- secretion was measured for 2h. Data are expressed as % of basal values and represent the means \pm SE of values determined every 15min from 6 rats. Lower panel shows Δ increase of HCO_3^- output for 2h. Data are presented as the means \pm SE from 6 rats.

*Significant difference from controls, $P < 0.05$.

Figure 3 Effect of cisapride on duodenal HCO₃⁻ secretion in rats. The HCO₃⁻ secretion was measured by perfusing a duodenal loop with saline and by adding 10mM HCl to the reservoir. Cisapride (3 mg/kg) was administered i.v. as a single injection after the basal secretion had well stabilized, and the HCO₃⁻ secretion was measured for 2h. Data indicate total HCO₃⁻ output obtained for 2h after administration of cisapride, and represent the means±SE from 6 rats.

Figure 4 Effects of atropine or bilateral vagotomy on the HCO₃⁻ stimulatory action of nizatidine, neostigmine and carbachol in the rat duodenum. The HCO₃⁻ secretion was measured by perfusing a duodenal loop with saline and by adding 10mM HCl to the reservoir. Neostigmine (0.03 mg/kg), carbachol (0.01 mg/kg) or famotidine (10mg/kg) was administered i.v. as a single injection after the basal secretion had well stabilized, and the HCO₃⁻ secretion was measured for 2h. Atropine (1mg/kg) was given s.c. 1h before administration of the above agents. Bilateral vagotomy was performed acutely at the cervical portion 2h before the administration of the agents. Data are presented as the means ±SE from 6 rats. Significant difference at $P < 0.05$; ^afrom corresponding groups without atropine; ^bfrom corresponding values observed for 1h before the treatment (time: -60-0 min)

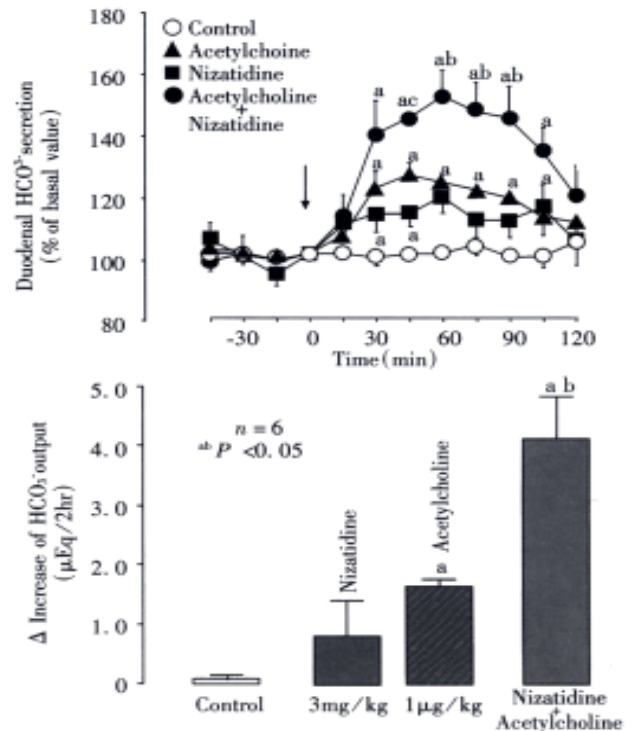

Figure 5 Effects of nizatidine and acetylcholine, either alone or in combination, on duodenal HCO₃⁻ secretion in rats. The HCO₃⁻ secretion was measured by perfusing a duodenal loop with saline and by adding 10mM HCl to the reservoir. Nizatidine (3mg/kg) and acetylcholine (0.003mg/kg), either alone or in combination, were administered i.v. after the basal secretion had well stabilized, and the HCO₃⁻ secretion was measured for 2h. Data are expressed as % of basal values and represent the means±SE of values determined every 15min from 6 rats. Lower panel shows Δ increase of HCO₃⁻ output for 2h. Data are presented as the means ± SE from 6 rats. Significant difference at $P < 0.05$ ^afrom control; ^bfrom nizatidine or acetylcholine.

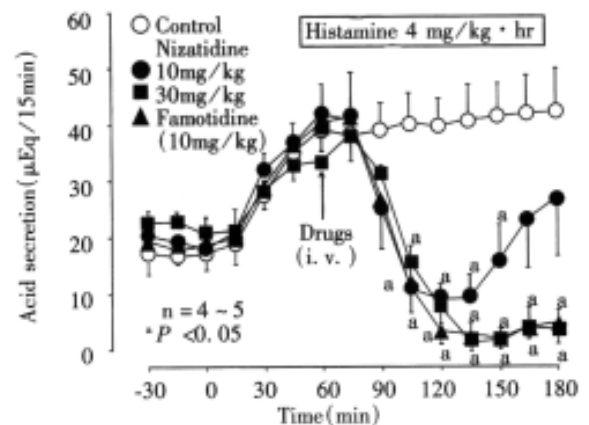

Figure 6 Effects of nizatidine and famotidine on histamine-induced gastric acid secretion in rats. A rat stomach mounted in an ex-vivo chamber was perfused with saline, and the acid secretion was measured by adding 100mM NaOH to the reservoir. The acid secretion was stimulated by i.v. infusion of histamine (4mg/kg/h), while nizatidine (10 and 30mg/kg) or famotidine (10mg/kg) was administered i.v. as a single injection 1h after the onset of histamine infusion, when the acid secretion had reached a plateau. Data are presented as the means±SE of values determined every 15min from 5 rats.

^a Significant difference from controls, $P < 0.05$.

Figure 7 Representative recordings of gastric motor activity in conscious rats, before and after administration of nizatidine. gastric motor activity was monitored as intraluminal pressure recordings, by using a miniature balloon placed in the stomach. Nizatidine (30mg/kg) was administered i.v. as a single injection after the basal motility had well stabilized. Atropine (1mg/kg) was given s.c. 1h after administration of nizatidine. Note that gastric motor activity was apparently enhanced by nizatidine at the doses that stimulate HCO_3^- secretion in the rat duodenum, and this action was completely blocked by atropine.

It is widely accepted that acetylcholine is a transmitter released by enteric excitatory neurons to influence gastrointestinal motility. Likewise, several studies showed that duodenal HCO_3^- secretion was increased by the vagal-cholinergic excitation^[17,18, 22,23]. Lenz *et al*^[22] reported that the HCO_3^- secretion was increased in response to both central and peripheral cholinergic agents. It is also known that the vagal-cholinergic pathway plays a role in the HCO_3^- secretory response to acid and sham feeding^[23]. Since the electrical stimulation of the vagus nerves increased duodenal HCO_3^- secretion mediated by the atropine-sensitive cholinergic pathway^[24], it is expected that this process is also stimulated by peripheral cholinomimetic agents. The present study clearly showed that nizatidine increased the HCO_3^- secretion by stimulating cholinergic excitation

through anti-AChE activity, and this effect was mimicked by neostigmine. These results support the contention that the HCO_3^- stimulatory effect of nizatidine in the rat duodenum is mediated by endogenous acetylcholine released from cholinergic neurons. Indeed, this action of nizatidine on the HCO_3^- secretion was totally abolished by bilateral vagotomy or prior administration of atropine. Certainly, the antagonism of H_2 -receptor does not account for the HCO_3^- stimulatory action of nizatidine, because famotidine did not have any effect on this secretion.

In the present study, the HCO_3^- secretion induced by nizatidine was not affected by either indomethacin or L-NAME, excluding the possibility for involvement of PG or NO in this response. We previously reported that the HCO_3^- response induced by cholinergic agents was not affected by indomethacin^[18]. Furukawa *et al*^[25] reported that NO stimulates the HCO_3^- secretion, mediated by endogenous PGs in isolated bullfrog duodenum. Thus, it is reasonable that the HCO_3^- response induced by nizatidine is not affected by the NO synthase inhibitor L-NAME. Segawa *et al*^[26] reported that nizatidine did not affect *in vitro* PGE_2 biosynthesis and even doses that markedly inhibit gastric acid secretion had no effect on the mucosal PGE_2 contents in rat stomachs. Hallgren *et al*^[27] found that the NO synthase inhibitors such as L-NAME caused an increase of both luminal alkalinization and luminal pressure in the rat duodenum and suggested that the HCO_3^- stimulatory action of L-NAME is due to the neural reflex resulting from the rise in luminal pressure through mechano-receptors. The same mechanism might be applied to the HCO_3^- stimulatory action of nizatidine, because this agent enhanced gastrointestinal motility, leading to increase of the luminal pressure. However, cisapride at the dose that clearly enhanced gastric motility did not affect the HCO_3^- secretion. Thus, it is unlikely that nizatidine stimulates duodenal HCO_3^- secretion due to the increase of luminal pressure, resulting from the smooth muscle contraction.

The secretion of HCO_3^- in the duodenum is the main defense mechanism against acid. Mucus adherent to the luminal surface of the mucosa provides a zone of low turbulence, allowing the development of a gradient for HCO_3^- from the luminal side^[12,13,28]. Small amounts of HCO_3^- protect the mucosa against large amounts of acid by neutralizing H^+ ions that diffuse back into the mucus layer^[13]. A number of studies demonstrated a close relationship between the mucosal ulcerogenic response and the duodenal HCO_3^- disorder^[12, 13,29]. Indeed, it is reported that patients with inactive duodenal ulcers have decreased production of HCO_3^- in the proximal duodenum during exposure

to acid^[30], though the exact mechanism involved remains unknown. In the present study, perfusion of the proximal duodenum with 100mM HCl for 4h produced extensive hemorrhagic damage in rats in the presence of indomethacin. However, nizatidine reduced the severity of duodenal damage at the dose which stimulated HCO_3^- secretion. These results confirmed that nizatidine afforded protection of the duodenal mucosa by increasing HCO_3^- secretion, in a PG-independent pathway.

It is known that the mucosal acidification increases the HCO_3^- secretion via both humoral and neural factors as well as endogenous PGs^[12,23,31]. Vasoactive intestinal polypeptide (VIP) is the most likely humoral factor mediating the HCO_3^- secretory response to acid, because it is a potent stimulant of duodenal HCO_3^- secretion and is released from nerve endings during the exposure of duodenal mucosa to acid^[17]. Odes *et al*^[32] reported that acetylcholine increases a release of VIP from enteric nerves via both muscarinic M_1 and M_3 receptors, which in turn stimulates HCO_3^- secretion in the duodenum. Since nizatidine significantly potentiated the HCO_3^- response to acetylcholine, it is possible that the acid-induced HCO_3^- secretion is also enhanced by the anti-AChE activity in the presence of nizatidine. Ueki *et al*^[11] demonstrated that the ED_{50} values of nizatidine for inhibition of acid output in rats overlapped the effective doses for stimulation of gastrointestinal motility and gastric emptying. We also showed that nizatidine increased duodenal HCO_3^- secretion at the doses that were effective in inhibiting histamine-induced acid secretion or in stimulating gastric contractile activity. These results suggest that the HCO_3^- stimulatory effect of nizatidine can be expected in duodenal ulcer patients who are treated with this drug at the antisecretory dose.

In summary, the present results clearly showed that the histamine H_2 -receptor antagonist nizatidine stimulates duodenal HCO_3^- secretion, and this action is associated with its anti-AChE activity and mediated by vagal-cholinergic mechanisms. It is assumed that the HCO_3^- stimulatory action of nizatidine is useful for treatment of duodenal ulcer, in addition to its anti-acid secretory and gastric prokinetic effects.

Han Y, Uno Y, Munakata A. Does flexible small-diameter colonoscope reduce insertion pain during colonoscopy. *World J Gastroentero*, 2000;6(5):659-663

Abstract

AIM It is well known that colonoscopy can be difficult due to abdominal pain induced during colonoscope insertion, if sedative agents are not given. Recently, an extra-flexible, small-diameter colonoscope (CF-SV, Olympus Inc., Japan) was developed in order to improve safety and comfort. The aim of this study was to access the usefulness of the CF-SV.

METHODS One hundred patients undergoing sigmoidoscopy were recruited and colonoscopy was performed by one experienced colonoscopist. First, a routine-type colonoscope (CF-230I) was inserted into the colon without sedation. When the patient complained of abdominal pain (even if mild), the scope was not advanced further and was withdrawn after the anatomic location of its tip was determined fluoroscopically. Then, the CF-SV was inserted until it reached the cecum or the site where abdominal pain occurred. Previous abdominal surgery and a abdominal disease were considered as unfavorable factors (UF) and the relationship between abdominal pain and UF, age and gender were investigated. Furthermore, the colonic insertion pressures in 36 patients with abdominal pain were measured with a force gauge.

RESULTS Thirty-four cases (34%) felt no pain with the CF-230I and successful pancolonoscopies to the cecum were performed. Sixty-six cases (66%) complained of abdominal pain. The procedure was painless for 47% of men and 24% of women, respectively. The CF-230I scope failed to reach the sigmoid-descending colon

junctions in 59 (89.4%) of the 66 patients complaining of abdominal pain. However, CF-SV reached proximal area in 94.9% of those who failed with CF-230I. The median pressure for pain-inducing was 700g/cm².

CONCLUSION Unsedated patients with UF were prone to complain of pain when the standard-type CF-230I scope was used. The newly developed extra -flexible CF-SV is useful for the aged and for those with UF or being prone to suffer from abdominal pain. Sedative agents may be unnecessary if this new type of colonoscope is used.

INTRODUCTION

Colonoscopy for patients who have undergone previous abdominal surgery, those with diverticular disease, women as well as the aged is technically difficult, even in expert hands^[1-8], and usually induces abdominal pain if sedative agents are not administered. One way of preventing pain during colonoscopy is to use a scope that is more flexible and thinner than the conventional scopes. It has been reported that success rate of colonoscopy could be significantly improved when a pediatric colonoscope was used instead of routine-type instrument for adults when stricture, fixation or painful looping was encountered^[9]. Kozarek *et al* achieved a similar increase in the success rate by using a small-caliber upper endoscope for colonoscopy in similar circumstance^[10]. In 1997, the softest and most flexible colonoscope (CF-SV, Olympus Inc., and 9.6mm in diameter with a 103cm working length) so far was developed^[11,12]. Moreover, a comparative study showed that fewer unsedated patients felt pain during colonoscopy with the CF-SV than with a conventional colonoscope^[11]. The aim of this self-controlled, prospective study was to evaluate whether less pain is experienced during colonoscopy with the CF-SV than with a routine-type colon oscope.

SUBJECTS AND METHODS

The study was approved by the ethics committee of Hirosaki University Hospital. One hundred consecutive patients of this hospital undergoing sigmoidoscopy over a 6-week period were recruited. For the purpose of scientific comparison all of the performance of colonoscopy was done exclusively by

Dr. Uno who has performed over 5000 colonoscopies.

Relationship between insertion pain and unfavorable factors (UF)

Each patient was placed on the X-ray table in the left lateral position. No sedating agent was given, but the anus was treated with xylocaine jelly, and a routine-type colonoscope CF-230I (Figure 1) (Olympus Inc. 13.6mm in diameter with a 130cm working-length) was inserted. As soon as the patient complained of abdominal pain, even it was mild, the colonoscope was advanced no further, the patient was moved to supine position and the anatomic location of the tip of the scope was determined by fluoroscopy. Then, the scope was pulled out and the air in the lumen was let out. The colonoscopist knew nothing about the patients' age, past history of surgery or abdominal diseases considered as UF of the patients until the procedure had been completed.

Re-insertion of CF-SV

The patients who suffered from abdominal pain with CF-230I were checked with CF-SV five minutes after CF-230I was withdrawn. When the patient complained abdominal pain of similar severity as that with CF-230I, the proximal location of the scope tip was confirmed fluoroscopically with the patient in supine position and the procedure was discontinued. If the patient did not complain of pain, insertion of the scope was continued until up to the cecum or the 103cm working length of the shaft had been inserted. Then, the proximal location of the tip was determined fluoroscopically and the procedure was terminated.

Measurement of the pain-inducing pressure during insertion

The first consecutive 36 patients who complained of pain during colonoscopy with CF-230I were investigated. The pain inducing pressure (g/cm²) initiated by the hand of the colonoscopist was measured with a force gauge, and the relationship between the insertion force and location of the pain was evaluated.

Statistics

All statistical analyses were performed using either Chi-squared test or differences at *P* values of less than 0.05 were regarded as significant.

RESULTS

Thirty-four patients (34%) were free of abdominal pain during colonoscopy with CF-230I and the scope was inserted up to the cecum. More of these pain-free subjects were male (21 cases, 61.8%) than female (13 cases, 38.2%) (Table 1). There was no significant difference (*P*<0.05) between the average ages of the males who did not complain of

pain (60.1 years) and those who did (59.0 years), but the average ages of the corresponding female groups (55.4yr. and 60.7yr., respectively) were significantly different (*P*<0.05), which suggests that aging females may be prone to pain during colonoscopy insertion. There was no significant difference between the average ages of the males and females who did not complain of pain.

Relationship between insertion pain and UF

Eighteen male patients had past histories of surgery or abdominal diseases: seven (38.9%) had undergone appendectomy; 3 (16.7%) had cholecystectomy; 2 (11.1%) of each had gastrectomy, Crohn's disease and ileus; one (5.6%) of each had diverticulitis, cancer of bladder, trauma, and a previous abdominal operation for an unknown reason. One of these patients had two UFs. Seventeen of these 18 patients with UF complained of abdominal pain during colonoscopy.

Thirty-four females had UF: 10 (29.4%) had cancer of the uterus; 8 (23.5%) had undergone appendectomy; 7 (20.6%) had hysterectomy for myoma uteri; 5 (14.7%) had ovarian neoplasms; 3 (8.8%) of each had undergone cholecystectomy and had peritonitis; 2 (5.9%) had carcinoma of the stomach or bladder, and one (2.9%) had ileus. Seven of these 34 patients had 2 of UFs. Thirty-one patients (91.1%) complained of no abdominal pain during colonoscopy with CF-SV. Only one (4.8%) of the 21 males who did not complain of pain had UF (Table 1). Seventeen (70.8%) of the 24 male patients with abdominal pain had UF (Table 1) and 7 (29.2%) did not. Three (23.1%) of the 13 females whose procedures were painless were UF-positive, whereas 31 (73.8%) of the 42 females with abdominal pain were UF-positive (Table 1) and 11 (26.2%) were UF-negative. There was significant difference (*P*<0.05) between the numbers of UF-positive patients receiving painless and painful colonoscopy.

Reinsertion of CF-SV

The anatomic location of the abdominal pain induced in 61 of the 64 patients with CF-230I was the sigmoid segment. However, in 59 of these 61 (96.7%) the CF-SV was successfully inserted proximal to sigmoid segment without causing abdominal pain (Figure 2). The remaining two patients who complained of abdominal pain during re-insertion of CF-SV were female and very short in stature. Among the 59 patients in whom the CF-230I was failed to pass through the sigmoid-descending colon junction, when re-inserted with CF-SV, it was passed in 56 (94.9%); transverse colon was passed in 30 (49.2%) and the ascending colon was reached in 14 (23.7%). Only one man (8.3%) and 6 women (17.6%) complained of abdominal pain with CF-SV, which was not inserted beyond the descending colon.

Figure 1 The standard colonoscope (CF-230 I) is shown on the top, the CF-SV is on the bottom.

Figure 3 The pressure associated with insertion-induced abdominal pain during colonoscopy.

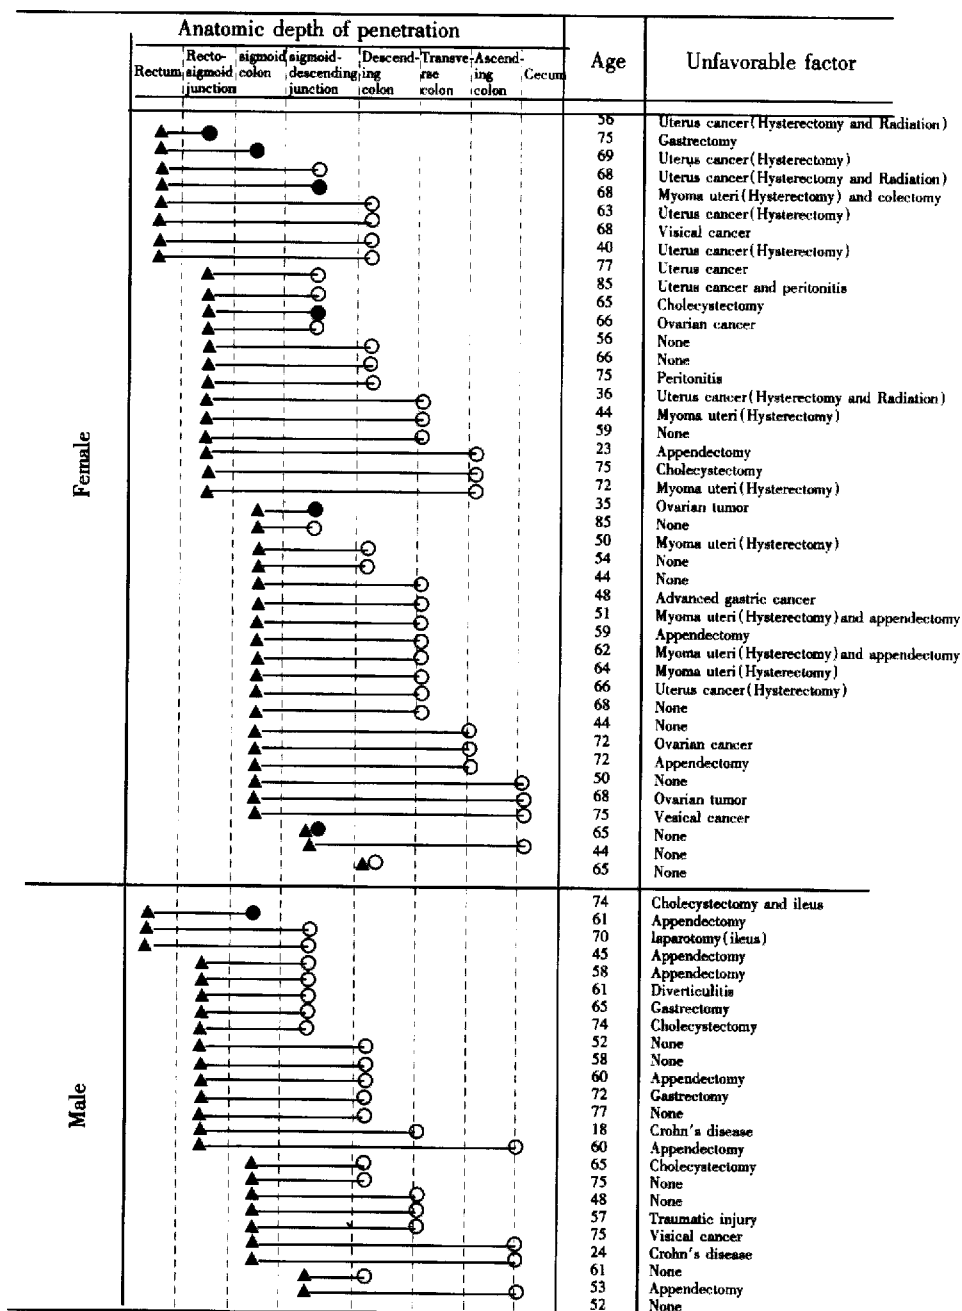

Figure 2 Anatomic depths of penetration of both colonoscopes, gender, patients' ages and unfavorable factors (UF).

▲: The location of insertion-induced abdominal pain with CF-230 I; ●: The location of insertion-induced abdominal pain with CF-SV; ○: Proximal area reached when re-inserted with CF-SV.

Table 1 Relationship between insertion-induced pain, gender, age and UF

	Insertion induced pain	Number of cases	Age (year) $\bar{x} \pm s$	UF-positive No.	%
Male	Negative	21	60.1 \pm 11.2	1	4.8
	Positive	24	59.0 \pm 14.8	17	70.8
Female	Negative	13	55.4 \pm 11.2	3	23.1
	Positive	42	60.7 \pm 13.9	31	73.8

Measurement of the pain-inducing pressure during insertion of colonoscope

The pain-inducing pressure during insertion ranged from 300 to 1200g/cm² (Figure 3) and the median was 700g/cm². In 24 of 36 patients (66.7%), the range was 500-700g/cm². Only one patient, a 56-year old woman with a history of hysterectomy and abdominal radiation therapy complained of a abdominal pain even when the insertion pressure was as low as 300g/cm², and the anatomic location of the pain was around the upper rectum with the CF-230I and the rectosigmoid junction with CF-SV. Abdominal pain was induced at a pressure of 400g/cm² only in three females: one is a 35-year-old young lady suffering from a giant ovarian tumor; the other two patients, even the CF-SV scope could not be advanced to the proximal segment (the reason remains unknown). Two patients, both were 61 years old male, did not complain of abdominal pain even when the pressure exceeded up to 1000g/cm². Interestingly, one of them was UF-negative, but the other had undergone appendectomy previously.

DISCUSSION

The Japanese Society of Gastrointestinal Endoscopy has investigated, by carrying out questionnaire surveys, and reported the incidence of complications during endoscopy every 5 years since 1983. According to their data, from 1983 to 1992, the estimated incidence of colonic perforation during diagnostic and therapeutic colonoscopy was 0.04%^[13], which is far lower than that in other countries^[14-16]. However, the incidence did not change during this period which means that if the number of colonoscopic examination increases, the absolute number of cases of perforation will inevitably goes up. In Japan, the number of colonoscopies performed each year has been estimated to be over three millions. Therefore, over 600 perforation will occur per year, 1-2 cases per day^[17]. If perforation can be prevented, colonoscopy will be performed far more frequently.

When the tip or bend of a colonoscope presses hard against the colonic mucosa, a seromuscular tear will probably occur, even when there is no muscularis injury^[18], and clinically, more damage occurs before the symptoms of perforation appear. In order to avoid such injuries, it is very important

that colonoscopists undergo special training to improve their skill. The problem of perforation might be resolved if the procedure is easy to perform and independent of experience and/or expertise.

In 1957, the "sigmoid camera" was developed in our institution (Hirosak University, Japan)^[19,20]. Examined with camera, it was not necessary to use sedation. Since then, colonoscopy without sedation had been performed till several years ago. In order to minimize abdominal pain during colonoscope insertion, the loop maneuver technique was introduced^[21]. However, in some patients with UF, although the maneuver was performed, the scope could not be inserted more proximally because of severe insertion-induced abdominal pain. Therefore, no wadays, in our institution, there are two indications for colonoscopy under sedation: when a patient complains of severe insertion-induced abdominal pain during the procedure; the patient prefers to be sedated.

In Japan, based on extensive experience, "Abdominal pain is a signal for some dangerous conditions" has become one of the most important precepts. In our study, the pressure to induce insertion-related abdominal pain was not higher than 1200g/cm². An *in vitro* experiment on perforation of the human colon^[18] showed that perforation occurred when the pressure reached up to 2-3kg/cm². Therefore, the precept of our institution is true. Recently, colonoscopy without sedation and with selective sedation has been investigated in institutes in which colonoscopy under sedation used to be a routine procedure^[22-24]. Furthermore, the cost and complications may be reduced when colonoscopy is performed without sedation. According to Rex^[25], the success rate of unsedated colonoscopy has uniformly been reported to be high in a small number of American reports, although the patients appear to have been selected. For example, in one study, attempted unsedated colonoscopy only in volunteers consisting of about 30% of consecutive patients undergoing colonoscopy. In another study, colonoscopy was performed in consecutive male veterans.

In Japan, colonoscopy without sedation has also been reported but the subjects were young males undergoing a health check-up and did not include elderly subjects or those with UF. In fact, we found that abdominal pain during colonoscope insertion usually occurred in patients who were elderly or UF-positive. The sigmoid colon was the area where pain occurred in most of the subjects undergoing colonoscopy without sedation^[26]. In patients who are very young, very old, have diverticular disease, a fixed colon due to previous abdominal surgery, underwent previous pelvic radiation, have ovarian neoplasms as well as other kinds of abdominal

pathological disorders, colonoscope advancement to the transverse colon was difficult because of making loops re-form in the sigmoid colon. This problem might be solved by introducing a stiff wire into the instrument channel to stiffen the colonoscope after it has been straightened^[27,28]. Recently, a new type of colonoscope with a shaft of variable stiffness has been developed^[29].

Yin F, Shi YQ, Zhao WP, Xiao B, Miao JY, Fan DM. Suppression of P-gp induced multiple drug resistance in a drug resistant gastric cancer cell line by overexpression of Fas. *World J Gastroentero*, 2000;6(5): 664-670

Abstract

AIM To observe the drug sensitizing effect and related mechanisms of *fas* gene transduction on human drug-resistant gastric cancer cell SGC7901/VCR (resistant to Vincristine).

METHODS The cell cycle alteration was observed by FACS. The sensitivity of gastric cancer cells to apoptosis was determined by *in vitro* apoptosis assay. The drug sensitization of cells to several anti-tumor drugs was observed by MTT assay. Immunocytochemical method was used to show expression of P-gp and TopoII in gastric cancer cells.

RESULTS Comparing to SGC7901 and pBK-SGC7901/VCR, *fas*-SGC7901/VCR showed decreasing G2 cells and increasing S cells, the G2 phase fraction of pBK-SGC7901/VCR was about 3.0 times that of *fas*-SGC7901/VCR, but S phase fraction of *fas*-SGC7901/VCR was about 1.9 times that of pBK-SGC7901/VCR, indicating S phase arrest of *fas*-SGC7901/VCR. FACS also suggested apoptosis of *fas*-SGC7901/VCR. *fas*-SGC7901/VCR was more sensitive to apoptosis inducing agent VM-26 than pBK-SGC7901/VCR. MTT assay showed increased sensitization of *fas*-SGC7901/VCR to DDP, MMC and 5-FU, but same sensitization to VCR according to pBK-SGC7901/VCR. SGC7901, pBK-SGC7901/VCR and *fas*-SGC7901/VCR had positively stained Topo II equally. P-gp staining in pBK-

SGC7901/VCR was stronger than in SGC7901, but there was little staining of Pgp in *fas*-SGC7901/VCR.

CONCLUSION *fas* gene transduction could reverse the MDR of human drug-resistant gastric cancer cell SGC7901/VCR to a degree, possibly because of higher sensitization to apoptosis and decreased expression of P-gp.

INTRODUCTION

Multidrug resistance (MDR), the principal mechanism by which many cancers develop resistance to chemotherapeutic drugs, is a major factor in the failure of many forms of chemotherapy^[1]. It affects patients with a variety of blood cancers and solid tumors, including breast, ovarian, lung and lower gastrointestinal tract cancers.

Tumors usually consist of mixed populations of malignant cells, some of which are drug sensitive while others are drug resistant. Chemotherapy kills drug sensitive cells, but may leave behind a high proportion of drug resistant cells. As the tumor begins to grow again, chemotherapy may fail because the remaining tumor cells are now resistant to it.

Resistance to therapy has been correlated to the presence of at least two molecular 'pumps' that actively expel chemotherapeutic drugs from the tumor cells. This action thus spares tumor cells from the effects of the drug, which has to act inside the cell at the nucleus or the cytoplasm. The two pumps commonly found to confer chemoresistance in cancer are P-glycoprotein (P-gp) and the so-called multidrug resistance-associated protein (MRP). But they are not the complete story, and can not explicate the phenomenon of MDR fully.

Recent studies indicate that some cancer cells are resistant to signals of apoptosis and so making cell life longer might be an important part of MDR mechanisms.

In this study, we assumed that inducing apoptosis in drug resistant tumors might reverse MDR. So we transfected *fas* gene, which is a key molecule in the signal transduction pathway of apoptosis, into drug resistant gastric cancer cells,

and observed the expression of target genes in transfectants and the sensitivity of transfectants to chemotherapeutic agents in order to find the pathway of signal transduction for reversing gastric cancer MDR.

MATERIALS AND METHODS

Materials

Gastric cancer cell line SGC7901, pBK-SGC7901/VCR (SGC7901/VCR is transfected by pBK-CMV expression vectors persistently), pBK-*fas* cDNA (1.83kb full length *fas* cDNA, was inserted into pBK-CMV expression vectors), and *fas*-SGC7901/VCR cell transfectants (SGC7901/VCR is transfected by pBK-*fas*-expression vectors persistently) were kept in our department. Chemical reagents were obtained from Sigma, except as noted. Chemical reagents including PMSF, SDS, and avidin-biotin peroxidase complex (ABC) kit were obtained from SABC and Promega. P-gp mouse IgG antibody and topoisomerase II (TopoII) mouse IgG antibody were kindly given by Dr. Liu. All the antibodies and rabbit anti-human Fas polyclonal antibody were products of Dako. RPMI1640 was obtained from GIBCO, fetal bovine serum from HYCLON E, mitomycin C (MMC) from Kyowa Hakko Kogyo Co. Ltd, vincristine (VCR) and doxorubicin (Dox) from the Twelfth Shanghai Pharmaceutical Product Factory, 5-fluorouracil (5-FU) from Shanghai Xudong Pharmaceutical Company, and cisplatin (DDP) from Shandong Qilu Pharmaceutical Product Factory.

Methods

Western blot analysis Cells in log phase were harvested and washed with PBS twice, then lysed in lysis buffer (150mmol/L Tris-Cl pH 8.0; 50mmol/L NaCl; 0.2mmol/L EDTA; 0.1mmol/L PMSF; 10g/L NP-40). SDS-PAGE was performed using 100µg or 150µg total protein per lane, one electrophoresis gel was stained with commassie brilliant blue R-250, another was blotted to nitrocellular filter. After blocking with 50g/L defatted milk, the filter was incubated with rabbit anti-human Fas polyclonal antibody overnight at 4°C, then washed three times 5min each time with TBS and incubated with HRP-conjugated goat anti-rabbit IgG at 37°C for 30min. Finally, the positive bands were visualized by incubation with peroxidase substrate solution D iaminobenzidine (DAB).

Cell culture MDR gastric cancer cell subline SGC7901/VCR was induced by pulse treatment of the parent cell line SGC7901 at a single dose of Vincristine. Having been exposed to 1.0mg/L Vincristine for one hour, SGC7901 cells were replated in drug-free culture medium to allow exponential growth of cells to be recovered prior to another stimulation. Once stable resistant

phenotype was developed, the SGC7901/VCR cells were grown in drug free growth medium.

Cytotoxicity assay Dose-survival curves defining the sensitivity of gastric cancer cell line SGC7901, pBK-SGC7901/VCR and *fas*-SGC7901/VCR cell transfectants to VCR, DDP, MMC, Dox and 5-FU were obtained using MTT cytotoxic assay. Cells in log growth period $(3-4) \times 10^7/L$ diluted with 200µL RPMI 1640 supplemented with 100mL/L fetal bovine serum were seeded into 96-well plates in triplicate for each treatment, after culturing for 12h, added Dox (0.1, 1, 10 and 100µg), DDP (0.1, 1, 10 and 100µg), 5-FU (0.7, 7, 70 and 700µg), MMC (0.1, 1.0, 10 and 100µg) and VCR (0.1, 1.0, 10 and 100µg) according to the clinically established plasma peak concentration. Three days later, 20µL MTT solution (5g/L) was put into plates, and then the supernatant was discarded after 4 hours, 150µL DMSO was added to melt crystal. A value was read at 590 nm wavelength.

FACS analysis Cells $(3-4) \times 10^7/L$ were seeded in 25cm² tissue culture flasks for 36h-40h, after reaching log growth, cells were digested by 2.5g/L trypsin and harvested by centrifugation. Then the cells were fixed with ethanol and stained with propidium iodide, and subjected to fluorescence-activated cell sorting (FACS) analysis for DNA content at the Fourth Military Medical University.

In vitro apoptosis assay Cells $(3-4) \times 10^7/L$ were seeded in 25cm² tissue culture flasks and allowed to reach log growth for 36h-40h. After exposure to apoptosis inducer VM-26 for 24h at two different doses 1.25µmol/L and 2.5µmol/L, subsequently culture the cells in RPMI 1640 supplemented with 100mL/L fetal bovine serum containing no VM-26 for 48h, then harvest the cells for genomic DNA extraction, and electrophoresis in 10g/L agarose gel at 50V for 1h^[2].

Immunocytochemistry Tissue immunocytochemical staining was done with the ABC kit. Cells $(3-4) \times 10^7/L$ were seeded in a glass slide in 100g/L RPMI 1640. After the cells attached tightly to the slides, and reached log growth for 36h-48h, slides were washed with PBS for 3-5 min, then immersed in 40g/L paraformaldehyde phosphated buffer solution for 5-10 min. Slides were immersed for 45min in 3mL/L peroxide in methanol (to deplete endogenous peroxidase) and normal goat serum diluted to 1:100 in PBS for 20min. Primary antibodies against P-gp, TopoII and control normal mouse serum were used at dilution of 1:100, applied to cell attached slides and incubated in a humidified chamber at a room temperature for 30min and 4°C

overnight. The slides were then washed with PBS for 10min. Biotinylated goat anti-mouse IgG was applied on to the cell sections, and incubated at room temperature for 30min. After washing with PBS for 10min, these tissues were incubated with avidin DH-Biotinylated peroxidase for 45min. Finally, color was developed by immersion of the sections in a peroxidase substrate solution DAB.

For each slide, the extent and intensity of staining with P-gp and TopoII antibody was graded on a scale of 0-4+ by a blinded observer on two separate occasions using coded slides, and an average score was calculated. The observer assessed all tissues on the slides to assign the scores. A 4+ grade implied that all staining was maximally intense throughout the specimen, while 0 implied that staining was absent throughout the specimen.

RESULTS

Western blot

SDS-PAGE (Figure 1A) showed no significant differences between *fas*-SGC7901/VCR protein and that of pBK-SGC7901/VCR control cells. Western blot (Figure 1B) indicated a weak band of M_r 36000-40 000 in lane 3 which is consistent with M_r of Fas protein, when 150 μ g total protein of pBK-SGC7901/VCR was loaded, while lanes 4 and 5 of *fas* transfectants had strong positive band of M_r 36 000-40 000 respectively, the band of lane 4 was slightly weaker than that of lane 5 because of quantity of loading.

Cytotoxic assay

As shown in Figure 2, *fas*-SGC7901/VCR cell transfectants were more sensitive to MMC, DDP and 5-FU. The survival rates of transfectants treated with VCR and Dox were only lowered slightly, compared with non-transfectants, which showed that *fas*-SGC7901/VCR cell transfectants remained resistant to VCR and Dox.

FACS analysis

By using FCM to analyze cell cycle, the apoptotic peak appeared only in *fas*-SGC7901/VCR cell transfectants and there were no significant differences between them in G1 phase. These data show that Fas takes part in induction of apoptosis and differentiation of gastric cancer cells. Analysis of cell cycle distribution demonstrated that the fraction number of *fas*-SGC7901/VCR cells in G1/0 phase, G2 and S phase was about 0.70, 0.06 and 0.24, that of pBK-SGC7901/VCR was about 0.67, 0.17 and 0.13 respectively, and the G2 phase fraction of pBK.SGC7901/VCR was about 3.0 times that of *fas*-SGC7901/VCR, but S phase fraction of *fas*-SGC7901/VCR was about 1.9 times that of pBK-SGC7901/VCR, indicating S phase arrest of *fas*-SGC7901/VCR (Table 1).

Table 1 Cell cycle distribution of three kinds of cell lines (Number fraction)

Cell line	G1	G2	S	G1/G2
SGC7901	0.73	0.11	0.16	0.188
pBK-SGC7901/VCR	0.67	0.17	0.13	0.186
<i>fas</i> -SGC7901/VCR	0.70	0.06	0.24	0.190

In vitro apoptosis assay

As shown in Figure 3, *fas*-SGC7901/VCR cell transfectants remained sensitive to VM-26, and characteristic DNA ladder bands of apoptosis appeared.

Immunocytochemistry

In order to assess whether the overexpression of Fas in drug resistant gastric cancer cell line SGC7901/VCR involved inhibition of other MDR inducing factors except induction of apoptosis, we detected topoisomerase II (Topo II) and P-gp protein expression in these cell lines by immunocytochemistry. There was no difference in the expression of Topo II among SGC7901, pBK-SGC7901/VCR and *fas*-SGC7901/VCR. All these had positive staining of Topo II, and an average score of about 2+ grades was calculated. P-gp staining on pBK-SGC7901/VCR was stronger than that on SGC7901, and scored a grade of 4+. But there was weak staining of P-gp on *fas*-SGC7901/VCR (Figure 4). These data suggested that Fas proteins increased sensitivity of drug resistant gastric cancer cell line SGC7901/VCR to chemotherapeutic drugs may be through decreasing P-gp protein.

DISCUSSION

Apoptosis is an important and well-controlled form of cell death that occurs under a variety of physiological and pathological conditions. This process has been recognized to be of major importance for embryonic development, tissue homeostasis, neurodegeneration, autoimmune diseases, AIDS, carcinogenesis, cancer progression,

specially for killing cancer cells induced by chemotherapeutic drugs^[3-9]. Once the apoptosis program is activated, it starts with blebbing of the membrane, followed by degradation of the chromosomal DNA by nucleases, resulting in condensation and fragmentation, finally, phagocytes remove cell fragments without causing any inflammatory reaction. Some proto-oncogenes

and tumor suppressor genes can regulate apoptosis^[10-18] and there are also accumulated evidences which show that these apoptosis regulating genes are important for the development of digestive system^[19-24].

Multidrug resistance represents a major obstacle in the successful therapy of neoplastic diseases. Studies have demonstrated that this form of drug resistance occurs both in cultured tumor cell lines as well as in human cancers. Recent studies indicate that genes that regulate apoptotic cell death might play an important role in determining the sensitivity of tumor cells to chemotherapy. Many chemotherapeutic agents are found to act through damaging DNA or regulating apoptosis related genes *p53*, *c-myc*, *bcl-2*, *bax*, *p21*, *c-H-ras* to trigger apoptosis^[25-28].

Strobel *et al*^[29] found that SW626 cells overexpressing BAX are sensitized to the cytotoxic effects of alkaloid derivatives such as paclitaxel and Vincristine, and demonstrate that these seemingly disparate effects are explained by an enhanced accumulation of paclitaxel in BAX-overexpressing cells, an effect due to diminished drug efflux. These data suggest that stable transfectants that overexpress BAX may be sensitized to apoptotic cell death through a novel mechanism involving the enhancement of intracellular levels of naturally occurring toxins. NicA mhlaoibh *et al*^[30] used an *in vitro* model, the resistant variant, DLKP-SQ/10p derived from human lung carcinoma clonal cell line DLKP-SQ to 10 sequential pulses of pharmacologically attainable doses of doxorubicin, demonstrating that overexpression of the pro-apoptotic *bcl-xS* gene in the DLKP-SQ/10p line partially reversed resistance not only to P-gp-associated drugs, doxorubicin, but also to 5-fluorouracil, indicating that the ratio of *bcl* family members may be important in determining sensitivity to chemotherapeutic drug-induced apoptosis.

Recently mutated *N-ras* oncogene has been implicated in melanoma resistance to cisplatin, both *in vitro* and *in vivo*, and the role of two other oncogenes, *bcl-2* and *p53*, which are already involved in the chemoresistance of hematological and solid malignancies. The finding that many chemotherapeutic agents can kill susceptible cells through the apoptosis pathway provides new molecular insight into chemoresistance mechanisms and suggests that apoptosis and/or resistance to apoptosis of tumor cells should be investigated to clarify further the mechanism of tumor chemoresistance^[31].

Anti-cancer drugs and cytotoxic cytokines such as members of the TNF/Fas-ligand family play a predominant role in apoptosis induction in tumor cells including gastric cancer^[32,33]. And compared

with normal tissues, malignant tumor cells, especially metastatic tumor cells present extremely lower expression of Fas, while most benign tumors are similar to their original tissues in the expression of Fas. It is hypothesized that malignant tumors might suppress Fas expression or lose Fas molecule in order to avoid the surveillance of Fas ligand. This explains the lack of Fas expression in drug resistant cells. Our laboratory found that Fas-antigen expression in human gastric cell line SGC7901/VCR is lower than that of SGC7901, and it seems that the alteration of Fas expression following drug-resistance is not restricted to one cell type. Cai *et al*^[34] also found that after being treated by anti-Fas in the presence of IFN-gamma, human breast carcinoma cell line MCF7/Adr (resistant to adriamycin) was resistant to Fas-mediated apoptosis, and this resistance was correlated with a loss of surface Fas-protein expression^[35]. Furthermore, the down-regulation of Fas expression and subsequent resistance to anti-Fas were observed in other drug-resistant cancer cell lines including human ovarian-carcinoma IGR-OV1/VCR cells and leukemic lymphoblast CEM/VLB cells. But no evidence shows whether the down-regulation of Fas expression increases resistance to not only anti-Fas, but also to other chemotherapy drugs, and whether there is crosstalking between MDR signaling and Fas expression.

We investigated whether the CD95/CD95L system plays a role in this process. We used the human gastric cell line SGC7901, and its derivative SGC7901/VCR (induced by sequential pulses of high dose of VCR and resistant to VCR) to determine the impact of acquired chemotherapeutic drug and cytokine resistance on susceptibility to Fas-induced cytotoxicity.

CD95 (Fas/APO-1) is a death-promoting receptor that belongs to the tumor necrosis factor (TNF) receptor I family^[36,37]. Triggering of the CD95 molecule by either agonistic antibodies or the natural ligand CD95L (FasL) induces apoptosis^[38]. Ligand binding induces trimerization of CD95, and the trimerized cytoplasmic region then transduces the signal by recruiting a molecule called FADD (Fas-associating protein with death domain) or MORT1 (mediator of receptor-induced toxicity), which binds to CD95 via interaction of the death domain at its COOH terminus^[39-43]. The NH₂-terminal region of FADD is responsible for downstream signal transduction by recruitment of a protein called FLICE (FADD-like interleukin-1 β -converting enzyme [ICE]) or MACH (MORT1-associated CED-3 homologue), recently designated as caspase-8^[44-46]. The NH₂ terminus of caspase-8 binds to FADD/MORT1, while its COOH-terminal region is related to the caspase-3 (CPP32) subfamily. Therefore, FLICE/ MACH

preferentially cleaves caspase-3 substrates such as poly (ADP) ribose polymerase (PARP)^[45], and ICE proteases including CPP32^[47].

In this study, there is evidence that Fas can increase sensitivity to the cytotoxic effects of therapeutic drugs through increasing cell arrests of S phase. MTT assays show that overexpression of Fas could increase sensitivity of gastric cancer cells, to the cytotoxic effects of topoisomerase II-directed chemotherapeutic agents such as VM-26, but not doxorubin. It is suggested that transduction of pro-apoptosis Fas gene into drug resistant cells is obviously helpful in increasing the drug sensitivity.

Considerable evidence has indicated that the multidrug transporter or P-glycoprotein plays a role in the development of simultaneous resistance to multiple cytotoxic drugs in cancer cells^[48-50]. P-glycoprotein appears to act as an energy-dependent efflux pump to remove various natural product drugs from the cells before they have a chance to exert their cytotoxic effects. But expression of the MDR1 gene product has been associated with a poor prognosis in clinical studies. To obtain insight into the mechanism of drug resistance, the expression of P-170 glycoprotein as potentially able to contribute to drug resistance was investigated in these three kinds of cell lines by immunochemical technology. We found that P-glycoprotein (P-gp) is overexpressed in multidrug resistant human gastric cancer cell line SGC7901/VCR than SGC7901, but there was little expression of P-gp on fas-SGC7901/VCR.

These data suggest that stable transfectants that overexpress Fas may be sensitized to apoptotic cell death through a novel mechanism involving the enhancement of intracellular levels of naturally occurring toxins such as alkaloid derivatives.

These results revealed that fas-gene transduction could reverse the MDR of human drug-resistant gastric cancer cell SGC7901/VCR to a degree, partly because of Fas induced decreased expression of P-gp.

Other observations suggest that P-gp may play a specific role in regulating some caspase-dependent apoptotic pathways, and there is a complicated cross talking between Fas and P-gp. Researchers found that classical multidrug resistant human CEM and K562 tumor cell lines expressing high levels of P-gp were less sensitive to multiple forms of caspase-dependent cell death, including that mediated by cytotoxic drugs and ligation of Fas, and inhibition of P-gp function also enhanced drug or Fas-mediated activation of caspase-3 in drug-resistant CEM cells^[51].

In this study we have demonstrated that inducing apoptosis by *fas* transduction correlates with the development of sensitivity to MMC, DDP, 5-FU to a degree, and Fas can repress P-gp through a series of cross-linked signal transduction. Therefore, apoptosis inducing gene products may

not only increase sensitivity to the cytotoxic effects of chemotherapeutic agents by means of apoptosis, but also through other signal transduction. So gene therapy of introducing pro-apoptosis inducing gene may be a good method to overcome MDR in tumors. However, the mechanism of MDR is much complicated, and in tumors the drug resistance is multifactorial. Research to overcome this resistance should therefore be directed towards a combined treatment that eliminates all of these.

Fish sauce and gastric cancer: an ecological study in Fujian Province, China

Lin Cai¹, Shun Zhang Yu², Wei Min Ye¹ and Ying Nan Yi¹

Subject headings stomach neoplasm/etiology; food habits; risk factors; nitrosamines; epidemiology; fish products; fish sauce; carcinogens

Cai L, Yu SZ, Ye WM, Yi YN. Fish sauce and gastric cancer: an ecological study in Fujian Province, China. *World J Gastroentero*, 2000;6(5): 671-675

Abstract

AIM To explore the relationship between consumption of fish sauce and the risk of gastric cancer in Fujian Province.

METHODS An ecological study was carried out. A total of 11 000 subjects from 55 townships were randomly selected from 10 counties within Fujian Province. All subjects were local residents who had been living in Fujian Province for more than 20 years, within the age group of 45-74 years. Trained interviewers conducted face-to-face interviews with a standardized questionnaire, which covered the frequency and amount of food intake, dietary habit, tobacco and alcohol consumption and history of chronic gastric diseases. Univariate and multivariate analyses were performed using Epi-info and SAS statistical packages, respectively.

RESULTS A significant correlation between monthly consumption of fish sauce and mortality of gastric cancer was found. Pearson's coefficient of correlation was statistically significant with $r = 0.7356$ for males, $r = 0.5246$ for females ($P < 0.01$). In the multivariate analysis, consumption of fish sauce still showed an association with the risk of gastric cancer. No significant positive correlation between esophagus cancer, liver cancer, colon cancer and consumption of fish sauce were observed.

CONCLUSION Long-term intake of fish sauce may be related to high mortality of gastric cancer. Consumption of fish sauce might be one of important and unique etiologic factors of gastric cancer in Fujian Province. Further studies are needed to confirm this ecological study.

INTRODUCTION

Fujian Province is a high-risk area of gastric cancer in China^[1]. The standardized mortalities of gastric cancer during 1986-1988 were 37-72 per 100 000 for men and 14-90 per 100 000 for women, accounting for 25.31% of total cancer mortality. In certain areas, the annual incidence of gastric cancer is more than 50 per 100 000 persons^[2]. The health of general population in Fujian Province is most seriously threatened by gastric cancer.

A number of potential risk factors for gastric cancer have been examined in previous studies^[3]. Among these, the dietary hypotheses are of particular interest^[4,5]. N-nitroso compounds derived from the consumption of preserved food may be associated with the risk of the disease^[6].

In the investigation of dietary factors, we have reported the relationship between high salt intake and gastric cancer in the high-risk area of Fujian Province^[7-9]. The salted food includes fish sauce, which is particularly favored by Fujian local residents. Fish sauce is usually produced from several kinds of sea fishes after prolonged fermentation processes. Its mutagenicity has been reported by several experimental studies^[10-12]. However, there have been few reports from population-based epidemiological study on the relationship between fish sauce and risk of gastric cancer. Therefore, this ecological study was carried out to explore the relationship between them in the area of Fujian Province.

MATERIALS AND METHODS

Study areas, subjects and methods

Gastric cancer is the most common cancer among the major types of cancer in Fujian Province. However, even within the province the death rate distribution of gastric cancer varies greatly among different areas. This ecological study included 55 townships in 10 counties. The retrospective investigations of death cause, which was a part of a national program, had been concluded in these areas.

In reference to the national gastric cancer death rate of 17.30/100 000 (95% confidence interval: 9.15/100 000-25.45/100 000, calculated by Poisson-normal-approximation method), the death rate among these 10 counties can be divided into three groups: ① High incidence area: Changle, Putian, and Fuzhou; ② Medium incidence area: Changtai, Huian, Shaxian, Sanming, Yongding, and Zhangpu; ③ Low incidence area: Fuan (Figure 1).

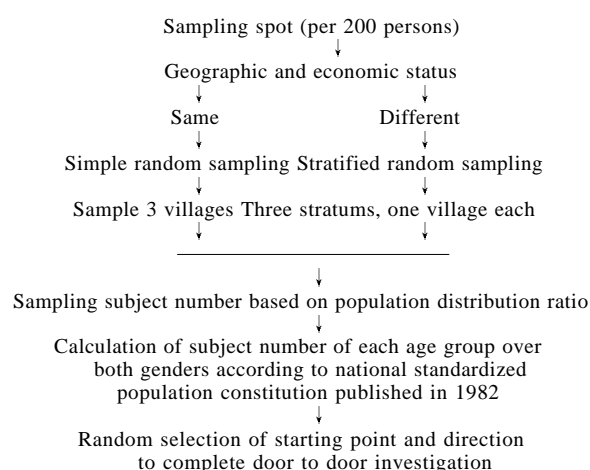

Figure 1 Gastric cancer mortality in 10 counties, Fujian, China, 1991.

A total of 200 subjects in each town (sampling spot) were interviewed. The 55 townships were randomly selected from 10 counties which include 11 000 subjects in this study.

All subjects of this study are local resident of more than 20 years, within the age of 45-74 years, who can clearly answer the questions asked by the interviewers. Specially trained interviewers conducted face-to-face interviews according to a standardized questionnaire, which covers the frequency and amount of food intake. The investigations also include demographic factors, dietary habit, smoking and alcohol consumption, and history of chronic gastric diseases.

Statistical analysis

The database was established using Epi-info, and the gastric cancer mortality for 45-74 age group was calculated based on world truncated standardized population constitution. The correlation coefficient and multiple regression analysis were carried out using SAS software.

RESULTS

Univariate analysis

The highest Pearson's correlation coefficient was found between gastric cancer mortality and average monthly consumption of uncooked fish sauce. Similar results were observed for both males and females, with Pearson's correlation coefficient for males of 0.7356 and 0.5246 for females ($P < 0.01$) (Table 1). Positive correlation were found between gastric death rate and fish sauce-related variables (Fish sauce consumption, population ratio who consume fish sauce, population ratio who consume uncooked fish sauce, and uncooked fish sauce consumption). Further, compared with other factors, larger Pearson's correlation coefficients were observed for all 4 variables (χ^1 - χ^4).

Table 1 Correlation analysis between exposure factors and standardized truncated mortality of gastric cancer (55 townships)

Factors	Pearson's coefficient of correlation	
	Male	Female
χ^1 Fish sauce average consumption (0.5kg/month)	0.5170 ^a	0.4261 ^a
χ^2 Population ratio who consume fish sauce	0.3576 ^a	0.2720 ^a
χ^3 Population ratio who consume uncooked fish sauce	0.6904 ^a	0.5086 ^a
χ^4 Uncooked Fish sauce average consumption (0.5kg/month)	0.7356 ^a	0.5246 ^a
χ^5 Salted fermented sea foods average consumption (0.5kg/year)	0.4863 ^a	0.3653 ^a

^a $P < 0.01$, ^b $P < 0.05$.

Smoking index: (amount of smoking/day×years of smoking)/age of starting smoking.

Gastric cancer mortality for 45-74 age group was calculated based on world truncated standardized population constitution.

Multi-variables analysis

Considering the possible confounding effects among factors, multivariate regression analyses were performed on other factors (χ^5 - χ^{18}) and each of fish sauce variables (χ^1 - χ^4) respectively. MAXR method from REG of SAS package was used. The optimum subset of variables was established which also includes fish sauce as one of variables. The consumption of fish sauce still shows association with the risk of gastric cancer in analysis after controlling the possible confounding factors (Tables 2-5). The corresponding multiple correlation coefficients indicate that the goodness of fit tests was significant.

Correlation analysis between exposure factor and other digestive tract cancers

The Pearson's correlation coefficients between each factor and truncated standardized mortality for esophagus cancer, liver cancer, and colon cancer were calculated separately and results are shown in Tables 6 - 8. There are no significant positive correlation among 4 variables for fish sauce consumption and any of the mortality rates among three other digestive tract cancers. In multivariate regression analysis, the variables that reflect fish

sauce consumption were not selected into the model when analyzing relationship between fish sauce and mortality of the other three cancers.

Colon cancer mortality for 45-74 age group was calculated based on world truncated standardized population constitution.

DISCUSSION

Gastric cancer is the second common cancer in the world today^[13]. It remains the leading cause of cancer death in China^[14]. In the studies of etiology and epidemiology on gastric cancer, the associations between gastric cancer risk and *Helicobacter pylori* (Hp) infection^[15-18], occupational exposures^[19], diet and life factors^[20-25], lack of essential trace elements^[26] have been observed. The most widely reported protective factors are dietary factor^[27-33]. It has been reported that a large amount of nitrite exists in most salted fishes and smoking meat, and may be related to the high gastric cancer incidence along coastal area and among Japanese or Chinese population.

Each local resident in Fujian Province consumed daily about 30mL fish sauce as one kind of condiments. Fish sauce is a liquid product of small marine fish and table salt (7:3). The fishes are completely liquefied after fermentation for 1-2 years. The salted fermented fish products may contain many precursors of N-nitroso compound derived from the proteins content of the fishes, which could synthesize N-nitrosamides under simulated human stomach conditions^[34]. N-nitrosamides is suggested as a major initial cause of gastric cancer^[35]. Zhang *et al*^[36] had analyzed the N-nitroso compound precursors from 49 fish sauce samples obtained from high risk area of gastric cancer in Fujian Province, and detected 630µM/mL of 17 free amino acids. After nitrosification the total amount of N-nitroso compound in samples was as high as 2.95µM/mL. The concentration of N-nitrosylamine from ethyl acetate extraction solution was 0.06µM/mL. Fish sauce is rich in creatinine and other nitrosamide precursors. It was mutagenic and carcinogenic for the glandular stomach of Wistar rats, after it was nitrosified under simulated human stomach condition^[37]. All these experiments have shown that fish sauce is potentially carcinogenic.

High incidence of gastric cancer may be attributed, to some extent, to some unique dietary habits in the high-risk area. This ecological study showed the positive relationship between gastric cancer mortality and fish sauce favored by Fujian residents. The relationship between gastric cancer and uncooked fish sauce intake is particularly obvious. Among four digestive tract cancers, only gastric cancer had a positive correlation with fish sauce consumption, which suggests that the association may be specific to gastric cancer. This study indicates that long-term use of fish sauce may be related to high gastric cancer mortality in the Fujian area.

This ecological comparison study may provide a possible hypothesis for the etiology of gastric cancer. Fish sauce has both N-nitroso compounds and a high salt content, which might partially

explain the high gastric cancer mortality along the Fujian coast. Further studies are needed to confirm our results. Recently, a population-based case-control study was conducted in Changle County, Fujian Province. The residents in Changle County had a high prevalence of *H. pylori* infection. However, no statistical significant difference was found in respect to presence of *H. pylori* infection between gastric cancer patients and controls. The results showed that fish sauce intake, deficiency in fresh vegetables were risk factors in gastric cancer^[38].

The development of human gastric cancer is a multistep and multifactorial process^[39]. A number of molecular events are involved in gastric carcinogenesis^[40]. Coordinate prevention and treatment measures must be taken, including changing the habit of taking fish sauce, nutrition guidance and cancer prevention education for general public. This would undoubtedly have positive effect on reducing the risk of gastric cancer in Fujian Province.

Abstract

AIM To investigate the morphological and ultrastructural changes in the human gastric carcinoma cell line BGC-823 after being treated with tachyplesin.

METHODS Tachyplesin was isolated from acid extracts of Chinese horseshoe crab (*Tachypleus tridentatus*) hemocytes. BGC-823 cells and the cells treated with 2.0mg/L tachyplesin were examined respectively under light microscope, scanning and transmission electron microscope.

RESULTS BGC-823 cells had undergone the restorational alteration in morphology and ultrastructure after tachyplesin treatment. The changes were as follows: the shape of cells was unanimous, the volume enlarged and cells turned to be flat and spread, the nucleocytoplasmic ratio lessened and nuclear shape became rather regular, the number of nucleolus reduced and its volume lessened, heterchromatin decreased while euchromatin increased in nucleus. In the cytoplasm, mitochondria grew in number with consistent structure relatively, Golgi complex turned to be typical and well-developed, rough endoplasmic reticulum increased and polyribosome decreased. The microvilli at cellular surface were rare and the filopodia reduced while lamellipodia increased at the cell edge.

CONCLUSION Tachyplesin could alter the malignant morphological and ultrastructural characteristics of human gastric carcinoma cells effectively and have a certain inducing differentiation effect on human gastric carcinoma cells.

INTRODUCTION

Horseshoe crab, a kind of marine animals, is a "live fossil" which has an unique status in evolution. It has many bioactive substances with special functions due to its primitive character. In recent years, many bioactive substances, including clotting factors, protease inhibitors, antibacterial substances, lectins and others, have been found in the hemocytes and hemolymph plasma of horseshoe crab^[1]. To seek the low molecular weight antitumor substances which can intervene in cellular signal transduction and regulate cell proliferation and differentiation^[2], we have isolated and purified a small polypeptide—tachyplesin from the blue blood of Chinese horseshoe crab (*Tachypleus tridentatus*) and appraised its antitumor activities^[3]. Then we have investigated the biological effects of tachyplesin on tumor cells systematically with the model system of human gastric carcinoma cell line BGC-823. This paper deals with the effects of tachyplesin on the morphology and ultrastructure of human gastric carcinoma cells by light microscopy and scanning and transmission electron microscopy.

MATERIALS AND METHODS

Tachyplesin isolation

Tachyplesin was isolated from acid extracts of hemocyte debris of Chinese horseshoe crab as described by Nakamura^[4] with minor modification.

Cell culture and treatment

BGC-823 cells were cultured in RPMI-1640 supplemented with 20% heat-inactivated fetal calf serum, 100 units/mL penicillin, 100 mg/L streptomycin and 50mg/L kanamycin at 37°C, 5% CO₂ in air. Then the cells were treated with the culture medium containing 2.0 mg/L tachyplesin after being seeded for 24 hours.

Sample preparation for the light microscopy

BGC-823 cells and the cells treated with 2.0mg/L tachyplesin were seeded in little penicillin bottles with cover slip strip, and grown in the normal culture medium or in the culture medium containing 2.0mg/L tachyplesin at 37°C in 5% CO₂ atmosphere for 72 hours respectively. The cells at cover slip strips were rinsed with D-Hank's solution twice at 37°C, fixed overnight in Bouin-Hollande fixative, stained with Hematoxylin-Eosin, and

observed under light microscope.

Sample preparation for scanning electron microscopy

BGC-823 cells culture and tachyplesin treatment were performed as the procedures for light microscopy. The cells at cover slip strips were rinsed with D-Hank's solution twice at 37°C, fixed in 2.5% glutaraldehyde for 2 hours and in 1% osmium tetroxide for 1 hour, dehydrated in ethanol, dried through the CO₂ critical point, gilded in vacuum and observed under the HITIACHS-520 scanning electron microscope.

Sample preparation for transmission electron microscopy

BGC-823 cells and the cells treated with 2.0mg/L tachyplesin were rinsed with D-Hank's solution twice, shaved into centrifuge tube with plastic scraper, followed by centrifugation at 2000rpm for 15min, and removed the supernatant. The precipitate was prefixed in 2.5% glutaraldehyde for 2h and postfixed in 1% osmium tetroxide for 2h, dehydrated in ethanol series, embedded in epoxy resin 618, stained with lead citrate and uranyl acetate, and observed under the JEM-100CXII transmission electron microscope.

RESULTS

Light microscopic observation

There were various forms in BGC-823 cells, such as epithelioid, round, shuttle-like and irregular shapes, as well as cancerous giant cells and soon. The volume of BGC-823 cells was small relatively,

nucleus was large and irregular with several nucleoli in it, and cytoplasm was few (Plate I, Figure 1). After being treated with 2.0 mg/L tachyplesin, BGC-823 cells had undergone a significant morphological change and appeared as normal differentiated epithelial cells. The cells tended to be

spread and flat apparently, their volume enlarged, cytoplasm was abundant, nucleus became relatively smaller with its shape rather regular, and the number of nucleoli was fewer. This feature was different from that of BGC-823 cells remarkably (PlateI, Figure 2).

Scanning electron microscopic observation

Under the scanning electron microscope, BGC-823 cells presented on spherical, shuttle-like and flat and spread shape. There were abundant microvilli at the surface of each type of cells. Microvilli were distributed densely at the surface of spherical cells while densely at the center and scattered at the edge of spread cells. Filopodia were abundant and arranged radiately, especially at the edge of spherical cells while there were relatively few filopodia and a little lamellipodia at the edge of spread cells (PlateI, Figures 3, 5). In contrast, the BGC-823 cells, after being treated with 2.0mg/L tachyplesin, also appeared in spherical, shuttle-like and flat and spread shapes, while the spread cells grew in number and spherical cells reduced. The cellular surface appeared rather smooth with a few small bubble and ruffled structure. The filopodia at cellular edge lessened and lamellipodia increased, especially large lamellipodia could be seen at the edge of flat and in spread cells. This surface feature was obviously different from that of BGC-823 cell (PlateI, Figures 4,6).

Transmission electron microscopic observation

It was revealed by transmission electron microscope that the necleo-cytoplasmic ratio of BGC-823 cells was relatively large, nucleus was irregular, many heterochromatins in the nucleus and nucleolus were large, varied in shape and with some nucleolus vacuoles. Meanwhile, rough endoplasmic reticulum was not well-developed, Golgi vesicle was few, arranged irregularly and Golgi cisterna swelled obviously, mitochondria were irregular and cristae within mitochondria arranged irregularly, polyribosome were abundant while free ribosome were few (PlateII, Figures 1,2). However, after 2.0mg/L tachyplesin treatment, the ultrastructure of BGC-823 cells had also undergone a significant change. The necleo-cytoplasmic ratio lessened, the nuclear shape became regular, most being round or oval, heterochromatin in nucleus decreased while euchromatin increased, the volume of nucleolus lessened, rough endoplasmic reticulum increased obviously, Golgi apparatus was well-developed and Golgi vesicle increased and arranged regularly, most of mitochondria were oval, and their cristae grew in number and arranged regularly, polyribosome reduced while free ribosome increased (PlateII, Figures 3-5). BGC-823 cells showed some ultrastructural characteristics of their normal relevant cells after being treated with tachyplesin.

DISCUSSION

There was significant difference in morphology and ultrastructure between tumor cells and their relevant normal cells. Tumor cells usually display some malignant morphological and ultrastructural characteristics such as that the nucleocytoplasmic ratio was relatively large, nucleus was large and malformed with several nucleoli in it, cell organelle were not well-developed and microvilli were abundant^[5]. Therefore, to observe and identify the changes of morphology and ultrastructure in tumor cells is important in determining the effects of exotic substances especially differentiatonal inducers on tumor cells^[6]. A series of research in which differentiation of gastric carcinoma, leukemia, hepatoma and lung carcinoma cells were induced by chemical inducers, have made it clear that the morphology and ultrastructure of carcinoma cells after induced treatment engendered a restorative alteration similar to those of relevant normal cells^[7-11].

BGC-823 cell is a poorly-differentiated human gastric adenocarcinoma cell line with fast-proliferation and high-malignant characteristics. Our results showed that BGC-823 cells had the typical malignant phenotypical characteristics of morphology and ultrastructure in tumor cells. However, in the BGC-823 cells after treatment with 2.0mg/L tachyplesin, it displayed the changes as follows: the cells were unanimous and tended to be spread and became flat apparently, the volume of cells enlarged, epithelioid-like cells grew in number, the necleo-cytoplasmic ratio declined, the shape of nucleus became relatively regular, the volume and number of nucleolus decreased, heterochromatin decreased while euchromatin increased, mitochondria and their cristae increased, Golgi complex was well-developed and typical, rough endoplasmic reticulum increased, polyribosome decreased while free ribosome increased, microvilli and filopodia decreased while lamellipodia increased. These changes were different from the morphology and ultrastructure of BGC-823 cells and similar to those of their relevant normal cells. It indicated that tachyplesin could alter the malignant phenotypical characteristics of morphology and ultrastructure in gastric carcinoma cells and make them take on the morphological and ultrastructural characteristics similar to those of their normal cells.

The action of tachyplesin is identical with those of chemical inducers on gastric carcinoma cells. It was reported that the human gastric carcinoma cell line SGC-7901 treated with sodium butyrate^[12], hexamethylenemine bisacetamide (HMBA)^[13] and all-trans retinoic acid^[14,15]. The shape of cell was rather regular and consistant, the nuclear shape became round and nucleolus shrank, the nucleocy-

cytoplasmic ratio lessened and hetrochromatin reduced, and the organelle were well-developed, and microvilli at cell surface decrease. These changes were unanimous with the changes of tachyplesin on gastric carcinoma cells in this paper. It further demonstrates that tachyplesin has the identical action with differential inducers of cancer cells, and it has a certain inducing differential effect on human gastric carcinoma cells. In this connection, it has a momentous significance for application of tachyplesin in tumor treatment and in the antitumor research of marine bioactive substance to study the acting mechanism of tachyplesin on tumor cells further.

Effect of arsenic trioxide on human hepatoma cell line BEL-7402 cultured *in vitro*

Hong Yu Xu, You Lin Yang, Yuan Yuan Gao, Qiao Li Wu and Guang Qiang Gao

Subject headings arsenic trioxide; hepatoma; flow cytometry; immunohistochemistry; microscopy; electron; apoptosis; gene expression

Xu HY, Yang YL, Gao YY, Wu QL, Gao GQ. Effect of arsenic trioxide on human hepatoma cell line BEL-7402 cultured *in vitro*. *World J Gastroentero*. 2000;6(5):681-687

Abstract

AIM To study the effect of a varying concentrations of arsenic trioxide on human hepatoma cell line BEL-7402 cultured *in vitro* and its mechanism of action.

METHODS The BEL-7402 cells were treated with arsenic trioxide (at the concentrations of 0.5, 1, 2 $\mu\text{mol/L}$, respectively) for 4 successive days. The cell growth and proliferation were observed by cell counting and cell-growth curve. Morphologic changes were studied with electronmicroscopy. Flow cytometry was used to assay cell-DNA distribution and the protein expression of Bcl-2 and Bax detected by immuno cytochemical method.

RESULTS The cell growth was significantly inhibited by varying concentrations of arsenic trioxide as revealed by cell counting and cell-growth curve, which was dose- and time-dependent. Arsenic trioxide treatment at 0.5, 1 and 2 $\mu\text{mol/L}$ resulted in a sub G1 cell peak, the apoptosis rate of the control group was 9.31% and that of 0.5 $\mu\text{mol/L}$ arsenic trioxide 15.53%, no significant difference was seen between the two. The apoptosis rates of 1, 2 $\mu\text{mol/L}$ arsenic trioxide were 19.10% and 21.87% respectively, which were much higher (both $P < 0.05$). Decrease of G₀/G₁ phase cells and increase of S phase cells were observed by flow cytometry, suggesting the inhibition effect of 0.5, 1, 2 $\mu\text{mol/L}$ arsenic trioxide on BEL-7402 cell lay in

the G₀/G₁ phase. Morphologic changes such as intact cell membrane, nucleic condensation, apoptotic body formation were seen under transmission electronmicroscopy, whereas the 0.5 $\mu\text{mol/L}$ arsenic trioxide-treated BEL-7402 cells showed decrease of nucleocytoplasmic ratio, round nucleus, well-differentiated organelles in the cytoplasm. The processes and microvilli on the cell surface of the experimental groups under scanning electron microscopy were significantly decreased. High expressions of Bcl-2 and Bax were detected in 1 and 2 $\mu\text{mol/L}$ arsenic trioxide-treated cells, these were 46%, 87.33% and 83.08%, 95.83% respectively, among which that of Bax was more significant. Arsenic trioxide treatment at 0.5 $\mu\text{mol/L}$ resulted in a higher expression level of Bcl-2 and lower expression level of Bax, which were 8.81% and 3.83% respectively, as compared with that of the control group (15.33%) ($P_1 < 0.01$, $P_2 < 0.01$).

CONCLUSION Arsenic trioxide not only inhibited proliferation but also induced apoptosis of human hepatoma cell line BEL-7402. The induced-apoptosis effect of 1, 2 $\mu\text{mol/L}$ arsenic trioxide was related to the expression level of Bcl-2 and Bax.

INTRODUCTION

Arsenic trioxide is the main ingredient of traditional Chinese medicinal, pi shi. Zhang P, *et al* first reported the effect of Arsenic trioxide on promyelocytic leukemia (APL) with satisfactory results. The rate of complete remission in patients who had not received any treatment before reached 73.33%, and was 52.38% in patients with recurrence, the longest remission period was more than ten years, and intravenous route of administration was the choice, no toxic or adverse effects were seen^[2-4]. There was no cross resistance between arsenic trioxide and other chemical drugs during the course of treatment of APL^[5]. Shen^[6] concluded that arsenic trioxide treatment was effective and relatively safe in APL patients refractory to ATRA and conventional chemotherapy. Inorganic arsenic trioxide was recently shown to induce apoptosis in NB4 promyelocytic leukemic cells^[7]. The present study was so designed as to broaden the anti-tumor

spectrum and to study the inhibitory effect of Arsenic trioxide on human hepatoma cell line and its mechanism of action, in order to provide some theoretical basis for its clinical use.

MATERIALS AND METHODS

Materials

Human hepatoma cell line BEL-7402 was purchased from the Cell Institute of Chinese Academy of Science. Arsenic trioxide was produced in Pharmaceutical Department of First Hospital of Harbin Medical University. RPMI 1640 was purchased from GIBCO. Propidium iodide and Rnase were from Sigma Chemical Co. A murine monoclonal antibody against human Bcl-2 and Bax oncoprotein and antimice rabbit polyclonal antibody were purchased from Maixin Co., Fuzhou.

Methods

Cell culturing Human hepatoma BEL-7402 cells were grown as monolayers in RPMI 1640 medium supplemented with 8% calf serum (CS), 100IU/mL penicillin and 100mg/mL streptomycin and incubated at 37°C in the humidified incubator with 5% CO₂/95% air. The exponent growing BEL-7402 cells were suspended in medium, planted 4-6×10⁵/flask or 3×10⁴/well into culture flask or 24-well plate.

Drug treatment The growing BEL-7402 cells planted into culture flasks or 24-well plates were incubated at 37°C in 5% CO₂/95% air for 24h. The medium was aspirated and replaced with medium containing arsenic trioxide (final concentration 0.5 μmol/L, 1 μmol/L, 2 μmol/L, respectively) as treatment groups and medium with non-arsenic trioxide as controls.

Determination of growth curve The human hepatoma BEL-7402 cells were digested with 0.25% trypsin, stained with 2% trypan-blue. The cell growth and proliferation of BEL-7402 cells were observed by counting the cell number every day. The non-blue-stained cells were viable cells or apoptotic cells and the blue-stained cells were necrotic cells.

Morphologic observation The BEL-7402 cells growth and morphologic changes were observed by OLYMPUS IX70 inverted phase-contrast microscopy. After incubated in medium containing 0.5 μmol/L, 1 μmol/L, 2 μmol/L arsenic trioxide (experimental groups) and non-arsenic trioxide (control groups) for 4 successive days, the cells were prefixed in 2.5% glutaraldehyde, postfixed in 1% OsO₄, dehydrated in ethanol series, and replaced in propene oxide. The cell samples attached to grids were examined with a JEM-1220 transmission electron microscope (TEM) and the cell

samples grown on covered glass-slide (made in non-enzyme digestion) were gilded in vacuum and examined with a HITACHI S-520 scanning electron microscope (SEM).

Flow-cytometry analysis^[1] After incubated in medium containing varying concentrations of arsenic trioxide and in the control groups for 4 days, the cells were digested with 0.25% trypsin, collected after centrifugation at 1000rpm for 10min, than washed two times with cold PBS by centrifugation (1000 rpm, 5 min), resuspended in 0.5mL PBS, adjusted to a cell concentration of 1×10⁶/L, and fixed with ice-cold 70% alcohol at 4°C (could the preserved for less than 2 weeks). The fixed water of single-cell suspension was discarded after centrifuged at 1000rpm for 10min, which was them washed twice with PBS (1000rpm, 5min), and adjusted to a cell concent ration of 1×10⁶/L, The DNA was stained with propidium iodide at 4°C for 30 minutes, then the suspension was analyzed on the apparatus at room temparature. According to ModFit LT software, the cells were divided into four parts: subG₁ phase, G₀/G₁ phase, S phase and G₂/M phase.

Immunocytochemistry The BEL-7402 cells of experimental groups and controls were seeded into 24-well plate (with cover glass-slide). After incubated in medium with 0.5 μmol/L, 1 μmol/L, 2 μmol/L arsenic trioxide respectively and non-arsenic trioxide for 4 days, the BEL-7402 cells were fixed with pure acetone for 10min, washed three times with PBS, acted upon by 0.25% 0.5% Triton X-100 for 10min, and washed Thrice with PBS. Bcl-2 and Bax protein in the BEL-7402 cells were detected with SABC method. The cell specimens were incubated with 0.3% hydrogen peroxide in methanol for 30 minutes to block the endogenous peroxidase activity, then washed in PBS and incubated in 10% normal goat serum for 20 minutes to reduce nonspecific antibody- binding. Specimens were then incubated with a 1:50 dilution of murine monoclonal antibody against human Bcl-2 or Bax oncoprotein overnight at 4°C, followed by washes Thrice with PBS, then incubated with biotinylated rabbit antimice polyclonal antibody at a dilution of 1:100 for 30 minutes followed by another 3 washes. Slides were then treated with streptoavidin-peroxidase reagent for 30 minutes at a dilution of 1:100 and were washed with PBS 3 times. Finally, slides were incubated in phosphate-buffered saline containing diaminobenzidine and 1% hydrogen peroxide for 10 minutes, counterstained with hematine, and mounted.

Statistics All the data were expressed as mean± standard deviation ($\bar{x} \pm s$), the differences between the rates of different groups were analysed by χ^2 test.

RESULTS

Effects of arsenic trioxide on the growth of the BEL-7402 cells

The BEL-7402 cells were incubated in medium containing 0.5 $\mu\text{mol/L}$, 1 $\mu\text{mol/L}$ and 2 $\mu\text{mol/L}$ arsenic trioxide respectively for 1 to 6 days. The cell-growth inhibitory effect of arsenic trioxide on cells was significant as revealed by cell counting, which was both dose-and time-dependent. During incubated in arsenic trioxide for 3 to 5 days, the speed of growth of BEL-7402 cells was remarkably slow, on the 6th day, the number of cells fell to the lowest level. The percentage of necrotic cells was less than 1% by trypan-blue staining (Figure 1).

Figure 1 The effect of As_2O_3 on cell growth of BEL-7402.

Morphologic changes

By inverted phase-contrast microscopy, one could find the attaching ability of BEL-7402 cells to the flask treated with 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$ arsenic trioxide was weaker as compared with that of the controls, and the growth markedly inhibited.

The BEL-7402 cells treated with arsenic trioxide underwent significant changes as seen in TEM, the nucleocytoplasmic ratio in BEL-7402 cells enlarged, with indentation of nuclei. The nucleocytoplasmic ratio in BEL-7402 cells treated with 0.5 $\mu\text{mol/L}$ arsenic trioxide was much smaller than that in controls, and the nuclei appeared round, with loss of nuclear indentation, but with well-differentiated organelles in the cytoplasm. When treated with arsenic trioxide at 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$ for 4 successive days, one could find intact cell membrane, nuclear condensation and apoptotic body formation, also, marked changes on the cell surface in SEM, there were abundant processes and microvilli on the surface of BEL-7402 cells in the control group, but much less in 0.5 $\mu\text{mol/L}$ arsenic trioxide group. The processes and microvilli were lost when treated with 1 $\mu\text{mol/L}$ and 2 $\mu\text{mol/L}$ arsenic trioxide (Figures 2, 3).

Determination of sub-G₁ peak

After treated with 0.5 $\mu\text{mol/L}$, 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$ arsenic trioxide for 4 successive days, the BEL-7402 cells were analysed by flow-cytometry. The apoptotic rate of cells in the control group was 9.31%, in 0.5 $\mu\text{mol/L}$ arsenic trioxide group, 15.53%, there was no statistical difference between the two ($P > 0.05$). The apoptotic rates of BEL-7402 cell in 1 $\mu\text{mol/L}$ and 2 $\mu\text{mol/L}$ arsenic trioxide were significantly higher than that of the control group, being 19.10% and 21.89%, respectively ($P_1 < 0.05$, $P_2 < 0.05$) (Table 1).

Analysis of cell cycle

After treated with arsenic trioxide at 0.5 $\mu\text{mol/L}$, 1 $\mu\text{mol/L}$ and 2 $\mu\text{mol/L}$ for 4 successive days, the DNA distribution of BEL-7402 cells showed great changes. The percentage of G₀/G₁ phase cell in the control group was 62.91%, that of S phase cell, 33.77%. The percentage of G₀/G₁ phase cell of the experimental groups decreased progressively more than that of the control groups with increase of concentration of arsenic trioxide, whereas the percentage of S phase cell was increased, but with no statistical difference between the two ($P > 0.05$) (Table 1).

Protein expression of Bcl-2 and Bax

After treated with 0.5 $\mu\text{mol/L}$, 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$ arsenic trioxide for 4 successive days, the expression of Bcl-2 and Bax protein were detected by immunocytochemistry. The positive expression rates of Bcl-2 in 1 $\mu\text{mol/L}$ and 2 $\mu\text{mol/L}$ arsenic trioxide were 46.00% and 83.08%, respectively, significantly higher than that in the control group ($P < 0.01$). This was also higher in 0.5 $\mu\text{mol/L}$ arsenic trioxide group, yet there was no statistical difference between them ($P > 0.05$). The positive expression rate of Bax in 0.5 $\mu\text{mol/L}$ arsenic trioxide was significantly lower than that of the control group ($P < 0.01$), but it was significantly higher in 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$ groups than that in the control group ($P_1 < 0.01$, $P_2 < 0.01$) (Table 2 and Figure 4).

Table 1 Influence of varying concentrations of arsenic trioxide on apoptotic rate and DNA distribution

Group	Apoptotic rate	DNA distribution (%)	
		G ₀ /G ₁	S
Control	9.31±0.24	62.91±1.30	33.77±0.41
0.5 $\mu\text{mol/L}$ As_2O_3	15.53±0.69	60.92±2.16	36.87±2.46
1 $\mu\text{mol/L}$ As_2O_3	19.10±1.02 ^a	57.55±2.24	40.14±2.87
2 $\mu\text{mol/L}$ As_2O_3	21.87±0.84 ^a	54.12±1.18	43.17±2.30

Treated group vs control group, ^a $P < 0.05$.

Table 2 Influence of arsenic trioxide on expression of Bcl-2 and Bax (%)

	Control	As ₂ O ₃ concentration ($\mu\text{mol/L}$)		
		0.5	1	2
Bcl-2 expression	4.33±0.29	8.81±0.84	46.00±3.61 ^b	83.08±8.16 ^b
Bax expression	15.33±1.04	3.83±0.29 ^b	87.33±2.02 ^b	95.83±2.36 ^b

Treated group vs control group, ^b $P < 0.01$.

Figure 2 Transmission electronmicroscopic observati on of ultrastructural changes in human hepatoma cells treated with 0, 0.5, 1, 2 $\mu\text{mol/L}$ As_2O_3 for 96h. The nucleocytoplasmic ratio enlarged with indentation of nuclei in BEL-7402 cells of 0 $\mu\text{mol/L}$ As_2O_3 group (A). The nucleocytoplasmic ratio become smaller, nuclei appear round, but with well-differentiated organelles in the cytoplasm in 0.5 $\mu\text{mol/L}$ As_2O_3 group (B). The intact cell membrane, nuclear condensation and apoptoti c body formation in 1, 2 $\mu\text{mol/L}$ As_2O_3 group (C,D).

Figure 3 Scanning electronmicroscopic observation of changes in human hepatoma cell membranes treated with 0, 0.5, 1, 2 $\mu\text{mol/L}$ As_2O_3 for 96h. There were abundant processes and micro villi on the surface of BEL-7402 cells in 0 $\mu\text{mol/L}$ As_2O_3 group (A). The processes and micro villi was much less in 0.5 $\mu\text{mol/L}$ As_2O_3 group (B). The processes and micro villi were lost when treated with 1, 2 $\mu\text{mol/L}$ As_2O_3 (C,D).

Figure 4 Bcl-2 expressions in human hepatoma cells. 0 μ mol/L As₂O₃ group (A). 0.5 μ mol/L As₂O₃ group (B).

DISCUSSION

It has been demonstrated that *in vitro* study is superior to *in vivo*, study, being also in consistency with the latter therefore, it is the main method in studying the effect of anti-tumor drugs currently^[8].

Inhibition of proliferation is the basic requirement of anticancer drugs^[9-16]. Recent clinical studies in China showed that arsenic trioxide is an effective and relatively safe drug in the treatment of acute promyelocytic leukemia. Chen^[17] found arsenic trioxide could trigger apoptosis of APL cell line NB4 cells, which was associated with downregulation of bcl-2 gene expressions and modulation of PML-RAR alpha chimeric protein. Advanced hepatocellular carcinoma has limited treatment options and prognosis is poor. Recent studies have focused on the apoptosis either by suppression of Bcl-2, Bcl-xL or promotion of Bik, Bax, Bak^[18-24]. Our results showed the BEL-7402 cell growth was significantly inhibited by arsenic trioxide at the concentrations of 0.5 μ mol/L, 1 μ mol/L and 2 μ mol/L, and the inhibition effect was not relevant to the cytotoxicity as shown by cell counting after trypan-blue staining. When incubated with arsenic trioxide for 3 to 5 days, the speed of growth of the BEL-7402 cells was remarkably slow. Furthermore, the percentage of G₀/G₁ phase cells was lower than that of the control group, the apoptotic rate of the experimental group was significantly higher. These indicated the inhibition effect of arsenic trioxide acted mainly on the G₀/G₁ phase cells. The

percentage of S phase cells was much increased, suggesting there might be synergistic effect when arsenic trioxide used in combination with other S-phase anti-cancer drugs.

Apoptosis is a complicated physio-pathologic process involving the suicidal mechanism^[25]. Many anticancer drugs can induce apoptosis of neoplastic cells, which opens a new avenue to treatment of cancer^[26]. Modern molecular biological investigations have indicated that apoptosis is regulated by many oncogenes, such as p53, c-myc, bcl-2, bax, bad etc.^[27-32]. Bcl-2 is an apoptosis-related gene and plays an important role in regulating apoptosis^[33-38], by blocking the final pathway of apoptotic signal transmitted system^[39-44]. Bcl-2 can inhibit the apoptosis stimulated by chemotherapeutic drugs, radiotherapy, heat shock, free radicals, Ca²⁺ and TNF etc.^[45-50]. Bax is a homologous protein of Bcl-2, in the form of homopolymer or isodipolymer Bcl-2/Bax^[51-54]. The ratio of Bax and Bcl-2 protein influences the apoptotic rate of cells stimulated by several external or internal factor^[55,56]. Chen's report showed that arsenic trioxide did not influence bax, bcl-x, c-myc, or p53 gene expression, but downregulates bcl-2 gene expression at both mRNA and protein levels^[56].

Our results suggested that the proliferation inhibitory effect of arsenic trioxide at 1 μ mol/L and 2 μ mol/L was related to apoptosis induction which was possibly regulated by the expression of Bcl-2, Bax. Oltval *et al*^[29] reported the number of apoptotic cells was higher when Bax protein was predominant. In our study, the apoptotic percentage by flow-cytometry assay was concordant with the protein expression level of Bcl-2 and Bax in 1 μ mol/L and 2 μ mol/L arsenic trioxide-treated cells.

Arsenic trioxide has dual effects on APL cells: preferential apoptosis at high concentration (0.5-2 microM) and partial differentiation at low concentration (0.1-0.5 microM)^[57]. Treatment of BEL-7402 cells with 0.5 μ mol/L arsenic trioxide showed intricate results in our study. The reasons were as follows: ① The apoptotic rate of BEL-7402 cell increased after 0.5 μ mol/L arsenic trioxide treatment, but had no statistical difference as compared with that of the control. Expression of the Bcl-2 protein was increased with arsenic trioxide treatment, whereas expression of Bax protein fell. Ogasawara *et al*^[58] confirmed that Fas system played an important role in hepatocytic apoptosis induction, therefore, other apoptosis-related gene expression might be involved in that treated with 0.5 μ mol/L arsenic trioxide. ② It had been seen that the nucleocytoplasmic ratio was decreased, the nucleus became round, with loss of indentation but there were well-differentiated organelles in the cytoplasm, suggesting a possible role for

0.5 μ mol/L arsenic trioxide in the induction of differentiation.

In conclusion, our study demonstrates the proliferation inhibition and apoptosis induction effects of arsenic trioxide at the concentrations of 0.5 μ mol/L, 1 μ mol/L and 2 μ mol/L on the human hepatoma cell line BEL-7402. It seems that arsenic trioxide can be a new adjuvant drug in treatment of liver cancer. Arsenic trioxide can be introduced into human body via hepatic artery catheterization to induce cell apoptosis. The present study provides some theoretical basis for its clinical use.

Abstract

AIM To study the effect of hepatocyte apoptosis and necrosis induced by TNF- α on the pathogenesis of acute severe hepatitis (ASH).

METHODS The model of ASH was prepared in D-galactosamine (GalN) sensitized BALB/c mice by injection of either endotoxin (ET) or tumor necrosis factor- α (TNF- α). Morphological changes of apoptotic hepatocytes were studied by both light and electron microscope and in site end labeling method (ISEL). Molecular biological changes of DNA ladder were observed by electrophoresis of extract from liver tissues. Biochemical changes were measured by alanine aminotransferase (ALT), aspartic aminotransferase (AST) and TNF- α . The relation between apoptosis and necrosis was evaluated simultaneously.

RESULTS The sequence of hepatocyte apoptosis, necrosis, and final death from ASH was observed both in GalN/ET and GalN/TNF- α group. Apoptosis was prominent at 3.5h and 6h after injection of inducer, while necrosis became dominant at 9h after challenge. The appearance of apoptosis was earlier in GalN/TNF- α group than that in GalN/ET group. Pretreatment of mice with antiTNF IgG1 may completely prevent the liver injury induced by GalN/ET.

CONCLUSION TNF- α can cause liver damage by inducing hepatic apoptosis and necrosis in mice with endotoxemia.

INTRODUCTION

Apoptosis is one of the cell death forms, which is quite different from cell necrosis in morphology, biochemistry and biology. Clinical studies showed that ET (Endotoxin, ET) and tumor necrosis factor- α (TNF- α) elevated obviously in the sera of patients with severe hepatitis. Recent researches showed that hepatocyte apoptosis was closely related with pathogenesis of hepatitis especially that of ASH^[1-11]. The present study deals with the effect of both apoptosis and necrosis induced by TNF- α on the pathogenesis in ASH, and their relationship.

MATERIAL AND METHODS

Reagents

Recombinant murine TNF- α and immunoglobulin (Ig) G1 fraction of anti-murine TNF- α were purchased from Pepro Tech EC LTD. Terminal-deoxynucleotidyl transferase (TdT) and Bio-11-dUTP Na salt were purchased from Dako LTD. Salmonella abortus equi endotoxin (ET) was purchased from Sigma Chemical Co. GalN was purchased from Chong Qing Medical University. Endogen mouse TNF- α ELISA Kit was provided by Endogen Inc. Unless otherwise specified, all other reagents were analytical reagents.

Animal and experimental methods

One hundred and thirty specific pathogen-free male BALB/c mice (from Shanghai Second Medical university animal breeding house) were divided into 7 groups: ① Control; ② GalN; ③ ET; ④ TNF- α ; ⑤ GalN/ET; ⑥ GalN/ TNF- α ; and ⑦ anti-TNF- α IgG1/GalN/ET.

Each group contained 20 mice except Group 7 which contained 10 mice. Both GalN (800mg/kg) and ET (2.4 μ g/kg) were injected intraperitoneally; Both TNF- α (1.0 μ g/kg) and anti-TNF- α IgG1 (100 μ g/mouse) were injected in tail vein. The control group received the same volume of normal saline.

Five mice were killed at 1.5 h, 3.5 h, 6 h, and 9 h respectively after injection. TNF- α , ALT, and AST were measured in the blood samples taken from the mouse heart. Tissue samples taken from liver were also prepared for morphological and molecular biological examinations.

The sections of liver tissue were stained with hematoxylin and eosin (HE), and ISEL^[12] for detection of apoptotic liver cells were performed, DNA was extracted from fresh liver tissue for further analysis of DNA ladder.

Department of Infectious Diseases, Rujin Hospital, Shanghai Second Medical University, Shanghai 200025, China

Dr. Guo Qing Zang, graduated from Xian Medical University as a postgraduate in 1990, associate professor of lemmology, engaged in diagnosis and treatment of viral hepatitis and hemorrhagic fever with renal syndrome, having 12 papers published.

RESULTS

Histological alterations of the liver in control, GalN, ET, and TNF- α groups

Hepatic lobular architecture was clear and intact without any abnormalities in the liver section of control group. Only mild swelling of hepatic cell was presented in GalN, ET and TNF- α groups. With the time prolonging from 1.5 h, 3.5 h, 6 h, to 9 h, the mild swelling become moderate degree. Neither apoptosis nor necrosis was present in HE and ISEL staining. No DNA ladder was found in any group mentioned above.

Histological alterations of the liver in GalN/ET group

No obvious liver cell alterations were present at 1.5 h on the section of HE staining and ISEL staining failed to detect positive signals of apoptosis.

Mild swelling of liver cells on HE section and a few apoptotic cells on ISEL section were present at 3.5 h (Figure 1A).

Obvious swelling of liver cells and lots of apoptotic cells were found at 6 h and mild dotted necrosis was also observed. Strong apoptotic positive signals could be detected in the cell nuclei.

Nine hours after GalN/ET injection, enormous apoptotic liver cells and pieces of hepatic necrosis with leukocytes infiltration can be seen (Figure 1B).

These data demonstrate that apoptosis occurred as an early event during the development of hepatic failure. Compared with the ET model, the majority of changes occurred earlier in the TNF model, which agrees with the phenomena that ET act on hepatocytes by inducing TNF- α .

Histological alterations of the liver in GalN/TNF- α group

Morphological changes of the liver in this group were basically the same as those in GalN/ET group but severer at 1.5 h, 3.5 h, 6 h and 9 h (Figures 2A, 2B), 1.5 h, 3 h, 6 h and 9 h after administering inducer, apoptosis positive rates of GalN/ET group were 0.0%, 0.2%, 1.21% and 3.14% respectively, while for the GalN/TNF- α group, were 0.2%, 0.5%, 2.57% and 3.19% respectively.

DNA fragment assay

DNA ladder was found at 6 h and 9 h after GalN/ET, GalN/TNF- α administration, but was not found at 1.5 h and 3.5 h after GalN/ET, GalN/TNF- α injection, and DNA ladder was not found in other groups (Figures 3A, 3B).

Electron microscopic assay

Electron microscopic study showed the chromatin condensation of apoptotic cells and near the nuclear lining (Figure 4).

Blockage of liver damage induced by GalN/ET by pretreatment of mice with anti-TNF- α IgG1

In the GalN/ET group pretreated with anti-TNF- α IgG1, only mild swelling of liver cells could be seen on the HE staining. Neither apoptosis nor necrosis could be found on ISEL staining. No DNA ladder was present on electrophoresis of agarose gel (Figure 3A).

Time course of apoptosis and necrosis

We compared the time course of typical morphology of apoptosis (chromatin condensation, apoptotic bodies) with ALT and AST (as a parameter for necrosis) in each group (Table 1). ALT and AST remained normal at 3.5 h after GalN/TNF- α challenge, at this time point, a small amount of apoptotic liver cells could be found. Apoptotic liver cells become obvious at 6 h, ALT and AST were elevated mildly at the same time. This finding indicated that apoptosis was already developed while the liver cell membrane still remained intact 6 h after challenge, suggesting that apoptosis occurred earlier than necrosis.

The prominent increase of ALT and AST occurred at 9 h, when a great number of necrotic liver cells were observed. Meanwhile, profuse apoptotic liver cells were also present even after the death of mice associated with ASH and electrophoresis of agarose gel still showed DNA ladder at the final stage.

Figure 1 Liver cells apoptosis in mice induced by GalN/ET. A 3.5 hours after GalN/ET, individual apoptotic cells are visible, apoptotic positive signal mainly locates in nucleus. ISEL \times 400 B 9 hours after GalN/ET, further increase of apoptotic liver cells and pieces of liver cell necrosis and bleeding with leukocytes infiltration appear. Apoptotic cells (a), apoptotic bodies (b), leukocytes (l) and necrosis (n). HE \times 400

DISCUSSION

ASH may be caused by viral infection and drug intoxication. It was believed that the large amount of liver cell death was necrosis due to associated immune damage mediated by dysfunction of host immune system and TNF- α may cause liver necrosis directly^[13,14]. Recent studies have shown that besides necrosis, hepatic apoptosis induced by TNF- α plays an important role in the course of ASH^[11,15-27]. Our study showed that only mild

injury could be found by injecting ET or TNF- α alone. While the combination of GalN with either ET or TNF- α can cause ASH in mice.

Liver cells may synthesize the protecting protein after exposure to injury factors. The process needs the participation of intact cyto-metabolism and protein-synthesis mechanism. GalN may specifically deplete uridine nucleotides in liver cell and influence its metabolic course, leading to a hepatic transcriptional block and the suppression of

protecting protein synthesis and then sensitizes the liver cell to TNF- α ^[28-34].

TNF- α may induce apoptosis of liver cell which is transfected by hepatitis B virus or other virus^[35-41], suggesting the cells infected by virus involved in TNF- α sensitivity.

The results of our study showed that TNF- α was mainly produced in the early stage of endotoxemia, and decreased obviously from 6h to 9h after challenge. TNF- α combined with TNF- α receptor on the membrane of liver cells through a series signal transmissi on activating caspase-3 and then inducing apoptosis, and TGF- β_1 can also produce similar effect which can induce apoptosis^[42-45], delayed treatment with the caspase 3-like protease inhibitor Z-VAD attenuated apoptosis by 81% to 88% and prevented liver cell necrosis^[46]. At the same time TNF- α can activate nuclear trans cription factor- κ (NF- κ) of hepatocytes^[47], Kupffer cells and endotheliocyte, which increases expression of ICAM-1, VCAM-1 and selectin, these inflammatory factors futher induce the in flammatory injury of hepatocytes, and TNF- α also induce Shwartzman-like reaction in the liver^[48]. Recent study demonstrated that mitochondria may be the centre of cell apoptosis, if mitochondrial structural alterations occur without functional failure, the cell dies by apoptosis. In contrast, if the injury is severe enough to lead to mitochondrial functional failure, the cell dies by necrosis^[49,50].

In summary, our results showed that TNF- α plays an important role in the course of hepatic apoptosis and necrosis. The blockage of liver apoptotic signal transmission and caspase activation induced by TNF- α with Z-VAD, anti-ET antibody and anti-TNF monoclon antibody can improve prognosis of fulminant hepatic failure^[2,42-46,51] and may prevent liver cell from apoptosis and necrosis and hence has an important significance in the prevention and treatment of ASH.

Huang XF, Wang CM, Dai XW, Li ZJ, Pan BR, Yu LB, Qian B, Fang L. Expressions of chromogranin A and cathepsin D in human primary hepatocellular carcinoma. *World J Gastroentero*, 2000;6(5):693-698

Abstract

AIM To determine the expression and clinical significance of chromogranin A and cathepsin D in hepatocellular carcinoma (HCC).

METHODS Double immunofluorescence staining techniques combined with laser confocal scanning microscopy (LSCM) was used to investigate chromogranin A and cathepsin D expressions in 85 HCC patients.

RESULTS Cathepsin D was expressed in 3 normal liver tissues, while in HCC the staining showed regional variation and the fraction of strongly stained cells increased as the tumors became less differentiated and usually clinically more malignant. Cells which showed strong positivity for cathepsin D were present in 71/85 (83.5%) cases. Strong expression of cathepsin D in cancer cells was related to histopathological features. They were more common in grade 3-4 (26/28, 92.9%) and grade 2 (46/53, 86.8%) tumors than in grade 1 tumors (1/4, 25.0%) ($P < 0.01$). No significant correlation was found between age and cathepsin D expression. In patients with positive cathepsin D reaction, the mean age was 52.1 ± 2.8 years (range 32-68 years) and in the group with negative reaction, the mean age was 51.3 ± 4.5 years (range 28-71 years). No obvious

relationship was observed between CgA expression in cancer cells and the histopathological features. The CgA positive rate was 75.0% (3/4) in grade 1, 71.7% (38/53) in grade 2, and 71.4% (20/28) in grade 3-4 ($P > 0.05$) tumors. The coexpression of CgA and cathepsin D was found by double labeled immunofluorescence staining techniques. The processing of cathepsin D was disturbed in HCC cells and accumulated in the cells. Cathepsin D had proteolytic activity and autocrine mitogenic effect, suggesting their functions in invasion. These findings demonstrated that the expression of cathepsin D in HCC had prognostic value.

CONCLUSION Chromogranin A and cathepsin D are expressed in a high proportion of HCC and the existence of cathepsin D in HCC might be related to processing of CgA. This is clearly a subject for further studies because of its potential clinical applications.

INTRODUCTION

The chromogranin A/secretogranin (CgA/Sg) acidic glycoprotein are widely distributed in vertebrate species. It has recently been proposed that CgA, a 50-kilodalton acidic glycoprotein, is costored and cosecreted with hormones and neurotransmitters in a variety of tissues. They thought to play a role in hormone packaging within secretory granules, in hormone secretion, and serve as prohormones for various proteolytic cleavage products^[1]. CgA can be processed to several biologically active peptides such as pancreastatin. The single copy human CgA gene was isolated from a human fetal liver gene library^[2]. The presence of CgA in hepatocellular carcinoma (HCC) was reported by Roskams *et al*^[3]. They found that occasional positive cells or clusters of weakly CgA immunopositive cells were present in HCC. Cathepsin D is a lysosomal aspartyl proteinase^[4], initially detected in breast cancer cell lines^[5], which is widely distributed in normal tissues. The proteinase cathepsin D might be related to tumor invasion and metastasis through various mechanisms associated with its proteolytic activity. It was shown to degrade *in vitro* extracellular matrix and activate

latent precursor forms of other proteinase involved in such processes^[6]. Experimental studies have already demonstrated that invasion of HCC cells can be abrogated by proteinase inhibitors. Growing evidence indicates that lysosomal cathepsin D may promote carcinogenesis and tumor progression. The metastatic activity of cathepsin D injected into athymic mice was significantly higher than that of control groups. These results show that overexpression of cathepsin D increased the transformed phenotype of malignant cells *in vitro* and their metastatic potency *in vivo*^[7]. Higher cathepsin D serum mass concentrations were found in HCC group as compared to control patients^[8]. Plasma and ascitic fluid of rats bearing the Yoshida ascites hepatoma AH-130 were shown to contain high levels of proteolytic enzymes belonging to different classes active at neutral and acidic pH. Compared with those measured in control rat plasma, and tumor-bearing animals, the activity levels of lysosomal cathepsin D activity was about 5-fold higher in both plasma and ascitic fluid^[9]. The expression of cathepsin D was significant predictors of the prognosis^[10]. The role of cathepsin D has been studied in human breast cancer progression^[6-8], but the results were highly variable and no agreement has yet been reached on its effects on clinical behaviour and prognosis. There has been no report available on the role of cathepsin D expression in the progression of human HCC. To analyse this, the double immunofluorescence staining techniques combined with laser scanning confocal microscopy (LSCM) were used to investigate CgA and cathepsin D expression in HCC patients.

MATERIALS AND METHODS

Patients

The study group comprised 85 patients with HCC diagnosed in 117 Hospital and Xijing Hospital of the Fourth Military Medical University from 1984 to 1997. The mean age of the patients was 51.4 ± 2.5 years (range 25-77 years). The female/male ratio was 28/57. The cohort was not entirely consecutive, since adequate tumor biopsy specimens for immunohistochemistry were not available in all cases.

Histological methods

The histological samples were surgically obtained biopsy specimens from the tumors which were fixed in buffered formalin (pH 7.0), embedded in paraffin, sectioned at 5 or 10 micrometer, and stained with haematoxylin and eosin. The samples were graded histologically into 1 (well differentiated, 4 cases), 2 (moderately differentiated, 53 cases), 3 (poorly differentiated, 26 cases), 4 (undifferentiated type, 2 cases) categories as described in detail before according to the Edmondson-Steiner's criteria^[11].

Immunohistochemistry

Five- or ten-micrometer sections from the primary HCC were employed in the fluorescent immunohistochemical analysis of cathepsin D protein, using rabbit anti-human cathepsin D antibody (Dako, Glostrup, Denmark) diluted 1:300 in 10mL/L bovine serum albumin (BSA)-phosphate-buffered saline (PBS). Several dilutions of the antibody were tested to find the optimal staining concentration, before the entire series was processed. The staining procedure was carried out as our previous reports^[12], without protease treatment. Briefly, the steps included: ① the sections deparaffinized in xylene, hydrated in ethanol, and washed in 0.01mol/L PBS, then pretreated with 30mL/L normal goat serum for 40min and rinsed in 0.1mol/L PBS; ② incubation for 1h in a 1:1000 dilution of the primary monoclonal antibody of CgA and in a 1:300 dilution of rabbit anti-human cathepsin D antibody in 10mL/L BSA-PBS; ③ simultaneous incubation with 1:50 diluted secondary antibodies (biotin-conjugated goat anti-rabbit IgG and FITC-conjugated goat anti-mouse IgG) in 10mL/L BSA-PBS. All secondary antibodies were obtained from SABCO (Luoyang, PRC); ④ incubation with 1:2000 diluted Texas-red-conjugated streptavidin (Sigma) for 30min. The sections were washed three times for 10min after incubation steps 2 to 4, respectively, and were finally mounted in 50g/L glycerin. The sections were examined with Bio-Rad 1024 LSCM. The specimens were excited with a laser beam at wavelengths of 568nm (Texas Red) and 488nm (FITC) and the emission light was focused through a pinhole aperture. The full field of view was scanned in square image formats of 512×512 pixels.

Scoring of CgA and cathepsin D protein expression

Firstly, the intensity of cytoplasmic fluorescence of the cancer cells in the entire section was scored into three categories. Cells showing no fluorescence for cathepsin D and CgA were considered as negative, cells with weak granular fluorescence (Figure 1) in the cytoplasm were scored as weak expressors, and cells with distinct cytoplasmic positivity (Figure 2) were scored as strong ones. Secondly, the fraction of cells in each of the staining categories in the entire section was also estimated in the areas with well-preserved tissue morphology. Areas with necrosis, or with distorted architecture, were excluded from the analysis. Thirdly, the presence in the invasion front of a distinct cathepsin D-positive cell zone composed of macrophage-like cells was scored positive or negative (determined in 65 cases). A breast cancer specimen showing intense uniform positivity for cathepsin D protein was used as a positive and negative control, with the expected results in all experiments. Since negative and weak

positive showed no association with other prognostic parameters, the cases were grouped into positive (strongly stained cells) or negative (negative or weakly positive cells only) for further analysis.

Controls

Primary antibodies were substituted by irrelevant antibodies and normal rabbit or goat serum as specific antibody control. PBS substituted for primary antibody as negative control. Primary antibody was omitted as blank control.

Statistical analysis

The Chi-square test was used in this study.

RESULTS

Relationship between expression of cathepsin D and histological features of HCC

Normal hepatocytes adjacent to carcinomas ($n = 3$) showed weak granular positivity for cathepsin D in the cytoplasm. Strong expression of cathepsin D in cancer cells was related to histopathological features (Table 1). Cells showing strong positivity for cathepsin D were present in 71/85 (83.5%) cases and were more common in grade 3-4 (26/28, 92.9%) and grade 2 (46/53, 86.8%) tumors than in grade 1 tumors (1/4, 25.0%, $P < 0.01$, Table 1). The positive reactivity was either granular or homogeneous in the cytoplasm (Figure 1). The positive cells distributed in disperse or patch pattern (Figures 1, 3, 4).

Relationship between expression of cathepsin D and patients' age

We found no significant correlation between age and cathepsin D expression. The mean age of patients with positive cathepsin D reaction was 52.1 ± 2.8 years (range 32-68 years) and 51.3 ± 4.5 years (range 28-71 years, $P > 0.05$) in the group with negative reaction.

Relationship between expression of CgA and histological grade of HCC

The CgA positive rate was 75.0% (3/4) in grade 1, 71.7% (38/53) in grade 2, and 71.4% (20/28) in grade 3-4 tumors (Table 2). No obvious relationship was observed between expression of CgA in cancer cells and the histopathological grades of HCC ($P > 0.05$). The positive reactivity was homogeneous in the cytoplasm (Figures 2, 4, 5).

Correlation of expression of cathepsin D and CgA in HCC

Coexpression of cathepsin D and CgA was found in most of HCC (56/85, Table 3, Figures 3, 4, 6). It accounted for 91.8% of CgA-positive cases, and 78.9% (56/71) of cathepsin D-positive ones. Colocalization of cathepsin D and CgA was yellow observed by LSCM (Figures 3, 4, 6).

Table 1 Relationship between expression of cathepsin D and histological features of HCC

Histologic grade	Expression of cathepsin D	
	Positive (%)	Negative (%)
1	1/4 (25.0)	3/4 (75.0)
2	46/53 (86.8) ^a	7/53 (13.2)
3+4	26/28 (92.9) ^b	2/28 (7.1)

^a $P < 0.01$ vs Grade 1; ^b $P < 0.01$ vs Grade 2,1.

Table 2 Relationship between expression of CgA and histologic grade of HCC

Histologic grade	Expression of CgA	
	Positive (%)	Negative (%)
1	3/4 (75.0)	1/4 (25.0)
2	38/53 (71.7) ^a	17/53 (28.3)
3+4	20/28 (71.4) ^b	8/28 (28.6)

^a $P > 0.05$ vs Grade 1; ^b $P > 0.05$ vs Grade 2,1.

Table 3 Relationship between expression of cathepsin D and CgA in HCC

Expression of CgA	n	Expression of cathepsin D	
		Positive	Negative
Positive	61	56	5
Negative	24	15	9
Total	85	71	14

DISCUSSION

CgA is the major member of the granin family of acidic secretory glycoproteins that are expressed in all endocrine and neuroendocrine cells. Granins have been proposed to play multiple roles in the secretory process. Intracellularly, granins play a role in targeting peptide hormones and neurotransmitters to granules of the regulated pathway by virtue of their ability to aggregate in the low-pH, high-calcium environment of the trans-Golgi network. Extracellularly, peptides formed as a result of proteolytic processing of granins regulate hormone secretion. Some conserved features of the mature CgA protein are polyglutamic acids, calcium-binding sites, and several pairs of basic amino acids. The first two features are important for its intracellular functions, and the latter characteristic suggested that peptides could be released from the molecule by precursor processing enzymes. Several biologically active peptides encoded within the CgA molecule, such as vasostatin, beta-granin, chromostatin, pancreastatin, and parastatin act predominantly to inhibit hormone and neurotransmitter release in an autocrine or paracrine fashion. The biosynthesis of CgA is regulated by many different factors, including steroid hormones and agents that act through a variety of signalling pathways. CgA biosynthesis and that of the resident hormone or neurotransmitter can be regulated differentially. The widespread distribution of CgA has made the measurement of circulating immunoreactive CgA a valuable tool in the diagnosis of neuroendocrine neoplasia, and CgA immunohistochemistry can help identify the neuroendocrine nature of tumors. Recent molecular biological studies are identifying those elements in the CgA gene promoter responsible for its specific neuroendocrine cell expression.

Cathepsin D was purified to apparently homogeneous form from normal human liver and hepatoma. The purified enzyme could not be distinguished between normal liver and hepatoma in terms of specific activity, subunit composition, antigenicity, amino acid composition and tryptic peptides. However, the hepatoma enzyme was treated with endo-beta-N-acetylglucosaminidase H, the acidic variant forms disappeared and were converted into forms identical to those of normal liver. The content of mannose-6-phosphate in the hepatoma enzyme was twice as much as that in the normal liver enzyme. Thus, charge heterogeneity found in hepatoma cathepsin D is ascribed to increased phosphorylation on oligosaccharides bound to the enzyme, most probably due to cancer-associated, impaired processing in carbohydrate moiety. A significant elevation of cathepsin D activity per tissue proteins was observed in hepatoma as compared to normal liver. In contrast, true specific activity per cathepsin D protein in hepatoma was significantly lower than that of normal liver. The lower true specific activity in hepatoma tissue may be attributed to an increased content in an inactive, large-molecular precursor form of the enzyme^[13].

Cathepsin D is encoded by a gene located on chromosome 11p15, but its increased expression is not usually due to gene rearrangement or amplification^[14]. Instead, it can be induced by estrogens or several other factors in the cellular micro-environment^[15,16]. Cathepsin D exists in the cell as a precursor for procathepsin D. In the normal hepatocytes, most of the procathepsin D is changed to an active form in the lysosomes, while in HCC cells the processing of procathepsin D is disturbed. Procathepsin D is accumulated in the cells, since smaller fraction is secreted than in normal liver tissues^[17]. Procathepsin D has proteolytic activity and autocrine mitogenic effect^[18], both of which suggest some functions in invasion and metastasis. Cathepsin D is a physiological regulator of other cathepsins (B and L) by activating their precursors^[19], or possibly by inactivating endogenous inhibitors of cathepsins^[20]. Cathepsin D was usually expressed in normal hepatocytes, while in malignant tumors the fluorescent staining showed regional variation and the fraction of strongly stained cells increased as the tumors became less differentiated and usually clinically more malignant. In HCC, increased expression was related to a high grade. The situation was also found in breast carcinomas^[21]. However, the dissemination of the tumor to lymph nodes and to distant sites suggested a relationship between invasive potential and the expression of cathepsin D. Strong expression of cathepsin D was associated with cell proliferation and expression of growth factor receptors^[22]. Our previous studies

also proved that the hepatoma cells expressed epithelium growth factor and its receptors^[22] and CgA^[23]. Thus, it is likely that the strong expression of cathepsin D is due to induction of cathepsin D synthesis by epithelium growth factor. The higher proliferation rate of strongly cathepsin D-positive tumors may be partly related to a mitogenic effect of cathepsin D^[18,24]. These findings, together with the clinical observations that a positive correlation between levels of expression of cathepsin D activity and malignant progression of some human neoplasms, seem to support this hypothesis^[25].

The prognostic value of cathepsin D expression in neoplasms is a matter of controversy and the results of this study suggest that the expression of cathepsin D in HCC cells has prognostic value over already established prognostic factors.

In conclusion, cathepsin D is expressed in a high proportion of HCC. This is clearly a subject for further studies because of its potential clinical applications. Chromogenic peptides act as substrates for cathepsins^[26], so the higher expression of cathepsin D, the lower expression of CgA in HCC and *vice versa*.

Jia XD, Han C. Chemoprevention of tea on colorectal cancer induced by dimethylhydrazine in Wistar rats. *World J Gastroentero*, 2000;6(5): 699-703

Abstract

AIM To investigate the chemopreventive effects of green tea and tea pigment on 1,2-dimethylhydrazine (DMH)-induced rat colorectal carcinogenesis.

METHODS Male weaning Wistar rats were randomly allocated into four groups. Rats in the positive control group were given s.c.injection of DMH, once a week for ten weeks; rats in tea-treated groups, with the same DMH treatment as in the positive group, received 2% green tea and 0.1% tea pigments; rats in the negative control group were given s.c. injection of the same volume of saline as well as DMH in the positive group. Animals were sacrificed and necropsied at the end of week 16 and week 32.

RESULTS Aberrant cryptic foci (ACF) were formed in animals in DMH-treated groups at the end of week 16. Compared to the DMH group, green tea and tea pigments groups had less ACF (148.25 and 204.25, respectively, $P<0.01$). At the end of week 32, all rats in DMH group developed large intestinal tumors. The results also showed that DMH increased labeling index (LI) of proliferating cell nuclear antigen (PCNA) of intestinal mucosa and the expression of ras-p21. However, in the tea-treated groups, PCNA-LI was significantly reduced as compared with the positive control group (36.63 and 40.36 in the green tea group and tea pigment group, respectively, at the end of the experiment, $P<0.01$). ras-p21 expression was also significantly reduced (2.07 and 2.36 in the colon tumors of rats in the green tea group and tea pigments group, respectively at the end of the experiment, $P<0.01$). Furthermore, green tea

and tea pigment inhibited the expression of Bcl-2 protein (2, 5, 1, 0 and 2, 4, 1, 0, respectively, at the end of the experiment $P<0.01$), and induced expression of Bax protein (0, 1, 3, 4 and 0, 1, 4, 3, respectively, $P<0.01$).

CONCLUSION Chinese green tea drinking inhibited ACF and colonic tumors formation in rats, which showed that tea had a significant chemopreventive effect on DMH-induced colorectal carcinogenesis. Such effects may be due to suppression of cell proliferation and induction of apoptosis in the intestinal crypts.

INTRODUCTION

Colorectal cancer is the third most common malignant neoplasm worldwide^[1]. In China, the incidence and mortality rates of colorectal cancer are increasing in recent decade, being the fifth leading cause of cancer deaths^[2].

Aberrant crypt foci (ACF) in the colonic mucosa have been hypothesized to represent precursor lesions of chemically induced colon cancer. Aberrant crypts can be identified by their increased size, thicker epithelial lining, and increased pericryptal zone^[3]. Various studies have supported the concept that ACF are precancerous lesions that can be used as biologic end points in the study of modulators of colon carcinogenesis^[4-9].

Tea is one of the most popular beverages consumed worldwide. Tea polyphenols is the major constituent of green tea, whereas tea pigments, the major constituent of black tea, is a compound which is mainly composed of teaflavin and tearubigin. Many studies on the possible modifying effect of green tea and tea polyphenols on experimentally induced colorectal cancer have been carried out during the last decades^[10], but there are few reports about the effect of black tea and tea pigments.

Carcinogen-induced ACF formation in rodent colon has been used as a short-term bioassay to evaluate the role of nutritional elements and to screen potentially new chemopreventive agents^[11], however, few reports have been found regarding the early detection of ACF corresponding to the later development of tumors^[12]. The purpose of our present study is to find out the effects of green tea and tea pigments on ACF formation and colorectal cancer induced by DMH in Wistar rats, and to appraise their possible mechanisms.

MATERIALS AND METHODS

Materials

Green tea and tea pigments were provided by the Institute of Tea Science and Research, Chinese Academy of Agricultural Sciences. The water extract of green tea was prepared freshly everyday as follows: 2g of green tea leaves (Long Jing brand) was dissolved in 100mL boiling water, allowed to stand at room temperature for 30 minutes, and then filtered. Tea pigment solution was prepared freshly daily.

Animals and treatment

168 weaning male Wistar rats were purchased from the Animals Breeding Center of Chinese Academy of Medical Sciences, Beijing, and were randomly allocated into four groups, 42 rats in each. The animals were maintained in a controlled environment at $24^{\circ}\text{C}\pm 1^{\circ}\text{C}$ and $50\%\pm 10\%$ relative humidity with an altering 12:12-hour light-dark cycle. Rats in group 1 (positive control) were given s.c. injection of DMH-2HCl (Sigma Chemical) once weekly for 10 weeks at a dose of 20mg/kg body weight. Animals in groups 2 and 3, in addition to the same carcinogen treatment as in group 1, received 2% green tea and 0.1% tea pigments, respectively, as the sole source of drinking fluid. Animals in group 4 (negative control group) were injected s.c. with equal volumes of physiological saline. Rats in group 1 and group 4 were given tap water as drinking fluid. Body weight of all animals was recorded weekly until the last DMH injection, and then every 4 weeks until the end of the study. The daily consumption of tea and water were also recorded. Animals were killed at weeks 16 and 32. The colons were rapidly removed and opened longitudinally, cleaned with cold saline, fixed in 10% formalin, dehydrated and embedded in paraffin. Five- μm -thick sections were processed for histopathological examination for proliferating cell nuclear antigen (PCNA) analysis, and bcl-2 and bax analysis. For ras-p21 analysis, colonic mucosa were scraped with a microscope slide and stored at -80°C until used. The number of tumors were counted and the length (L), width (W) and height (H) of each tumor were measured to calculate the tumor volume ($V=L\times W\times H\times \pi/6$).

Quantification of ACF

ACF were quantified following the protocol established by McLellan and colleagues^[13]. Fixed colon specimens were stained in 0.02% methylene blue, and the number and growth of ACF were assessed under the light microscope. Criteria used to identify the ACF included: ① increased size, ② thicker epithelial cell layer, and ③ increased pericryptic zone. To determine crypt multiplicity, ACF were further categorized as small (1-3 crypts/focus), medium (4-6 crypts/focus), and large (≥ 7 crypts/focus).

Immunohistochemical analysis of PCNA

Two deparaffinized sections were used for PCNA staining by using a Straptavidin/ Peroxidase (SP) kit (ZYMED). Following the instructions, the anti-PCNA monoclonal antibody (mouse anti rat, ZYMED) was diluted with antibody-diluting buffer (1:100) and used for tissue sections.

The PCNA labeling index (LI) was determined by identifying 10 well-oriented crypts in which the base, lumen, and the apex of crypts displayed a U-shaped configuration. The PCNA-LI was calculated as the number of positive cells per crypt divided by the total number of cells per crypt multiplied by 100.

Measurement of ras-p21 expression

The expression of ras-p21 was detected by Western blot^[14]. Briefly, colonic mucosa and tumor specimens were washed in ice-cold phosphate-buffered saline (PBS) and suspended in disruption buffer. The specimens were homogenized and left on ice for 30min. The extracts were purified by centrifugation at $12\,000\times g$ for 20min at 4°C .

Clear extracts of colonic mucosa and tumors corresponding to 100 μg total protein were subjected to SDS-PAGE according to the method of Laemmli^[15]. The separated protein was then transferred to nitrocellulose membrane and detected with mouse monoclonal antibody pan-ras. Densitometric analysis of immunoblots were then performed for quantification of each band.

Immunohistochemical analysis of Bcl-2 and Bax

Bcl-2 and Bax were stained using the same method as PCNA staining except using the rabbit polyclonal Bcl-2 antibody (ZYMED) in 1:100 dilution and rabbit polyclonal Bax antibody (ZYMED) in 1:100 dilution.

Positive cells were quantified by two independent observers, expressed as the percentage of the total number of cells, and assigned to one of 4 categories: 1, 0% - 25%; 2, 25% - 50%; 3, 50% - 75%; and 4, 75%-100%.

Statistical analysis

Body weight, tea consumption, number of ACF, number of tumors, PCNA-LI and ras-p21 expression among the 4 groups were compared by Student's *t* test. Tumor volumes and the grading of Bcl-2 and Bax expression were compared by the Wilcoxon-rank test.

RESULTS

General observations

Table 1 presents the body weight of the 4 groups of animals. At the end of week 32, then compared with the negative control group, the body weights in the other three groups (DMH-treated) decreased.

However, analysis of the data revealed no significant differences between them. In addition, the quantity of tea and water consumption in 4 the groups were also not significantly different.

ACF formation

ACF was formed in DMH-treated groups (groups 1-3), but there was no ACF formation in the negative control group (group 4). Compared with the positive control group (group 1), the total number of ACF per colon in tea-treated groups 2 and 3 decreased significantly ($P < 0.01$). Small, medium and large ACF in tea-treated groups were also significantly different from group 1 (Table 2).

Cancer formation

The results of cancer formation are listed in Table 3. At the end of the experiment, all rats in the positive group developed colonic cancer, but none was developed in the negative control group. Animals that consumed 2% green tea and 0.1% tea pigments had significantly fewer cancer than that of the positive control group, and the mean volume also dramatically lower.

Immunohistochemical analysis of PCNA

Table 4 shows the immunohistochemical analysis of PCNA-LI. After 16 and 32 weeks, the PCNA-LI in DMH-treated groups increased significantly over the negative control group. Oral administration of 2% green tea and 0.1% tea pigments diminished the PCNA-LI ($P < 0.01$).

Western blot analysis of *ras*-p21 expression

Table 5 summarizes the results of Western blot analysis for *ras*-p21 expression in both colonic mucosa and the cancers. At the end of weeks 16 and 32, Green tea and tea pigments significantly suppressed the expression of *ras*-p21 in colonic mucosa and cancer as compared with the positive control group ($P < 0.01$).

Bcl-2 and Bax expression

The results of immunohistochemical analysis of Bcl-2 and Bax expression are shown in Tables 6 and 7. At the end of weeks 16 and 32, Bcl-2 expression was significantly suppressed in tea-treated groups as compared with the positive control group, while Bax expression was significantly induced in groups 2 and 3 ($P < 0.05$ or $P < 0.01$).

Table 1 Body weights during the study ($\bar{x} \pm s$)

DISCUSSION

It is recognized that colon carcinogenesis is a multistep process that includes sequential selection and propagation of preneoplastic lesions. ACF are present in carcinogen-treated rodent colons as well as in humans at high risk for colon cancer development and in patients with colon cancer^[16,17]. Several studies investigating the genotypic, morphological, and growth features of ACF have supported the contention that ACF are preneoplastic lesions^[4]. The ACF system is frequently used to identify and study the modulation of colon carcinogenesis. The results of the present study indicated drinking 2% green tea and 0.1% tea pigments significantly inhibited the formation of ACF, and decreased significantly the numbers and size of tumor. Some epidemiologic studies revealed an inhibitory effect of green tea on the incidence of colorectal cancer^[18,19]. In addition, many experimental studies have demonstrated that green tea and tea polyphenols have significant inhibitory effects on rodent colorectal carcinogenesis^[20]. Our study also demonstrated that 2% green tea significantly inhibited DMH-induced ACF formation and colorectal cancer. Black tea consists of significant amount of tea pigments including teaflavins, tearubigins, etc. Teaflavins have antioxidative and antimutagenic effects^[21]. However, very few studies on animal tumorigenesis model have been reported. Morse *et al*^[22] demonstrated that teaflavins in drinking water reduced esophageal tumor induced by N-nitrosomethylbenzylamine (NMBzA) in rats. We have observed that tea pigments have significant inhibitory effects on oral carcinogenesis^[23]. The present study demonstrated that as little as 0.1% tea pigments could significantly inhibit colorectal tumor induced by DMH in rats. It has been suggested that tea pigments may play important roles on the protective effect of black tea in chemical carcinogenesis models.

Abnormal cellular proliferation is one of crucial mechanisms in carcinogenesis^[24]. PCNA is an auxiliary protein of the DNA polymerase delta, reaching an expression peak during the S-phase of the cell cycle and playing an important role in cellular proliferation^[25,26]. PCNA-LI has been used as an intermediate biomarker in chemoprevention of colorectal cancer^[27]. Zheng *et al*^[28] observed that vitamin A significantly decreased PCNA-LI in the AOM-induced colorectal cancer animal model. Another study gave similar result^[29]. In this study, both green tea and tea pigments significantly inhibited PCNA-LI at the end of weeks 16 and 32.

Recent evidence indicates that activation of ras proto-oncogenes, coupled with the loss or inactivation of suppressor genes induces a malignant phenotype in colonic cells^[30]. The *ras* proto-oncogenes (c-Ki-ras, c-Ha-ras and N-ras)

constitute a family of highly conserved genes encoding a structurally and functionally related 21 kd protein, referred to as *ras*-p21, which is anchored to the cytoplasmic face of the plasma membrane, binds to the guanine nucleotides GTP and GDP. Ras activation represents one of the earliest and most frequently occurring genetic alterations associated with human cancers, especially in cancer of colon^[31-34]. Elevated levels of *ras*-p21 were correlated with increased cell proliferation, histological grading, nuclear anaplasia and degree of undifferentiation^[35,36]. In experiments where mutated *ras* genes are selectively inactivated, the pre-existing tumor phenotype reverts to a more normal form, indicating activated *ras* may be necessary for the maintenance of malignant behavior^[37]. Recent studies have demonstrated a strong correlation between dietary modulation of carcinogen-induced *ras* activation and consequent tumor outcome^[38]. Singh *et al*^[39] had suggested that determination of *ras*-p21 might be a useful marker to evaluate the effectiveness of tumor inhibitory properties in colon carcinogenesis. In this study, the DMH-induced expression of *ras*-p21 was significantly suppressed both in tumors and in uninvolved colonic mucosa by oral feeding of 2% green tea and 0.1% tea pigments.

Colorectal cancer is believed to result from a series of genetic alterations that destroys normal mechanisms controlling the cell growth^[30,40]. Apoptosis or programmed cell death appears to be an important mechanism in deletion of tumor cells rather than increased cell proliferation^[41-43]. The *bcl-2* proto-oncogene is a known inhibitor of apoptosis and may therefore allow an accumulation of genetic alterations that become propagated by cell division and potentially contribute to neoplastic development^[44-46]. The *bcl-2* gene encodes a 25 kd protein that localizes to the mitochondrial membrane, nuclear envelope, and endoplasmic reticulum^[47]. Sinicrope *et al*^[48] analyzed the expression of Bcl-2 oncoprotein during colorectal tumorigenesis and concluded that abnormal activation of *bcl-2* gene appeared to be an early event on colorectal tumorigenesis that can inhibit apoptosis *in vivo* and may facilitate tumor progression. Increased *bcl-2* expression could occur in conjunction with changes in the expression of other members of the *bcl-2* family, including those counteract the antiapoptotic effects of Bcl-2. One candidate in this regard is Bax, a dominant repressor of Bcl-2 that forms heterodimers with Bcl-2 and accelerates rates of cell death^[49,50]. A recent study found that the development of IQ induced colorectal tumors was accompanied by the progressive inhibition of programmed cell death which was associated with increased expression of the antiapoptosis protein Bcl-2 and decreased expression of Bax^[51]. In our study, the expression

of Bcl-2 was inhibited significantly by oral 2% green tea and 0.1% tea pigments, while the expression of Bax was induced significantly. The results demonstrated that green tea and tea pigments induced apoptosis.

In conclusion, the present study indicated that green tea and tea pigments significantly inhibited ACF and colorectal cancer induced by DMH, and our study further supported the hypothesis that ACF are precancerous lesions of colorectal cancer and the ACF system can be used as a short-term bioassay to screen potentially new chemopreventive agents and to evaluate the effect of protective factors at a very early stage of the carcinogenic process. Although the mechanisms of the inhibitory effects of tea preparations on carcinogen-induced colorectal carcinogenesis have not been fully elucidated, our study showed that inhibition of proliferation and induction of apoptosis may be two important mechanisms.

ACKNOWLEDGEMENTS We thank Dr. Qi-Kun Chen of the Institute of Tea Science and Research, Chinese Academy of Agricultural Science for his generous offer of tea samples, and are also grateful to Dr. Chung S. Yang of Rutgers University for his kind review of our manuscript.

Ascorbic acid secretion in the human stomach and the effect of gastrin

Bi Guang Tuo¹, Yong Hui Yan¹, Zheng Long Ge², Gang Wei Ou² and Kui Zhao¹

Subject headings gastric mucosa; gastrins; vitaminC; plasma; gastric juice; *Helicobacter pylori*

Tuo BG, Yan YH, Ge ZL, Ou GW, Zhao K. Ascorbic acid secretion in the human stomach and the effect of gastrin. *World J Gastroentero*, 2000;6(5):704-708

Abstract

AIM To investigate the changes of gastric mucosal ascorbic acid secretion in patients with nonulcer dyspepsia and the effect of gastrin on it, and to relate any observed changes to *H. pylori* infection and mucosal histology.

METHODS Ascorbic acid secretions in patients were examined by collecting continuously gastric juice for one hour after having aspirated and discarded fasting gastric juice. Using the clearance rate (mL/min) of ascorbic acid from blood to gastric juice represented ascorbic acid secretion in the gastric mucosa. Ascorbic acid concentrations in plasma and juice were measured by ferric reduced method.

RESULTS Gastric ascorbic acid secretions in *H.pylori*-positive patients (1.46mL/min, range 0.27-3.78) did not significantly differ from those in *H.pylori*-negative patients (1.25mL/min, 0.47-3.14) ($P>0.05$). There were no significant differences in ascorbic acid secretions between patients with mild (1.56mL/min, 0.50-3.30), moderate (1.34mL/min, 0.27-2.93) and severe (1.36mL/min, 0.47-3.78) inflammation ($P>0.05$). There were no significant differences in ascorbic acid secretions between patients without activity (1.45mL/min, 0.27-3.14) and with mild (1.32mL/min, 0.61-2.93), moderate (1.49mL/min, 0.50-3.78) and severe (1.43mL/min, 0.51-3.26) activity of chronic gastritis either ($P>0.05$). Ascorbic acid secretions in patients with severe atrophy (0.56mL/min, 0.27-1.20) were markedly lower than those in patients with out atrophy (1.51mL/min, 0.59-3.30) and

with mild (1.43mL/min, 0.53-3.78) and moderate (1.31mL/min, 0.47-3.16) atrophy ($P<0.005$). There was a significant negative correlation between ascorbic acid secretion and severity of atrophy (correlation coefficient = -0.43, $P<0.005$). After administration of pentagastrin, ascorbic acid secretions were markedly elevated (from 1.39mL/min, 0.36-2.96 to 3.53mL/min, 0.84-5.91) ($P<0.001$).

CONCLUSION Ascorbic acid secretion in gastric mucosa is not affected by *H. pylori* infection. Gastric ascorbic acid secretion is markedly related to the severity of atrophy, whereas not related to the severity of inflammation and activity. Gastrin may stimulate gastric ascorbic acid secretion. A decreased ascorbic acid secretion may be an important factor in the link between atrophic gastritis and gastric carcinogenesis.

INTRODUCTION

Ascorbic acid, a powerful antioxidant, is potentially important for the prevention of gastric cancer. It may be able to protect against gastric cancer by scavenging nitrite and preventing the formation of carcinogenic N-nitroso compounds within gastric juice^[1-5]. In addition, it is capable of scavenging reactive oxygen metabolites^[6-8] that may damage gastric mucosal DNA^[7] and play a role in the development of experimental gastric carcinoma and precancerous lesions induced by N-methyl N-nitro N-nitrosoguanidine^[9] whereby it may also protect against gastric cancer. Various epidemiological studies have clearly shown that high dietary vitamin C intake may reduce the risk of gastric cancer^[10-12]. *H. pylori* infection has been associated with gastritis, peptic ulcer and an increased risk of gastric cancer^[13-17], but its precise role in gastric carcinogenesis is still unknown^[18]. Some previous studies have shown that ascorbic acid is present in the gastric juice of healthy subjects in concentrations considerably higher than those in plasma^[19-21]. This high ratio of gastric juice to plasma ascorbic acid implies active secretion of ascorbic acid by gastric mucosa. It has been recognized recently that gastric juice ascorbic acid concentrations are decreased markedly in subjects with *H. pylori* infection^[22-27] and chronic

gastritis^[19-21,26]. This change of gastric juice ascorbic acid concentrations in *H. pylori*-infected patients may be an important factor in the link between *H. pylori* infection and gastric carcinogenesis. However, these studies only observed the changes of ascorbic acid concentrations in gastric juice. The changes of ascorbic acid secretion in gastric mucosa have rarely been studied. The purpose of this study is, therefore, to investigate the changes of ascorbic acid secretion in gastric mucosa, to assess their relationships to *H. pylori* infection and mucosal histology, and to explore the effect of gastrin on ascorbic acid secretion.

SUBJECTS AND METHODS

Subjects

Fifty-five consecutive cases shown nonulcer dyspepsia by endoscopy and type B ultrasonography were studied. None of them had undergone upper gastrointestinal surgery, nor had taken any drugs over the previous two weeks.

Methods

Collection of samples All patients were studied at the same time (6:00 am) after a 10-hour overnight fast. A 2mL sample of venous blood was withdrawn into a heparinised tube for measurement of plasma ascorbic acid concentration. Then a nasogastric tube was inserted into the patient's stomach. Gastric juice was continuously collected for one hour by a constant suction pump after having aspirated and discarded fasting gastric juice. One hour later, 20 consecutive patients of them were immediately given pentagastrin (6 μ g/kg) intramuscularly and followed by collecting gastric juice for one hour again. Each gastric sample was analyzed for volume and ascorbic acid concentration.

Ascorbic acid measurement Venous blood and gastric juice samples were immediately stored at 4°C after being collected. Ascorbic acid concentrations in the plasma and gastric juice were measured by ferric reduced method^[28] within 10 hours. This method is based on the quantitative rapid reduction of ferric to ferrous by ascorbic acid and the colorimetric measurement of the ferrous through its formation of a colored complex with bathophenanthroline. Briefly, the venous blood samples were centrifuged at 3000 \times g for 20min and gastric juice for 40min before ascorbic acid assay. Then 0.2 mL aliquots of the gastric juice and the plasma supernants were mixed with 0.75mL of 5% trichloroacetic acid to precipitate protein, which were then removed by centrifugation at 3000 g for 20min. Subsequently, 0.5mL of the further supernants were mixed with 1.0mL of acetate buffer, 2.0 mL of bathophenanthroline solution, 0.5mL of ferric chloride solution, and 0.2mL of phosphoric acid solution. Finally, the concentration

was determined with a spectrophotometer at 536nm against standards. Ascorbic acid secretion in gastric mucosa was estimated by clearance rate of ascorbic acid from blood to gastric juice (mL/min), which was calculated by the formula: clearance rate = GV/Bt, where V is the volume of gastric juice collected over t min (mL), G the concentration of ascorbic acid in gastric juice (μ mol/L), B the concentration of ascorbic acid in plasma (μ mol/L), t = 60min.

H. pylori detection and histopathological examination

Three antral biopsies were obtained from every patient for *H. pylori* detection and histopathological examination. One biopsy from the lesser curvature was used for a rapid urease test. Other two biopsies (one from the lesser curvature and another from the greater curvature) were used for Warthin-Starry stain for *H. pylori* and hematoxylin-eosin stain for histopathological examination. Patients were considered to be *H. pylori* positive if one of the two tests was positive, whereas to be *H. pylori* negative if all negative. The severity and extent of gastric inflammation, activity and atrophy were graded on a scale of mild, moderate and severe according to the Sydney System^[29].

Statistical analysis The data in the text were expressed as median values with ranges. Statistical analysis was carried out using non-parametric Mann-Whitney U test. The Spearman rank correlation test was used to calculate correlation coefficients. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Among the 55 patients studied, 31 were *H. pylori* positive and 24 negative. According to the histological division of the Sydney System, 14 had mild inflammation, 17 moderate inflammation, and 24 severe inflammation; 16 had no activity, 11 mild activity, 14 moderate activity and 14 severe activity; 17 had no atrophy, 16 mild atrophy, 12 moderate atrophy and 10 severe atrophy.

Gastric ascorbic acid secretion and *H. pylori* infection

Gastric ascorbic acid secretions in *H. pylori*-positive patients (1.46mL/min, 0.27-3.78) did not differ significantly from those in *H. pylori* negative patients (1.25mL/min, 0.47-3.14) ($P > 0.05$).

Gastric ascorbic acid secretion and gastric inflammation

Gastric ascorbic acid secretions in patients with mild, moderate and severe inflammation were respectively 1.56 mL/min (0.50 - 3.30), 1.34mL/min (0.27 - 2.93) and 1.36mL/min (0.47 - 3.78). There were no significant differences between them ($P > 0.05$).

Gastric ascorbic acid secretion and activity of gastritis

Gastric ascorbic acid secretions in patients without activity and with mild, moderate and severe activity were respectively 1.45mL/min (0.27 - 3.14), 1.32 mL/min (0.61 - 2.93), 1.49 mL/min (0.50 - 3.78) and 1.43mL/min (0.51 - 3.26). There were no significant differences between them either ($P>0.05$).

Gastric ascorbic acid secretion and gastric atrophy

Gastric ascorbic acid secretions in patients without atrophy and with mild, moderate and severe atrophy were respectively 1.51 mL/min (0.59 - 3.30), 1.43 mL/min (0.53 - 3.78), 1.31 mL/min (0.47-3.16) and 0.56mL/min (0.27 - 1.20). Ascorbic acid secretions in patients with severe atrophy were significantly lower than those in patients without atrophy and with mild and moderate atrophy ($P<0.005$). There were no significant differences between patients without atrophy and with mild and moderate atrophy ($P>0.05$). With the progress of atrophy, ascorbic acid secretion was gradually decreased, with a significant negative correlation (correlation coefficient = -0.43, $P<0.005$).

Effect of gastrin on ascorbic acid secretion

In 20 patients given pentagastrin, gastric ascorbic acid secretions rose from 1.39mL/min (0.36-2.96) to 3.53mL/min (0.84 - 5.91). There was very significant difference between them ($P<0.001$).

DISCUSSION

Some previous studies have found that gastric ascorbic acid concentrations in *H. pylori*-positive patients and patients with chronic gastritis are markedly lower than those in *H. pylori*-negative patients and healthy controls^[19-27]. However, little is known the changes of ascorbic acid secretion in the stomach. It is also uncertain whether low gastric juice ascorbic acid concentrations in *H. pylori*-infected patients are induced by impairing gastric mucosal ascorbic acid secretory capacity or other causes. Some researchers speculate that lower gastric juice ascorbic acid concentrations in *H. pylori*-infected patients are mainly related to the impaired gastric secretory capacity in the presence of gastritis induced by *H. pylori* infection. The reason for this notion is that there is a significant negative correlation between gastric juice ascorbic concentration and grading of polymorphonuclear leucocyte infiltration induced by *H. pylori* infection^[22,25]. However, some studies have shown that *H. pylori* can potentiate the polymorphonuclear leucocyte oxidative burst^[30,31], which is accompanied by a considerable production of reactive oxygen metabolites. Ascorbic acid in

gastric juice may be in itself consumed in the course of scavenging these reactive oxygen metabolites. In addition, some studies on gastric mucosal ascorbic acid levels suggest that gastric mucosal ascorbic acid concentration is not related to *H. pylori* infection^[32,33] and presence of inflammation^[34]. In order to investigate whether gastric ascorbic acid secretion is affected by *H.pylori* infection and the changes of gastric mucosal histology, we made an investigation on gastric ascorbic acid secretion in patients with *H. pylori* infection and chronic gastritis through collecting continuously gastric juice for one hour after having aspirated and discarded fasting gastric juice. We found that Gastric mucosal ascorbic acid secretions in *H. pylori*-positive patients did not significantly differ from those in *H.pylori*-negative patients. The changes of gastric ascorbic acid secretion were independent of the severity and extent of gastric inflammation and activity. However, gastric ascorbic acid secretions in patients with severe atrophy were significantly lower than those in patients without atrophy or with mild and moderate atrophy. There was a significant negative correlation between gastric ascorbic acid secretion and severity of atrophy. The results indicate that gastric ascorbic acid secretion is not influenced by *H. pylori* infection. *H. pylori* infection might lower ascorbic concentration in gastric juice through other mechanisms. A number of reasons could be responsible for low gastric juice ascorbic acid concentration induced by *H. pylori* infection. In addition to potentiating polymorphonuclear leucocyte burst described above, one study has shown that the cytochrome c-like water soluble oxidant of *H.pylori* may destroy ascorbic acid in the gastric juice of infected patients^[35]. *H. pylori* can also secrete many kinds of enzymes which have higher enzyme activity^[36]. It has been shown that *H. pylori* markedly influences the metabolism of certain endogenous organic molecules^[36-38]. These enzymes and the local biochemical alterations induced by *H. pylori* might influence the metabolism of ascorbic acid and lower the ascorbic acid concentration in gastric juice. Ascorbic acid is a powerful antioxidant and is potentially important for the prevention of gastric cancer. It may protect against gastric cancer by either preventing the formation of carcinogenic N-nitroso compounds in gastric juice^[11-51] or scavenging reactive oxygen metabolites that may damage gastric epithelium^[6-8]. Various studies have shown that ascorbic acid levels in gastric juice are related to the incidence of gastric cancer^[39-41]. Blood ascorbic acid levels in patients with gastric cancer were markedly lowered^[42-44]. These studies suggest that the decrease of ascorbic acid in gastric juice can increase the risk of gastric carcinogenesis. Chronic atrophic gastritis is an important precancerous condition and has been associated with an increased

risk of gastric carcinogenesis is^[45,46]. Previous studies have shown that an environment of hypochlorhydria in atrophic gastritis favors an overgrowth of nitrite-forming bacteria and increasing the formation of nitrite and N-nitroso compounds^[47-50]. However, as ascorbic acid is a powerful antioxidant, it may react with nitrite to form dehydroascorbic acid and nitrous oxide and prevent the formation of carcinogenic N-nitroso compounds. Only when the nitrite in gastric juice is in excess of reduced capacity of ascorbic acid in gastric juice, are carcinogenic N-nitroso compounds available. In the present study, it has been found that gastric ascorbic acid secretions in patients with severe atrophy are markedly decreased. There is a significant negative correlation between gastric ascorbic acid secretion and severity of atrophy. We speculate that this change of gastric ascorbic acid secretions in patients with atrophy may be an important factor in the link between atrophic gastritis and gastric carcinogenesis. Some studies have shown that the supplementation of ascorbic acid may elevate the ascorbic acid concentration in gastric juice^[34,51,52], so the diet rich in vitamin C may decrease the risk of gastric cancer in patients with gastric atrophy.

The mechanism whereby gastric mucosa secretes ascorbic acid is unclear. Some studies on the rats have shown that gastric ascorbic acid secretion is physiologically regulated not only by muscarinic receptor-associated cholinergic stimulation^[53] but also by CCK receptor-associated humoral stimulation^[54]. Our study found that gastric ascorbic acid secretion was markedly elevated after given pentagastrin. The result indicates that gastrin may also stimulate gastric ascorbic acid secretion. In the present study, it was observed that the changes of gastric ascorbic acid secretion were related to the severity of atrophy, whereas not related to the severity of inflammation and activity. As the histologic alteration of atrophy is the loss of specialized gland, we speculate that gastric glands may participate in the secretion of ascorbic acid. However, the detailed mechanism about gastric ascorbic acid secretion will be further investigated.

Abstract

AIM To clone expressed genes associated with repair of irradiation-damaged mice intestinal gland cells treated by small intestinal RNA, and to explore the molecular mechanism of exogenous nucleic acids improving repair of intestinal crypt.

METHODS The animal mode of test group and control group was established, forty-five mice being irradiated by γ ray were treated with small intestinal RNA as test group, forty mice being irradiated by γ ray were treated with physiological saline as control group, five mice without irradiation were used as normal control, their jejunal specimens were collected respectively at 6h, 12h, 24h, 4d and 8d after irradiation. Then by using LD-PCR based on subtractive hybridization, these gene fragments differentially expressed between test group and control group were obtained, and then were cloned into T vectors as well as being sequenced. Obtained sequences were screened against GeneBank, if being new sequences, they were submitted to GeneBank.

RESULTS Ninety clones were associated with repair of irradiation-damaged intestinal gland cells treated by intestinal RNA. These clones from test group of 6 h, 12 h, 24 h, 4 d and 8 d were respectively 18, 22, 25, 13, 12. By

screening against GeneBank, 18 of which were new sequences, the others were dramatically similar to the known sequences, mainly similar to hsp, Nmi, Dutt1, alkaline phosphatase, homeobox, anti-CEA ScFv antibody, arginine/serine kinase and BMP-4, repA. Eighteen gene fragments were new sequences, their accept numbers in GeneBank were respectively AF240164-AF240181.

CONCLUSION Ninety clones were obtained to be associated with repair of irradiation-damaged mice intestinal gland cells treated by small intestinal RNA, which may be related to abnormal expression of genes and matched proteins of hsp, Nmi, Dutt1, Na, K-ATPase, alkaline phosphatase, glkA, single stranded replicative centromeric gene as well as 18 new sequences.

INTRODUCTION

After exposure to large dose ionizing radiations, the larger intestinal gland cell lesion is the main cause of death in humans and animals. How to enhance intestinal gland cell survival rates has become a problem to be solved. In order to increase the mouse crypt survival after irradiation, we have done a series of experiments, and finally confirmed that when a portion of the crypts was devastated by irradiation, a compensatory recovery of the intestinal epithelium by remaining crypts occurred involving three consecutive periods such as the rapid cell proliferation of the viable crypts, the fission of the proliferative crypts and the increase of crypt numbers^[1]. The nucleic acid fragment containing several hundred base pairs (bp), or even any one of the nucleic acid precursors (mononucleotides, nucleosides, and bases) can enhance the crypt survival rate by 25% or so, further confirming that the effectiveness of exogenous nucleic acids depends not upon the action exerted by their highly polymerized state, but upon their various enzymatic degradation products^[2]. Our experimental results suggest that the nucleic acids (DNA, RNA) and their precursors may be used as one of the effective measures for the treatment of intestinal radiation

syndrome that may occur in the war time as well as in the peaceful use of atomic energy^[3-5]. However, the molecular mechanism how nuclear acids and precursors improve the repairing of irradiation-damaged intestinal gland cells is unclear. In order to clarify this molecular mechanism, we used long distance-PCR based on subtractive hybridization, isolated and cloned these genes associated with repairs of irradiation-damaged mice intestinal gland cells treated by intestinal RNA. Our studies lay foundation for further clarifying molecular mechanism of repair of radiation-damaged crypt.

MATERIALS AND METHODS

Reagents

PolyATtract® system 1000 kit from Promega was used for extraction of mRNA, SMART PCR cDNA synthesis kit (Clontech) for transcription of mRNA, Wizard® plus Minipreps DNA purification for purification of PCR production, Advantage2PCR kit (Clontech) for LD-PCR, and PE-5700 quantitative PCR cyler used for thermal cycle. PGEM-T easy vector system was purchased from Promega, γ -³²-pdATP from Beijing Fu Rei Company, and the other reagents were from Beijing Yuan Ping company.

Establishment of the model and sample collection

Ninety BALB/c male mice with body weight of 18g-22g and 10-12 weeks old were randomly assigned into two groups, *i.e.* test group and control group. They were injected with 5g·L⁻¹ barbiturate sodium 40 mg·kg⁻¹, put in organism radiation box, and then were irradiated on mice abdominal region by using ⁶⁰Co γ ray at the reagent rate of 149.47-151.13cGy·min⁻¹, and finally reached total reagent of 1150cGy. Small intestinal RNA was diluted into 100mg·mL⁻¹. Two hours after mice being irradiated, each mouse in test group was injected 0.4mL RNA liquid, and each mouse in control group was injected 0.4mL physiological saline by using local intestinal cavity expanding injection method^[6]. After that, the mice were raised according to conventional method. These mice were killed respectively at 6 h, 12 h, 24 h, 4 d and 8 d after irradiation, and jejunal tissues were quickly taken out, washed by physiological saline, and then were kept in liquid nitrogen. In order to avoid single difference, these samples were mixed together under identical condition.

Sample processing and LD-PCR based on subtractive hybridization

Extraction of mRNA was done according to manual of PolyATtract system 1000, and quantificated. mRNA transcription was done according to manual from SMART PCR cDNA synthesis kit. Subtractive hybridization between test group and control group

was done as follows: take out 0.1 μ g mRNA from the control group, add Biotinylated oligo(dT) probe (50 μ mol·L⁻¹), 70°C 5min, then add into the first strand cDNA, and hybridize for 24 h at 42°C, finally add Streptavidin magnesphere particles and mixed, magnetic steel was used to attract production of two stranded hybrids and get rid of them, and then repeat the processing twice. Take out the upper liquid, and add double volume absolute alcohol to the upper liquid to precipitate cDNAs, finally dissolve them in 10 μ L Nuclease-free water. Take 10 μ L of the first strand cDNA as template, sequentially add PCR-grade water 74 μ L, 10 \times advantage 2 PCR buffer 10 μ L, 50 \times dNTP mix-10 μ L, 50 \times advantage 2 polymerase mix 1 μ L, PCRprimer Mix 2 μ L, 50mmol·L⁻¹ MgCl₂ 3 μ L, mixed well, centrifuged for several seconds, using two steps such as 95°C 1min, 95°C 15s, 68°C 6min, 30cycles, in the end elongated at 68°C for 6min, take out 10 μ L production to run 12 g·L⁻¹ agarose gel electrophoresis.

Cloning and identification of PCR products

PCR products were purified using Wizard plus Minipreps DNA purification system, and dissolved in 10 μ L water. According to the manual, PCR products were cloned into PGEM-T easy vector, transferred into JM109, positive clone picked up, cultured overnight, plasmid extracted out, and identified by cutting with BstZ1. Products cut by BstZ1 were labelled γ -³²-pdATP at terminal, and used as probe, and hybridized with mRNA of test group and control group^[7].

Sequencing and screening against GeneBank

These obtained clones were positively sequenced by using Model 377 sequencing instrument. Obtained sequences were screened against GeneBank, if being new sequences, these sequences were submitted to GeneBank^[8].

RESULTS

LD-PCR based on subtractive hybridization

In test group of 6 h, 12 h, 24 h, 4 d and 8 d, products after subtractive hybridization were successfully amplified by LD-PCR, obtained bands centered on 1-1.5kb or so (Figure 1).

Figure 1 Electrophoresis result of production of LD-PCR.

Cloning and identification of PCR products (Figure 2)

Figure 2 Results of cloning and identification of production of PCR. 1-4, 6-9: Results of part products cut by Bstz1; 5: Marker. Ninety of positive clones were obtained from test group, positive clones of 6 h, 12 h, 24 h, 4 d and 8 d in test group were respectively eighteen, twenty-two, twenty-five, thirteen, twelve.

Identification of hybridization (Figure 3)

Figure 3 Part results of hybridization with RNA.

A: Test group; B: Control group

Dot blots confirmed that these genes were overexpressed in test group, and lower expressed in control group, that is, these genes were associated with repair of intestinal gland cells treated by RNA.

Sequencing and searching for GeneBank

These clones were sequenced according to the results of sequencing and searching against GeneBank, eighteen were new sequences, eighty-two were dramatically similar to the known sequences.

In test group of 6h, similar sequences mainly were as follows: mRNA for heat shock protein,

Nmi mRNA, Dutt1 protein, mRNA for Na, K-ATPase gamma subunit, mRNA for surface glycoprotein, Zinc finger type transcript factor, porcine growth hormone-releasing hormone gene, monocyte/macrophage Ig-related gene, telomerase-associated protein, HOX1b protein, arginine/serine kinase.

In test group of 12h, similar sequences were: Alkaline phosphatase mRNA, alkaline phosphatase 2, glkA gene, single stranded replicative centromeric gene, DMBT1, tRNA-Met gene, homeobox protein, thyroxine-binding globulin gene, alpha-a-plasmin inhibitor gene.

In test group of 24h, similar sequences were: anti-CEA ScFv antibody, anti-DNA heavy chain, mRNA for Ig kappa chain, anti BONT/A Hc ScFv antibody, mRNA for collagenase, AE0199 immunoglobulin heavy chain, Mouse Ig gamma-chain, Ig rearranged gamma-chain mRNA, anti-c-myc antibody, anti-CD30 moab ki₄ ScFv, anti-BSA antibody, D1 heavy chain, epidermal growth factor, anti-NP antibody IgH, mRNA for arginine/serine kinase.

In test group of 4d, similar sequences were: Dual specificity phosphatase, family mRNA telomerase-associated protein, anti-human erbB-2, tazarotene-induced gene2, betaine-GABA transporter gene, copy complex subunit 7a, mRNA for stress-activated protein, FK506 binding protein, calcium/calmodulin dependent gene, PEST phosphatase interactin gene, haptoglobin mRNA, acyl-ACP desaturase, mRNA for sodium channel, peroxidase, BMP-4 gene, bone morphogenetic protein.

In test group of 8d, similar sequences were: Ig variable region, DNA for mouse Ig, DNA for flexible peptide, tsr glkA, proteinase-3 neuroactin, EWS gene, repA protein.

Eighteen new sequences

No.1 sequence (AF240164)

DISCUSSION

After exposing to large dose ionizing radiation, intestinal crypt radiation death occurs, and no effective therapeutic measures are available to combat it. Data showed that the devastation or death of the crypt after irradiation is the crucial factor responsible for the pathogenesis. We have performed a series of experiments intending to increase the crypt survival after-irradiation in mice and confirmed that the nucleic acids (DNA, RNA) and their precursors may be used as one of the measures for the treatment of intestinal radiation syndrome that may occur in the war as well as in the peaceful uses of atomic energy^[1-5]. However, the concrete molecular and cellular mechanisms are unknown.

Human genome group comprised 100 thousand of genes, which are selectively expressed, and determined the whole life course of organism, alteration of gene expressed levels is positioned at the centre of controlling biological adjustment mechanism^[8]. Therefore, we think, after irradiation, between test group treated by RNA and the control group treated by physiological saline must exist differently expressed genes, which indicate that those genes were closely associated with intestinal crypt damage and repair. To isolate and clone these genes may not only be helpful to clarify the molecular mechanism of nuclear acids treatment, but also provide important basic theory for gene therapy of irradiation damage.

In the study, using BALB/c mice as studying target, we obtained 90 of genes associated with repair of irradiation damaged intestinal gland cells. Data confirmed that hsp was increased at mRNA level after chronic radiation, PARP, serine protease-like gene, *p53*, *bcl-2*, *bax*, arginase I, *ihsr* PB7, *Cdx1*, *NPT*, *PCNA*, *D1b-1*, *c-Ha-ras*, *c-*

myc, *c-fos* and so on were also increased at mRNA levels, which were correlated closely with drug treatment of irradiation damaged intestinal cells^[9-25]. In our experiment, such as *Nmi* mRNA, *Dutt1* protein, mRNA for Na, K-ATPase gamma subunit, mRNA for surface glycoprotein, Zinc finger type transcript factor, porcine growth hormone-releasing hormone gene, monocyte/macrophage Ig-related gene, telomerase-associated protein, *HOX1b* protein, arginine/serine kinase, alkaline phosphatase mRNA, alkaline phosphatase 2, *glkA* gene *et al* were also closely correlated with repair of irradiation damaged intestinal crypt, what especially interesting was that *RSG5* and *ODC* were identical to obtained sequences, data showed that *RSG5*, and *ODC* were overexpressed in irradiation-damaged intestinal crypt, and played an essential and positive role during DNA damage recovery and survival^[26,27], our results also fully supported the conclusion. Although their concrete mechanism is not clarified, they may increase protein products by means of increased transcript levels to improve repair of irradiation-damaged intestinal crypt, and to suppress apoptosis of crypt cells^[32].

Langberg *et al*^[28] confirmed that immunological factors participated in the course of repair of irradiation damaged intestinal crypt such as IL-1, TGF-beta1, PDGF-AA, c-EGFR, EGF, TGF-beta-3. In our experiment, anti-CEA ScFv antibody gene, anti-DNA heavy chain, mRNA for Ig kappa chain, anti-BONT/A Hc ScFv antibody gene, mRNA for ScFv collagenase, AE0199 immunoglobulin heavy chain, mouse Ig gamma-chain, Ig rearranged gamma-chain mRNA, anti-c-myc antibody gene, anti-CD30 mAb ki-4 ScFv, anti-BSA antibody gene, D1 heavy chain, epidermal growth factor, anti-NP antibody IgH, mouse Ig

gammachain and haptoglobin were likely to be correlated closely with repair of irradiation damaged intestinal crypt. What is especially interesting is several gene fragments were partly identical to sequences of ScFv genes, this point was not able to be expressed clearly. Our results support that immunological factors exert effect on the course of repair of irradiation damaged intestinal crypt^[29-45].

In our experiment, eighteen novel sequences were obtained, their concrete functions are still unclear. But we believe that these genes are closely associated with irradiation treatment, only if we clarify the function of these genes, and according to the changes of these genes, to design a controlling measure, we are likely to decrease irradiation damage, and also provide new thoughts for tumor radiation treatment^[46-64].

In summary, our results primarily demonstrate that nuclear acids are capable of improving repair of irradiation damaged intestinal crypt, its action may be closely correlated with increased mRNA levels of some genes, also with immunological factors, but the concrete molecular mechanism such as signal transduction and suppression of apoptosis still needs further studies^[65-89].

INTRODUCTION

Dendritic cells (DCs) play a key regulatory role in antitumor immunity, especially in its immune accessory role via MHC-I molecules^[1-5]. We have recently reported that DCs were able to enhance the killing activity of Lymphokine and PHA activated killer (LPAK) cells *in vitro*^[6-8]. In the present study, we evaluated the effects of GM-CSF and TNF upon antitumor activities of freshly isolated dendritic Cells in human peripheral blood (DC-0) and those cells cultivated for 36 hours *in vitro* (DC-36). To perform such an evaluation, we compared killing effects of LPAK cells with additional DC-0 or DC-36 on hepatoma cell line (BEL-740 2) under regulation of GM-CSF or TNF. This study provided some basic data for further antitumor research.

MATERIALS AND METHODS

Tumor cell line

Human hepatoma cell line BEL-7402 was purchased from experimental center of Sun Yat-Sen University of Medical Sciences.

Isolation of DCs

According to our previous method^[9], peripheral

blood mononuclear cells (PBMNC) from healthy volunteers were prepared by using Ficoll-Hypaque ($\rho = 1077\text{g/L}$) centrifugation method. Interface cells were collected and washed three times to remove platelets. Discontinuous Percoll density gradient centrifugation (Percoll: Pharmacia, Sweden) was employed, and then interface cells between 35% and 50% were collected which were called as preliminary enrichment of DCs and divided into two shares. One share (DC-0) was panned immediately; other one (DC-36) further cultured in PRMI-1640 with 100mL/L inactivated fetal calf serum (100mL/L FCS PRMI-1640) at 37°C in a full humidified 50mL/L CO₂ atmosphere for 36 hours, and panned. The non-adherent fractions of two shares as DC-0 and DC-36 were washed and collected for the experiments.

Preparation of LPAK cells^[9]

The PBMNCs were prepared in the same procedure as above, cultured $2 \times 10^9/\text{L}$ population with the final concentration of rhIL-2 1000ku/L and PHA 20mg/L in 100mL/L FCS PRMI-1640 at 37°C in a full humidified 50mL/L CO₂ atmosphere for 7 days. Half volume of the solution was replaced by fresh culture medium at the fourth day.

Anti-tumor experiment

The anti-tumor experiments were divided into two groups and each contained five experimental subgroups. Two ratios of effect (LPAK) to target (BEL-7402) (5:1 and 10:1) were used in all groups. ① DC-0 group: d group: BEL-7402 ($8 \times 10^7/\text{L}$) + LPAK + DC-0 ($8 \times 10^6/\text{L}$); g1 group: d group + GM-CSF (500 ku/L); g2 group: d group + GM-CSF (100ku/L); t1 group: d group + TNF (5000ku/L); t2 group: d group + TNF (500ku/L); ② DC-36 group: each experimental group was the same as that in DC-0 group except DC-36 in place of DC-0 in the same concentration. These experimental groups were called D group, G1 group, G2 group, T1 group and T2 group respectively. In addition, L groups as the corresponding control groups, BEL-7402 + LPAK, experimental control group only consisted of BEL-7402, its population was $8 \times 10^7/\text{L}$. Culture medium control group only contained 100mL/L FCS-PRMI-1640 with the supernatant of LPAK cells at a concentration of 50μL/culture well. All of these

Received 2000-04-03 Accepted 2000-06-25

groups were cultured in 96-well-culture plates and each group had 3 wells at 37°C in a full humidified 50mL/L CO₂ atmosphere for 48 hours. Cytotoxicity assay was detected by using neural red uptake method.

Cytotoxicity assay (neural red uptake method)^[10]

0.1mL 0.3mL/L neural red solution was added in each well for another 1 hour of culture. Following three washings with phosphate-buffered saline (PBS), 0.1mL HCl-ethanol solution was added in each well. The absorption value (A value) of each well was immediately read by BIO-RAD 3550-UV type automatic ELISA reader at 570nm wavelength. The formula of cytotoxicity is as follows:

$$\left(1 - \frac{\text{Experimental group A} - \text{medium control group A}}{\text{Control group A} - \text{medium control group A}}\right) \times 100\%$$

The experimental results were analyzed through analysis of variance by using GB-STAT statistic software. The experiment repeated four times at the same condition.

RESULTS

Influence of DC-0 and DC-36 on cytotoxicity activity of LPAK cells

The cytotoxic activity of L group, d group and D group was enhanced when their ratios of effect to target increased ($P < 0.01$). Their cytotoxic activity were D group > d group > L group ($P < 0.01$) respectively while in the same ratio of effect to target (Figure 1).

Influence of GM-CSF on DC-0 and DC-36 in helping LPAK cells killing effect

When there were two ratios of effect to target, cytotoxic activity of g1 group and g2 group were obviously higher than d group ($P < 0.01$), meantime, cytotoxic activity of G1 group and G2 group were greatly higher than D group ($P < 0.01$). However, the difference between g1 group and g2 group was not distinct ($P > 0.05$), also there were no difference between G1 group and G2 group ($P > 0.05$). But there were obviously different between g1 group and G1 group ($P < 0.01$), at the same time, the difference between g2 group and G2 group were distinct ($P < 0.01$) (Figure 2).

Influence of TNF on DC-0 and DC-36 in helping LPAK cells killing effect

While there were two ratios of effect to target, cytotoxic activity of t1 group or t2 group was evidently higher than that of d group ($P < 0.01$), meantime, cytotoxic activity of T1 group or T2 group was markedly higher than that of D group ($P < 0.01$). However, the differences between t1 and t2 group, and between T1 and T2 group were distinct ($P < 0.01$). Furthermore, there were difference between t1 and T1 group ($P < 0.01$), at the same time, between t2 and T2 group ($P < 0.01$) (Figure 3).

Figure 2 Influence of GM-CSF on DC-0 and DC-36 in helping LPAK cells killing activity *in vitro*.

Figure 3 Influence of TNF on DC-0 and DC-36 in helping LPAK cells killing activity *in vitro*.

DISCUSSION

In recent years, it is considered that mature DCs in human peripheral blood have high stimulating function, which efficiently presents tumor-peptide epitopes leading to induce cytotoxic T lymphocytes (CTL) to produce stronger specific antitumor immune response^[11-14]. LPAK cells after 7-day induction chiefly express similar phenotype with the CD₁₆⁻, CD₈⁺, CD₃⁺ CTL subtype^[15-18]. In our experiments, cytotoxic activity in D group was obviously higher than in d group, which demonstrated that the proportion of mature DCs in DC-36 group was higher than those in DC-0 group and DC-36 group could stimulate LPAK cells to exert stronger antitumor immune response. This effect suggested that a lot of precursor cells of DCs and immature DCs in freshly isolated DCs could

differentiate into mature DCs after 36h cultivation, which coincided with Young's opinion^[19]. In human peripheral blood, however, not all the precursor cells and immature DCs are able to automatically differentiate into mature DCs *in vitro*. It is GM-CSF that promotes the differentiation, maturation and activation of DCs. GM-CSF can not only initiate and promote development of DCs from MHC II⁻, MHC II⁺ precursors and immature DCs, but also upregulated CD₈₆- expression on DCs, which make DCs to have activating and controlling antitumor immune function^[20-24]. Cytotoxic activity difference between G₂ (g₂) group and G₁ (g₁) group were not distinct, this finding illustrated that maturation and activation of DCs did not result from one factor but from combination of multiple factors. In addition, the different time required in different developing stage of DCs populations must be considered. Although developing time in DC-36 group was longer than that in DC-0 group, not all DCs in DC-36 group differentiated into mature DCs. Therefore, increasing GM-CSF concentration alone was senseless. This phenomenon may be helpful in further study of antitumor immunity and clinical research.

In the case of TNF addition, cytotoxic activity was increased greatly, this finding attributed to three roles of TNF: 1, TNF is able to serve as the first signal, which affects DCs development in their early stage or whole stage, leading to upregulate the GM-CSF receptor level of DCs^[21]. The supernatant of LPAK cells with minor quantity of cell growth factors such as TNF was added into culture medium to afford synergetic effect with GM-CSF; 2, TNF upregulates expression of CD₈₀, CD₈₃, CD₈₆ and MHC-II in a short period^[25,26]. Because these molecules are crucial for efficient antigen presenting, they promote the differentiation, development and activation of DCs. 3, TNF itself can kill tumor cells directly^[27-32]. Compared with two t groups, cytotoxic activity of T₁ and t^a-1 groups were higher than that of T₂ and t₂ groups, which showed that in DC-36 groups there was plenty of time for immature DCs to evolve into mature DCs after the addition of TNF. Furthermore, T₁ (t₁) group had higher cytotoxic activity than T₂ (t₂) group, which was further increased when TNF dosage was raised. This phenomenon may attribute to antitumor effect of TNF itself and the synergetic effect between LPAK cells and TNF.

In conclusion, as compared with uncultured DC-0, cultured DC-36 from freshly isolated DCs had greater cooperative effect with GM-CSF or TNF. Moreover, they enable DCs to fulfill stronger antitumor effect.

INTRODUCTION

Programed cell death plays an important role in the genesis of cancer^[1-5]. Certain cancer genes can regulate apoptosis. Recently, several proteins that are structurally related to Bcl-2, an inhibitor of apoptosis, have been identified^[6-11]. Therefore, novel strategies and agents that target specific molecular pathways, as well as triggering a process of cell death, are being evaluated in the treatment of several neoplasms. The homologous Bcl-2 and Bcl-x1 proteins can extend cell survival by suppressing apoptosis^[12,13], whereas the proapoptotic proteins (e.g. Bax, Bak, Bik) act as dominant cell death inducers when overexpressed^[14,15]. C-myc not only can promote cell growth, but also induce apoptosis. Many studies have shown that oncogene plays an important role in the growth, progression and metastasis of solid tumors. Recently, several oncogene factors have been identified. Primary liver cancer remains one of the most common malignancies worldwide, with an annual incidence of approximately 1 million cases^[16,17]. It bears the character of portal venous invasion, so metastases are often presented when the cancer is discovered. We use immunohistochemical method to detect the protein expression of Bcl-2, Bax, c-myc and use TdT-mediated dUTP nick end labeling (TUNEL) method to detect the apoptosis index. The purpose of our study was to evaluate the function of these proteins and their relationship with the clinical characteristics of hepatoma.

MATERIALS AND METHODS

Clinical material

Twenty-two resected hepatoma specimens in our hospital from 1994 to 1998 were studied. All the specimens were confirmed by pathology. Twenty-seven were men, and 5 women, average age 50.26 years. No patient had received chemotherapy or radiation therapy before surgery. All the specimens together with some paracancerous tissues were fixed in 100mL/L formaldehyde solution and embedded in paraffin. Five μ m thick sections were cut and mounted on glass slides.

Immunohistochemical determination and in situ hybridization detection

Immunohistochemical determination of Bcl-2, Bax and c-myc Immunohistochemical studies were performed using ABC method. The antibodies of Bcl-2, Bax and c-myc were bought from Boshide Biotechnology, Inc (Wuhan). Immunohistochemical assay was performed as described by the manufacturer. Immunohistochemical studies were performed using the streptavidin-biotin method. Sections were dewaxed in xylene, taken through ethanol, and then incubated with 3mL/L hydrogen peroxide in methanol for 30min to block endogenous peroxidase activity. Sections were then washed in phosphate-buffered saline and incubated in 100mL/L normal goat serum for 20min to reduce nonspecific antibody binding. Specimens were then incubated with a 1:50 dilution of a primary antibody overnight at 4°C, followed by three washes with PBS. Sections were then incubated with biotinylated goat antirabbit immunoglobulin G at a dilution of 1:100 for 30min followed by 3 washes. Slides were then treated with streptavidin-peroxidase reagent for 30min at a dilution of 1:100 and were washed with PBS 3 times. Finally, slides were incubated in PBS containing diaminobenzidine and 10mL/L hydrogen peroxide for 10min, counterstained with methyl green, and mounted. Normal rabbit immunoglobulin-G was substituted for primary antibody as the negative control. Slides were interpreted for antigen expression by two investigators without knowledge of the corresponding clinicopathologic data. Ten optical fields, about 500-1000 cells were counted in each slide under the high power ($\times 400$) microscopy. Results presented as -, indicated 25% slightly positively stained cells; +, 25%-50% positive cells; ++, 50%-75% positive cells; +++, >75% positive cells.

In site hybridization dectetion

Apoptosis was further confirmed by the TdT-mediated DUTP nick end labeling (TUN EL) method using a detection kit from Boshide Biotechnology, INC (Wuhan).

Sections were dewaxed in Xylene, taken through ethanol, and then incubated with 30mL/L hydrogen peroxide in methanol for 30min, washed with PBS, incubated in dialysate solution for 2min on ice, and incubated with TUNEL reaction mixture at 37°C for 30min. Samples were washed with PBS, incubated with converter PO D at 37°C for 1h and stained with 3, 3'-diaminobenzidine tetrahydrochloride. A negative control using all reagents except terminal transferase was performed in parallel. The nucleus of positive cells was stained brown as detected under light microscopy. Ten optical fields, about 500-1000 cells were counted in each slide under the high power (×400) microscopy. The apoptosis index is the percentage of positive cells in 1000 cells.

Statistical analysis

Statistical significance was determined by using χ^2 test or Student's *t* test.

RESULTS

The protein expressions of Bcl-2, Bax, c-myc and apoptosis

The rate of Bcl-2 protein positive expression in human hepatocellular carcinoma was 22.73% and it was 18.18% in paracancerous tissues. No difference was seen as compared with each other ($P>0.05$). The rate of Bax positive expression was 45.45% in carcinoma tissue and 77.27% in paracancerous tissues ($P<0.01$). The rate of c-myc protein expression was 81.82% in carcinoma tissues and 72.73% in paracancerous tissues ($P>0.05$). The apoptosis index in hepatocellular carcinoma was 9.55% and was lower than that in paracancerous tissues ($P<0.01$).

The relationship between the protein expressions of Bcl-2, Bax and apoptosis index in cancerous tissues and paracancerous tissues

The apoptosis index of Bcl-2 positive group was higher than that of Bcl-2 negative group, but no difference was found between them ($P>0.05$); The apoptosis index of Bax positive group was significant higher than that of Bax negative group ($P<0.01$) (Table 1).

Relationship between protein expressions of Bcl-2, Bax and protein expression of c-myc in cancerous tissues

In the carcinoma tissues, the expression of c-myc was not related to the expression of Bcl-2 and Bax (Table 2).

Table 1 The relationship between the protein expressions of Bcl-2, Bax and apoptosis index in cancerous tissues and paracancerous tissues

	Case	Apoptosis index %
Cancerous tissues		
Bcl-2 negative	17	9.12±5.37
Bcl-2 positive	5	11.00±5.48
Bax negative	12	5.83±1.95
Bax positive	10	14.00±4.59 ^b
Paracancerous tissues		
Bcl-2 negative	18	16.39±5.89
Bcl-2 positive	4	12.50±5.00
Bax negative	5	10.00±3.54
Bax positive	17	17.35±5.62 ^b

^b $P<0.01$ vs compared with Bax negative group.

Table 2 The relationship between the protein expressions of Bcl-2, Bax and the protein expression of c-myc in cancerous tissues

	c-myc positive	c-myc negative
Bcl-2 positive	3	1
Bcl-2 negative	15	3
Bax positive	14	3
Bax negative	4	1

DISCUSSION

Apoptosis, a normal cellular process that provides the orderly existence and death of cells in a programmed fashion, may be positively or negatively modulated by several external or internal factors^[18-22]. Modern molecular biology investigations have indicated that proliferative inhibition of some neoplasm cells is related to apoptosis induction regulated by the oncogene expression of these cells^[23-26]. Recently, regulating apoptosis gene is divided into two groups, existence gene and death gene. Living gene includes improving cell proliferation gene, c-myc and improving cell existence gene, Bcl-2^[27-29]. Death gene includes suppressing cell proliferation gene i.e. p53 and promoting cell death gene, i.e. Bax^[30,31]. It is generally considered that Bcl-2 is an important gene for cell survival, the Bcl-2 gene can inhibit the apoptosis by blocking the last tunnel of apoptotic signal transmitted system^[32-37], C-myc is a kind of effective protein of the karyomitoses signal, which can trigger and regulate the transcription of the genes related with proliferation^[38]. Some recent study showed that Bcl-2 and Bax play important roles in regulating apoptosis in prostate cancer, mammary cancer and gastric carcinoma^[39-41]. But there has been no report on the relationship between regulating apoptosis gene and apoptosis index in human hepatocellular carcinoma.

We detected the protein expression of Bcl-2, Bax and c-myc in hepatocellular carcinoma and paracancerous tissues using immunohistochemical stain. The rate of Bcl-2 protein positive expression in human hepatocellular carcinoma was 22.73 %,

and 18.18% in paracancerous tissues. No statistical difference was seen between them ($P>0.05$). The result was similar to that of Guo *et al.*^[42]. The rate of Bax protein positive expression in hepatocellular carcinoma was 45.45%, and 77.27% in paracancerous tissues. We have found that Bcl-2 and Bax play a crucial role in the genesis of hepatoma. The higher expression of Bcl-2 and the lower expression of Bax suppressed apoptosis. These broke the balance between cell proliferation and apoptosis, and resulted in carcinogenesis. Bcl-2 protein blocks apoptosis by binding to and suppressing the action of Bax, a positive regulator of cell death. The expression of c-myc was higher in the carcinoma tissue than that in paracancerous, but no difference was seen as compared with each other. The result was similar to the report of Yang^[43]. The c-myc proto-oncogene, usually implicated in cell transformation, differentiation and cell cycle progression, also has a central role in some forms of apoptosis^[44,45]. These opposite roles of c-myc in cell growth and death require other gene products to dictate the outcome of c-myc expression on a cell. We thought that the higher expression of Bcl-2 could not effect cell proliferation, the higher expression of c-myc could improve cell proliferation. The paracancerous tissues may be in the precancer state. But the mechanism of regulating cell apoptosis is intact. The balance of cell proliferation and death was not broken, cell was still in normal state. The paracancerous tissues could become cancer following the enhancing of cell proliferation and the imbalance in regulating apoptosis. Bissonnette RP found that Chinese hamster ovary cell apoptosed due to the proliferation of c-myc gene, but it would be suppressed by Bcl-2 gene^[35], and cell would be in a balanced state of proliferation and apoptosis resulting from the appropriate expression of c-myc gene. The balance would be broken by some factors. A 'two signal' model emerges, in which c-myc can provide the first signal, leading either to apoptosis or proliferation, and certain growth factors may provide a second signal, to inhibit apoptosis and allow c-myc to drive cells into the cell cycle. Bcl-2 may substitute for the putative signal, as suggested by the abilities of Bcl-2 to delay apoptosis after growth-factor withdrawal and to cooperate with c-myc in transforming cells^[46]. In our study, no relationship was seen between the expressions of c-myc and Bcl-2 or Bax. We propose that c-myc activation affords the advantage of proliferation is essential for carcinogenesis, because the proliferative and apoptosis functions of c-myc are tightly coupled, it is impossible to select only for one without the other. In our study, the number of cases was insufficient to reflect the relationship.

Now, there are a lot of methods to detect apoptosis. But TdT-mediated dUTP nick end labeling method is the most accurate one^[47]. It could find the DNA broken in the early stage and accurate localization, so it is most accurate to reflect the status of apoptosis. Using this method, the apoptosis index of paracancerous tissue was 15.68%, which was higher than that of cancer tissues, 9.55%. There was no difference of apoptosis index between the positive and negative expression of Bcl-2. There was significant difference between the apoptosis index in Bax positive and negative group. We thought the balance of the expression of Bcl-2 and Bax may decide whether the cell is alive or dead. The isodipolymer with Bax and Bcl-2 could decide the protein molecules of active Bcl-2 or not. Bcl-2 could have different effects on inducing or inhibiting apoptosis. So isodipolymer Bcl-2/Bax is more accurate in reflecting the status of a poptosis. There were significant differences between the apoptosis index in cancer tissues and paracancerous tissues. It is valuable to study whether apoptosis index could become an index in judging canceration or not.

In conclusion, our study demonstrated that apoptosis plays an important role in the genesis of hepatoma, Bcl-2/Bax could reflect accurately the status of apoptosis. Apoptosis index was the most accurate index to reflect apoptosis, and may become an index for judging carcinogenesis. It is also valuable to study whether c-myc is affected by Bcl-2 and Bax expression.

INTRODUCTION

Hepatocellular transplantation (HCT) could provide a therapeutic alternative to orthotopic liver transplantation (OLT) in the treatment of hepatic metabolic defects and experimental hepatic failure^[1-4]. Under appropriate conditions, the engrafted liver cells can continue to express liver-specific functions for an indefinite period of time. The major limitation of many animal studies in HCT is that, since the donor hepatocytes are often indistinguishable from those of the host, it has often been difficult to demonstrate a clear correlation between engraftment and the therapeutic effect. In order to verify engraftment dependent on the therapeutic response, a recombinant retroviral vector carrying marker genes is used to label the donor hepatocytes^[5,6]. The vector is capable of transducing hepatocytes, integrating gene stably into the genome and directing expression. Efficient retroviral-mediated gene transfer has introduced the possibility of targeting genetic markers to hepatic cells and somatic gene therapy for liver diseases^[7-11]. Stable integration and expression of retroviral genes is dependent upon active division of the infected cell^[9-13]. Although hepatocytes maintain growth potential *in vivo* and are capable of substantial regeneration following partial hepatectomy, their ability to grow in culture is quite limited.

In the present study, we explored the optimal culture system for hepatocyte proliferation and the potential for retroviral-mediated gene transfer into primary hepatocytes. We successfully demonstrated the efficient and stable transduction of primary culture of adult rat hepatocyte by replication of defective retrovirus carrying β -gal gene and NeoR gene.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats weighing 140g - 200g were provided by Experimental Animal Center of Shanghai Second Medical University.

Sources

Hepatocyte-specific collagenase and culture medium were purchased from GIBCO-BRL (Gaithersburg, MD). Insulin, dexamethasone, transferrin, polybrene and epidermal growth factor (EGF) were Sigma Chemicals products (St. Louis, MO). 4CL-5Bt-3indolyl- β -galactoside (X-Gal) was purchased from Hua Mei Biotech Co. ³H-TdR was purchased from Neucleic Energy Institute. Tissue/cell DNA extract kit was purchased from Shanghai Hua Shun Biotechnical Limited Co. Culture plastic dishes were Nunclon Co product.

Isolation and culture of hepatocytes

Rat hepatocytes were prepared by the modified procedure of Seglen with a two-step collagenase perfusion combined with 49.5% Ficoll centrifugation^[14-15]. The dissociated cells were suspended in hormonally defined medium: M199 containing 10% fetal calf serum (FCS), 10⁻⁸M insulin, 10⁻⁶M dexamethasone and 5mg/L transferrin. They were seeded at a density of 3×10⁴ cells/cm² on a 35mm tissue culture plastic dishes, and grown at 37°C in a 5% CO₂ environment. The medium was changed 4h after seeding, and replaced by different culture mediums: group A with M199 containing 5% FCS, 10⁻⁸M insulin, 10⁻⁶M dexamethasone, 5mg/L transferrin; group B with M199 containing 5% FCS, 10⁻⁸M insulin, 10⁻⁶M dexamethasone, 5mg/L transferrin plus 10μg/L EGF. The medium was renewed every 24h thereafter.

Production of retroviral infected hepatocytes

PA317 cell line producing simultaneously the

recombinant retrovirus PGCEN/ β -gal expressing β -galactosidase gene (LacZ) and neomycin-resistance gene (NeoR) was a gift from Prof. Cheng Shishu (Human Genetic Therapy Research Center, SSMU). These two genes were controlled by the same promotor. Its structure is shown in Figure 1. The producer PA317 was maintained in DMEM supplemented with 10% FCS. Virus-containing medium was harvested from the producers after 16-20 hrs, filtered through a 0.45mm filter unit, and used for infecting the cultured hepatocytes. The viral titer ranged from 1 to 2×10^6 blue colony-forming unit (bcfu)/mL, when tested with NIH 3T3 cells.

Figure 1 Structure of bicistronic retroviral vector rPGCEN/ β -gal. Arrow below vector indicates initiated site of transcription.

Hepatocytes in group B were grown for 1 to 5 days. Three dishes were selected randomly at 24, 48, 72, 96 and 120 hrs. The medium was removed and rinsed with PBS. The cells were incubated for 6 hrs with 1mL of viral supernatant plus 8 μ g of polybrene per mL. Then the viral supernatant was cultured by replacing with fresh medium. Repeat the infection once a day for 24 to 96 hrs.

Detection of LacZ expression by X-Gal staining

Cells infected with PGCEN/ β -gal virus constitutively produced high levels of cytoplasmic β -galactosidase. In order to detect β -gal activity, infected hepatocytes were washed in phosphate-buffered saline (PBS) containing $\text{Ca}^{2+}/\text{Mg}^{2+}$, and fixed 5 min in 4% formaldehyde in PBS pH 7.4, rinsed again with PBS, then stained at 37°C with X-Gal (1g/L) for 2-24 hrs, as previously described^[16]. Blue precipitate in infected cells were seen under microscope. Areas of X-gal-stained rat primary hepatocyte culture dishes were quantitated for transduced cells using VIDAS computer-assisted image analysis. Three fields were randomly chosen and gene transductive efficiency was evaluated as follows:

$$\text{Gene transduction efficiency(\%)} = \frac{\text{Blue-stained cells areas}}{\text{Total cells areas}} \times 100\%$$

Measurement of hepatocyte DNA synthesis

In this assay, cells were cultured in absence or in presence of EGF for various durations. DNA synthesis was measured by ^3H -thymidine incorporation. Cultures in 35 mm-dish were treated with ^3H -thymidine (1 μ Ci/mL) for 5 hrs before harvest. Cells were detached by trypsinization at

37°C, washed with PBS twice and counted. The cells were lysed with distilled water. DNA were precipitated with 5% trichloroacetic acid and absolute ethanol, and collected on glass fiber-filters. DNA were then assayed for radioactivity in a liquid scintillation counter. ^3H -thymidine incorporation in DNA was expressed as cpm/ 10^5 cells.

Glucose-6-phosphatase activity by cytochemical procedure

Glucose-6-phosphatase activity was detected by the lead phosphate enzyme cytochemical procedure^[17]. Characteristic brown/black cytoplasmic staining was seen if cultured hepatocytes expressed glucose-6-phosphatase.

Detection of NeoR expression by molecular method

DNA from cultured cells was isolated by proteinase K digestion in 10mM Tris-hydrochloric acid (pH 8.0) and 1% sodium dodecyl sulfate at 55°C for 2 hrs, followed by phenol extraction and ethanol precipitation. According to the reference^[10], the primer was synthesized by Bioengineering Research Center in Shanghai of Chinese Academy of Science. The nucleotide sequences of NeoR primers were as follows:

Sense 5'CAAGATGGATTGCACGCAGG 3',
antisense 5'CCCGCTCAGAAGAACTCGTC3'790bp.

The total 50 μ L PCR reaction system consisted of 10 \times amplification buffer solution 5 μ L, 2.5mmol/L DNTP 4 μ L, 25mmol/L MgCl_2 3 μ L, 25 μ mol/L primer 2 μ L, reverse transcription product 10 μ L, and added ddH₂O up to 50 μ L mixing together, and added to *Taq* DNA polymerase 0.5 μ L after denatured for 5min. The amplification condition was predenatured at 94°C for 1min, 60°C for 1min, 72°C for 1.5min altogether for 30 cycles, finally, extension at 72°C for 10 min.

Ten μ L PCR product ran in agarose gel (1%, containing ethidium bromide 0.5mg/L) electrophoresis at 100 V for 40min and photographed under ultraviolet lamp.

RESULTS

Isolation and culture of hepatocytes

Each rat liver weighing 150-200 g was perfused by modified two-step collagenase via portal vein. The yield of hepatocytes was 1- 2×10^8 cells. The viability was over 95%. The cells were seeded at densities of 3×10^4 cells/cm² on 35mm dish. They became attached to the dishes in 3-4 hrs. Hepatocytes became polygonal epithelium-like structure. The majority of cells were mononucleated; some were bi-or multi-nucleated. The membranes were clearly seen. Hepatocytes started to divide in aggregates a few hours after

attachment and became confluent within 3-4 days (Figure 2).

Influence of EGF on hepatocytes proliferation in vitro

In order to compare the DNA synthesis in hepatocytes, the level of ^3H -thymidine incorporation in the cell layer was measured in EGF stimulated and unstimulated primary hepatocyte cultures. After the addition of $10\mu\text{g/L}$ EGF to the cultures, the level of ^3H -thymidine incorporation began to increase at 48hr of culture, and reached the peak on the 5th day. Fifty-nine-folds increase of ^3H -TdR incorporation was found in EGF-treated cultures compared to conventional cultures. The differences between the two culture conditions were statistically significant at 48, 72, 96 and 120 hrs ($P<0.01$). The addition of $10\mu\text{g/L}$ EGF to the culture increased 50 times incorporation at 120 hrs as compared with that at 24 hrs. There was also significant difference between the two time points (Table 1).

Table 1 Effect of EGF on DNA synthesis of rat hepatocyte by ^3H -TdR incorporation [cpm/(10^5 cell·h)]

Group	Time in culture (day)				
	Day 1	Day 2	Day 3	Day 4	Day 5
Group A	34±3	29±6	25±6	31±4	22±3
Group B	26±3 ^a	42±6 ^b	263±27 ^b	876±112 ^b	1287±215 ^{bc}

^a $P<0.05$, vs Group A; ^b $P<0.01$, vs Group A; ^c $P<0.01$, vs Day 1 of Group B.

Retrovirus transduction in cultured hepatocytes and detection of LacZ expression

Triplicate cultures of infected hepatocytes were analyzed *in situ* for retrovirus transduction and expression by cytochemical staining for β -galactosidase. Cells that expressed viral-directed β -galactosidase was exhibited specifically by this procedure. Although the proliferation of rat primary hepatocyte was limited, the highest rate of infection was obtained by adding EGF. The rate of infection was gradually increased on the first 4 days, reached the peak on the 4th day of infection, but transduction efficiency dropped gradually in cultures on the 5th day of infection. The transduction efficiency in repeated infection group was about 22% (Figure 3).

Expression of hepatocyte function

We used a liver-specific cytochemical stain to detect the functional hepatocytes. The expression of glucose-6-phosphatase was analyzed in culture at different periods by cytochemical staining. Characteristic brown/ black cytoplasmic staining was seen in >85% of the cells at 48 hr of culture. The activity was still present at a slightly diminished level in >60% of cells on the 6th day.

PCR detection of NeoR gene

Transduction with PGCEN/ β -gal was also assessed by PCR detection of NeoR gene. Analysis of PCR product showed that the amplified product with 790bp was visualized with ethidium bromide after electrophoresis in transduced rat hepatocytes, while this specific PCR product was absent in nontransduced primary rat hepatocytes (Figure 4).

Figure 2 Morphology of hepatocytes in culture. $\times 100$

Hepatocytes became polygonal epitheliumlike structure. The majority of cells were mononucleated; Some cells were bi- or multi-nucleated. The membranes were visible. Hepatocytes became confluent at 4 days postplating.

DISCUSSION

Two-step collagenase perfusion via portal vein is the conventional method for availability of hepatocytes, reports were available regarding cultured hepatocytes prepared by this method. In our present study a two-step collagenase perfusion in combination with 49.2% ficoll gradient centrifugation was used. This technique provided a higher yield of viable rat hepatocyte with a minimal nonparenchymal cells. It was helpful to culture hepatocytes *in vitro* and to perform various studies of hepatocytes, such as establishment of cell bank and retrovirus-mediated gene transfer.

It is generally considered that efficient transduction of retroviral gene is dependent upon active proliferation of infected cells^[9-13]. Although hepatocytes maintain growth potential *in vivo* and are capable of substantial regeneration following partial hepatectomy, the ability of adult hepatocytes to grow in culture without growth factors stimulation is limited^[18-25]. In this experiment, with addition of 10µg/L EGF to the conventional culture, the cells retained their ability to proliferate, and showed excellent hepatocyte morphology. We were able to demonstrate that these cells could divide in short-term culture, and could be infected with recombinant retrovirus.

Liver cell transplantation can support the impaired liver. If the transplanted cells exhibit a growth preponderance and specific liver functions, they will rapidly replace the patient's hepatocytes. Glucose-6-phosphatase is a well-recognized specific enzyme expressed by the hepatocytes. It can be detected in viable hepatocytes by cytochemical staining. In our experimental system, hepatocytes could be isolated and cultured under conditions that maximized the division of parenchymal cells and prolonged the expression of glucose-6-phosphatase activity more than 10 days. The labelled donor hepatocytes via transducing these cells with a recombinant retroviral vector carrying a marker gene is used for evaluating the fate and function of the transplanted cell *in vivo*. Our data demonstrate that recombinant retroviruses are efficient tools to transfer marker gene into rat primary hepatocytes. The rat hepatocytes proliferated increasingly under EGF stimulation, 20% of the cells could be transduced. Our experiments of ³H-TdR incorporation corroborate the observation of Chenoufi *et al*^[25]. We found that the cells had a high DNA synthetic rate that could be increased by adding EGF. In the first four days after plating, efficient transduction correlates positively with the state of proliferation ($r = 5.427$, $P < 0.05$). Transduction rate decreased after the fifth day. Thus, our results indicate that the susceptibility to retroviral infection of hepatocytes varies with the ability of the cell proliferation, functional status of hepatocytes such as the level of receptor expression and many other factors^[9-13].

retroviral vector was frequently used in gene therapy^[26,27]. Recombinant retroviral vector PGCEN/β-gal used in the present study is an bicistronic retroviral vector expressing β-galactosidase gene and NeoR gene simultaneously, because these two genes were connected by the internal ribosome entry site of encephalomyocarditis virus and controlled by the same promotor^[28]. Transduction efficiency was estimated by detection of β-gal gene expression by *in situ* staining, which was shown clearly and quantitatively. NeoR gene and target gene could be detected in the integrated cells from DNA level by PCR or southern blot^[29-31]. PCR method increased the sensitivity of detection, which is helpful in tracing the life span of transplanted cell *in vivo*^[30,31]. One study indicates that primary rat hepatocytes can be efficiently transduced by a NeoR and β-gal-expressing recombinant retrovirus (PGCEN/β-gal). This approach is now being used to determine the most efficient way of cell transplantation and to investigate the location, life span and function of the transplanted hepatocytes.

Effects of heat shock on change of HSC70/HSP68, acid and alkaline phosphatases before and after rat partial hepatectomy

Ai Ling Lu and Cun Shuan Xu

Subject headings partial hepatectomy (PH); liver regeneration; conserved heat-shock protein 70/induced heat-shock protein 68 (HSC70/HSP68); acid phosphatases; alkaline phosphatases

Lu AL, Xu CS. Effects of heat shock on change of HSC70/HSP68, acid and alkaline phosphatases before and after rat partial hepatectomy. *World J Gastroentero*, 2000;6(5):730-733

INTRODUCTION

Only the liver has the great capability of regeneration in mammal^[1]. Few hepatocytes are in the phase of division in the normal liver of an adult mammal (including human beings)^[2-4], but the remaining hepatocytes can be induced to proliferate quickly by partial hepatectomy (PH), and, to some degree, they stop dividing and re-differentiate into cells functioning as hepatocytes^[5,6]. This shows that liver regeneration is a delicate process in which the cellular dedifferentiation, multiplication and re-differentiation are regulated accurately^[7-9]. In the past decades, the liver regeneration of mammal has been regarded as one of the best model to study the restructuring and regeneration of tissues and organs, cellular multiplication, dedifferentiation, re-differentiation, stress response and regulation of physiology and biochemistry^[10-13]. Most studies of liver regeneration focus on observing the changes in cellular morphology, structure, physiology, biochemistry, metabolism^[14-16], separation and function of liver regeneration factors^[17-20], and how to initiate the regeneration of hepatocytes. However, there are few studies focusing on some biomacromolecules, e.g. heat shock proteins, proteinases, phosphatases, peroxidases in connection with the above. How these biomacromolecules affect liver regeneration is very worth studying. This paper reports some preliminary approaches regarding these aspects.

MATERIALS AND METHODS

Materials

Sprague-Dawley rats (Weighing 200g-250g) were provided by the experimental animal house of College of Life Science of Henan Normal University. Chemicals and reagents were of analytical grade, rat monoclonal antibody-1 HSC70/HSP68 (StressGen SPA-820) from anti-human HSC70/HSP68 combined specifically with 1-180 amino acids region of N-end of HSC70/HSP68 of humans, primates, rabbit, rat and ox; antibody-2 (Sino-American) was goat anti-mouse IgG-AP, S-P was marked by peroxidase (Sino-American).

Methods

Samples The rats were divided into groups at random (5 rats/group). In the first group (L): under ether anaesthesia, 2/3 of the liver was cut according to the method of Higgins^[21], and rats were made to recover for 2 h, 4 h, 6 h, 8 h, 10 h, 12 h, 16 h, 20 h, 24 h, 36 h, 48 h, 72 h, 96 h and 144h at room temperature. The second group (H-L): 2/3 of the liver was cut when recovered for 8h at room temperature (25°C) after heat shock (at 46°C for 30min), and then recovered as the first group. The third group (L-H): 2/3 of the liver was cut and recovered for 4h before heat shock (at 46°C for 30min), and then recovered as the first group. The rats were killed and bled by taking off the eyeballs. Liver was washed until it became white through coronary vein perfusion^[22], then put into the culture dish with icy physiological salt solution, and sheered into pieces for homogenating in the buffer (40 mmol/L NaCl, 20 mmol/L Tris-HCl, pH 7.5) at 4°C, and centrifugated for 10min at 12000×g. The supernatant was aliquoted and stored at -85°C.

Spectrophotometry of the activity of ACP and AKP

Homogenate 0.1mL was added to 0.4mL buffer (0.25 mol/L MgCl₂, 0.2 mol/L Tris-Cl, pH 7.5 for AKP; 0.35mol/L C₆H₇O₇Na·2H₂O NaOH-HCl, pH 5 for ACP), and 0.4mL 0.01mol/L β-glycerophosphoric acid sodium (0.4mL physiological salt solution as control), mixed and incubated for 30min at 37°C, added with 0.1mL 50% C₂O₂Cl₃ (trichloroacetic acid and homogenate

were added simultaneously for control), remixed, then added 2mL distilled water and 3mL reagent (3 mol/L H_2SO_4 : H_2O : 0.02 mol/L $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$: 0.6 mol/L Vit C = 1 : 2 : 1 : 1) mixed and incubated for 25min at 45°C , and cooled at room temperature. The photoabsorption value at 660nm was determined and the content of phosphate from standard curve calculated.

Qualitative analysis of HSC70/ HSP68 by stereologic method

According to Weibail^[23], five pieces of sections were counted at high power (5×10 and 5×40) for each sample, and the number of positive cells (P_{xi}) and total cell of detecting field of Vision (P_{ri}) counted separately. By the equation of $U_v = \sum P_{xi} / \sum P_{ri}$, the stereodensity of positive liver cells was calculated, the highest value was regarded as 100%, then statistic analysis was made.

RESULTS

Change of comparative content of HSC70/ HSP68 and activity of ACP and AKP in the first group

During the liver regeneration (0h - 144h), the activity of ACP was extremely strong at 4h and 48h and that of AKP was at 16h and the content of HSC70/HSP68 was at 96h. The change of AKP activity and heat shock protein content were almost consistent, however, the peak of ACP activity occurred ahead of 12h and 24h as compared with the two former ones correspondingly (Figure 1).

Figure 1 Change of the HSC70/HSP68 content, ACP and AKP activity in the first group.

Change of comparative content of HSC70/ HSP68 and activity of ACP and AKP in the second group

During liver regeneration after heat shock (0h-144 h), the activity of ACP and AKP changed almost consistently, which reached the peaks at 16h and 36h. Although the content of HSC70/HSP68 had three peaks (4h, 12h and 36h), the change was similar to that of ACP and AKP after 8h in liver regeneration (Figure 2).

Figure 2 Change of HSC70/ HSP68 the content, ACP and AKP activity in the second group.

Change of comparative content of HSC70/ HSP68 and activity of ACP and AKP in the third group

During liver regeneration (0h - 144 h), the activity of ACP was very extremely strong at 12h and 36h, and had the small peak at 72h. But AKP had three peaks at 12h, 36h and 96h, and that of HSC70/HSP68 content appeared at 36h and 48h. The change of ACP activity was similar to that of AKP, but it was negatively relative to that of HSC70/HSP68 -content (Figure 3).

Figure 3 Change of the HSC70/HSP68 the content, AKP and ACP activity in the third group.

Change of comparative activity of ACP in the three groups

The change of ACP activity was very similar in the second group (H-L) and the third group (L-H), but being different greatly from that of the first group (Figure 4).

Figure 4 Change of the ACP activity in the three groups (by spectrophotometry).

Change of comparative activity of AKP in the three groups

The change of AKP activity was very complex in the three groups, from 8h to 12h, AKP activity all went up; but, at 12h-48h, that of AKP in the first group was almost inverse to that of the other two groups; at 96h, they were proportional in the first and the second group, and negatively relative to that of the third group (Figure 5).

Figure 5 Change of the AKP activity in the three groups (by spectrophotometry).

Change of comparative content of HSC70/HSP68 in the three groups

The content of HSC70/HSP68 had two peaks at 16h and 96h in the first group, but at 12h and 36h in the second group, and at 16h and 48h correspondingly in the third group. Moreover, the content of HSC70/HSP68 was the lowest in the third group (Figure 6).

Figure 6 Change of the HSC70/HSP68 content in the three groups (by stereologic analysis).

DISCUSSION

The reversible regulation mechanism of phosphorylation and dephosphorylation and the irreversible regulation mechanism of protein degradation are regarded as two important ways which regulate the living action of cells^[24-27]. As we know, that a series of signal transductive pathways are activated and many proteins are phosphorylated and dephosphorylated are involved in promoting G₀-phase cell into cell cycle^[28-30]. In

the early phase of liver regeneration, the increase of phosphatase activities (ACP and AKP) can be related to G₀-phase cell into cell cycle. However, the peaks of ACP and AKP activity can be related to the two hepatocyte cycles (0 h - 36 h and 36 h - 96 h) and a non-hepatocyte cycle (96h - 114h)^[31] during the whole process of liver regeneration (0 h - 144h).

In the first group, the first peak of ACP and AKP activity appeared at G₁/S checkpoint and S-phase respectively. In the second and the third group, perhaps, because of heat shock, the peak of ACP was delayed, that of AKP was moved up, they all appeared at 12h, but the second peak of them were also consistent. It is supposed that heat shock can affect the synthesis of normal protein (including ACP). When cell can synthesize normal protein, some cells have entered into the first S-phase during liver regeneration, at which ACP and AKP may be synthesized simultaneously. That there were three peaks of AKP activity and the second and third peak just appeared at G₁-phase of liver regeneration are well worth further studying.

The family of HSP70 is known as molecular chaperone, which can help the new peptides to transfer, promote the new polypeptides to trim and to assemble in endoplasmic reticulum^[32-34]. Moreover, the family of HSP73 can recognize the polypeptides with KFEKQ sequence and combine them, and help the protein in cell transfer into lysosome to degrade^[35,36]. The process of liver regeneration with the synthesis and degradation of many proteins may need the family of HSP70. In recent years, the studies show that heat shock proteins play an important role in cellular differentiation, dedifferentiation and proliferation^[37,38]. The first peak of heat shock protein content reported in this paper was just at 12h-16h during liver regeneration, at which hepatocytes are in S-phase; the second peak was just the peak of non-hepatocyte in S-phase. When rats treated by heat shock before partial hepatectomy, the first peak of HSC70/HSP68 was delayed by 20h or so. These showed that heat shock may affect the expression of HSC70/HSP68. In contrast, treated rats by heat shock after partial hepatectomy, the peak of HSC70/HSP68 expression appeared at the same time as that of only partial hepatectomy group (at 16h), however, the content of HSC70/HSP68 in the former group was decreased by 40% than the latter. The results were consistent with that of two continuous treatment by heat shock done by Xu *et al*^[39].

In general, liver regeneration is a very complex physiological and physiochemical process. How on earth HSC70/HSP68, proteinase, ACP and AKP affect only and/or cooperately during liver regeneration should be further studied.

INTRODUCTION

Hepatitis B virus (HBV) is regarded as one of the main etiologic factors involved in the development of human hepatocellular carcinoma (HCC)^[1-20]. The open reading frame (orf) of X gene of HBV encoded a transactivating factor is the evidence that strongly supported the notion that the X gene of HBV DNA integrated in HCC genomic DNA could contribute to the carcinogenesis of liver cells by activation of some related cellular genes *in trans*^[8,9]. But it was found that the functional orf of X gene was absent in some HCCs harbouring HBV genomic DNA^[6-14]. However, the 3'-truncated preS/S sequence of HBV DNA, which also encodes a transcriptional transactivation factor, was found in all analyzed HCCs harbouring HBV genomic DNA^[20-27]. These findings indicate that transactivation of some cellular genes by the expression product of 3'-truncated preS/S sequence of HBV integrated in the genomic DNA of liver cells is a possible mechanism for HBV-associated oncogenesis^[11]. The transcriptional transactivity also can be produced in the cultured cells transfected with an artificial 3'-truncated preS/S gene of HBV genomic DNA^[1]. To explore the *in vivo* function of 3'-truncated preS/S region of HBV, we cloned the 3'-truncated preS/S region from wild-type HBV genomic DNA and constructed its expression vector for using in transgenic mice. Then, by using

pronuclear microinjection method, we obtained two transgenic mouse lines expressing 3'-truncated preS/S region from 15 new born mice. These transgenic mouse lines are helpful to identify the function of the expression product of 3'-truncated preS/S *in vivo* and the relationship between 3'-truncated preS/S and HBV-associated oncogenesis.

MATERIALS AND METHODS

Materials

Plasmids Vectors pBR322HBV carrying wild-type HBV genomic DNA and pBluescript were preserved in our laboratory. Expression vector pcDNA3.1, containing MCV promoter was provided by Dr. Yu Hong-Yu.

Cells *E. coli* DH5 α was preserved in our laboratory.

Animals C57BL/6 and BALB/c mice were preserved by our transgenic animal laboratory (SPF level). All mice were maintained on a 14:10 light-dark schedule (lights off at 10 pm, on at 8 am.).

Main reagents Restriction endonucleases, T₄ DNA ligase and DNA large fragment (klenow) polymerase were purchased from Promega company. QIA quick gene gel kit and plasmid extraction kit were from QIA gene. Anti-HBV preS1 kit was purchased from α - company.

PCR primers design and synthesis Primers were synthesized by Sangon. Positive primer: 5' GGCCAGA- GGCAATCAGGTAGGAGG 3', Negative primer: 5' TGGGTGAGGCAGTAGTCGG- AACAGG 3'. The primers are from 1607 to 1934bp of HBVadr genomic DNA sequence, containing 327bp. We also used the T₇ primer, upstream the positive primer.

Methods

Plasmid construction A 2.0kb fragment, containing 3'-truncated preS/S of HBV genome, was cut out of pBR322HBV digested with *Xba*-I and was subcloned into pBluescript, which was named pBluescript - *Xba* 2.0. The 3'-truncated preS/S region was obtained from pBluescript - *Xba* 2.0 digested with *Bst* E II and *xba* I. Its 3'-end was filled with klenow fragment and dNTPs, and inserted into *Bam* HI site of expression vector pcDNA3.1 which also filled, named pcDNA3.1 PreS/S. Restriction endonucleases digesting and sequencing were used to identify the construction.

Transgenic mice The pcDNA3.1-PreS/S DNA was purified and dissolved in TE buffer (10mM Tris-HCl, 0.2mM EDTA, pH 7.5) at a final concentration of 1mg/L (-2000 copies/pl). After pronuclear microinjection, the eggs were implanted into oviducts of pseudopregnant recipients to enable further development before term.

DNA isolation To isolate tail fragments from 10-day-old mice, approximately one third of the tail was cut and placed into a screw-capped 1.5mL microcentrifuge tube containing 500μL of TB buffer. The tubes containing the tail fragments were incubated overnight at 55°C. They were extracted once with 500μL of 1:1 (v/v) equilibrated phenylchloroform, and precipitated with 2 volumes of ethanol. After centrifugation, precipitates were resuspended in 500μL water.

DNA analysis The PCR amplification conditions were used with Taq DNA polymerase. For a 50μL reaction, mix the following components: 1μg template DNA, 0.5μL dNTP 10mm, 10u-Taq, 5μL PCR Buffer (10×), 41.5μL deionized water.

We use the following cycling parameters: initial denaturation at 94°C for 5min; followed by 35 cycles at 94°C for 30s; 58°C for 30s; and 72°C for 1min; and then final extension at 72°C for 7min. The products were run on a 2% agarose gel.

Expression analysis The 100μL of blood was extracted from the mouse developed from a microinjected eggs. After centrifuged in microfuge for 5min, the supernatants were isolated and analyzed by ELISA.

RESULTS

Clone of 3'-truncated preS/S and construction of its expression vector

The approximate 2.0kb fragment containing the preS/S was cloned from HBV genomic DNA, from which 3'-truncated preS/S region was cut out and subcloned into the expression vector pcDNA3.1, and then was identified by the restrictive enzyme and sequence analysis. The results showed that the structure was identical with our design (Figures 1 and 2).

Production of transgenic mice

The recombinant construct containing CMV promoter sequences fused to 3'-truncated preS/S region, which encodes a transcriptional transactivation factor, was microinjected into fertilized eggs from C57BL/6 mice. Of 243 microinjected eggs implanted into oviducts of 20 pseudopregnant recipient mice 15 developed to term and gave rise pups. However, only 7 of them survived and the others died within several hours after birth. DNA from the 7 mice were isolated and analyzed by PCR. It was found that 2 of them were positive for the injected transgene (Figure 3). Besides, we also noticed that the embryos from the microinjected eggs had a high miscarriage and mortality rate during the course of their development and growth in comparison with the experience in our laboratory.

Expression of 3'-truncated preS/ S gene in Transgenic mice

The serum samples were collected from the 2 mice harbouring the 3'-truncated preS/S region under the control of CMV promoter and the expression product of the recombinant gene in transgenic mice was analyzed by ELISA, in which the antibody against HBV preS1 was used as the first antibody. The results showed that 2 of them were positive for PreS1 (Table 1). Following the founders conformed, a series of expression analysis was carried out at different time points during the development. It was found that the 3'-truncated preS/S region could be stably expressed in the transgenic mice.

DISCUSSION

The full-length preS/S sequence integrated in nearly all HCCs can't show any trans-activity. However, one copy of the preS/S sequence with 3'-truncation could show a definite trans-activity^[1]. We constructed the expression vector of 3'-truncated preS/S gene, which can be expressed in cultured mammalian cells. So this vector should be very useful for exploring the biological function of expression product of 3'-truncated preS/S gene and for identifying whether 3'-truncated preS/S gene in HCCs is a causative factor of HBV-associated oncogenesis.

During the process of generating transgenic mice, the miscarriage rate and mortality rate seemed to be much higher than that in the producing transgenic mice harbouring other genes^[28-30]. This phenomenon indicates that besides the some common reasons for the death of transgenic mice there might be some other factors. It is possible that there are some effects of the trans-activation of the expression product of the 3'-truncated preS/S like those of the 3'-truncated preS/S integrated in HCCs of human being on the development of mouse embryos and its early growing of the pups after birth.

The 2 transgenic mouse founders could express 3'-truncated preS/S sequences stably. These results indicate that the 3'-truncated preS/S is integrated in their genomic DNA, which is similar to those existing in the HCCs of human being. So we believe that the 2 transgenic mouse lines can be employed as the model for exploring the *in vivo* function of the expression product of 3'-truncated preS/S and relationship between 3'-truncated preS/S and HBV-associated oncogenesis.

INTRODUCTION

Although several specific detecting methods had been applied to determine the hepatitis virus, there was a lot of cryptogenic hepatitis without any known hepatitis infectious marker^[1]. The prevalence of hepatitis G virus (HGV) (also known as GB-C virus) infection has been reported to be 5%-13% in patients with non-A-E hepatitis and cirrhosis, however, there is little evidence suggesting that HGV causes hepatitis in human^[2-6]. Although cryptogenic liver diseases are almost certainly related to a variety of etiologies, one or more as-yet-unidentified infectious agents are likely to account for a proportion of these cases.

In December 1997, a novel DNA virus was reported by Nishizawa *et al*^[7] to be associated with elevated aminotransferase levels in patients with post-transfusion hepatitis of unknown etiology (non-A-G hepatitis). This virus was designated transfusion transmitted virus (TTV). Then, Luo *et al*^[8] and Wei *et al*^[9] also detected TTV in the sera of patients from an outbreak of cryptogenic hepatitis in south China. And TTV was also detected in patients with post-transfusion hepatitis in China^[10]. In subsequent analyses, TTV is an un-enveloped single-stranded DNA virus for which a sequence of 3800 bases was determined^[11]. Evidence of potential hepatotropism of TTV was reported with TTV DNA detected in liver tissue^[12]. Histopathological study indicated that the characteristics of liver histology of TTV infected patients are portal inflammation and interlobular

bile duct damage^[13]. TTV was proposed as the part of causative agent of non-A to G hepatitis. Seroepidemiological studies have shown TTV to have global distribution^[12,14,15]. Although the potential association of TTV with cryptogenic hepatitis is intriguing, the pathological and clinical significance of this virus remains to be established. To assess more thoroughly the etiological role of TTV in the causation of hepatitis, we determined the frequency of TTV infections and their relationship to liver disease in several cohorts of liver diseases and rural population.

PATIENTS AND METHODS

Rural population

Nighty males and 89 females aged from 1 to 73 years were from a natural village with total population of 190 in southeast of Yunnan Province. Among them, 90 persons were of nationality of Han, others of Yi.

Patients with cryptogenic hepatitis

Forty-four patients with cryptogenic hepatitis were admitted in hospital between January 1993 and May 1999, with negative assays for sera marker of hepatitis virus A-E, and also negative assays for anti-nuclear antibody, anti-smooth muscle antibody, EB virus antibody, CMV antibody and anti-mitochondrial antibody. Part of patients were confirmed with liver biopsy suggestive of acute hepatitis.

Patients with HBV related chronic liver diseases

The prevalence of TTV infection was also determined in five cohorts of HBV related chronic liver disease: ① HBsAg asymptomatic carrier (AsC) ($n=52$); ② Chronic hepatitis B (CHB) ($n=46$); ③ Chronic hepatic failure ($n=40$); ④ Active liver cirrhosis ($n=39$); ⑤ Hepatocyte carcinoma (HCC) ($n=21$). The diagnosis accorded with diagnostic criterion of viral hepatitis in the Fifth Science Meeting of Infectious Disease and Verminosis (Beijing, 1995)^[16].

Nested PCR for the detection of TTV DNA

Evidence for TTV infection was determined by detection of TTV DNA by nested PCR. Nucleic acids were extracted from 100 μ L serum. TTV DNA was determined by PCR with nested primers described by Okamoto *et al*^[11] that sensitively detect TTV DNA, irrespective of different

genotypes, as well as by Ampli-Taq- DNA Polymerase. In brief, the first round of PCR was performed with RD038 primer (sense: 5'-TGA CTG TGC TAA AGC CTC TA-3') and NG059 (antisense: 5'-ACA GAC AGA GGA GAA GGC AAC ATG-3') for 35 cycles (94°C, 45 seconds; 54°C, 45 seconds; 72°C, 60 seconds [additional 7 minutes for the last cycle]), and the second-round PCR was performed with NG061 (sense: 5'-GGC AAC ATG TTA TGG ATA GAC TGG-3') and NG063 (antisense: 5'-GAC CGT AAA ATG GTA AAG GTT TCA-3') for 35 cycles with the same conditions. The size of the second-round PCR was 271bp. The amplicons were electrophoresed in 2% agarose gel, stained with ethidium bromide, and photographed under ultraviolet light. All assays were performed in an amplicon-free work area. Positive and negative

results were confirmed with repeated assays.

Direct sequencing of the amplicons

Direct sequencing of the amplicons was carried out by Cybersyn.

Statistical analysis

Prevalence of TTV infection (as measured by TTV DNA detectable in serum by PCR) in rural population and several cohorts of liver disease was determined. Data analysis was carried out using χ^2 test. And the liver function test of chronic hepatitis B was analysed using *t* test.

Prevalence of TTV infection (Table 1)

Table 1 Prevalence of TTV infection among study cohorts

Groups	TTV positive rate (n)	TTV negative rate (n)	Total
Rural population	10.61(19)	89.39(160)	179
Cryptogenic hepatitis ^a	38.63(17)	61.37(27)	44
HBsAg asymptomatic carrier	9.62 (5)	90.38(47)	52
Chronic hepatitis B ^b	15.22 (7)	84.78(39)	46
HBV related active liver cirrhosis ^c	22.5 (9)	77.5(31)	40
HBV related hepatic failure ^d	23.08 (9)	76.92(30)	39
Hepatocyte carcinoma ^e	9.52 (2)	90.48(19)	21
Total	16.15(68)	83.85(353)	421

^a $\chi^2 = 20.486$, $P < 0.005$ vs rural population; ^b $\chi^2 = 0.713$, $P > 0.25$ vs HBsAg asymptomatic carrier; ^c $\chi^2 = 0.749$, $P > 0.25$ vs chronic hepatitis B; ^d $\chi^2 = 0.853$, $P > 0.25$ vs chronic hepatitis B; ^e $\chi^2 = 0.000$, $P > 0.9$ vs HBsAg asymptomatic carrier.

Rural population

Nineteen of 179 (10.61%) unselected healthy peoples were detected TTV DNA positive. The prevalence of TTV infection was independent of sex, age and nationality (Table 2).

Table 2 The prevalence of TTV infection in a natural village in Yunnan Province, regarding of sex, nationality and age

Result	Sex ^a			Nationality ^b			Age ^c			
	Male	Female	Total	Han	Yi	Total	<14	14-55	>55	Total
TTV positive	7	12	19	8	11	19	5	13	1	19
TTV negative	83	77	160	82	78	160	47	102	11	160
Total	90	89	179	90	89	179	52	115	12	179
Prevalence(%)	7.8	13.5	10.6	8.9	12.4	10.6	9.6	11.3	8.3	10.6

^a $\chi^2 = 1.535$, $P > 0.2$; ^b $\chi^2 = 0.568$, $P > 0.4$; ^c $\chi^2 = 0.178$, $P > 0.9$.

Patients with cryptogenic hepatitis

The prevalence of TTV infection in patients with cryptogenic hepatitis was 38.63% (17 of 44). Two of the TTV-infected patients with fulminant hepatic failure, while the others with mild hepatitis.

Patients with HBV related chronic liver disease

The prevalence of TTV infection of AsC, CHB, ALC, CHF and HCC was 9.62% (5/47), 15.22% (7/39), 22.5% (9/31), 23.08% (9/30) and 9.52% (2/19), respectively. It seemed that the state of illness was related with the co-infection of TTV. However, there was no statistical difference between the prevalences (Table 1).

Effect on liver function test of TTV co-infection

While co-infected with TTV, the state of illness did not exacerbate in patients with CHB (Table 3). In patients with active liver cirrhosis and chronic hepatic failure, there were no significant differences in results of laboratory tests in patients with and without TTV DNA ($P>0.2$) whereas the co-infection of TTV increased the mortality of patients with hepatic failure ($P=0.038$).

Table 3 Effect on liver function test of TTV co-infection in patients with chronic hepatitis B

Liver function test	TTV negative	TTV positive	<i>t</i> value	<i>P</i> value
ALT(U/L)	347.0±286.5	282.3±230.2	0.523	>0.5
AST(U/L)	199.9±171.8	140.8±105.3	0.742	>0.2
Protein A/G	1.24±0.28	1.26±0.12	0.140	>0.5
TBil(μmol/L)	34.1±30.6	22.8±9.3	0.883	>0.2
Prothrombin (s)	17.7±5.5	15.6±1.53	0.783	>0.2

DISCUSSION

The recent discovery in Japan by Nishizawa *et al*^[7] of a novel parenterally transmissible, unenveloped, single-stranded DNA virus (TTV) in patients with non-A-G posttransfusion hepatitis had raised some important questions about TTV as a potential cause of liver disease.

Previous study indicated that TTV infection was common in healthy individuals, blood donors, HBsAg AsC, patients on hemodialysis and patients with various liver diseases, however played a minimal role on liver disease^[17-26]. Another paper suggested TTV may cause chronic hepatitis in a limited number of patients, but remains dormant most of the time^[27]. In our study, we found 10.61% of healthy individuals with normal liver function test were infected with TTV, and the prevalence was independent of sex, age and nationality. The result indicated TTV infection was common in healthy individuals. However, frequency of TTV infection in patients with cryptogenic hepatitis was significantly higher. As evidence of potential hepatotropism of TTV had been reported with TTV-DNA titers shown to be 10

to 100 folds greater in liver tissue than in serum^[11,12], TTV would account for part of the reason for patients with cryptogenic hepatitis. As we know that there are many HBsAg AsC, whereas HBV causes many hepatitises. This study suggested that the majority of individuals with TTV could be asymptomatic carriers, with only a small proportion of carriers actually developing hepatitis.

Generally, co-infection of hepatitis virus would lead to exacerbation of hepatitis. While co-infected with hepatitis A and B virus, patients encountered exacerbation of illness, with more severe abnormal results of laboratory tests and higher mortality^[28]. In histopathological evaluation, co-infection of hepatitis virus had no significant difference in development of liver cirrhosis^[29]. Previous study indicated that superinfection of TTV does not exert deleterious effects on the liver disease induced by HCV. Triple infection, HCV and TTV plus HBV or HGV, did not cause severe liver disease^[27]. In current study, prevalence of TTV infection in HBsAg AsC and patients with chronic hepatitis B, HBV related liver cirrhosis and chronic hepatic failure was 9.62%, 15.22%, 22.5% and 23.08% respectively. There was no significant difference among prevalence of TTV infection, suggesting the minor effect on liver disease of co-infection of TTV. The comparison of levels of ALT, AST, total bilirubin, A/G of serum protein and prothrombin time between TT virus-positive and-negative patients did not show any differences, as accorded with another report^[30]. However, TTV co-infection increased the mortality of patients with hepatic failure.

Most cases of chronic hepatitis, cirrhosis, and HCC in developed countries are caused by HBV or HCV infections and heavy alcohol intake. A relatively small proportion of liver diseases is of unknown etiology. The recently discovered HGV seems to have no actual role in causing acute or chronic liver disease^[31], whereas the role of the more recently discovered TTV is still to be defined. To inquire the relationship between TTV infection and HCC, we investigated the prevalence of TTV infection in HBV infected patients with HCC, and compared with HBsAg AsC. The result indicated similar prevalence in both cohorts (9.52% vs 9.62%, $P>0.9$), which did not support the hypothesis of an association between TTV infection and HCC, and accorded with previous studies^[32,33]. Another report indicated that TTV was not specific for HBV-negative and HCV-negative patients with HCC. For all TTV-positive patients, the TTV genome was not integrated into host hepatocyte DNA^[34]. In conclusion, TTV was common in general population and several cohorts of liver disease. Though the majority of individuals with TTV could be asymptomatic carriers, TTV would account for part of cryptogenic hepatitis. As TTV

co-infection did not affect the state of HBV infection, further study on pathogenic effect on liver disease of TTV infection should be continued.

INTRODUCTION

The etiopathogenesis of ulcerative colitis (UC) remains obscure, due to lack of an ideal animal model^[1-8]. With the improvement of theory and methodology in the last 30 years, people used to adopt chemicals (acetic acid, ethanol, carrageen, etc.), immunotechniques (humoral or cellular immunity, immune complex) and substance derived from UC patients to set up various kinds of UC animal model, which mimic the pathologic changes of human UC, so far these remain far from reality^[6-10]. A possible exception is the spontaneous colitis developed in the cotton-top tamarin when captured, but this animal is rarely available and expensive preventing its usage^[11]. Therefore, establishing an ideal animal model becomes the focus and key of the research study of UC. Nowadays, the models produced by 2,4-dinitrochlorobenzene (DNCB) and acetic acid (AA) came into use because of their simplicity and pathologic changes simulating those of human UC^[12-21], however, the characteristics of short course of DNCB method and absence of immunoreactivity in AA method, these two models are not ideal either. In the present study, we established a new rat UC model produced by combination of DNCB and AA, and observed the changes of general condition, the disease course, the pathology, ultrastructure, apoptosis, immunoreaction and intracolonic pressure, in order to develop a more ideal UC animal model.

MATERIALS AND METHODS

Materials

Eighty healthy male and female adult Wistar rats weighing 250g - 350g were used in this study. They were provided by the Department of Experimental Animal of our hospital, and were raised in the SPF environment (constant temperature, humidity and sterilized water, food and padding) and acclimatized to the surrounding for 7 days prior to the experiments.

DNCB (First Reagent Factory of Shanghai), AA (Dongtai Reagent Factory), CD₄, CD₂₉ and FITC or PE conjugated monoclonal antibodies (Immunotech, Marseilles, France), PC polygraf HR multichannel recording system (CTD-SYNECTICS Ltd), scanning electron microscope (EX1200, Japan), flow cytometry FACScan (Becton Dickinson Immunocytometry System).

Methods

Animal models Eighty Wistar rats were divided randomly into 4 groups, 20 each. Group A (DNCB + AA): after the nape hair was depleted by 10% Na₂S, DNCB acetone solution (20g/L) was dropped to the nape of the rats (0.3mL for each) once daily for 14 days, on the 15th day, nylon catheter (3mm in diameter) was inserted into the colon at the site of 8cm from the anus, and 0.25mL 0.1% DNCB, 50 mL/L 0.04 mol/L solution alcohol were infused, on the 16th day, 2mL AA solution (80mL/L) were infused into the same site for 15s, then 5mL normal saline (0.9%) was used to washout AA. Group B (DNCB only): from the 1st day to the 14th day, the method was similar to that for Group A, from the 15th day to the 18th day, 0.25 mL 0.1% DNCB (50 mL/L) alcohol solution (0.04mol/L) were infused into the colon at 8cm depth by the same nylon catheter once a day for each. Group C (AA only): 2mL AA (80mL/L) solution were infused into the colon at 8 cm depth by intracolonic administration with nylon catheter (3mm in diameter) for 15s, then 5mL saline for washing the AA. Group D (saline control): equivalent volume of normal saline was given in the method similar to that for Group A.

Pathological observation After the model had been established, the rats were killed at wk1, 2, 4, 8 and 16, and the distal colon (7cm-9cm) were removed longitudinally and washed to remove the luminal contents, tissues were fixed in 10% neutral-buffered formalin, dehydrated according to the routine, embedded in paraffin wax and sectioned.

Finally, the sections were stained with HE and observed microscopically. Apoptotic cells were identified morphologically^[22], for cell shrink age, chromatin condensation, formation of apoptotic bodies. Apoptosis was calculated randomly by counting the apoptotic bodies in the lamina propria for at least 200 cells^[22].

Electron microscopy The tissues were cut into small pieces (0.5mm in diameter) and fixed first in 2.5% glutaraldehyde buffered in 0.1M PBS (pH 7.2) at 4°C for at least 2h. The tissues were washed with the same buffer and then fixed in 1% osmium tetroxide in phosphate buffer at 4°C for 2h, dehydrated in graded series of acetone and embedded in epoxy resin 812. The ultra-thin sections were observed under EX1200 electron microscope.

Measurement of CD₄⁺CD₂₉⁺ Blood CD₄⁺CD₂₉⁺ were measured using flow cytometry according to our previous article^[15,23].

Colonic pressure and motility Intracolonic pressure and motility were measured according to our previous report through pressure transducer and recorded by PC Polygraf HR multichannel recording system^[24] (Figure 1). During manometry, the catheter lumen was infused with 0.9% saline at 0.2mL/min using a miniature hydraulic infusion pump. The baseline resistance of intra colonic pressure was set at zero. The catheter (outer diameter 3mm with 4 side holes for 4 channels) was inserted into the colon at 9cm depth from the anus without laparotomy, and was withdrawn at 1mm-2mm increment, and measurement was not started until 5min after the tip of the catheter dropped out into the rectum.

Statistical analysis The data were expressed as $\bar{x} \pm s$, and analyzed, using the Student's *t* test $P < 0.05$ was considered significant.

RESULTS

General condition and disease course Anorexia, bloody diarrhea, mucus in stools were seen in all A, B and C groups after 1 to 2 weeks, which lasted for 16 weeks in group A with weight loss and 8 weeks in group C, while in group B, the bloody diarrhea and mucus in stools decreased gradually and recovered 2 weeks later. No symptoms were observed in group D.

Pathological findings Diffuse hemorrhage, edema, congestion, superficial ulceration in the mucosa with infiltration of lymphocytes, plasma cells and polymorphonuclear cells, cryptitis, crypt abscess could be observed in all A, B and C groups (Figure 2), and these characteristics lasted for 16 weeks in group A and 8 weeks in group C while only 2 weeks in group B. In group D, the bowel wall was normal by

gross and microscopic examinations.

Ultrastructural changes There were decreased number of cells, shortened microvilli, swollen mitochondria with depleted ridge, maldevelopment of goblet cell and increased number of lysosomes during the acute phase (Figure 3), which recovered to normal gradually (Figure 4).

Apoptosis The apoptosis indexes, 9.9 ± 3.8 in group A, 8.6 ± 3.5 in group B, 8.1 ± 2.9 in group C, were significantly higher than those in group D (4.0 ± 2.1 , $P < 0.05$). Under scanning electronmicroscope, shrinkage of cells, condensation and margination of chromatin could be seen (Figure 5).

Immunoreactivity The changes of CD₄⁺CD₂₉⁺ in ulcerative colitis models were shown in Table 1.

CD₄⁺CD₂₉⁺ increased significantly ($P < 0.01$) in group A and B but not in group C and D 1 week after set up of model ($P > 0.05$).

Table 1 Changes of CD₄⁺CD₂₉⁺ in ulcerative colitis models (% , $\bar{x} \pm s$)

Group	n	Prior to set up of model	1 week after set up of model
A	20	5.01±2.01	11.17±2.18 ^b
B	20	4.95±1.87	10.98±2.87 ^b
C	20	4.93±1.96	5.06±2.03
D	20	4.76±1.56	4.91±1.93

^b $P < 0.01$ vs prior to set up of model.

Colonic pressure and motility One week after set up of the model in group A, the basal intracolonic pressure was apparently lower than that of the pre-model (proximal pressure: 0.78 kPa ± 0.13 kPa vs 0.88 kPa ± 0.14 kPa, distal pressure 0.76 kPa ± 0.11kPa vs 0.89kPa±0.15kPa, $P < 0.05$). The frequency of migrating motor complex waves *in vivo* were significantly faster 1 week after set up of the model as compared with that prior to (1.59/ min ± 0.27/ min vs 0.60/ min ± 0.12/ min, $P < 0.05$) in 7 rats of group A, this belonged to the pathologic colon of high dysrhythmia. The amplitude of migrating motor complex waves decreased markedly in 10 rats of group A after 1 week of post-model than that of pre-model (proximal pressure: 0.64 kPa ± 0.24 kPa vs 1.98 kPa ± 0.38 kPa, distal pressure: 0.92 kPa ± 0.37 kPa vs 2.45kPa±0.63kPa, $P < 0.01$), which belonged to asthenia colon. In the other 3 rats, while the proximal amplitude of migrating motor complex waves were lowered significantly (0.96 kPa ± 0.31kPa), the distal amplitude of migrating motor complex waves remained still higher (2.35kPa± 0.50kPa).

Success rate The ulceration pattern was present in all 20 rats of group A, the success rate therefore, could be considered 100%.

DISCUSSION

So far, the precise etiopathogenesis of UC remained unelucidated^[1,25-40], though experimental colitis had been produced by various methods mimicking human UC somehow, up to the present there is not one ideal animal model which conforms with human UC in pathogenesis, pathology and biologic behavior^[6-21,41,42]. An ideal animal model should fulfill the following requirements^[15,24]: ① it should reflect the histological characteristics of the diseases; ② it should be autoimmune in nature; ③ it should have the similar clinical manifestations as in human UC; ④ it should be simple and reproducible. In this study, the UC model produced by AA method was related to its chemical stimulation to the colonic mucosa^[12-14], which led to increment of vascular permeability and activate inflammation mediators, resulting in bloody diarrhea, mucus in stools and histological features as diffuse edema, congestion and ulceration, crypt abscess and mucosal infiltration of inflammation cells. It can be used to study the inflammatory mechanism and anti-inflammatory drugs^[43-45], but it lacked the immune response which is a drawback.

DNCB is a hapten, when bound with tissue proteins will be able to elicit immunologic response and induce colitis^[18-21]. The clinical symptoms and histological features, in particular $CD_4^+CD_{29}^+$ cells are similar to those of human UC, but the self-limited course of 2 weeks, is too short to be utilized as an ideal model.

In order to overcome these shortcomings we establish a new chronic UC model by using DNCB and AA in combination which has the following advantages^[15-17]. ① Clinically it manifests mucus in stools, bloody diarrhea and weight loss, just like those occur in human UC. ② It can reflect the pathologic characteristics of UC, such as continuous superficial colonic inflammation. Microscopically there exist mucosal edema and congestion, infiltration of lymphocytes, plasma cells and polymorphonuclear cells, crypt abscesses and ulceration. ③ It is an immune response model, immunology is well studied in UC^[1,46-49]. One of the important immunoregulatory abnormality in UC is related to the T cell response^[23,50]. CD_4 interacts with HLA class II molecules, CD_4 positive T cells can be divided into Th1 and Th2 cells whereas CD_{29} reacts with 130 KD integrin β_1 subunit which is expressed as a heterodimeric complex with one of six α subunits, forming the very late activation antigen (VLA) subfamily of adhesion receptors. The β_1 subunit has a broad distribution, and is expressed on lymphocytes, monocytes but weakly on granulocytes. These receptors are involved in a variety of cell-cell and cell-matrix interactions. Co-expression of CD_4^+ and CD_{29}^+ can be used as a marker to identify the Th1 cells subgroup, whose main function is to help B lymphocyte to induce

antibody production and cell-mediated dissolution^[15,23]. The increase of CD₄⁺CD₂₉⁺ can lead to highly activated B lymphocyte and immunoregulatory abnormality. In this test, CD₄⁺CD₂₉⁺ cells are significantly higher after the set up of models by combination of DNCB and AA, Which is in accord with the requirement of immune response similar to that in human UC. ④ It has a long disease course, if can last at least for 16 weeks with chronic damage of the bowel hence, eligible for the assessment of the drug effects. ⑤ The ultrastructural features are similar to those of human UC. The decreased number of epithelial cells and shortened microvilli, swelling of mitochondria with depletion of ridges can lead to impairment of water absorption of colon resulting in diarrhea. The maldevelopment of goblet cell, may lead to mucus in stools. ⑥ The above findings are not only consistent with the changes in human UC^[51-59], but also concordant with other reports^[60,61]. The model produced by combination of DNCB and AA is a more ideal animal model of UC. Apoptosis was first described by Kerr^[62] and is referred to as programmed cell death, which is genetically controlled. In active UC, injury is common. Did apoptotic cells increase in colonic epithelia which led to ulceration This hypothesis had been studied since 1996^[63-67]. Apoptosis of the normal colon was localized in the superficial epithelium, far less than one apoptotic body per crypt. In active UC, the loss of epithelial cells occurred mainly by apoptosis in crypts of involved and uninvolved adjacent areas, resulting in impairment of protective mucosal barrier. The mediators of apoptosis are partly related to the Fas/Fas-L interaction and/or changes in Bcl-2 expression. Our previous study demonstrated the number of apoptotic cells of colonic mucosal epithelial cells in human UC increased as shown by flow cytometry^[68]. This led to the damage of the barrier resulting in ulceration. Under scanning electron microscope, shrinkage of cells, condensation and margination of chromatin could all be seen.

The symptoms of diarrhea and abdominal pain are partly related with colonic motility disturbance^[69-75]. In this study, we first used PC Polygraf HR multichannel recording system to measure the intracolonic pressure and motility in physiological and pathological conditions from multiple sites over prolonged periods. The resultant signals were digitized, analyzed and displayed in a readily interpretable manner, and could be easily subjected to a variety of statistical manipulations, as the colon was situated within the abdominal cavity, the temperature, humidity and pH were maintained by the rats themselves, and not interfered by operative maneuver. In this study, UC rats are characterized by decreased intracolonic basal pressure and disturbance of frequency and amplitude

of migrating motor complex which may lead to the symptoms of urgency, diarrhea and abdominal pain. In conclusion, the new chronic UC rat model produced by combination of DNCB and AA is similar to human UC in clinical manifestations, histology, ultrastructural changes, immune response, apoptosis and colonic motility, and it is simple, inexpensive and reproducible with high successful rate.

INTRODUCTION

Epidermal-growth-factor receptor^[1] (EGFR) is a polypeptide with 1186 amino acids, which binds to EGF family growth factors. Two major natural ligands in the family interact with EGFR: one is EGF, the other is transforming growth factor- α (TGF- α)^[2]. When EGF or TGF- α , binds to EGFR, tyrosine kinase activity is induced which in turn triggers a series of events regulating the cell growth^[3-8]. The importance of EGFR in growth regulating pathways was confirmed by the fact that enhanced expression of this receptor was found in brain glioblastomas, breast, lung, ovarian, colorectal, and renal carcinomas^[9,10]. Elevated EGFR levels correlated with poor prognosis in human tumors^[11-17], for this reason, it seemed to be that EGFR would be a logical target for cancer therapy.

Previous reports had shown that monoclonal antibodies to EGFR were effective in the treatment of many human carcinoma cells^[18-20]. Other drug therapies which targeted the EGFR had also been successful. Kunkel had shown a drug that inhibited EGFR tyrosine kinase activity could inhibit the growth of A431 cells in nude mice^[10]. Yoneda also reported that selective inhibitors of EGFR tyrosine kinase activity, such as tyrphostins, could inhibit the growth of squamous carcinoma in nude mice^[21].

Antisense oligodeoxynucleotides inhibit gene expression on a highly selective and target sequence in a specific manner^[22-25]. Specific oligonucleotides hybridize to complementary mRNA and decrease protein expression^[26-29]. Antisense oligonucleotides against proto-oncogenes or growth factors had already been shown to be successful in cell

lines^[18,30]. For example, an antisense oligonucleotide to the erbB2 gene product had been shown to inhibit protein production in a breast cancer cell line^[31]. Akino reported inhibition of *in vivo* growth and metastases in malignant pituitary tumors with an antisense compound to the PTHrp (parathyroid hormone-related peptide)^[32]. An oligonucleotide to the c-myc gene inhibited the growth of thyroid carcinoma cell lines^[33]. Phosphorothioate antisense oligodeoxynucleotides targeted against human c-raf-1 kinase producing potent antiproliferative effects on cell culture and *in vivo* antitumor effects against a variety of tumor types^[34].

The co-expression of EGFR along with TGF- α in human colon cancer cell lines, also in colon carcinoma tissue, had led to the suggestion that the autocrine stimulation of EGFR by its ligands could be a mechanism for tumor cells to escape from normal growth controls^[35]. Previous studies in our laboratory confirmed over-expression of EGFR in HR8348 cells^[36]. In this investigation, we hypothesized that growth and proliferation of HR8348 could be inhibited by EGFR ASODN. In this report 15-mer EGFR ASODN was synthesized and the effects of EGFR ASODN on cell proliferation and tumorigenic rate of HR8348 cells were observed.

MATERIALS AND METHODS

Cell line

The liver metastasis of human colorectal cancer cell line HR8348 was developed by Zhang *et al*^[37] and cultured at 37°C in a humidified atmosphere containing 50mL/L CO₂ in RPMI1640 medium (Gibco) supplemented with 100mL/L heat-inactivated fetal calf serum (FCS), penicillin (50× 10³ units/ mL), and streptomycin sulfate (50mg/L) unless otherwise specified.

Synthesis of oligonucleotides

The AEGFR oligonucleotide sequence, 5'-CCGTGGTCATGCTCC-3' is complementary to EGFR cDNA 3811-3825, which contains the opal translation termination codon at residues 3817-3819. The control oligonucleotide sequence, a randomized phosphodiester 15-mer oligonucleotide with the sequence 5'-GCTGACGCACTGACT-3' (RC 15) is not complementary to any cDNA. Oligodeoxynucleotides were synthesized on an automated DNA synthesizer.

Formation of the lipid-ODN complex

ODN and liposome, Lipofectamine (Gibco-BRL), were each diluted to 0.1mL with RPMI1640 (serum and antibiotic free) and then mixed together, following the manufacturer's protocols. The lipid-

ODN complexes were used in gene transfection immediately after its formation.

Treatment of cells

To determine the effect of anti-EGFR oligonucleotides on HR8348 cell proliferation, MTT method was adopted. Forty μL HR8348 cells (1×10^4) in 96-hole culture dishes were treated at 37°C for 5h with either free or lipid-ODN mixture and then added 200 μL fresh medium with 100 mL/L fetal calf serum for a further 48h. At this point, the cells were washed twice with (serum free) RPMI1640, and RPMI1640 200 μL , added MTT (5g/L) 20 μL and the cells were incubated at 37°C for 4h, then added and quantified the DMSO.

Flow cytometry analysis

Cells of 0.8mL (1.5×10^6) were plated in 35mm tissue culture plates and added 0.2mL of the lipid-ODN mixture. The cells were incubated for 5h at 37°C , and then 4mL of RPMI1640 medium with 100mL fetal bovine serum was added for 48h, then cells were harvested, and analyzed for cell-cycle distribution by a FACScan flow cytometer.

Assay for tumorigenicity in nude mice

HR8348 cells (1×10^7) treated with or without ODN were injected subcutaneously in 6-week-old nude mice (Swiss nu/nu). The animals were monitored for tumor formation every week.

RESULTS

Antiproliferative activity of AEGFR on HR8348 cell line

A short exposure of HR8348 cells (5h) to the oligonucleotides was followed by an additional 3-day growth in maintenance medium with 10% FCS. MTT assay showed that treatment of HR8348 cells with liposome encapsulated AEGFR resulted in a 82.5% reduction in proliferation as compared with untreated cells, whereas RC15 group resulted in a 12.6% reduction in proliferation compared with untreated cells (Table 1).

Cell cycle assay

The HR8348 cells treated with AEGFR displayed an increased percentage of cells in the G_1/G_0 phase and a decreased percentage of cells in the S phase (Table 2).

Decreased tumorigenicity in AEGFR-treated HR8348 cells

The AEGFR cells displayed a marked inhibition on tumorigenicity rate in nude mice as compared with control cells (Table 3).

DISCUSSION

Colorectal carcinomas generally show a poor response to conventional chemotherapeutics^[38]. Several growth factors are involved in the control of colon carcinoma cell proliferation. In particular, the epidermal growth factor (EGF), transforming growth factor- α (TGF- α) and their receptor EGFR which are frequently overexpressed. EGF and TGF- α are structurally related peptides that stimulate DNA synthesis and cell growth. Both EGF and TGF- α recognize and compete the same cell membrane receptor (EGFR) through which they mediate their biological action. It has been recently demonstrated that autocrine secretion also exists in the human colon carcinoma tissue and which enables uncontrollable growth of the tumor cells. In the autocrine hypothesis^[39], the increased EGFR activity during tumorigenesis is attributed to autocrine stimulation by TGF- α . TGF- α produced by transformed cells acts on the cell surface EGFR to promote unrestrained cell proliferation. Being consistently amplified in human tumors of ectodermal origin, EGFR is shown to be an active factor in development and proliferation of neoplasia. Over-expression of EGFR can promote transformation of cells.

In this study, EGFR ASODN could inhibit the proliferation of human colorectal carcinoma cell lines. The antisense compound could also inhibit significantly the cell growth *in vivo* when compared to a scrambled oligonucleotide control. This inhibition is specific since the control oligonucleotide had no effect on cell proliferation and cell growth *in vivo*.

At this moment, we do not know the precise mechanism of inhibition. It could simply be that interfering with the initial step in the cell cycle or mRNA expression, disrupting the cascade of events leading to cell proliferation. The mechanism, however, could be much more complicated. The antisense compounds could decrease levels of cyclin-dependent kinases (CDK) which are essential to cell cycle progression. Treatment of human prostatic and colon carcinoma cells with EGFR antibody could decrease CDK levels resulting in G_1 arrest^[11,40]. Another possibility is that treatment with the EGFR antisense oligonucleotides induces apoptosis, a phenomenon observed in human colon carcinoma cells when the EGFR was blocked by its monoclonal antibody^[11,40].

Antisense oligodeoxyribonucleotides have

shown great efficacy in the selective inhibition of gene expression. In fact, antisense oligonucleotides directed against TGF- α , EGFR, are able to inhibit growth and transformation of several human carcinoma cell lines. These data suggest that the EGF-like growth factors and their receptors offer potential usefulness as targets for experimental therapy of human colon carcinoma. In our study, both cell growth and DNA synthesis of human colorectal carcinoma cell line HR8348 could be inhibited by EGFR ASODN, perhaps due to blockage of autocrine stimulation cycle of EGFR by its ligands. Cell cycle analysis indicated that with AEGFR-treatment, the proportion of cells in G₀/G₁ increased, and proliferation index (PI) was lower than that in the control group. This inhibition effect of cell proliferation by specifically repressing growth-receptor productions strongly indicated the presence of this autocrine hypothesis of tumor-cell growth.

Lipofectamine^[41] was cationic liposomes. Cationic liposomes represent synthetic genetic delivery systems that avoid the potential infectious complications of viral vectors. Due to its absence of cellular toxicity, convenience and high efficiency, liposome is used widely in gene transfection. It can provide a complex with a net positive charge that can associate with the negatively charged surface of the cell and it can be taken up by cells, and this method is useful for introducing large DNA molecules, oligonucleotides, and RNAs into mammalian cells. *In vivo* gene transfer with DNA-cationic liposome complexes has been proven to be safe to the host, low in cost and relatively easy in preparation, if can be used in the treatment of cancer.

This study demonstrates that it is possible to identify oligonucleotides which selectively inhibit the expression of EGFR by an antisense mechanism, provided that a careful search for optimal target sites on the mRNA is conducted and delivery of the oligonucleotides to cells in culture is facilitated by the use of cationic liposomes. These results warrant further assessment of the compounds in inhibition of cell growth *in vivo* and in their possible use as therapeutic agents in the treatment of human cancer.

Wang XJ, Yuan SL, Li CP, Iida N, Oda H, Aiso S, Ishikawa T. Infrequent *p53* gene mutation and expression of the cardia adenocarcinomas from a high-incidence area of Southwest China. *World J Gastroentero*, 2000;6(5):750-753

INTRODUCTION

Adenocarcinomas of the cardia are the lesions arising from the proximal stomach or within 3cm of the gastroesophageal junction^[1,2]. These cancers tended to be advanced at the time of presentation, usually with poor prognosis^[2]. In recent decade, the incidence of adenocarcinoma of gastric cardia and esophagus are increasing steadily, while there has been a decrease in the proportion of the cancers arising from the distal stomach^[3-8]. The biological and epidemiological features of the cardia adenocarcinoma were distinct from those arising from the distal stomach^[9,10]. The specific etiologic factors involved in the increasing incidence remained unresolved^[1,5-10].

Significantly higher levels of DNA aneuloidy^[11,12], *p53* protein expression^[1,12-17] and mutations^[1,18] have been reported in gastric cardia tumors, compared with tumors arising in the gastric antrum. *p53* expression may be used as a marker in the early detection of cardia adenocarcinoma^[2], mutations of *p53* gene at specific codons in human cancers may be an indication of specific exposure or genomic susceptibility^[14,15,19-22], and may serve as

a reporter gene reflecting exposure to specific carcinogen^[14,21-23]. The previous studies^[1,11-23] suggested that the mutation and functional inactivation of *p53* gene might play some important roles in the carcinogenesis of cardia adenocarcinomas etiologically.

In this study, the *p53* gene mutation spectrum and protein overexpression were investigated in the cardia adenocarcinoma from a high-incidence area of Southwest China, comparison of mutation spectra was made with those in cardia adenocarcinomas from other regions, some clues may be drawn to the etiology and carcinogenesis of cardia adenocarcinomas in the local area.

MATERIALS AND METHODS

Patients and samples

All 20 cases of cardia adenocarcinoma specimens were collected from patients surgically treated in Yanting County Cancer Hospital of Sichuan Province in Southwest China. Of all 20 patients, 17 (85%) were male, 3 (15%) were female, age ranged from 46 to 69 years (mean, 54.9 years). None had received any treatment before the operation; all patients were diagnosed as having cardia adenocarcinoma arising within the gastroesophageal junction^[2]. None was associated with Barrett's esophageal epithelium. All tissue specimens were routinely processed, formalin-fixed, and paraffin-embedded. Paraffin sections were stained with hematoxylin and eosin (HE) for histopathological examination, and were used for DNA isolation and detection of *p53* protein by immunohistochemical staining.

DNA isolation

The paraffin embedded blocks were sectioned at 10µm, attached to glass slides and used for genomic DNA isolation by means of Pinpoint Slide DNA Isolation System (Zymo Research, USA), according to the manufacturer's instructions. Briefly, a 1mm² area of cancer tissue with few other cells except cancer cells was localized on HE staining slides under microscopy in each case; the 10µm slides were de-paraffinized, rehydrated through graded alcohols and air dried. With reference to the HE staining slides of the same case, the PP solution was applied to the localized area of each case. After air dry for 30-45 min, the PP solution embedded tissues were peeled and removed from the glass slides, and added into the tubes

Received 2000-04-03 Accepted 2000-07-31

containing 50μL extraction buffer and 5μL proteinase K solution, then incubated at 55°C for 4 hours, heated at 95°C for 10min. The isolated DNA was further purified with DNA binding buffer and mini-spin column and PP wash buffer supplied by the manufacturer.

PCR and asymmetric PCR amplification

To amplify the DNA segments of exons 5-8 of p53, 100ng-200ng aliquots of template DNA were added in a total volume of 25μL- PCR reaction mixture containing 1×PCR buffer, 0.2mM of each dNTP (PE Applied Biosystems), 1μM of each primer and 2.0 units of AmpliTaq Gold DNA polymerase (Perkin Elmer). Initial denaturation at 94 was performed for 9min, followed by 50 cycles of 30 sec at 94°C, 30 sec at 52°C or 58°C (depending on the primers), 45 sec at 72°C and a final extension of 7min at 72°C. The primers used in this study covered the portions of exons 5 - 8 of the human p53 gene as described before^[24].

Twenty microliters of PCR products were run on a 2.0% agarose gel for examining the specificity of PCR reaction and DNA recovery, the specific bands were cut, recovered by Sprec-DNA Recovery Filter Tubes (Takara Biomedical, Japan), and purified according to the manufacturer's instruction. The recovered DNA fragments were used as templates for asymmetric PCR amplification. The two single-stranded DNA fragment of each exon were amplified with asymmetric PCR by using only one primer, respectively, except of the doubled primer, the conditions of asymmetric PCR were the same as those of the first PCR amplification.

DNA sequencing

Asymmetric PCR products were purified by alcohol precipitation, one fourth of purified product was used for DNA sequencing. DNA sequencing was performed by dideoxynucleotide method using the Thermo Sequenase cycle sequencing kit (Amersham, Life Science) and γ^{32} p-ATP (Amersham, Pharmacia Biotech). The sequence ladder was resolved in 7.0M urea and 6% polyacrylamide gel. After electrophoresis, the gel was dried in the Bio-Rad gel dryer before exposure to X-ray film for 6-12 hours at -70°C. When base changes were identified repeated sequencing of the same or complementary DNA strand was performed for confirmation^[19].

Immunohistochemical analysis of p53 proteins

P53 protein was detected immunohistochemically with the avidin-biotin-peroxidase method^[25]. Briefly, tissue sections were de-paraffinized and re-hydrated through graded alcohols. Antigen retrieval was performed by microwave oven heating in 0.1mM citrate buffer (pH 6). Then, endogenous peroxidase activity was blocked with 3% H₂O₂, and after treatment with normal serum, the sections were incubated with CM1 polyclonal rabbit p53 antibody (Novocastra, Newcastle upon Tyne, UK) at

a dilution of 1:500, overnight at 4°C, with biotylated second antibody 20min, and with avidin-biotin-peroxidase complex 20min at room temperature. Subsequently, the sections were subjected to color reaction with 0.02% 3, 3 diaminobenzidine tetrahydrochloride containing 0.005% H₂O₂ in PBS (pH 7.4), and were counterstained with hematoxylin lightly. In each staining run, a known p53 positive sample of colon cancer was added as a positive control, and a section of the same colon cancer tissue incubated in PBS instead of CM1 was included as a negative control.

Approximate percentage of p53 positive tumor cell nuclei in carcinoma were assessed and scored as follows: negative (-), <10% (+), 10% - 50% (++), >50% (+++); The intensity of staining in p53 positive cell nuclei was compared with the negative control and scored as follows: negative (-), weak (+), moderate (++), strong (+++)^[25].

RESULTS

p53 mutations in cardia adenocarcinoma

In all 20 cases of cardia adenocarcinomas, only 2 mutations (10%, 2/20) of p53 gene were detected in 2 cases. There were ATC-ACC, T to C transition in one occurred at codon 195 in exon 6 and CGC-AGC, C to A transversion in another at codon 283 in exon 8. Two were missense mutations. A representative mutation is shown in Figure 1.

p53 overexpression in cardia adenocarcinomas

All immunostainings for p53 protein were confined to the cell nuclei (Figure 2), the positive cell number varied from 10% to more than 50%; The intensity of staining ranged from moderate to strong. Seven out of 20 (35%, 7/20) were detected with p53 protein overexpression.

In addition, in 2 cases with p53 gene mutations, one was p53 protein-positive (96 - 236, codon 195: ATC-ACC); one was negative for p53 protein (96-237, codon 283:CGC-AGC). All paracancerous normal tissues were p53-negative. In 5 cancers with lymph node metastasis, 2 were p53-positive of both cancer and lymph node, and 3 were p53-negative in both tissues. The positive cases with p53 gene mutations and/or p53 protein overexpression are summarized in Table 1.

Table 1 The positive cases with p53 gene mutation and/or p53 protein overexpression in cardia adenocarcinomas

Patient No.	Exon	Codon	Nucleotide change	Amino acid change	p53protein expression
96-114	-	-	-	-	+++
96-123	-	-	-	-	+++
96-166	-	-	-	-	++
96-185	-	-	-	-	++
96-236	6	195	ATC-ACC	Ile-Thr	+++
96-237	8	283	CGC-AGC	Arg-Ser	-
96-270	-	-	-	-	++
96-432	-	-	-	-	++

The negative cases without p53 gene mutations and protein expression were not listed.

Figure 1 Results of sequence analysis of the *p53* gene in the cardia adenocarcinomas from a high incidence area of Southwest China, case 96-236 showed a ATC-to ACC mutation at codon 195 of exon 6.

DISCUSSION

The present study investigated the *p53* gene mutation and protein expression in a series of 20 cases of cardia adenocarcinomas from a high incidence area of Southwest China, the rates of *p53* mutation and protein expression were lower than those reported previously.

There were less reports of *p53* mutation and protein expression in cardia adenocarcinomas than those in other cancers (<http://www.irac.fr/p53/homepage.htm>)^[26], such as, hepatocellular carcinoma^[27-29], esophageal cancer and gastric cancer^[14,20-22]. Li *et al*^[30] detected *p53* mutations in 3 out of 4 cardia adenocarcinomas (3/4), 6 mutations were identified in exons 5-8 of *p53* gene in 6 out of 14 cardia adenocarcinomas (6/14, 42.9%) from Linxian, China, 3 were missense mutations, and 3 were non-sense mutations^[18]. Recently, a high *p53* mutation rate (63%, 26/41) in cardia adenocarcinomas from North Ireland was reported^[1]. As for the *p53* protein expression, the positive rates reported in cardia adenocarcinoma were 59% (24/41)^[1], 44% (11/25)^[2], 56% (20/36)^[12], and 76.5% (13/17)^[13], respectively. These results suggested that *p53* mutation and expression played an important role in carcinogenesis of cardia adenocarcinoma, and *p53* gene mutations reflected exposures to specific carcinogens in the

environment^[14,19,21-23].

Conversely, in our series, only 2 cases of *p53* gene mutation (10%) and 7 cases of *p53* protein expression (35%) were detected in 20 cardia adenocarcinomas from a high incidence area of China. It had been proposed that the comparison of *p53* gene mutation spectra in tumors of different origin might reveal similarities or differences concerning the endogenous and exogenous molecular processes contributing to tumor development^[24], and might reflect site-specific difference (cardia or antrum) or regional exposure to particular environmental agents^[31]. The results in this study suggested that *p53* gene mutation might play some role in some subset of cardia adenocarcinomas, but, it is not the major causation in carcinogenesis of gastric cardia in local area, or the risk factors in the local environment are different from those in other regions.

To the best of our knowledge^[1,18,26,30], the two mutations detected in the present study were rare in cardia adenocarcinomas. Mutation of *p53* gene at codon 195 from ATC to ACC was reported in ovarian cancer^[32], brain tumors^[33], lung cancers^[34,35], and adenocarcinoma of Barrett's esophagus^[36], etc.^[26]; Mutation at codon 283 was of polymorphism in previous studies: It was from CGC to TGC in hepatocellular carcinoma^[37] and colorectal cancers^[38], CGC to CTC in ovarian tumor^[39], CGC to GGC in lung cancer^[40,41], etc.^[26]. But, in this series, the mutation at codon 283 was from CGC to AGC, C:G-A:T transversion, no such a mutation was reported previously. It was further suggested that the environmental risk factors and their mechanism of actions in local area were different from those in other regions^[1,18,30].

The discordance between *p53* protein expression and *p53* gene mutation was noted in many other studies^[1,25,35], one case with *p53* gene mutation was negative for *p53* protein immunohistochemical staining in this study, since the frameshifts or non-sense mutations in the coding sequences of the gene might result in truncated or unstable forms, even non-expression^[25]. No mutations in exons 5-8 were detected in other 6 cases with positive *p53* protein, the possibilities to account for this apparent discordance might be: Firstly, the missense mutation lay in the region of the gene not screened in this study. Although *p53* gene mutations occurred frequently in the so-called 'hot-spot' region of exons 5-8^[35], a review of 50 studies that carried out sequencing of the entire coding region of *p53* gene reported that 13% up to 30% of missense mutations were located outside exons 5-8^[23]; Another possibility was that the mechanism other than mutations resulted in inactivation and stabilization of *p53* protein. Binding to viral oncoproteins, e.g. HPV E6, and cellular oncoproteins, e.g. mdm2, had been shown to result in *p53* stabilization and in the inactivation

of wild-type function^[41,42]. Our previous studies indicated that there was a high prevalence of HPV16 of esophageal cancer patients and health population in this high incidence area^[43,44]. In these instances, p53 overexpression represented the functional, but not the structural, inactivation of p53 gene^[1].

We conducted a preliminary investigation of p53 gene mutation and p53 protein expression in 20 cases of cardia adenocarcinomas from a high incidence area in Southwest China, to elucidate the etiology and carcinogenesis of cardia adenocarcinoma in the local area. The low p53 gene mutation and expression rates, and different mutation spectrum suggested that p53 gene mutation and functional inactivation might play some roles in the subset of cardia adenocarcinomas in this high incidence area. Besides p53 gene abnormalities, there might be some other environmental risk factors and other genetic abnormalities contributing to the high incidence of cardia adenocarcinomas in this area, which deserves further investigation.

Shen XZ, Chow JFL, Koo MWL, Cho CH. Gene expression profiles in gastric mucosa of sleep deprivation rats. *World J Gastroentero*, 2000; 6(5):754-758

INTRODUCTION

Stress has been shown to induce gastric mucosal lesions and lower the effectiveness of the mucosa as a barrier^[1-6]. In rats, gastric ulcers can be produced by cold-restraint stress^[7-9] and it is frequently employed as a model for the study of the mechanisms of stress on ulcer formation. Cold-restraint stress however is not normally encountered in human subjects while sleep deprivation is a common experience among city dwellers, night shift workers and medical professionals. It imposes stress on the body, and produces a variety of health problems^[10-14]. Sleep deprivation may affect the epithelium linings of the gastrointestinal tract, because stress been demonstrated to produce gastric mucosal lesions in rats^[15,16]. Although various factors has been proposed to account for this process, the precise mechanism of how sleep deprivation to affect the gastric mucosa barrier, especially at the molecular level, still remains unclear. In this project we observed the effect of sleep deprivation on the defensive factors of gastric mucosa, and used cDNA expression arrays to identify genes expressed abnormally in gastric mucosa of sleep deprivation rats.

MATERIALS AND METHODS

Rats and reagents

Male Sprague Dawley rats weighing 180g - 200g were used in the experiments. They were housed in a temperature (22°C + 1°C) and humidity (65% -

70%) controlled room with a day night cycle of 12 hours. The rats were given standard laboratory diet (Ralston Purina Co. Chicago, IL) and tap water *ad libitum*. Rats were starved for 24 hours and water withdrawn 1 hours prior to any oral or intragastric administration of agents in order to obtain an uniform distribution of those agents onto the gastric mucosa. All chemicals used in this study were purchased from Sigma Chemical Co. (St. Louis, USA) unless specified otherwise. The present study has been examined and approved by the Committee on the Use of Live Rats for Teaching and Research of the University of Hong Kong.

Sleep disturbance

Rats for sleep disruption were placed inside a computerized rotating drum while the control animals were left undisturbed in a stationary drum. The drum was rotated 180° in 30s at 5min intervals and was programmed to switch off for 1h every day at 1:00 p.m. to allow for an hour of undisturbed sleep. Sleep disturbance was continued for 1wk before the animals were killed and the organ weight was determined. Daily water and food consumption as well as the body weight was recorded throughout the whole experimental period.

Ethanol-induced gastric mucosal damage

Rats were starved for 24h before 1mL of 500mL/L ethanol was administered orally to induce acute gastric mucosal damage^[17]. Rats were killed 2h later by a sharp blow on the heads followed by cervical dislocation. The stomach was removed and opened along the greater curvature. The gastric lesion area (mm²) was traced onto a glass plate and subsequently measured on a graph paper with 1mm² divisions. The total lesion lengths divided by the number of rats in each group was expressed as the mean ulcer index^[18].

Cold-restraint-induced gastric mucosal damage

Rats were put inside the close-fitting tubular wire-mesh cages and restrained inside a cold room for 2h. At the end of the experimental period they were killed and stomachs prepared for ulcer measurement as described previously^[18].

Collection of gastric mucosa

Rats were killed by ether anesthesia followed by cutting off the abdominal aortic artery. The stomachs were removed rapidly, opened along the

greater curvature, and rinsed with cooled normal saline thoroughly. A longitudinal section of gastric tissue was taken from the anterior part of the stomach and then fixed in 100mL/L buffered formalin for 24h. It was cut into sections of 5 μ m and then used in histological examination. Gastric mucosa was taken from the remaining part of the stomach by scraping with a glass slide on a glass dish on ice. They were wrapped by a piece of aluminum foil, immediately froze in liquid nitrogen and stored at -70°C until assayed.

cDNA expression arrays^[19-24]

Total RNA for cDNA expression arrays was isolated from the gastric mucosa of rats by using the Atlas™ Pure Total RNA Isolation Kit (CLONTECH Laboratories, Inc. CA. Cat.#: K1038-1). cDNA was synthesized and radioactive labeled using 5 μ g total RNA from sleep deprivation rat and normal control rat according to standardized protocols (CLONTECH Laboratories, Inc. CA. PT3140-1). Atlas™ cDNA Expression Arrays (CLONTECH Laboratories, Inc. CA.) was used for differential expression screening. Each Atlas Array includes 588 of cDNA spotted in duplicate on a positively charged nylon membrane. Plasmid and bacteriophage DNAs are included as negative controls to confirm hybridization specificity, along with several house keeping cDNA as positive controls for normalizing mRNA abundance. After a high-stringency wash, the membranes were exposed to X-ray film (Kodak BioMax MS film Cat.# 118 8077) at -70°C with an intensifying screen for 3d. The gene expression pattern of 588 genes in gastric mucosa of normal and sleep deprivation rats was analyzed and compared on a computerized densitometer. Signals that genes were absent or present on one of the two membranes were identified visually.

Statistics

The data were statistically analyzed with the unpaired two-tailed Student's *t* test.

RESULTS

Effect of sleep deprivation on body weight

Sleep disturbed rats had the same water and food consumption when compared with the control however there was a slower increase in the percentage (%) of body weight among the sleep disturbed animals (Table 1). The decrease in % body weight gain was observed as early as 2d after sleep disturbance, and after that they gain in weight; although slower; but in a parallel fashion to that of the control (Table 1, all values at $P<0.05$). Sleep disturbance induced a significant increase in adrenal weight (240 μ g/g \pm 8 μ g/g body weight) when compared with the control (215 μ g/g \pm 6 μ g/g body weight). There was no difference in weights for the thymus and spleen between the two groups.

Effect of sleep deprivation on cold-restraint stress induced gastric ulceration

After rats were restrained in 4°C for 2h, the ulcer index in gastric mucosa of sleep deprivation rats (41.7mm² \pm 8.3mm²) was significantly higher ($P<0.01$) than it in control rats (Figure 1). The results indicated that the sleep disturbance aggravated cold-restraint stress induced gastric ulceration.

Effect of sleep deprivation on ethanol induced gastric ulceration

After the 500mL/L ethanol challenge, the ulcer area found in the rats with 7d sleep deprivation (19.15mm² \pm 4.2mm²) was significantly lower ($P<0.01$) than the corresponding control (53.7mm² \pm 8.13mm²), as shown in Figure 2.

cDNA expression array

Figure 3 shows the result obtained by hybridizing two cDNA array membranes with radioactive-labeled cDNA from gastric mucosa of control normal rat and from gastric mucosa of 7d sleep deprivation rat. More than 10 differentially expressed genes were found in total 588 genes, most of them were digestive enzyme related genes, one of the overexpression gene in the gastric mucosa of sleep deprivation rat was identical to that of inducible heat shock protein 70.

Figure 1 Effect of sleep disturbance on cold-restraint stress induced (4°C for 2h) gastric ulceration in rats. Values are means \pm SEM of 12 rats in each group; ^b $P<0.01$, vs control group.

Figure 2 Effect of sleep deprivation on ethanol induced (500mL/L ethanol 1mL p.o. for 2h) gastric ulceration in rats. Error bars represent SEM, $n=10$ for each group. ^b $P<0.01$, vs control group.

Figure 3 cDNA array: Differential gene expression in gastric mucosa of normal control rat (A) and sleep deprivation rat (B).

Sleep deprivation may decrease the following genes expression (Arrow 1-6): 1: bile-salt-stimulated lipase; 2: pancreatic lipase related protein 2 precursor; 3: triacylglycerol lipase precursor; 4: elastase 2 precursor; 5: trypsinogen II; 6: chymotrypsinogen B precursor, and increase the following genes expression (Arrow a-c): a: low-density lipoprotein receptor precursor; b: glucose transporter type 1; c: transferrin receptor protein. The dot for over expressed inducible heat shock protein 70 gene is circled.

Table 1 Effect of sleep disturbance on the percentage gain in body weight

Groups	Percentage gain in body weight						
	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7
Control	7.2±2.6	14.4±2.2	18.3±2.4	23.9±2.2	28.5±3.1	33.1±3.6	37.7±3.2
Sleep disturbed	4.8±2.5	7.7±2.3 ^a	10.5±2.3 ^a	16.2±2.5 ^a	19.9±2.4 ^a	24.6±2.7 ^a	27.2±3.1 ^a

Values are means±SEM of 12 rats in each group; ^a*P*<0.05, vs control group.

DISCUSSION

In this experiment a rotating drum was used to produce sleep disturbance in rats and it was found to be an effective model for stress induction. Sleep disturbed rats had a smaller percentage gain in body weight and this was observed 2d after sleep disturbance. This suppressive effect was not intensified after d2 and the sleep deprived rats gained in weight in a fashion paralleled to that of the controls. The statistical differences between all values of percent age gain in body weight were maintained at *P*<0.05 level (Table 1). The slowing of weight gain was not due to a reduction in food intake as there was no difference in food and water consumption between the two groups. This may be the result of an increase in catabolic process that was generally observed in sleep deprived animals^[25-27].

It has been found that sleep disturbance aggravated cold-restraint stress induced gastric ulceration (Figure 1). The aggravation may be the result of lowered effectiveness of the mucosal barrier. Cold-restraint stress has been shown to produce blood stagnation in the gastric mucosa^[25], and sleep disturbance imposed psychological stress on the rats as was demonstrated by an increase in the adrenal weight. The increase in adrenal weight could be due to the activation of the hypothalamus-pituitary-adrenal axis producing an overstimulation on the adrenal glands^[28-31]. All these factors may

lead to the decrease in basal gastric mucosal blood flow and affect the defensive function of gastric mucosa. Results of this experiment indicated that the sleep deprivation did not aggravate the 500mL/L ethanol induced gastric ulceration as expected, on the contrary, it did show some protective effect for ethanol challenge.

The human genome project's large-scale sequencing efforts have generated partial sequence data for thousands of genes. Although many of these genes have been assigned to functional classes, the roles they play in various biological processes have yet to be elucidated. An important step toward understanding these roles is defining gene expression profiles, i.e. comparing patterns of expression in different tissues and developmental stages, in normal and disease states, or in distinct *in vitro* cell conditions. This can be accomplished using RT-PCR, RNase protection assays, Northern blot analysis, *in situ* hybridization, immunohistochemistry or Western blotting^[32-44], but these methods focus on only a few genes at a time. A more promising approach for analyzing multiple genes simultaneously is the hybridization of entire cDNA population to nucleic acid arrays. This technology has a wide range of application, including investigating normal biological and disease processes, profiling differential gene expression, and discovering potential therapeutic and diagnostic drug targets^[19-24]. In this experiment, for further

investigation the reason why sleep deprivation protect gastric mucosa from ethanol insult, cDNA arrays were used to search for genes that were differentially expressed in gastric mucosa of sleep deprivation rats compared to gastric mucosa of control rats. More than 10 differentially expressed genes were found in total 588 genes (Figure 3), most of these were digestive enzyme related genes, one of the overexpression gene was inducible heat shock protein 70 gene. A variety of chemicals, viruses, and noxious stimuli such as trauma, hypoxia, or ischemia trigger the heat shock response and the subsequent synthesis of heat shock proteins^[45-47]. Substantial evidence showed that heat shock is capable of protecting cells, tissues, organs, and animals from a subsequent, normally lethal heating, as well as from other types of noxious condition^[48]. The protective effect of heat shock is likely mediated by overexpressed heat shock protein 70, because there is a lag between heat shock and the development of protection correlated with the production of heat shock protein 70, and protection is affected when heat shock protein 70 production is inhibited by treatment with inhibitors^[49-51]. The overexpression of heat shock protein 70 was reported to protect guinea pig gastric mucosal cells from ethanol damage^[52]. In conclusion, sleep disturbance imposed psychological stress on the rats as was demonstrated by decreasing body weight gain and increasing in the adrenal weight. Defensive function of the gastric mucosa was weakened by sleep deprivation thus predisposing it to ulcer formation induced by cold-restraint stress. On other hand, sleep deprivation decreased ethanol induced mucosa damage. This protective effect may be mediated by over expression of inducible heat shock protein 70 in gastric mucosa. Our experiment also showed that the cDNA arrays are the powerful approach to rapidly identify the gene expression profiles.

Xu CD, Chen SN, Jiang SH, Xu JY. Seroepidemiology of *Helicobacter pylori* infection among asymptomatic Chinese children. *World J Gastroentero*, 2000;6(5):759-761

INTRODUCTION

Increasing data has demonstrated that *Helicobacter pylori* (*H. pylori*), a spiral gram negative bacterium, colonized in human stomach, can cause type B gastritis^[1-3], is strongly associated with gastric and duodenal ulceration^[4-6], and has been implicated in the causation of gastric carcinoma^[7-9] and mucosa-associated lymphoid tissue (MALT) lymphomas^[10-11]. It has been reported that there is relationship between *Helicobacter pylori* infection and children's gastroenterologic disease, the most convincing evidence of the role of *H. pylori* in peptic ulcer disease is provided by studies showing that recurrence rate of ulcer is markedly reduced by eradication of the bacteria from the gastric antrum^[12-15].

Recent partly retrospective epidemiologic study in adults suggested that *H. pylori* infection mainly occurred during childhood^[16-18], and its actual colonization in gastric mucosa would be determined by many factors during childhood^[19-21]. In the previous studies, we have demonstrated that the prevalence of *H. pylori* infection of children with gastrointestinal disease is high^[22]. Therefore, children are considered to be the highest risk population.

This study was undertaken to determine the prevalence of *H. pylori* infection, among asymptomatic Chinese children, and its relation with the socioeconomic status of their families.

MATERIAL AND METHOD

Study subjects

Of 1119 children aged 7 - 14 years from three primary schools (one public school in rural area, one private school and another public school in urban area) in Shanghai, China, 568 are male and 551 are female.

Sample collection and methods

A questionnaire was given to the parents of all children. The questionnaire gathered sociodemographic information, parent occupation and life habit including feeding habit for children, and information on household density (number of adults, children and rooms, not including bathrooms, toilets, and small kitchens).

A serum sample (1.5mL) was obtained from each subject and stored at -20°C and assayed in batches for *H. pylori* IgG antibodies using a commercial enzyme linked immunoadsorbent assay (ELISA), Helico Bio-Rad GAP IgG kit. Using these criteria, the sensitivity of the ELISA is 100% with specificity of 92%.

Statistical analysis

Data were analyzed using the statistical package of SAS. The prevalence of *H. pylori* infection in different age was assessed using the χ^2 test. Differences with *P* values lower than 0.05 were considered statistically significant.

RESULTS

H. pylori seroprevalence in asymptomatic children

Questionnaires were returned from 1119 subjects, aged 7-14 years. Serum *H. pylori*-IgG antibodies of 1119 children were measured by ELISA method and showed that 458 children were *H. pylori* seropositive (40.93%). Two hundred and fifty-eight of 568 boys were positive (45.42%) and 200 of 551 girls were positive (36.38%). Seroprevalence of *H. pylori* for boys was significantly higher than that of girls (*P*=0.002).

The age and seroprevalence rates of *H. pylori* infection are summarized in Table 1. From Table 1 we can see that seroprevalence of *H. pylori* increased significantly with age, the mean increasing rate being 3.55% per year from 7-11 years of age.

Table 1 Prevalence of *H. pylori* infection of children aged 7-12 years

Age (year)	No. of samples	No. of positive samples	Rate(%)
7	165	51	30.91
8	146	51	34.93
9	167	65	38.92
10	167	77	46.11
11	226	110	48.67
12	167	79	47.30
Total	1119	458	40.93

***H. pylori* prevalence in rural and urban area**

One hundred and seventy-one of 543 children living in urban area, and 287 of 576 living in rural area were positive. Seroprevalence rate with reference to age and distribution (rural and urban) are shown in Table 2. The overall prevalence in rural area was significantly higher than that in urban area.

***H. pylori* prevalence in different families**

Prevalence of *H. pylori* in children lived in different families is shown in Tables 3 and 4. These results showed that *H. pylori* seropositivity rate was significantly higher in children whose parents were engaged in manual occupations than in children whose parents with non-manual occupations.

Table 2 Comparison of community distribution in asymptomatic children with *H. pylori* infectionV

Age (year)	Urban			Rural			P value
	No. of samples	No. of positive samples	%	No. of samples	No. of positive samples	%	
7	88	21	23.86	77	30	38.95	0.036
8	69	11	15.94	77	40	51.95	0.001
9	90	33	36.67	77	32	41.56	0.518
10	83	32	38.55	84	45	53.57	0.052
11	92	40	43.48	134	70	52.54	0.195
12	40	9	22.50	127	70	55.12	0.001

DISCUSSION

The epidemiology of *H. pylori* infection in human is interesting, particularly in regard to gastroduodenal disease associated with gastric colonization by the organism. But most epidemiologic studies of *H. pylori* infection have been performed in adults^[7,18]. Data on the incidence of *H. pylori* infection in children are limited^[23-26]. These factors such as age, socioeconomic level and living conditions, especially during childhood, have been considered to be important determinants in the acquisition of the microorganism. In developed countries the prevalence of *H. pylori* infection among children is low, in contrast to what is observed in developing countries, where most children are infected by the age of ten. In seroprevalence studies from western

Australia^[27] and Canada^[28], *H. pylori* was predominantly acquired in childhood. In addition, individuals born in an earlier birth year had a higher risk of acquiring *H. pylori* than those born in a later one. In a study from Toronto *H. pylori*-specific IgG serum antibodies were identified in 74% of parents and 82% of siblings of children with culture-proved infection^[29]. In the same study, seroprevalence in the control group was 24% and 13% for parents and children, respectively. Clustering of *H. pylori* infection among families suggested that acquisition of the infection in childhood might be due to the transmission from person to person.

The present study has shown that *H. pylori* infection rate of Chinese asymptomatic children is high. The mean infection rate of *H. pylori* of 1119

subjects aged 7-14 years is 40.93% and 45.42% among boys and 36.38% among girls. Infection rate in boy is significantly higher than that in girls ($P=0.002$). This result is different from the data of small sample that we reported previously (no difference in sex). Our results showed that seroprevalence of *H. pylori* increased significantly with age in asymptomatic children, *H. pylori* infection rate is 30.90% in children aged 7 years; 34.93%, aged 8 years; 38.92%, aged 9 years; 46.11%, aged 10 years; 48.67% aged 11 years; and 47.30% aged 12 years. The prevalence rates were similar to that reported by Pelsler^[30].

Our results also showed that *H. pylori* infection of Chinese children is influenced by many factors such as socioeconomic status, hygienic condition, cultural level, life habit particularly non-separate feeding, etc. The prevalence of *H. pylori* in rural area is higher than that in urban area (49.83% vs 31.48%, $P=0.001$). There is an inverse relationship with the socioeconomic status of the family. *H. pylori* infection rate of children is not the same in different families. It was 47.93% in worker's family, 43.90% in peasant's family, 32.74% in intellectual family, and 30.43% in other families with higher income. Therefore *H. pylori* prevalence of children from non-manual families is lower than that of children from manual families (30.42% - 32.74% vs 43.90% - 47.93%, $P<0.005$). We also found that there is an association between high prevalence and household density, close personal contact, particularly common use of the same bowl. These may provide the opportunity for transmission of infection from parents to children.

CONCLUSION

H. pylori prevalence among Chinese children is high and it increases with age. It has an inverse relationship with the socioeconomic status of the children's family.

Chen DL, Wang WZ, Wang JY. Epidermal growth factor prevents gut atrophy and maintains intestinal integrity in rats with acute pancreatitis. *World J Gastroentero*, 2000;6(5):762-765

INTRODUCTION

There is abundant evidence that stressful insults such as acute pancreatitis may significantly alter the metabolism of the gut mucosa and therefore its barrier integrity, resulting in an increase in mucosal permeability and subsequent trans location of enteric bacteria and their endotoxins^[1-9]. The fact that most bacteria associated with acute pancreatic and peripancreatic infections are of enteric origin implies that the gut plays a major role in the pathogenesis of pancreatic infection^[10-16]. Thus various therapeutic modalities have been undertaken to maintain gut mucosal metabolism and function as well as to reduce the bacterial translocation during acute pancreatitis.

In recent years, much attention has been focused on hormonal regulation as one of the effective therapeutic strategies. Epidermal growth factor (EGF), which presents in large amount in the salivary and Brunner's gland, and in a variety of secretions including saliva and milk, is a potent mitogen for small intestinal cells both *in vivo* and *in vivo*. Parenteral nutrition with administration of exogenous EGF has been shown to increase DNA and protein content in the small intestine^[17-20]. EGF can also regulate intestinal brush border enzymes functionally^[21,22].

The aim of this study is to evaluate the protective effects of EGF on intestinal barrier function in rats with acute pancreatitis under total

parenteral nutrition (TPN).

MATERIALS AND METHODS

Materials

Forty-one male Sprague Dawley rats, each weighing approximately 210g, were purchased from the Experimental Animals Center of Fourth Military Medical University. The rats were given water *ad libitum* and a standard rat food diet. They were subjected to alternate 12h periods of darkness and light. After overnight fasting, the rats underwent placement of a central venous catheter through a right external jugular vein under sodium pentobarbital anesthesia (40mg·kg⁻¹, intraperitoneally). The central venous catheters were tunneled subcutaneously and attached to a spring coil/brass swivel mechanism, which allowed for free movement of the animals in cages. Acute pancreatitis was induced by intraductal infusion of 35g·L⁻¹ sodium taurocholate solution (1.0mL·kg⁻¹) after clamping the proximal end of the common bile duct and puncture through the duodenum into the biliary-pancreatic duct^[23-27]. On the day of cannulation (d0), rats were randomly divided into one of the two groups. The control group (n=21) was fed a conventional parenteral nutrition solution; the EGF group (n=20) was fed besides the identical parenteral nutrition formula as in the control group, EGF (0.1mg·kg⁻¹) was injected subcutaneously twice daily.

The TPN solutions were prepared in a laminar flow hood and were sterilized by membrane filtration. The composition of these solutions is shown in Table 1^[28].

Methods

On d1 and d5 after induced acute pancreatitis, every 8 animals in each group were anesthetized with 40mg·kg⁻¹ sodium pentobarbital respectively. A midline abdominal incision was made and a 60cm length of small intestine, 20cm distal from the ligament of Treitz, was ligated at both ends. Then, 1.0mL fluorescein isothiocyanate (FITC)-dextran 4000 (25g·L⁻¹) solution was injected into the lumen of this ligated segment. A blood sample was withdrawn from the superior mesenteric vein 30min later for the analysis of plasma FITC-dextran with a fluorescence spectrophotometer at an excitation wave length of 480nm, an emission wave length of

530nm, and expressed as mg of FITC-dextran per L of plasma^[29-31].

For histologic evaluation, 2cm of proximal jejunal segment was fixed in 100mL·L⁻¹(V·V⁻¹) formalin, embedded in paraffin, and stained with hematoxylin-eosin. Three paraffin sections were prepared from each fixed tissue sample, and each slide was analyzed. Villus height and area were measured in 10 well orientated villi, giving a total of 30 villis for each jejunal segment. Measurements were made in a blind fashion on coded slides, and mean values were obtained^[32,33].

Samples of jejunal mucosa were scraped and used for the measurement of mass and enzyme activity. The activities of sucrase and maltase were determined by the method of Dahlqvist^[34]. Myeloperoxidase (MPO) activity was determined by the method of Bradley *et al*^[35]. The protein content in each sample was estimated according to the method of Read *et al*^[36].

Statistical analysis

Data were expressed as $\bar{x} \pm s$ as indicated in each table. The significance of any difference between the two groups was determined with the Student's *t* test. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Mortality rate

During the 5d of TPN after induced acute pancreatitis, the mortality rate was similar in the two groups. Specifically, 4.8% (1/21), 23.8% (4/21) in the control group and 5.0% (1/20), 20.0% (3/20) in EGF group on d1 and d5 respectively. This did not reach statistical significance.

Changes in body mass

The initial body mass in the two groups was similar (213g±8g in the EGF group vs 210g±6g in the control group) and there was no significant change on d1 (214g±9g in the EGF group vs 211g±6g in the control group). But the final body mass gain was significantly greater in the EGF group than in the control group on d5 (15g±2g in the EGF group vs 4g±1g in the control group, $P < 0.01$).

Changes in mucosal wet mass, villus height and area

Mucosal wet mass, villus height and area in the control group decreased significantly as compared with the EGF group on d5 ($P < 0.01$, Table 2).

Changes in intestinal permeability

Plasma FITC-dextran level in the control group increased significantly as compared with the EGF group on d5 ($P < 0.01$, Table 3).

Changes in activities of sucrase, maltase and MPO

Activities of sucrase and maltase in the control group decreased significantly as compared with those in the EGF group on d5 ($P < 0.05$, $P < 0.01$, respectively). However, MPO activity in the control group increased significantly as compared with that in the EGF group on d5 ($P < 0.01$, Table 4).

DISCUSSION

The effects of EGF on intestinal integrity were investigated in an experimental acute pancreatitis model in rats. TPN was used in both groups to mimic the clinical setting in as much as acute pancreatitis patients are often nourished by TPN. Acute pancreatitis can lead to ischemic damage of intestinal mucosa. Administration of TPN even to healthy experimental animals is associated with progressive intestinal atrophy, which is characterized by reduction of mucosal mass, villus

height and area, mucosal wall thickness, etc^[37-41], so that combination of acute pancreatitis and TPN might lead to more damage to the gut mucosa than TPN or acute pancreatitis alone. EGF was selected because it has been suggested to be a potent mitogen for small intestinal cells both *in vitro* and *in vivo*^[42-44]. A previous study by our group also demonstrated that EGF could increase DNA and protein content in the small intestine^[45].

In this study, the body mass gain in the EGF group was significantly greater than in the control group on d5. This may be contributed to an anabolic effect of EGF^[44]. On d5, the significantly increased mucosal mass, villus height and area in jejunum were also found in the EGF group as compared with the control group. This is because that EGF can enhance intestinal glutamine influx and supply more energy for mucosal regeneration so as to attenuate intestinal atrophy. And it is also related to the increased mucosal protein and DNA content in small intestine^[46,47]. The results suggest that the administration of exogenous EGF may prevent intestinal atrophy in rats with acute pancreatitis under TPN.

For the assessment of barrier function of intestinal mucosa, a permeability test can be a suitable method. Pantzar *et al*^[31] suggested that nondegradable dextrans could be used as permeability markers and reflected the proteolysis-independent passage of proteins through the small intestinal epithelia. Because there may be a paracellular route through the tight junctions for the markers with M_r below 30000 instead of a transcellular route as suggested for the larger molecules. In the present study, permeability of the small intestine to FITC-dextran 4000 (mean M_r , 4000), through the tight junctions of the intestinal epithelia, increased significantly in the control group as compared with the EGF group on d 5. The results indicate that EGF may prevent an increase in permeability of the small intestine to FITC-dextran 4000 in rats with acute pancreatitis under TPN.

Tissue damage can be caused either directly or indirectly by the oxidative metabolism of the infiltrating polymorphonuclear leukocytes (PMNs). It is believed that after specific membrane perturbation by stimuli, PMNs may exhibit a burst in oxygen consumption and start to generate active oxygen metabolites, which may lead to oxidative stress in tissues. So, the accumulation of PMNs in affected organs is considered to be one of the causative factors of multiple organ failure (MOF). MPO is an essential enzyme for PMNs function and a useful indicator of its infiltration. Evidence indicates that normal small intestine bears a low background of MPO activity, and the enzyme activity increased significantly in ischemic small intestine followed by PMNs infiltration^[48,49]. MPO activity also increased in the lung of rats with acute

pancreatitis^[50,51]. It is still unclear whether PMNs infiltration may be involved in the damage of small intestine in acute pancreatitis. In the present study, MPO activity in the control group increased significantly as compared with the EGF group on d5. It indicates that EGF may reduce PMNs accumulation in intestinal mucosa, thus minimizing oxidative stress in rats with acute pancreatitis under TPN.

Sucrase and maltase, which lie in villus brush border, are two kinds of important disaccharidases. They are often used as the markers of the normal cell proliferation and digestive function in small intestine^[29,30,34]. In this study, activities of sucrase and maltase in the control group decreased significantly compared with the EGF group on d 5. Maintenance of sucrase and maltase activities indicates that EGF may alleviate damage of jejunum in rats with acute pancreatitis under TPN.

In summary, the present study demonstrated that treatment with EGF can lead to body weight gain, reduce gut atrophy and PMNs accumulation in intestinal mucosa, prevent increased intestinal permeability and maintain sucrase and maltase activities in acute pancreatitis rats under TPN.

Xia ZW, Inoue Y, Ohse M, Shinka T, Kuhara T. A study on α -ketoadipic aciduria by gas chromatographic-mass spectrometry. *World J Gastroentero*, 2000;6(5):766-769

INTRODUCTION

α -ketoadipate (α -KA), an intermediate in the catabolism of L-lysine, hydroxylysine, and L-tryptophan, undergoes oxidative decarboxylation to form glutaryl-CoA and then dehydrogenates to form crotonyl-CoA, the latter undergoes further degradation and enters in TCA cycle, as shown in Figure 1. α -ketoadipic aciduria (Mckusick 245130) is a rare inborn error in the metabolism of α -KA to glutaryl-CoA and is characterized by the increased excretion of α -KA, α -amino adipate (α -AA) and α -hydroxyadipate (α -HAA). Since Przyrembel *et al* first described it in 1975^[1], only 13 cases of α -ketoadipic aciduria have been reported over the past 25 years, including 7 symptomatic, and 6 asymptomatic ones even in the symptomatic siblings with α -ketoadipic aciduria^[1-10]. The clinical manifestations of this metabolic disorder showed heterogeneity. However, no follow-up study on either symptomatic or asymptomatic case has been available so far. We followed up two cases of α -ketoadipic aciduria clinically and metabolically using organic solvent extraction, new urease-pretreatment and gas chromatography-mass spectrometry (GC/MS).

delivery were uneventful. Their clinical data were collected after diagnosis of α -ketoadipic aciduria.

Reagents

Creatinine-d₃ (methyl-d₃) was purchased from Nippon Sanso Ltd., Tokyo, Japan, and 2-amino adipate, 2-oxoadipate, 2, 2-dimethylsuccinate (DMS) and urease type C₃ were obtained from Sigma Chemical Co. St. Louis, MO, USA. All chemicals were of analytical grade.

Quantitation of α -KA, α -HAA, α -AA and glutarate

Twenty nmol of DMS was used as the analyte of internal standard for preparing standard curves of α -KA and glutarate, 50nmol of DMS was also chosen as the analyte of internal standard for making standard curves of α -AA and α -HAA. Comparing with peak area of internal standard, quantitation of urinary α -KA, α -HAA, α -AA and glutarate was performed using standard curves.

Sample preparation

Urine samples from two cases were collected at different detecting time. All samples were frozen at -20°C until analysis. Creatinine was determined and urine volumes equivalent to 1 μ mol creatinine were prepared prior to GC/MS analysis by organic solvent extraction^[11] or urease-pretreatment^[12]

Measurement

Samples were analyzed using GC/MS-computer systems of QP-5000 (Shimadzu, Japan) and HP-6890 (Hewlett Packard, USA) as well as the new diagnostic method described previously^[12,14,15]. The concentrations of these compounds were normalized to urinary creatinine and expressed as mmol per mol creatinine.

Loading tests of tryptophan and lysine (each was 100mg/kg of body weight) were made in Case 1 at the age of 1 year and 4 months.

RESULTS

The two cases were followed up clinically for a period of 15 years (8 months-15 years in Case 1) and 5 years (1 day - 5 years in Case 2), respectively. Case 1 was slightly delayed in growth after birth and CT on his head showed mild cortical atrophic change at the age of 9 months. At 1 year and 4 months, the analysis of first urine sample

revealed high levels of α -KA and α -AA using GC/MS. Loading test was performed. The values of α -KA, α -HAA, glutarate and α -AA reached 16-fold, 4-fold, 9-fold and 4.5-fold, respectively after lysine was taken orally. The concentrations of these four compounds increased 7-fold, 2-fold, 3-fold and 4-fold, respectively after tryptophan was also administered orally. Treatment was carried out with a low-lysine diet (70mg/kg daily) and a low-tryptophan diet (17mg/kg daily) after diagnosis. His CT was within normal range and his mild cortical atrophic change disappeared at the age of 4 years. The dietary treatment was discontinued due to normal development. His growth is normal at present. Case 2 developed cyanosis, clonic seizures and hypoglycemia 1 day after birth, then grew normally without low protein restriction.

Excretion of abnormal urinary metabolites profile compatible with α -ketoadipic aciduria in two cases was continuously observed using organic solvent extraction, urease-pretreatment and GC/MS techniques (Table 1). Total ion current (TIC) chromatogram of TMS derivatives of organic acid in urine from Case 1 is shown in Figure 2. Ten

major compounds were identified. Peak 4, 6 and 7 represent glutarate, α -HAA and α -KA, respectively. Figure 3 shows the TIC of TMS derivatives of metabolites in urine from the same patient using urease-pretreatment and 9 major compounds were confirmed. Peak 2, 4, and 5 demonstrated glutarate, α -HAA and α -AA, respectively. Abnormal metabolites profile of α -KA, α -HAA, α -AA and glutarate were also detected in the urine of Case 2 with those techniques. Compared to the case with α -ketoadipic aciduria, three abnormal peaks, including α -KA, α -HAA and glutarate after organic solvent extraction and α -AA, α -HAA and glutarate using urease-pretreatment, did not appear in the urine from healthy age-matched control at same retention time. The value of α -AA is much higher than that of α -KA, and glutarate was also detected and found increased in the urine of two cases. The concentrations of α -KA, α -HAA and glutarate ranged between 9-49 mmol/mol creatinine, 12-55 mmol/mol creatinine and 9-216 mmol/mol creatinine, respectively. The amounts of α -AA were 92-450 mmol/mol creatinine in analysis of urinary amino acid (Table 1).

Table 1 Urinary concentrations of metabolites

Cases	Detecting age	α -KA	α -AA	α -HAA	Glutarate	Total value of metabolites
1	1.4yrs	33(ND)	223(2-25)	28(ND)	29(0.04)	313

IS: added as an internal standard.

DISCUSSION

In analyzing organic acid, GC/MS has been proven by several institutions to be the most efficient method for chemical diagnosis of inborn error of metabolism.

In 1991, Shoemaker *et al* reported that urinary organic acids, amino acids and sugar could be analyzed simultaneously by GC/MS after excessive urea in the urine was degraded with urease and removed. This method, however, takes several hours, needs skillful technicians, and is not so practical. Therefore, Shoemaker's procedure was simplified for use in multiple sample analysis^[12]. As a result, rapid practical and simultaneous analysis of amino acids and organic acids became possible. Further improved-procedure was adopted, which is a stable isotope dilution method using not only d_3 -creatinine but also stable-isotope-labeled amino acids as internal standards. It only takes 1 hour for pretreatment of one sample and is a highly comprehensive diagnostic tool for a wide range of metabolic disorders^[13]. However, for detecting α -KA, the approach of organic solvent extraction is more sensitive than that of urease-pretreatment in this study.

α -ketoadipic aciduria was first described by Przyrembel *et al* in 1975 since then 7 cases have been reported^[1-3,6-9] using GC/MS or other analytical methods, and some subjects with α -ketoadipic aciduria were found by re-examination^[3]. In addition to symptomatic cases, 6

asymptomatic cases have also been reported^[2-5,10]. Up to now no follow-up study on this case with or without symptoms has been described by employing organic solvent extraction, urease-pretreatment and GC/MS techniques.

Almost all probands were identified when prominent spots of α -AA were noted on amino acid chromatography of urine, with subsequent investigations demonstrating α -aminoadipic acidemia and increased urine concentrations of α -KA and α -HAA. Different clinical symptoms were also described according to 7 affected individuals. The major manifestations include psychomotor retardation (5 cases)^[1,3,6-8], men talretardation (3 cases)^[1-3], hypotonia (3 cases)^[1,3,7] and seizures (2 cases)^[6,8]. The data indicate that the individuals with α -ketoadipic aciduria presented with nonspecific symptoms, but the central nervous system may be especially vulnerable. In this study, two cases showed symptoms at onset, including an 8-month-old boy with growth retardation (Case 1) and a boy with seizures (Case 2) as described above symptoms. In the two cases, the values of α -KA, α -AA, α -HAA and glutarate were always high at the different detecting time using present method. Meanwhile, loading tests of lysine and tryptophan were performed at 1 year and 4 months in Case 1. The concentrations of α -KA, α -AA, α -HAA and glutarate increased after lysine or tryptophan was taken orally. So the diagnosis of α -ketoadipic aciduria was confirmed. Three abnormal peaks were

still identified in recent detection as α -KA, α -HAA and glutarate after organic solvent extraction, and the three abnormal peaks of α -AA, α -HAA and glutarate also appeared by urease-pretreatment compared with healthy age-matched control.

In normal condition, α -KA and α -HAA could not be detected and only a trace of α -AA and glutarate exist in the urine, and when the patients are in the interim period, organic acid and amino acid in serum and urine are normal^[7]. In this study, abnormal excretion of these compounds was found and the value of α -AA was much higher than that of α -KA in the urine of two cases, but we still considered and diagnosed them as α -ketoadipic aciduria. Based on this α -amino adipic aciduria is caused by the deficiency of mitochondrial α -amino adipic acid aminotransferase, which leads to elevated urinary excretion of α -AA without α -KA.

A small amount of glutarate was also detected in urine in the two cases, but the level was much lower than that found in glutaric aciduria type I, and 3-hydroxyglutarate was not detected, so it is almost certainly because of spontaneous decarboxylation of α -KA or artifact^[6,7].

The accumulated metabolites suggest a block in α -ketoadipic acid dehydrogenase, and intact mutant fibroblasts are almost totally unable to oxidize α -amino[1-¹⁴C] adipate and α -keto[1-¹⁴C] adipate to ¹⁴CO₂, but a defect in α -ketoadipic acid dehydrogenase has not been demonstrated directly. If α -ketoadipic and α -ketoglutaric acid dehydrogenase are indeed the same, it is not clear a defect can produce so mild a phenotype. This may indicate that the two enzymes are different. Vallat *et al* recently reported that significant increment of α -AA occurred in the plasma and urine of 8 vigabatrin (VGB) treated children suggesting that VGB strongly inhibit α -amino adipic acid transaminase, α -ketoadipic acid dehydrogenase, or glutaryl-CoA dehydrogenase^[16,17]. However, more knowledge about underlying the mechanism is required.

Although protein restriction was reported to improve clinical symptoms like Case 1 and Case 2 in which no seizures occurred without treatment. Our results and results previously reported^[3,8], suggest that the clinical course of α -ketoadipic aciduria is incongruity and the condition is not apparently deleterious. Some authors investigated normal siblings of the patients, who excreted excessive amounts of α -KA and α -AA, and thought mental retardation may result from other causes^[2,3]. Others researchers consider that the analysis of mass spectrometry for this disorder would not be useful because α -ketoadipic aciduria is a nondeleterious inherited metabolic defect. But up to now, the relationship between the biochemical abnormality and clinical manifestations in α -ketoadipic aciduria

is still unclear.

Inheritance as an autosomal recessive trait is inferred from the pedigrees. There is no evidence so far that heterozygous carriers can be distinguished from control subjects. The incidence is not known. For these reasons, it is necessary to follow up this case with α -ketoadipic aciduria using GC/MS in order to clarify the mechanism of the clinical heterogeneity of this defect.

ACKNOWLEDGMENTS We are indebted to Dr. Isamu Matsumoto (Professor Emeritus, Kanazawa Medical University) for his continuing interest and encouragement.

Case Report

Metastasis in an axillary lymph node in hepatocellular carcinoma: a case report

Michael R. Alison¹, Gladwyn Leiman² and Michael C. Kew¹

Subject headings liver neoplasms; axilla; lymph nodes; lymphatic metastasis; case report

Alison MR, Leiman G, Kew MC. Metastasis in an axillary lymph node in hepatocellular carcinoma: a case report. *World J Gastroentero*, 2000;6(5):770-772

INTRODUCTION

Although hepatocellular carcinoma often metastasizes to regional lymph nodes, spread to more distant lymph nodes is rare^[1-7]. Involvement of axillary lymph nodes by metastases appears not to have been documented. We report a patient with hepatocellular carcinoma (HCC) with a metastasis in a lymph node in the right axilla, and discuss possible routes by which such spread might occur.

CASE REPORT

M.S., a 28-year-old black African woman presented to the medical service of the Johannesburg Hospital in April 1999 with a 2-month history of worsening pain in the right upper quadrant of the abdomen, increasing abdominal girth, yellow discoloration of the sclerae, and generalized pruritus. She had been hospitalized in Zimbabwe 3 weeks earlier, when an enlarged gland in her right axilla was biopsied. This showed the histological features of a "cancer originating in the liver". She was told that there was no effective treatment for her disease and was discharged. The patient had previously been well and did not smoke cigarettes or drink alcohol. Since the birth of her only child 5 years earlier, she had been receiving intramuscular injections of Depo-Provera® for contraception.

Physical examination revealed a young woman who was deeply jaundiced and pale, and showed evidence of recent weight loss. Extensive tribal scarification of the skin was evident. She was afebrile. Her blood pressure was 100/70 mmHg, pulse 115/min, and respiratory rate 20/min. She had florid nasopharyngeal candidiasis and shotty

generalized lymphadenopathy. A lymph node measuring 3 by 4cm, which was firm and adherent to adjacent tissues, was present in the right axilla. The overlying skin showed a healing scar. Her liver was enlarged to 10cm below the right costal margin (total span 22cm) and was extremely tender, and the surface was smooth. A bruit could not be heard over the liver. Tense ascites was present. Splenomegaly was not obvious and distended abdominal wall veins were not seen. Air entry at both lung bases was reduced, but no adventitious sounds were heard. A grade 2 ejection systolic murmur was heard at the left sternal border. The remainder of the examination was unremarkable.

A plain X-ray of the chest revealed an abnormally raised right hemidiaphragm, but was otherwise normal. Abdominal ultrasonography confirmed the presence of ascites. The liver was enlarged with a generally coarse echogenic pattern but with areas with a mixed hyperechoic/ hypoechoic pattern. Enlarged regional or para-aortic lymph nodes were not seen and the kidneys were normal.

The serum α -fetoprotein concentration was 150 μ g/L (normal less than 20 μ g/L). The hemoglobin level was 11g/dl, total serum bilirubin 94 μ mol/L (conjugated bilirubin 49 μ mol/L), total protein 77g/L, albumin 27g/L, alkaline phosphatase 261U/L, aspartate aminotransferase 418U/L, alanine aminotransferase 65U/L, and γ -glutamyl transpeptidase 365U/L. Serosanguinous fluid was obtained on ascitic tap, but on malignant cells were seen on cytological examination.

Hepatitis B virus surface and e antigens and IgG antibody to the core antigen were present in the serum. Hepatitis C antigen and antibody were negative. The human immunodeficiency virus Elisa test and Western blot were positive. The CD4 T cell count was 398, and the CD4:CD8 ratio 0.8:1.

Fine needle aspiration of the enlarged lymph node was performed. Slides were fixed for Papanicolaou staining and air-dried for Diff-Quik staining. Microscopic examination of the slides revealed a background of blood, with moderate numbers of large neoplastic epithelial cells (Figures 1 and 2). The cells were present in both small clusters and as single cells. They were round or oval in outline, and their cytoplasmic margins well defined. The cytoplasm was dense and eosinophilic on the Papanicolaou stain, with a minor population of cells showing cytoplasmic vacuolation. Nuclear

cytoplasmic ratios were high, and nuclei centrally located. The nuclei, generally single but very occasionally binucleate, were round, with coarse hyperchromatic chromatin, and very prominent macronuclei. In occasional cell groups, fine capillaries transected the cell aggregates. These cytological features are in keeping with those found in HCC^[8-10]. The alcohol-fixed slide was destained and used for cytochemical analysis. With good positive and negative controls, the cells were found to be negative for both cytokeratin 7 and 20. This cytokeratin profile points to carcinoma cells arising in the liver or kidneys, or to squamous cell carcinoma of the lung^[11].

On the basis of the cytomorphology, the metastasis was considered most likely to have arisen in a hepatocellular carcinoma^[8-11]. Renal carcinoma of this degree of differentiation would demonstrate eccentric nuclei in less well defined cytoplasm, with finer chromatin than noted here. Squamous cell carcinoma of bronchogenic origin would be unlikely to show the cytoplasmic vacuolation seen in some of these cell groups.

The patient was discharged on palliative treatment, and was subsequently lost to follow up.

Figure 1 High power magnification of a cluster of cells from the axillary node aspirate, demonstrating pleomorphism and crowding of large poorly differentiated malignant cells. Papanicolaou stain $\times 200$

Figure 2 Single-lying cell from the axillary node aspirate, demonstrating high nuclear to cytoplasmic ratios, central nuclei, and prominent nucleoli. Diff-Quik $\times 400$

DISCUSSION

Although most patients with HCC present clinically in well defined ways, a large number and wide diversity of unusual presentations have been described^[6]. A lack of awareness of these presentations can result in the diagnosis being delayed or even missed. Because we were unaware that HCC can spread to axillary lymph nodes, this diagnosis was initially discounted even though the clinical features were typical in other respects.

A review of the literature reveals no reports of axillary lymph node metastases complicating HCC^[1-7]. In particular, four necropsy studies in populations with a high incidence of this tumor (two in Japan^[4-7], one in South Africa^[1], and one in Hong Kong^[3]) and involving more than 1000 patients do not mention this route of spread.

There are two possible routes by which HCC could spread to axillary lymph nodes. The primary tumor in our patient involved most parts of the liver. Tumors located in the upper part of the right hepatic lobe (under the bare area of the liver) could spread via lymphatic vessels to lymph nodes on the upper surface of the diaphragm and thence to either mediastinal or parasternal lymph nodes^[12,13]. Malignant cells could then track along intercostal lymphatic vessels to reach the axillary lymph nodes. Spread from mediastinal lymph nodes via intercostal lymphatic vessels is presumed to be responsible for axillary lymph node metastases in bronchogenic carcinoma^[14]. Mediastinal glands were not radiologically evident in our patient although based on the experience with bronchogenic carcinoma^[14], this does not exclude this mode of spread. Alternatively, malignant cells could spread from the portal venous system to the umbilical region via a patent umbilical vein, or could reach the umbilicus by direct spread from the anterior peritoneum or by lymphatic spread from para-aortic glands invaded by the tumor^[15], as shown by the finding of a Sister Joseph's nodule in an occasional patient with hepatocellular carcinoma^[16]. The malignant cells could then drain along subcutaneous lymphatic channels to axillary lymph nodes^[17]. The absence of an obvious Sister Joseph's nodule or even periumbilical induration in our patient makes this route less likely but does not exclude it.

Wu MC, Shen F. Progress in research of liver surgery in China. *World J Gastroentero*, 2000;6(6):773-776

INTRODUCTION

Liver surgery, was started in the late 1950s in China and has developed rapidly in the past 40 years^[1]. The study on the diagnosis and treatment of primary liver cancer in China underwent four stages: ① In the 1950s, the anatomical study of the liver lay a solid foundation for liver resection^[2]. ② In the 1960s and 1970s, studies mainly focused on the detecting methods of AFP and other tumor markers, clinical and pathologic characterion of small liver cancer and epidemiology of liver cancer. ③ In the 1980s, imaging diagnostic techniques, such as CT, MRI, DSA, Doppler ultrasonography, etc., and new therapeutics^[3], such as hepatic artery chemo-embolization, percutaneous intra-tumoral ethanol injection, hepatic artery ligation with targeted chemotherapy^[4], and some new concepts such as radical regional resection, re-operation of the recurrent liver cancer, two-stage resection, the combined surgical management of liver cancer complicated with hepatic duct thrombus, splenomegaly and portal hypertension were introduced. These comprehensive treatment further improved the liver cancer surgery. ④ In the 1990s, attention was mainly focused on the biotherapy and liver transplantation. The progress in the diagnosis and treatment of primary liver cancer in recent years are summarized as follows.

EARLY DETECTION OF LIVER CANCER

The methods for early detection of liver cancer include: ① People aged more than 35 years, with a history of hepatitis, HBV or HCV infection, cirrhosis or chronic hepatitis, should be taken as a high risk population. Periodical monitoring of this population is the key step to detect early liver

cancers; ② AFP and B-US screening is, at present, the most sensitive, convenient and economical method for detecting early liver cancers; ③ for patients with low level AFP, the AFP variant detection is helpful^[5]. As to the patients with negative AFP, other liver tumor markers can also be used; ④ combined with CT, MRI, CTA or DSA, B-type ultrasonography is useful in the early diagnosis and localization of liver cancer; and ⑤ fine needle puncture for cytologic study and ethanol injection under ultrasonography is also helpful.

TREATMENT OF LIVER CANCER

At present, hepatectomy remains the treatment of choice for primary liver cancer^[6]. The efficacy of surgical intervention has been raised rapidly and significantly since 1978^[7]. The main reasons are as follows: ① the improvement of diagnostic methods for early cancer, ② renewal of surgical concepts; ③ improvement of surgical techniques and perioperative management^[8], and ④ the development of comprehensive therapy postoperatively. The pathological data from our group showed that 86.5% liver cancers were concomitant with cirrhosis or chronic hepatitis. The regular or extended hepatectomy might lead to severe decompensation of liver function. Therefore, the modality of liver resection drifted from an extended one to an irregular radical local resection^[9]. With presence of chronic hepatitis or cirrhosis, the radical local resection modality not only increases the resectability, but also significantly decreases the surgical mortality rate and attains the same long-term effect as the extended resection, or even better. The patients used to be given conservative therapy when one or more complications occurred such as jaundice, severe portal hypertension and esophageal varices with or without hemorrhage. With the accumulation of clinical experience, obstructive jaundice resulting from oppression of hepatic hilus or cancerous thrombi invading the biliary duct could be treated with hepatectomy or the removal of the biliary duct thrombi if hepatocellular jaundice and other contraindications could be excluded^[10]. Usually, the jaundice disappeared gradually after operation. In the patients with splenomegaly, hypersplenism and esophageal varices with or without hemorrhage, the hepatectomy can also be performed together with splenectomy plus ligation of varices or with splenorenal shunt. In the past, the comprehensive therapy was mainly used for advanced liver cancers

that were unresectable^[11]. But now, this concept has been extended and includes ① the pre- and post-operative comprehensive therapy for resectable liver cancer to prevent recurrence; ② palliative removal of irresectable tumors followed by anti-cancer therapy to shrink the tumor mass and prolong the tumor bearing survival period; and ③ comprehensive therapy for temporarily non-eligible surgical patients, with the hope of performing two-stage resection and long-term tumor bearing survival period.

Comprehensive therapy includes surgical and non-surgical treatment^[12], the former including hepatectomy, hepatic artery ligation (HAL), operative hepatic artery embolization (OHAE), drug delivery system (DDS), intraoperative ethanol injection, microwave consolidation^[13], laser gasification, freezing, etc. and the latter including transcatheter arterial chemo-embolization (TACE)^[14], B-US directed percutaneous ethanol injection (PEI) or other drugs^[15], radioisotopes and bio-agents, biotherapy, radiotherapy and traditional Chinese medicine.

Rational comprehensive therapy with multimodality is superior to a single method in terms of effectiveness^[16]. The tetralogy of comprehensive surgical therapy, which is the combination of HAL, OHAE, DDS and radiotherapy performed in 603 advanced liver cancers in our hospital, showed that the rates of two-stage resection and 1, 3 and 5-year survival rates were significantly higher than that of a single procedure (HAL or OHAE). The incidence of recurrence was only 7.4% in the 27 cases treated with comprehensive immunochemotherapy (cytokines plus low-dose chemotherapy) after resection, whereas in the control groups, it was 32%. In 86 operated cases, DDS chemotherapy was performed and the total incidence of one-year recurrence was 34.9%, while in hepatic artery, portal vein and hepatic artery combined with portal vein groups were 33.3%, 34.6% and 23.6%, respectively. Non-surgical comprehensive therapy was eligible for all patients with unresectable liver cancer, the TACE and intra-tumoral drug injection being most popular. In a series of 8000 TACE cases, the 3-year survival rate was 13.9%. The drugs we used in the B-US directed local drug injection were absolute ethanol, ³²P radioisotope, OK432, TNF-alpha and IL-2. The 2-year survival rate in 700 patients receiving PEI was 80.0%, with a total of 3000 injections given. In another group of 113 patients receiving TACE in combination with PEI, the tumors shrank in most patients (91.2%) in varying degrees, and the total 2-year survival rate was 81.6%. Among them, 11 out of 71 patients with tremendous, solitary tumor received two-stage resection after the tumor shrinkage and the two-stage resection rate was 15.49%.

Comprehensive therapy is not simply a random combination of various methods. The design of the

protocol should be individualized and case-specific. The regimen of the comprehensive therapy is multiple in medical literature. We propose two principles: ① The two methods used should be complimentary; and ② no contradiction in their effects and the side effects should not be additive. At the same time, attention should be paid to the toxic effect of each method and not to pose damage to the liver function. Besides, special emphasis should be laid on the effectiveness and use of traditional Chinese medicine in comprehensive therapy.

In 1978, we reported that a two-stage resection of a large-sized liver cancer shrunk after HAL procedure. Since then, this procedure has become a promising modality for unresectable large liver cancers. At present, the comprehensive surgical methods for massive liver cancer shrinkage comprise HAL, HOHAE and DDS, and non-surgical procedures, such as TACE, PEI, target therapy and radiotherapy. A rational combination of these methods enables some unresectable tumors to become resectable if they were sequentially employed. From 1974 to 1994, 649 patients received this therapy and 73 of them had their tumors resected with a resectability rate of 11.1% without operative death. The 5-year survival rate was 61.5% postoperatively, the longest survival being 17 years. The pathological data in this group showed that there were still some viable cancer cells remained although the tumor had shrunk due to the comprehensive therapy, it was still essential to remove the tumor remnants. At present, two-stage resectability rates are still very low, because no generally accepted criteria for tumor resectability. We propose that the two-stage resection is indicated only for those really unresectable, otherwise, the one-stage removal is of first choice; rational employment of comprehensive therapy is crucial for tumor shrinkage; and the unresectable liver cancers should be subjected to non-surgical comprehensive therapy, such as TACE, PEI and guided chemoimmunotherapy as the first choice.

BASIC RESEARCH IN LIVER CANCER

In the 1960s, the study of the liver cancer focused on the basic surgical study, including the anatomy of the liver, the postoperative hepatic metabolism and the effects of hilar occlusion on the hemodynamics and the metabolism of the liver. In that period, epidemiological study of the HBV and aflatoxin on liver cancer were completed in small samples. The first hepatoma cell line in the world was established, and the induced liver cancer models in rats were set up in many institutes. However, the study only stayed at the basic clinical level.

In the 1970s, much research work was concentrated on the relationship of AFP and the liver cancer. Various assays for AFP were set up and their sensitivity and specificity were tested. The

clinical and pathological characteristics of small liver cancer were documented. Contaminated food, water and HBV were shown as the main factors promoting liver cancer in high incidence areas as shown by epidemiological study in China. The first-line prophylactic strategy, that is, water control, fungi prophylaxis and hepatitis control was established. For the first time, liver cancer study in China appeared to have its own characteristics.

In the 1980s, liver cancer study in China reached cellular and molecular levels. The relationship between HBV and liver cancer was corroborated at the molecular level^[17]. The relationship between the DNA content of the liver cancer tissues and their biological features was documented with pathological study in liver cancer at cellular and molecular levels. Gene spectrum of liver cancer was found. HBV-DNA integration was verified as the activation factor of some oncogenes. The immunological status of liver cancer hosts and its relationship with tumor were studied^[18]. The biological significance of the agglutinin, sugar, gangliosides, serum enzymes^[19] and protein to liver cancer and also the interventional methods were observed. Monoclonal antibodies specifically targeting the membrane antigens had been generated, and their localization *in vivo* and targeted treatment were studied^[20]. A lot of work was done on the serum tumor markers.

In the 1990s, a series of oncogenes and tumor suppressive genes were found by cellular, molecular and gene-manipulating methods. The relationship of HBV, HCV, aflatoxin and other cancer-inducing factors and the mutation of oncogenes and tumor suppressive genes, and their mechanisms were elucidated. The role of the genes, such as *p16*, *p53* and *nm23-H1* and the enzymes and adhesive molecules such as metalloproteinase, CD44, ICAM-1, integrin in metastasis and recurrence of liver cancer were verified. The clonogenicity of the liver cancer was studied with DNA, oncogene and tumor suppressive gene. The mechanisms of the cell cycle control, apoptosis, senescence evading and the escape of the immunologic surveillance of liver cancer cells were studied. And in the related study of the cellular signal transduction in these processes, the negative control genes on the liver cancer growth were found. The liver cancer-related genes were found with screening of a large amount of liver cancer genome, and even in some genes, their functions and chromosome localization were also elucidated^[21]. In immunological study, many kinds of tumor vaccines have been produced. Many researches in gene therapy, induction-differentiation, prophylactic control of neoangiogenesis of liver cancer are being carried out, reaching world advanced level.

LIVER TRANSPLANTATION

It is controversial about the indications of liver

transplantation in liver cancer^[22]. In massive liver cancers, recurrence after transplantation is unavoidable due to vascular invasion and distal metastasis as well as the use of immunosuppressive agents^[23]. On the contrary, the therapeutic effects of liver transplantation on small liver cancers complicated with severe cirrhosis are corroborated. Comparing the therapeutic effects of hepatectomy and liver transplantation, Bismuth concluded that the 3-year survival rates were almost the same, while the tumor-free 3-year survival rate was higher by liver transplantation than by hepatectomy. As to the small liver cancer (mononodular or binodular, with a diameter less than 3cm), the results of liver transplantation were even better. Selby *et al* showed that the total 5-year survival rate in 105 cases of unresectable liver cancer of different stages that received liver transplantation was 36%, of whom the 5-year survival rate from stage one to three was 52.1%, while in stage four, it declined to 11%. They concluded that liver transplantation was fit for liver cancer in early stage (≤ 2 cm, no vascular invasion and no distal metastasis). Although we do not have enough data, liver transplantation should not be regarded as a routine therapeutic method because of high incidence of liver cancer, liver donation shortage and high cost in our country.

PERSPECTIVE

Further progress of liver cancer research in our country depends on the progress in multiple factors, such as further studies of the individual and circumstantial factors on the genesis of liver cancer and its mechanisms, the mechanisms of metastasis and recurrence after hepatectomy^[24], the recognition of liver cancer-specific antigens and genes and their signaling pathways, in order to find out the measures intervening the genesis and growth of the tumor. Attention should be paid to the precancerous lesions of liver. The definition of precancerous lesion at molecular level and the study on blockage of its transformation will enhance the efficacy of liver cancer treatment. In clinical practice we should stick to the principles of early diagnosis and early management, and the surgical treatment is still the treatment of choice. Pre- and post-operative TACE and other comprehensive treatment modalities should be studied to improve the tumor-free survival. The regional therapy of liver cancer, such as the intra-tumoral injection treatment and regional treatment should be generated with new techniques and new approach. The radiotherapy, biological therapy and traditional Chinese medicine are hopeful. The regimens we employ now are to be combined to fit different cases. Shrinkage of the massive liver cancer into small one and anti-recurrence therapy are the main goals of our practice. The liver transplantation should be actively applied for early liver cancer.

Due to the large number of people infected with HBV or HCV as the background of liver cancer, the liver cancer is still a major life threatening disease among Chinese people, therefore, surgical treatment should be further strengthened.

Changing trends of surgical treatment of hilar bile duct cancer: clinical and experimental perspectives

Zhi Qiang Huang, Ning Xin Zhou, Da Dong Wang, Jian Guo Lu and Ming Yi Chen

Subject headings bile duct neoplasms/surgery; liver neoplasms/surgery; bile duct neoplasms/pathology; gene, suppressor, tumor; immunohisto chemistry; polymerase chain reaction; gene therapy; gene expression; portoenterostomy, hepatic

Huang ZQ, Zhou NX, Wang DD, Lu JG, Chen MY. Changing trends of surgical treatment of hilar bile duct cancer: clinical and experimental perspectives. *World J Gastroentero*, 2000;6(6):777-782

HISTORICAL POINT OF VIEW

Carcinoma of the confluence of the hepatic ducts has been thought to be a rare disease until recently. Carcinoma of the large hepatic ducts was rarely diagnosed correctly preoperatively. Because of its deeply seated location, resection was once thought to be impossible. In 1957, Altmeier^[1] reported 3 cases of sclerosing carcinoma of the major intrahepatic bile duct. One of the cases was operated upon for seven times within three years without a correct diagnosis until metastatic adenocarcinoma was found around the hepatic porta. However, this patient lived for three and half years after the first operation.

Klatskin^[2] was the first one who drew attention to the hilar bile duct (HBD) carcinoma as a kind of tumor with definite clinical features. His paper was entitled as "Adenocarcinoma of the Hepatic Duct at its Bifurcation within the Porta Hepatis. An unusual tumor with distinctive clinical and pathological features" was reported in the *Am J Intern Med* in 1965. Thirteen cases, were analyzed from 1947-1963. Klatskin pointed out in his paper that "The purpose of this report is to draw attention to the unusual clinical and pathological features of adenocarcinoma as that arise in the hepatic duct at its bifurcation within the porta hepatis". He laid emphasis on the fact that such type of tumor was often small-sized with a clear margin, metastasis has rarely been found, and the patient often died of prolonged biliary obstruction and liver failure

instead of tumor growth.

In our experience, slow progression of the tumor may be encountered very occasionally^[3,4]. In our series of 157 cases of HBD carcinoma, we encountered a male patient of 61 years of age, who had received operation of insertion of endoprosthesis because of jaundice about 5 years ago. After the operation, he developed repeated attacks of chills, fever and jaundice. We re-explored this patient and found that a well-localized tumor mass at the bifurcation of the hepatic duct, which was removed completely, and a choledochoenterostomy was created. Pathology of the resected tumor showed a highly differentiated adenocarcinoma of the confluence of the hepatic duct. The patient lived without recurrence for already 10 years since the last operation.

From January 1986 to January 1999, in the department of hepatobiliary surgery of our hospital 157 cases of hilar bile duct carcinoma (Table 1) were treated surgically. These experiences together with a series of experimental studies form the basis of this report^[5-7].

Table 1 Surgical treatment of cases of hilar bile duct carcinoma (1986-1999 in this hospital)

Treatment	No. of patients	%
Resection	106	67.5
Radical resection	59	37.6
Biliary drainage	51	32.5
Total	157	100.0

TUMOR EXTENSION AND STAGING

The biliary tract is a continuous structure from its beginning as Hering's tubule to the lower part of the common bile duct. The exact confinement of Klatskin tumor has not been accurately defined. Therefore, many terms have been adopted for the description of the same or not the same conditions. Carcinomas arising from the intrahepatic small bile ducts are often called cholangioma, which is one of the primary liver tumors. But, as to those tumors arising from the larger intrahepatic duct near the hilum and invading the hepatic confluence at its late stage may be difficult to be differentiated from those arising from the hilar bile duct^[8-10]. We are of the opinion that hilar bile duct cancer consisted of those cholangiocarcinomas of large bile ducts, which invaded the hepatic duct confluence^[11,12].

Research Institute of General Surgery, The General Hospital of PLA, Beijing 100853, China

Zhi Qiang Huang, graduated from the former National Zhong Zheng Medical College in 1944, now the academicien of the Chinese Academy of Engineering, professor of surgery of the Postgraduate Military Medical College, Beijing, and the Director of the Research Institute of General Surgery, the General Hospital of PLA, Beijing

Received 2000-05-12 **Accepted** 2000-09-12

There are many criteria for staging of hilar bile duct carcinoma such as those proposed by Bismuth-Corlette (1975)^[13], Gazzanign (1993)^[14], pTNM (*Am J Co Cancer*), TNM (UICC), and the T-staging classification (Blumgart 1998)^[9].

Bismuth and Corlette proposed the most widely used clinical pathological classification of hilar bile duct cancer in 1975^[13]. However, this classification is of value only in defining the origin of the tumor. Clinically, when tumor originated from one of the hepatic ducts (Bismuth-Corlette Classification Type III), jaundice will not be an early symptom, and, in fact, it may appear relatively late and clinical jaundice appeared only when tumor invaded the hepatic pedicle as the tumor advanced to the confluence of the hepatic duct to obstruct the opposite hepatic duct orifice^[15]. Therefore, we often found that the tumor was unresectable in patients suffering from jaundice only for two weeks duration. In such cases, atrophy of one lobe (either the right or the left lobe) of the liver was present^[16,17]. For staging of tumor progression, Gazzanign proposed a new staging criterion in 1993^[14]. But it is difficult to exactly define the degree of tumor progression before operation. Recently, Blumgart (1998)^[9] proposed a T-staging criteria which depends on the radiological features of tumor involvement of the portal vein and the presence of ipsilateral lobar atrophy in HBD cancer (Table 2). Since involvement of the portal vein is the chief independent risk factor in determining the resectability of bile duct cancer, therefore, it seems to be a simplified idea and is readily useful in clinical practice.

Table 2 T-staging of hilar bile duct cancer (Blumgart)^[9]

T 1	No vessel involvement or liver atrophy
T 2	With ipsilateral liver atrophy No portal vein involvement
T 3	With ipsilateral portal vein involvement With or without associated liver atrophy No main portal vein involvement
T 4	Any of the followings Bilateral 2nd order hepatic duct involvement Main portal vein involvement

THE EVER-WIDENING CURATIVE RESECTION

Since the turn of the 1980s, in order to increase the radicality of tumor resection, radical resection of hilar bile duct cancer was proposed to include skeletalization of vascular structures of the liver pedicle, the combination of hepatic lobectomy, the wide dissection of regional lymph nodes, and even the inclusion of hepatobiliary pancreaticoduodenectomy^[18-21].

The overall resectability rate of hilar bile duct cancer in China was rather low before 1985. In the Southwest Hospital, Chongqing, 60 surgical cases (1975-1985) of HBD cancer were explored with a

resection rate of 8.3%. In a nationwide survey of surgical cases of extrahepatic bile duct cancer from 1978-1988 conducted by the Chinese Surgical Society, 422 surgical cases of hilar bile duct cancer were collected, the average resectability rate was about 10% (Table 3)^[22]. This result was quite similar to the report from Bismuth (1960-1985) that in 178 cases with a resectability rate of 10%^[13].

Table 3 Resectability of bile duct cancer in China (a nationwide survey, 1978-1988)

Location	No.patients	No.resected	%
Proximal	422	44	10.0
Middle	179	41	22.9
Lower	147	50	34.0
Total	748	135	18.0

However, after the year of 1985, more enthusiastic attitude was adopted in the surgical treatment of HBD carcinoma, which resulted in increase of resectability rate, and decrease of operative mortality rate. In our hospital from 1986 to 1990, 31 cases were resected among the 50 explored cases, with a resectability rate of 62%, and no 30-day postoperative death^[23,24]. Similar trend of changes was also found in other hospitals in China^[25].

However, the resectability rate varies which was much dependent on the policy of surgical intervention toward bile duct cancer. This differences may be partly due to the awareness of the disease and early diagnosis, and, even more important, the different attitude toward the choice of operative intervention in case of hilar bile duct carcinoma. In our hospital, we found that biliary drain age and stent placement by operative means had less late complications than that obtained by transcutaneous or transendoscopic route (Table 4). This finding was also confirmed by Guthrie^[26] that operative intrahepatic biliary enterostomy of the III segmental duct carried a lower postoperative cholangitis than the percutaneously placed endoprosthesis (19% and 55%, respectively). Therefore, we adopted the surgical therapy for all HBD cancer patients who are considered to be indicated for the operation.

Table 4 Biliary drainage and postoperative cholangitis in HBD cancer

Operation	No. of patients	No cholangitis(%)	Recurrent cholangitis(%)
Resection	59	74.6	25.4
Intern.drain.	11	36.4	63.3
Extern.drain.	21	52.4	47.6

The need of preoperative percutaneous transhepatic biliary drainage (PTBD) in jaundiced patients is still a debatable subject^[27]. We used this approach in only one case when extended right

lobectomy was considered necessary. Recently, we planned a staged operation for a patient who needed a hepaticobiliary pancreaticoduodenectomy. We agreed with Nimura that preoperative biliary drainage is beneficial only in cases if extensive resection will be needed, and it should not be treated as a routine procedure^[28]. We resected the caudate lobe of the liver only when the lobe was invaded by the tumor; otherwise, we transected the caudate segmental duct. In our experience, the hepatic artery, when encased by the tumor, may be excised en masse without harmful effect. Reconstruction of the portal vein after resection was undertaken under vascular control.

OUTCOME OF SURGICAL TREATMENT

During the 6th China National Biliary Surgical Conference held in Guangzhou in 1991, 139 cases of resection of HBD carcinoma were reported with a mortality rate of 0%-22%, being 5% on the average. The surgical treatment of HBD cancer of our hospital can be divided into two periods. The first period was from 1986 to 1993, during which 31 cases were resected with no 30-day postoperative death, 4 cases were living and tumor-free for more than 5 years (Table 5). During the second period, 32 cases were resected but no 5-year survival up to present (Table 6). Totally, from 1986 to 1999, 157 cases of HBD cancer were treated surgically in the General Hospital of PLA, Beijing, 106 of them were resected with a resectability rate of 67.5%, and 37.6% being considered radical resection (resection margins free of tumor cells). The 1, 3 and 5-year survival rate in the radical resection group was 96.7%, 23.3%, and 13.3%, respectively. In the palliative resection group (tumor cells present at one of the resection margins), no patient survived longer than 3 years^[23]. But, in the recent 3 years (1996-1999), 40 (74%) of the 54 surgical cases of HBD carcinoma were resected, in which, 23 (57.5%) resections were considered radical. This represents the changing trends towards earlier operation in those patients.

Table 5 Tumor-free long-term survivals after radical resection of hilar bile duct carcinoma

Case	Sex	Age	Type	Histology	Operation	Follow-up
1	M	47	Nodular	Tubular Ca	B-D resection, lobectomy	6yr3mo
2	F	50	Papillary	Papillary Ca	B-D resection	7yr2mo
3	M	63	Nodular	Well dif.	B-D resection, Lt lobectomy	7yr10mo
4	M	53	Nodular	Well dif.	B-D resection	8yr3mo

B-D: bile duct; Ca: adenocarcinoma; Well dif.: well differentiated

re: resection

At present, however, the late result of HBD cancer is still discouraging^[29]. Boerma^[30] reviewed the English literature published before 1990, resection of the tumor was obtained in 581 cases with an average mortality rate of 13%, the average survival period was 21 months, and the 1, 3 and 5-year survival rate was 67%, 22%, and 11% respectively. Recently, Nakeeb^[31], from Johns Hopkins Medical Center, reported 109 cases resected with a 1, 3 and 5-year survival rate of 68%, 30% and 11%, and compared the cases treated with hepatic resection ($n=15$) with the cases without hepatic resection ($n=94$), which showed that there was no difference in the 1, 3 and 5-year survival rate, but the 5-year survival rate was better in those with negative margin (19%) than those with positive margin (9%). Nimura from Japan reported the result of a 5-year cure rate of 31% in 127 resected cases^[28]. In the report from the Liver Transplantation Center in Pittsburg^[32,33], 28 cases of HBD carcinoma underwent extensive resection including hepatic lobectomies and vascular reconstruction, the post-operative 30 days mortality rate was 24%, but only one patient survived 5 years (Table 7).

Table 7 Survival rate after resection of hilar bile duct cancer (reported series)

Author	n	Rx (%)	Mortality rate (%)	Survival rate (%)		
				1yr	3yrs	5yrs

Rx: radical resection; †:collected series

Therefore, Madariaga^[33] from the Pittsburg group raised the question that the possible beneficial effect obtained through extensive operative procedure for HBD carcinoma is outweighed by the accompanying high morbidity and high mortality rate, so that the real significance of extensive surgery is questioned. Madariaga claimed that, for HBD carcinoma, it may be useless to prosuite for a cure resection as such is rarely possible, it may be encouraging to have a palliative resection if the operative morbidity and mortality rate can be kept much lower. We reach the same contention, that is, radical cure of hilar bile duct cancer is unlikely at present and should be left to those patients who may have an early diagnosis and early operation. But for most patients, efforts should be made to obtain a good palliative outcome with less postoperative complications.

Finally, we realized that carcinoma of the hilar bile duct, which rarely ran a "benign" course as described by Altemeier and Klatskin, is not an uniform disease, and is a regional disease rather than a local affection. It can metastase along the perineural space by a "jumping" fashion and invade adjacent tissue and blood vessels and lymphatics^[34-36], therefore, surgical excision is bound to be unradical in the region of the porta hepatitis for anatomical reasons.

EXPERIMENTAL STUDIES FOR FURTHER UNDERSTANDINGS OF HEPATIC HBD CANCER

Carcinoma of the hepatic duct bifurcation was considered a slowly growing malignancy and might have a better prognosis. However, from recent experience, this conclusion has been challenged. The long-term result of surgical resection of HBD carcinoma has been far from satisfactory. The 5-year survival rate of the radical resection group was from 13.3% to 17%^[6,23]. Patients often died of local recurrence and hepatobiliary failure. Therefore, a research on the mode of recurrence in HBD carcinoma was undertaken by the author and his collaborators^[35-39].

Coordinated clinical and pathological studies showed that metastasis of HBD cancer occurred rather early in the clinical cases. Therefore, in 32 cases of resections, metastasis was evidenced in 26 (83.9%) of the cases. The mode of spread was nerve invasion in 57.7%, direct liver invasion in 42.3%, soft tissue infiltration in 42.3%, liver metastasis in 7.7%, and lymph node metastasis was only found in one case (1.8%). Histologically, 21 (65.6%) of the 32 resected specimens were well-differentiated adenocarcinoma, 6 papillary adenocarcinomas, 3 were of low differentiation, and 2 carcinoma simplex^[4].

Cholangiocarcinoma cells frequently metastased along the perineural lymph space. In 40 resected cholangiocarcinoma specimens, perineural space infiltration index (PNI) by cancer cells in relation to the median survival time was investigated, the result showed a reverse correlation (Table 8).

Table 8 Neural infiltration index and median survival time

Differentiation of tumor cells	PNI*	Median survival time (mos)
Papillary	0.31±0.12	32
High	0.39±0.18	13.5
Moderate	0.74±0.39	10.8
Low	0.85±0.41	7.2

* PNI>7.0: severe nerve infiltration

In 78 surgical cholangiocarcinoma resection specimens (collected between 1989-1996), the significance of neural cell adhesion molecule (NCAM) in relation to clinicopathological findings was investigated, 68 of the 78 specimens showed

nerve infiltration, blood vessels infiltration in 72, and lymphatic infiltration was present in 68. In 68 cases with neural infiltration, positive expression for NCAM was found in 51 cases. Furthermore, a reverse relationship was found between the positive NCAM expression and the degree of tumor cell differentiation (Table 9)^[40,41].

Table 9 Expression of NCAM and tumor differentiation

Cell type	NCAM Expression	
	(-)	(+)
Papillary	5	3
High diff.	10	12
Moderate diff.	8	16
Low diff.	3	21

$P=0.0267$, $\chi^2=9.20$

For further demonstration of spread of cholangiocarcinoma cell along the perineural space, observations of computer assisted 3 dimensional reconstruction of the pathological sections was made in 2 cases, totally 110-200 slides were selected for reconstruction using a SHOW 3D image analysis system. The results showed that a dense net-work of small vascular and lymphatic channels together with a branching net-work of tumor infiltrates are closely related along the nerve fiber. By using the "wire framing" technique to visualize the interior structures, it was demonstrated that the tumor cells stayed in perineural space, lymphatics, and small vessels far from the primary focus of carcinoma. Probably, carcinoma cells involving a nerve at a place far from the original site must have reached there via lymphatics, vascular vessels or by direct invasion. These facts might be important in explaining the high recurrence rate of HBD carcinoma after conventional radical resection^[42].

To investigate the relationship between hepatitis B and C virus infection of the bile duct mucosa and the occurrence of bile duct carcinoma, 51 excised bile duct cancer specimens from 1995 to 1998 were taken from the Department of Pathology, General Hospital of PLA, Beijing, for histochemical and IS-PCR studies. Five (9.8%) of the 51 cases of extrahepatic bile duct cancer (EBDC) showed positive reaction for HBsAg in the tumor tissue. Positive reaction was expressed as brownish granules in the cytoplasm of cancer cells, and no case was detected as inclusion bodies, membranous type, nor granules were seen in the nucleus or the cell membrane. A positive serum HBsAg was found in 3.9% of the 51 cases. Therefore, from this study, it was evident that HBV can infect the epithelial cells of the bile duct. In China, a positive rate of serum HBsAg was expected to be about 10% of the population. It may be concluded that, from pathological studies, HBV infection may not be strongly related with the

development of EBDC. However, as to the significance of HCV infection, the result may be on the contrary. Examination of the HCV NS₅ antigen in the 51 EBDC cases, 14(27.5%) showed positive expression in the cancer tissue. The pattern of antigen distribution in the cancer cells was similar to that of HBV granules, which was brownish granules distributed in the cell cytoplasm with no nucleus or cell membrane staining. Since the positive rate of anti-HCV was 0%-2.4%^[43,44] in Chinese population, the positive rate of 27.5% found in the cancer tissue was much higher than the average, and may indicate a positive relationship between HCV infection and the development of EBDC^[45,46]. This finding was in accordance with the recent report by Yin *et al*^[47]. The mechanism of cancerous changes of HCV infected bile duct mucosal cells may be the consequence of bile duct cell destruction and hyperplastic proliferation.

Further study was made with in situ polymerase chain reaction (IS-PCR) in paraffin-embedded sections of 51 cases of EBDC, the results showed that 8 (15.9%) of the 51 cases was positive for HBV, the positive cells of HBV DNA were mainly clustered in the cancer tissue. In 2 cases, the brownish granules were exclusively located inside the nucleus of the cancer cells. Therefore, there is a rather high incidence of HBV infection in EBDC in spite of a negative serum test for HBsAg, and the integration of HBV DNA in the cell nucleus may play an important role in the carcinogenesis of EBDC.

Study of positive HCV RNA in the 51 cases of EBDC with IS-PCR revealed that 18 (35.4%) had detectable HCV RNA, of which, 15 were plus-strand RNA, and 3 were minus-strand RNA. Twelve detectable RNA was located in the cytoplasm, and 6 were in the nucleus. The positive cells of HCV RNA were mainly clustered in the cancer cells. Of 34 control specimens, only 2(5.9%) had detectable HCV RNA. These results suggested that HCV infection might be involved in the carcinogenesis of carcinoma of extrahepatic bile duct.

In recent years, studies of cancer pathogenesis have provided evidences that cancer is a disease developed through a process of cytogenetic disorders. It is now known that activation of proto-oncogen and inactivation of tumor suppressive gene are the most common genetic alternations in tumor, especially the loss of the function of tumor suppressive gene is considered as a key step in tumor progression. So the restoration of the function of tumor suppressive gene is a major approach for gene therapy for cancer. In recent years, attention has been focused on the *p16* gene, which resides within a locus commonly deleted in established cancer lines (almost 75%).

In a series of 51 specimens of EHBC, we detected the expression of *p16* gene so as to identify

the relationship between the expression of *p16* gene and the occurrence of metastasis and prognosis of the patients. Furthermore, we investigated the efficiency to transfer interest gene (Ad-*p16*, Ad-*p53*), cooperation of Ad-*p16* with Ad-*p53*, Ad-*p16* with CDDP and evaluated their inhibitory effect on human cholangiocarcinoma cell line QBC939^[48] *in vitro* and Ad-*p16* with CDDP *in vivo*. The results revealed that expression of *p16* analyzed with S-P immunohistochemistry method, was found in 43.14% of the 51 EHBC, but the positive rate varied significantly in the pathological grading, nerve invasion, prognosis and option of surgical procedure ($P<0.05$). The growth rates of the Ad-*p16*-infected QBC939 cells were inhibited by 35.1% (8 days), and Ad-*p53*-infected QBC939 cells were inhibited by 24.4% (8 days). The growth rates of the Ad-*p16*-infected QBC939 cells with CDDP (0.5mg/L) were inhibited by 77.7%. The suppression effects mediated by expression of the exogenous *p16* and *p53* in tumor cell resulted mainly from apoptosis and G1 arrest, while the suppression effects mediated by CDDP in tumor cell were mainly produced by apoptosis and G2 arrest. Experimental gene therapy on the nude mice model bearing subcutaneous tumor of QBC939 cells showed that intratumor instillation of Ad-*p16* and intra-abdominal instillation of CDDP inhibited the growth of the tumors. The average size of the Ad-*p16*-treated, CDDP-treated or Ad-*p16* with CDDP-treated tumors was inhibited by 30.0%, 41.0% and 62.6% respectively, as compared with that of the tumors injected with Ad-LacZ^[49,50]. However, gene therapy of EHBC cholangiocarcinoma, as in most of the malignant tumors, still has a long way to go.

INTRODUCTION

Helicobacter pylori (Hp) infection is closely related to gastrointestinal hormones and involves the formation of gastritis, gastric carcinoma and peptic ulcer^[1-7]. Its pathogenesis relevant to pathophysiological changes of gastrointestinal hormones are described as follows according to individual hormone.

HP INFECTION AND GASTRIN

Gastrin is a basic stimulus to parietal cells in producing gastric acid, and shows two ways in acid production: one directly stimulates parietal cell and the other acts on enterochromaffin-like (ECL) cell to release histamine by which stimulates parietal cells. So the formation of gastric acid and hyperchlorhydria is one of the physiopathological implications of gastrin. Hp infection in patients leading to increased release of gastrin from antral G cells and hypergastrinemia formation is currently an interesting medical problem^[8-11].

Hypergastrinemia produced by Hp infection

It is well known that Hp infection induces hypergastrinemia. In patients with normal gastroscopic features, those infected with Hp had significantly higher basal serum gastrin levels than non-infected individuals, and were similar to DU patients who are almost entirely infected with Hp. Therefore, hypergastrinemia seems to be associated with Hp infection, and is not a distinctive feature of DU disease^[12].

Hp-infected hypergastrinemia may be produced by cytokines^[13,14]: ① TNF- α : antral G cells (both

human and canine) undergoing TNF- α - pretreatment significantly increased in both basal and bombesin-stimulated gastrin release (compared to control); TNF- α increased in Hp infection, so the Hp-infected hypergastrinemia may be due to TNF- α - stimulation to G cells; ② IL-8: IL-8 stimulated gastrin release from isolated G cells, and this effect was dose-dependent and potentiated by Hp extract products.

The density of antral G cells was evaluated by expression of gastrin mRNA. The G cell density in patients with Hp infection was significantly higher than in controls; after eradication of Hp, the density was significantly lower as compared with pre-eradication value. The study suggests that increased gastrin mRNA is directly related to Hp infection^[15].

In a study of DU and non-ulcer dyspepsia (NUD), the Hp (absence of CagA gene and presence of VacA alleles s2 and m2) was only found in NUD (not with DU), and associated with lesser extent of gastrin increase and higher value of tryptase. The CagA negative s2m2 strain of Hp may be less dangerous for the gastric mucosa than other Hp strains, since it enhances tryptase production by gastric mucosal mast cells. This enzyme is thought to stimulate tissue turnover and favour wound healing^[16]. We may predict that the development of DU or NUD would probably depend upon the strains of Hp.

Combined serum levels of gastrin and pepsinogen (PG) were used to study Hp infection^[17-19]. As a screening procedure to show the status of Hp infection, both levels significantly increased in Hp infection, and significantly decreased after Hp eradication. The high levels may indicate Hp infection and the significant decrease after treatment may indicate cure, and reappearance of high levels suggests reinfection. The level of PG-II could be more useful in this situation^[18]. To classify DU, serum PG-I concentrations reflect the chief cell mass. Blood samples were taken before and at 15, 30, and 60 min after test meal, and the serum concentrations of fasting PG-I and gastrin were measured after meal. The area, under the serum gastrin 1h curve, was taken as integrated gastrin response (IGR). The DU patients (Hp positive) were divided into two groups (hyper-IGR and normal-IGR, with significant difference). The hyper-IGR DU patients

Received 2000-05-12 **Accepted** 2000-09-12

had higher serum PG-I concentrations, and suggest to be acid hypersecretors^[19].

Change of acid (parietal cells) sensitivity to gastrin. In a study of three groups of subjects (DU patients, *Hp*-negative and *Hp*-positive healthy volunteers), the MAO (maximal acid output), and the acid sensitivity to gastrin were measured (serum gastrin required to achieve 50% MAO during intravenous administration of gastrin). The result revealed that the *Hp* positive healthy volunteers showed significantly higher gastrin concentrations, which meant less sensitive than the other two groups. The DU group had significantly higher MAO. Conclusively, a combination of decreased sensitivity to gastrin in infected healthy volunteers and increased maximal acid secretory capacity in patients with DU underlies their different acid response to *Hp*-induced hypergastrinemia, and they are caused by the hypergastrinemia^[8].

In patients with end stage of renal disease on dialysis, the hypergastrinemia was induced by *Hp* infection in stomach, and the serum gastrin concentrations were decreased to normal range following eradication of *Hp*^[20]. Either *Hp* infection or omeprazole administration can cause hypergastrinemia, and both of them would cause severe hypergastrinemia, which may exert potential deleterious effects. Since omeprazole treatment produced a similar percentage increase in serum gastrin, it is appropriate to eradicate *Hp* prior to commencing proton pump inhibitor treatment in order to reduce the degree of hypergastrinemia^[21,22].

Evidence indicated that gastrin concentrations decreased to normal range after *Hp* eradication^[11,23-26].

***Hp* INFECTION AND SOMATOSTATIN (SS)**

***Hp* infection and D cells**

Hp infection is associated with exaggeration of gastrin release following meals or bombesin stimulation attributed to a defect of SS secretion of antral D cells^[27,28]. Mucosal cytokines (TNF- α and IL-8 are predominant ones) were increased in *Hp* infection. TNF- α could stimulate the isolated canine gastric D cells to increase SS release dose-dependently, and the stimulatory effect was potentiated by IL-8 and inhibited by octreotide. In conclusions, TNF- α can regulate SS release from cultured D cells in a divergent manner^[29].

***SS* inhibition on *Hp* proliferation**

In *Hp* infection, SS contents in antral mucosa and gastric juice, and number of D cells were decreased, and less expressions of SS mRNA and *Hp* eradication resulted in restoration of those indices, suggesting the *Hp* inhibition on SS release. In different SS concentrations *in vitro*, SS at

$10^{-11}\text{mol}\cdot\text{L}^{-1}$ significantly suppressed the proliferation of cultured *Hp*. SS at a similar level in human gastric juice ($\approx 10^{-11}\text{mol}\cdot\text{L}^{-1}$) indicated an inhibitory effect of SS in the gastric lumen on *Hp* proliferation in humans^[30].

Lipopolysaccharide (LPS) of Hp and SS

LPS inhibits the binding of SS to its gastric mucosal receptors. The antiulcer agents, sucralfate, ebrotidine and sulglycotide, possess the ability to restore the receptor-SS binding by 92.5%, 94.9% and 84%, respectively. Conclusively, LPS of *Hp* inhibits the SS binding to its receptor, and results in less SS effect, more gastrin and gastric acid secretion, and ulcer formation^[31,32].

***Hp* infection and gastrin-somatostatin equilibrium**^[33-41]

SS from D cells inhibits G cells, and decreased SS results in increase in gastrin secretion; gastrin stimulates, and SS inhibits parietal cells in gastric acid release. So, gastrin and SS form the gastrin-SS equilibrium, which was even called mechanism of gastric regulatory physiology. Phenomena related to imbalance of gastrin-SS equilibrium are as follows:

① hypergastrinemia: *Hp* infection influences D cells firstly to diminish SS release, then increases release of gastrin and acid, leading to the milieu favoring ulcer formation; eradication of *Hp* gets rid of the imbalance; the large mass of parietal cells in DU patients might be due to the long-term trophic effect of gastrin on parietal cells, and 6-12 months after *Hp* eradication, the MAO (representing parietal cell mass) fell significantly; this investigation supports the viewpoint; ② atrophic pangastritis: the degree and extent of gastritis affect destructive number of cells (D, G and parietal) which lead to the released amounts of SS, gastrin and acid in severe destruction; the resultant hyperchlorhydria tends to ulcer formation, and hypochlorhydria to develop carcinoma; pangastritis involving much more D cells and parietal cells may play an important role in imbalance of gastrin-SS equilibrium; ③ increased cytokines (TNF- α and IL-1 β) in *Hp* infection lead to gastrin-SS imbalance with hyperchlorhydria or hypochlorhydria, and then forming DU or carcinoma; ④ hypergastrinemia of *Hp* (CagA) gastritis is due to decreased density of D cells; ⑤ water extract of either *Hp*(CagA and VacA) positive or *Hp*(CagA and VacA) negative delayed ulcer healing as compared with saline controls in rats, because of impairment of gastrin-SS link; ⑥ in *Hp*(+) DU patients, the amount change of T lymphocyte subsets was obviously correlated with those of gastric active inflammation, serum gastrin, and SS in gastric juice, indicating that gastrin and SS played a role in immune regulation. Gastrin-SS equilibrium restores after *Hp*

eradication. SS may be the most widely effective gastrointestinal hormone in human body, and it is worthy of further studies^[42].

***Hp* INFECTION AND GASTRIN RELEASING PEPTIDE (GRP)**

GRP can stimulate gastric acid secretion, and is particularly valuable in detecting disturbances of gastric secretory function of patients with DU and *Hp* infection. Its attractiveness lies in the fact that it simultaneously activates many physiological control processes, both stimulatory and inhibitory. This facilitates the detection of a defect in any of the controls involved in regulating biological function. Other gastrointestinal functions such as gallbladder contraction, pancreatic secretion and gastroesophageal motility are subject to complex regulatory controls, and GRP may also be of value in investigating disturbances of these processes^[43].

GRP effect on gastrin and SS mRNAs in humans infected with Hp

GRP stimulates gastrin secretion, but also inhibits its release via SS. Exogenous GRP stimulates a greater increase in plasma gastrin concentrations in *Hp* infected patients than in uninfected controls. This is due to less inhibition on gastrin mRNA in *Hp* infection, probably because of low stimulated SS levels in *Hp* infection^[44].

PAO from GRP in DU patients before and after Hp eradication

In a study of gastric acid increment in DU patients, the GRP stimulated PAO (PAOGRP) and pentagastrin stimulated PAO (PAOPG) were measured in *Hp* positive DU patients and in *Hp* negative as controls. This study has shown that BAO, PAOGRP and PAOPG are significantly higher in *Hp* positive DU than in *Hp* negative controls. All decreased significantly six months after *Hp* eradication to fall within the range of controls. These results are compatible with a hypothesis that acid hypersecretion in DU is caused by *Hp* infection^[45]. Peterson's investigation showed a similar result that GRP stimulated hypergastrinemia and hyperchlorhydria which were lowered to normal range after *Hp* eradication^[46].

HP INFECTION AND GROWTH FACTORS

***Hp* infection and epidermal growth factor (EGF)**

EGF was found in at least seven individuals, and four of them were expressed in gastrointestinal tract. They were EGF, transforming growth factor alpha (TGF- α), amphiregulin (AR), and heparin binding-epidermal growth factor (HB-EGF). EGF and TGF α have the same receptor, EGFr. EGFs combined to their receptors which widely existed

over cellular membrane to regulate cell growth and play biological roles. EGF serves gastrointestinal tract with cell growth, ulcer healing and suppression of acid secretion^[47].

Acute exposure to *Hp* caused cell damage and impaired the processes of cell migration and proliferation in cultured gastric mucosal cells *in vitro*. EGF-related growth factors play a major role in protecting gastric mucosa against injury, and are involved in the process of gastric mucosal healing. In the study of Romano *et al*, using MKN 28 gastric mucosal cells (derived from gastric adenocarcinoma), *Hp* increased mucosal (MKN 28 cells) generation of EGF-related peptides; the inhibitory effect of *Hp* on the reparative events mediated by EGF-related growth factors might play a role in the pathogenesis of *Hp*-induced gastrointestinal injury^[48].

Hp inhibits both EGF binding to its receptors and EGF-stimulated gastric cell proliferation, and they are the mechanisms of peptic ulcer formation and its difficulty in healing^[49-52]. In a study of gastric luminal release of EGF, the stomach was capable of secreting large amounts of EGF, and pentagastrin appeared to be a potent stimulus to gastric EGF release; the *Hp* infection reduced the release of gastric EGF, and eradication of *Hp* resulted in the augmentation of basal and pentagastrin-induced EGF release into the stomach. Since the eradication of *Hp* infection in DU patients resulted in DU healing which was accompanied by an increase in EGF release, conclusively, EGF plays a crucial role in DU healing^[53,54]. Accordingly, it also plays a major role in ulcer formation.

***Hp* infection and hyperproliferation of gastric mucosal epithelium**

The overexpression of C-myc gene protein and EGFr (receptor of EGF) may be the molecular basis for hyperproliferation of gastric mucosal epithelium in *Hp* infection^[55].

***Hp* infection and growth factors in gastric juice**

The EGF concentrations in gastric juice were affected by *Hp* and pH. There were four situations in NUD patients studied: ① EGF was 80% lower in *Hp*(+) than in *Hp*(-); ② those with pH<4.0 in gastric juice had significantly lower EGF concentrations; ③ those with gastric juice pH>4 showed similar concentrations of EGF in both *Hp*(+) and *Hp*(-) groups; ④ those with both *Hp*(+) and pH<4.0 had further reduction in EGF concentrations. These results suggested that *Hp* may elaborate factors that accelerate its proteolytic degradation or inhibit its rate of synthesis and/or secretion; pH reduction (<4) may increase EGF degradation; the diminished content of EGF at low pH, especially in *Hp*-positive patients, may

facilitate the development of mucosal damage. The TGF- α concentrations in gastric juice remained unaffected by *Hp* or pH^[56].

The cytoprotective effect of sulglycotide

In studying *Hp* protease activity and its suppression by sulglycotide, it was found that the *Hp* protease evoked a 61.7% degradation of PDGF (platelet derived growth factor) and a 62.3% degradation of TGF β ; introduction of sulglycotide to the reaction assay system caused a dose-dependent inhibition in PDGF and TGF β proteolysis by the *Hp* protease; the maximal inhibitory effect was obtained with sulglycotide at 100mg·L⁻¹, at which dose an 84.4% decrease in PDGF and 88.3% decrease in TGF β degradation were achieved; the results provide a strong evidence for the effectiveness of sulglycotide in the protection of gastric mucosal growth factors against degradation by *Hp*^[57].

Eradication of Hp related to EGF and TGF

EGF and TGF- α are potent gastric secretory inhibitors, mitogens, and mucosal protectors, and their gastric mucosal expression and luminal contents are closely related to *Hp* infection. A study of DU and NUD patients showed that chronic *Hp* infection and resulting antral gastritis were associated with increased plasma gastrin and increased mucosal cell proliferation, probably due to enhanced expression of EGF and TGF- α ; the *Hp* eradication decreased plasma gastrin, but the increase in gastric EGF and TGF- α contents was sustained, suggesting that they may be involved in ulcer healing^[58].

Effect of *Hp* infection on gastric mucosal expression of EGF, TGF- α , and EGFr. In a study of Konturek *et al*, the DU patients with *Hp*(+) were accompanied by increased mucosal expression and contents of TGF- α , EGF, and EGFr, and eradication of *Hp* infection enhanced all of them and contributed to ulcer healing^[59]. Russo *et al* also indicated that *Hp* eradication resulted in a significant increase in expression of EGF and TGF- α ; *Hp* possibly inhibited the mucosal expression of EGF and TGF- α ^[60]. The results from different authors seem not wholly consistent. It is appropriate to study further.

Implications of Hp, mucosal growth factors and gastric acid in pathogenesis of DU and gastric carcinoma

It has been revealed that patients with DU and gastric carcinoma possessed 3 common features which contributed to the pathogenesis of the two diseases: they were *Hp* infection, increase in gastric mucosal and luminal growth factors (EGF, TGF- α), and hypergastrinemia. They remained different in hyperchlorhydria in DU patients, and in patients

with gastric carcinoma. These changes returned to normal values two years after *Hp* eradication in DU patients. The hypochlorhydria was possibly due to atrophy of oxyntic mucosa and overexpression of growth factors in gastric mucosa may be implicated in the pathogenesis of both DU and gastric cancer. Hypergastrinemia, hypochlorhydria, and increase in mucosal growth factors are predisposing to gastric cancer^[61].

Hp infection and insulin-like growth factor-1 (IGF-I)

Taha *et al* measured gastric and fasting serum concentrations of IGF-I in patients with and without *Hp* infection. As a result, IGF-I was detected at very low concentrations in gastric juice and in mucosal incubates. The median serum IGF-I concentration was 88 μ g·L⁻¹ in the patients infected with *Hp* compared with 90 μ g·L⁻¹ in the non-infected controls; IGF-I concentrations significantly dropped to 77 μ g·L⁻¹ following eradication therapy. Conclusively, the similarity in baseline IGF-I concentrations in the presence and absence of *Hp* suggests that their subsequent drop after treatment is more likely to be produced by the treatment^[62].

HP INFECTION AND OTHER GASTROINTESTINAL HORMONES

Hp infection and insulin

It is true that *Hp* gastritis resulted in increased secretion of basal and meal-stimulated gastrin, which is also a physiologic amplifier of insulin release. In order to confirm whether *Hp* gastritis may enhance nutrient-stimulated insulin secretion, both glucose and a mixed meal stimulated insulin response were investigated in *Hp* positive gastritis and *Hp* negative control subjects. The areas under the curve (AUC) for serum insulin following both oral glucose and a mixed meal in the patients with *Hp* gastritis were significantly higher than those of non-*Hp* controls. After *Hp* eradication, the AUC for serum insulin following oral glucose and mixed meal decreased significantly, and serum basal and meal-stimulated gastrin levels also obviously decreased. These results suggest that *Hp* gastritis enhances glucose and meal-stimulated insulin release probably by increasing gastrin secretion^[63].

Hp infection and glicentin

Glicentin seems to promote intestinal metaplasia (IM) in the gastric mucosa. In order to clarify whether *Hp* infection accelerates glicentin gene expression, glicentin mRNA was investigated using gastric biopsies. The results disclosed that glicentin mRNA was significantly correlated with histological IM and was positively correlated with *Hp* infection. Conclusion is that *Hp* infection is associated with

the induction of glicentin in the gastric mucosa, thus supporting the hypothesis that *Hp* infection accelerates IM of the stomach^[64].

Hp infection and cholecystokinin (CCK)

In healthy subjects, CCK has the feedback control of postprandial gastrin release and gastric acid secretion, but in *Hp*-positive DU patients the CCK loses its control effect. Eradication of *Hp* restores the inhibitory effect of CCK on postprandial gastrin release and gastric acid secretion. This suggests that *Hp* infection eliminates or lessens the inhibitory effect of CCK on gastrin release^[65].

Hp infection and gastric inhibitory polypeptide (GIP)

There was no significant difference of serum GIP levels among groups of gastrectomy (total, subtotal), healthy subjects, *Hp* infection, age, gender, body mass index, smoking. Only the elapsed time since operation in patients following total gastrectomy exhibited a significant positive correlation with their GIP levels ($r = 0.89$, $P < 0.05$). Hence GIP is less important in mediating gastric acid secretion, and *Hp* does not influence its levels^[66].

Long term omeprazole therapy for reflux esophagitis: follow-up in serum gastrin levels, EC cell hyperplasia and neoplasia

Pankaj Singh, Anant Indaram, Ronald Greenberg, Vernu Visvalingam and Simmy Bank

Subject heading gastroesophageal reflux; proton pump inhibitors; enterochromaffin cell; hypergastrinemia; carcinoid tumor; biopsy

Singh P, Indaram A, Greenberg R, Visvalingam V, Bank S. Long term omeprazole therapy for reflux esophagitis: follow-up in serum gastrin levels, EC cell hyperplasia and neoplasia. *World J Gastroentero*, 2000;6(6):789-792

Abstract

AIM To evaluate the long-term safety of omeprazole in patients of gastroesophageal reflux disease resistant to treatment with H₂ receptor antagonist.

METHODS We prospectively followed 33 patients on omeprazole therapy for severe erosive esophagitis for 5-8 years, with periodic gastrin levels, *H. pylori* infection, gastric biopsies for incidence of ECL cell hyperplasia, carcinoids, gastric atrophy and neoplasia. A total 185 patient follow-up years and 137 gastric biopsies were done.

RESULTS Among the 33 patients, 36% reached their peak gastrin levels in an average of 8 months to one year, then drifted Down slowly over 1-2 year period to just above their baseline level, 24% of the patients had a peak gastrin level above 400ng·L⁻¹ and one patient had a peak level above 1000ng·L⁻¹. One patient had a mild ECL cell hyperplasia which was self limiting and did not show any dysplastic changes. Eighteen percent of patients were positive for *H. pylori* infection. The gastric biopsies did not show gastric atrophy, intestinal metaplasia or neoplastic changes.

CONCLUSION In a series of 33 patients followed for 5-8 years on omeprazole therapy

for severe reflux esophagitis, we did not observe any evidence of significant ECL cell hyperplasia, gastric atrophy, intestinal metaplasia, dysplasia or neoplastic changes.

INTRODUCTION

Acid suppression therapy plays a pivotal role in the medical management of reflux esophagitis. The most recently developed acid suppressive agents, the proton pump inhibitors (PPIs) directly inhibit hydrogen ion exchange and inhibit acid secretion in response to all stimulatory agents^[1-5]. The PPIs are benzimidazole derivatives, which are converted to active metabolites within the acidic confines of the secretory canaliculi of the gastric parietal cells. They promote oxidation of sulphhydryl components of the proton pump, leading to irreversible inactivation of the enzyme^[1]. Recovery of acid secretion requires synthesis of new proton pumps. There is now a definite evidence that PPIs are more effective than H-2 receptor antagonists in treating esophagitis, severe refractory reflux disease and non-healing esophageal ulcers, providing faster healing and symptomatic relief^[6-9]. Esophagitis is however a chronic problem, as early relapses have been observed after cessation of H-2 blockers and omeprazole^[7,8]. Therefore, maintenance treatment is often required in treating the reflux esophagitis. H-2 blocker has failed, as an effective maintenance agent in preventing the relapses^[9,10]. There is enough evidence to support the role of PPIs as an effective agent in maintaining healing of erosive esophagitis^[8,11-16]. However, questions regarding the long-term safety of the proton pump inhibitors have been raised. The resulting hypo-/achlorhydria and resulting hypergastrinemia have been implicated in the development of enterochromaffin cell hyperplasia and gastric carcinoids^[17-20]. The epidemiological evidence of increased incidence of gastric fundal carcinoma has further raised concerns regarding, gastric atrophy and the long-term use of PPIs in acid related peptic diseases, especially in patients with *H. pylori*

infection^[21].

Considering the efficacy of PPIs and possibility of their role in development of EC cell hyperplasia, it was logical to study their safety profile as long term maintenance therapeutic agents in esophagitis.

MATERIALS AND METHODS

At Gastroenterology Department, Long Island Jewish Medical Center 33 patients with severe reflux esophagitis of grade 2 and above, whose symptoms were not responding to H₂ blockers and motility agents were enrolled in the study. Patients were started on omeprazole (PPI) either daily or on an alternate day regimen and were followed periodically for symptom relief, endoscopic healing, plasma gastrin level, *H. pylori* infection and gastric biopsies for occurrence of neoplasia. Esophagitis was graded endoscopically using the following scale: grade 0, normal appearing; grade 1, mucosal edema, hyperemia and/or friability; grade 2, one or more erosions/ulcerations involving <10% of the distal five cm of the esophagus; grade 3, erosions/ulceration's involving 10% to 50% of the distal 5cm of the esophagus or an ulcer 3mm-5mm in diameter. In cases of Barrett's esophagus, the area 5cm proximal to the squamo-columnar junction was evaluated; grade 4, multiple erosions involving 50% of the distal 5cm of the esophagus or a single ulcer >5mm in diameter. Whenever clinically feasible, all endoscopies for a particular patient were performed by the same endoscopist. Complete healing of erosive reflux esophagitis was defined as the return of esophageal mucosal inflammation to grade 0 or grade 1.

Periodic plasma gastrin levels were measured after an 8 hours fast prior to endoscopy. Four gastric biopsy specimens of full thickness of the mucosa (two fundal, two antrum) were obtained at the screening visit and at the end of 8-12 weeks to assess healing. At intervals of 6 to 12 months periodic upper endoscopies were performed to monitor for carcinoids, gastric atrophy and gastric neoplasia. Bouin's fixed, paraffin-embedded, 3 microns hematoxylin and eosin-stained sections of each biopsy specimen were evaluated and graded for active and chronic inflammation. The presence of intestinal metaplasia, atrophy, dysplasia and neoplasia was evaluated. The enterochromaffin like cells of the oxyntic gastric mucosa were assessed using Grimelius stain sections and Solcia's scale of gastric endocrine growth. Two independent pathologists who were blinded to each other's assessments of the biopsy specimens reviewed gastric biopsies.

H. pylori infection was assessed by identifying the organisms and chronic inflammation in the biopsy specimens, serum *H. pylori* IgG antibodies or by CLO test. Out of the 33 patients, 22(66%) were male and 11(34%) were female (Table 1).

The mean age of the patients was 76 years with a range of 34 to 86 years (Figure 1). Twenty-six (78%) patients were on omeprazole daily 10mg-20mg or 10mg-20mg twice daily. Seven (21%) patients were on alternate day 10mg-20mg omeprazole therapy for severe reflux esophagitis (Table 1). The average period of follow-up was for 6 years, with a range of 3 to 8 years, a total of 185 patient years of follow up (Figure 2). The total number of biopsies done was 137, averaging 4, with a range of 2 to 13.

Table 1 Type of treatment and sex distribution (n=33)

Group	Number
Alternate day omeprazole therapy	7
Daily omeprazole therapy	26
Male patients	22
Female patients	11

RESULTS

Twelve (36%) of the patients reached their peak plasma gastrin levels in one year, and then drifted to a level above their baseline levels in 1 to 2 years. Three (9%) reached their peak in 2 years, 5 (15%) in 3 years, 3 (9%) in 4 years, 5 (15%) in 5 years, 2 (6%) in 7 years, 1 (3%) in 8 years (Figure 3). Eleven (33%) of patients had plasma gastrin levels below 100pmol·L⁻¹, 24% of patients above 400pmol·L⁻¹ and in one patient it was above 1000 pmol·L⁻¹. Gastric biopsies showed normal mucosa on initial biopsy in 26 and gastritis in 7. On repeat biopsy 7 changed from normal to gastritis and 4 from gastritis to normal. Nineteen were normal at all times. Of the 6 *Hp*+ (*H. pylori* positive) patients, 1 was normal on all occasions, 2 showed gastritis, 2 varied from normal to gastritis and 1 from gastritis to normal. Of the 27 *Hp* negative patients, 18 were normal at all times, 1 showed gastritis, 5 varied from normal to mild gastritis and 3 from gastritis to normal. No atrophy was diagnosed at any time over the 5-8 years, on any of the 137 biopsy specimens.

EC cell hyperplasia was seen in one of the biopsies. Neither fundal gastric neoplasia, nor carcinoids were seen (Table 2).

Table 2 Results of gastric biopsies in-patients on long term omeprazole therapy for reflux esophagitis

Pathology	Number
Normal throughout the treatment	19
Normal at onset, later gastritis changes	7
Initial fundal gastritis	7
Initial gastritis changed to normal	4
ECL cell hyperplasia	1
Barretts esophagus	4
<i>H. pylori</i> infection +ve	6
<i>H. pylori</i> infection -ve	27

Figure 3 Time to reach maximum plasma gastrin levels in patients treated with long term omeprazole.

DISCUSSION

Esophagitis is a chronic problem with frequent early relapses^[7,8]. Therefore, it is not only important to treat the reflux disease but also to prevent relapses. It is now known that PPIs are more effective than H-2 receptor antagonist in treating refractory reflux disease^[1,6,12-16] providing faster healing and symptomatic and in preventing early relapses^[9,10]. Concerns were raised regarding the safety of PPI as a long-term maintenance agent^[17-19]. In our study, we found omeprazole to be a safe drug even when used over a long period. Hypochlorhydria,

encountered with PPIs has strong association with hypergastrinemia^[28]. Hypochlorhydria leads to fall in the secretion of somatostatin from antral D cells. Somatostatin is a major negative feedback mediator of gastrin release and its absence leads to persistent gastrin release^[22-25]. Because PPI's are better inhibitors of gastric acid secretion than H-2 receptor antagonist is, they are associated with higher gastrin levels. Freston *et al* and other studies showed that plasma gastrin levels generally peak in the first four months of treatment with PPIs and stabilize without further increase thereafter^[26,27]. In our studies, the gastrin level peaked on an average in initial 8-12 months of treatment. The early peak in other studies could have been because of development of gastric atrophy in some of their patients^[26,27]. The same reason was postulated for the eventual decline in gastrin level. Although we also observed the decline in gastrin level after a period of 1-2 years, but we did not observe gastric atrophy in any of our patients. It is not yet clear why after some time the gastrin levels came down. The consequences of hypergastrinemia have aroused interest because gastrin has a trophic effect on gastrin cell, especially ECL cells^[26,27]. Rat model studies, have revealed that sustained hypergastrinemia secondary to PPIs are associated with increased ECL cell hyperplasia and carcinoid tumor^[26-28]. These changes regress on bringing back the gastrin level to previously normal levels. In our study, we did not observe the similar relation between gastrin and ECL cell hyperplasia and carcinoid. This is in concordance with other studies done on long term safety profile of PPIs^[8,11-16,29]. However, it would be inappropriate to associate similar relations in humans, given that rats have a higher density of gastrin ECL cells and a greater gastric response to hypochlorhydria than humans^[21,30]. This is further supported by the fact that, PPIs when used in other animals (e.g. dogs, guinea pigs, hamsters, mice), do not cause ECL cell carcinoids.

Borch *et al*^[31] identified ECL cell carcinoids in approximately 4% of patients with pernicious anemia, thus raising the concern that this may be of relevance to use of PPIs. This seems unlikely as patients who developed carcinoid in his study had gastrin level 10-20 times normal level versus 2-4 folds during omeprazole treatment. The carcinoids were observed on an average after a period of 19 years of persistent severe hypergastrinemia^[31]. The development of carcinoid has also been observed in patients with hypergastrinemia secondary to Zollinger Ellison syndrome. All of these cases had coexisting familial MEN-I α -syndrome^[28]. This combined group of ZES and MEN-I α comprises 25% of all Zollinger Ellison syndromes and the fact that all the cases of carcinoid has been observed only in this subgroup suggests that familial factor also plays an important role in carcinoidogenesis^[28].

It would appear from available information that severe and sustained hypergastrinemia is required to produce ECL cell hyperplasia. When coupled with other factors, such as genetic trait of MEN-1 syndrome, it may lead to carcinoid formation.

In conclusion, our results show that omeprazole is a safe drug, when used for a long-term maintenance treatment in healing reflux disease.

Abstract

AIM To investigate the hepatitis C virus (HCV) infection in the tissues of carcinoma of extrahepatic bile duct and study their correlation.

METHODS HCV NS5 protein and HCV RNA were detected by labeled streptavidin biotin (LSAB) method and *in situ* reverse transcription polymerase chain reaction (IS-RT-PCR) in sections of 51 cases of carcinoma of extrahepatic bile duct and 34 cases of control group (without malignant biliary disease).

RESULTS In 51 cases of carcinoma of extrahepatic bile duct, HCV NS5 protein was detected in 14 (27.5%), which was clearly stained in the cytoplasm of cancer cell but not in the nucleus or cell membrane. HCV RNA was detected in 18 (35.4%), which was located in the nucleus of cancer cell in 12 cases and in the cytoplasm in 6 cases. HCV NS5 protein and RNA coexistence was found in 2 cases. In 34 cases of control group, HCV RNA was detected in 2 (5.9%). HCV NS5 protein and RNA positive cells were found either scattered or in clusters.

CONCLUSION The prevalence of hepatitis C

viral infection in the tissues of carcinoma of extrahepatic bile duct was significantly higher than in control group ($\chi^2=9.808$, $P=0.002$). The findings suggest a correlation between HCV infection and carcinoma of extrahepatic bile duct, which is different from the traditional viewpoint. HCV infection might be involved in the development of carcinoma of extrahepatic bile duct.

INTRODUCTION

Cancer of bile duct arises from malignant transformation of the epithelia of bile duct. It is even less common than gallbladder carcinoma, and seen in 0.01%-0.46% of all autopsies^[1] and its pathogenesis has not been fully understood. Cancer of bile duct is different from hepatocellular carcinoma (HCC) in etiologic factors, the former is not correlated to HBV or HCV infection and liver cirrhosis, traditionally^[2]. It has been reported that only 10%-20% patients with bile duct cancer accompany liver cirrhosis, but 70%-90% patients with HCC are associated with liver cirrhosis^[3-5]. There is a high incidence of bile duct cancer in the southeast Asia, and liver fluke infection due to *clonorchis sinensis* and *opisthorchis viverrini* is the most frequently cited cause of bile duct cancer^[6,7]. Now the development of bile duct cancer has been linked to hepatolithiasis, *clonorchis sinensis*, congenital dilatation of bile duct, and chronic inflammatory bowel disease^[8-11]. In China, 0.33%-9.7%, patients with hepatolithiasis^[12,13], 2.1%-21% with the choledochal cyst^[14-17] and 0.22% with *clonorchis sinensis* infestation^[18] are simultaneously complicated with bile duct cancer. Bile duct cancer simultaneously complicated with gallstone, choledochal cyst, and *clonorchis sinensis* infestation accounts for 6.15% - 16.9%^[19-22], 7%^[15] and 6.4%^[23] in total bile duct cancer of the corresponding period, respectively. But the incidence of bile duct cancer complicated with ulcerative colitis simultaneously is not estimated in literature in China now. These investigations indicated, therefore, that Chinese patients with bile duct cancer suffered from above-mentioned diseases before only account for one third or a half of the

Received 2000-04-24 Accepted 2000-05-12

total patients with bile duct cancer. In extrahepatic biliary carcinoma in China, carcinoma of extrahepatic bile duct covered 75.2%^[24], the incidence of carcinoma of extrahepatic bile duct tends to increase over the past decade, but its cause is still unclear^[24].

Hepatitis C virus (HCV) is a RNA virus with a genomic size of 9.6kb, and now known to be the chief cause of transfusion-associated non-A, non-B hepatitis, which has been reported to occur in 7%-10% patients who received transfusion^[25,26]. More than 50% of individuals exposed to HCV develop chronic infection. Of those chronically infected individuals, about 20%-30% will develop liver cirrhosis and/or HCC when followed for 20 or 30 years^[27]. In China, the prevalence of HCV antibodies in blood donors as measured by the second or third generation assays is about 0%-4.6%^[28,29], and in a rural population the HCV infection rate is up to 15.3%^[30], which indicates that China is a relatively high incidence area of HCV infection. *In situ* reverse-transcription polymerase chain (IS-RT-PCR) has been successfully applied to the detection and localization of HCV RNA in formalin-fixed paraffin-embedded liver sections^[31,32], indicating that it becomes easy to detect the low level of HCV RNA. This study aims to investigate the HCV infection in the tissues of carcinoma of extrahepatic bile duct (51 cases) and control group specimens (34 cases) by detecting HCV NS5 protein and RNA using labeled streptavidin biotin (LSAB) method and IS-RT-PCR, and to determine their correlation.

MATERIALS AND METHODS

Carcinoma of extrahepatic bile duct tissues

Fifty-one cases of carcinoma of extrahepatic bile duct, and 34 specimens as control group (including 10 cases of choledochal cyst, 8 cases of hepatolithiasis, 2 cases of congenital dilatation of the intrahepatic bile duct, 2 cases of cystadenoma and 2 cases of adenoma of common bile duct, and 10 cases of wall of extrahepatic bile duct near gallstone) were collected from Department of Hepatobiliary Surgery, General Hospital of People's Liberation Army (PLA). All specimens were resected from 1995 to 1998, and fixed and embedded routinely. All carcinomas of extrahepatic bile duct were diagnosed as adenocarcinoma by the Department of Pathology, General Hospital of PLA. Five-micrometer thick for malin-fixed paraffin-embedded sections were prepared.

Primers and probe preparation

Primers and probe were all located at the highly conserved 5' non-coding region of the HCV genome. The oligonucleotide primers and probe were synthesized, and the probe was labeled with biotin (Sangon Co.Ltd). The sequences of outer primers are: sense, 5'-GGCGACACTCCACCATAGATC 3' (1-

21nt), antisense, 5' GGTGCACGGTC-TACGAGACCT 3' (304-324nt). The sequences of inner primers are: sense, 5' CTGTGAGGAAC-TACTGTCTTC 3' (28-48nt), antisense, 5' CCC-TATCAGGCAGTACCACAA 3' (264-284nt). Probe sequence is: 5' ACACCGGAATTGC-CAGGACGACCGGGTCCTTTCTTG 3' (142-177nt).

HCV NS5 protein detection by LSAB method

The sections were dewaxed and rehydrated routinely, and then treated for 5min with 0.03% hydrogen peroxide in methanol to eliminate endogenous peroxidase activity. Antigen of the tissues was prepared in microwave oven. Sections were incubated with normal goat serum for 5min, and then incubated with anti-HCV-NS5 IgG (diluted 1:50) at 4°C overnight. After washed with phosphate buffered saline (PBS), sections were incubated with biotin-labeled goat anti-mouse IgG (diluted 1:200) for 45 min at 37°C. Sections were then incubated with horseradish peroxidase streptavidin (S-A/HRP) for 45min at 37°C. After washed with PBS, peroxidase activity was developed using 3,3'-diaminobenzidine (DAB, 0.3g/L) for 15min. The DBA detection method yields a yellow precipitate. Sections were subsequently counterstained with hematoxylin.

Negative control groups

PBS substituting for anti-HCV-NS5 IgG, biotin-labeled goat anti-mouse IgG, S-A/HRP, and omitting DBA in procedure served as negative controls, respectively.

HCV RNA detection by is RT-PCR method

The sections were deparaffinized with fresh xylene and graded alcohols, followed by PBS for 5min. The tissues were digested with proteinase K (30mg/L, 37°C, Sigma) for 15min and rinsed with DEPC-treated PBS three times, and then treated with Rnase-free Dnase I (700U/mL, Promega) at room temperature overnight or 37°C 2h in a humidified chamber. The sections were then fixed twice in 95% and 100% alcohol each for 3min. RT was achieved with 30μL- RT solution for each section (1×RT buffer, dNTP 250μM each, antisense of outer primer 1μM, Rnasin 1U/μL, AMV reverse transcriptase 0.4u/μL Promega) in a humidified chamber at 42°C for 60min. The reaction solution was dripped away and was hed with DEPC-treated PBS twice each for 5min, then fixed twice in 95% and 100% alcohol each for 2min, and the 50μL PCR solution for each section was applied which consisted of MgCl₂ 2.5mM, 1×PCR buffer, each primer 1μM, dNTP 250μM, *Taq* DNA polymerase 4U/50μL and BSA 3g/L. The "hot-start" approach was employed during which *Taq* DNA polymerase was added at 80°C. The *In situ* amplification of target sequences was performed in a

thermal cycler (GeneAmp *In situ* PCR System 1000 [Perkin Elmer]), using two primer pairs. The cycling conditions used were: the initial denaturation step at 94°C for 4min followed by 20 cycles of denaturation at 94°C for 2min, annealing at 55°C for 1.5min, and final extension of 72°C for 3min. The cover slip was removed. The sections were washed with PBS for 5min and fixed in 100% alcohol for 10min, then second PCR amplification was made. Except inner primers substituted for outer primers, the remaining steps were the same as the initial PCR amplification. The cover slip was removed. The sections were washed with PBS, and fixed in 100% alcohol for 10min. Sections in PBS were heated at 80°C for 10min, and put on ice. Then hybridization solution (probe 2.5mg/L, 50% deionized formamide, 5×SSC, 1×Denhardt's solution, sssDNA 100mg/L) was added on the slides at 37°C overnight. The section was washed with serial SSC, and covered with 10% normal sheep serum. The specimens covered with S-A/HRP at 37°C for 45min. DAB solution was added in slides at 37°C for 15min. The sections were incubated in the dark and checked at a 5min interval. The DBA detection method yields a yellow precipitate. After development, the sections were counterstained with hematoxylin. Positive cells and their histological distribution were examined.

Negative control groups

Hepatitis B liver tissues; HCV RNA positive specimens digested by Rnase (10g/L) at 37°C for 1h; HCV RNA positive specimens omitted AMV reverse transcription; HCV RNA positive specimens omitted Taq polymerase; and no probe control.

RESULTS

In 51 cases of carcinoma of extrahepatic bile duct, HCV NS5 protein was detected in 14 (27.5%), which was clearly stained in the cytoplasm of cancer cell but not in the nucleus or cell membrane. The positive signals of NS5 protein were distributed diffusely in the cytoplasm (Figure 1). The positive immunochemical reaction was not obtained in the same section when PBS substituted for anti-HCV-NS5 IgG, as did omission of the primary antibody from the staining procedure.

HCV RNA sequence was detected in 18 (35.4%) of 51 cases of carcinoma of extrahepatic bile duct. HCV RNA was located in the nucleus in 12 cases (Figure 2), and in the cytoplasm in 6 cases (Figure 3). In 34 cases of control group, HCV RNA sequences were detected in 2 (5.9%) (Figure 4). The HCV RNA positive signal was located occasionally in the mononuclear cells. After treated by Rnase or omitting AMV, Taq polymerase and probe in the procedure, no sections showed HCV RNA positive signal.

HCV NS5 protein and RNA coexistence were found in 2 cases. HCV NS5 protein and RNA

positive cells were found to be either scattered or in clusters. In the cytoplasm, some positive signals of HCV NS5 protein and RNA were so strong that it might be difficult in determining nucleic positive.

DISCUSSION

Although HCV is considered essentially to be hepatotropic, some studies indicate that it can also be found in the extrahepatic tissue, such as peripheral blood mononuclear cells^[33-37], kidney tissue and salivary glands^[38]. In the present study, HCV NS5 protein and RNA were found in cells of carcinoma of extrahepatic bile duct, which further demonstrates that HCV has wide host cells, and the main nucleic localization of HCV RNA in cells of carcinoma of extrahepatic bile duct was resembled the localization of HCV RNA in HCC^[39]. The incidence of HCV infection in the tissues of carcinoma of extrahepatic bile duct is significantly higher than in control group ($\chi^2 = 9.808$, $P=0.002$). This study indicates a correlation between HCV infection and carcinoma of extrahepatic bile duct, which is different from the traditional viewpoint. HCV infection is not correlated to bile duct cancer^[2]. It is inferred that HCV infection, being similar to hepatolithiasis, choledochal cyst, etc., may be one of the risk factors involved in the development of carcinoma of extrahepatic bile duct.

HCV is a plus-strand RNA virus^[40]. HCV RNA and proteins can be detected in cells of HCC^[41-46], and infection with the HCV is now known to be a major risk factor for the development of HCC^[47-51]. But HCV genome does not integrate into the genome of infected cells^[52,53]. For hepatitis B virus (HBV), integration of HBV DNA into host chromosomes raises the possibility of a direct carcinogenic effect of HBV through interaction with oncogenes, growth factors, or tumor suppressor genes^[54-58]. The mechanism of carcinogenesis of HCV is not fully understood now, which may be involved in proteins HCV gene encoding. It has been noted recently that the HCV core protein demonstrates diverse biological functions, including the regulation of cellular and unrelated viral genes at the transcriptional level, and has some potential direct carcinogenic effects *in vitro*. HCV core protein could activate human c-myc, early promoter of SV10, Rous sarcoma virus LTR and HIV-1 LTR^[59], inhibit cisplatin-mediated apoptosis in human cervical epithelial cells and apoptosis induced by the overexpression of c-myc in Chinese hamster ovarian cells^[60], and repress transcriptional activity of P53 promoter^[61]. Translocated expression of HCV core protein may also inhibit apoptosis in the tissue of HCC^[62]. REF cells cotransfected with HCV core and H-ras genes became transformed and exhibited rapid proliferation, anchor-independent growth, and tumor formation in athymic nude mice^[63]. Transformation of NIH3T3 cells to the tumorigenic phenotype by the nonstructural protein NS3 of HCV was demonstrated and the proteinase activity associated with this protein was suggested as the

cause of transformation^[64]. HCV NS3 protein may exert its hepatocarcinogenic effect in early stage on host cells by endogenous pathway which may bring about mutation of p53 gene and transformation of hepatocytes^[65]. NS5 protein from HCV-1b ORF includes NS5A and NS5B. Recently, NS5A protein is reported to be a potent transcriptional activator^[66], and can repress the interferon-induced protein kinase through direct interaction with each other^[67]. The experimental data suggest that HCV gene products have a function of gene regulation, and can modulate cell growth and differentiation, and may be directly involved in the malignant transformation of HCV-infecting cells. But how HCV infection is involved in the development of carcinoma of extrahepatic bile duct needs further research.

Abstract

AIM To explore the status of extrahepatic hepatitis C virus (HCV) infection and replication in hepatitis C patients, and its potential implication in HCV infection and pathogenicity.

METHODS By reverse-transcriptase polymerase chain reaction (RT-PCR), *in situ* hybridization (ISH) and immunohistochemistry, HCV RNA, HCV replicative intermediate (minus-strand of HCV RNA), and HCV antigens were detected in 38 autopsy extrahepatic tissue specimens (including 9 kidneys, 9 hearts, 9 pancreas, 5 intestines, 2 adrenal glands, 2 spleens, 1 lymph node, and 1 gallbladder) from 9 hepatitis C patients, respectively; and the status of HCV replication in extrahepatic tissues was studied.

RESULTS By RT-PCR, all 9 patients were positive for HCV RNA in kidney, heart, pancreas, and intestine, but only 6 (66.7%) patients were positive for HCV replicative intermediate. HCV RNA and HCV antigens were detected in kidney, heart, pancreas, intestine, adrenal gland, lymph node, and gallbladder in 5 (55.6%) and 6 (66.7%) patients by ISH and immunohistochemistry, respectively. HCV RNA

and HCV antigens were not detected in these extrahepatic organs in 3 (33.3%) patients, although their livers were positive for HCV. HCV replicative intermediate detected by RT-PCR was consistent with HCV RNA and HCV antigens detected by ISH and immunohistochemistry ($Kappa = 0.42-0.75$). HCV RNA and HCV antigens were detected in myocardial cells, epithelial cells of intestinal glandular, interstitial cells of kidney, epithelial cells of tubules and glomerulus, pancreas acinar cells and epithelial cells of pancreatic duct, epithelial cells of mucous membrane sinus of gallbladder, cortex and medulla cells in adrenal gland, and mononuclear cells in lymph node. HCV RNA was also detected in bile duct epithelial cells, sinusoidal cells, and mononuclear cells in liver tissues by ISH.

CONCLUSION HCV can infect extrahepatic tissues, and many various tissue cells may support HCV replication; extrahepatic HCV infection and replication may be of "concomitant state" in most of patients with hepatitis C. The infected extrahepatic tissues might act as a reservoir for HCV, and play a role in both HCV persistence and reactivation of infection. HCV as an etiologic agent replicating and expressing viral proteins in extrahepatic tissues itself contributes to extrahepatic syndrome associated-HCV infection in a few patients with chronic HCV infection.

INTRODUCTION

Hepatitis C virus (HCV) was discovered in 1989^[1], and is in a separate genus of the virus family *Flaviviridae*. Some aspects of cell tropism of *Flaviviridae*, such as the yellow fever virus and the dengue fever virus, have been clarified by *in situ* staining technique^[2]. Different members of the *Flaviviridae* family infect a distinct, wide array of cells, resulting in multi-faceted disease expression. It should be noted that even a single amino acid change in the envelope molecule may modulate or even change the cell tropism and virulence of flaviviruses^[3,4]. It may only be inferred that HCV may gain access to and replicate in extrahepatic tissues when compared with other flaviviruses. In

1985, the report of Hellings *et al* showed that HCV, which was previously known as the non-A, non-B hepatitis virus, was successfully transmitted via the infusion of PBMC (peripheral blood mononuclear cells) purified from the patients; and then, Nouri Aria *et al* reported that HCV RNA and HCV replicative intermediate (minus-strand of HCV RNA) were detected in the cytoplasm and nuclei of mononuclear and biliary epithelial cells in liver tissue by ISH. Other studies also indicated that HCV can transmit from mother to infant, possibly occurring in utero^[5,6]. These results suggested that HCV might replicate in PBMC and nonhepatic cells. In recent years, studies in extrahepatic HCV infection focused on readily obtainable tissue and body fluid samples such as PBMC^[7-10], saliva, semen, urine, ascites, and biliary juices^[11,12]. Subsequently, HCV replication in cells of the hematopoietic lineage has been demonstrated^[8-10,13]. The results showed that it might be of pathological significance in HCV infection^[8,10,14,15]. Recently, HCV RNA and HCV replicative intermediate in lymph node, pancreas, adrenal gland, thyroid, spleen, ovary, and uterus were detected by RT-PCR^[16,17], but there was lack of *in situ* detection of HCV RNA in these extrahepatic tissues.

During HCV infection, the viral burden and subsequent tissue damage were mainly confined to the liver^[18-22]. However, several extrahepatic syndromes associated with HCV infection have been reported^[23-26], which include mixed cryoglobulinaemia, glomerulonephritis, lymphoma, and other extrahepatic diseases such as porphyria cutanea tarda^[27]. Up to now, little is known about the mechanisms and the role of HCV in the development of these extra hepatic syndromes; and the extrahepatic tissue cells that support viral replication have not been identified. Accordingly, we conducted reverse-transcriptase polymerase chain reaction (RT-PCR), *in situ* hybridization (ISH), and immunohistochemistry for HCV RNA, HCV replicative intermediate, and HCV antigens in several extrahepatic tissues from 9 hepatitis C patients in an attempt to explore the status of extrahepatic HCV infection and replication, and its potential implication in HCV infection and pathogenicity. We believe that the information so derived could lead to a better understanding of the mechanisms of both HCV persistence and reactivation of infection, and the role of HCV in the development of extrahepatic syndromes associated with HCV infection.

MATERIALS AND METHODS

Patients

Nine patients with severe viral hepatitis (1986-1994, diagnosed by autopsy, according to the Diagnostic Criteria of Viral Hepatitis Prevention

and Cure Guideline, China'95), 8 male, 1 female, aged 25-48 years, Han nationality, were included in this study. All the patients were positive for HCV antigens and HCV RNA in livers, and their sera were positive for HBV markers. Thirty-eight paraffin-embedded autopsy extrahepatic tissue specimens (including 9 kidneys, 9 hearts, 9 pancreas, 5 intestines, 2 adrenal glands, 2 spleens, 1 lymph node, and 1 gallbladder) were provided by the Department of Pathology and Anatomy, Third Military Medical University, China.

Main reagents

Mouse monoclonal anti-HCV NS3, NS5 and CP10^[28]. A digoxigenin-labeled cDNA antisense probe to the 5'-non-coding region of the HCV genome was 145bp in length (provided by the Division of Clinical Immunology, Tongji Medical University). HCV genome primers were derived from the highly conserved 5'-non-coding region of the HCV genome, and were synthesized by Gibco BRL; outer primers: sense 5'-ACTCCACCA TAGATCATCCC 3', antisense 5'-AACACTACTCGGCTAGCAGT-3'; inner primers: sense 5'-TTCACGCAGAAAGCGTCTAG-3', antisense 5'-GTTGATCC AAGAAAGGACCC-3'.

RT-PCR

RNA was extracted from 2 to 3 pieces of 5µm thick paraffin-embedded extrahepatic tissue sections (31 specimens, including 9 kidneys, 9 hearts, 9 pancreas, and 4 intestines) cut from the same pathological blocks as used for ISH and immunohistochemistry with TRIzol (Gibco BRL).

RT-PCR was performed as previously described^[29,30]. The expected size of the amplified product was 145bp. The PCR products were analyzed by agarose gel electrophoresis. The sera which were negative for HCV RNA and HCV replicative intermediate and the distilled water were used as negative control.

Immunohistochemistry and ISH

Immunohistochemistry and ISH were performed as previously described^[28,31]. Liver specimens-positive for HCV RNA and HCV antigens were used as positive control. Ten autopsy extrahepatic tissue specimens from viral hepatitis patients, whose livers were negative for HCV antigens and HCV RNA, and 10 autopsy extrahepatic tissue specimens from patients with rabies were used as negative control. Furthermore, control slides were treated with ribonucleases (RNase) and deoxyribonuclease (DNase) before hybridization; and the digoxigenin-labeled probe was substituted with non-labeled HCV cDNA probe, which was used as control in ISH as well.

RESULTS

Detection rates of HCV RNA and HCV antigen in

the tissues

By RT-PCR, all 9 (positive in 20 specimens, 64.5%) patients were positive for HCV RNA in kidney, heart, pancreas, and intestine, but only 6 (66.7%), (positive in 11 specimens, 35.5%) of 9 patients were positive for HCV replicative intermediate (Figure 1). By ISH and immunohistochemistry, positive staining for HCV RNA and HCV antigens in kidney, heart, pancreas, intestine, adrenal gland, lymph node, and gallbladder were found in 5 (55.6%), (positive in 11 specimens, 28.9%) of 9, and 6 (66.7%), (positive in 23 specimens, 60.5%) of 9 patients, respectively. Positive rates of HCV RNA and HCV antigens in single extrahepatic organ are shown in Table 1. Three (33.3%) of 9 patients were negative for HCV RNA and HCV antigens in these extrahepatic organs, although their livers were positive for HCV.

Table 1 Results of HCV RNA and HCV antigens detection in extrahepatic organs and livers

Tissue	Cases	HCV RNA (+)			HCV antigens (+)		
		RT-PCR	ISH		NS3	NS5	CP10
Kidney	9	7	4*	3	6	5	4
Heart	9	5	3*	2	5	4	4
Pancreas	9	5	3*	2	6	6	5
Intestine	5	3/4	1/4*	1	3	2	0
Adrenal gland	2			1	1	1	0
Spleen	2			0	0	0	0
Lymph node	1			1	1	1	1
Gallbladder	1			1	1	0	1
Liver	9	9	7*	9	8	7	7

Note: *Minus-strand RNA detected.

The positivity of minus-strand RNA detected by RT-PCR was consistent with that of HCV RNA and HCV antigens detected by ISH and immunohistochemistry ($Kappa = 0.42-0.75$).

Expression of HCV RNA and HCV antigens in the tissues

HCV antigen staining was only seen within the

cytoplasm with homogenous, inclusive or submembranous distribution. The hybridization signal was observed in both cytoplasm and nuclei, with a greater proportion of cytoplasm signal.

HCV existed in these extrahepatic organs except 2 spleens. There were HCV RNA and HCV antigen positive expressions in myocardial cells, epithelial cells of intestinal glandular, interstitial cells of kidney, epithelial cells of tubules and glomerulus, pancreas acinar cells and epithelial cells of pancreatic duct, epithelial cells of mucous membrane sinus of gallbladder, cortex and medulla cells in adrenal gland, and mononuclear cells in lymph node (Figures 2-10). The amount of HCV positive cells in extrahepatic tissues was obviously less than that in liver tissues. In addition, there were some differences in HCV expression in various cells among different extrahepatic tissues, e.g. the amount of positive cells in heart tissue was less than that in kidney, pancreas, and intestine. In liver tissues, HCV antigens were only detected in hepatocytes, but hybridization signal of HCV RNA was seen in not only hepatocytes, but also bile duct epithelial cells, sinusoidal cells, and mononuclear cells (Figures 10 - 12). The amount of HCV positive cells in liver tissues was lower than 1%^[28], but obviously higher than those in extrahepatic tissues.

Negative control

The samples (such as extrahepatic tissues, sera, and the distilled water) from the subjects of control groups were negative for HCV RNA and HCV antigens detected by RT-PCR, ISH, and immunohistochemistry, respectively. Using RNase treatment of the extrahepatic tissues before hybridization, the HCV RNA staining in these tissue cells faded. DNase treatment did not reduce HCV RNA signal in these tissue cells. Using non-labeled cDNA probe, HCV RNA hybridization signal was not observed in these tissues.

DISCUSSION

Extrahepatic HCV infection was found in hepatitis C patients, recently. But as RT-PCR is fraught with problems^[32,33], contradictory data related to extrahepatic HCV infection have been reported^[16,17,34-36], and there have been few *in situ* detection of HCV in extrahepatic tissues, the identification of extrahepatic HCV infection and replication has been controversial.

In this study, HCV RNA and HCV replicative intermediate in kidney, heart, pancreas, and intestine were detected by RT-PCR, but more importantly, the localization of HCV RNA and HCV antigens (NS3, NS5 and CP10) in kidney, heart, pancreas, intestine, adrenal gland, lymph node, and gallbladder was demonstrated convincingly by ISH and immunohistochemistry, and various tissue cell types harboring HCV such as pancreas acinar cells were also identified. Moreover, the positivity of HCV replicative intermediate detected by RT-PCR was consistent with that of HCV RNA and HCV antigens in these tissue cells detected by ISH and immunohistochemistry ($Kappa=0.42-0.75$). More recently, we used a digoxigenin-labeled HCV oligonucleotide sense probe and detected HCV replicative intermediate in the extrahepatic tissues-positive for HCV RNA and HCV antigens by ISH (data being summarized). These results showed that HCV could infect extrahepatic tissues, and various tissue cells might support viral replication. Recently, Lorient *et al*^[37] reported that gallbladder epithelial cells from HCV-negative subjects were successfully infected by HCV *in vitro*, and ISH and immunohistochemical studies identified pancreas and gastric mucosa as the sites of HCV infection^[38,39]. These reports support the results of our studies.

So far, there have been few reports on the status of extrahepatic HCV infection and replication in hepatitis C patients. In order to explore this issue, we compared with the status of HCV expression between extrahepatic tissue and liver, and also among different extrahepatic tissues, the results indicated that the detection rates of HCV in extrahepatic tissues were low^[40], and the amount of HCV positive staining cells in extrahepatic tissues was also obviously lower than that in livers; and there were differences in HCV expression in various cells among different extrahepatic tissues. These results suggested that the levels of extrahepatic HCV infection and replication were relatively low as compared with those of livers; and there were differences in the status of HCV replication among different extrahepatic tissues. Whether HCV can bring about cell injury of infected extrahepatic tissues is not well understood because of the lack of extrahepatic histopathological observation. Recently, some reports showed that HCV is an causal agent in the pathogenesis of hypertrophic

cardiomyopathy and chronic myocarditis^[41,42], and that the patients' gastroduodenal mucosal lesions might be associated with HCV infection^[43]. However, most of the patients with hepatitis C did not have extrahepatic clinical manifestations^[44]. In our previous studies, we found no relationship between the HCV expression in extrahepatic tissue cells and tissue lesions^[45]. We speculate that extrahepatic HCV infection and replication may be of "concomitant state" in most of patients with hepatitis C, while liver was a key organ in HCV infection and pathogenicity^[18,21,31,45], i.e. HCV may replicate in various tissue cells, but viral replication may not cause obvious cell injury of these infected tissues.

Zignego *et al*^[46] reported that the infected PBMC might act as a reservoir for HCV. In this study, various tissue cells may support viral replication. These extrahepatic tissue and PBMC reservoirs are considered to provide the source of HCV for the patient's liver reinfection and recurrence of infection after liver transplantation for hepatitis C. Once the immunologically privileged sites are infected, HCV is more difficultly eliminated by the host and/or antiviral therapy, which might play a role in both HCV persistence and reactivation of infection after interferon therapy^[18,47].

At present, little is known of the mechanisms and the HCV role in the development of HCV-related extrahepatic syndromes. Some reports showed that the vasculitic and kidney damage in mixed cryoglobulinemia and glomerulonephritis associated with HCV infection might be mediated by immune mechanisms^[48,49]. However, in this study, HCV may replicate and express viral proteins in many tissue cells such as interstitial cells of kidney, epithelial cells of tubules, and glomerulus. It is noticeable that some of the cell types found to harbor HCV are also associated with HCV-related extrahepatic syndromes such as glomerulonephritis. In addition, HCV antigens were also found in mesangial and paramesangial cells and epithelial cells of tubules in glomerulonephritis kidney tissues^[24,48], and in lymphoid cells in hyperplastic reactive lymphadenopathy^[50]; HCV RNA and/or HCV replicative intermediate were detected in residual parotid epithelial cells in the parotid non-Hodgkin's lymphoma lesion by ISH^[51], and in epineurial cells in mixed cryoglobulinemia-associated neuropathy by *in situ* RT-PCR^[52]. HCV as an etiologic agent replicating and expressing viral proteins in extrahepatic tissues itself contributes to extrahepatic syndrome associated-HCV infection in a few patients with chronic HCV infection. For example, a pathogenetic role of HCV as an exogenous trigger might be hypothesized in the parotid non-Hodgkin's lymphoma^[51], or in hypertrophic cardiomyopathy^[41]. In hepatitis B

patients, several extrahepatic syndromes associated-HBV infection have been considered to be mediated by immune complexes or other immunological mechanisms, but various vasculitic and other HBV-related skin lesions are associated with local HBV replication. So Mason *et al*^[53] suggested that once the HBV-related immune complexes are captured by the vascular endothelium, the vasculitic damage might also be mediated by viral replication and immune mechanisms. We speculate that HCV might use a similar mechanism to bring about the vasculitic and kidney damage in the development of mixed cryoglobulinemia and glomerulonephritis associated-HCV infection.

Abstract

AIM To investigate the effect of *Boschniakia rossica* (BR) extract on expression of GST-P, p53 and p21^{ras} proteins in early stage of chemical hepatocarcinogenesis in rats and its anti-inflammatory activities.

METHODS The expression of tumor marker-placental form glutathione S-transferase (GST-P), p53 and p21^{ras} proteins were investigated by immunohistochemical techniques and ABC method. Anti-inflammatory activities of BR were studied by xylene and croton oil-induced mouse ear edema, carrageenin, histamine and hot scald-induced rat paw edema, adjuvant-induced rat arthritis and cotton pellet-induced mouse granuloma formation methods.

RESULTS The 500mg/kg of BR-H₂O extract fractionated from BR-Methanol extract had inhibitory effect on the formation of DEN-induced GST-P-positive foci in rat liver (GST-P staining was 78% positive in DEN+AAF group vs 20% positive in DEN+AAF+BR group, $P<0.05$) and the expression of mutant p53 and p21^{ras} protein was lower than that of hepatic preneoplastic lesions (33% and 22% positive respectively in DEN+AAF group vs negative in DEN+AAF+BR group). Both CH₂Cl₂ and H₂O extracts from BR had anti-inflammatory effect in xylene and croton oil-induced mouse ear edema (inhibitory rates were 26%-29% and 35%-59%, respectively).

BR-H₂O extract exhibited inhibitory effect in carrageenin, histamine and hot scald-induced hind paw edema and adjuvant-induced arthritis in rats and cotton pellet-induced granuloma formation in mice.

CONCLUSION BR extract exhibited inhibitory effect on formation of preneoplastic hepatic foci in early stage of rat chemical hepatocarcinogenesis. Both CH₂Cl₂ and H₂O extracts from BR exerted anti-inflammatory effect in rats and mice.

INTRODUCTION

Boschniakia rossica (BR) Fedtsch. et Flerov is a parasitic plant growing on the root *Alnus* plants (Betulaceae)^[1]. It is one of the valuable medicinal plants growing mostly on the Changbai Mountain at 1450-1800 meters above sea level, Jilin, China. It is also distributed in the Democratic People's Republic of Korea (DPRK), Japan and Russia. *Boschniakia rossica* is named "Bu Lao Cao" (antisenile plant), because it has effects of tonifying the Kidney and strengthening Yang, and has been used as a tonic or invigorating medicine in China. Yin ZZ *et al* isolated four iridoid compounds from *Boschniakia rossica* of the Changbai Mountain by chromatographic techniques. Their structure was determined by means of the spectra of nuclear magnetic resonance (NMR) and mass spectra^[2]. We discovered that Methanol extract of *Boschniakia rossica* exerted inhibitory effect on the formation of diethylnitrosamine (DEN) induced GST-P-positive foci in the liver of F344 rats^[3,4] and BR also has antioxidative activities^[5,6]. In the present study, we report the inhibitory effect of BR-water extract fractionated from BR-Methanol extract on the expression of GST-P, p53 and p21^{ras} proteins in early stage of rat chemical hepatocarcinogenesis and its anti-inflammatory activities in rats and mice.

MATERIALS AND METHODS

Chemicals

Diethylnitrosamine (DEN), 2-Acetylaminofluorene (AAF), determination kit for GGT and histamine

were purchased from Sigma Chemical Co.(USA). Vectastain ABC kit (pk 4001) was obtained from Vector Laboratories Inc. (USA); anti-GST-P antibody was kindly supplied by Professor Shigeki Tsuchida, Second Department of Biochemistry, Hirosaki University School of Medicine, Japan. p53 (DO-1) and pan ras (F-132) monoclonal antibody were purchased from Santa Cruz Biotechnology.

Preparation of the extract of *Boschniakia rossica*

Boschniakia rossica harvested from the Changbai Mountain area was used and the plants were identified by the authors. They were dried, cut, made into powder and extracted for overnight with Methanol five times. The Methanol extract was fractioned with CH_2Cl_2 and H_2O , and H_2O extract was vacuum-concentrated. The extract was dried by speed vacuum.

Animals and treatment

Male Wistar rats, aged 6 weeks and weighing 160g-180g were used in the experiments of hepatocarcinogenesis. The male Wistar rats (180g-200g) and Kunming strain mice (20g-22g) were used in the anti-inflammatory experiment. Animals were housed in groups of 5 animals in plastic cages with stainless-steel grid tops at room temperature with a 12h light/dark cycle.

Induction of preneoplastic hepatic foci^[7-11]

Enzyme-altered hepatic foci and hyperplastic nodules were induced by the modified protocol of Solt and Farber. The animals were divided into 3 groups. The rats in groups B and C were given a single i. p. injection of DEN (200mg/kg body weight) dissolved in saline to initiate hepatocarcinogenesis. After 2 weeks on basal diet, the rats received 0.004% 2-AAF in the diet for the following 6 weeks. Group C, after 2 weeks of injection of DEN, was given the diet containing 0.004% 2-AAF+500mg/kg BR for the following 6 weeks as a BR treatment group. Group A, as a control group, was intraperitoneally injected with the saline instead of DEN and then maintained on basal diet for 8 weeks. All rats of experimental and control groups were subjected to two-thirds partial hepatectomy (PH) at the 3rd week. Rats in each group were killed for examination at the 8th week.

Immunohistochemical staining for GST-P, p53 and p21^{ras}^[12-16]

Rat liver slices were fixed with ice-cold acetone and embedded in paraffin. Immunohistochemical staining for GST-P was performed by ABC method using anti-GST-P antibody; immunohistochemical staining for p53 and p21^{ras} proteins was performed using p53 (DO-1) and pan ras (F-132) monoclonal antibody, respectively.

Quantitative analysis

The number and the area of GST-P-positive hepatic foci larger than 0.1mm in diameter were analyzed using the microscopic quantitative analyzer (OC.M 19m/m Square 10/10×10, Tokyo, Japan).

Investigation of anti-inflammatory activities of BR extract^[17-19]

Xylen or croton oil-induced mouse ear edema An edema was induced on the right ear by topical application of xylene in mice 30 minutes after oral administration of 500mg/kg-1000mg/kg BR- H_2O extract or BR- CH_2Cl_2 extract. The left ear was controlled. Ear edema was measured by comparing the difference in weight (mg) between the same size of left and right ears 30 minutes after xylene-induction and 4h after croton oil-induction of inflammation and swelling degree and inhibition rate were calculated.

Carrageenin-induced rat paw edema An edema was induced on the rat right hind paw by aponeurosis injection of 0.15mL of 1% carrageenin in 0.9% saline. Test drug (500mg/kg-1000mg/kg of BR- H_2O extract) was given orally 30 minutes before the injection of carrageenin. The volume of the right paw was measured before injection and at 1, 2, 3, 4, 6 and 24h after induction of inflammation. The edema was expressed as an increase in paw volume due to carrageenin injection. The results were obtained by measuring the volume difference before and after injection of the right paw. The swelling degree of paw and inhibition rate of edema were calculated.

Histamine-induced rat paw edema An edema was induced on the right hind paw of rat by subplantar injection of 200μg/0.1mL of histamine. Test drug (500mg/kg of BR- H_2O extract) was given 30 minutes before the injection of histamine. The volume of the right paw was measured before injection and 0.5, 1, 2, 3 and 4h after induction of inflammation. The swelling degree of paw and inhibition rate of edema were calculated.

Hot scald-induced rat paw edema Edema was induced on the right hind paw of rat by hot scald. The right hind paw of rat soaked in thermostate water bath maintained at $53^\circ\text{C} \pm 0.5^\circ\text{C}$ and cut-off time was 14 sec and test drug (500mg/kg of BR- H_2O extract) was given 30 minutes before the hot scald test. The volume of the right paw was measured before test and 1, 2, 3, 4, 5, 6 and 24 h after induction of inflammation. The swelling degree of paw and inhibition rate of edema were calculated.

Adjuvant-induced arthritis in rats The Arthritis was induced by injection of 0.1mL complete Freund's adjuvant into the subplantar region of the right hind paw of rats. Five hundred mg/kg of BR- H_2O

extract was orally administrated 30 minutes before the injection of adjuvant and the BR extract was given daily for 3 days after induction of inflammation. From the 8th day the BR extract was given daily for 7 days more. The volume of the right paw was measured before injection and at 18h, and on day 3, 6, 9, 12, 15, 18, 21 and 24 after induction of inflammation. The swelling degree of paw and inhibition rate of edema were calculated.

Cotton pellet-induced granuloma formation Pellets of surgical aseptic cotton weighing 15mg were implanted in both scapular regions in mice. The test drug (250mg/kg-500mg/kg) was administered daily for 7 days, and on the 8th day, the granulomatous tissues were removed. The pellets were dried overnight at 60°C and weighed. The dry weight was considered the weight of the granuloma. The results of this subacute inflammation were compared with the control group.

Statistical analysis Statistical analysis was made using the χ^2 test and the Student's *t* test. Values of $P < 0.05$ were considered statistically significant.

Results

Effect of *Boschniakia rossica* extract on expression of GST-P, p53 and p21^{ras} proteins during chemical hepatocarcinogenesis in rats Immunohistochemical investigation of expression of

GST-P, p53 and p21 protein in DEN-induced preneoplastic hepatic foci (group B), in administration of BR extract in the Solt-Farber protocol of rats (group C) and control (group A) are summarized in Table 1. GST-P staining was 78% positive in group B and 20% positive in group C, while in group A it was negative (B vs C, $P < 0.05$). Expression of oncogene products p53 and p21^{ras} protein in group B was 33% and 22% positive, while in groups A and C it was negative. The number (no/cm²) and area (mm²/cm²) of GST-P-positive hepatic foci in group C given DEN-AAF+BR was significantly decreased as compared with the values of group B given DEN-AAF (B vs C, $P < 0.001$ and $P < 0.05$) and these quantitative values are shown in Table 1 and Figure 1.

Effect of extract from BR on the anti-inflammatory activities in rats and mice

Both CH₂Cl₂ and water extract from BR have inhibitory effect in the xylene and croton oil-induced mouse ear edema, its inhibitory rate was 26%-29% and 35%-59% respectively (Tables 2 and 3) and exert inhibitory effect in the cotton pellet-induced granuloma formation in mice (Tables 8 and 9). BR-H₂O extract fractionated from BR-Methanol extract exhibited inhibitory effect in carrageenin, hot scald and histamine-induced rats hind paw edema (Tables 4, 6 and 7) and adjuvant-induced arthritis in rats (Table 5).

Figure 1 Immunohistochemical staining for GST-P in rat hepatic preneoplastic lesions induced by Solt-Farber protocol (A and B), in rat liver treated with DEN and AAF plus BR for 6 weeks (C and D), and in normal rat liver (E).

A, GST-P-strongly positive minifoci in group B $\times 400$; B, GST-P-strongly positive large foci in group B, $\times 100$; C, GST-P-positive single cell in group C, $\times 400$; D, GST-P-weakly positive two cells in group D, $\times 400$; E, GST-P was negative in group A, normal rat liver, $\times 200$; F, Hematoxylin and eosin staining for preneoplastic hepatic foci in group B, $\times 200$.

DISCUSSION

Changes in GST-P, p53 and p21^{ras} proteins during chemical hepatocarcinogenesis in rats

Placental form of glutathione S-transferase (GST-P) was first isolated from rat placenta as a sensitive marker enzyme in chemical hepatocarcinogenesis of rat by Sato *et al* in 1984^[20-24]. GST-P is considered to be an accurate marker for very early “initiated cells”^[21,24]. GST- π , purified from human term placenta, is related to rat GST-P in many properties and is grouped into the class Pi. It is of important clinical value. GST- π is also a useful human tumor marker for hepatoma, esophageal, gastric and colonic carcinomas and its preneoplastic lesions^[12-15,25-32]. Thereafter, using DEN as a initiator and AAF as a promoter, modified system based on Solt-Farber method was designed to screen the medium-term bioassay of chemical-induced carcinogenesis by Ito *et al*^[33]. This screening system was used in this study and successfully induced the preneoplastic GST-P-positive hepatic foci and nodules. Recently Tsuda H *et al* developed a trial

for an initiation bioassay system. Initiation potential was assayed on the basis of significant increase in values of preneoplastic GST-P positive foci. This protocol may be useful for detection of the initiation potential of carcinogens irrespective of their mutagenicity^[34].

We investigated the effect of *Boschniakia rossica* on formation of GST-P positive preneoplastic hepatic foci during chemical hepatocarcinogenesis. The results demonstrated that BR-H₂O extract fractionated from BR-Methanol extract with CH₂Cl₂ and H₂O has inhibitory effect on DEN-induced GST-P positive preneoplastic hepatic foci in early stage of rat chemical hepatocarcinogenesis. We consider that it is related to its antioxidative action of *Boschniakia rossica*^[4]. Recently there are reports that GST-P is as a sensitive marker for preneoplastic hepatic foci during chemical hepatocarcinogenesis in rats^[35-40]. It indicated that GST-P and GST- π are very sensitive tumor markers for basic research, prevention and cure of cancer.

Rat chemical hepatocarcinogenesis can be

divided into several steps: initiation, promotion, and progression stages. During the initiation stage, alterations of specific genes and in particular the activation of cellular proto-oncogenes occurs. During the promotion stage, groups of preneoplastic cells have been observed in many organs prior to appearance of malignant cancers, and in rat chemical hepatocarcinogenesis enzyme-altered foci and hyperplastic nodules have been excited^[21]. Recently many scientists reported expression of ras, jun oncogene^[42,47-49], p53 tumor suppressor gene^[41,43,45,52-54], and nm23 tumor metastasis suppressor gene^[44,46,50,51] in hepatocellular carcinoma, esophageal, gastric, and colonic carcinomas. Smith *et al.*^[41] reported a p53 gene mutation occurring in foci of enzyme-altered hepatocytes induced by diethylnitrosamine in F 344 rats. We observed the relation to the expression of GST-P, ras gene product p21^{ras} protein and suppressor gene product p53 protein in preneoplastic hepatic foci of rat liver. The results suggest that one-third of GST-P positive foci were positive for p53 protein and approximately one-fourth of GST-P positive foci were also positive for p21^{ras} protein in group B, while in rat liver of group C treated with DEN and AAF plus BR for 6 weeks p53 protein and p21^{ras} were not immunohistochemically detectable. Our result is similar to the report by Smith *et al.*, and also is similar to that GST-P appearing at an early stage of chemical hepatocarcinogenesis, when oncogene product c-jun was not immunohistochemically detectable, reported by Suzuki *et al.*^[42]. These results indicate that BR-H₂O extract fractionated from BR-Methanol extract exhibited an inhibitory effect on DEN-induced preneoplastic hepatic foci in rats administered with BR for 6 weeks during chemical hepatocarcinogenesis.

Anti-inflammatory activities of *Boschniakia rossica*

Results of the present study demonstrated that BR-extract exerted significant anti-inflammatory activities. An inhibitory effect of H₂O extract and CH₂Cl₂ extract from BR was observed in the acute inflammatory process, such as xylene and croton oil-induced mouse ear edema, carrageenin induced rat hind paw edema and inflammatory factors such as histamine and hot scald-induced rat hind paw edema. Anti-inflammatory action of BR was also observed in the chronic inflammation process, such as cotton pellet-induced granuloma formation in mice and immune inflammation process, such as adjuvant-induced arthritis in rats. The experimental model of inflammation induced by carrageenin is highly sensitive to non-steroidal anti-inflammatory drugs, and it has long been accepted as a useful pharmacologic tool for investigating new anti-inflammatory drugs. The oral administration of the BR-H₂O extract (500mg/kg) inhibited the edema

formation by 49.8 % and 65.8% in 2 and 24 hours, respectively, after the administration of carrageenin in rats. Indomethacin, the standard anti-inflammatory drug used in this experiment, inhibited the edema by 46.5% and 40% in 2 and 24 hours. The anti-inflammatory effect of extract from BR was also observed in the cotton pellet-induced granuloma formation in mice. The daily oral administration of 250mg/kg and 500mg/kg of BR-CH₂Cl₂ extract, using this model, showed on the eighth day an inhibitory effect of 25% and 35%, and 250mg/kg and 500mg/kg of BR-H₂O extract 35% and 34%, respectively. The mechanism of anti-inflammatory action of *Boschniakia rossica* can be related to the chemical structure of BR. Recio *et al.*^[55] reported that Iridoids is an anti-inflammatory agent. The results obtained in present study suggest that CH₂Cl₂ extract and H₂O extract from BR have anti-inflammatory effects. We isolated four iridoid compounds, a group of cyclopentano[c]pyran monoterpenoids, from *Boschniakia rossica*, and among them 8-epideoxyloganin acid was shown to exhibit a strong anti-inflammatory activity. Based on the results obtained in this study, we conclude that extract from BR exerted an anti-inflammatory effect.

Abstract

AIM To study the molecular mechanisms of retinoic acid (RA) on proliferation and expression of cyclin-dependent kinase inhibitors (CKI), i.e. p16, p21 and p27 in cultured rat hepatic stellate cells (HSC) stimulated with transforming growth factor beta 1 (TGF- β 1). **METHODS** HSC were isolated from healthy rat livers and cultured. After stimulated with 1mg/L TGF- β 1, subcultured HSC were treated with or without 1nmol/L RA. MTT assay, immunocytochemistry (ICC) for p16, p21, p27 and β -smooth muscle actin (β -SMA) protein, *in situ* hybridization (ISH) for retinoic acid receptor beta 2 (RAR- β 2) and p16, p21 and p27 mRNA and quantitative image analysis (partially) were performed.

RESULTS RA inhibited HSC proliferation (41.50%, $P < 0.05$), decreased the protein level of β -SMA (55.09%, $P < 0.05$), and induced HSC to express RAR- β 2 mRNA. In addition, RA increased the protein level of p16 (218.75%, $P < 0.05$) and induced p21 protein expression; meanwhile, p27 was undetectable by ICC in both control and RA-treated HSC. However, RA had no influence on the mRNA levels of p16, p21 or p27 as determined by ISH.

CONCLUSION Up-regulation of p16 and p21 on post-transcriptional level may contribute, in part, to RA inhibition of TGF- β 1 initiated rat HSC activation *in vitro*.

INTRODUCTION

Hepatic stellate cells (HSC) play crucial roles in the development of liver fibrosis^[1-6]. Stimulated HSC transform from vitamin A-rich quiescent cells to myofibroblast-like cells characterized by the expression of α -smooth muscle actin (α -SMA), loss of retinoids and diminished retinoid signaling^[4-15]. Exogenous retinoids such as retinoic acid (RA) may recover the contents of retinoids and nuclear retinoic acid receptors (RAR) in HSC and therefore suppress hepatic fibrogenesis, but the mechanisms of RA on HSC inhibition were not well understood^[3,16-27]. Recent studies on other cell types have shown that modulation of cell cycle regulatory proteins might contribute to RA-induced inhibition of cell proliferation and differentiation^[28-37], and Kawada *et al*^[38] reported that expression of G1 cyclin was involved in cell cycle transition of HSC from G1 to S. The present study was designed to investigate the effects of RA on negative cell cycle regulators cyclin-dependent kinase inhibitors (CKI) in cultured rat HSC stimulated with transforming growth factor beta-1 (TGF- α 1). The results showed that RA inhibited HSC activation may be in part due to post-transcriptional up-modulation of p16 and p21.

MATERIALS AND METHODS

Reagents

Collagenase IV, pronase E, Nycodenz, RA and 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide or tetrazolium (MTT) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Recombinant human TGF- β 1 was from Oncogene Science (Uniondale, NY, USA). Dulbecco's modified Eagle's medium (DMEM) was Gibco/BRL- product (Life Technologies, Inc. Grand Island, NY, USA). Newborn calf serum, plastic tissue culture flasks and multi-plates were from Corning Incorporated (Corning, NY, USA). Polyclonal anti- α -SMA antibody was purchased from Dako A/S (Glostrup, Denmark). Antibodies to p16, p21 and p27 were from Santa Cruz

Biotechnology, Inc. (Santa Cruz, CA, USA). ABC kit and DAB were from R & D Systems (Minneapolis, MN, USA). DIG Nucleic Acid Label and Detect Kit and Taq DNA polymerase were from Roche Diagnostics GmbH (Mannheim, Germany).

Isolation and culture of HSC

Cells were isolated from healthy Sprague-Dawley male rats (weighing 400g-450g) as described by Weiner *et al*^[26] with minor modifications by the laboratory^[39], seeded onto 25cm² plastic tissue culture flasks and incubated at 37°C in a humidified 5% CO₂/95% air. The medium was replaced 24h after seeding and every 48h thereafter. After they reached confluence (10d after planting), activated HSC were subcultured onto plastic tissue culture multi-plates with or without coverslips.

Experiments were performed on cells between serial passage 1 and 3 using three independent cell lines.

Cell treatments

Activated HSC were depleted of serum for 48h, followed by incubation with 1mg/L TGF- α 1 for another 48h, and then the medium was removed and cells maintained in DMEM with or without 1nmol/L RA for 48h. Preliminary dose dependence experiments indicated that 1mg/L TGF- β 1 or 1nmol/L RA had significant influence on HSC proliferation.

Proliferation assay

Cell proliferation was measured by MTT assay as previously described^[40] with minor modifications. Briefly, during the last 4h of incubation the cells were loaded with 10 μ L of freshly prepared and filtered MTT (5g/L in PBS) per well. The medium was then replaced with 100 μ L absolute ethanol and the cells were left for 30min for color development, followed by reading on Vmax[®]R Kinetic Microplate Reader (Molecular Devices Corporation, Sunnyvale, California, USA) at 570nm wavelength.

Immunocytochemistry (ICC)

Cells grew on coverslips were fixed, permeabilized, blocked with 1% serum in PBS, and then incubated with primary antibodies to either α -SMA, p16, p21 or p27. ABC assay and DAB system were used to detect the proteins^[41] and photomicrographs were taken with an Olympus microphoto-microscope (Olympus Optical Co. LTD., Shinjuku-ku, Tokyo, Japan).

In situ hybridization (ISH)

cDNA probes for human RAR- β 2 and p16 were gifts from the Department of Biochemistry, School of Basic Medical Sciences, Fudan University; and cDNA fragments for rat p21 and p27 were presented as gifts by Dr. Chen Guang-Ping. Fragments were labeled with digoxigenin using random priming assay.

ISH was performed as previously described^[39] with immunohistochemical detection using an alkaline phosphatase (AKP) conjugated anti-digoxigenin monoclonal antibody. Hybridization signal was visualized through the substrates of AKP (NBT and BCIP). Photomicrographs were taken with an Olympus microphoto-microscope again.

Image analysis

Quantitative analysis of protein and mRNA were performed by scanning using KS 400 Imaging System 3.0 (Carl Zeiss Vision GmbH, Germany) and means of density values were determined.

Statistical analysis

Data were presented as mean values \pm S.D. and statistical significance was assessed by Student's *t* test.

RESULTS

RA inhibited HSC proliferation and α -SMA expression

As shown in Figure 1, there were fewer (41.50%, $P < 0.05$) HSC in RA-treated cells compared with control cells. In addition, RA decreased expression of α -SMA (55.09%, $P < 0.05$; Figure 2 and Table 1).

RA induced RAR- β 2 mRNA

To evaluate retinoid signaling, ISH was performed to determine RAR- β 2 gene expression. No mRNA was detected in control cells, but HSC treated with RA did express RAR- β 2, indicate RA induced expression of RAR- β 2 in HSC (Figure 3), and therefore enhanced retinoid signaling.

Expression of CKI

To further clarify the mechanisms of RA on cell cycle regulation in HSC, protein and mRNA levels of CKI were determined. As shown in Figure 4, p27 was undetectable by ICC in both control and RA-treated HSC. In addition, RA increased the protein levels of p16 (218.75%, $P < 0.05$) and p21 protein was detected in HSC treated with RA (Figure 4 and Table 1).

ISH results showed that the mRNA level of p16, p21 or p27 was not influenced by RA (Figure 5 and Table 1).

Figure 1 RA inhibited HSC proliferation. TGF- β 1-stimulated rat HSC were cultured and treated with or without 1nmol/L RA for 48h, followed by MTT assay as described in MATERIALS AND METHODS. ^a $P < 0.05$ vs control.

Table 1 Effects of RA on α -SMA and CKI expression in HSC

Group	α -SMA (protein)	RAR- β 2 (mRNA)	p16		P21		p27	
			Protein	mRNA	Protein	mRNA	Protein	mRNA
Control	0.285 \pm 0.050	ND	0.160 \pm 0.024	0.377 \pm 0.043	ND	0.285 \pm 0.043	ND	0.165 \pm 0.021
RA	0.157 \pm 0.042 ^a	0.227 \pm 0.24	0.350 \pm 0.029 ^a	0.353 \pm 0.023	0.0339 \pm 0.034	0.277 \pm 0.027	ND	0.179 \pm 0.023

ND: not determined; ^aP<0.05 vs control

- Figure 2** RA decreased the protein level of α -SMA. TGF- β 1-stimulated HSC were treated with (A) as described in Figure 1, and then immunocytochemistry was performed to detect α -SMA protein. ABC \times 200 (B) or without RA

- Figure 4** Expression of CKI protein. Immunocytochemical study was performed to detect CKI, i.e. p16 (A), p21 (B). ABC \times 200 (C) expression in control (A) or RA-treated HSC

Figure 5 mRNA expression of CKI. mRNA of p16 (A.), p21 (B.) (C.) or p27 (D.) was determined with ISH in control (E.) or RA-treated HSC (F.). NBT/BCIP \times 200

DISCUSSION

TGF- β 1 is one of the most fibrogenetic cytokines on HSC, which initiates HSC activation characterized by loss of retinoids, proliferation, and expression of α -SMA and extracellular matrix^[2,6,42-45]. Our results showed that even 48h depletion of serum could not completely suppress the expression of α -SMA, implying that serum depletion can not reversibly suppress TGF- β 1-initiated activation of rat HSC in culture.

RA may modulate cell growth and differentiation through retinoid signaling^[30,46-49], mainly by nuclear retinoid X receptors and RAR. Present study showed that RA inhibited HSC proliferation and down-regulated α -SMA protein, demonstrating that RA may suppress HSC activation induced by TGF- β 1. Our results showed that RA induced RAR- β 2 mRNA, which may then modulate expression of some other genes including CKI^[28-37,50-52]. In addition, cells in controls displayed no RAR- β 2 mRNA, agreeing with its insufficient to completely suppress HSC activation again.

The protein level of p16 was increased in RA-treated HSC with detectable p21 protein, while RA had no influence on those mRNA levels, suggesting

RA may up-regulate p16 and p21 gene expression on the post-transcriptional level. p16 or p21 can inhibit cyclin-CDK complexes and then prevent G1 transition^[53-58]; therefore, our study indicates that RA induced inhibition of TGF- β 1-initiated HSC activation may be in part due to up-modulation of p16 and p21 on the post-transcriptional level, and reveals a new mechanism of RA induced HSC inhibition.

Abstract

AIM To assess the effect of ACE inhibitor and AngII type 1 (AT1) receptor antagonist in preventing hepatic fibrosis caused by CCl₄ administration in rats; to investigate whether or not there are expression of AT 1 receptors on hepatic stellate cells; and to observe the effect of AngII on proliferation and ECM synthesis of cultured HSCs.

METHODS Studies were conducted in male Sprague-Dawley rats. Except for the hepatofibrotic model group and the control group, in three treated groups, either enalapril (5mg/kg), or losartan (10mg/kg), or enalapril + losartan were given to the fibrotic rats by daily gavage, and saline vehicle was given to model and normal control rats. After 6 weeks, liver fibrosis was assessed directly by hepatic morphometric analysis, which has been considered the gold standard for the quantification of fibrosis. The expressions of AT 1 receptors and (α -smooth muscle actin, α -SMA) in liver tissue or isolated hepatic stellate cells (HSCs) were detected by immunohistochemical techniques. The effect of AngII on HSC proliferation was determined by MTT method. Effect of AngII on collagen synthesis of HSCs was determined by ³H-proline incorporation.

RESULTS Contrasted to the fibrosis in rats of the model group, groups of rats treated with

either enalapril or losartan, or a combination of two drugs showed a limited expansion of the interstitium (4.23 ± 3.70 vs 11.22 ± 4.79 , $P < 0.05$), but no difference was observed among three treated groups (5.38 ± 3.43 , 4.96 ± 2.96 , 4.23 ± 2.70 , $P > 0.05$). Expression of AT 1 receptors was found in fibrotic interstitium of fibrotic rats, whereas in normal control rats they were limited to vasculature only to a very slight degree. AT 1 receptors were also expressed on activated HSCs in the culture. At concentrations from 10^{-9} to 10^{-5} mol/L, AngII stimulated HSC proliferation in culture in a dose-dependent manner. Increasing AngII concentrations produced corresponding increases in ³H-proline incorporation. Differences among groups were significant.

CONCLUSION Angiotensin-converting enzyme inhibitors and AT 1 blocker may slow the progression of hepatic fibrosis; activated HSCs express AT 1 receptors, and AngII can stimulate the proliferation and collagen synthesis of HSCs in a dose-dependent manner; and activation of RAS may be related to hepatic fibrogenesis induced by CCl₄.

INTRODUCTION

Liver fibrosis is a consequence of chronic liver injury from different causes, including alcohol, toxins, chronic viral infections, metabolic disease, etc. In liver fibrogenesis there is an increased deposition of extracellular matrix (ECM) in the perisinusoidal and periportal spaces. The activated hepatic stellate cells (HSCs), have now been identified as the primary source of ECM synthesis in liver fibrogenesis^[1-3]. The pathogenetic significance of HSC relies on their ability to be activated into myofibroblast-like cells with enhanced production of ECM^[4,5]. Proliferative cytokine like platelet-derived growth factor and fibrogenetic cytokines like transforming growth factor- β (TGF- β) are major cytokines involved in the activation process, causing enhanced proliferation of HSC and matrix synthesis^[6,7].

Researches increasingly show that locally synthesized angiotensin II (Ang II), as a fibrogenetic factor, is involved in cardiac fibrosis^[8,9], renal interstitial fibrosis^[10,11], and pulmonary fibrosis^[12,13]. Thus, treatment with angiotensin-converting enzyme (ACE) inhibitor or angiotensin II type 1 (AT1) receptor antagonist may attenuate the cardiac fibrosis that occurs in experimental myocardial infarction^[8], and may also retard the progression of renal glomerulosclerosis and interstitial fibrosis^[14,15] and pulmonary fibrosis^[16].

It is believed that Ang II has a direct fibrogenetic effect, independent of its systemic hemodynamic effect. The evidence supporting this notion comes from *in vitro* studies showing that the AT1 receptor is present on interstitial fibroblasts, such as cardiac fibroblasts^[17], renal interstitial fibroblasts^[18], and that Ang II directly increases ECM synthesis in cultured fibroblasts.

We hypothesized that the activation of local RAS might also be related to hepatic fibrogenesis. Thus, it is important to ascertain the existence of expression AT1 receptor on HSCs in the process of hepatic fibrosis. If this hypothesis is true, new preventive and therapeutic approaches may be provided to hepatic fibrosis. This study was designed: to assess effects of ACE inhibitor, enalapril, and AT1 receptor antagonist, losartan, on hepatic fibrosis induced by CCl₄; and to investigate whether or not there is expression of AT1 receptors on HSCs.

METHODS

Animals and therapeutic regimen

Adult male Sprague-Dawley rats (Animal Centre of Shanghai Medical University, China) weighing 180g-200g were housed in temperature and light-controlled room. The rats were divided into five groups ($n=10$ in each group): the control group, model group and three treated groups. Except for rats of the control group, all rats were given subcutaneous injection of 40% CCl₄ (CCl₄:olive oil 2:3), 0.3mL/100g, every 3 days for 6 weeks). Simultaneous treatments with enalapril (Changzhou Pharmacy, China) ($5\text{mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$), losartan (Merk Co. England) ($10\text{mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$), or enalapril + losartan administration (once a day by gavage for 6 weeks) were withdrawn a day before the rats were killed for study.

Serum analysis

After sacrificing the rats, blood samples were immediately taken and centrifuged at 4°C, and plasma were kept at -20°C for assays. The aspartate transaminase (AST) and alanine transaminase (ALT) activities were determined by

the standard enzymatic methods. The serum levels of angiotensin II and renin activity were determined by radioimmunoassays (kit purchased from Northern Biot Co, China).

Image analysis of liver fibrosis

Liver fibrosis was assessed directly by hepatic morphometric analysis, which has been considered to be the gold standard for the quantification of fibrosis. For image analysis, three liver fragments ($>10\text{mm}^2$) were randomly taken in the right, median, and left lobes of each rat liver. The liver sections were fixed in a 10% solution of formaldehyde in 0.1mol/L phosphate-buffered saline (pH 7.4), and embedded in paraffin. Five-micrometer slides were prepared. Collagen expression was detected with standard van Gieson staining. The histomorphometric analysis was performed on a KS400 image analysis system (German). The liver slides were placed on the X-Y motorized stage of microscope after equalization of light intensity. The percentage of fibrosis or area of fibrosis could be obtained in microscopic fields. Total liver area of fibrosis was expressed as the mean of the percentage of fibrosis in the three liver fragments.

Expression of α -SMA and AT1 receptor in liver tissue

Immunohistochemical methods were used to detect the expressions of α -SMA and AT1 (anti-rat rabbit polyclonal AT1 antibody was the product of Santa Cruz Biot Co, USA) receptors in liver tissue.

Cells isolation and culture

HSCs were isolated from normal male Sprague-Dawley rat (500g-600g body weight) liver by a combination of pronase-collagenase perfusion and density gradient centrifugation, as previously described^[19], and identified by positive ultraviolet autofluorescence. Primary HSCs were cultured in 24-well plastic culture plate at a density of 5×10^5 cells/L, and maintained in Dulbecco's modified Eagle medium (DMEM) with 15% fetal calf serum (FCS) (Sigma) and penicillin/ streptomycin. After seven days, the cells were washed with PBS, and the expression of α -SMA (Monoclonal antibody purchased from Maixin Biot Co. China) was determined by immunohistochemical method. The expression of AT1 receptor was detected by immunofluorescence staining with anti-rat rabbit polyclonal antibody (Santa Cruz Biot) and labeled with fluorescein-isothiocyanate (FITC, Sigma).

Effect of AngII on HSCs proliferation

The effect of AngII on HSC proliferation was determined by MTT method. After being cultured

for 4 days, HSCs were digested with 0.25% trypsin and then cultured in serum-free medium in 96-well culture plate (200 μ L per well), to which was added AngII (to make a series of final concentrations: 10^{-9} , 10^{-8} , 10^{-7} , 10^{-6} , 10^{-5} mol/L). Each concentration included six wells, while the serum-free medium served as a control. After being cultured for 48 hours, HSCs were supplemented with 20 μ L MTT (5g/L) (Fluka Co. Product) and incubated for another 6 hours. Then the supernatant was discarded by aspiration and the HSC preparation was shaken with 200 μ L DMSO for 10 minutes, before the OD value was measured at 490nm.

Effect of AngII on collagen synthesis of HSCs

Collagen synthesis was determined by 3 H-proline incorporation. After cultured for 48 hours, HSCs were further cultured for additional 48 hours in serum -free medium containing 2 μ L 3 H-proline in various concentrations of Ang II (the final concentrations being 10^{-9} , 10^{-8} , 10^{-7} , 10^{-6} , 10^{-5} mol/L). Subsequently, HSCs were digested with 0.25% trypsin and collected on glass fiber membrane, then washed with PBS. After being dried, HSCs were suspended in 10mL scintillation solution for 12 hours. The radioactivity was determined by liquid scintillation and expressed as cpm / 2.5×10^5 cells.

Statistical analysis

Data were presented as mean \pm SEM. Comparisons among three or more groups were made by one-way ANOVA followed by Dunnett's *t* test. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Effects of RAS inhibitors on rat serum levels of ALT and AST Contrasted with rats of the control group, as shown in Table 1, rats receiving CCl_4 had increased serum ALT and AST significantly. However, chronic administration of enalapril and losartan prevented the increase in ALT and AST ($P < 0.01$, Table 1).

Serum renin activity and Ang II levels Serum renin activity ($\mu\text{g} \cdot \text{L}^{-1} \cdot \text{h}$) of rats in the model group was three times higher than that of the control group ($P < 0.01$). Serum Ang II (ng/L) levels of model group also increased two times than that of control group ($P < 0.01$). Treatment with RAS inhibitors significantly decreased the serum renin activity and

serum levels of Ang II ($P < 0.05$, Table 2).

Fibrosis quantification As expected, there was an increase in the area of fibrosis in rats of the model group compared with that of the control group. There was a significant decrease of fibrosis in all three treated groups ($P < 0.05$), but no significantly difference was observed between the enalapril and losartan treated groups ($P > 0.05$, Table 3).

Table 1 Effects of RAS inhibitors on rat serum levels of ALT and AST

	<i>n</i>	ALT(U/L)	AST(U/L)
Control	10	99.50 \pm 18.78	244.50 \pm 46.52

^a $P < 0.01$ vs Control; ^b $P < 0.05$ vs Model.

Immunohistochemistry Expressions of AT1 receptors and α -SMA in liver tissue were detected by immunohistochemical methods. AT1 receptors mainly localized in the vasculature of liver tissue in the normal control rats. In rats of the model group, the expression of AT1 receptors mainly localized in the fibrotic areas, correlated with the expression of α -SMA. Enalapril, losartan, and combined treated groups showed a reduced AT1 receptor staining.

After culturing HSCs for seven days, the expression of AT1 receptors in HSC could be detected by FITC-immunofluorescence, together with the expression of α -SMA (Figure 1A-1D).

Effect of AngII on HSCs proliferation and collagen synthesis

Over a wide range of concentrations from 10^{-9} to 10^{-5} mol/L, AngII stimulated cultured HSCs proliferation in a dose-dependent manner (Figure 2). Increasing AngII concentration produced an increase in 3 H-proline incorporation (Figure 3). Differences among groups were significant ($P < 0.05$).

Table 3 Fibrosis measurements

	Control	Model	Enalapril	Losartan	Enalapril+losartan
Area of fibrosis	0.94 \pm 0.33	11.22 \pm 4.79 ^a	5.38 \pm 3.43 ^b	4.96 \pm 2.96 ^b	4.23 \pm 3.70 ^b

^a $P < 0.01$ vs Control; ^b $P < 0.05$ vs Model.

Figure 1A-1D A: Under the 328nm ultraviolet, HSCs had an autofluorescence. (×400 times) B: After cultured five days, HSCs transformed into myofibroblast-like cells. (×400 times) and expressed α-SMA (C, staining with DAB), labeled with FITC, expression of AT1 receptor was observed (D).

Figure 3 Effect of Ang II on collagen synthesis of HSC.

DISCUSSION

The present study demonstrates for the first time the expression of AT1 receptor subtype in fibrotic liver tissue and in primary cultured rat HSC.

In recent years, a series of investigations demonstrated that fibrogenesis was related to the activation of local RAS^[20-24]. Expression of AT1 receptors in several types of interstitial cells, such as cardiac fibroblasts^[17], renal interstitial fibroblasts^[18] and lung fibroblasts^[25]. *In vitro* study suggested that Ang II induced a net stimulation of collagen synthesis and expression of TGF-β via AT1 receptors in a dose-dependent manner^[26-30]. Blockade of AT1 receptors has been shown to inhibit DNA and collagen syntheses in interstitial cells after myocardial infarction^[31,32], renal and pulmonary injury^[15,33], and retarded the progression of cardiac, renal and pulmonary interstitial fibrosis^[34-41].

It is believed that the activation and proliferation of HSCs are major processes in hepatic fibrosis, although its pathogenesis has not been fully clarified^[42-45]. The expression of AT1 receptors in HSCs and fibrotic liver tissue supports the notion that activation of local RAS might be related to hepatic fibrogenesis induced by CCl₄. Our results showed that in rat livers, the expression of AT1 receptors in fibrotic areas correlated with the expression of α-SMA. In primary cultured HSCs, the expression of AT1 receptors also correlated with α-SMA. These findings indicated that, as a growth factor of interstitial cells, Ang II might prompt activation of HSCs in the process of hepatic fibrosis. Although both ACE inhibitor and AT1 receptor antagonist could alleviate hepatic fibrosis, as our results showed, a combination of these two gave no added effects of slowing the progression of hepatic fibrosis.

Another interesting finding in our study was that ACE inhibitor and AT1 receptor antagonist could attenuate the hepatocytic injury induced by CCl₄, suggesting their cytoprotective effects by virtue of antifibrogenesis.

As the principal effector molecule of RAS, the production of a profibrogenic cytokine, TGF-β was

enhanced by Ang II in progressive fibrosis of heart and kidney. Recently, Powell *et al*^[46] demonstrated that a statistically significant relationship was observed between inheritance of high TGF- α and angiotensinogen-producing genotype and the development of progressive hepatic fibrosis. Patients with chronic hepatitis C virus infection who inherited neither of the profibrogenic genotype had no or only minimal fibrosis. The documentation of a significant relationship between angiotensinogen genotype and fibrosis also suggested that Ang II might be another mediator of ECM production in the liver.

In conclusion, our investigation demonstrated that: ① ACE inhibitor and AT1 receptor antagonist might slow the progression of hepatic fibrosis induced by CCl₄, but a combination of the two gave no additive effect; ② activated HSCs expressed AT1 receptors, and Ang II could stimulate the proliferation and collagen synthesis of HSCs in a dose-dependent manner; and ③ local activation of RAS in liver tissue might be related to hepatic fibrogenesis induced by CCl₄.

Zhao YL, Meng ZD, Xu ZY, Guo JJ, Chai SA, Duo CG, Wang XY, Yao JF, Liu HB, Qi SX, Zhu HB. H2 strain attenuated live hepatitis A vaccines: protective efficacy in a hepatitis A outbreak. *World J Gastroentero*, 2000;6(6):829-832

Abstract

AIM To investigate the protective efficacy of H2 strain attenuated live hepatitis A vaccines (H2-strain vaccines) in hepatitis A (HA) outbreaks.

METHODS With the permission of their parents, 5551 pre-school and grade 1-3 primary school children were inoculated with 1 dose ($10^{6.5}$ TCID₅₀) of H2-strain vaccines in a nonrandomized, controlled trial conducted in Fucheng County, Hebei Province in May 1997. Another 6485 children in the same grades and compatible in gender and age were enrolled as controls. Epidemiological and serological survey was conducted to evaluate the protective efficacy of the vaccines. ELISA was used to detect serum IgM anti-HAV.

RESULTS HA outbreak started in early May 1998, peaked in the middle of the same month, and lasted about 80 days. Overall 302 HA cases were found, 192(63.58%) were 5-9 years old. One vaccinee and 25 control cases were found to have hepatitis A, which account for 0.28% (1/356) and 5.92% (25/422) of all vaccinees and controls in the 14 villages, respectively. The

protective efficacy of vaccines was 95.27% (95% CI: 85.83%-104.72%). In subjects tested for anti-HAV IgM from 13 villages, 1(0.40%) overt and 11(4.06%) asymptomatic HAV cases were found in 271 vaccinees, but 21(6.69%) of overt and asymptomatic ones were found in 314 controls.

CONCLUSION H2 strain vaccines were excellent in preventing overt hepatitis A, but not so effective in preventing asymptomatic hepatitis A virus infection. A booster dose might be needed to get permanent reliable immunity.

INTRODUCTION

Hepatitis A (HA) is the most common infectious diseases in China. Its notified incidence rates in recent years were 10-20 per 100 000. As severe under-reporting existed, the real incidence rates were possibly 10-fold higher than the notified rates. Community-wide outbreaks occurred at intervals of 5-10 years. The development of HA vaccine made this disease preventable. Two kinds of HA vaccines are available now in China: inactivated HA vaccine and live attenuated HA vaccine. Inactivated HA vaccine, with good tolerance, stability and immunogenicity, proved to be a good selection in developed countries^[1-3]. But most Chinese people refuse them for its considerably high cost. Live attenuated HA vaccine, with only about 1/10 expenses of the inactivated ones, proved to be the best alternatives. China-made H2 strain live attenuated HA vaccine (H2-strain vaccine), has been studied and on trial for more than 10 years, now is the best available one in China. Previous studies showed that it was safe, immunogenetic and had satisfactory preventive effect on sporadic HA^[4,5].

In May 1997, a controlled trial was performed in Fucheng County of Hebei Province, China, 5551 children were inoculated with H2 strain vaccine. Another 6485 children were set as controls. One year later, an outbreak of HA occurred in this county. We conducted an epidemiological and serological survey on this outbreak to evaluate the preventive effect of H2 strain vaccine on HA outbreaks.

METHODS

Vaccination

The H2 strain HA vaccine ($10^{6.5}$ TCID₅₀, 1mL) used were produced by Zhejiang Academy of Medical Sciences. Subjects were children from pre-school class and grade 1-3 primary school who had no history of viral hepatitis or HA vaccination. One dose of vaccine was inoculated to each of the 5551 children with the permission of their parents. Another 6485 children who were in the same grade but refused to accept the vaccines were enrolled as controls. The two groups were compatible in gender and age. The vaccinations were finished in May 1997.

Criteria of diagnosis

Overt HAV infection or HA ① Those with symptoms and signs of acute hepatitis (fever, jaundice, anorexia, vomiting, abdominal discomfort, etc.), elevated serum alanine aminotransferase (ALT) levels and a positive test for serum anti-HAV IgM; ② with negative anti-HAV IgM for untimely serum collection, with significant epidemiological contact history to HA and without positive test results of hepatitis B, diagnosed by town clinics or higher level hospitals.

Asymptomatic or subclinical HAV infection Those who were seropositive for anti-HAV IgM but had no symptoms of hepatitis.

Novel HAV infection Those who were diagnosed as overt or asymptomatic HA cases.

Collection of HA cases

In order to avoid under-reporting, special persons were designated to be in charge of reporting HA cases in each village, school or town clinic, on the basis of previously existed infectious diseases reporting system. HA cases were collected mainly through the following ways: ① routine infectious disease notification; ② periodical review the results of outpatient and laboratory examinations in local hospitals; ③ periodical meeting of designated physicians in the town or village; and ④ direct visit to villages and schools where HA cases were found by trained specialists.

Interview of HA cases

All the HA cases from the trial population and some others from HA amassed villages were interviewed by specialists. A questionnaire was filled out for each case and his/her parents. Three mL serum sample was drawn from each of them for the detection of anti-HAV IgM.

Serological study

A serological survey was performed on trial populations from 13 villages (including 10 of the 14 villages with HA cases and 3 other villages). Serum

samples were obtained from 80.2%(271/338) of the vaccinees and 83.3%(314/377) of the controls. Serum anti-HAV IgM was detected by ELISA kits made by Beijing Wantai Bio-medical Limited Company, batch number: 8080104.

Analysis

All data from epidemiological survey or serological test were input into FoxBASE database. ANOVA (variances to be homogeneous) or Kruskal-Wallis one way analysis (variances to be different) was used to compare the means. Chi square test was used to compare the rates by more than two. Mantel-Haenszel (M-H) test or Fisher exact 1-tailed test was used to compare two rates. All these analyses were done by EPI INFO 6.0 software. Calculation of vaccines' protective efficacy (VE): $VE = (P_1 - P_2) / P_1 \times 100$. The 95% confidence intervals (95% CI) of $VE = VE(\%) \times 1.96 \times (1/P_1^2 \times P_2 Q_2 / N_2 + P_2^2 / P_1^4 \times P_1 Q_1 / N_1)^{1/2}$. P_1 and N_1 are the morbidity rate and sample number of control group, $Q_1 = (1 - P_1)$; P_2 and N_2 are the morbidity rate and sample number of vaccine group, $Q_2 = (1 - P_2)$.

RESULTS

Status of vaccination

With 307 003 population, Fucheng county was divided into 10 administrative towns, or further, 615 administrative villages. The distribution of vaccine group and control group was shown in Table 1. There were 5551 subjects in the vaccine group, which account for 1.8% of the whole population or 7.74% of the 1-15 year-old children in the county.

Features of the outbreak

Cases of HA found during the first 9 months of 1998 are shown in Table 2. The incidence rates remained in sporadic level during the first 4 months (<10 cases each month) and an increasing tendency could be noticed in April. The morbidity began to rise significantly in the first ten days of May (46 cases), peaked on the next ten days (154 cases), lowered to sporadic level on the last ten days of June, and another small peak appeared on the second ten days

in July. The outbreak lasted about 80 days with 302 HA cases found. The incidence rate was 98.37/100 000. Two hundred and eighty-seven cases (95.03%) were found in the main outbreak period about 50 days (from the beginning of May to the second ten days of June), nine cases found in the second ten days of July might be secondary cases.

Most (255, 84.44%) HA cases were found in Gucheng town where the incidence rate reached 638.18/ 100 000. Others were found in Jianqiao (19 cases), Jiangfang (19 cases), Fucheng (6 cases), Manhe (2 cases) and Wangji (1 case) towns. The incidence rates in the 5 towns were 108.95, 78.51, 11.80, 7.42 and 4.66 per 100 000, respectively. No case was found in the other 4 towns.

The mean age of all HA cases was 8.81 years \pm 6.87 years(ranged 1 year-63 years, median 7 years, most cases (252, 83.44%) aged 3 years-11 years and 192(63.58%) aged 5 years-9 years. More male cases were found than female ones (1.65:1) Table 3.

We tested 127 1-15 year old HA cases and 112 (88.19%) were anti-HAV IgM positive. The results are shown in Table 4. The mean ages of the 4 groups were not statistically different ($F=2.03$, $P>0.05$, ANOVA). Following the prolonging of the interval between HA attack and interview, decreasing trends were observed in anti-HAV IgM positive rate ($r=-0.7811$, $P>0.05$, linear correlation) and S/CO of anti-HAV IgM ($r=-0.9948$, $P<0.01$, linear correlation), the former being not statistically significant.

Protective efficacy of vaccines (VE)

In the HA outbreak, twenty-six HA cases were found in trial population, one in vaccine group and 25 in control group. They were distributed in 14 trial villages. The incidence rates of vaccine group and control group in the 14 villages were 0.28%(1/356) and 5.92%(25/422), respectively. The VE was 95.27% (95% CI: 85.83%-104.72%), Table 5.

Table 5 Incidence rates of the trial population in the 14 villages invested

Villages	Vaccine group			Control group		
	No. of Subjects	No. of HA cases	Incidence rate	No. of Subjects	No. of HA cases	Incidence rate

Dainan	25	0	0.00	22	1	4.55
Total	356	1	0.28	422	25	5.92

We tested 80.2%(271/338) subjects of vaccine group and 83.3%(314/377) subjects of control group in 13 villages. The sampling rates of the two groups were not significantly different ($\chi^2=1.16$, $P>0.28$, M-H test). Results are shown in Table 6.

Table 6 Comparison between vaccine group and control group on HAV infection features

Groups	No. of Subjects	IgM anti-HAV(+)		Clinical HA cases		Subclinical infection		Novel infection		Clinical/subclinical ratio
		No.	%	No.	%	No.	%	No.	%	
Vaccine	271	12	4.4	1	0.4	11	4.1	12	4.4	1:11
Control	314	39	12.4	21	6.7	21	6.7	42	13.4	1:1
Relative risk		2.8		18.1		1.7		3.0		6.0
95%CI		1.5-5.3		2.5-133.9		0.8-3.4		1.6-5.6		0.9-40.2
χ^2		11.7		16.0		1.9		13.9		
P value		<0.001		<0.001		>0.5		<0.001		<0.01
Statistical method		M-H		M-H		M-H		M-H		Fisher

From Table 6 we found that anti-HAV IgM positive rate, HA incidence rate, HAV novel infection rate and ratio between HAV overt infection and asymptomatic infection were all significantly higher in control group than in vaccine group. HAV asymptomatic infection rate in control group was also higher than in vaccine group, but not statistically significant.

DISCUSSION

H2-strain vaccine was developed by Zhejiang Academy of Medical Sciences and proved to be safe and immunogenic^[6,7]. Its VE on sporadic HA was studied in a few trials. The results showed that it was dose-dependent. In early years, the titre of live HA vaccines was considerably low ($10^{5.0-5.5}$ -TCID₅₀) and the VE was only 79% - 90%^[8]. Researchers recommended $\geq 10^{6.5}$ TCID₅₀ as a standard dose in recent years. Large-scale trial showed that a dose of H2-strain vaccine $10^{7.0}$ TCID₅₀ induced 94.84% anti-HAV seroconversion and 100% VE^[5]. Our study showed that a dose of H2-strain vaccine ($10^{6.5}$ TCID₅₀) could induce >95% VE in HA outbreak. The result was comparably satisfactory.

Although only 1 HA case was found in vaccine group, 11 subclinical HAV infection cases were observed. This was understandable considering the low geometric mean titre (GMT, about 100mIU/mL)^[5] of serum anti-HAV after inoculation of live vaccines. We concluded that the vaccine was not so effective in preventing HAV infection as in preventing overt HA. The natural HAV infection 1 year after vaccination might act as a natural booster dose and induce life-long immunity. This was an ideal result. But the result might be different if the outbreak comes a few years later. The necessity of a booster dose, therefore, remains to be further studied.

The occurrence of the HA outbreak showed that 7.74% coverage of HA vaccine in children aged 1-15 year's was not enough to prevent HA outbreaks. Since the beginning of reporting viral hepatitis (HV) by type in 1990, only 1 HA outbreak

(1992, the incidence rate was 176/ 100 000) was observed in Fucheng County. The HA incidence rates remained at sporadic level between 1993 and 1997 (4.89-44.63/100 000). The accumulation of susceptible subjects might be the basic reason for the HA outbreak in 1998.

Although HA cases were found in 6 of the 10 towns in the county, most cases were found in Gucheng Town. Another HA outbreak will probably occur in the other 9 towns in a few years. So HA vaccination was still needed in Fucheng County. As the outbreak occurred in summer and most cases were less than 10 years of age, we suggested that another vaccination program be performed among children aged below 10 in next spring in the county except Gucheng town.

The fairly high positive rate (88.19%) of serum anti-HAV IgM in cases tested within 4 months after the attack showed that it was feasible to use anti-HAV IgM as an index in the retrospective study of HA outbreaks which occurred in recent 4 months.

A high frequency of GBV - C/HGV coinfection in hepatitis C patients in Germany

Jie Yan¹ and Reinhard H. Dennin²

Subject headings GB Virus C; hepatitis G virus; hepatitis C virus; coinfection; polymerase chain reaction; sequencing; dominant viral subtype, Germany

Yan J, Dennin RH. A high frequency of GBV-C/HGV coinfection in hepatitis C patients in Germany. *World J Gastroentero*, 2000;6(6):833-841

Abstract

AIM To detect infection rate of GBV-C/HGV in hepatitis C patients, to determine the methods of higher sensitivity and the primers of higher efficiency for GBV-C/HGV RNA detection and to study the dominant subtype and mutation of GBV-C/HGV.

METHODS Quantitative RT-PCR for detection of HCV RNA concentration in serum samples, RT-nested PCR with two sets of primers for detection of GBV-C RNA, RT-PCR ELISA with two sets of primers for detection of HGV RNA, nucleotide sequence and putative amino acid sequence analysis.

RESULTS The positive rates of GBV-C RNA at the 5'-NCR and NS3 region in 211 serum samples from the patients with HCV infection were 31.8% and 22.8% respectively. The positive rates of HGV RNA at the 5'-NCR and NS5 region in the same samples were 47.9% and 31.8% respectively. The total positive rate of GBV-C/HGV RNA was as high as 55.5%. HCV copy numbers in the patients without GBV-C/HGV coinfection were statistically higher than that in the patients with GBV-C/HGV coinfection ($P < 0.01$). Frequent mutation of nucleotide residue was present in the amplification products. Frameshift mutation was found in two samples with GBV-C NS3 region nucleotide sequences. All nucleotide sequences from amplification products showed higher homology to HGV genome than to GBV-C genome even

though part of the sequences were amplified with GBV-C primers.

CONCLUSION A high frequency of GBV-C/HGV coinfection existed in the hepatitis C patients. RT-PCR ELISA was more sensitive than RT-nested PCR for detection of GBV-C/HGV RNA. The primers derived from the 5'-NCR was more efficient than those derived from the NS3 and NS5 regions. A reverse relationship was found to exist between HCV RNA concentration and GBV-C/HGV infection frequency. HGV was the dominant subtype of the virus in the local area. The major mutations of GBV-C/HGV genomes were random mutation of nucleotide residue.

INTRODUCTION

Hepatitis G virus C (GBV-C) and hepatitis G virus (HGV) were recently identified as novel member of Flaviviridae family associated with human non A-E hepatitis^[1-5]. The two viral agents are different isolates of the same virus because of their high homology in nucleotide sequences and putative amino acid sequences^[6,7]. GBV-C/HGV can be transmitted parenterally through transfusions of blood, blood products, intravenous drug user, hemodialysis and vertical transmission^[8-19]. Although GBV-C/HGV were considered to be the major causative agent of human non A-E hepatitis, many later investigative data revealed that GBV-C/HGV infection rates in non A-E hepatitis patients were lower than 15%^[20-25]. GBV-C genome does not have the gene responsible for encoding core protein^[26,27]. HGV capsid protein is absent or defective and the capsid may be provided by another virus^[2,28]. Therefore, coinfection of GBV-C/HGV with other viruses is an interesting and important subject for investigation. The reported GBV-C/GV infection rates in hepatitis C patients were approximate 20%^[29-32] but a quite lower coinfection rate of HGV and HCV (5.6%) was also reported^[33]. Contradictory data about the clinical importance of GBV-C/HGV infection and nucleotide sequence mutation of the viral isolates indicated that the pathogenesis is and variability of the virus are not fully understood^[34-44].

In this study, GBV-C/HGV RNAs in the 211 serum samples of hepatitis C patients were detected by RT-nested PCR and RT-PCR ELISA with four different sets of primers. The GBV-C/HGV RNA

positive amplification products from part of the serum samples were cloned and then sequenced. The results of this study may contribute to the determination of GBV-C/HGV coinfection frequency in hepatitis C patients, choice of the methods with high sensitivity and the primers with high efficiency for GBV-C/HGV RNA detection and understanding the mutation of GBV-C/HGV genomes.

MATERIALS AND METHODS

Materials

211 serum samples of hepatitis C patients were obtained from the hospitals in Leubeck and in Koln of Germany. The 211 samples were confirmed to be HCV RNA positive by using HCV Monitor-TM Test Kit (Hoffmann LaRoche). This test is a routine work in our laboratory for quantitative detection of HCV RNA. HCV RNA concentration in the 211 samples ranged from 200 to 4 166 000 copies per milliliter of serum. All serum samples were HBV negative by using EIA and PCR. T-A Cloning Kit was purchased from Invitrogen. All other materials used in this study were purchased from Boehringer Mannheim.

Methods

Total serum RNA isolation Highly Pure RNA Isolation Kit was used to prepare total RNA from the samples according to the manufacturer's instruction.

Reverse transcription (RT) reaction Ten μ L total RNA preparation was mixed with 10 μ L RT master mixture containing 0.2 mmol/L dNTP, 50 nmol/L hexanucleotide, 20 U M-MuLV-reverse transcriptase, 20 U RNA inhibitor and 4 μ L 5 \times RT buffer (pH 8.3), and incubated at 37°C for 45 min.

RT-nested PCR for GBV-C RNA detection Two sets of primers derived from GBV-C 5'-NCR and NS3 region were used in the RT-nested PCR^[45]. 5'-NCR external primers: 5'-ATGACAGGGTTGGTAG GTCGTAAATC-3' (sense), 5'-CCCCACTGGTC CTTGTCAACTCGCCG-3' (antisense). 5'-NCR internal primers: 5'-TGGTAGCCACTATAGGTGG-GTCTTAA-3' (sense), 5'-ACATTGAAGGGCGACG-TGGACCGTAC-3' (antisense). NS3 region external primers: 5'-GCT CGCCTATGACTCAGCAT-3' (sense), 5'-GTCACCTCAACGACCTCCTC-3' (antisense). NS3 region internal primers: 5'-ATCCATAATTGAGAC AAAGCTGGA-3' (sense), 5'-CCACCAACCCACAGTCGGTG-3' (antisense). For the first PCR round, 10 μ L- RT product was mixed with PCR master mixture containing 20 pmol/L primers, 0.2 mmol/L dNTP, 3 U *Taq* polymerase and 10 μ L 10 \times PCR buffer (pH 9.1) and 25 mmol/L MgCl₂. For the second PCR round, 5 μ L product from the first PCR round was used as template and the other reaction reagents were the same as that in the first PCR round except the

primers. The volume per reaction in the two rounds was 100 μ L. The PCR parameters were described as the following: 94°C 3 min (\times 1); 94°C 30 s, 56°C 30 s, 72°C 30 s, (\times 10); 94°C 30 s, 56°C 30 s, 72°C 35 s, (\times 25, 5 s in addition for each of the following cycle); and 72°C 7 min (\times 1). The products of RT-nested PCR were detected by 2% ethidium bromide stained agarose gel electrophoresis.

RT-PCR ELISA for HGV RNA detection HGV RNA in the samples was detected by Hepatitis G Virus Primer and Capture Probe Set Kit according to the manufacturer's instruction. This kit contains two sets of primers for detection of HGV 5'-NCR and NS5 RNA and two sets of capture probes for detecting PCR products. 5'-NCR primers: 5'-CGGCCAAAAGGTGGTGGATG-3' (sense), 5'-CGACGAGCCTGACGTCGGG-3' (antisense). NS5 region primers: 5'-CTCTTTGTGGTAGTAGC-CGAGAGAT-3' (sense), 5'-CGAATGAGTCAG-AGGACG GGGTAT-3' (antisense). 5'-NCR capture probe: 5'-Biotin-GGTAGCCA CTATAGGTGGG-3'. NS5 region capture probe: 5'-Biotin GTTACTGAGAGCAGCTCAGAT-3'. *Taq* and two polymerase mix in this kit was used in PCR to allow DIG-11-dUTP incorporating the products during amplification process. The PCR parameters were described as the following: 94°C 3 min (1 \times); 94°C 30 s, 55°C 30 s, 72°C 30 s (10 \times); 94°C 30 s, 55°C 30 s, 72°C 35 s (5 s in addition for each of the following cycle, 30 \times); 72°C 7 min (1 \times).

The RT-PCR products were detected by using PCR ELISA DIG Detection Kit according to the manufacturer's instruction. The PCR ELISA is a liquid phase hybridization/DIG detection system. It was found that DNA fragments amplified from HGV RNA could also be seen in 2% ethidium bromide stained agarose gel if the OD value at 405 nm by RT-PCR ELISA was higher than 1.0.

Analysis of nucleotide sequences and putative amino acid sequences The target DNA fragments in GBV-C RT-nested PCR products or HGV RT-PCR products (DIG-11-dUTP replaced by dTTP) were cloned into PCR2.1 plasmid by using T-A Cloning Kit according to the manufacturer's instruction. The plasmid was amplified in *E. coli* and then recovered by the Sambrook's method^[46]. The inserted sequences were analyzed by MWG-BIOTECH. The homology of the nucleotide sequences and putative amino acid sequences was compared with the those thow reported^[1,2].

RESULTS

GBV-C and HGV RNA detection rates Seventy-four of the 211 serum samples (35.1%) were GBV-C RNA positive, 41 of the 74 samples (55.4%) were GBV-C RNA positive for both the 5'-NCR and NS3 region, 26 of the 74 samples (35.1%) were only 5'-NCR RNA positive and only 7 of the 74 samples (9.5%) detected NS3 region RNA. A statistically

significant difference ($\chi^2=4.32$, $P<0.05$) was found to exist between the positive rates of GBV-C 5'-NCR (67/211) and those of NS3 region (48/211).

One hundred and five (49.8%) of the 211 serum samples were HCV RNA positive, 63 of 105 samples (60.0%) were HGV RNA positive for both the 5'-NCR and NS5 regions, 38 of the 105 samples (36.2%) were only 5'-NCR RNA positive and 4 of the 105 samples (3.8%) were only detectable for NS5 region RNA. A statistically significant difference ($\chi^2=11.43$, $P<0.01$) was also found between the positive rates of HGV 5'-NCR (101/211) and NS5 region (67/211). The respective target fragments amplified from GBV-C 5'-NCR, NS3 region and HGV 5'-NCR, NS5 region are shown in Figures 1, 2.

Total positive rate of GBV-C/HGV and distribution of the positive samples One hundred and seventeen (55.5%) of the 211 serum samples were GBV-C and/or HGV RNA positive and 94 of the 211 samples (44.5%) were negative for both viral RNAs, 62, 12 and 43 of the 117 samples were positive for both viral RNAs, GBV-C RNA positive and detectable HGV RNA respectively. The distribution of the 117 samples is shown in Table 1.

Relationship between HCV RNA concentration and GBV-C/HGV infection frequency The range of HCV RNA concentrations of the 211 serum samples was 200-4 166 000 copies/mL. A statistically significant

difference ($t'=2.559$, $P<0.01$) was present in the HCV RNA copy numbers of the group with GBV-C and/or HGV RNA positive samples (mean = 344 000 HCV RNA copies/mL) and the group with both viral RNA negative samples (mean = 556 000 HCV RNA copies/mL). In addition, HCV RNA concentration in each of 21 cases of the 211 samples was higher than 1 000 000 copies/mL. Six of the 21 cases distributed in GBV-C and/or HGV RNA positive group and the other 15 cases belonged to the negative group. In comparison with the two percentages (6/211 and 15/211), a statistically significant difference was also found ($\chi^2=4.06$, $P<0.05$).

Table 1 Distribution of 117 GBV-C and/or HGV positive samples

GBV-C		HGV		Positive cases	Positive rate (%)

Figure 2 Target amplification fragments from HGV 5'-NCR and NS5 region. (1 and 14: markers; 2 and 8: negative serum samples; 7 and 13: blanks; 3-6: four HGV 5'-NCR RNA positive serum samples; 9-12: four HGV NS5 region RNA positive serum samples)

Nucleotide sequence analysis The homology of the nucleotide sequences of GBV-C 5'-NCR RT-nested PCR products from 3 serum samples compared with the reported GBV-C sequence^[1] and the reported HGV sequence^[2] was 81.8%, 81.1%, 82.5% and 97.6%, 97.2%, 99.3% respectively. The homology of the two reported sequences at the 5'-NCR was 81.8%. The homology of the nucleotide sequences of GBV-C NS3 region RT-nested PCR products from 6 samples compared with the reported GBV-C sequence^[1] and the reported HGV sequence^[2] was 80.2%, 82.3%, 81.5%, 84.4%, 85.6%, 85.2% and 86.8%, 88.1%, 88.1%, 88.1%, 86.8%, 87.7% respectively. The homology of the two reported nucleotide sequences at the NS3 region was 84.4%. Although the primers used in the RT-nested PCR derived from GBV-C genome, each of the 9 nucleotide sequences showed a higher homology to HGV than to GBV-C. These nucleotide sequences are shown in Figures 3, 4.

The homology of the nucleotide sequences of HGV 5'-NCR RT-PCR products from 3 samples compared with the reported HGV sequence^[2] and

the reported GB V-C sequence^[1] was 95.2%, 99.3%, 98.6% and 86.4%, 87.1%, 87.8% respectively. The homology of the two reported sequences at the 5'-NCR was 86.4%, whereas the homology of the nucleotide sequences of HGV NS5 region RT-P CR products from 3 serum samples compared with the reported HGV^[2] sequence and the reported GBV-C sequence^[1] was 95.3%, 96.3%, 96.3% and 94.4%, 94.4%, 93.4% respectively. The homology of the two reported sequences at the NS5 region was 93.4%. These nucleotide sequences are shown in Figures 5, 6.

The homology in comparison of these sequences mentioned above did not contain the primer sequences.

The putative amino acid sequence analysis Putative amino acid sequences translated from the 6 nucleotide sequences from GBV-C NS3 region and the 3 nucleotide sequences from HGV NS5 region were respectively compared with the reported HGV and GBV-C sequences^[1,2]. These putative amino acid sequences were shown in Figures 7, 8.

DISCUSSION

As mentioned in the introduction, the reported GBV-C/HGV infection rates in non A-E hepatitis patients were lower than 15% and the reported GBV-C/HGV and HCV coinfection rates were approximate 20%. In this study, a high total positive rate (55.5%) of GBV-C and/or HGV RNA in hepatitis C patients was found. Such a high frequency of GBV-C and/or HGV and HCV coinfection including most of the reported coinfection rates, suggested that GBV-C/HGV coinfecting with HCV may be one of the features of its prevalence.

GBV-C RNA positive rate in the 211 samples by using RT-nested PCR was 35.1%. HGV RNA positive rate in the same samples by RT-PCR ELISA was as high as 49.8%. Statistical analysis of the two positive rates indicated that RT-PCR ELISA is more sensitive than RT-nested PCR ($\chi^2 = 9.32$, $P < 0.01$).

In the 211 serum samples, the positive rate

(31.8%) of GBV-C 5'-NCR was higher than that (22.8%) of GBV-C NS3 region ($\chi^2 = 4.32$, $P < 0.05$) and the positive rate (47.9%) of HGV 5'-NCR was also higher than that (31.8%) of HGV NS5 region ($\chi^2 = 11.43$, $P < 0.01$). These data led to the conclusion that the primers derived from the 5'-NCRs were more efficient than those derived from the NS regions^[47]. According to the results of nucleotide sequence analysis, this efficiency difference of primers was probably due to the higher conservation of sequences within the 5'-NCRs. In addition, only 26 of the 117 GBV-C and/or HGV RNA positive samples were positive for all the four viral genomic regions. It suggested that application of multiple primers is helpful to increase positive rate of GBV-C/HGV RNA detection.

A reverse relationship of HCV RNA concentration and GBV-C/HGV infection frequency was found in this study. This finding suggested that GBV-C/HGV and HCV might suppress each other *in vivo*. This reverse

relationship seemed to be contradictory to the high GBV-C/HGV and HCV coinfection rate. However, this kind of situation of cocurrence and competition is a normal phenomenon among microorganisms. For example, HBV and HCV coinfection is frequent in Asia but HCV was found to suppress the replication of HBV and vice versa to a lesser extent [48-50].

In this study, the homology of nucleotide sequences in the products amplified with the primers derived from HGV genome was higher in the reported HGV sequence than in the reported GBV-C sequence. Such results could be expected, however, all nucleotide sequences in the products amplified with the primers derived from GBV-C genome also showed higher homology with the reported HGV sequence. These data reveal the fact that: HGV and not the GBV-C, is the dominant subtype in the local area. Besides, these existed random mutations in a large number of nucleotide residue in all amplification products and two showed frameshift mutation which indicate that mutation of GBV-C/HGV genomic sequences occurs easily at the subtype level.

Pan QS, Fang ZP, Huang FJ. Identification, localization and morphology of APUD cells in gastroenteropancreatic system of stomach-containing teleosts. *World J Gastroentero*, 2000;6(6):842-847

Abstract

AIM To identify the type localization and morphology of APUD endocrine cells in the gastroenteropancreatic (GEP) system of stomach-containing teleosts, and study APUD endocrine system in the stomach, intestine and pancreas of fish species.

METHODS Two kinds of immunocytochemical (ICC) techniques of the streptavidin biotin-peroxidase complex (SABC) and streptavidin-peroxidase (S-P) method were used. The identification, localization and morphology of APUD endocrine cells scattered in the mucosa of digestive tract, intermuscular nerve plexus and glandular body of northern snakehead (*Channa argus*), ricefield eel (*Monopterus albus*), yellow catfish (*Pelteobagrus fulvidraco*), mandarin fish (*Siniperca chuatsi*), largemouth bass (*Micropterus salmoides*), oriental sheatfish (*Silurus asotus*), freshwater pomfret (*Colossoma brachypomum*) and Nile tilapia (*Tilapia nilotica*) were investigated with 8 kinds of antisera.

RESULTS The positive reaction of 5-hydroxytryptamine (5-HT) immunoreactive endocrine (IRE) cells was found in the digestive

tract and glandular body of 8 fish species in different degree. Only a few gastrin (GAS)-IRE cells were seen in *C. argus*, *M. albus* and *P. fulvidraco*. Glucagon (GLU)-IRE cells were not found in the digestive tract and glandular body but existed in pancreatic island of most fish species. The positive reaction of growth hormone (GH)-IRE cells was found only in pancreatic island of *S. chuatsi* and *S. asotus*, no positive reaction in the other 6 fish species. *Somatostatin* (SOM), calcitonin (CAL), neurofilament (NF) and insulin (INS)-IRE cells in the stomach, intestine and pancreas of 8 kinds of fish were different in distribution and types. The distribution of all 8 APUD cells was the most in gastrointestinal epithelium mucosa and then in digestive glands. The positive reaction of SOM- and 5-HT-IRE cells was found in intermuscular nerve plexus of intestine of *P. fulvidraco* and *S. chuatsi*. Only GH-IRE cells were densely scattered in the pancreatic islands of *S. chuatsi* and *S. asotus*, and odd distribution in the pancreas of *S. asotus*. SOM-IRE cells were distributed in the pancreatic islands of *S. asotus*, *C. Brachypomum* and *T. nilotica*. There were INS-IRE cells in the pancreatic islands of *S. chuatsi* and *S. asotus*. Eight kinds of APUD cells had longer cell body and cytoplasmic process when they were located in the gastrointestinal epithelium, and had shorter cell body and cytoplasmic process in the gastric gland, and irregular shape in the esophagus and pancreatic island.

CONCLUSION Eight kinds of IRE cells were identified in the GEP system of stomach-containing teleosts. These endocrine cells were scattered in gastrointestinal mucosa, intermuscular nerve plexus, gland body, pancreatic gland and islands under APUD system. CAL- and GH-IRE cells in the pancreatic islands of fishes showed functional diversity for these two hormones. Their morphological feature provides evidence of endocrine-paracrine and endocrine-exocrine acting mode. This research can morphologically prove that the GEP endocrine system of fish (the lowest vertebrate) is almost the same as of mammal and human.

INTRODUCTION

In recent years, APUD (amine precursor uptake and decarboxylation) cells in the digestive tract attracted worldwide attention. It was a research domain developed quickly in recent years, especially gastrointestinal hormones^[1-7]. Gastrointestinal tract was not only the digestive organ but also the biggest and most complex endocrine organ in animal^[8]. It has been proved that gastrointestinal hormones were not only related with feeding behavior but also with nutrition of gastrointestinal tract. At present it has been applied to clinical practice^[9-24]. The endocrine tumor of digestive tract could occur in gastrointestinal tract and liver or in pancreatic gland^[25,26], even over ninety per cent of carcinoid occurred in gastrointestinal^[27-40]. What is the hormone's effect on it So it is of special significance to study endocrine cells in digestive system. Up till now, researches about digestive tract in animal have been reported^[41], but the research data about fish having close relations with human food are scarce. The distribution of APUD cells in the gut of 8 stomachless teleosts was reported^[42]. In the present paper, ICC studies on APUD cells in the GEP system of stomach-containing teleosts were reported further, delving into difference of gastrointestinal hormone types, secretory way, distribution and cell's shapes among fish, mammal and human, in order to provide basic materials for studying gastrointestinal endocrinology, gastroenterology, origin and prevention of disease in digestive system and its treatment.

MATERIALS AND METHODS

Specimens and section

Ricefield eel (*M. albus*), northern snakehead (*C. argus*), oriental sheatfish (*S. asotus*), mandarin fish (*S. chuatsi*), and yellow catfish (*P. fulvidraco*) were bought separately from the aquatic products market in Wuhan; freshwater pomfret (*C. brachypomum*) and Nile tilapia (*T. nilotica*) were bought from The Second Fish and Stock Farm in Hongshan District of Wuhan; largemouth bass (*M. salmoides*) was bought from Nanhu Fish Farm. We reared above 8 kinds of fish temporarily in fresh water for 24 hours, then according to the methods in references^[43-46], and collected the samples and made the sections. Monoclonal antibody of GH was used only in SABC ICC stain method^[46], S-P ICC stain method was used in the other 7 kinds of antibody^[43].

Reagents and antisera

The details of the different antisera, the working dilutions and main reagents used in this study are listed in Table 1.

ICC staining steps and control

The steps of S-P ICC stain and control references and

the SABC ICC staining steps and control followed references^[43,46].

Observation, photomicrograph and count

Five fishes used for each species in all 8 kinds of teleost studied, 7 specimens of each fish were observed and photomicrographed under the Olympus (BH-2) photomicroscope. The dark brown positive cells on section were counted under 10×20 times field. The average number of positive cells from 10 fields selected randomly in each specimen part was the IRE cell number of this part in each fish. The average number of 5 fishes of each species was quantified IRE cell's distribution density in every part. The distribution density was showed with five grades.

RESULTS

Types and distribution of APUD cells

APUD cell types, distribution and density in different parts of GEP system of 8 kinds of stomach-containing teleosts are listed in Table 2. It can be seen from Table 2 that IRE cell types and distribution quantity were the least in the esophageal epithelium, only GAS, SOM and CAL-IRE cells were found in the esophageal epithelium mucosae of *M. albus* (Figure 1). IRE cells were the most common types and the highest distribution density in the gastric epithelium and glands of 8 kinds of fish (Figures 3, 5, 7, 9, 10, 12); then in the intestine (Figures 2, 4, 8, 11, 13, 14). GLU- and INS-IRE cells were mostly located in every specimen of pancreatic island. SOM- and 5-HT-IRE cells were found in the gastrointestinal intermuscular nerve plexus of *P. fulvidraco* and *S. chuatsi* separately (Figure 8, Table 2). No GAS, 5-HT, CAL- and NF-IRE cells were seen in the pancreatic island of all 8 kinds of teleosts. There were 5-HT-IRE cells in the digestive tract of all fish species; only a few GAS-IRE cells were distributed in the esophagus and stomach of *C. argus*, *M. albus* and *P. fulvidraco*; GH-IRE cells were distributed in a small amount in the pancreas of *S. asotus*, but were scattered in the pancreatic islands of *S. chuatsi* and *S. asotus*; and were not seen in the gastrointestinal tract of 8 kinds of fish species. In gastrointestinal tract, APUD cells were distributed between epithelium mucosa and glandular epithelium (Figures 1-14). Negative reaction was found in all controls.

Morphological feature of APUD cells

According to the distribution of APUD cells, their morphology was of great diversity. APUD cells located in stratified squamous epithelium of esophagus were scattered or piled in distribution, and irregular in shape, and had a shorter cytoplasmic process (Figure 1). While the APUD cells distributed between gastrointestinal columnar epithelium had a longer cell body, an apical

cytoplasmic process extended to the gastrointestinal lumen or a basal process extended to the basement membrane (Figures 2, 4, 9, 11-14). The APUD cells located in gastric glands were mainly pyramid-shaped (Figures 5-7,10), their cytoplasmic process extended to the gastrointestinal lumen. In the pancreatic islands of *S.chuatsi* and *S.asotus*, GLU-IRE cells were located in the edge of

pancreatic islands (Figures 15, 18) and SOM, INS- and GH-IRE cells scattered in the whole pancreatic islands (Figures 16, 17, 19). Their shapes were irregular, some had a longer cytoplasmic process (Figure 18), the secretory granules were clear (Figure 19) in some of IRE cells. There were a few scattered GH-IRE cells in the pancreatic exocrine area of *S.asotus* (Figure 19).

DISCUSSION

The distribution of APUD cells in the GEP system of stomach-containing teleosts and in the digestive system of human and stomachless teleosts is quite different. GAS-IRE cells existed in human GEP system^[8,14-16] and in the intestine of 7 kinds of stomachless teleosts^[42], but at present study, GAS-IRE cells were not seen in the digestive system of 7 fish species except in the esophagus of *M. albus* and in the stomach of *C. argus* and *P. fulvidraco*. After ICC identification of APUD cells in the gut of 7 stomachless teleosts, the 5-HT-IRE cells were not found in the gut^[42], but in the intestine of 7 stomach-containing teleosts except *M. albus*. Rombout and Reinecke^[47] found SOM-IRE cells only existing in the stomach of stomach-containing teleosts; but at present studies, SOM-IRE cells were seen in the esophagus of *M. albus*, the gastric epithelium and intermuscular nerve plexus of *P. fulvidraco*, the gastric epithelium of *S. chuatsi* and *T. nilotica*. GLU-IRE cells existed universally in the gut of stomachless teleosts^[42], but in this study they were not found in the gastrointestinal tract of 8 stomach-containing teleosts.

It was reported that there were 4 APUD cell types: B cell (secreting INS), PP cell (secreting pancreatic polypeptide), A cell (secreting GLU) and D cell (secreting SOM) in the pancreatic island of fish species^[48]. In our studies, CAL-IRE cells were found in the pancreatic island of *S. asotus* and *M. salmoides*. Calcitonin was a hormone secreted by ultimobranchial gland of fish species^[49], and also was found in the secretory cells of prolactin hormone of rat hypophysis^[50]. But up to now, no report showed that CAL-IRE cells exist in the pancreatic island of fish species. CAL-IRE cells in the pancreatic island of *S. asotus* and *M. salmoides* were morphologically long shuttle-shaped which was different from other endocrine cells in the pancreatic island which had the shorter cytoplasmic process and irregular shape. This specific morphological feature provides evidences that CAL-IRE cells in the pancreatic island of *S. asotus* and *M. salmoides* may adapt to some specific physiological functions and conduct endocrine paracrine action^[8].

It is a common knowledge that there are GH-IRE cells in the meso-adenohypophysis of fish species and can promote the growth of them. Our studies demonstrated that there was no GH-IRE cell in the gastrointestinal tract of fish species^[46], and GH was not gastrointestinal hormone. However our studies found for the first time that GH-IRE cells in the pancreatic islands of *S. chuatsi* and *S. asotus*, and in the exocrine pancreas of *S. asotus* had scattering distribution. It is evidenced that GH-IRE cells were not only located in the endocrine organ-pancreatic island but in the digestive gland in a small amount. It shows morphological evidence of brain-

gutpeptide with an endocrine-exocrine mode of action^[51]. It suggests that the GH-IRE cells existed simultaneously in the hypophysis, pancreatic island and pancreas, and the other brain-gut peptide or brain-pancreas peptide varied in pattern of distribution, and the diversity of physiological function of GH-IRE cells based on their morphology.

Abstract

AIM To investigate the expression of multiple genes and the behavior of cellular biology in gastric cancer (GC) and other gastric mucosal lesions and their relations to *Helicobacter pylori* (*H. pylori*) infection, tumor staging and histological subtypes.

METHODS Three hundred and twenty-seven specimens of gastric mucosa obtained via endoscopy or surgical resection, and ABC immunohistochemical staining were used to detect the expression of p53, p16, Bcl-2 and COX-2 proteins. *H. pylori* was determined by rapid urea test combined with pathological staining or ¹⁴C urea breath test. Cellular image

analysis was performed in 66 patients with intestinal metaplasia (IM) and/or dysplasia (Dys). In 30 of them, both cancer and the paracancerous tissues were obtained at the time of surgery. Histological pattern, tumor staging, lymph node metastasis, grading of differentiation and other clinical data were studied in the medical records.

RESULTS p16 expression of IM or Dys was significantly lower in positive *H. pylori* chronic atrophic gastritis (CAG) than those with negative *H. pylori* (CAG: 54.8% vs 88.0%, IM:34.4% vs 69.6%, Dys: 23.8% vs 53.6%, all $P<0.05$), Bcl-2 or COX-2 expression of IM or Dys in positive *H. pylori* cases was significantly higher than that without *H. pylori* (Bcl-2: 68.8% vs 23.9%, 90.5% vs 60.7%; COX-2: 50.0% vs 10.8%, 61.8% vs 17.8%; all $P<0.05$). The mean number of most parameters of cellular image analysis in positive *H. pylori* group was significantly higher than that in negative *H. pylori* group (Ellipser: 53 ± 14 , 40 ± 12 μm , Area 1: 748 ± 572 , 302 ± 202 μm^2 , Area-2: 3050 ± 1661 , 1681 ± 1990 μm^2 , all $P<0.05$; Ellipseb: 79 ± 23 , 58 ± 15 μm , Ratio 1: $22\%\pm5\%$, $13\%\pm4\%$, Ratio-2: $79\%\pm17\%$, $53\%\pm20\%$, all $P<0.01$). There was significant correlation between Bcl-2 and histologic pattern of gastric carcinoma, and between COX-2 and tumor staging or lymph node metastasis (Bcl-2: 75.0% vs 16.7%; COX-2: 76.0% vs 20.0%, 79.2% vs 16.7%; all $P<0.05$).

CONCLUSION p16, Bcl-2, and COX-2 but not p53 gene may play a role in the early genesis/progression of gastric carcinoma and are associated with *H. pylori* infection. p53 gene is relatively late event in gastric tumorigenesis and mainly relates to its progression. There is more cellular-biological behavior of malignant tumor in gastric mucosal lesions with *H. pylori* infection. Aberrant Bcl-2 protein expression appears to be preferentially associated with the intestinal type cancer. COX-2 seems to be related to tumor staging and lymph node metastasis.

INTRODUCTION

Gastric cancer (GC) is a worldwide disease with a dismal prognosis. A better understanding of its pathogenesis and biological features is crucial in improving the diagnosis and treatment^[1]. Tumorigenesis of GC is attributable to the interaction of environmental and genetic factors^[2-12]. In addition to dietary factors, *Helicobacter pylori* (*H. pylori*) infection has been regarded recently as a presumed environmental factor contributing to the tumorigenesis of the disease based on the theory that *H. pylori* infection may enhance cellular proliferation and therefore lead to somatic mutations of critical genes^[13-24]. However, the increase of *H. pylori* in the gene alterations as p53, p16, Bcl-2, and COX-2 remain unclear^[25-30].

GC consists of two distinct histological types: intestinal and diffuse types^[31]. They differ not only in morphology but also in their clinical and epidemiological characteristics. A different spectrum of genetic changes is believed to be involved in the intestinal type rather than in the diffuse type^[32]. Whether such genes as p53, p16, Bcl-2, and COX-2 play different roles in these two different types is not known^[33-38].

Little is known about the sequential genetic changes associated with the progression of GC as compared with colon cancer. In terms of its natural history, GC may be divided into early and advanced stages according to the invasiveness of tumor cells. Many reports have described genetic alterations in GC, but few have compared these alterations between the early and advanced stages^[35-37, 39,40].

It is necessary to shed further light on gastric tumorigenesis, the loss of p16 and the overexpression of mutant p53, Bcl-2, and COX-2 were investigated in patients with GC and other gastric mucosal lesions. The status of *H. pylori* infection, tumor staging, and histological types were correlated with alterations of these four genes and behavior of cell biology.

PATIENTS AND METHODS

Patients and samples

A total of 327 patients with histologically confirmed GC (60 cases) and other gastric mucosal lesions (chronic superficial gastritis, CSG; chronic atrophic gastritis, CAG; intestinal metaplasia, IM; dysplasia, Dys; 84, 56, 78, and 49 cases, respectively) were enrolled in the study. Those cancers were resected in the first affiliated hospital of Nanjing Medical University between 1996 and 1998. Both cancer and the neighboring nontumorous tissue of 30 patients were obtained at the time of surgery. The histological slides were independently reviewed by one pathologist, who was unaware of the parameters to be investigated. Tumors were classified as intestinal or diffuse types according to the Lauren's criteria. The extent of tumor invasion

was further divided into early or advanced GC according to the criteria proposed by the Japanese Research Society for Gastric Cancer. It is defined as an early GC if the tumor is limited in the mucosa and submucosa, and advanced GC if the tumor invades the muscularis propria. Lymph node metastasis, grading of differentiation and other clinical data were obtained from medical records, and the status of *H. pylori* infection was determined by a rapid urease test and a histological examination (Giemsa stain)/ ¹⁴C urea breath test.

Immunohistochemistry

The specimens in paraffin blocks were sectioned into 4μm in thickness. The first section was routinely stained with HE for histological diagnosis, and additional sequential sections were retained for immunohistochemistry. Immunostaining for p53, p16, Bcl-2, and COX-2 was performed by a standard avidin-biotin-peroxidase complex detection system. Mouse monoclonal antihuman p53 (diluted with PBS to 1:50; Oncogene Science, Inc, USA), rabbit polyclonal anti-p16 (diluted with PBS to 1:80, Dako, USA), mouse monoclonal antihuman Bcl-2 (diluted with PBS to 1:100; Dako, USA), and rabbit polyclonal anti-COX-2 (diluted with PBS to 1:50; Gene Company Limited) were used as the primary antibodies. Tissue sections were dewaxed, microwaved, and rehydrated. The sections were boiled for 30 minutes in 10mM/L citrate buffer solution (pH 6.0) using a microwave heater for antigen retrieval. Endogenous peroxidase activity and nonspecific binding were blocked by incubation with 30mL/L hydrogen peroxide (H₂O₂) and nonimmune serum, respectively. The slides were then incubated sequentially with primary mouse monoclonal or polyclonal antibodies overnight at 4°C, with a biotinylated goat anti-mouse secondary antibody (diluted with PBS to 1:200) for 30min, with peroxidase-conjugated asreptavidin for 10min, and finally, with 3,3'-diaminobenzidine -tetra-chloride (0.25mg dissolved in 1mL 0.2mL/L hydrogen peroxide) chromogen substrate for 10min so that demonstration of binding sites with peroxidase reaction was obtained. Negative control sections were prepared by substituted primary antibody with buffered saline, and positive control sections were obtained from known positive sections. The percentage of positively stained cells was evaluated for each tissue section after counting 1000 cells at high power field. Tissues were classified as being immunohistochemically positive if ≥5% of cells stained and showed distinct nuclear staining for p53 dominant nuclear staining and a little cytoplasmic staining for p16, nuclear membrane or cytoplasmic staining for Bcl-2 and cytoplasmic staining for COX-2. The staining intensity was expressed as weakly positive (+), moderately positive (++) and strongly positive (+++).

Cellular image analysis (CIA)

CIA was performed in 66 patients (*H. pylori* positive 33, *H. pylori* negative 33) with intestinal metaplasia (IM) and/or dysplasia (Dys). CIA (Vidas, Opton, Germany) supported by the Department of Cellular and Molecular Biology, Shanghai Second Medical University, which was used to study the following parameters: Fshape (shape factor), Fllipser (long axle, μm), Fllipseb (short axle, μm), Ratio₁ (nucleus to cytoplasm ratio, %), Ratio₂ (structure atypical index, %), Area₁ (area of nuclear, μm^2), Area₂ (area of cytoplasm, μm^2), taking the mean value of the parameters for analysis.

Statistical analysis

Statistical analysis system (SAS) software package for *t* test, χ^2 test, and Wilcoxon Scores (Rank Sums) test. A value of $P < 0.05$ was considered statistically significant.

RESULTS

Expressions of p53, p16, Bcl-2, and COX-2 proteins

The positive rates of p53, p16, Bcl-2, and COX-2 in GC were 46.7%, 38.3%, 68.3%, and 75.0% respectively. The positive rate of p53 gene in GC was significantly higher than that in DYS ($P < 0.05$); p16 gene expression in CSG or CAG was significantly higher than that in GC ($P < 0.01$) or Dys ($P < 0.05$). As to Bcl-2 expression, there was no significant difference between Dys and GC ($P > 0.05$), the positive rate of Bcl-2 expression in DYS or GC was significantly higher than that in CSG, CAG or IM ($P < 0.01$, $P < 0.05$). In

addition, COX-2 expression in GC was also significantly higher than that in Dys or IM ($P < 0.05$, Table 1).

Table 1 Expressions of p53, p16, Bcl-2, and COX-2 proteins in gastric mucosal lesions (n,%)

Lesion	n	p53	p16	Bcl-2	COX-2
GC	60	28(46.7) ^a	23(38.3)	41(68.3) ^{ba}	45(75.0) ^a
Dys	49	10(20.4)	20(40.8)	36(73.5) ^{ba}	18(36.7)
IM	78	1(1.3)	43(55.1)	33(42.3)	21(26.9)

p53:^a $P < 0.05$ GC-Dys; p16: ^b $P < 0.01$ CSG- Dys or GC, ^a $P < 0.05$ CAG-Dys or GC; Bcl-2: ^b $P < 0.01$ Dys (GC)-CSG or CAG; ^a $P < 0.05$ Dys (GC)-IM; COX-2:^a $P < 0.05$ GC-Dys (IM).

The expression of p53, p16, Bcl-2 and COX-2 proteins in gastric mucosal lesions with *H. pylori* infection

No significant difference for the positive rate in p53 expression of GC or Dys between positive *H. pylori* and negative *H. pylori* group ($P > 0.05$). There was also no significant difference for p16, Bcl-2, or COX-2 expression in GC between positive *H. pylori* and negative *H. pylori* group ($P > 0.05$). However, the positive rate and staining intensity of p16 expressions of CAG, IM or Dys with *H. pylori* infection were significantly lower than those without *H. pylori* infection ($P < 0.05$, $P < 0.01$). On the contrary, Bcl-2 and COX-2 expressions of IM or Dys with positive *H. pylori* were significantly higher than those with *H. pylori* ($P < 0.05$, Tables 2,3).

Expressions of *p53*, *p16*, *Bcl-2*, and *COX-2* proteins in GC related to tumor staging and histological types

No correlation between *p53*, *p16*, or *Bcl-2* expression and pathologic staging; grading of differentiation, or status of lymph node metastasis was observed ($P>0.05$), there was significant correlation between *Bcl-2* and types of GC ($P<0.05$). However, there was significant correlation between *COX-2* and pathologic staging or lymph node metastasis (all $P<0.05$), no correlation between *COX-2* expression and type or grading of differentiation (all $P>0.05$, Table 5).

DISCUSSION

GC remains a common disease with a dismal prognosis in China and other Asian countries. Both genetic and environmental factors, such as *H. pylori* infection and dietary carcinogens, are crucial in cancer development and progression. The role of genetic changes in the pathogenesis of GC has recently received considerable attention^[26-28]. The development of GC is a multistep process with

accumulation of multiple oncogene activations and inactivation of tumor suppressor gene.

A number of molecular events are being recognized as implicating a part in the gastric carcinogenesis^[41]. Among these, mutation of the tumor suppressor gene *p53* is well described in gastric adenocarcinomas^[42] as is loss of heterozygosity on chromosome 17p, the locus of *p53*^[43]. The wild type acts functionally as a tumor suppressor gene^[44] and may also have a role in preventing replication of the damaged DNA^[45] while failure of this function in mutant *p53* may lead to instability of the genome and predisposed to the development of aneuploidy^[46]. The missense mutations of *p53* genes have frequently been associated with the progression of GC^[34,47].

Progression of cells through the different phases of the cell cycle is closely regulated by phase-specific activators and inhibitors. A novel cell cycle control gene, the *p16* gene, also referred to as CDKN2, MTS1, or INK4A, which encodes components of cell cycle checkpoints, has been cloned and characterized. *p16* gene is located on chromosome 9p21 and has been described as one of the principal negative regulators of the early G₁ phase. Changes in this gene could thus lead to uncontrolled cell growth and contribute to tumorigenesis^[35,48]. Recent studies have shown that the *p16* gene is indeed inactivated in a wide range of cancer cell lines and primary tumors^[48,49]. *p16* gene may correlate with tumorigenesis and tumor expansion due to decrease or loss of gene products in gastric cancer^[50,51]. However, studies on changes in *p16* genes in GC remain scanty^[38].

Recently, emphasis has been placed on the role of apoptosis and its regulation in carcinogenesis. In the gastrointestinal tract, apoptosis has been demonstrated to play an active role in the maintenance of the mucosa. Apoptosis may play a role in selection of clonal subpopulations with high growth potential resulting in malignant transformation^[52]. The *Bcl-2* protooncogene, located on chromosome 18, codes for a 26Kd protein involved in inhibiting apoptosis^[53]. *Bcl-2* protein is believed to play a role in the gastric carcinogenic sequence where it has been demonstrated in dysplastic epithelium^[54]. Aberrant *Bcl-2* protein expression has been noted in gastric epithelial Dys and in CAG^[36].

In addition, there was no expression of a novel isoenzyme of cyclooxygenase, cyclooxygenase-2 (COX-2) in normal tissue, however, large expression occurred in inflammatory sites. Recently, some researches show that there is an increasing expression of COX-2 in gastrointestinal tumors^[37,55]. Although the potential role of the four genes' protein expression have been recognized to be related to the carcinogenic sequence, that the role of *H. pylori* infection may promote changes of

gene remains unclear^[26,27,29,56]. Moreover, the relationship between these gene alterations and histological types, tumor staging, lymph node metastasis, grading of differentiation remains controversial^[34,35,37,40]. Hence, we undertook the present study to investigate the effect of *H. pylori* infection on changes in the four genes and to further study their relation to types of GC and tumor progression.

H. pylori infection has been documented as an important risk factor for GC^[57]. Chronic inflammation due to persistent *H. pylori* infection would be expected to cause repetitive degeneration and regeneration of the mucosal epithelium that could facilitate malignant transformation. While epithelial cell proliferation is not carcinogenic in itself, it is likely to promote neoplastic transformation in combination with additional factors, such as genetic alterations and oncoprotein overexpression. In the current study, we noted that the positive rate of *p53*, *p16*, *Bcl-2*, and *COX-2* in GC was 46.7%, 38.3%, 68.3%, and 75.0% respectively and four genetic changes were not different between positive *H. pylori* and negative *H. pylori* GC. However, the positive rate and staining intensity of *p16* expression of CAG, IM or Dys with positive *H. pylori* were significantly lower than those with negative *H. pylori*. On the contrary, *Bcl-2* expression of IM or DYS with positive *H. pylori* was significantly higher than that with negative *H. pylori*. *p16* or *Bcl-2* gene expression alteration might play a role in the early development/promotion of gastric carcinoma and was associated with *H. pylori* infection^[50,51,58]. It seemed that *H. pylori* infection was not related to *p53* gene alteration^[30,59,60] because *p53* gene overexpression was closely associated with the potential for advancement of tumor and a poorer prognosis in patients with GC^[25,41,58,59,61,62] (Tables 1-3). The result was different from that reported by Chang *et al*^[63]. In the early stage of *H. pylori* infection, it not induces apoptosis in the gastric epithelium, at least in part due to downregulation of antiapoptotic *Bcl-2*^[26] but promotes proliferation due to activation of oncogene^[14]. However, persistent *H. pylori* infection would cause deletion of *p16* gene and overexpression of *Bcl-2*^[27], leading to overproliferation of gastric epithelium. In addition, inducible *COX-2* is an important regulator of mucosal inflammation and epithelial cell growth. The expression of *COX-2* gene is the result of direct response to *H. pylori* infection^[28,29]. Our study found that *COX-2* expression of IM or Dys with positive *H. pylori* was significantly higher than that with negative *H. pylori*. It is possible that the induced *COX-2* in positive *H. pylori* gastric mucosal lesions plays a role in gastric carcinogenesis. Moreover, we found that the mean number of parameters of CIA except Fshape in the

positive *H. pylori* group was significantly higher than that in the negative *H. pylori* group. It confirms that there are more cellular-biological behaviors of malignant tumor in gastric mucosal lesions with *H. pylori* infection.

Histologically, GC can be classified into intestinal and diffuse types based on the differences between precancerous lesions and glandular formation^[31]. The intestinal type GC predominates in the elderly and has a similar histological appearance to colonic cancer, while the diffuse type GC occurs more commonly in younger patients with scattered tumor cells. The possible alterations of *p53* suppressor gene were even in samples of gastric cancer and non-tumoral mucosa. Mutation of *p53* suppressor gene was frequent in gastric carcinoma^[64]. Overexpression of *p53* was more frequent in early intestinal than early diffuse GC^[59]. In the current study, *p53* was not different between the two types^[33,65]. Although not statistically significant^[65], differences in *p53* immunopositivity between the various growth patterns were observed, with tumors invading the submucosa tending to show a higher frequency of staining than mucosal tumors (60.0% vs 40.0%). Tumors with lymph node metastases showed higher frequency of *p53* staining (57.7%). We also found immunopositivity for *p53* in 80.0% GC of low and undifferentiated tumor cells. These observations support the suggestion that overexpression of *p53* is associated with tumor progression in gastric carcinogenesis and may be related to prognosis^[34,39,40,47]. Although the *Bcl-2* proto-oncogene is important in determining tumor cell susceptibility to apoptosis, data about its clinical importance in GC are not available^[66]. A significantly higher expression of *Bcl-2* protein was found in the intestinal type than in the diffuse type of GC (75.0% vs 16.7%, $P < 0.05$) in our studies^[36,67]. No correlation was also found between *Bcl-2* expression and the prognostic parameters, depth of invasion, differentiation, and lymph node invasion. Although not statistically significant, well and moderately differentiated tumors were more often *Bcl-2*-positive than poorly differentiated tumors, and lymph node negative tumors were more often *Bcl-2*-positive than nodal positive tumors. *Bcl-2* expression has no prognostic impact on GC^[36], which was different from the report of Inada *et al*^[66]. Little is known about the role of *p16* gene alterations in the genesis of GC^[68,69]. This result suggested that no correlation between *p16* expression and grade of pathologic staging, grading of differentiation, or lymph node status was observed. *p16* gene played a limited role in tumor progression^[25,68], which was discordant with some other reports^[38]. Finally, no correlation was present between *COX-2* expression and type or grading of differentiation (all $P > 0.05$), however, there was significant correlation between *COX-2*

and pathologic staging or lymph node metastasis (all $P < 0.05$). It was proposed that COX-2 played an important role in the development of GC^[37,55,70].

In conclusion, prolonged and persistent *H. pylori* infection may promote Bcl-2 and COX-2 protein overexpression, but suppress p16 protein expression in gastric precancerous lesions. It seems that *H. pylori* infection is not related to p53 gene alteration because the p53 gene overexpression is relatively a late event in gastric tumorigenesis and is mainly relates to progression. However, p16, Bcl-2, and COX-2 gene expression alterations might play a role in the early development/ promotion of gastric carcinoma but not in tumor progression and aberrant Bcl-2 protein expression appears to be preferentially associated with the intestinal type tumors. Moreover, there is significant correlation between COX-2 and pathologic staging or lymph node metastasis. p53, p16, Bcl-2, and COX-2 not only play independent but also synergistic role in the development and progression of gastric cancer^[25,71].

Abstract

AIM To evaluate the potential of RA-538 gene therapy for gastric carcinoma.

METHODS Human gastric carcinoma cell line SGC7901 treated with Ad-RA538 or Ad-LacZ were analysed by X-gal stain, MTT, DNA ladder, Tunel, flow cytometric analysis, PCR, and Western Blot *in vitro*. The tumorigenicity and experimental therapy in nude mice model were assessed *in vivo*.

RESULTS Ad-LacZ could efficiently transfer the LacZ gene into SGC7901 cells. X-gal-positive cells at MOI 25, 50, 100, and 200 were 90%, 100%, 100%, and 100% respectively. Ad RA538 could strongly inhibit cell growth and induced apoptosis in SGC7901 cells. The proliferation of the Ad-RA538-infected SGC7901 cells was reduced by 76.3%. The mechanism of killing of gastric carcinoma cells by Ad-RA538 was found to be apoptosis by DNA ladder, Tunel and flow cytometric analysis. The tumorigenicity in nude mice using Ad-RA538 showed that all three mice failed to form tumor from 7 to 30 days compared with Ad-LacZ and parent SGC7901 cells. Experimental therapy on the nude mice model bearing subcutaneous tumor of SGC7901 cells

showed that intratumor instillation of Ad-RA538 inhibited the growth of the tumors. Ad-RA538-treated tumors were inhibited by 60.66%, compared with that of the tumor injected with Ad-LacZ and mock.

CONCLUSION The expression of Ad-RA538 can inhibit growth and induce apoptosis of gastric cancer cell *in vitro* and *in vivo*. Ad-RA538 can be used potentially in gene therapy for gastric carcinoma.

INTRODUCTION

Gastric carcinoma is one of the most common malignant tumors in the world. It is treatable by surgical resection in the early stages, but advanced gastric carcinoma does not usually respond to conventional therapy^[1-6]. Therefore gene therapy represents an attractive alternative for the treatment of gastric carcinoma. Present studies suggest that overexpression of oncogenes, with or without functional loss of tumor suppressor genes, is responsible for the progression of human malignancies through multistep processes^[7-13]. On the basis of this multiple hit model of carcinogenesis, cancer gene therapy has rapidly developed as alternative to conventional cancer therapy. It is widely accepted that c-myc gene plays a pivotal role in regulating cell proliferation and differentiation. Some studies indicated that c-myc gene has a close relationship with carcinogenesis^[14-16]. Using subtractive hybridization strategy, RA538 was isolated, a cDNA clone from a human esophageal cancer cell line before and after RA-treatment^[17]. It is proved that RA538 can induce differentiation and apoptosis of tumor cell and down-regulate c-myc gene expression^[18-21]. In the present study, we treated a human gastric carcinoma cell line with adenovirus-recombinants carrying RA538 or LacZ gene.

MATERIALS AND METHODS

Cell lines and culture

Human gastric carcinoma cell line (SGC 7901) was obtained from the Academy of Military Medical Sciences, China. Human embryonic kidney cell line (293) was kindly provided by Professor Zhan Qi-Ming (Academy of Sciences, China). SGC 7901 cells were grown in RPMI 1640 medium supplemented with 10% fetal bovine serum. Two hundred and ninety-three cells were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum.

Recombinant adenovirus production

The recombinant, replication-deficient type 5 adenoviruses that have been developed for gene therapy contained deletions of the E1 and E3 regions. The vector was constructed by homologous recombination in 293 cells of the PJM17 plasmid containing the right end of Ad5 (Microbix Biosystems Inc., Canada) and a plasmid containing 0-16 m.u. of left end of pAd CMV (a gift from Zhang Wei-Wei). A recombination adenovirus vector, called Ad-RA538 containing the human RA-538 cDNA fragment, the total 3.8kb of RA538 suppressor gene was constructed. Ad-RA538 and Ad-LacZ were constructed by National Laboratory of Molecular Oncology, Department of Cell Biology, Chinese Academy of Medical Sciences. The resulting vector was plaque-purified twice on 293 cells and propagated. Virus stocks were titered by plaque-forming assay on 293 cells. Ad-RA538 and Ad-LacZ were identified by polymerase chain reaction (PCR).

Recombinant adenovirus infections of the cell lines were carried out by dilution of viral stock to certain concentrations, addition of viral solution to cell monolayers (0.5mL per 6cm dish), and incubation at room temperature for 30min with agitation every 10min. This was followed by addition of culture medium and the return of the infected cells to the 37°C incubator.

Adenovirus transduction efficiency

Gastric carcinoma cells were seeded in 6cm culture plates at a density of 1×10^6 cells /dish and cultured 12 hours. Cells were infected with Ad-LacZ at a multiplicity of infection with 25, 50, 100 and 200 (MOI). After 48 hours, the cells were washed with phosphate-buffered saline (PBS), treated with 5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside (X-gal). X-gal-positive cells were revealed by a blue precipitate in the cell.

Assay of cell growth

Cells were seeded at 8×10^3 cells/ well in 96-well plates and were infected with either Ad-RA538, Ad-LacZ and PBS (Mock) at 25, 50, 100 and 200 MOI within 12-24 hours. At different time after

adenoviral infection, 3-2, 5-diphenyltetrazolium bromide (MTT) assay was performed. Cell viability is proportional to the absorbance at the test wave length (525nm).

DNA extraction and gel electrophoresis^[22]

Cells were lysed in guanidine-isothiocyanate and DNA was extracted by benzyl chloride using Herrmann M'ethord^[5]. RNA was digested with 1 μ g/mL RNase A 50 μ g of each DNA sample was loaded on to a 18g/L agarose gel.

TUNEL assay

Air dried cell samples were fixed with paraformaldehyde solution for 30min. Slides were rinsed with PBS and incubated with blocking solution (0.3% H₂O₂ in methanol) for 30min. Slides were rinsed with PBS and incubated in permeabilisation solution (0.1% Triton X-100 in 0.1% sodium citrate) for 2min in ice. TUNEL reaction mixture were added with 50 μ L in sample. Slides were incubated in a humidified chamber for 60min at 37°C, and analysed under a fluorescence microscope. Converter-POD were added with 50 μ L in sample. Slides were incubate in a humidified chamber for 30min at 37°C. Slides were rinsed with PBS for three times. DAB substrate solution were added with 50 μ L-100 μ L for 15min. Slides were rinsed with PBS for three times and were stained with hemotoxin. Slides were mounted under glass coverslip and analysed under light microscope.

Flow cytometry

The cells were fixed in 70% ethanol, treated with 0.1g/L RNase A, and with 100mg/L propidium iodide. Cell cycle phase distribution were analysed by flow cytometry (Coulter Epice, ELITE, ESP, USA).

Polymerase chain reaction

The polymerase chain reaction (PCR) was designed to amplify a 800bp fragment of the adenovirus gene using primer (5'-primer TCGTTTCTCAGCAGCTGTTG; 3'-primer CATCT-GAACTCAA GCGTGG) and a 300bp fragment of the RA538 gene using primer (5' primer ATGGGT-GAACA ACAGAAGAG-3' primer TTAGA-GATTCAGATTGGCT). Hot-start PCR amplification was performed. In a Pektin-Elmer 2400 thermocycler using the following program: 1 \times 95°C for 5min; 30 \times 95°C for 1min; 59°C for 50sec; 72°C for 50sec; and 1 \times 72°C for 7min. The final concentration for all PCR components in a 25 μ L volume was as follows: 100 μ M of each of extracted genomic DNA and 1 unit of Taq polymerase in 1 \times Taq polymerase buffer. PCR products were run on 1% agarose gels.

Western blot analysis

Total cell lysates were prepared by lysing the cell

with sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) sample buffer after rinsing the cells with PBS. For the SDS-PAGE analysis, each lane was loaded with cell lysates equivalent to 6×10^4 cells (30 μ L). The protein in the gel were transferred to nitrocellulose filter (NC filter, Bio-Rad Company, California, USA). The membranes were blocked with 0.5% dry milk in PBS. The primary antibodies used were mouse anti-human c-myc or β -actin monoclonal antibody (Santa Cruz, California, USA), and the secondary antibody was horseradish peroxidase-conjugated rabbit anti-mouse IgG (Amersham, Uppsala, Sweden). The membranes were hybridized according to the Amersham's ECL protocol. The membrane was exposed to X-ray film.

Tumorigenicity assay of SGC7901 cell growth after treatment with Ad-RA538

The gastric cancer cells were infected with Ad-RA538 and Ad-LacZ at a dose of 100 MOI. An equal number of cells was treated with PBS and mock infection. Twenty-four hours after infection, the treated cells were harvested and rinsed with PBS. For each treatment, 10.6 cells in 0.1 mL were injected to BALB/c male nude mice. Tumor formation was evaluated after 4 weeks.

Adenovirus treatment in vivo

Mice (BALB/c nude mice aged 5 weeks) were inoculated with 10^6 SGC 7901 cells into the flank. Tumors were allowed to grow to 5 mm in diameter. The animals were divided into three groups: Ad-RA538 injection; Ad-LacZ injection and PBS injection. There were five nude mice in each group. Ad-RA538 or Ad-LacZ (1×10^9 pfu/each/100 μ L) or PBS/100 μ L were directly injected into the tumor centre of each nude mouse at d1, d3 and d5. Tumor sizes were observed 4 weeks after the injection, and estimated with calipers.

Statistics

Data are presented as means \pm standard errors of the means. Comparisons among different groups of samples were made by two-tailed *t* test and χ^2 test.

RESULTS

Recombinant adenovirus prediction

Ad-RA538 and Ad-LacZ were propagated on 293 cells. Their titers were 3.0×10^9 pfu/mL and 3.0×10^{11} pfu/mL respectively. Ad-RA538 and Ad-LacZ were identified by PCR. Ad-RA538 showed expression of RA538 gene. Ad-LacZ showed expression of adenovirus gene.

Adenovirus transfection efficiency in SGC7901 cell line

The time course of β -galactosidase (β -Gal) expression was first determined by counting the

percentage of X-Gal-positive cells at 48 h after infection with Ad-LacZ. Ad-LacZ could efficiently transfer the LacZ gene into SGC7901 cells. And X-gal-positive cells at MOI 25, 50, 100 and 200 were 90%, 100%, 100% and 100% respectively.

Inhibition of SGC 7901 cells growth

The degree of growth inhibition was measured by MTT assay. The growth rates of Ad-RA538 infected SGC 7901 cells were inhibited by 76.3 % (MOI 200, 8 day) as compared to Ad-LacZ and Mock ($P > 0.01$) (Table 1). Ad-RA538 induced apoptosis in SGC 7901 cells.

DNA fragmentation

SGC7901 cells were treated with MOI 100 Ad-RA538 for 2, 4 and 6 days. Figure 1 shows that the electrophoresis pattern after treatment with Ad-RA538. DNA fragmentation became apparent at d2, d4 and d6. The peak of ladder pattern was detected at d6. Ladder pattern was not detected in Ad-LacZ treated cells.

Figure 1 DNA ladder of Ad-RA538 on SGC7901 cells.
lane 1: Ad-lac Z (2d); lane 2: Ad-RA538 (2d);
lane 3: Ad-lacZ (4d); lane 4: Ad RA538 (4d);
lane 5: Ad-lacZ (6d); lane 6: Ad-RA538 (6d).

TUNEL assay

SGC 7901 cells treated with Ad-RA538 were assayed for apoptosis by TUNEL. SGC 7901 cells could induce apoptosis. The abnormal chromatin clumps, nuclear membrane wrinkling, nuclear collapse, cytoplasm bubble and cytomembrane wrinkling had appeared after treatment with Ad-RA538. Apoptotic cells were not shown by TUNEL assay in Ad-LacZ treated cells. In this kit terminal deoxynucleotidyl transferase, which catalyzes polymerization of nucleotides to free 3'-OH DNA ends in a template-independent manner, was used to

label DNA strand breaks. After substrate reaction, stained cells can be analyzed under light microscope (Figure 2).

Flow cytometric analysis

A flow cytometric analysis was performed on SGC 7901 cells infected with Ad-RA 538 and Ad-LacZ. Apoptotic cells of Ad-RA538 infected cells played a peak in the flow cytometry histogram. Apoptotic peak was 34.2% at d2. The cell cycle G-2M arrest were shown at d2, d4 and d6. The apoptosis peak and cell cycle arrest were not found in Ad-LacZ treated cells (Table 2).

c-myc expression in Ad-RA538 infected cells

The expression of c-myc protein in SGC 7901 cells was detected by western blot analysis after Ad-

RA538 infection for 1, 3, 5 or 7 days. Ad-RA538 may down-regulate expression of c-myc gene (Figure 3).

Inhibition of tumor growth in vivo

The tumorigenicity in nude mice of using Ad-RA538 showed that three of these mice failed to form tumor from d7 to d30 compared with Ad-LacZ and parent SGC 7901 cells ($P>0.01$) (Figure 4). The tumorigenicity in nude mice using Ad-LacZ and parent SGC 7901 cells was 100%.

Experimental therapy on the nude mice model bearing subcutaneous tumor of SGC 7901 cell showed that intratumor instillation of Ad-RA538-treated tumor were inhibited by 60.66%, compared with that of the tumor injected with Ad-lacZ and mock (Figures 5,6).

Figure 2 TUNEL assay of Ad-RA538 and Ad-LacZ on SGC 7901 cells.

DISCUSSION

The ability to infect numerous different cell types and the absence of requirement for dividing cells make adenovirus an attractive candidate for *in vivo* gene therapy^[23]. They can be grown to a very high titer, and can be easily concentrated to reach titers of 10^{13} - 10^{14} particles per milliliter. Adenoviral vectors are very effective agents for gene transfer with extremely high transduction efficiency for a wide variety of cell types. In this study, adenovirus vector has high transduction efficiency for SGC 7901 cells, and can mediate a high level of expression of interested gene in transduced cells. The percentage of X-gal staining positive SGC 7901 cells 48h after infection with Ad-LacZ was 90% at MOI 25. Ad-RA538 could strongly inhibit growth and induce apoptosis of SGC 7901 cells. It may be related to high transduction efficiency of adenovirus for SGC 7901 cells.

It is known that activation of proto-oncogene and inactivation of tumor suppressive gene are the most common genetic alternation in tumor^[24-33]. Using subtractive hybridization strategy, RA538 was isolated, a cDNA clone from a human esophageal cancer cell line before and after retinoic acid (RA) treatment. RA can induce differentiation and apoptosis of tumor cell^[34-37]. It is proved that RA538 can induce differentiation and apoptosis of tumor cell and down-regulate c-myc gene expression^[17,18,38-41]. Reducing the expression of c-myc may effectively suppress the proliferation and malignant phenotype of cancer cells^[42-48] and to counter c-myc gene amplification in gastric carcinoma cells^[49]. The effects of Ad-RA538 on human gastric carcinoma cell line were examined both *in vitro* and *in vivo*. Ad-RA538, containing the human RA538 cDNA fragment, was constructed. Firstly, Ad-LacZ could transfer the LacZ gene into more than 90% of gastric carcinoma cells. Ad-RA538 could successfully inhibit expression of c-myc protein. These data showed the

capability of adenovirus to transfer exogenous genes efficiently into gastric carcinoma cell line. Secondly, the growth inhibitory effect of Ad-RA538 was then examined. In c-myc gene amplification on gastric carcinoma cell line SGC7901, the growth inhibition by infection with Ad-RA538 correlated with both transduction efficiency and adenovirus dose. The growth rates of Ad-RA538 infected SGC 7901 cells were inhibited by 76.3%. DNA fragmentation, TUNEL and flow cytometric analysis suggested that Ad-RA538 could strongly induce apoptosis of gastric carcinoma cells. Some reported that tumor suppressive gene BCL-XS could inhibit the proliferation and malignant phenotype of cancer cells^[50], Bouillelet^[51] reported that strA6, a retinoic acid-responsive gene could induce apoptosis of tumor cells. These are the same with our studies about Ad-RA538. Our studies with the tumorigenicity in nude mice and experimental therapy on the nude mice model using Ad-RA538 also supported these findings and showed that Ad-RA538 may be useful to inhibit the growth of gastric tumors. Our studies suggested that adenovirus-mediated RA538 overexpression may result in the elimination of tumor cells by apoptosis, and inhibition of proliferation, thus reducing the tumor burden. In conclusion, these findings indicated that the Ad-RA538 might promote efficient tumor cell death and inhibit tumor cell proliferation. The use of these vectors may be a potential tool for reducing tumor growth *in vivo* and treatment of gastric carcinoma.

Wu HG, Zhou LB, Shi DR, Liu SM, Liu HR, Zhang BM, Chen HP, Zhang LS. Morphological study on colonic ulcerative colitis treated by moxibustion. *World J Gastroentero*, 2000;6(6):861-865

Abstract

AIM To observe the therapeutic effect of moxibustion on ulcerative colitis and its influence on the colonic mucosal morphology.

METHODS Forty-six patients with ulcerative colitis were randomly divided into the moxibustion with herbal medicine underneath group and the western medicine group. Thirty patients were treated with the above moxibustion and 16 patients with Salicylate fapyridine(SASP). The colonic mucosa of 13 patients in the moxibustion group was observed by colonoscopy before and after the treatment. Mucin was also analyzed by H.E and AB-PAS staining.

RESULTS Seventeen patients were clinically cured, 12 were improved and 1 unchanged in the moxibustion group. In the control group, 5 patients were clinically cured, 7 improved and 4 unchanged. Thirteen patients with active UC were taken as the subjects for histopathologic analysis in this study. The colonic mucosal lesions were remarkably improved and the characteristic of the mucin also changed. In most sections, the chronic inflammation of mucosa was greatly ameliorated ($P<0.01$). The inflammatory cell infiltration much decreased

and neutrophils, disappeared in most sections ($P<0.001$). The goblet cells significantly increased ($P<0.001$); crypt paracrypt abscess or mucosal ulceration was seen ($P<0.001$).

CONCLUSION The rate of cure of ulcerative colitis by moxibustion with herbal medicine beneath is superior to that by SASP. This sort of moxibustion can effectively improve the colonic mucosal lesions and restore the proportion of mucoprotein to near normal.

INTRODUCTION

Chronic ulcerative colitis (UC) is autoimmune in nature^[1-3]. Aminosalicyclic acid and corticosteroids are the drugs most commonly used in treatment of UC^[4-19], but long-term use may give rise to adverse effects. At present, many of them can be treated by combined western medicine and TCM^[20-28], or Chinese herbs^[29-41] or acupuncture^[42,43]. The present study is primarily aimed at the effectiveness of moxibustion on the morphological study of colonic mucosa in ulcerative colitis.

SUBJECTS AND METHODS

Subjects

Forty-six cases of UC were out-patients and in-patients who were diagnosed according to the diagnostic criteria established by National Academic Conference on Digestive System Diseases held in Taiyuan, 1993^[3], and were randomly divided into two groups: moxibustion with herbal medicine underneath (designated below as moxibustion) group and the SASP group. Differentiation of symptoms and signs by TCM was classified according to the criteria described in "Internal Medicine" edited by Shanghai College of TCM. The moxibustion group was made up of 30 cases, including 16 males and 14 females, mean age of 38.75 years (25-63). The course of illness ranged from 5 months to 18 years. The control group comprised 16 cases, including 9 males and 7 females with a mean age of 37 years (27-69), the course of illness ranged from 4 months to 17 years.

Methods of treatment

Method in the moxibustion group Selection of

acupoints: The main acupoints of the two groups: Zhongwan (RN 12), Qihai (RN 6) and Zusanli (ST 36 Bilateral); Dachangshu (BL 25 bilateral), Tianshu (ST 25, bilateral), and Shangjuxu (ST37, bilateral) were used alternately. Auxiliary acupoints was added to different clinical types: Pishu (BL 20) for deficiency of Spleen and Stomach; Shuifen (RN 9) for accumulation of damp-heat Ganshu and Pishu for stagnancy of Liver-qi and deficiency of Spleen; Guanyuan (RN 4) for deficiency of both Spleen-yang and the Kidney-yang, Zhongzhu (KI 15) for constipation and Yinbai (SP 1) for pus and bloody stool.

Preparation of medicinal pads for moxibustion: *Radix Aconiti Praeparata*, *Cortex Cinnamomi*, *Radix Salviae Miltiorrhizae*, *Flos Carthami*, *Radix Aucklandiae*, *Rhizoma Coptidis*, etc were respectively ground into fine powder and stored for use. *Rhizoma Coptidis*, *Radix Salviae Mitio rrhizae* and *Flos Carthami* were used as main ingredients for the type of accumulation of damp-heat, supplemented with an appropriate amount of *Radix Aucklandiae*; *Radix Aconiti Pracparata* was used as the main ingredient for other types of the syndrome, supplemented with a suitable amount of *Cortex Cinnamomi*, *Flos Carthami*, *Radix Salviae Miltiorrhizae* and *Radix Acucklandiae*. Each medicinal pad contained herbal powder 2.5g which was mixed up with rice wine 3g to make paste. The paste was then made into pads of 2.3cm in diameter and 0.5cm in thickness.

Method of moxibustion Mugwort floss was made into moxacones, each being 2.1cm in base diameter, 2cm in height, and about 2g in weight, which were then placed on the medicinal pads and ignited. For deficiency of spleen and stomach, 3 moxa cones were used for each acupoint; for the type of accumulation of damp-heat, 2 cones were used for Dachangshu (BL 25), Tianshu (ST 25), Zhongwan (CV 12), Qihai (CV 6) and 4-7 cones for Zusanli (ST 36) and Shangjuxu (ST 37) until a strong warm sensation was felt by the patient; for stagnancy of liver-qi and deficiency of spleen, 3 cones were needed; for deficiency of both spleen-yang and kidney-yang, 3 cones were needed for the main acupoints and 4-7 cones for the auxiliary acupoints; for constipation, 2 cones were used on Zhongzhu (KI 3) and one cone was used on Tianshu (ST 25); and for serious pus and bloody stool, 4-7 moxacones were needed on Yinbai (SP 1). The treatment was given once daily, 12 treatments constituting a therapeutic course with an interval of 3 days between each two courses. After 5 courses of treatment the results were analyzed.

Method in the control group Patients were given Salicylazosulfapyridine 1g each time, 4 times a day at the beginning, and 0.5g each time, 4 times daily

in the convalescent period. After 3 months of treatment the results were analyzed.

Criteria for therapeutic effects

Clinically cured: clinical symptoms and signs disappeared, and colomoscopy showed disappearance of ulceration of colonic mucosa without recurrence after follow-up for 6 months. Improved: symptoms and signs ameliorated significantly, colonoscopy indicated amelioration of mucosal pathological changes. Ineffective: Clinical symptoms, signs and colonoscopy showed no significant difference before and after treatment.

Indexes and methods of observation

Pathological observation of colonic mucosa All specimens were taken from the most masked region or the edge of mucosal ulceration during colonoscopy. Three specimens were obtained in each patient, fixed with formalin, embedded in paraffin and sectioned, followed by H.E staining and pathologic observation.

Analysis of the mucin in colonic mucosa

AB-HID and AB-PAS methods were used for the staining.

RESULTS

Analysis of therapeutic effects

Seventeen patients were clinically cured, 12 were improved and one was ineffective, which made up 56.66%, 40.00%, and 3.33% respectively in the moxibustion group. In the control group, 5 patients were clinically cured, 7 improved and 4 ineffective, which accounted for 31.25%, 43.75%, 25.00% respectively. The cure rate in the moxibustion group was superior to that in the control group ($P<0.01$).

Changes of colonic mucosal histopathology and mucin

Thirteen patients with active UC were taken as the subjects for histopathologic analysis in this study.

Pathological changes before treatment The mucosa showed non-specific inflammation. The lamina propria showed hyperemia and edema with a great number of plasma cells, lymphocytes, mononuclear cells, neutrophils and eosinophils infiltration. The goblet cells in the body of the gland reduced in various extent, even disappeared, and replaced by columnar cells (Figures 1-3). Vacuoles, could be seen in the distal region of the nucleus (Figure 2). No mucin was present in the vacuoles. The lumen of gland became dilated, irregular or branched in some lesions, some regions were neplaced by immature glandulas body of smaller volume. The neutrophilic infiltration was present in the inter-epithelial cells

Figure 1 The colonic mucosa shows hyperemia, edema and inflammatory cell infiltration. The goblet cells in the body of gland decrease remarkably, which are composed of columnar cells.

Figure 2 The lesion is the same as above. The arrowhead shows an infranuclear vacuole.

Figure 3 The lesion is the same as above. The arrowhead shows a crypt abscess. H.E. $\times 100$

Figure 4 The majority of acid mucin in the body of gland disappear. AB-PAS staining $\times 100$

Figure 5 The majority of mucin sulfate in the body of gland disappears. HID-AB staining $\times 100$

Figure 6 The mucin in the body of gland decreases. The amount of neutral mucin relatively increases (arrowhead). AB-PAS staining $\times 100$

Figure 7 The colonic mucosa shows mild hyperemia, with less mucosal inflammatory cell infiltration. The goblet cells in the body of gland show no reduction. H.E. $\times 100$

Figure 8 The reduction of acid mucin is not obvious. AB-PAS staining $\times 100$

Figure 9 No reduction of mucin sulfate occurs. HID-AB staining $\times 100$

in majority of sections. Most of sections showed crypt abscesses (Figure 3), abscesses near crypts and ulceration of the mucosa. The amount of mucin in the body of the gland of the colonic mucosa in all patients decreased or decreased remarkably. As to the change of the mucin characteristic, most of the acid mucins in the body of gland disappeared (Figure 4). Most of AB-PAS staining was negative, mucin sulfate in the body of gland disappeared (Figure 5). HID-AB staining became hypochromatic. As the mucin in the body of gland decreased, the amount of neutral mucin increased relatively (Figure 6).

Changes after moxibustion treatment The mucosal inflammatory lesions in the majority of sections from the 13 patients with active UC abated remarkably. No hyperemia and edema were seen. Inflammatory cell infiltration decreased. In the majority of sections, neutrophil infiltration disappeared. Crypt abscesses, abscesses near crypts and ulceration of the mucosa were not seen. The reduction of the goblet cells in the body of gland was not obvious (Figure 7). The amount of mucin in the body of gland was almost normal. AB-PAS staining showed no obvious reduction in acid mucin (Figure 8). HID-AB staining showed no reduction in mucin sulfate (Figure 9).

The occurrence and severity of the main pathologic lesions before and after treatment (Table 1a,ab).

DISCUSSION

The clinical manifestations of UC is non-specific, and the disease is usually diagnosed by fibercolonoscopy and biopsies^[44-51]. All sections were examined and reexamined by the same pathologist. The sections showed typical pathologic features of UC, such as chronic mucosal inflammation, neutrophil infiltration, reduced goblet cells, crypt abscesses, mucosal ulceration.

In recent years, many studies on the change of colonic mucus were carried out. It was suggested that it might be the prodromal change of carcinoma of large intestine. As we all know, UC is a precancerous lesion of colon carcinoma. In this group, most mucin sulfate in glandular body disappeared whereas neutral mucin was relatively increased. We also found that the reduction of mucin was associated with the degree of local inflammation, the more severe the inflammation, the more obvious the reduction of mucin. The mucosa in this region also showed certain histologic characteristics: The goblet cells in the glandular body decreased remarkably or disappeared. With appearance of simple columnar cells which were lack of mucin section. The lumen of some mucosal glands became dilated, branched or irregularly arranged.

According to TCM, chronic non-specific ulcerative colitis belongs to the category of "Changpi" (bloody stool) and "Xiuxie" (diarrhea), and results from deficiency and hypofunction of spleen and stomach, accumulation of damp-heat, stagnancy of the liver-qi and deficiency of spleen, or insufficiency of spleen -yang and kidney-yang. In this study, good curative effect was achieved by the treatment of the moxibustion. The results showed that this moxibustion has the function of warming yang, promoting flow of qi and blood, improving the lesional blood circulation, and is helpful to hemostasis and the absorption of inflammatory products, and eventually attains the goal of the neogenesis of granulated tissue in the region of ulceration, and the repair of mucosal epithelium.

Guo XZ, Friess H, Shao XD, Liu MP, Xia YT, Xu JH, Buchler MW. KAI1 gene is differently expressed in papillary and pancreatic cancer: influence on metastasis. World J Gastroentero, 2000;6(6):866-871

Abstract

AIM To compare KAI1 in cancer of papilla of Vater and pancreas to evaluate whether there are differences in biologic behavior which might account for prognosis.

METHODS We compared the expression in 24 papillary and 29 pancreatic cancers using Northern blot analysis, immunochemical assay and *in situ* hybridization, and investigated whether early diagnosis or molecular differences predict the outcome in these tumor entities.

RESULTS By Northern blot analysis there is no statistical difference of KAI1 levels in normal and cancerous papilla. No association between KAI1 mRNA expression and tumor stage or tumor differentiation was found in the tumors. By immunohistochemical assay, KAI1 staining in cytoplasm of papillary cancer cells was similar to that of normal papillary cells. By *in situ* hybridization, the results of KAI1 mRNA expression in normal and cancerous papilla were similar to those with immunohistochemical assay. The normal and cancerous pancreas tissues were also analyzed by the methods used in papillary samples.

CONCLUSION Although the biologic roles of KAI1 have not been clarified, our results suggest that KAI1 may restrict the progression of malignant papillary cancer, but its expression might not have any effect on the characteristics of papillary tumor, whereas by the analysis of

KAI1 gene, its reduced expression is closely related to the progression and metastases of pancreatic cancer.

INTRODUCTION

Metastasis is a complex process, involving local invasion, inward and outward infiltration of tumor cells, and decreased host immunological responses^[1-4]. In carcinoma of papilla of Vater, lymph node metastases are present at the time of diagnosis in 31%-52% of the patients and by radical tumor resection, 5 year-survival rates of reached 21%-61%^[3]. In contrast to cancers of the papilla of Vater, cancer of pancreas has a dismal prognosis. Most pancreatic cancers have already had local or distant metastasis which restricts palliative surgical procedures. Therefore, median survival period of 4-6 months in most patients with pancreatic cancer remains in reality. The aggressive growth behaviour of pancreatic cancer results in a death/incidence ratio of approximately 0.99 in the United States and also in most European countries^[4,5].

The reason why pancreatic cancer has a prognosis different from that of the papilla of Vater is not known. It was postulated that earlier diagnosis due to jaundice accounts mainly for the better prognosis of papilla of Vater cancer patients. However, it is not known whether differences in tumor biologic behavior play any role in the difference in prognosis.

KAI1 has been identified to influence the metastatic ability of a various gastrointestinal cancer cells or other tumors^[6-22]. The gene is located on human chromosome 11p 11.2^[23]. Recently, it was reported that decreased KAI1 mRNA expression correlated with the metastases of pancreatic cancer^[24]. After transfer of the KAI1 gene into highly metastatic prostatic cancer cells, the metastatic ability was suppressed, whereas their primary tumor is not affected^[23]. These results suggested that decreased KAI1 expression is involved in the progression to metastatic cancers. However, whether changes in expression of tumor metastases influencing gene account for the better prognosis of papilla of Vater cancers is not known. Currently, it is believed that the better prognosis of

papilla of Vater cancer patients compared with pancreatic cancer patients caused no differences in tumor growth and metastasis formation but from the earlier establishment of the diagnosis. Therefore, in the present studies, we compared KAI1 in papilla of Vater and pancreatic cancer patients to evaluate whether there exist differences in tumor biological behavior which might account for the differences in prognosis.

MATERIALS AND METHODS

Patients

Nine normal human papilla of Vater tissue specimens (4 females, 5 males, mean age \pm SD: 35.7 \pm 6.5 years, ranging 23-43); and 16 normal human pancreatic tissue specimens (6 females, 10 males; mean age \pm SD: 36.6 \pm 10.7 years, ranging 10-47) were obtained through a multiorgan donor program in 9 cases. The whole pancreas was obtained with the duodenum and the papilla of Vater was completely resected. Tissue specimens from 24 patients with carcinoma of the papilla of Vater (9 females and 15 males, mean age \pm SD: 58.4 \pm 14.1 years, ranging 16-81) were obtained following a Whipple's operation. The diagnosis of cancer of the papilla of Vater was confirmed by histopathological analysis. According to the TNM classification^[25] there were 2 stage I, 9 stage II, 11 stage III and 2 stage IV tumors. Pancreatic cancer tissues were obtained from 14 female and 15 male patients after operation. The median age of the pancreatic cancer patients was 64 years, ranging 37-78. The partial duodenopancreatectomy (Whipple's operation) and distal pancreatectomy was performed in 26 and 3 patients, respectively. According to the TNM classification of the International Union Against Cancer^[25], the patients were in stage I, 3 cases, stage II, 10 cases and stage III 16 cases; their gradings were well differentiated in 7, moderately in 17 and poorly differentiated in 5.

Tissue sampling

For RNA extraction and Northern blot analysis, normal and tumor specimens were frozen in liquid nitrogen immediately after surgical removal and stored at -80°C until use. Additionally, freshly removed normal and cancerous tissue samples were immediately fixed in formaldehyde solution for 12h-24h and paraffin-embedded for *in situ* hybridization and immunohistochemical assay.

Northern blot analysis

Total RNA was extracted by the single-step guanidinium isothiocyanate method^[26] size-fractionated on 1.2% agarose 1.8mol/L formaldehyde gels^[26], and stained with ethidium bromide for verification of RNA integrity and loading equivalency. The RNA was electro-transferred onto nylon membranes (Gene Screen,

Du Pont International, Regensdorf, Switzerland) and cross-linked by UV irradiation. For hybridization a digoxigenin-(DIG) labeled KAI cRNA probe and ³²P-labeled 7S cDNA probe were used.

Prehybridization for KAI1 was performed for two hours at 65°C in a buffer containing 50% formamide, 5 \times SSC (sodium chloride/ sodium citrate buffer), 2% blocking reagent (Boehringer Mannheim GmbH, Mannheim, Germany) and 0.1% Nauroyl sarcosine. After adding the DIG-labeled KAI1 antisense probe, hybridization was carried out at 65°C for 18 hours. The filters were washed afterwards for 5min, in 2 \times SSC, and 0.1% SDS. At room temperature, followed by two washes at 68°C for 15min each in 0.1 \times SSC and 0.1% SDS. The filters were then incubated in 20mL blocking buffer (1% blocking reagent in 100 mmol/L maleic-acid, 150mmol/L sodium chloride and 175mmol/L sodium hydroxide) containing 1 μ L anti-DIG alkaline phosphatase antibodies (Boehringer Mannheim) for 30min, washed with blocking buffer for 15min, and incubated with 4iL CDP-Star (25mmol; Boehringer Mannheim). The membranes were then exposed to X-ray films for 15sec. At room temperature as previously reported^[27,28]. In order to assess equivalent RNA loading, the membranes were rehybridized with the ³²P- labeled mouse 7S cDNA probe that cross-hybridizes with human 7S RNA^[28-30] to verify equivalent RNA loading. The membranes were prehybridized for 4-8 hours at 42°C in a buffer that contained 50% formamide, 1% sodium dodecyl sulfate, 0.75mol/L NaCl, 5mmol/L EDTA, 5 \times Denhardt's solution, 100mg/L salmon sperm DNA, 10% Dextran sulfate, and 50mmol/L sodium phosphate (pH 7.4). The hybridization was carried out at 42°C for 18 hours by adding the labeled cDNA probe 1 \times 10⁵ cpm /mL. The blots were rinsed twice in 2 \times SSC at room temperature and washed three times at 55°C in 0.2 \times SSC and 2% SDS.

The blots were then exposed at -80°C to Fuji X-ray films with intensifying screens for 24-48 hours. The intensity of the KAI1 and 7S signals was quantified by video densitometric analysis (Biorad 620, New York, USA) as previously reported^[10,26]. The ratio between the KAI1 signal and the corresponding 7S signal was calculated for each sample.

Immunohistochemistry

From each normal and cancer tissue sample, three tissue sections were examined. After deparaffinizing and hydrating, tissue sections were submerged for 15min in Tris-buffered saline (10mmol/L Tris HCl, 0.85% NaCl, pH 7.4) containing 0.1% (vol/vol) Triton X-100 and briefly rinsed 3 times for 1min-2min in TBS solution. Following incubation in methanol containing 0.6% hydrogen peroxide for 30min to block endogenous peroxidase activity, the

slides were covered with 10% normal goat serum at 23°C for 30min then incubated overnight with mouse monoclonal anti-human KAI1 antibody (antibody C33, kindly supplied by Dr.J.C.Barrett, Institute of Environmental Health Sciences, National Institutes of Health, Research Triangle Park, NC, USA). After washing with TBS buffer, biotinylated goat anti-mouse immunoglobulin and streptavidin-peroxidase complex (Kirkegaard & Perry Laboratories, Gaithersburg, MD) were added at 23°C for 45 and 30min, respectively, followed by incubation with a 3, 3'-diaminobenzidine tetrahydrochloride and hydrogen peroxide mixture. The slides were counterstained with Mayer's-hematoxylin.

In situ hybridization

In situ hybridization was performed as reported previously in detail using DIG-labeled cRNA probes^[31]. Tissue sections of normal and cancerous samples were processed always simultaneously. In addition, the consecutive tissue slides were processed, one slide each was incubated with the sense probe, a antisense probe. The prehybridization, hybridization and washing conditions were the same for pancreatic and papilla of Vater tissue samples. Four μ m tissue sections were deparaffinized, rehydrated, and incubated in 0.2mol/L HCl for 20min. After washed with 2 \times SSC, the tissues were permeabilized with proteinase K at a concentration of 35mg/L for 15min at 37°C. After post-fixation with 4% paraformaldehyde in saline phosphate buffer (5min) and washing in 2 \times SSC, the sections were prehybridized for 1h at 60°C, in a buffer containing 50% formamide (v/v), 4 \times SSC, 2 \times Denhardt's reagent and 250 μ g RNA/mL. Hybridization was performed overnight at the same temperature in 50% (v/v) formamide, 4 \times SSC, 2 \times Denhardt's reagent, 500 μ g RNA/mL and 10% dextran sulfate (v/v). The final concentration of the DIG-labeled KAI1 probes (antisense or sense) was approximately 0.5ng/ μ L. After hybridization, excess probe was removed by washing in 2 \times SSC, and by RNase treatment: 100U/mL RNase TI and 0.2U/mL RNase DNase-free (Boehringer Mannheim) at 37°C for 30min. Washings were performed at 60°C for pancreatic tissue slides and 63°C in 2 \times SSC (10min), and twice in 0.2 \times SSC (10min each). Afterward the sections were incubated with an anti-digoxigenin antibody conjugated with alkaline phosphatase (Boehringer Mannheim). For the color reaction 5-bromo-4-chloro-3-indolyl phosphatase and nitro blue tetrazolium (Sigma, Buchs, Switzerland) were used.

Pretreatment of the slides with RNase abolished the hybridization signals, and hybridization with the sense probes corresponding to the antisense probes failed to produce an *in situ* hybridization signal.

The *in situ* hybridization signals were semiquantitatively evaluated by two independent observers blind to patient status followed by resolution of any differences by joint review and consultation with a third observer. The *in situ* hybridization results were scored as previously described^[32]; (-) no detectable signal; (+) weak detectable signal; (++) moderate detectable signal; and (+++) strong detectable signal.

Preparation of KAI1 sense and antisense cRNA probes

To prepare digoxigenin-labeled KAI1 cRNA probes for Northern blot analysis and *in situ* hybridization, a 500bp fragment of human KAI1 cDNA was subcloned into the pCR-II vector (Invitrogen, San Diego, USA), which contains promoters for DNA-dependent SP6 and T7 RNA polymerases. After linearization of the plasmid, the antisense KAI1 probes were transcribed using SP6 polymerase and the Ribomax System (Promega Biotechnology, Madison, WI, USA). A DIG-labeled KAI1 cRNA probe was used for Northern blot analysis and *in situ* hybridization. To evaluate the specificity of the *in situ* hybridization reaction, DIG-labeled sense probes of KAI1 were generated after linearization of the plasmid with Bam-HI and Hind-III, respectively and *in vitro* transcription with T7 polymerase and the Ribomax System (Promega Biotechnology, Madison, WI, USA)^[33]. For the *in situ* hybridization experiments, the KAI1 antisense and sense probes were shortened to a length of approximately 150 bases^[27].

Preparation of 7S cDNA probe

To verify equivalent RNA loading on Northern blot membranes, all filters were rehybridized with a murine 190bp Bam HI fragment or 7S cDNA which cross-hybridizes with human 7S RNA as previously reported^[28,29,34]. The 7S cDNA probe was radiolabeled with [α -³²P]dCTP (3000Ci/mmol; DuPont, Boston, USA) using a random primer labeling system (Pharmacia Biotech AG, Dubendorf, Switzerland)^[28,29].

Statistical analysis

Results were expressed as median and range or as mean \pm SD. For statistical analysis the Mann-Whitney U test and the Chi-square test were used. Significance was defined as $P < 0.05$.

RESULTS

KAI1 mRNA expression by Northern blot analysis
Papillary samples Measureable KAI1 mRNA signal was detected in 67% of the normal papillary tissue samples. In papilla of Vater cancer samples KAI1 mRNA expression was present in 46%. Densitometric analysis of the expression signals revealed a 1.07 fold (not significant) increase in

KAI1 mRNA levels in papillary cancer compared with the normal controls when all cancerous tissue samples were included. When only cancer samples with increased KAI1 mRNA expression level were statistically analyzed, the increase was 1.60-fold (not significant). The papillary cancer samples with lymph node metastases present at the time of tumor resection were compared with papillary tumor samples in lymph node-free metastases, no difference ($P>0.05$, Table 1) in KAI1 mRNA levels was found.

Pancreas The expression signals by densitometric analysis exhibited 2.2-fold increase ($P<0.05$) in KAI1 levels in pancreatic cancer compared with the normal controls when all cancerous tissue samples were included. When only cancer samples with increased KAI1 expression levels were statistically analyzed, the increase was 2.8-fold ($P<0.05$). There was a significant negative correlation between KAI1 ($r=0.59$) mRNA levels and the tumor staging ($P<0.0007$, Table 1). Primary pancreatic cancer samples in which lymph node metastasis were present at the time of tumor resection (stage III) exhibited significantly lower KAI1 mRNA levels compared with primary tumor samples without lymph node metastasis at the time of tumor resection (stage I/II; Table 1, $P<0.005$).

Comparison between papillary and pancreatic cancer samples The mRNA levels of KAI1 gene in pancreatic cancers were higher than that in papillary cancers ($P=0.03$). Statistical analysis of the densitometric data revealed that these differences were statistically significant.

Immunohistochemistry of KAI1

Papilla of Vater In the normal samples of papilla of Vater, moderate to strong KAI1 immunoreactivity was present in the cytoplasm of epithelial cells. In addition, strong membranous immunostaining was found for KAI1 in the normal samples of papilla of Vater. Papillary cancer cells exhibited a similar staining like normal samples of papilla of Vater. However, only a few cancer cells showed membranous KAI1 immunoreactivity in tumors with or without metastases.

Pancreas KAI1 immunoreactivity was weakly detectable in the normal pancreas in a few acinar and ductal cells and strong KAI1 immunostaining was present in all pancreatic islets. Other results were similar to that seen with *in situ* hybridization.

KAI1 mRNA expression by *in situ* hybridization

To localize the exact site and cellular distribution of KAI1 mRNA expression, *in situ* hybridization was performed in normal and cancerous tissue samples.

Papilla of Vater In the normal papilla of Vater,

moderate to strong KAI1 mRNA staining was present in the cytoplasm of most epithelial cells. Lymphocytes in the submucosal areas of the normal papilla of Vater exhibited weak or moderate expression of KAI1 mRNA. In the papilla of Vater cancer samples, a similar intensity of KAI1 mRNA staining was present in the cytoplasm of cancer cells compared with normal epithelial cells. Fibroblasts of the connective tissue surrounding papillary cancer cells showed weak to moderate KAI1 mRNA staining. The intensity of KAI1 mRNA signals in samples of primary papilla of Vater cancer with or without metastases was not different.

Pancreas In normal pancreatic tissue samples only very faint KAI1 mRNA staining was found in a focal pattern in a few acinar and ductal cells of the normal pancreas. In contrast, pancreatic cancer cells demonstrated moderate to strong cytoplasmic KAI1 mRNA staining. However, the staining intensity for KAI1 mRNA in the pancreatic cancer cells was dependent on the tumor staging. Cancer cells of tumors without lymph node or distant metastases (Stage I /II) exhibited stronger KAI1 mRNA staining than primary tumor samples in which lymph node metastases were present (stage III). The stroma cells surrounding the pancreatic cancer lesions exhibited low levels of KAI1 mRNA expression. Similarly, only low KAI1 mRNA level was found in lymphocytes infiltrated in the cancer samples.

DISCUSSION

Patients with carcinoma of papilla of Vater have the best prognosis in all patients with periampullary carcinomas^[35]. The most possible reason for it is the aggressive surgery carried out in early tumor stage or the tumor possessed a different biological local growth behavior and spreading characteristic. In contrast to cancer of papilla of Vater, pancreatic head carcinoma has a dismal prognosis and it was believed previously to be due to late diagnosis^[36]. It

is very difficult to distinguish patient with jaundice between papillary cancer and pancreatic cancer. Hence, the search for sensitive and reliable prognostic factor is of primary importance. The level of KAI1 mRNA expression were associated with clinical parameters influencing metastasis in gastrointestinal cancers in different ways^[24,28,29]. Tumor invasion and metastasis might be contributed by the down-regulation of KAI1^[24], whereas no significant KAI1 mRNA expression was found in gastric cancer and esophageal cancer with poor prognosis and metastases^[29]. These findings suggest that the effects of KAI1 on metastasis depend on the underlying malignancy.

In papillary cancer, no information about KAI1 has been obtained recently. By Northern blot analysis our results showed that the KAI1 mRNA level was not different in primary papillary carcinoma with or without lymph node metastases.

KAI1 immunoreactivity was mainly located in the membrane and/or cytoplasm of normal and/or cancerous papillary epithelia cells. By *in situ* hybridization, the results of KAI1 mRNA expression in normal and cancerous papilla were similar to those with immunohistochemical assay. Our findings indicate that KAI1 in papillary cancers exhibits different KAI1 mRNA expression patterns from prostate and pancreatic cancers^[23,29]. This suggests that KAI1 may limit the progression only in malignant papillary cancers, and this expression might have no effect on the characteristics of papillary tumors. Furthermore, the divergent expression patterns of KAI1 in the investigated cancer tissues show that it plays a role in the formation and metastases of these malignancies, that are different from those in previously analyzed tumors of the prostate, pancreas, breast, or the lung^[23-25,35]. However, by immunohistochemical assay and *in situ* hybridization, there was some heterogeneity of KAI1 mRNA expression levels in the cancers of papilla.

Our results showed that reduced expression of KAI1 mRNA might be regarded as the potential candidates for predicting tumor metastasis and invasion in pancreatic cancer. A few prospective randomized trials were reported that decreased expression of KAI1 gene was associated with metastasis in pancreatic cancer^[24]. By contrast to Northern blot analysis, similar expressions of KAI1 mRNA in immunohistochemistry and *in situ* hybridization were found. Down-regulation expression was only present in the patients with lymph nodes and distant metastases. We suggested that the expression of KAI1 gene could predict the prognosis of patients with pancreatic cancer. It is well known that the accumulation of genetic alterations causes the progression of tumors^[37]. But there are very few reports on its relationship with the mechanism of metastases in pancreatic cancer. K-ras, P16, P53, DPC4 and BRCA2 gene

influenced the tumor-suppressive pathways in pancreatic cancer. Underscoring the multigenic nature of cancer, and tumor PX101, having alterations identified in the five genes exemplified the extent of accumulation of genetic alterations^[38].

Cancer is a disease of gene alterations accumulated in several genes resulting in the development of the tumor^[39-50]. Multiple genetic lesions with either activating dominant oncogenes or inactivating tumor-suppressor genes have been recognized in human pancreatic cancer^[38]. Although our results suggest that expression of KAI1 gene is not associated with papillary cancer, it is closely related to metastases and prognosis of pancreatic cancer, and serves as a biological marker beneficial to diagnosis and treatment of pancreatic cancer. By further study on the pathogenesis of metastasis, the problem of how to prevent the early metastasis of pancreatic cancer will be solved.

INTRODUCTION

Intervention therapy has become one of the main therapies of hepatic cancer^[41,43,46,50]. The introduction of hepatic arterial perfusion and embolization has provided opportunities for a secondary operation on patients with intermediate and advanced cancer^[42,51-53], thus prolonging patients' life and improving their life quality^[1]. However, intractable ascites and hemorrhage of upper digestive tract caused by portal hypertension still greatly threatened the patients' life^[2,7-9,11,14,17,19-25,39]. So far there has been little report on the incidence rate of hepatic arteriovenous fistula (HA-V)^[4] and the relationship between its typing and hepatic cancer as well as portal hypertension^[3,6,12,18,26-28,31,32,34,54,59]. In the present study, a series of observation and analysis were made for 110 cases of hepatic arteriovenous fistula concurrent with intermediate and advanced hepatic cancer.

MATERIALS AND METHODS

Clinical data

One hundred and ten cases were selected from the 583 cases of hepatic cancer, which were clinically verified by radiological images and admitted to our department from 1989 to 1999. The cases were diagnosed as hepatic arteriovenous fistula by

Department of Interventional Radiology, Tangdu Hospital, Fourth Military Medical University, Xi'an 710038, Shaanxi Province, China. Ms. Wei Ping Guo, graduated from the 4th Military Medical University in 1992 as a postgraduate, associate professor and deputy physician, major in radiological interventional treatment of cancer, having over 30 papers and 1 book published.

Seldinger technique with DSA, among which, 102 were males and 8 females aged between 27 years and 70 years (average 48.5 years). One hundred and three cases were primary and 7 were secondary hepatic cancer. The latter include 3 cases of primary carcinoma of colon, 2 carcinoma of ampulla, 1 carcinoma of pancreas and 1 cardiac cancer. Among the 110 cases, there were 58 (52.72%) cases of concurrent ascites and 31 (28.18%) hemorrhage of upper digestive tract.

Examination

Examination of hepatic arteriovenous fistula All the cases underwent percutaneous femoral puncture by Seldinger technique. Guided by X-ray, the head of the conduct cannula was placed in the celiac artery and upper mesenteric artery. Through the cannula, 38% cardiografin or Ultravis t of 20mL-25mL at a time and at a rate of 4mL/S-5mL/S was perfused with high pressure while the arteries were photographed continuously at 2 frames per second until the pylic stem was developed or the photography lasted up to 20 seconds. The DSA results indicate that portal vein, hepatic vein or inferior caval vein in hepatic arterial phase or hepatic parenchymic phase developed ahead of the expected time could be diagnosed as concurrent hepatic arteriovenous fistula. The 110 cases of hepatic arteriovenous fistula received DSA examination for a total of 273 times, for some cases once at least and some 9 times at most.

Barium meal examination of upper digestive tract

Thirty cases received routine pneumobarium double contrast examination.

Gastrofiberscopy Thirty-three cases took routine gastrofiber scopy.

Statistical analysis χ^2 test and U test were performed according to NoSA software package.

RESULTS

Among the 583 patients with hepatic cancer, 110 were found to have hepatic arteriovenous fistula, which indicated an average incidence rate of 18.86%. From 1989 to 1999, the annual incidence

rate of hepatic arteriovenous fistula ranged from 2.38% to 47.72%, as shown in Figure 1.

Of the 110 cases of hepatic arteriovenous fistula, 57 had their focuses in the right lobe (51.81%), 13 in the left lobe (11.81%) and 40 involved both (36.36%). Seventy-four were massive (67.27%), 21 nodular (19.09%) and 15 diffuse (13.63%). Eleven were aberrant in their hepatic arterial origins (10.00%), of which 7 were of the right vagohepatic artery, 1 of the common vagohepatic artery, 1 of the right vagoaccessary hepatic artery (all the above-mentioned 9 aberrant cases originated in the superior mesenteric artery), and the others, 1 left vagohepatic artery originated in the left arterial gastric and 1 common vagohepatic artery in the right diaphragmatic artery. DSA detected sufficient blood supply in 89 cases (89.90%), moderate blood supply 14 (12.72%) and poor supply 7 (6.36%).

According to the locations of the fistula or the abnormal split-flow, the 110 cases can be divided into two main types: 95 peripheral (86.36%) and 15 central (13.63%). Hepatic arteriovenous fistula usually occurs in the cases with sufficient blood supply and massive hepatic cancer (Table 1) There were 103 simple cases (93.63%) and 7 complicated cases (6.36%) (Table 2).

Table 1 The relationship between locations of hepatic arteriovenous fistula and the typing as well as neoplastic blood supply

Location	<i>n</i> ^a	Typing ^b			Neoplastic blood supply		
		Massive	Nodular	Diffuse	Sufficient	Moderate	Poor
Peripheral	95	67	18	10	79	9	7
Central	15	7	3	5	10	5	0
N=110		74	21	15	89	14	7

^aPeripheral cases significantly outnumbered central ones ($P<0.05$, $\chi^2=6.05$).

^bMassive cases significantly outnumbered diffuse ones ($P<0.05$, $\chi^2=6.09$). There is no difference between massive ones and nodular ones, or nodular ones and diffuse ones ($P>0.05$).

Peripheral ones outnumbered central ones in blood supply ($P<0.05$, $\chi^2=7.34$). Sufficient blood supply cases significantly outnumbered cases of moderate blood supply ($P<0.05$, $\chi^2=5.83$). There is no difference between those with sufficient and poor supply, or with moderate and poor supply ($P>0.05$).

One hundred and three cases (93.63%) are simple ones which indicate hepatic arterioportal vein fistula in 97 cases (88.18%) (Figure 2), hepatic arteriovenous fistula in 4 cases (Figure 3), hepatoinferior vena cava fistula in 2 cases (Figure 4). Seven cases are complicated ones which indicate both HA-IV fistula and HA-PV fistula in 3 cases, both HA-IV fistula and HA-V fistula in 1 case, first HA-V and then HA-IV fistula in 1 case, HA-IV fistula first and then HA-PV fistula in 1 case, three HA-PV fistulas in 1 case (Figures 5-7). The simple ones are more than complicate ones significantly (Table 2).

Portal hypertension is clinically characterized by ascites and hemorrhage of the upper digestive tract. Barium meal examination and gastrofiberscopy of upper digestive tract of the

portal hypertension cases indicated that the positive rate of varices of esophagus detected by gastrofiberscopy was significantly higher than that by barium meal examination. The positive rate of ascites by gastro fiberscopy was 100% whereas that by barium meal check up was only 56.66% ($P<0.01$, $U=4.08$). The positive rate of hemorrhage of upper digestive tract detected by gastrofiberscopy was 96.96% whereas that by barium meal checkup was 53.33% ($P<0.01$, $U=3.77$). It is worth notice that among the 52 patients with concurrent hepatic arteriovenous fistula who received neither gastrofiberscopy nor barium meal exam, the incidence rates of ascites and hemorrhage of upper digestive tract were 46.15% and 19.23% respectively, from which the possible existence of esophageal varices could not be excluded.

DISCUSSION

In the present study, we analyzed the relationship between the incidence rate and typing of hepatic arteriovenous fistula and the typing and blood supply of hepatic cancer, compared and analyzed ascites and hemorrhage of upper digestive tract by gastrofiberscopy^[57,60-62], barium meal checkup and DSA. According to the results of these investigations, we have come to the following conclusions.

Hepatic arteriovenous fistula claims a relatively high incidence rate^[3,5,35-40], among hepatic cancer cases, with an average of 18.86% and every 4 or 5 years as a cycle of change. Primary hepatic cancer accounts for 93.63% of concurrent hepatic arteriovenous fistula cases.

Hepatic arteriovenous fistula is usually found in cases of sufficient blood supply and massive type hepatic cancer, which usually indicates the severity of lesion.

The incidence rate of hepatic arterio-pylic fistula (HA-PV) is significantly higher than that of other types of abnormal hepatic arteriovenous split flow, which indicates that hepatic arteriovenous fistula is an important factor that leads to concurrent portal hypertension of moderate and advanced hepatic cancers^[39].

Portal hypertension caused by hepatic arteriovenous fistula is clinically and chiefly characterized by ascites (52.72%) and secondarily by hemorrhage of upper digestive tract (28.18%)^[8,11,30].

Barium meal checkup and gastrofiberscopy of upper digestive tract of concurrent portal hypertension cases indicate that the positive rate of esophageal varices detected by gastrofiberscopy was much higher than that by barium meal checkup^[44,48,49]. Ascites and hemorrhage accounted for 46.15% and 19.23% of the 52 patients with hepatic arteriovenous fistula who did not receive barium meal checkup and gastrofiberscopy^[19,29]. It

is thus suggested by the authors that gastrofiberscopy should be performed in patients with moderate and advanced cancers no matter whether they have concurrent ascites and hemorrhage of upper digestive tract or not. Gastrofiberscopy should be included in the routine examinations^[10,13], especially for patients with concurrent ascites and hemorrhage of upper digestive tract so as to detect esophageal varices as early as possible and treat it timely^[15,17,18].

Hepatic arteriovenous fistula is usually found in hepatic cancers of the peripheral type^[47], which indicates that embolisation of hepatic artery can block the neoplastic blood supply and inhibit neoplastic growth^[48]. In the meantime, the embolisation can also block the abnormal split-flow between hepatic arteries and veins, relieve ascites and hemorrhage of upper digestive tract caused by portal hypertension as well as the distant metastasis caused by venous shunt.

The current therapies applied to the treatment of hepatic cancer mainly include hepatic arterial perfusion, embolisation, local injection of absolute alcohol guided by ultrasonography, radio frequency therapy, etc^[45,55,58]. However, it is difficult for ultrasonography and CT to preliminarily detect hepatic arteriovenous fistula which is highly incidental to primary hepatic cancer of massive and sufficient blood supply types. Besides, the abnormal split-flow between hepatic arteries and veins may inhibit the effect of these therapies and even give rise to some complications^[12,26,31,56].

Therefore, we conclude that DSA should be included as an important part of the routine examination for the treatment of moderate and advanced hepatic cancer. In order to detect hepatic arteriovenous fistula early and treat the patients with embolisation timely, DSA should be given especially to hepatic cancer patients with concurrent ascites and hemorrhage of upper digestive tract^[5,6,16,17,33,34].

Wang LT, Zhang B, Chen JJ. Effect of anti-fibrosis compound on collagen expression of hepatic cells in experimental liver fibrosis of rats. *World J Gastroentero*, 2000;6(6):877-880

INTRODUCTION

Liver fibrosis is mainly characterized by the excessive synthesis and decreased degradation of extracellular matrix (ECM), especially the synthesis and deposition of collagen. Almost all kinds of cells in the liver have participated in the production of collagen. The most important ones are hepatic stellate cells (HSC) and hepatocytes^[1-3]. We have observed the collagen expression of normal and fibrotic rat liver, compared its expression in passaged HSC of the normal liver and in the primary HSC of the fibrotic liver. Serum pharmacological method was used to study the influence of anti-fibrosis compound prescription (ACP) on the production of collagen in hepatocytes and HSC of rats.

MATERIALS AND METHODS

Experimental animal

Wistar male rats of 250g-300g were used to separate the hepatocytes, of 300g-350g were used to separate HSC. The rats were provided by Shanghai Centre of Experimental Animals. Animal model of liver fibrosis was formed by intraperitoneal injection of DMN (10mg/kg) 3 times a week for three weeks.

Drugs and pharmacological serum preparation

ACP (composed of *Radix Astragali seu Hedysari*, *Herba Leonuri* *Radix Curcumae*, etc.), prepared by the Pharmaceutical Department of Shuguang Hospital, contained 2g/mL crude drugs. Colchicine (Supplied by Serva Company) was prepared at the concentration of 0.3g/L. ACP and

colchicine were instilled into the stomach of the rats once a day for 1 week. One hour after the last time of instillation, blood was drawn in aseptic condition and serum was separated. After 30 minutes of inactivation at 56°C, it was packed and refrigerated separately.

Separation and culture of rat hepatocytes

After anesthesia of the rats, a tube was inserted through the portal vein to infuse collagenase perfusion (0.05% of collagenase IV, 0.007% trypsin inhibitor magnesium-free Hank's medium, pH 7.4) to digest the liver and disperse the liver cells. Density gradient centrifugation was done with 49.2% (v/v) lymphocytic separation fluid to purify the liver cells. Then culture medium 199 with 10% calf serum (added with 10⁻⁸mol/L of insulin and 10⁻⁸mol/L of dexamethasone) was used to suspend the cells to 5×10⁵/mL and was inoculated to the 60mm culture plate and stored in the incubator with 5% CO₂ and 37°C. After 4 hours, it was replaced by 5% calf serum in 199 medium for primary culture.

Separation and culture of the HSC

After anesthesia of the rats, a tube was inserted through the portal vein to infuse D-Hank's liquid to cleanse the blood in liver. Then the perfusion medium with enzyme (Hank's medium containing 0.05% of collagenase IV and 0.1% Pronase E) for cyclic infusion. The liver was cut into pieces, and re-digested. After centrifugation with 18% (w/v) Nycondenz density gradient centrifugation, the purified HSC was suspended in DMEM containing 20% calf serum attending 5×10⁵/mL for inoculation and culture. After full growth, the normal HSC was passaged while the HSC from the rat with fibrotic liver were processed in primary culture.

Assay of immunohistochemistry

The hepatocytes or HSC were inoculated in the plate covered with a piece of glass with a density of 5×10⁵/mL. The hepatocytes after cultured for 2 days, 5% medicated serum or controlled serum was used to incubate for 48 hours. After 5 days, the HSC adhered to the plate were incubated in 10% medicated serum or controlled serum for 72 hours. The cells were then divided into ACP group with medicated serum of ACP, colchicine group with

medicated serum of colchicine and control group with serum from normal rats. After culture, the glass slides were taken out to detect type I, III and IV collagen by ABC method of immunohistochemistry. After staining, the light density of the cells in each group was tested with the computer image analysis system. The higher the density, the deeper the positive staining.

RESULTS

Comparison of the production of collagen between normal and fibrotic hepatocytes

The immunocytochemical staining indicated that the collagen of the normal hepatocytes was negative, the light density of the collagen type I, III and IV was 3.80, 4.30 and 3.90 respectively, the staining of those three kinds of collagen in cytoplasm of the fibrotic hepatocytes was significantly increased. The staining of collagen type I was the deepest one, the next was type III. The light density of these three kinds of collagen was 42.40, 32.10 and 27.40 respectively. There was significant difference in the cells between the two groups ($P < 0.01$).

Influence of the ACP on the collagen expression of type I, III and IV in hepatocytes from the fibrotic rat

The staining of the type I, III and IV collagen was positive in cytoplasm of hepatocytes from the fibrotic liver. After treatment with serum processed by the ACP, the staining obviously turned lighter as compared with the control group, indicating that the collagen expression of the type I, III and IV of the cells was reduced. The inhibition of colchicine serum group on collagen type I was close to the group of ACP, while the effect on expression of the collagen type III and IV was weaker (Table 1) than those of the ACP group.

Comparison of the collagen expression between passage HSC and fibrotic HSC

The immunocytochemical staining indicated that positive staining of the type I, III and IV collagen appeared in both of the normal passage HSC and the fibrotic HSC. The collagen expression of the cells in both groups was nearly similar. But the correlation analysis on type I and III showed that the collagen expression of the type III in passage HSC was significantly increased, type I/type III was 0.91. However, the collagen expression of type I in fibrotic HSC increased more significantly as compared with that of type III. Type I/ type III was 1.22 (Figure 1).

Influence of the ACP on the collagen expression of type I, III and IV fibrotic HSC

ACP medicated serum could significantly reduce the staining of collagen type I, III and IV in fibrotic HSC and could remarkably inhibit the collagen type

IV and I. The effect was better than that of the colchicine group. Compared with the control group, the positive staining of the HSC in the colchicine group became lighter. However, its inhibition on the expression of collagen type III was close to that of ACP (Table 2).

Figure 1 Comparison of the collagen expression between the passaged HSC and the fibrotic HSC.

DISCUSSION

The cells responsible for the production of collagen in the liver have aroused many scholars' attention. Recent studies have confirmed that HSCs are the key cells to produce collagen in the liver. The activated HSC can excessively synthesize collagen^[4-6]. Through automatic secretion and multiplication, they maintain a constant progression of fibrosis and play very important roles in the course of liver fibrosis^[7-10]. There are different ideas as to whether the hepatocytes can synthesize collagen. There are contradictory reports about whether there exists collagen mRNA or not in the hepatocytes^[11-14]. The latest studies have proved that the hepatocytes can synthesize collagen^[15-18]. Immunohistochemical studies have discovered that there is no collagen of the type III in the hepatocytes of normal liver. However, small quantity of it was found in the hepatocytes of fibrotic liver^[19]. It can

be inferred that the excessive synthesis of collagen which may lead to liver fibrosis, is related to the constant abnormal regeneration of hepatocytes. Through *in situ* hybridization, we have discovered that the fibrotic rat liver induced by CCl₄ can express procollagen mRNA $\alpha 1$ (I) and $\alpha 1$ (III) in the hepatocytes of early, middle and advanced stages. This shows that the hepatocytes can synthesize the collagen type I and III, and also participate in the course of liver fibrosis^[19,20].

The hepatocytes can synthesize at least the collagen of type I, III, IV and V while in the normal liver, collagen synthesis in hepatocytes is quite weak or even inhibited. In the process of liver fibrosis, the synthetic activity of collagen was remarkably increased^[21]. This study indicates that in normal liver, hepatocytes do not express or seldom express collagen and that in the fibrotic liver the expression of collagen type I, III and IV in hepatocytosol is more significant. When the hepatocytes are impaired or under the stimulation of certain factors, the capacity of the hepatocytes to synthesize collagen will be activated^[22,23]. As to a single liver cell, its capacity to synthesize collagen is much lower than that of the HSC. However an absolute majority of the cells in the liver are hepatocytes, and their capacity to synthesize collagen should not be overlooked. And in chronic liver disease, the degeneration and necrosis of the hepatocytes can directly or indirectly stimulate non-parenchymal cells like HSC to increase collagen production, thus exerting great effort on liver fibrosis^[24-27].

At the early stage of liver fibrosis, collagen type IV increases first and then gradually decreases, while the collagen type III increases and expresses predominantly. In the developing and advanced stages, the collagen type I gradually increased, and collagen of both type I and III significantly increased, especially the type I^[11,28,29]. After passage culture of the HSC from normal liver, a series of changes have been observed in their features and the production of collagen and the expression scale is evidently increased. So HSC is regarded as *in vitro* cell model of fibrosis and is extensively used in the *in vitro* experiment of liver fibrosis^[30-33]. In order to be close to the collagen expression of the *in vitro* HSC during the fibrosis of liver, the experiment was also made using the HSC of the primary culture from the fibrotic liver. The collagen expression of the HSC from passage culture and HSC from primary culture of the fibrotic liver was tested by immunocytochemical staining. Positive staining was observed in the collagen type I, III and IV.

When fibrosis occurs in the liver, the total amount and varieties of the collagen produced by HSC in the process of liver fibrosis are

changed^[34-36]. Such change is related to the course of liver fibrosis. Maker^[37] has discovered that in the culture of HSC from normal SD rats, the gene expression of type I collagen is the weakest, while the gene expression of the collagen type III or IV is comparatively stronger. However, The mRNA of type I collagen is 30 times that of normal and type III is 5 times that of normal due to difference in culture time and in the expression of procollagen mRNA in the HSC from both the normal liver and fibrotic liver. At the early stage of fibrosis, the expression of the collagen type III is more significant, while at the advanced stage the expression of the collagen I type is more remarkable. The passage culture for the HSC separated from the normal liver is about 2 weeks, while the time for *in vivo* modeling of the HSC in the fibrotic liver is 4 weeks. The experimental results show that the collagen expression of type III in passage HSC is significantly increased, while the increase of collagen expression of type I in passage HSC is more significant. It seems to show that these two kinds of cells bear the features of the HSC at the early and advanced stages of fibrosis.

Seropharmacological studies indicate that ACP can significantly inhibit the excessive synthesis of collagen by the hepatocytes and HSC under the condition of liver fibrosis^[38]. *In vitro* experiment, medicated serum can eliminate the effect of impurity and acidity in the Chinese pharmaceutical preparation on the growth of cells, making it more closely mimic the absorption and metabolism of drugs *in vivo*^[39,40], and bringing the pharmaceutical effect into full play.

INTRODUCTION

Liver fibrosis is an excessive deposition of extracellular matrix (ECM) resulted from both increased synthesis and decreased degradation^[1-3]. Matrix metalloproteinases (MMPs) represent a group of neutral proteinases with variable substrate spectra. Their activity may be regulated at the level of gene transcription, proenzyme activation and inhibition of active enzyme by specific inhibitors such as the tissue inhibitor of metalloproteinases (TIMPs). The remodeling of extracellular matrix during chronic liver disease may partially be attributed to the altered activity of matrix metalloproteinases and their tissue inhibitors (such as TIMPs)^[4,5]. Hepatic stellate cell (HSC) (fat storing cell, Ito cell, lipocyte) is the main source of ECM production in liver fibrosis^[6-13], which also can express and secrete matrix metalloproteinase-2 (MMP-2) and tissue inhibitor of metalloproteinases-1 (TIMP-1) in the primary culture^[14-16]. The alteration of MMP-2 and TIMP-1 expression may be implicated in the hepatic fibrogenesis.

In this study, we examined the expression of MMP-2 and TIMP-1 in liver tissue and HSC isolated from normal and CCl₄ induced fibrotic rat respectively, in order to explore the role of MMP-2 and TIMP-1 during hepatic fibrogenesis.

Methods

Development of a CCl₄-induced fibrotic rat model

Test group rats ($n=12$) received subcutaneous injection of 40% CCl₄ diluted with olive oil at a dose of 0.3mL/100g of body weight twice a week for 6-8 weeks. Hepatic fibrosis was induced by CCl₄^[17].

Separation, purification and identification of rat HSC

We modified the procedures of Friedman's methods^[18] to improve the yield and viability of HSC. HSC was isolated from control and experimental animals by collagenase perfusion and density gradient centrifugation^[19-21]. Rats were anesthetized with 1% sodium pentobarbital 0.2mL/kg of body weight. The liver was perfused through the portal vein *in situ* with heparinized calcium-free solution (142mmol/L NaCl, 6.7mmol/L KCl, 10mmol/L HEPES, 5.5mmol/L NaOH, pH 7.4) at 37°C for 10min at a flow rate of 30-40 mL/min and the inferior vena cava cut at the same time. Until the perfusion solution from inferior vena cava turned colorless and the liver became white, the liver was carefully excised and placed on a special appliance, and then

perfused with 0.1% Pronase E and 0.05% collagenase added enzymatic solution (67mmol/L NaCl, 6.7mmol/L KCl, 100mmol/L HEPES, 66mmol/L NaOH and 5mmol/L CaCl_2) at 37°C for 20min at the same flow rate. After the liver turned yellow and became soft, it was cut into pieces and incubated in 30mL enzymatic solution with 0.05% DNase on a magnetic stirrer at 37°C for 30min. At the end of the incubation period, the suspension was filtered through screen mesh and the filtrate in Hank's solution was centrifuged at 450×g for 7min. The cell pellets were repeatedly resuspended in Hank's solution and centrifuged for three times to further dissociate the cells. The cells were separated by density gradient centrifugation with 1:2 v/v 18% Nycodenz at 1450 ×g for 17min at 4°C. HSC, which remained at the upper and middle interface, was collected and washed twice in DME followed by centrifugation at 450×g for 8min to remove hepatocyte debris. The pellet was resuspended in a small amount of DME and used for further studies. Cell viability was evaluated from the capacity of the cells to exclude trypan blue. Desmin positive cell was identified by immunohistochemistry.

Total RNA isolation Total RNA was extracted from liver tissue of the control and fibrotic rats using TRIZOL reagent. HSC was pelleted by centrifugation, lysed with TRIZOL reagent by repetitive pipetting and diluted as 1mL of the reagent per 5×10^6 - 6×10^6 of HSC. Incubate the homogenized samples for 5min to permit the complete dissociation of nucleoprotein complexes, add 0.2mL of chloroform per 1mL of TRIZOL reagent, cap sample tubes securely, shake tubes vigorously by hand for 15s and incubate for 2-3 min at room temperature. Centrifuge the samples at 12 000×g for 15min at 4°C. After centrifugation, the mixture was separated into a lower red phenol-chloroform phase, an interphase, and a colorless upper aqueous phase. Transfer the aqueous phase to another tube, add 0.5mL of isopropanol per 1mL of TRIZOL reagent according to the initial homogenization, incubate samples for 10min at room temperature and centrifuge at 12 000×g for 10min at 4°C. Remove the supernatant, wash the RNA pellet once with 75% ethanol, add at least 1mL of 75% ethanol/mL of TRIZOL reagent according to the initial homogenization. Mix the sample by vortexing and centrifuge at 7 500×g for 5min at 4°C, remove the supernatant, and briefly vacuum-dry the RNA pellet. The RNA precipitate can be stored in RNase-free water at -70°C. Dissolve 2μL RNA sample (1:50) for measuring OD_{260} and OD_{280} by UV spectrophotometer. Three μL RNA sample was electrophoresed through a 1.1% denaturing agarose gel with ethidium bromide.

RT-PCR Four μg of total RNA in 1μL water was

reversely transcribed. The RNA sample was incubated at 70°C for 10 min with 1μL Oligo (dT)₁₂₋₁₈ (0.5μg/μL) and 10μL 0.1% DEPC, then placed on ice bath for at least 1min. Then the reagents including 2μL of 10×PCR buffer; 2μL of 25mmol/L MgCl_2 ; 1μL of 10mmol/L dNTP mix; 2μL of 0.1mmol/L DTT and 0.5μL of 40U RNasin were added to each RNA/primer mixture. After mixing, the tubes were incubated at 42°C for 5 min. One μL (200U) of SUPERScript II RT was added to each tube and incubated at 42°C for 50min and 70°C for 15min. The sample was chilled on ice bath. One μL RNase H was added and incubated at 37°C for 20min. Then PCR was made or stored at -20°C. The following reagents were added to a 500μL polypropylene microcentrifuge tube: ① 5μL of 10×PCR buffer; ② 3μL of 25mmol/L MgCl_2 ; ③ 5μL of 10×dNTP; ④ 0.5μL of 5U/μL TaqE; ⑤ two pairs primer mixture (β-actin primer was used for internal control); ⑥ 2μL room temperature sample and ⑦ water to 50μL. The components were concentrated at the bottom of the tube by centrifugation and covered with mineral oil. PCR incubation was carried out in a programmable thermal controller. During each PCR cycle (40 cycles), the samples were heated to denature template complexes (94°C 180s initially and 60s during all subsequent cycles), cooled to 56°C to anneal template and primers (60s) each cycle and heated to 72°C to extend for 60s. The final 72°C incubation was extended for additional 10min to maximize strand completion. The samples were then rapidly cooled to 4°C and kept on ice bath or frozen until analysis. After amplification, 10μL of each PCR reaction mixture was electrophoresed through a 2.0% agarose gel with ethidium bromide (0.1%). The size of the markers are 1000bp, 750bp, 500bp and 300bp. The gel was photographed over UV light at the same exposure and development time for all gels photographed. The bands on the film were scanned by densitometry for quantitation. The PCR products were electrophoresed in the same gel and ratios for MMP-2/β-actin and TIMP-1/β-actin were determined to eliminate gel-to-gel or film-to-film variance.

Statistical analysis Data were expressed as mean ± SD ($\bar{x} \pm s$)^[22].

RESULTS

Expressions of MMP-2 and TIMP-1 in HSC

MMP-2 mRNA was undetectable in HSC isolated from normal rat liver, but it was detected in HSC from fibrotic rat liver. TIMP-1 mRNA was detected both in HSC from normal and fibrotic rat liver (0.25 ± 0.16 and 0.56 ± 0.09), and the expression was increased markedly in liver fibrosis ($P < 0.02$).

Levels of MMP-2 and TIMP-1 mRNA in liver tissue
MMP-2 mRNA was detected both in normal and fibrotic rat liver tissue (0.86 ± 0.09 and 0.99 ± 0.05). Although the level of MMP-2 mRNA was increased in fibrotic liver tissue, there were no significant differences between them ($P > 0.05$). TIMP-1 mRNA was detected in normal and fibrotic liver tissue (0.46 ± 0.03 and 1.36 ± 0.62). TIMP-1 expression was enhanced remarkably in fibrotic liver tissue ($P < 0.05$).

DISCUSSION

MMP-2 degrades collagen IV, V, VII and X, as well as elastic, fibronectin, and denatured collagen type I^[23]. Collagen type IV is the primary component of basement membrane. Therefore, the increment of MMP-2 can result in the damage of membrane in the space of Disse, which will activate the perisinusoid cells including HSC and promote hepatic fibrogenesis. Our results showed that the MMP-2 mRNA was only detected in HSC isolated from fibrotic liver, not in HSC from normal rat liver. This provided evidence for MMP-2 expression involving in liver fibrosis^[24]. Comparing with cell culture, isolating HSC from liver and extracting RNA directly to determinate the level of MMP-2 mRNA can more exactly reflect the situation *in vivo*, because the HSC has been activated in the process of culture *in vitro*. The MMP-2 mRNA was detectable in normal liver tissue. It indicated that there were sources other than HSC. In consistency with our findings, *in situ* hybridization showed low levels of MMP-2 gene transcripts in some mesenchymal cells of portal tracts, central veins and sinusoids of normal human liver tissue^[25]. Although the level of MMP-2 mRNA was increased in fibrotic liver tissue^[26], there were no significant differences between fibrotic and normal liver tissue ($P > 0.05$). We inferred that the increased MMP-2 mRNA was mainly from activated HSC and exerted effect at local area. This suggested that the expression of MMP-2 by HSC might be important in liver fibrogenesis^[24,26].

Liver fibrosis is associated with excessive accumulation of extracellular matrix, particular collagen type I and III^[27-29]. Collagen type I may comprise over 70% of extracellular matrix as compared to 40%-50% in normal liver. Besides an increase of collagen synthesis, decrease of fibrolysis may be an important factor responsible for the preferential accumulation of interstitial collagens^[30]. MMP-1 has a substrate specificity for native type I and III collagens. Reduced MMP-1 activity may therefore contribute to the patterns of extracellular matrix constituents in fibrotic liver. TIMP-1 is a major inhibitor of MMP-1 by combining with the active enzymes^[31-34]. TIMP-1 expression was enhanced markedly both in liver tissue and HSC

during liver fibrogenesis. It indicated that the increase of TIMP-1 expression is a main cause possibly for the reduced collagen degradation^[35-40].

In conclusion, there were no detectable gene transcripts of MMP-2 in HSC isolated from normal rat liver, and it was expressed by HSC during liver fibrogenesis. This suggested that the expression of MMP-2 is determined by the state of activation of HSC. The marked increase of TIMP-1 expression may result in the prominent deposition of interstitial collagens by inhibition of matrix metalloproteinases (especially MMP-1). Both MMP-2 and TIMP-1 make contributions to the liver remodeling and the progression of liver fibrosis.

Li X, Meng Y, Yang XS, Wu PS, Li SM, Lai WY. CYP11B2 expression in HSCs and its effect on hepatic fibrogenesis. *World J Gastroentero*, 2000; 6(6):885-887

INTRODUCTION

It has been reported that renin-angiotensin system exists in tissue^[1] and aldosterone can be synthesized in extra-adrenal tissue including heart, blood vessels^[2] and brain^[3]. Recent studies have brought rich evidences in favour of aldosterone as a strong stimulator of fibrogenesis and mitogenesis^[4-9]. Recently Wu PS reported that aldosterone synthase gene -CYP11B2 can be expressed in hepatic stellate cells (HSCs) of liver^[10]. As the activation of HSCs is the central event in fibrogenesis of liver^[11-26], we undertook the present study to investigate the relationship between hepatic fibrogenesis and locally produced aldosterone in liver.

MATERIALS AND METHODS

The establishment of animal model

Male Wistar rats (250g-280g, $n=48$, purchased from Animal Center of the First Military Medical University) were divided into 2 groups randomly. Model group ($n=24$): the rats were injected with 40% CCl₄ (the mixture of CCl₄ and olive oil) 0.25mL/100g subcutaneously three times a week. Control group ($n=24$): the rats were injected with olive oil only.

Histology

At the end of the week 4, 6, 8, and 10, 6 rats in

each group were sacrificed. The rat liver was regularly fixed, embedded, sliced and stained with VG and HE. Cryosections of liver tissue were rinsed in 0.2g/L gold chloride solution for 6h at room temperature, then the sections were placed in 50g/L sodium thiosulphate for 5min and mounted with resin.

Extraction of total RNA

The tissue of liver was promptly frozen in liquid nitrogen and stored at -70°C prior to use. Total RNA was extracted with GTC solution (6M guanidinium thiocyanate, 5mM sodium citrate, 5g/L sodium sarcosyl, 0.1M beta. mercaptoethanol). The amount of total RNA was measured at 260nm using an ultraviolet spectrophotometer.

RT-PCR for CYP11B2 mRNA

One microgram of total RNA was incubated at 25°C for 30min in 20μL reverse-transcriptase buffer containing 20u AMV reverse transcriptase and 2μL random primer p(dN)6(Boehringer Mannheim, Germany). Reverse transcription was terminated by heating at 99°C for 5min. The polymerase chain reactions were performed in 50μL PCR buffer containing 0.32μg of each primer and 2.5 u Taq DNA polymerase (Promega). Samples were subjected to 30 cycles of PCR amplification. Each cycle includes denaturation at 94°C for 1min, annealing at 56°C for 1min, and primer extension at 72°C for 2min. The rat CYP11B2 PCR primers were 5'-ACCATGGATGTCCAGCAA-3' and 5'-GAGAGCTGCCG AGTCTGA-3', synthesized by Shanghai Cell Institute according to the published sequences of Oaks and Raff^[27], corresponding to positions 657-954 of the gene that does not cross-react with the CYP11B1 gene. As control, β-actin primers were used and had the following sequences: 5'-TTTCTGGCAAGTTAGGTTTGTCAA-3' and 5'-CCTAGCACCATGAAGATCAA-3'^[28]. Each 6μL amplification mixture was subjected to electrophoresis on 15g/L agarose gel, and DNA was visualized by ethidium bromide staining. The signal intensity was quantified by a computerized medical image-processing system (GDS-7500, UVP, England). Six separate gels were run for the enzyme, and the data were then averaged. The ratio of CYP11B2 to β-actin was used to express relative mRNA levels.

In situ hybridization

The Wistar rats (model group, 6th week, $n=6$; control group, $n=6$) were anesthetized by intraperitoneal injection of pentobarbital, and perfused with 9g/L NaCl and 40g/L paraformaldehyde solution buffer at pH 7.4 in 0.1M phosphate buffered saline (PBS). Each specimen was divided into halves, immersed in the same fixative solution for 4h at 4°C. After the tissue samples were rinsed in PBS containing 300g/L sucrose, cryosections 10μm thick were cut and mounted on polylysine-coated slides. *In situ* hybridization^[29], slides were washed in 0.1M PBS, treated with 3g/L triton X-100 for 20min, washed in 0.1M glycine for 5min; and incubated in 2μg/mL proteinase K at 37°C for 30min, fixed in buffered 40g/L paraformaldehyde at RT for 10min, washed in PBS for 20 min; immersed in 2.5g/L acetic anhydride in 0.1M triethanolamine solution at RT for 10min, washed in 2×SSC for 15min; incubated in a prehybridization mixture at RT for 8h. After blotting the solution, the slides were incubated in a hybridization solution consisting of 500g/L formamide, 5×SSC, 20g/L SDS, 1×Denhardt's solution, 100mg/L salmon sperm DNA, 100g/L dextran sulfate, 2mg/L Digoxigenin labeling probe (Boehringer Mannheim, Germany) at 42°C for 24h. After hybridization, the slides were washed in 4×SSC, 2×SSC, 1×SSC, 0.5×SSC and 0.05M PBS at 37°C for 20min respectively. The detection procedure was performed according to the maneuver of DIG DNA labeling and detection kit (Boehringer Mannheim, Germany). The slide exposure duration was 12 hours at 4°C. The slides were dehydrated in ethanol and mounted with resin. A negative control was prepared for each sample using a hybridization solution without CYP11B2 probe. We selected 7 high power fields randomly and counted the positive cells per high power field.

Statistics

Analysis of data was performed with one way ANOVA (SPSS 7.5) and rank sum test. Results were expressed as mean \pm SD, a value of $P<0.05$ was regarded as statistical significance.

RESULTS

Morphological changes

Observed with naked eyes, at the end of week 4, the liver surface of model group presented tiny particle-like changes. After that, the tissue became hard and shrank progressively.

Microscopically, at the end of week 4, fibroblasts proliferated obviously in the portal tracts of model group, and collagen invaded into the

hepatic lobules along with the injured limiting laminae, but the collagen was not completely connected with each other. At the end of week 6, most rats developed cirrhosis in model group.

RT-PCR

The expressions of CYP11B2 mRNA in model group were significantly up-regulated compared to those in control group ($P<0.01$). The levels of CYP11B2 mRNA in model group (week 8) were higher than those in model group (week 4) ($P<0.05$), without significant difference between the two groups ($P>0.05$) (Figures 1,2).

In situ hybridization

Duck purple precipitate was localized in the endoplasm of HSCs corresponding to the gold chloride stained section. The number of positive cells per high power field in model group (4.5) was higher than that in control group (0.55) ($P<0.05$).

Figure 1 (PDF) The ratio of CYP11B2/ β -action presents the relative level of CYPP11B2.

Figure 2 Lanes 1: model group (week 4) β -actin; Lanes 9: model group (week 4) CYP11B2; Lanes 2: model group (week 8) β -actin; Lanes 8: model group (week 8) CYP11B2; Lanes 7: model group (week 10) CYP11B2; Lanes 4: control group β -actin; Lanes 6: control group CYP11B2; Lanes 5: Makers

DISCUSSION

It has been reported that renin-angiotensin system exists in tissues. Aldosterone can be synthesized in extra-adrenal tissue including blood vessels and brain. Aldosterone is a strong stimulator of fibrogenesis and mitogenesis which exerts a marked effect on stimulating the proliferation of myofibroblasts and collagen production.

There are two genes encoding the enzymes of aldosterone biosynthesis^[30,31]. One is P450 11 β (CYP11B1) that is responsible for the early steps of aldosterone biosynthesis. The other is P450 aldo (CYP11B2) that encodes the key enzyme for the final steps of its biosynthesis.

HSCs are mesenchymal cells located in the space of Disse. They demonstrated synthetic activity of collagen and other extracellular matrix proteins involved in hepatic fibrosis. As a source of cytokines, prostaglandins and other bioactive substances, they play a crucial role in the mechanisms of liver injury, regeneration and fibrosis. Now, fat-storing cell function is expanding from a retinol (fat)-storing site to a center of extracellular matrix metabolism and mediator production in the liver. Transition of the stellate cells from the vitamin A- storing phenotype to "activated" or "myofibroblastic" cells is the central pathobiochemical event for liver fibrosis^[32-36].

Using RT-PCR, we clearly provided direct evidence for the expression of CYP11 B2 mRNA in liver. The expression was up-regulated when fibrogenesis occurred. *In situ* hybridization further revealed that the expression of CYP11B2 mRNA located in the endoplasm of HSCs increased in fibrotic liver.

In conclusion, based on present study, we first proposed that there is a positive acting relationship between the expression of CYP11B2 in HSCs and fibrogenesis of liver. Locally produced aldosterone in liver is likely to promote the process of fibrogenesis. The present study provides a new way to investigate the mechanism and treatment of hepatic fibrosis.

ACKNOWLEDGMENTS The author thanks Dr. Michio I from Keio University, Japan for kindly supplying the rat CYP11B2 cDNA.

INTRODUCTION

A high prevalence of antibodies to hepatitis C virus (HCV) (range from 3.3% - 80%) has been reported in hemodialysis (HD) patients^[1-20], and worrisome as it often becomes chronic and induces chronic liver disease^[7,14,15], therefore the nephrologists face a major challenge of how to prevent it. The main route of HCV transmission is parenteral, and most cases of HCV infection are thought to be related to blood transfusion, intravenous drug addiction, or HIV infection^[1,6,9-10,21-24], but an increased prevalence of anti-HCV has also been reported in non-transfused HD patients without identifiable risk factors^[1,2,5,6,10-12,15,18,25,26]. In fact, some recent reports and our report outline that HCV-negative patients who shared dialysis machines with HCV-positive patients were seroconverted within HD period^[1,5,8,12-16,25-35]. We undertook a prospective study to assess the incidence and the risk factors for HCV infection in HD patients.

MATERIALS AND METHODS

Subjects

A total of 346 patients at our HD center followed up from June 1, 1995 to December 1, 1997, and 63 patients in June 1995 were included in the study.

Received 2000-07-05 Accepted 2000-07-21

They were dialyzed for 1 to 92 (mean 23.4) months. Their age ranged from 20-76 years (mean 44.7 years).

From June 1995 to November 1995, December 1995 to May 1996, June 1996 to November 1996, December 1996 to May 1997, June 1997 to November 1997, additional 42, 39, 45, 65 and 71 new patients were included, respectively. Of these 262 patients, 226 had recently started HD, 15 resumed HD after a transplantation failure and 21 had been transferred from other units. Their age range was similar to that of previously included patients. In December 1997, 21 patients who recently started HD, were included, their age range was similar to that of previously included patients.

In June 1996, the sera of 62 patients were tested for anti-HCVIgM, anti-HCVIgG and HCV RNA. Among them, 38 were males and 24 females, their age ranged from 16-71 years (mean 44.6 years), mean duration of HD was 16.1±7.6 months (1-96).

Anti-HCV antibodies

All patients at our HD center were tested every 3 months for the presence of anti-HCV antibodies during the follow-up period. All blood samples were obtained before HD, and were centrifuged, serum stored at -80°C until testing. The kits for examining anti-HCVIgM and anti-HCVIgG were purchased from Shanghai Chang Zhang Chemical Reagent Company, and were tested by the Laboratory of Microbiology, The Second Military Medical University.

HCV RNA

Primers were designed from the conserved 5'-noncoding (5'-NC) region of the HCV genome. S1: 5'-CACTCCACCATGAATCA CTC-3', AS1: GGTG-CACGGTCTACGAGACC-3', S2: 5'-ACTCCCCTG-TGAGAAGCTAC-3', AS2: 5'-CTCGCAAGCACCC-TATCAGG -3'. A RT-PCR assay procedure was performed as previously described^[1].

Risk factors for seroconversion (SC) for HCV

All data of risk factors for HCV were collected by using special questionnaire, including the sex, age, renal function, HBV marker, EPO, infection at hospital, history of CAPD and kidney transplantation, duration of dialysis, history of transfusion, ALT abnormality, dialyzer reused.

Dialysis and disinfection procedure

HD was performed using dialysis machines from Baxter, Fresenius. We used bicarbonate dialysis fluid (flow 500mL/min). Water quality and bacterial count were monitored regularly. HD patients have been dialyzed with Cuprophane, polysulfone or hemophan dialyzer. A strict chemical disinfection using Citrosteril, run at 85°C for 35min after each dialysis session, was adopted before using the machine for the next patient. It was hoped that both the high temperature bath and the low pH offered by Citrosteril would be enough to combat HCV. But our patients shared machines indiscriminately.

Statistical analysis

Results are expressed as mean±SEM as indicated. Unpaired Student's *t* test, χ^2 and Fisher's exact test were used. *P* values <0.05 were considered as significant.

RESULTS

Prevalence of HCV marker in June 1996

In June 1996, the total positivity of HCV marker (HCVM) was 59.7% (37/62), 27 patients (43.6%) were anti-HCVIgM positive, 29 (46.8%) anti-HCVIgG positive, 34 (54.8%) HCV RNA positive, 22 (35.5%) anti-HCVIgM, anti-HCVIgG and HCV RNA positive, 27 were anti-HCVIgM and HCV RNA positive, 22 were anti-HCVIgM and anti-HCVIgG positive, 26 anti-HCVIgG and HCV RNA positive, 34 patients at least one of anti-HCVIgM and anti-HCVIgG positive, 3 each were anti-HCVIgG positive or HCV RNA positive only.

Sixty-two patients were divided into two groups, GI: 43 HD patients with histories of transfusion, ALT abnormality, kidney transplantation and HBV markers positive; GII: 19 HD patients without the history and abnormality as those of GI. Comparison of detection of HCVM in GI and GII is shown in Table 1.

When comparing the clinical manifestation between HCVM positive and negative groups, no significant differences were found with respect to the sex, age, renal function, HBV marker, EPO and history of CAPD; but there were significant differences with regard to the duration of dialysis, history of transfusion, ALT abnormality and kidney transplantation (Table 2).

Relationship between dialysis times and HCV markers is shown in Table 3. The risk of HCV marker positivity increased significantly as the duration on HD increased ($\chi^2=9.23$, *P*<0.01). Seven patients were dialyzed for more than 3 years (mean 5 years) and 100% HCVM positive.

Relationship between number of transfusion and HCV markers is shown in Table 4. The risk of HCV marker positivity increased significantly as the number of transfusion increased ($\chi^2=21.14$, *P*<0.01). There were 8 patients with positive HCV

markers in 22 patients without histories of transfusion. Among them, 6 (27.3%) were anti-HCVIgM positive, 7 anti-HCVIgG positive, and 6 HCV RNA positive. When comparing the clinical manifestation between HCVM positive and HCVM negative groups in 22 patients without transfusion, no significant differences were found with respect to the sex, age, renal function, HBV marker, EPO and history of CAPD and kidney transplantation; but there were significant differences in the duration of dialysis and ALT abnormality (Table 5).

Positive prevalence of anti-HCV antibodies in consecutive six-month period

Positive prevalence of anti-HCV antibodies was found in six consecutive period of 6 months as shown in Table 6.

Positive prevalence of anti-HCV antibodies was found in uremic patients when they entered into our HD center as shown in Table 7. Among the 283 new patients admitted to our HD center, 11 (3.9%) were positive for anti-HCV. Of the 11 patients, 6 had histories of kidney transplantation, and 3 were transferred from other units, they all had histories of transfusion, only 2 patients with positive anti-HCV antibody started HD recently.

Adequacy of serologic follow-up

Out of 346 patients followed up from June 1995 to December 1997, 48 did not complete the study as a result of death (*n*=22), kidney transplantation (*n*=24), transfer to other dialysis units (*n*=1), and transfer to peritoneal dialysis (*n*=1).

Incidence of SC for HCV

During the follow-up period (1-30 months), 80 patients had seroconversion (SC) for anti-HCV positive; 298, 167, 87, 48 and 11 were followed up for 6, 12, 18, 24, and 30 months; and their positive seroconversion rates were 6.4%, 11.9%, 20.7%, 35.4% and 54.5%, respectively. Of the 80 seroconverted patients, 57 patients had histories of transfusion, mean number of transfusion being 12.5U±6.2U.

ALT level in seroconverted patients

ALT determinations obtained every one month from the onset of HD were reviewed in 23 (28.8%) patients with SC. SC was preceded (1 to 6 months) by an unexplained, sustained (5 cases) or interrupted (18 cases) elevation of ALT level. This rise was not accounted for by hepatitis B virus infection or hepatotoxic drugs, and was noted for the first time since the initiation of HD. During the follow-up period, 4 patients had liver cirrhosis, 8, 3, 4 and 5 months after HD, respectively, 1 died after SC for 10 months, others remained in our HD center.

Serologic follow-up of seroconverted patients

All 80 seroconverted patients remained positive throughout the follow-up.

Table 1 Comparison of detection of HCV in GI and GII

Parameter	GI(%) (n=43)	GII(%) (n=19)	P value
anti-HCVIgM (+)	21 (48.8)	6 (31.6)	>0.05
anti-HCVIgG (+)	25 (58.1)	4 (21.1)	<0.05

DISCUSSION

Non-A, non-B hepatitis is a major worldwide health problem. It accounts for more than 90% of transfusion associated hepatitis cases^[21], and was associated with a high incidence of chronic carrier state and subsequently progressive liver disease^[7,21]. In 1989, HCV was isolated from most cases of blood-borne non-A, non-B hepatitis by Choo *et al*^[36], the HCV was considered as the major cause of such disease, and HCV has evoked great interest, a plethora of reports have appeared in the literature for HD patients. Different prevalence rates of anti-HCV have been reported from different countries and the reported rates varied from as low as 3.3% in Newzland^[14], 39% in South America^[6], 44%-60% in the Far-Eastern countries^[29] to as high as 80.0% in Egypt^[16]. By contrast, the country-wide anti-HCV prevalence among volunteer blood donors is 0.86%^[31]. Our results showed that the positivity of anti-HCVIgM was 43.6% (27/62), anti-HCVIgG 46.8% (29/62) and HCV RNA 54.8% (34/62), the total positivity was 59.7% (37/62). By excluding the HD patients with histories of transfusion, ALT abnormality, history of kidney transplantation and positive HBV markers, the positivity of HCV was 42.2% (8/19). So HCV infection in our HD center is a very serious problem.

Our findings that 3 HD patients had detectable serum HCV RNA despite their anti-HCV negativity confirms previous observations, although figures vary considerably, ranging from 1% to 15%^[3,4,37]. Fernandez *et al*^[37] reported that 53 anti-HCV negative blood donors were examined for HCV RNA, and within the study group 4 patients (12.9%) were HCV RNA positive. The existence of HCV viremia without specific antibody expression in HD patients differs significantly when compared with blood donors who represent a control population. One explanation to account for the difference is that HCV RNA positivity precedes anti-HCV SC in an acute infection^[3]. Another possible explanation is that the immunosuppression

that characterizes HD patients may be responsible for the inability to express detectable amount of serum anti-HCV in the same way as is observed in kidney and liver transplantation recipients^[19,38]. Therefore, detection of HCV RNA can improve positivity of HCV infection, as the compensation of inadequacy of anti-HCV.

Prospective studies of HCV infection in HD patients were fewer and the conclusions were not consistent^[8,22, 28,29,32-34,39]. Dentico *et al*^[11] using a less sensitive ELISA I test reported in 115 Italian HD patients, a yearly incidence of SC for HCV falling from 6.1% to 2.2% between 1984 and 1990. Two small prospective studies relying on the ELISA I test in 35 and 62 HD patients followed for 12 and 18 months, reported a yearly incidence of 11.4%^[23] and 6%^[40], respectively. Chan *et al*^[4] using ELISA II test prospectively reported a yearly incidence of 4.9% in 39 HD patients followed for 19 months. Jadoul *et al*^[28] reported prospectively the SC for HCV in 401 HD patients, the SC rate averages 1.7% per year. More recently, in a prospective study relying on the ELISA II test in 187 HD patients followed for 36mo, a yearly incidence of SC for HCV was 22.6%^[29]. Our study defined prospectively the SC using the sensitive ELISA II in a large series of 346 HD patients. During the 1-30 months follow-up period, a total of 80 patients had SC for anti-HCV positive; 298, 167, 87, 48 and 11 patients were followed up for 6, 12, 18, 24, and 30 months; their positive SC was 6.4%, 11.9%, 20.7%, 35.4% and 54.5%, respectively.

Our study confirms that blood transfusion is an important risk factor for the transmission of HCV in HD patients. We have demonstrated a positive correlation between the two which increased with the increase in the number of transfusion units. Similar results have been reported by many other investigators^[1,2,8,9,12,15,19,21-23,31]. In addition, the introduction of screening of blood products for anti-HCV has led to a decline in the incidence of post-transfusion hepatitis^[24].

However, factors other than transfusion contribute to the transfection of HCV as demonstrated by the absence of blood transfusion in 23 of the 80 patients with SC. Interestingly, other studies have detected HCV antibodies in up to 19%-39% of HD patients who never received blood transfusion^[9,25,41]. The span of dialysis was significantly longer in anti-HCV positive patients than in anti-HCV negative patients^[1,5,12,19,25,31]. The risk of acquiring HCV infection on HD has been estimated to be 10% per year^[29]. These facts raised the possibility of nosocomial transmission. This hypothesis is supported by our observations that patients dialyzed in a bed adjacent to that of an anti-HCV positive patients had significantly higher risk of SC than the others in our unit^[1,8,12,15,23,31]. But until recently, the route of nosocomial transmission is not very clear. Transmission of

infection to dialysis staff by needle-stick injury^[1,25,26], breakdown in standard infection control practices^[1,23,26,28,42,43], physical proximity to an infected patient^[1,8,25,28], through dialysis machines^[1,25, 26], dialyzer membranes^[44], hemodialysis ultrafiltrate^[13,44] and reprocessing of dialyzers^[14,19] implicated a variety of potential modes of HCV transmission.

Several studies advocated the segregation of HCV (+) from HCV (-) patients to prevent nosocomial transmission^[9,22,25,29]. Implementation of a rigorous separation between patients according to their HCV status is rather cumbersome. Also in treating HBV positive patients, this would imply up to four separate facilities (B+C+, B+C-, B-C+ and B-C-). However, there are strong arguments against a policy of isolating anti-HCV positive patients because: HCV is not as infective as HBV, circulates in low titers in infected serum and is rapidly degraded at room temperature^[45]; and Currently licenced anti-HCV test detects non-neutralizing antibodies, does not distinguish between current and post infection, and a negative test does not exclude HCV infection^[42]; although isolation may protect uninfected patients, it might also increase the risk of superinfection in patients originally infected with a single strain^[46]. Infection with two or more different HCV genotypes has been observed in HD patients and 13% of patients referred for renal transplantation^[47]. Grouping of anti-HCV positive patients in dialysis units might thus increase their risk acquiring multiple HCV strains.

In view of the above debate, the centers for Disease Control and Prevention in the U.S. (CDC) recommend dedicated machines, patient isolation or a ban on reuse in HD patients with HCV infection^[48,49]. Such measures are detailed in the universal precautions for prevention of transmission of blood borne pathogens in health care settings^[47,49] and recommended precautions for patients undergoing hemodialysis who have AIDS or non-A non-B hepatitis delineated by the CDC^[48]. They include cleaning and disinfection of instruments, machines and environmental surfaces that are routinely touched, avoidance of sharing of articles between patients, frequent handwashing and use of glove.

In conclusion, the status of HCV infection in HD patients was a very serious problem, contamination appears to be both transfusion and nosocomial. Strict adherence to the 'CDC guidelines' and isolation of HCV positive patients during dialysis sessions are recommended. Further long-term studies are needed to confirm these conclusions.

ACKNOWLEDGMENT The authors would like to thank Professor Wu Zhao-Long for improving the English language in this paper.

INTRODUCTION

Chronic gastritis might be a disease of the highest morbidity in the world. Since Warren and Marshall successfully isolated and cultured *Helicobacter pylori* (*H. pylori*) from a gastric antrum biopsy^[1], intensive researches produced a historic change in the etiology and treatment of gastroduodenal diseases^[2-14]. Stimulated by this momentous discovery, a group of gastroenterologists mainly from Europe and pathologists presented a novel classification of gastritis (so-called the Sydney system) at the 9th World Congress of Gastroenterology in Sydney, Australia, in 1990^[15]. In the Sydney system, attempts were made to incorporate etiologic, topographic, and morphologic criteria into a clinically relevant scheme. It usually involves the histopathological analysis of the biopsy specimens obtained from the arbitrary sites in the antrum or corpus. In September 1994, a group of gastric pathologists from various parts of the world gathered in Houston, Texas, USA, to reprove the Sydney system 4 years after its introduction^[16]. One of the most controversial issues at the Houston Workshop was the concept of atrophy. Since the relationship of *H. pylori* with gastric adenocarcinoma rests on the natural history of atrophical gastritis induced by the bacterial infection^[17-23], it is very important to identify the histological lesions. According to the Sydney system, *H. pylori*, chronic and active inflammations were usually recognized and scored

with an agreement of degree of accuracy, but the judgments of the atrophy were often poor^[24-31]. Although many factors are involved in the failure of responsible detection of the atrophy, the biopsy sites in gastric mucosa may be one of most important factors for this lack of concordance. In this study, we collected biopsy specimens from the antrum, corpus and angularis simultaneously to compare the differences among the biopsy sites for the evaluation of mucosal atrophic inflammation.

MATERIAL AND METHODS

Patients

A total of 1598 cases underwent endoscopic and histological examinations. Among them, 1047 cases were male and 551 females (a male:female ratio of 1.9:1) with an average age of 53.2 years (ranged 11 to 94 years). All cases were diagnosed by endoscopy, which consisted of 76 normal subjects, 85 chronic superficial gastritis, 116 atrophic gastritis, 297 erosive gastritis (173 flat-erosive type and 124 elevated erosive type), 467 gastric ulcer, 175 duodenal ulcer, 77 gastroduodenal ulcer, 194 hyperplastic polyp, 23 adenoma, 74 carcinoma, and 14 submucosal tumors. The atrophic change in gastric mucosa by endoscopy was evaluated and scored as “-, -/+, +, ++, +++” by observing the location of the atrophic border in gastric supra-angulus on the mucosal changes, such as fine transparent capillaries in the pale colored and rather thin mucosa. Biopsies were obtained from the three fixed sites (3-points biopsy): the greater curvature of the lower antrum, the greater curvature of the corpus and the supra-angulus. All biopsies were taken from an area of intact mucosa at a distance from any focal lesion, such as an ulcer or erosion.

Assessment of *H. pylori* infection and mucosal inflammation

Biopsy specimens for histological examination were fixed in 10% formalin and processed routinely to paraffin and 3µm sections. *H. pylori* were identified as curved, rod or coccoid by toluidine blue and immunostaining according to our previous report^[32-34]. The biopsy sections were stained with haematoxylin-eosin. The histological chronic inflammation and activity were assessed and scored according to the Sydney system. Lymphocytes and plasmacytes were responded for chronic

inflammation and PMN for activity. It was scored based on the density of inflammatory cells in both lamina proprias and glandular epithelium. The histological atrophy was identified when the gastric glands were correspondingly shortened and widely separated^[15]. In order to avoid the variation, only the cases with muscularia mucosa were judged for histological atrophy, in which, the lower layer of glands almost touch the muscularia mucosa in normal mucosa.

Statistical analysis

The data were analyzed by the Student's *t* test and the *Chi*-square test. *P* values less than 0.05 were considered significant.

RESULTS

The infective rate of *Hp* evaluated by biopsy in different sites

By means of toluidine blue and *H. pylori* antibody staining, *H. pylori* was easily identified in the lower third of the superficial mucous layer and in the gastric pits. The prevalence of *H. pylori* evaluated by different biopsy specimens was not obviously different (Table 1). The positive cases of *H. pylori* infection were 983 (61.5%), 1196 (74.8%) and 994(62.2%), respectively in antrum, corpus and angulus. No significant difference was found in the detective rates among the different site biopsies.

Table 1 Infective rate of *Hp* evaluated by different site biopsy

	Cases	<i>Hp</i> infective rate (%)		
		Antrum	Corpus	Angulus
Normal	76	30(39.5)	35(46.1)	31(40.8)
Superficial gastritis	85	34(40.0)	42(49.0)	37(43.5)
Erosive gastritis	297	160(53.9)	164(55.2)	156(52.5)
Atrophic gastritis	116	90(77.6)	102(87.9)	79(68.1)
Gastric ulcer	467	314(67.2)	368(78.8)	326(69.8)
Gastric carcinoma	74	38(51.4)	43(58.1)	

Though the detective rate for *H. pylori* infection was slightly improved by combining the biopsy in the three sites of gastric mucosa (Table 2), the difference was not statistically remarkable among one point biopsy in the antrum and two-points in the antrum-corpus, or three points in the antrum-corpus-angulus ($P>0.05$).

Table 2 Infective rate of *Hp* evaluated by combined biopsies

	Cases	One point (Antrum)	Two points (Antr.corp.)	Three point (Antr.corp.angu)
Normal	76	39(51.3)	46(60.5)	47(61.8)
Superficial gastritis	85	34(40.0)	46(54.1)	48(56.5)
Erosive gastritis	297	160(53.9)	190(64.0)	195(65.7)
Atrophic gastritis	116	90(77.6)	107(92.2)	107(92.2)
Gastric ulcer	467	314(67.2)	399(85.4)	406(86.9)
Gastric carcinoma	74	38(51.4)	61(82.4)	64(86.5)

Mucosal inflammation and atrophy identified in the biopsy specimens from different sites

In the 1598 biopsy cases, the histological changes of gastric mucosa were evaluated by combining the results of observation in three different biopsy sites. It was found that there were 1413(88.4%) cases with mucosal chronic inflammation, in which, lymphocytes and plasmocytes were observed in both lamina proprias and glandular epithelium. PMN infiltration, which was responsible for the activity of chronic inflammation, was found in 1287 (80.5%) cases and intestinal metaplasia in 773 (48.8%) cases. A total of 1292 cases with muscularia mucosa met the standard for atrophy evaluation, histological atrophy was found in 489 (37.8%) cases.

By comparing the results of different sites biopsies, it was surprised to find that the mucosal inflammation and activity were in concordance evaluated among the antrum, corpus or angulus, but the detective rates for atrophy and intestinal metaplasia were remarkably higher in angulus. In the antrum biopsy specimen, 26.6% and 26.1% showed mucosal atrophy and intestinal metaplasia respectively, however, 65.4% and 31.8% were identified in angularis biopsy (Table 3) with significant difference ($P<0.05$) compared with those in antrum and corpus.

Table 3 Histological lesions identified in different biopsy sites

	Lesion identified		
	Antrum	Corpus	Angulus
Inflammation	1268(72.9)	1290(74.1)	1249(71.8)
Activity	1039(59.7)	1148(65.9)	1071(61.6)
Atrophy*	130(26.6)	96(19.6)	320(65.4) ^a
Intest.metaplasia	455(26.1)	137(17.7)	554 (31.8) ^a

* only 1292 cases in all three points judgable included.

^a $P<0.05$, vs the results of antrum and corpus.

The endoscopical atrophy and histological confirmation

Cases (1290) with muscularia mucosa examination were evaluated histologically and compared with the results of the judgment of endoscopy (Table 4). Among them, mucosal atrophy could be judged in 487 cases, 106 were negative and 697 cases were suspected. The biopsy specimens were further examined based on the correspondingly shortened and widely separated glands. Angular biopsy was found more available for the atrophical identification, in which, 48.3% endoscopical atrophy was confirmed, but in antrum or corpus biopsy, only 22.2% or 15.8% cases were verified. Better agreement of mucosal atrophy was reached in the cases with the 3+ score of endoscopical atrophy. Although the confirmation for endoscopical atrophy was slightly improved when the evaluation was made based on the different points biopsy, the difference was not statistically significant ($P<0.05$).

Table 4 The accuracy of endoscopic atrophy

Endoscopy atrophy	Cases	Evaluation by separate point		
		Antrum	Corpus	Angulus
Negative	106	10(9.4)	9(8.5)	15(14.2)
Suspected	697	124(17.8)	47(6.7)	171(24.5)
Positive	487	108(22.2)	77(15.8)	235(48.3)
+	252	47(18.7)	36(14.3)	103(40.9)
++	201	46(22.9)	35(17.4)	107(53.2)
+++	36	15(41.7)	6(16.7)	27(69.2)

Mucosal atrophy identified in different diseases

Histological atrophy not only occurred in the atrophic gastritis, but also in different gastric lesions, even in normal subjects (Table 5). The confirmation of mucosal atrophy in different diseases also varied with the biopsy specimens from different sites. In angular biopsy, the histological atrophy was much easier to be identified than in antrum. By the evaluation from the angular specimens, the occurrence of mucosal atrophy ranked the highest in the atrophic gastritis (82.2%), then in the carcinoma and adenoma and gastric ulcer. Though the occurrence of atrophy was lower in the endoscopic normal mucosa, superficial and chronic gastritis, there were still about 13.6% to 35.1% cases with the change of histological atrophy.

Table 5 The occurrence of histological atrophy in different diseases

Endoscopic diagnosis	Cases	Histological atrophy (%)		
		Antrum	Corpus	Angulus
Normal	69	6(8.7)	5(7.2)	15(21.7)
Superficial gastritis	79	15(18.9)	8(10.1)	23(29.1)
Flat erosion	152	26(17.1)	5(3.3)	33(21.7)
Elevated erosion	119	29(24.4)	7(5.9)	39(32.7)
Atrophic gastritis	107	59(55.1)	35(32.7)	88(82.2)
Gastric ulcer	387	134(34.6)	39(10.1)	175(45.2)
Duodenal ulcer	135	36(26.7)	8(5.9)	47(34.8)
Gastroduodenal ulcer	64	21(32.8)	5(7.8)	28(43.8)
Hyperplastic polyp	111	14(12.6)	8(7.2)	33(29.7)
Adenoma	11	3(27.3)	3(27.3)	6(54.5)
Carcinoma	46	22(47.8)	6(13.4)	27(58.7)
Submucosal tumors	12	3(25.0)	2(16.7)	3(25.0)

DISCUSSION

Since Warren and Marshall successfully isolated and cultured *H. pylori* from gastric antrum biopsy, the intensive researches into *H. pylori* infection during the past decade have provided important insights into the pathophysiology of gastric diseases^[1-16]. It was suggested that over the past years there was a slow progression of chronic gastritis with atrophy and intestinal metaplasia developing, and that the proportion of the population affected increased with age, and was high in geographical areas with a high risk of cancer^[35-45]. It is now generally supposed that *H. pylori* is one of the important factors in the etiology of chronic gastritis. Recently, a positive

relationship between *H. pylori* and gastric cancer was reported simultaneously by several authors^[45,46]. In light of these observations, it is important to determine the prevalence of atrophic gastritis and intestinal metaplasia since both of these lesions are closely related to the gastric cancer. There have been many reports as to the distribution of *H. pylori* colonization and atrophic gastritis, but usually only involve in small group of cases, and most researchers have not taken into consideration the effect of biopsy from the different sites of gastric mucosa on the atrophic evaluation^[47-52]. Though the Sydney system, a novel classification of gastritis usually based on the biopsy from antrum or corpus for histological analysis, can incorporate etiologic, topographic and morphologic criteria, the agreement for atrophic assessment is often poor^[15, 16]. Since many factors are involved in the failure of detection of the atrophy, the biopsy sites in gastric mucosa may be one of the most important factors responsible for this lack of concordance. In this study, we collected biopsy specimens from the antrum, corpus and angulus simultaneously in 1598 cases to compare the differences among the biopsy sites for the evaluation of mucosal atrophic inflammation.

As to the distribution of *H. pylori* and inflammation in the stomach, Genta *et al* reported that *H. pylori* was distributed evenly throughout the stomach^[26,27]. In this study, we found that the prevalence of *H. pylori* infection evaluated by different biopsy specimens was not obviously different. The positive cases of *H. pylori* infection were 61.5%, 74.8%, and 62.2%, respectively in antrum, corpus and angulus. This finding corresponds closely to Genta's. Since no significant difference was found in the *H. pylori* detective rates among the different site biopsies, it was suggested that one of the biopsies from antrum, corpus or angulus was enough for the evaluation of bacterial infection.

It is interesting to find that mucosal inflammation and atrophy identified in the biopsy specimens from different sites were varied. The evaluation for mucosal inflammation and activity was in concordance among the antrum, corpus or angulus, but the detective rates for atrophy and intestinal metaplasia were remarkably higher in angularis. In the antrum biopsy specimen, only 26.6% and 26.1% showed mucosal atrophy and intestinal metaplasia respectively, however, 65.4% and 31.8% were identified in angularis biopsy.

The endoscopic atrophy or metaplasia was suggested by a group of researchers for the chronological spread of atrophic gastritis and the evaluation of the entire stomach^[36,40]. A border between the normal mucosa and that showing atrophic gastritis was recognized by endoscopy, and this was designated as the endoscopic atrophic border. In this study, 1292 cases with muscularia

mucosa identification were evaluated histologically based on the correspondingly shortened and widely separated glands for the atrophical identification. The histological atrophy was only observed in half of the cases of the endoscopical atrophy, and in the cases without endoscopical atrophy, 20.8% cases still showed histological atrophy, though better agreement of mucosal atrophy was reached in the cases with the 3+ score of endoscopical atrophy. If biopsy was only taken from the antrum or corpus, the concordance of endoscopical atrophy with the histological atrophy was poor.

It is believed for a long time that the atrophic gastritis extends from the antrum to the body with age. Satoh *et al* indicated that *H.pylori* infection was usually associated with antral atrophic gastritis and intestinal metaplasia^[36]. In contrast to this concept, we found by analysis of 1598 cases that both atrophy and intestinal metaplasia were much more commonly identified in angularis than in antrum, no matter of the different number of *H.pylori* colonization or the different diseases. Although it remains to be further confirmed whether the real histological origin of atrophy or intestinal metaplasia developed first from the angulus, we should take this fact into consideration in evaluation on biopsy. Histological atrophy not only occurred in the atrophic gastritis, but also in different gastric lesions, even in normal subjects. The confirmation of mucosal atrophy in different diseases also varied with the biopsy specimens from different sites. In angular biopsy, the histological atrophy was much easier to be identified than in antrum. By the evaluation of the angular specimens, the occurrence of mucosal atrophy ranked the highest in the atrophic gastritis (82.2%), then in the carcinoma and adenoma and gastric ulcer. Although the occurrence of atrophy was lower in the endoscopical normal mucosa, superficial and chronic gastritis, still about 13.6% -35.1% cases had the change of histological atrophy.

In conclusion, our results based on the analysis of 1598 cases of gastric mucosal histology indicate that antrum biopsy is suitable for *H.pylori* evaluation, but supra-angular biopsy is more reliable for atrophy and intestinal metaplasia observation.

INTRODUCTION

Apoptosis, described by Kerr^[1] in 1972, plays a key role in all types of regulated cellular processes in multicellular organisms. It is defined as a morphologic change, including fragmentation of the DNA, cell shrinkage, dilation of the endoplasmatic reticulum, cell fragmentation and formation of apoptotic bodies^[2,3]. One of the abilities of apoptotic cell is to trigger its own engulfment by phagocytic cells prior to cell lysis, which is crucial to the avoidance of the tissue damage and inflammation associated with necrosis^[4]. Apoptotic cells lose membrane phospholipid asymmetry and expose phosphatidylserine (PS) on the outer leaflet of the plasma membrane, macrophages then phagocytose apoptotic cells after specific recognition of the exposed PS^[5]. Annexin V (AV), having a high affinity for PS in the presence of Ca²⁺ ions^[6] and inhibition to PS-dependent procoagulant reactions^[7], is proved to be a very useful general probe for early apoptosis-associated membrane change on live cells before the nuclear condensation events and fragmentation of the DNA^[8].

Gastric carcinoma is estimated to be one of the most frequent *Cancers* in the world. According to Lauren's classification^[9], gastric carcinoma can be divided into adenocarcinomas of diffuse and intestinal type, which differ in growth pattern, morphology, and some phenotypic markers. Recently, apoptotic index and apoptotic genes have been found different in both types^[10,11]. In this study, we investigated the quantitations of early

apoptosis in both intestinal and diffuse gastric carcinoma and their adjacent non-neoplastic tissues with regard to classification and differentiation, and whether the exposure of PS could be inhibited by Bcl-2 protein through various pathways.

MATERIALS AND METHODS

Patients

The 27 surgically resected specimens used for this study were obtained from consecutive patients with gastric Cancer in the Department of General Surgery, Affiliated Hospital of Xuzhou Medical College during the period from April to September 1999. The patients received neither chemotherapy nor radio therapy before undergoing gastrectomy. After tissue sections of 0.5cm³ were excised from the carcinomatous and adjacent non-neoplastic tissues, they were embedded in ice box, and brought back to FCM laboratory. In addition, formalin fixed and paraffin embedded tissue specimens were used for pathological diagnosis according to the Lanren's classification. All cases had adequate clinical information.

Preparation of single-cell suspension

The tissues (carcinomatous and adjacent non-neoplastic tissues) were thoroughly washed with an excess of ice-cold phosphate buffered saline (PBS), immersed in PBS and minced quickly to approximately 0.5mm³ pieces using a pair of sharp scissors. After two more washings with PBS to remove red blood cells, these pieces were dispersed into single cells through an nylon screen (300 holes/cm³) by the press of an glass rod.

Detection of early apoptosis

The cell samples were washed with ice-cold PBS after centrifugation at 500×g for 5 minutes at 4°C. Supernatant was discarded, and finally the cell pellets were resuspended in ice-cold, diluted bind buffer to 2×10⁶ cells/mL. Five µL AV FITC (Immunotech, Cat. No.2375) solution and 5µL propidium iodide (PI, Immunotech, Cat. No.2375) were added to 490µL of the prepared cell suspension. And then the mixture was mixed gently and kept on ice and incubated for 10min in the dark. Aliquots were directly aspirated into a FACSCalibur flow cytometer (USA BD Company) for analysis with simultaneous monitoring of green fluorescence for AV-FITC and red fluorescence for PI. The FCM software (Cell Quest) was used to

calculate and analyze the AV+/PI- cells^[12].

Statistical analysis

To analyse the correlation among early apoptosis, necrosis, viable cells in gastric carcinomatous and adjacent non-neoplastic tissues, the Student's *t* test and the Pearson's correlation coefficient were performed with State statistical software.

RESULTS

Clinical and pathological information

The 27 patients with gastric carcinomas (16 male and 11 female), including 9 intestinal and 18 diffuse tumors, with a mean age at operation of 57.4 ± 13.1 years (ranging from 31 to 88 years). There were 7 cases of early (restricted to mucosa and submucosa) and 20 cases of advanced gastric carcinomas, respectively. The mean tumor size was $4.4 \text{ cm} \pm 2.0 \text{ cm}$ (ranging from 1.0 cm - 8.0 cm). Lymph node metastasis was found in 16 cases.

Detection of early apoptosis with AV and PI

Figure 1 shows typical flow cytometer histograms for gastric carcinoma and adjacent non-neoplastic tissues. AV was an able to bind to viable cells of normal or abnormal tissues as it can not penetrate the phospholipid bilayer and PS did not expose to the outer leaflet. In apoptotic cells, however, the bilayer lose its symmetry when PS was flipflopped from the inner to outer leaflet. Once the cells were dead, the integrity of the plasma membrane was lost and the penetration was enhanced promptly. The bivariate AV/PI analysis by cytogram showed that viable cells were negative for both AV and PI (LL), apoptotic cells were AV positive (LR), while dead cells were positive for both AV and PI (UR).

Early apoptosis in various histological types

By bivariate AV/PI analysis using flow cytometer, the percentages of early apoptosis of carcinomatous or non-plastic tissues were $16.7\% \pm 5.2\%$ ($\bar{x} \pm s$) and $9.3\% \pm 3.9\%$, respectively. The apoptotic index of carcinoma was significantly higher than that of the adjacent non-neoplastic tissue, the difference being statistically significant (Table 1). However, the same result only appeared in carcinomatous tissues of diffuse and intestinal carcinomas, whereas no difference was found in adjacent non-neoplastic tissues (Figure 2).

Table 1 Percentages of three subpopulations in gastric carcinomas

	AV+/PI-	AV+/PI+	AV-/PI-
Normal	9.3 ± 3.9	4.1 ± 2.5	85.7 ± 5.6
Vicious	16.7 ± 5.2^a	6.1 ± 2.7^b	76.7 ± 8.1^b

^a $P < 0.001$, ^b $P < 0.01$ vs normal (adjacent non-plastic tissues).

Correlation between early apoptosis and necrosis

The early apoptosis did not demonstrate a dose correlation with the necrosis, i.e. the correlation coefficients between AV+/PI- and AV+/PI+ in tumors or normal tissues were 0.3650 and 0.3877 respectively. And the early apoptosis was not correlated with sex, age, tumor size, lymph nodes metastasis, whereas closely correlated with depth of invasion.

Figure 1 Bivariate AV/PI analysis of the gastric carcinoma (A) and adjacent non-neoplastic (B) tissues. The different labeling patterns in this assay identify the different cell subpopulations. i.e. region LL, viable cells (AV-/PI-), region LR, apoptotic cells (AV+/PI-), region UR, dead cells (AV+/PI+).

Figure 2 Early apoptosis in diffuse and intestinal gastric carcinomas. 1 and 2 were EAIs in carcinomatous tissues of diffuse and intestinal tumor, $19.0\% \pm 3.9\%$ and $12.0\% \pm 4.3\%$ ($P = 0.0002$); 3 and 4 were in adjacent non-neoplastic tissues, $10.8\% \pm 3.3\%$ and $7.3\% \pm 4.2\%$ ($P = 0.0516$).

DISCUSSION

In this report, we investigated the early apoptosis in diffuse and intestinal gastric carcinomatous and adjacent non-neoplastic tissues by AV/PI bivariate flow cytometry. Apoptosis, found in the normal tissues and in virtually all malignant tumors^[13], is defined morphologically as the double-strand cleavage leading to the formation of fragments that are detected usually by agarose gel electrophoresis (Ladder) or terminal deoxynucleotidyl transferase mediated dUTP-digoxigenin nick end labelling technique (TUNEL). The results, however, derived from the Ladder or TUNEL methods only presents the latter process of apoptosis and can not be analyzed quantitatively^[14-16].

With the development of the study on the role and basic mechanisms underlying apoptosis, the externalization of phosphatidylserine (PS), a kind of plasma membrane lipid, which results in the loss of phospholipid asymmetry, is a downstream event of early caspase activation^[8,17] and recognized as an early and ubiquitous phenomenon event in apoptosis^[5]. Based on the abilities of annexin V (AV) to bind to PS with high affinity and of propidium iodide (PI) to permeate the membrane losing integrity to stain DNA, AV and PI can be added simultaneously to the cell suspension to discriminate among viable, apoptotic and dead cells^[18]. Viable cells with its membrane's integrity and asymmetry were kept, and AV negative/PI negative were manifested (Figure 1, LL). After PS was exposed to the surface of membrane, apoptotic cells were presented with AV positive/PI negative (Figure 1, LR), whereas the necrotic cells with AV positive/PI positive (Figure 1, UR) were indicated when the membrane loses its integrity. In our study on fresh specimens, we found that the suspension from gastric carcinomatous and adjacent non-neoplastic tissues was identified easily to three subpopulations, among which the EAs were different statistically. The percentages of apoptosis (AV positive/PI negative) were $16.7\% \pm 5.2\%$ and $9.3\% \pm 3.9\%$, respectively, being higher than those reported in literature^[19]. The reason might be that the experiments method are different and the sensitivity and specificity of AV/PI bivariate FCM are high, we therefore think that the results from our study can reflect objectively the spontaneous occurrence of apoptosis.

The externalization of phosphatidylserine (PS) plays a potential role in cellular kinetic significance. It has been shown that tumorigenic cells expressed relatively larger amounts than that of normal keratinocytes by semiquantitative analysis^[20] of PS in the outer leaflet of the cells. The same results were seen in our study. At the execution phase of apoptosis, PS was displayed at the outer membrane by flippases, scramblase and other proteinases. Possibly, with the participation of autologous cytophilic antibodies, components of the clotting

cascade, and special phospholipases, macrophages discriminate between "self" and altered "self" by recognizing, phagocytosing, and disposing of effete or tumorigenic cells. Furthermore, it was found in cells that the binding of PS and AV could suppress phagocytosis^[21]. That is, the expression of PS on the outer membrane leaflet of cells serves as a recognition moiety for macrophages.

There are various reports regarding the relationship between apoptotic indices and histological type in gastric carcinomas^[22,23], the significance of apoptosis in human gastric carcinomas suggested that the higher occurrence of apoptosis in well differentiated carcinomas reflects their slow-growing nature, and poorly differentiated carcinomas escape from this process. However, our results differed from the reports above. According to Lauren's classification, gastric carcinomas can be divided into adenocarcinomas of diffuse and intestinal type. One of the main difference between them is the degree of infiltration by macrocytes histologically, i.e. intestinal carcinomas grow with no or little infiltration whereas diffuse carcinomas do inversely. It might be that the heterogeneity of diffuse carcinomas is higher than that of intestinal carcinomas, the cells are prone to be initiated by multiple triggers of apoptosis, such as DNA damage, Fas ligand binding or withdrawal of growth factors^[24-27].

In recent studies, at the trigger and execution phase of apoptosis, the expression of bcl-2, bax^[28-30] was demonstrated to play important roles in cell life. Bcl-2 and Bax are members of the group proteins that regulate the apoptotic pathway, that is, Bcl-2 acts as an inhibitor of apoptosis, opposing Bax effects on cell life. Bcl-2 could protect cells from apoptosis in several ways, such as inhibition from transmembrane streaming of Ca^{2+} ion, blockage in releasing of cytochrome C, formation of heterodimers with Bax. In addition, Bcl-2 may regulate special PS-sensitive signal transduction pathway by protecting lipids from peroxidation^[31,32]. Some clinicopathological studies demonstrated that Bcl-2 appears to be preferentially associated with the intestinal type carcinomas and more prevalent in poorly differentiated ones^[33-35].

In conclusion, the early apoptosis has been investigated in gastric carcinomatous and adjacent non-neoplastic tissues by AV/PI bivariate flow cytometry. The early apoptosis is clearly related to tumor and its differentiation and depth of invasion.

INTRODUCTION

Genetic instability is a common property of many human cancers^[1], including those of HNPCC^[2,3]. A novel form of genetic instability involving somatic alterations, such as deletions and insertions in simple repeated sequences^[4], has been found. Microsatellites are relatively short runs of tandemly repeated sequences scattered throughout the genome^[5,6]. Ubiquitous alterations in these sequences were initially detected by unbiased DNA fingerprinting in a subset of colorectal cancer^[7,8], implying the presence of genome-wide genetic instability. Subsequently, amplification by polymerase chain reaction (PCR) of a few microsatellite loci should be used to reveal this microsatellite instability (MSI) in colorectal cancers^[9,10] and other malignancies^[11-14].

MSI was observed to be a common feature of HNPCC^[15]. Physical mapping and finding of mutations in HNPCC patients revealed that a human homologues of the *Escherichia coli* DNA mismatch repair (MMR) enzyme MutS was one of the candidate genes for HNPCC and was named hMSH2^[16]. Human homologues of the *E.coli* and yeast mismatch repair enzymes hMLH1, hPMS1 and hPMS2 have also been associated with HNPCC^[17]. Defects of these mismatch repair genes have been reported to produce MSI in bacteria and yeast, and a high mutation rate of microsatellites has been

observed in HNPCC patients and in cell lines established from HNPCC tumors^[18]. Therefore, MSI in HNPCC is one of the results of mutations in these mismatch repair genes. In the present study, we analyzed MSI, expression of MMR genes and cell proliferation activity in colorectal cancer (CRC) patients with familial predisposition, to reveal the characteristics of these patients' genetic defects and to afford the biological basis for screening high-risk relatives of CRC.

MATERIALS AND METHODS

Patients

Forty-six colorectal cancer patients who underwent surgical resection between 1993 and 1995 at Nanfang Hospital in Guangzhou, China, were analyzed. These included 26 patients with familial predisposition (Group A) by summarizing clinic archives and surveying their pedigrees, and 20 randomly selected colorectal cancer patients without familial predisposition (Group B). In Group A, 4 patients were eligible HNPCC according to the Amsterdam criteria^[15].

PCR

Genomic DNA was extracted from formalin fixed, paraffin embedded tumor tissues and corresponding normal tissues, respectively, using a modification of the method reported previously^[19-21]. About 100ng of genomic DNA was used for PCR amplification of microsatellite sequences.

Microsatellite instability

Four microsatellite loci, D2S119, D2S123, D5S107 and D17S250 were analyzed in all patients, using silver staining polymerase chain reaction-single strand conformation polymorphism (PCR-SSCP) technique^[22,23]. We classified patients as positive for MSI when the PCR product using tumor DNA revealed the presence of extra bands or shifting bands that were not visible in the PCR product of the corresponding normal tissue DNA, and these changes were found in at least two microsatellite loci, called MSI-H^[24,25].

Immunohistochemical staining of hMLH1, hMSH2 and proliferation cell nucleus antigen (PCNA)

hMLH1, hMSH2 enzyme was detected using a rabbit polyclonal antibody, and PCNA, a

monoclonal antibody (Dako Co). By streptavidin-peroxidase (SP) immunohistochemical method^[26], we defined positive cases as those of hMLH1, hMSH2 that showed staining of tissues (tumor or normal) cell nuclei or cytoplasm in clusters^[27], and PCNA that showed staining of tumor cell nuclei in clusters^[28,29]. The label index (LI) of PCNA was analyzed.

Flow cytometry for DNA analysis

Using Flow Cytometry (Type of EPICS ELITE), the DNA index (DI), heteroploid rate, proliferation index (PI) and S-phase percentage were assayed in tumor cells. We defined heteroploid cells as that DI was not between 0.90 and 1.10.

Statistical analysis

Two-tailed Fisher's and χ^2 exact tests were used to analyze the significance of differences between the groups. The significance level was set at $P < 0.05$.

RESULTS

All patients were detected for MSI in four microsatellite loci (Figure 1). MSI was detected in 20 (76.9%) out of 26 patients in Group A. The MSI-positive (MSI-H) proportion in Group A was 46.2% (12/26), significantly higher than 10% (2/20) in Group B ($P < 0.05$). Three of 4 HNPCC patients in Group A were MSI-positive.

We examined the association of MSI with clinicopathologic characteristics of CRC patients with familial predisposition, and elucidated the following features: ① An early age of onset (Table 1). Patients positive for MSI in Group A tended to have a younger mean age at onset than patients in Group B ($P < 0.01$) and patients negative for MSI in Group A. ② A preponderance of tumors in the proximal colon (Table 2). Proximal colon includes cecum, ascending and transverse colon^[30]. Among patients positive for MSI, 9 (64.3%) of 14 tumors were located in the proximal colon. In contrast, among patients negative for MSI, 9 (28.1%) of 32 tumors were located in the proximal colon ($P < 0.05$). In MSI-negative patients, tumors in Group A also had a proclivity for the proximal colon (5/9) but tumors in Group B did not (4/14). ③ Correlation with a poorly differentiated phenotype (Table 2). Among patients positive for MSI, 11 (78.6%) of 14 tumors were poorly differentiated adenocarcinomas. It was significantly higher than that among MSI-negative patients ($P < 0.05$). Also in tumors of Group A, the poor differentiation rate positive MSI was higher than that of negative MSI. ④ Proclivity for extracolorectal malignancy. Among patients in Group A, 6 cancers were associated with cancers in other organs (2 in uterus, 2 in stomach, 1 in bladder, and 1 in bile duct), and 5 of these were positive for MSI. In contrast, there was no patient with cancers in other organs in Group B.

Immunohistochemically, contrast with Group B, patients in Group A tended to be negative for hMLH1 protein staining in tumor tissues, and hMLH1, hMSH2 protein staining in normal tissues (Figure 2, Table 3). Among patients positive for MSI, 6 of 14 colorectal tumors were negative for hMLH1 together with hMSH2 protein, whereas 4 of 32 tumors negative for MSI ($P < 0.05$). The LI of PCNA staining (Figure 3) in tumors of Group A was 0.54 ± 0.10 , which was lower than that of Group B (0.62 ± 0.07), $P < 0.01$, meanwhile in cancer tissues with MSI-positive, the LI was 0.53 ± 0.10 , which was lower than that of negative MSI (0.59 ± 0.08), $P < 0.05$.

According to flow cytometry (Table 4), the heteroploid rate of DNA in tumors of Group A was 23.1%, PI and S-phase percentage in tumors with positive MSI were 14.34 ± 5.49 and 8.18 ± 2.55 . In contrast with that of Group B and negative MSI respectively, they decreased obviously ($P < 0.05$).

Table 1 MSI and mean age at onset of colorectal cancer

Group	MSI	n	Age($\bar{x} \pm s$)
HNPCC		4	41.8 ± 7.7^b
A	+	12	45.4 ± 8.3^b
	-	14	49.6 ± 9.7
B	+	2	57.5 ± 9.2
	-	18	58.9 ± 11.0

^b $P < 0.01$ vs Group B; Fisher's test.

DISCUSSION

MSI is the phenotype of a profound genomic instability caused by a mutator phenotype mechanism for cancer^[31,32]. Four microsatellite loci (D2S119, D2S123, D5S107 and D17S250) used in our study resemble to the loci recommended by NCI workshop^[25]. The ratio of MSI-positive patients in Group A (46.2%) was significantly higher than that among randomly selected patients in Group B (10%). These results showed that MSI was an important contributor in CRC with familial predisposition. Colorectal tumors with MSI exhibit several clinicopathologic characteristics. In this study, we confirmed that the age at onset of cancer in Group A was younger than that in Group B, especially in HNPCC patients and patients with MSI-positive in Group A. We also confirmed that the ratio of proximal colon tumors, complication by extracolorectal malignancies and poorly differentiated carcinomas in patients with positive MSI were higher than those with negative MSI, and these characteristics were significant in Group A. These results suggested that it was possible and effective to identify high-risk relatives of CRC by applying pedigree survey together with MSI detection.

Leach *et al* established the method for detecting the products of MMR gene mutation^[33]. If the MMR genes mutate, there may be a kind of methylation on promoter in transcription. And it brings the products in C-termination which block the normal expression of MMR genes. Therefore, negative for hMLH1, hMSH2 staining means potential mutation of MMR genes in tumor or normal tissues, and positive means no mutation^[27,34]. In our study, we found that in Group A the incidence of negative hMLH1 staining in tumor tissues and hMLH1, hMSH2 staining in normal tissues was significantly high (Table 3). Among patients positive for MSI, ratio of negative hMLH1 together with hMSH2 staining in tumors was also higher than that among patients negative for MSI. It suggested that the rate of hMLH1, hMSH2 abnormality in CRC patients with familial

predisposition increased in colorectal tumors and normal tissues. The colorectal epithelium of this group could have wide gene abnormality. And these gene changes had obviously been related with MSI.

According to the previous studies, the expressions of PCNA^[35,36], DNA ploid and proliferation phases of cells^[37,38] are the important markers for diagnosing and prognosticating cancers. We found that the LI of PCNA staining of tumor cells in Group A and MSI-positive group were lower than that in Group B and MSI-negative group respectively. According to Flow Cytometry, the heteroploid rate of DNA in tumor cells of Group A was lower than that of Group B. PI and S-phase percentage in tumor cells with positive MSI were also lower than those in negative MSI. It was reported that the metastasis and recurrence in colorectal cancer with MSI (due to replication error, RER) were less than in sporadic cancer. The low invasion of cancer could be explained that the mutation was too frequent and complicated to express the phenotype of metastasis and recurrence^[18]. Our study showed that this low invasion was also associated with the decreased proliferation activity in colorectal cancer with familial predisposition and MSI.

Studies on MSI, MMR gene expression and proliferation kinetics showed the characteristics of colorectal cancer with familial predisposition. According to this, the early diagnosis and warning system^[39] of colorectal cancer can be established. It is important to screen high-risk relatives of colorectal cancer and diagnose colorectal cancer early^[40].

INTRODUCTION

Gut originated infection (GOI) has been recognized as a potential factor for postburn irreversible shock, early sepsis and multiple system organ failure^[1-5]. The intestinal mucosal barrier injury has been implicated as the cause of postburn GOI^[6-8]. However, pathogenesis of the lesion is not well known. Platelet activating factor (PAF), an endogenous phospholipid mediator, has recently been proposed as an important mediator of postburn intestinal mucosal barrier injury and gut originated infection^[9-11]. But the mechanism of PAF is not well defined. In this study, we have evaluated sequential hemodynamic changes in the intestinal mucosa after burn injury and investigated the role of PAF by assessing whether pretreatment against intestinal mucosal hemodynamic disturbance and pathologic damage, so as to further explore the role and its mechanism of PAF in postburn intestinal mucosal barrier injury.

MATERIALS AND METHOD

Animals

Wistar rats, male or female, weighing 220 g±30 g were used. They were provided by Animal Laboratory, Institute of Burn Research, Third Military Medical University.

Experimental design

Animals were randomly divided into three groups: group 1 (*n*=10) served as a control with sham, burn injury; group 2 (*n*=40), burned rats that had

undergone 30% TBSA III° burn; group 3 (*n*=40), rats that received PAF antagonist WEB2170 (5mg/kg) by intraperitoneal injection immediately after burn and repeated every 8 hours^[12]. WEB2170 was provided by Boeringer Ingelheim Pharmaceuticals Inc, Federal Republic of Germany. The index was observed on postburn 6, 12, 24, and 48 hours.

Burn model

Rats were anesthetized intraperitoneally with 80mL/kg body weight, ketamine hydrochloride, and their backs were shaved. They were placed in a mould that left approximately 30% of their body surface area exposed. The exposed surface was immersed in 92°C water for 18s. This type of burn injury is a fullthickness burn. Animals were resuscitated with 40mL/kg of lactated Ringer's solution.

Measurement of intestinal mucosal blood flow

The intestinal mucosal blood flow was directly measured with a laser-Doppler flowmeter^[13], made by Nakai university. The unit was expressed as mv.

Measurement of intestinal intramucosal PH (PHi)^[14,15]

Rats were anesthetized after fasted overnight, a midline abdominal incision was made. Fifteen cm segments of ileum were isolated, cannulated proximally and distally, and 3mL saline was injected into the ileal segment. After 30min, 1mL intestinal perfusion and 1mL arterial blood were collected for measurement of Pco₂ in intestinal perfusion and [HCO₃⁻] in arterial blood. The intestinal mucosal PHi was calculated from the Henderson-Hasselbach equation:

$$PHi = 6.1 + \log(Pco_2 \times 0.0307)$$

Measurement of intestinal water content^[16] Five cm segments of ileum were excised and weighed for wet weight, and placed in to 140°C oven for 4 hours and weighed again for dry weight. The intestinal water content was calculated using the following formula:

$$\text{Water content} = (\text{wet weight} - \text{dry weight} / \text{wet weight}) \times 100\%$$

Histologic examination of intestinal mucosa The ileum was fixed in 10% formalin and processed by the routine techniques. Specimens were stained with hematoxylin and eosin and examined histologically under light microscope.

Statistical analysis

All data were expressed as $\bar{x} \pm s$, and statistical analyses were made using Student's *t* test.

RESULTS

The changes of intestinal mucosal blood flow

The intestinal mucosal blood flow began to decrease significantly on postburn 6h and became lowest on postburn 12h as compared with control group. In PAF-antagonist treatment group, the intestinal mucosal blood flow was significantly increased compared with burn group (Table 1).

The changes of intestinal mucosal PHi

The intestinal mucosal PHi in burn group was significantly lower than in control group on postburn 6h, 12h, and 24h, but not on postburn 48h. In PAF antagonist treatment group, intestinal mucosal PHi was significantly increased compared with burn group (Table 2).

The changes of intestinal water content

The changes of intestinal water content on postburn 6h and 48h were not significantly different, but on postburn 12h and 24h, it was significantly increased as against burn group. The intestinal tissue water content in treatment group on 12h and 24h was significantly lower than in the burn group (Table 3).

The histologic changes of intestinal mucosa

In the burn group, extensive vascular congestion and edema were noted in ileal mucosa. Subepithelial space at the tip of the villi was developed, and lacteals were dilated. The degenerative fragmentation and atrophy of mucosal villi were

apparent on postburn 12h and 24h. These changes were significantly reduced in PAF antagonist treatment group.

DISCUSSION

The intestinal mucosal blood flow is an important factor for maintaining the structure and function of intestinal epithelial cells^[17-19]. Some studies have indicated that gastrointestinal mucosal blood flow significantly decreased following early burn injury^[20-22]. Binnaka *et al.*^[23] reported that gastric mucosal blood flow fell rapidly to 40% of normal value on postburn 2h on a rat model with 30% TBSA III° burn. Tokyay *et al.*^[24] reported that intestinal blood flow decreased significantly to 25% -30% of the baseline on 2h and 4h of the early postburn phase, and during the late phase at 48h to 30% of the baseline again on a pig model with 40% TBSA III° burn. The results showed that intestinal mucosal blood flow significantly decreased to 65% of normal value on postburn 6h to 46% on postburn 12h, to 68% and 82% on postburn 24h and 48h. The intestinal mucosal ischemia following burn was proved again. The decrease in the intestinal mucosal blood flow caused a decrease in oxygen delivery (DO₂) and a marked increase in oxygen consumption (VO₂) in intestinal epithelial cells^[25,26]. When DO₂ fell below a critical level, further decrease in DO₂ can induce anaerobic metabolism and decrease in cells PH, causing the damage of intestinal epithelial cells^[27,28]. The results also showed that the intestinal mucosal PHi was significantly decreased following burn injury compared with control group. It is suggested that hypoxia in intestinal epithelial cells occurs following burn.

PAF is a phospholipid mediator released from stimulated leukocyte, platelets, endothelial cells and mast cells, etc. PAF has a potent vasoactive effect^[29,30]. intravascular infusion of PAF can induce hypotension and extensive vasoconstriction in heart, lung, brain and gastrointestinal, and a marked increase of vascular permeability as well^[31,32]. PAF-induced responsiveness was significantly attenuated by PAF antagonist^[33,34]. It was reported that PAF antagonist can significantly reduce intestinal mucosal ischemia and pathological damage caused by endotoxin shock and hemorrhagic shock^[35-38]. In this study, treatment with antagonist WEB2170 for the scalded rats could significantly increase the intestinal mucosal blood flow and PHi, decrease intestinal tissue water content and alleviate the pathological damage of intestinal mucosa. Conclusion can be drawn that PAF is one of the important factors causing postburn disturbance of intestinal mucosal microcirculation.

Zhou X, Li N, Li JS. Growth hormone stimulates remnant small bowel epithelial cell proliferation. *World J Gastroentero*, 2000;6(6):909-913

INTRODUCTION

Currently the major treatment choices for short bowel syndrome are parenteral nutrition and small bowel transplantation^[1]. Both therapies involve great fiscal challenge and recurring complications. Recent years have witnessed the promising experimental results of pharmacological rehabilitation of remnant small bowel^[2-10]. Preliminary clinical trial also indicates salutary effect of growth hormone on patients with short bowel syndrome^[11,12]. However, the mechanism by which growth hormone benefits the patients remains unclear.

In this animal experiment we attempted to address the possibility that administration of exogenous growth hormone (GH) after massive small bowel resection can stimulate remnant small intestinal epithelial cell proliferation.

MATERIALS AND METHODS

Animals

Adult male Sprague-Dawley rats (Shanghai Laboratory Animal Center, the Chinese Academy of Sciences) were allowed to acclimate to our laboratory conditions for at least 5 days. The animals were fed standard commercial rat pellet chow, which contained crude protein 25%, fat 10%, crude fiber 50%, calcium 1.0%, phosphate 0.8% (Jiangsu Province Jiangpu Laboratory Animal Feeds Factory, Nanjing, China) and tap water ad libitum. Constant room temperature (22°C) with 12h light and dark cycles were supplied. The experiment protocols described below were

approved by the Animal Care and Use Committee of Jinling Hospital.

Experimental design

After an overnight fasting, all animals were anesthetized by intraperitoneal injection of ketamine hydrochloride (100mg/kg). Resect-control animals ($n = 10$) and growth hormone-resect (GH-resect) animals ($n=10$) underwent 80% mid-small bowel resection, leaving 7cm of proximal jejunum and 7cm of terminal ileum. Control-transect animals ($n=10$) underwent bowel transection of ileum 7cm proximal to the ileocecal valve. Postoperatively, animals were allowed to drink water libitum on the first day, and chow on the beginning of the second postoperative day. Somatropin (1IU/kg) (Saizen, Laboratories Serona S.A., 1170 Aubonne, Switzerland) was administered subcutaneously once daily at 16:00 from the first postoperative day to the day of killing. All animals were sacrificed at about 08:00 to 10:00 on the 29th postoperative day. Residual ileum from 2cm distal to the anastomosis to the ileocecal valve was excised and luminal contents were removed. In transected animals anatomically similar segments were removed. The first 1cm of the excised ileum was for histological analysis. The mucosa of the following 2cm segment was scraped for nuclear acid analysis. And the mucosa of the remaining ileum was scraped for flow cytometric analysis.

Plasma insulin-like growth factor-I (IGF-I) determination

Total plasma IGF-I concentrations were measured after acid-ethanol extraction with the use of DSL-2900 rat IGF-I radioimmunoassay kit (Diagnostic Systems Laboratories Inc., Webster, Texas, USA).

Mucosal histological image analysis and immunohistochemical assay for proliferating cell nuclear antigen (PCNA)

Fixed specimens of ileum were embedded in paraffin and oriented to provide cut sections parallel with the longitudinal axis of the bowel. Four-micrometer-thick slices were mounted and stained with hematoxylin and eosin. Villus height, crypt depth and mucosal thickness were measured using a videoassisted integrated computer program (HPIAS-1000 True Color Image Analysis System). Villi were chosen on the basis of the ability to completely visualize the central lymphatic channel and crypts to

visualize the crypt-villus junction on both sides of the crypt. At least 15 villi and crypts were counted per sample.

The immunohistochemical staining for PCNA was performed by Labeled Streptavidin-Biotin method (S-P) with staining kit (Fuzhou Maxim Biotech, Inc., Fuzhou, China) following the instructions of the manufacturer. Those cells with brown-stained nuclei were reckoned as positively stained cells. The PCNA index was measured as a percentage of the number of positively stained cells over the total number of cells in the crypt. Five high-resolution fields from each slide were randomly chosen for measurement.

Flow cytometric analysis

Freshly scraped small bowel mucosa was mechanically dispersed through wire mesh and collected into cold (4°C) phosphate buffered solution (PBS). The cell suspension was washed and filtered through 60µm nylon mesh and adjusted to a concentration of 1×10^6 cell/mL. Aliquots of 1mL mucosal cell suspension were centrifuged at $500 \times g$ for 10min and the cell pellets were subjected to DNA labeling with method described in^[13]. The stained cells suspension was analyzed using an Epics XL flow cytometer (Coulter Corp., Hialeah, FL, U.S.A.). The percentages of cells in the G₀/G₁, S, and G₂/M phases of the cell cycle were determined. The cell proliferative activity was measured by proliferative index (PI), calculated by $(S+G_2/M)/(G_0/G_1+S+G_2/M) \times 100\%$.

Semiquantitative reverse transcription (RT)-polymerase chain reaction (PCR)

Total RNA was extracted from the ileal mucosa using TRIzol reagent (GIBCO BRL, Gaithersburg, MD, U.S.A.) following the instructions of the manufacturer. Concentrations of total RNA were determined spectrophotometrically at A₂₆₀. RT reactions were carried out using 2.5µg of total rat RNA and a cDNA synthesis kit (Promega, Madison, WI, U.S.A.) in a final reaction volume of 20µL. Synthetic oligonucleotides (Sango Biotech. Corp., Shanghai, China) for cDNA amplification were as follows: 5'-gcgatgaggaaccgcattgccgcctccaagt-3' (sense), 5'-cgcacagtctgcc ggccaataggccgct-3' (anti-sense) for *C-jun* and 5'-catttccggtgca cgatggag-3' (sense), 5'-ggcatcctgcgtctgacacgtg-3' (anti-sense) for β -actin respectively. The PCR amplified products were of 459-base-pair for *C-jun* cDNA and 599-base-pair for β -actin cDNA respectively. PCR was performed using 6.0µL of reverse transcription product and a master mixture containing 10mmol/L Tris-HCl (pH 8.8), 1.5mmol/L MgCl₂, 75mmol/L KCl, 0.2mmol/L dNTPs, 5' and 3'-*C-jun*-oligonucleotides (0.25µmol/L each), 5' and 3'- β -actin oligonucleotides (0.25µmol/L each), and 2.0 unit Taq polymerase (GIBCO BRL, Gaithersburg, MD,

U.S.A.). The samples were denatured initially at 94°C for 5min. Amplification was performed on Gene Cyclor (Bio-Rad, Japan). The cycling condition was selected for β -actin as denaturing at 94°C for 1min, annealing at 58°C for 1min, and extension at 72°C for 1min for 28 cycles; for *C-jun* as denaturing at 94°C for 1min, annealing at 61°C for 1min, and extension at 72°C for 1min for 33 cycles. The final cycle was followed by an extension step at 72°C for 10min. The PCR amplifiers were subjected to electrophoresis through 1.6% agarose gel containing 0.5mg/L ethidium bromide, visualized by ultraviolet illumination. The electrophoresis gel images analyzed with Kodak Digital Science 1D Image Analysis Software (Eastman Kodak Company, Rochester, NY, U.S.A.). The expression of *C-jun* was measured as a ratio compared with β -actin.

Statistical analysis

Results were presented as mean \pm SD. Statistical analysis was performed using one-way ANOVA. Possible post hoc comparison of pairs of means was conducted by Duncan's multiple range test. A probability value of less than 0.05 was considered significant.

RESULTS

Body weight

There was no significant difference in the body weight among three groups before operation. After bowel resection, body weight decreased gradually and reached the nadir by the end of the first postoperative week. Then the body weight gradually rose at a speed slower than those undergoing bowel transection. One week after the operation, animals in control-resect group and GH-resect group had similar body weights, which were significantly lower than those in control-transect group. Growth hormone treatment resulted in significant increase in body weight gain at the end of the experiment (Table 1).

Table 1 Effect of growth hormone on body weight

	Control-transect (n=10)	Control-resect (n=10)	GH-resect (n=10)
Day 0	249 \pm 13	251 \pm 11	244 \pm 10
Day 8	287 \pm 11	205 \pm 10 ^a	211 \pm 11 ^a
Day 29	351 \pm 13	297 \pm 16 ^a	332 \pm 15 ^b

Day 0: before operation; Day 8: 1 week after operation; Day 29: 4 weeks after operation. Data are expressed as mean \pm SD;

^aP<0.05, vs control-transect group; ^bP<0.05, vs control-resect group.

Plasma IGF-I concentrations

Plasma IGF-I concentrations in both sets of resected animals (0.84mg/L \pm 0.08mg/L in control-resect; 1.03mg/L \pm 0.07mg/L in GH-resect) were lower than those in control-transect group (1.56mg/L \pm 0.14mg/L, P<0.05).

However, GH administration had significantly increased plasma IGF-I level compared with control-resect animals ($1.03\text{mg/L} \pm 0.07\text{mg/L}$ vs $0.84\text{mg/L} \pm 0.08\text{mg/L}$, $P < 0.05$) (Figure 1).

Figure 1 Plasma IGF-I concentration 28 days after 80% mid-small intestine resection in animals from three groups.

^a $P < 0.05$, vs control-transect group; ^b $P < 0.05$, vs control-resect group.

Table 2 Effect of growth hormone on small intestinal mucosal parameters

	Control-transect (n=10)	Control-resect (n=10)	GH-resect (n=10)
Villous height (µm)	180±40	270±40 ^a	340±30 ^b
Crypt depth (µm)	92±17	105±11	120±24 ^a
Mucosal thickness (µm)	320±40	510±80 ^a	520±50 ^a
PI value (%)	3.7±2.0	4.4±1.7	7.6±2.0 ^b
PCNA index (%)	1.6±0.5	3.6±0.6 ^a	8.8±1.1 ^b
<i>C-jun</i> mRNA (%)	10.7±0.7	19.5±2.5	49.2±1.0 ^b

Data are expressed as mean±SD; ^a $P < 0.05$, vs control-transect group; ^b $P < 0.05$, vs control-resect group.

Mucosal parameters

As indicated in Table 2, animals in control-transect group and control-resect group had similar cryptal depth, PI value, and *C-jun* mRNA level. Small bowel resection resulted in significant increase in villous height, mucosal thickness and PCNA index in control-resect group compared with those in control-transect group. GH treatment led to greater villus height, PI value, PCNA index, and *C-jun* mRNA level in GH treatment group than in control-resect group. The crypt depth in GH treated animals was significantly greater than that in control-transect animals.

DISCUSSION

Our animal experiment demonstrated that small bowel resection led to significant increase in villous height, mucosal thickness and PCNA index, which proved that our massive small bowel resection model had induced adaptive hyperplasia in remnant ileum. We chose to study the remnant ileum because previous studies had revealed that after massive small bowel resection the remnant ileum bore greater adaptive potential than the remnant jejunum^[14,15]. Moderate dose of rhGH

($1\text{IU} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$) stimulated further hyperplasia of remnant small bowel mucosa, which was manifested by increased villous height, PI value, and PCNA index. *C-jun* encoded a member of the AP-1 complex of transcription factors that were known to increase after various mitogenic stimuli. Previous studies had demonstrated that enhanced intestinal proliferative activity was associated with augmentation of intestinal expression of *C-jun*^[16,17]. Semi-quantitative analysis of *C-jun* mRNA revealed enhanced expression of *C-jun* in GH-resect animals, which further reflected increased proliferative activity.

The result of our study was consistent with the notion that GH is an important growth factor for small intestinal mucosa. Complete GH depletion due to hypophysectomy caused pronounced hypoplasia of small intestinal mucosa with decreased villous height and reduced cryptal cell proliferation. Simple replacement of GH can restore mucosal proliferative activity^[18]. Hypophysectomy was shown to impair the adaptive hyperplasia in response to small bowel resection^[19]. Study of the transgenic mice overexpressing the bovine growth hormone demonstrated that chronic GH excess could produce hyperplasia in small intestinal mucosa whether food intake was *ad lib* or restricted^[20]. Short-term GH administration has also been shown to promote further hyperplasia of remaining small intestinal mucosa, which was not associated with appetite variation^[2].

Plasma IGF-I is primarily derived from liver and GH is the principal stimulus for IGF-I synthesis in liver as well as in peripheral tissues^[21]. Apart from GH, nutritional status is another major regulator of plasma IGF-I concentration^[22]. Both calorie restriction and protein restriction have been shown to down-regulate the plasma IGF-I level. In this study, massive small bowel resection significantly lowered the plasma IGF-I concentrations in two bowel-resected groups. This may be attributed to bowel resection-induced impairment of nutrient absorption as the mean body weights of these two groups were significantly decreased. Nevertheless, animals in GH-resect group had higher plasma IGF-I concentrations than those in control-resect group. This suggests that as a powerful stimulatory agent for IGF-I synthesis, GH is still effective in enhancing IGF-I synthesis even in condition of mild nutritional restriction.

GH and IGF-I can both exert marked anabolic effect, stimulate nitrogen accretion, and lean body weight gain even when nutrition supply is restricted mildly or moderately^[23]. Therefore, in our experiment, improved body weight gain in GH-resect group could at least partially result from the anabolic effect of GH. On the other hand, GH treatment stimulated the remnant small bowel

mucosa hyperplasia and increased the absorptive area of the remnant small bowel in GH-resect group. As adaptive enlargement of absorptive area of remnant small bowel is a major mechanism by which the absorptive capacity of the remnant small bowel can be enhanced^[24], it is reasonable to speculate that the nutrient absorption function of animals in GH-resect group was improved by GH treatment. The accelerated body weight gain in GH-resect group therefore is very likely due to the combined effect of increased nutrient absorption and improved anabolic metabolism.

The enterotrophic effect of GH observed in this study may well be mediated by GH-induced enhancement of local IGF-I production within the intestinal mucosa. Convincing evidence has shown that IGF-I is a very important intestinal growth factor. Systemic IGF-I administration increased rat small bowel mass in normal rat^[25], in parenterally fed rat^[26], in catabolic status induced by dexamethasone^[27], in compensatory intestinal mucosa hyperplastic status^[9], as well as in post-transplantational status^[28]. GH transgenic mice have increased expression of endogenous IGF-I locally within small bowel as well as increased plasma concentrations of IGF-I, whereas IGF-I transgenic mice have increased IGF-I serum level, local expression in small bowel, and secondary GH deficiency. However, the effects on small bowel growth are similar in these two transgenics^[20,29]. These observations suggest that IGF-I mediates most of the enterotrophic effects of GH. Besides, recent studies on IGF-I null mice have proved definitely that IGF-I is essential for postnatal somatic growth and mammary development in response to GH^[30,31]. These discoveries make it very possible that IGF-I mediates the enterotrophic effect of GH. In addition, recent gene targeting study has demonstrated that liver-derived IGF-I is not essential for normal postnatal growth^[32]. This discovery gives strong emphasis to the importance of IGF-I locally produced. In support, GH induced high serum IGF-I level is not necessarily associated with enhanced growth of peripheral tissues^[33,34]. Therefore, we deduce that IGF-I produced locally within intestinal mucosa mediates the enterotrophic effect of GH.

However, Vanderhoof and his colleagues have published conflicting data, which failed to prove the mitogenic effect of short-term GH administration on rat intestinal mucosa^[35,36]. Close examination of the experimental conditions revealed that in one of the two studies continuous subcutaneous infusion of rhGH at a dosage of $3\text{mg}\cdot\text{kg}^{-1}\cdot\text{day}^{-1}$ failed to produce significant change in serum concentrations of insulin-like growth factor (IGF) and IGF-binding protein-3 (IGFBP-3) whether the animals had undergone bowel transection or resection^[35]. On

the other hand, serum IGF-I and IGFBP-3 both are known to be up-regulated by serum GH concentration^[37]. So unaltered serum levels of IGF-I and IGFBP-3 may be taken as evidence for insufficient action of GH in their experiment. On the contrary, in our experiment rhGH at $11\text{IU}\cdot\text{kg}^{-1}\cdot\text{day}^{-1}$ was sufficient to increase rat plasma IGF concentration in bowel-resected rats. In another study the authors increased the dosage to $12\text{mg}\cdot\text{kg}^{-1}\cdot\text{day}^{-1}$, which produced significant increase in serum IGF concentration. However, they had not observed GH mitogenic action on intestinal mucosa^[37]. To interpret these phenomena, other difference in experimental conditions should be emphasized. First, the control of food-intake, both the presence and quantity of which have been established as important regulators of postransectional small bowel adaptive hyperplasia^[38,39]. Vanderhoof *et al* had employed pair-feeding to distinguish the effect of diet and GH, while our animals were fed *ad lib*. Though our preliminary observation indicated unremarkable difference in food-intake between the control-resect group and GH-resect group, at present, we cannot decide whether the effect of food-intake on intestinal proliferation in our experiment is involved in the effect of GH administration. Second, the ages of experimental animals were different, we and Shulman *et al* used adult rats while Vanderhoof *et al* used young rats. Therefore it is most possible that the responsiveness of intestinal mucosa to GH stimulation is influenced by age. These apparently inconsistent observations indicate the complexity of growth regulation of intestinal mucosa and warrant further studies to explore the influence of age and food intake on the enterotrophic effects of GH.

These findings of our animal experiment certainly cannot be used directly to extrapolate the condition in human beings. However, the possibility that patients with short bowel syndrome may be benefited by the same mechanism from GH administration during the early adaptation stage is of important clinical relevance. After massive small bowel resection, the adaptation of the remnant small bowel usually takes months to 2 years^[40,41]. Augmentation or acceleration of the adaptive process means not only less hospital care and expense on parenteral nutrition but also better well-being and life quality.

In summary, we have observed that GH administration stimulates remnant small intestinal mucosa proliferation though whether it is due to direct GH action on intestinal mucosa or due to indirect effect of increased food-intake induced by GH administration has not been clearly determined in this study. Early GH treatment may benefit patients immediately after massive small bowel resection.

Gu YP, Gu JY, Li JS. Pancreaticoduodenal transplantation with portal venous and enteric drainage in rats. *World J Gastroentero*, 2000;6(6): 914-916

INTRODUCTION

The use of combined pancreatic and renal transplantation in patients with diabetes and end-stage renal failure has gained widespread recognition as an acceptable treatment option. The prevailing method used for transplantation of the pancreas involves anastomosis of the graft's portal vein and the recipient's iliac vein to provide systemic venous drainage of the graft, and a duodenocystostomy to provide bladder drainage of exocrine secretions^[1]. Although graft survival rates have improved with the use of this technique, potential postoperative problems arise due to the physiologically abnormal exocrine and venous drainage of the pancreas allograft. Bladder drainage of exocrine secretions increased the loss of bicarbonate in the urine, creates electrolyte derangements, and contributes to dehydration leading to a state of metabolic acidosis^[2-4]. Pancreatic secretions drained into the bladder also provide a constant source of irritation to the bladder mucosa, accentuating the abnormalities associated with autonomic diabetic dysfunction. This environment subsequently led to recurrent hematuria, infection, and repeated episodes of graft pancreatitis^[5-7]. The method of pancreas transplantation with portal venous and enteric drainage can overcome these problems. One of the earliest series of portal pancreatic transplants was reported in 1984^[8]. Because of the complex surgical technique, big animal models were used widely in the pancreas transplantation research^[9-11], up to now, there has been only portal venous drainage in

segmental pancreatic transplantation in rats^[12]. In our study, we established an animal model of pancreaticoduodenal transplantation with portal venous drainage through the superior mesenteric vein and enteric drainage in rats in order to achieve a better understanding of the immunology and physiology of this graft.

METHODS

Inbred male Wistar rats (220g-330g body weight) were used as the recipients and the donors, the recipient weight was 50g higher or so than the donor. At the beginning, all recipients were measured for blood insulin concentrations using radioimmunoassay as previously described^[13], diabetes was induced by a single intravenous injection of streptozocin (Sigma Chemical Co, St. Louis, MO) at a dose of 55mg/kg. Rats with nonfasting plasma glucose levels of more than 22mmol/dL were used as recipients.

The donors received 5% glucose and 0.9% saline for 24 hours and the recipients received 2.5% glucose and 0.45% saline for 24 hours before surgery. They were anesthetized with an intraperitoneal injection of pentobarbital (40mg/kg) and chloral hydrate (160mg/kg i.p.) supplemented with the pentobarbital as required.

We used a modified method reported by Lee and Li^[14,15], to minimize graft trauma. Pancreaticoduodenum was harvested from the donor rats with an attached segment of donor's aorta including the superior mesenteric artery and celiac truncus as arterial inflow and the portal vein was maintained for venous outflow, and the proximal end of duodenum was ligated with 3-0 silk and the 2cm of distal duodenum was removed. The spleen arteries and veins were ligated with 5-0 silk, but did not remove the spleen. The graft was flushed with 2mL-3mL cold heparinized lactated Ringer's solution (25U/mL), removed, and stored in cold lactated Ringer's solution (4°C) until transplantation into the recipient rat. Finally, 2.5mL-3mL fresh blood was taken from the donor's abdominal aorta with 5U heparin.

All the recipients were given 8mL-12mL of 0.9% saline by subcutaneous injection and were opened via a middle incision. Segments of the recipient abdominal aorta were mobilized below the vessels to the left kidney. A modified Lee's clamp^[16] was placed across the aorta. The aorta was punctured with a 30 gauge needle and opened via a longitudinal arteriotomy. The lumen was flushed

with heparinized lactated Ringer's solution. The superior mesenteric vein was isolated at a low level. The superior mesenteric vein was controlled proximally with a microvascular clamp and was ligated distally with 5-0 silk and the superior mesenteric artery was ligated at the same level and manner. The superior mesenteric vein was cut off between the microvascular clamp and silk ligation point as closely as possible to the latter, and the lumen was flushed with heparinized lactated Ringer's solution. The ischemia small intestine (about 30%-40%) and ileocecum were removed, an end-to-end intestinal anastomosis was performed using one layer of full thickness 7-0 nylon suture. The donor graft was removed from the ice water and wrapped by a wet gauze sponge packed with ice crystals.

The venous anastomosis was made first. After ensuring that the vein was not twisted, an end-to-end anastomosis of the donor portal vein and the recipient superior mesenteric vein was made using 10-0 nylon interrupted suture. The vein was irrigated with saline to keep the vessel walls apart during the venous anastomosis and gently teased apart before tying the sutures to avoid stricture of this anastomosis. Next, an end-to-side arterial anastomosis of the donor arterial segment and the recipient abdominal aorta was performed using continuous 9-0 nylon suture. The venous clamp was released first, followed by the arterial clamp. The arterial anastomosis was compressed lightly with a dry sponge for 1-2 minutes after reperfusion. Finally, we performed an end-to-side intestinal anastomosis of the donor distal end duodenum and the recipient jejunal side and removed the donor spleen.

Twenty milliliters of warm saline was instilled in the peritoneal cavity prior to closing the abdomen, 2.5mL-3mL donor blood was injected via the dorsal penile vein as the final procedure.

The time for the donor surgery was about 45 minutes, and for the recipient surgery was 90 minutes, the vein anastomosis was 25 minutes and the arterial anastomosis 15 minutes.

The rats were kept on a warming blanket and under a heating lamp for the first 24 hours. They usually recovered from the anesthesia within 1 hour after the operation. They were given 30mL-40mL of 2.5% glucose and 0.45% saline daily containing 150mg piperacillin sodium by subcutaneous injections for the 36-48 hours, followed by normal diet accordingly.

RESULTS

We finished 67 cases of consecutive pancreatic transplantations with portal vein drainage through superior mesenteric vein and enteric drainage. Forty-six rats survived over 7 days, the success rate was 68.6%(46/67). The most common causes of postoperative deaths within the first few hours were

venous thromboses in the anastomosis (18.9%, 12/67). Eight deaths occurred due to hypovolemic shocks within the first 48 hours, one death due to enteric leakage. Rats that survived over 48 hours generally could survive indefinitely. The nonfasting plasma glucose levels of successful rats (91.3%, 42/46) were turned normal. Though the other four cases were still hyperglycosemia, the plasma glucose levels became significantly lower than the preoperative value. All successful 46 cases were measured for insulin concentrations again, the values did not change significantly.

DISCUSSION

Most patients with a systemically draining pancreatic graft displayed both hyperinsulinemia and insulin resistance, sensitivity and responsiveness to insulin in removing glucose decreased^[17]. In this model of pancreas allograft using venous drainage into portal vein and enteric drainage rather than systemic vein and bladder exocrine drainage, it is more closely approximated to enteric drainage and venous drainage of the pancreas allograft in physiology and to avoid the impairment of the first-pass removal of insulin by the liver, otherwise it leads to hyperinsulinemia and insulin resistance^[7,17,18]. Meanwhile, we chose the venous anastomoses at lower level of superior mesenteric vein without heparinizing the recipient rather than the portal vein in order to avoid the venous thromboses at high level and prevent the whole intestinal injury. Once the venous thrombosis happened, the graft could be removed without impairment of the recipient intestine, and the manipulation was rather easy.

The venous thromboses were the most common causes of postoperative deaths, the high blood flow through superior mesenteric vein and the technique of venous anastomosis were responsible for the venous thromboses. To overcome high blood flow through superior mesenteric vein, we took the following measures: ① the recipient was 50g heavier than the donor; ② remove 2cm of donor's distal duodenum; ③ ligate the donor spleen arteries and veins at operation. The end-to-end anastomosis of the donor portal vein and the recipient mesenteric vein was likely to be twisted and narrowed, we therefore, performed the venous anastomosis first and solved these problems readily.

It has been indicated that hypovolemic shock is the most common cause of deaths occurring immediately after transplantation in the small animal. Continuous rat intravenous infusion of the tail vein and the dorsal penile vein, were adopted by many colleagues^[19]. But we gave the recipient 8mL- 12mL of 0.9% saline by subcutaneous injection at the beginning and 2.5mL-3mL fresh blood via the dorsal penile vein as the final procedure^[19], instead of keeping long-time continuous intravenous infusion during the surgical

procedure. The 2.5mL-3mL donor blood could eliminate the most frequent causes hypovolemic shock of postoperative mortality after organ transplantation.

The enteric drainage of exocrine secretion can avoid the loss of bicarbonate in urine, otherwise which will result in eletrolyte derangements and dehydration, leading to a state of metabolic acidosis. These distinct advantages reduced postoperative complications markedly in rats, and provided a better understanding for the immunology and physiology of the pancreaticoduodenal transplantation. These are of important clinical significance.

Liu XL, Dai CC, Miao Y, Du JH, Zhang ZS, Chen SZ. Detection of *-ras* gene point mutation in fine needle aspiration and pancreatic juice by sequence special primer method and its clinical significance. *World J Gastroentero*, 2000;6(6):917-919

INTRODUCTION

The point mutation rate of *k-ras* gene at codon 12 in pancreatic adenocarcinoma is reported to be as high as 90%^[1-30], and with no mutations in normal pancreas tissues or other pancreatic disorders. We have detected the presence of *k-ras* gene mutation and its mutant styles since 1994 by PCR-SSP in the FNA or pancreatic juice obtained from pancreatic adenocarcinoma tissues.

MATERIALS AND METHODS

Sources of samples

Eighty-eight copies of samples were collected by fine needle aspiration preoperatively under ultrasound guidance or with direct viewing intraoperatively from January 1994 to December 1996, among which there were 35 pancreatic adenocarcinoma, 20 chronic pancreatitis, 8 ampullary carcinoma, 7 bile duct carcinoma, 6 insulinoma and 12 normal pancreas tissues. All the aspirates were routinely smeared, then mixed with 50μL lysis solution and stored in the Eppendorf tubes. Another 47 pancreatic juice samples were obtained by ERCP or puncturing from pancreatic duct intraoperatively or from external drainage postoperatively, including 17 pancreatic adenocarcinoma. The juice volume was more than 1.5mL. All the samples were immediately frozen in liquid nitrogen and stored at -70°C.

Preparation of samples

FNA samples The aspirates were quickly made into 2 - 5 pieces of smears for light microscopic observation. The other aspirates mixed with 50μL lysis solution were added in proteinase K, making the final concentration of 500mg/L. The mixture was then incubated at 55°C for 2 hours and put into water bath at 95°C for 10 minutes to inactivate proteinase K, then 15μL supernatant was collected after centrifugation for PCR detection.

Pancreatic juice samples Pancreatic juice was put into 1.5mL Eppendorf tube and underwent high speed centrifugation. Some parts of the sediments were used for smears (2-5 pieces), the residual parts were completely washed with PBS, centrifuged and added 50μL lysis buffer solution. The subsequent procedures are the same as used in FNA specimens.

PCR detection

Our primers were synthesized and supplied by Shanghai Bio-Engineering Research Center. The sequences of primers were: R1=5'GGTAGTTG-GAGCTC3', R2=5'GTAGTTGGAGCTGT3', R3=5'GTAGTTGGAGCTGA3', R4=5'CTATTGTTG-GATCAT ATTCG3'. The primers combination were R1-R4 to amplify 89bp fragment of CGT mutation and R2-R4, R3-R4 to produce 88bp fragments of GTT and GAT mutation respectively. The PCR kits were purchased from Shanghai Huamei Biological Products Corporation (PCR KitA system) and the DNA amplifier is the Perkin-Elmer 2400 model. The reaction volume was 50μL containing 50mmol/L KCl, 10mmol/L Tris-HCl pH = 8.5, 1.7mmol/L MgCl₂, 0.01% gelatin, 0.08% Triton-X-100, 1.0μmol/L of each primer, 200μmol/L of each dNTP and 1.5 units of Taq DNA polymerase. Three amplification reactions were performed for each sample. There were 35 circles including denaturation at 94°C for 45 seconds, annealing at 55°C for 45 seconds and extension at 72°C for 45 seconds. Each reaction was set with positive and negative control, the primers and templates of positive control were included in the PCR kitA system. The template was prepared from human genome DNA with its amplification fragment of 110bp. Fifteen μL amplifying products were loaded on 8% acrylamide gel electrophoresis under 120 volts for 50 minutes, stained with ethidium bromide

and then observed, and photographed under UV transillumination.

RESULTS

PCR findings

There were 32(91.4%) positive cases and 3(8.6%) negative ones in FNA samples of pancreatic adenocarcinoma. The mutant styles included 15 GTT, 11 GAT and 6 CGT. Among the 17 pancreatic juice specimens, 16 (94.1%) were positive and 1 (5.9%) negative with 9 cases of GTT, 4 GAT and 3 CGT. No mutations occurred in aspirates or pancreatic juice specimens of insulinoma, chronic pancreatitis, ampullary carcinoma, bile duct carcinoma, duodenal papilla carcinoma and normal pancreas tissues.

Cytological results (Table 1)

Table 1 Cytological findings of FNA and pancreatic juice in PA, AC and BDC

	FNA(No. %)				Pancreatic juice (No. %)			
	No	P	SP	N	No	P	SP	N
PA	35	20(57.1)	9(25.7)	6(17.2)	17	2(11.8)	2(11.8)	13(76.4)
AC	8	4(50.0)	2(25.0)	2(25.0)	3	0(0)	0(0)	3(100.0)
BDC	7	4(57.1)	2(28.6)	1(14.3)	3	0(0)	0(0)	3(100.0)

FNA=fine needle aspirates, PA = pancreatic adenocarcinoma, AC = ampullary carcinoma, BDC = bile duct carcinoma, P = positive, SP=suspicious positive, N = negative

DISCUSSION

Comparison of different methods for detecting k-ras gene point mutation in pancreatic adenocarcinoma

It has been reported that the k-ras gene at codon 12 had a high incidence of mutation in pancreatic adenocarcinoma, usually presented with CGT, GTT, and GAT styles, occasionally showed TGT, AGT ways. At present, the available methods for detecting its mutation include PCR-RMCA^[1,2], PCR-ASO^[3-11,24-26], PCR-DSM^[12-17], PCR-SSP^[18,31], PCR-RFLP^[17,19-27,33] and PCR-SSCP^[28-30,32], among which PCR-SSP is the simplest and quickest one. No enzyme cut, hybridization, radioactive and non-radioactive imaging technique were needed. It only took a few hours to complete the entire procedure. Tada *et al* collected 9 samples of pancreatic juice for detection by PCR-SSP in 1993^[18]. The results showed that all the 6 cases of pancreatic adenocarcinoma had positive findings and one cholelithiasis, two chronic pancreatitis had no mutation. The number of samples, however, was too small to have any statistical significance. We have used the PCR-SSP method on FNA and pancreatic juice samples of pancreatic adenocarcinoma since 1994. The point mutation rate of k-ras gene was 91.4% and 94.1% respectively without false positive.

Comparison of FNA and pancreatic juice cytological results with PCR-SSP findings

Currently, the accuracy rate for diagnosis of pancreatic neoplasms by FNA technique is about 58%-83%, and the positive rate of pancreatic juice cytology is less than 10%. Our research in FNA and pancreatic juice cytology also supports these results. It indicates that PCR-SSP has advantages in the differential diagnosis of benign and malignant pancreatic diseases compared with cytological examination, but it has little diagnostic value in ampullary carcinoma and bile duct carcinoma.

Significance of detecting k-ras gene point mutation by PCR-SSP

Pancreatic adenocarcinoma is one of the commonly encountered tumors and the incidence is increasing with age. By now there has been no satisfactory method for early diagnosis. It is still very difficult to define the character of the pancreatic mass and to differentiate between tumor-like pancreatitis and pancreatic adenocarcinoma or chronic pancreatitis and whole-pancreas adenocarcinoma. The commonly used imaging examinations (such as type B ultrasound, CT) have no qualitative diagnostic value. Determination of serum tumor markers (CA19.9, CA50, CA242, etc.) has only 60%-70% sensitivity or specificity and the false positive rate may be as high as 30%-40%. The positive rate of pancreatic juice cytology is too low (<10%) and FNA method could yield indefinite results because of the insufficient samples or atypical cellular manifestation. It is, therefore, helpful for us to use PCR-SSP technique to detect the point mutation of k-ras gene at codon 12 when we are not sure about the diagnosis of pancreas disorders. It may serve as a practical method for distinguishing pancreatic benign masses from malignant ones, and making a definitive diagnosis of pancreatic adenocarcinoma.

INTRODUCTION

Acute pancreatitis is a common and potentially fatal disease which is associated with considerable morbidity and a mortality rate of approximately 30%; its pathogenesis remains unknown^[1]. The cause of death is often due to multiple organ failure which frequently complicates severe acute pancreatitis. In particular, acute lung injury often occurs at an early stage of severe acute pancreatitis and develops into adult respiratory distress syndrome (ARDS)^[2,3].

Numerous studies have been done to clarify the mechanisms of acute lung injury in AHNP. Activated leukocytes and inflammatory mediators, such as interleukin-1 and tumor necrosis factor α -have been suggested to play a predominant role in the development of acute lung injury in AHNP^[4-6]. Further investigation have found that pretreatment of mice with antineutrophil serum results in reduction of severity of pancreatitis and complete prevention of lung injury^[7]. More recently, Hofbauer *et al*^[8-10] postulated that the pancreatitis-associated lung injury (PALI) might be dependent on the continued generation and action of platelet-activating factor (PAF). Yamaguchi *et al*^[11] have suggested that the PAF antagonist TCV-309 effectively prevented cytokine-induced neutrophil chemoattractant expression by bronchoalveolar macrophages and subsequent PALI. Furthermore, attenuation of pancreatitis and prevention of PALI could be achieved with recombinant PAF acetylhydrolase. P-selectin is a key determinant of

leukocyte recruitment, which is upregulated in the pulmonary endothelium during acute pancreatitis^[12]. However, detailed mechanisms of acute lung injury in AHNP has not been elucidated.

In the current study, sodium taurocholate-induced pancreatitis rat models was used to investigate the apoptosis of alveolar epithelial cells and expression of apoptosis-regulated gene in PALI, and the relationship between TGF β_1 and apoptosis.

MATERIAL AND METHODS

Material and chemicals

Sodium taurocholate was obtained from Sigma Chemical Co.(USA). *In situ* cell death detection kit, POD was purchased from Borehinger Mahheim Co. (Germany), proteinase K was from Merck Co.(USA), the purified goat anti-bax polyclonal antibody and mouse anti-p53 monoclonal antibody were from Santa Cruz Biotechnology Inc. (USA), the goat anti-TGF β_1 polyclonal antibody was from Promega Co.(USA), and immunochemical SP kit was from Biotech Co.(USA). Other materials and chemicals were obtained from commercial sources.

Animals

Male Wistar rats, weighing 200g-250g, were used. Animals were bred and housed in standard cages in a climate-controlled room with an ambient temperature of 22°C \pm 2°C and a 12-hour light/dark cycle. They were fed standard laboratory chow, given water *ad libitum*, and fasted overnight before each experiment.

Models for pancreatitis

Male Wistar rats were anesthetized with 2.5% pentobarbital (0.1mL/100g body weight intraperitoneally). A midline laparotomy was performed, followed by the ligation of the bile-pancreatic ducts close to the liver and duodenum. Then pancreatic duct was retrogradely injected 5% sodium taurocholate (0.1mL/100g body weight) for 1 minute, and stagnant for 4 minutes. For control, sham operation or retrograde infusion of normal saline into the pancreatic duct was performed as described above, 2, 5 and 14 hours after sodium taurocholate infusion, laparotomy was performed again and blood samples were collected aseptically from the abdominal aorta. The pancreas and right lung were rapidly removed and fixed in 10% neutral phosphate buffered formalin for histological study. Pancreatitis was confirmed by measuring amylase levels before and after the

experiment and by histological examination.

Serum amylase activity

Serum amylase activity was measured by a chromogenic method with the phadeba amylase test.

Detection of apoptosis

Morphological examination Paraffin-embedded pancreas and lung samples were sectioned (4 μ m), stained with hematoxylin/ eosin (H & E), and examined by an experienced morphologist who was unaware of the sample identity^[13,14].

TUNEL on light microscope TdT-mediated dUTP nick-end labeling (TUNEL) was performed according to the method of Gavrieli *et al*^[15,16] with some modification. Briefly, the sections were deparaffinized by heating for 20 minutes at 60°C, rehydrated in descending concentrations of ethanol (100%, 95%, 90%, 80%) and then immersed in double distilled water (DDW). After rehydration, the sections were incubated with 20mg/L proteinase K for 15 minutes at room temperature. The slides were washed in DDW for 2 minutes 4 times and covered with 0.3% hydrogen peroxidase in methanol for 30 minutes at room temperature to inactivate endogenous peroxidase. The slides were rinsed with phosphate-buffered saline (PBS, pH 7.4) 5 minutes three times and incubated the slides to 50 μ L TUNEL reaction mixture for 60 minutes at 37°C. After washing in PBS, the slides were incubated with 50 μ L Converter-POD for 30 minutes at 37°C. The reaction products were visualized by immersion in diaminobenzidine solution. For positive controls, TUNEL was performed after deoxyribonuclease treatment. For negative controls, TUNEL was performed with labeling solution instead of TUNEL reaction mixture. Observations and photographs were made using an Olympus microscope. TUNEL positive nuclei were counted in fields ($\times 40$) magnification chosen at random, and the number of labeled nuclei per total nuclei in those fields was expressed as the apoptotic index (AI).

Immunohistochemical staining Immunohistochemical staining was performed to explore the expression of apoptosis-regulated gene bax and p53, as well as TGF β_1 . Consecutive 4 μ m paraffin-embedded tissue sections were subjected to immunostaining with streptavidin peroxidase technique. The sections were deparaffinized, rehydrated in descending concentrations of ethanol and then digested by incubation with 0.1% trypsin for 20 minutes at 37°C. Tissue sections were submerged for 15 minutes in 0.1M PBS containing 0.1% Triton X-100. Endogenous peroxidase activity was blocked by incubating the slides with 0.3% (vol/vol) H₂O₂ in methanol, followed by washing in PBS. The sections were incubated for 30 minutes

at room temperature with normal goat serum before overnight incubation at 4°C with either goat anti-bax polyclonal antibody diluted 1:50 in PBS, mouse anti-p53 monoclonal antibody diluted 1:50 in PBS or goat anti-TGF β_1 polyclonal antibody diluted 1:100 in PBS. After washing in PBS, slides were treated with biotinylated link immunoglobulins biotinylated goat anti-mouse IgG antibody was used for bax and p53 staining. The slides were then incubated for 30 minutes with streptavidin-biotin-peroxidase complex and were visualized by a 10 minutes application of diaminobenzidine substrate. The sections were counterstained with hematoxylin to identify nuclei and observed under a light microscope. It was judged that positive staining nuclei were brown, and immunolocalized nuclei. The positive rate of bax and p53 were counted in fields (40 \times) magnification chosen at random, and the number of positive staining nuclei per total nuclei in those fields was expressed as the positive rate.

Statistical analysis

Results were expressed as the mean and standard error of the mean (SEM). The significance of changes was evaluated by using Student's *t* test when the data consisted of only two groups or by analysis of variance (ANOVA) when comparing three or more groups. A *P* value <0.05 indicated a significant difference.

RESULTS

Acute hemorrhagic necrotizing pancreatitis

AHNP was manifested by a rise in serum amylase activity and morphological evidence. In all animals a marked elevation of serum amylase levels was observed at 2, 5, and 14 hours after sodium taurocholate infusion. The morphological changes were observed after sodium taurocholate infusion and included obvious acinar cell necrosis, fat necrosis, extensive neutrophils infiltration, microthrombosis of pancreatic vessels and massive intralobular hemorrhage. In addition, 1 rat (25%) died before the end of the experiment (14 hours after sodium taurocholate infusion), whereas other animals survived the entire observation period.

Histological findings

The morphological changes observed in lung included pronounced interstitial edema associated with massive neutrophils infiltration, alveolar wall thickening and foci of vascular thrombosis in large vessels. Simultaneously, increase of pulmonary microvascular permeability was found.

Evidence of apoptosis

Morphological examination In the H&E staining, alveolar epithelial cells presented pyknotic nuclei, cell shrinkage, condensation of chromatin and formation of apoptotic bodies, etc. which were the typical morphological features of apoptosis.

Figure 1 (PDF) AI of alveolar epithelial cells in sodium taurocholate-induced pancreatitis-associated lung injury. AHNP was induced by retrograde injections into the pancreatic ducts of 5% sodium taurocholate (0.1mL/100g body wt) in rats. Results shown are the MEAN±SEM for four or more animals in each group. Asterisks indicates ^b $P<0.01$ when the AI of alveolar epithelial cells at 5 hours after induction of AHNP compared with 2 and 14 hours after induction of AHNP.

Figure 2 (PDF) The positive rate of bax and p53 protein in alveolar epithelial cells after sodium taurocholate-induced pancreatitis-associated lung injury. AHNP was induced by retrograde injections into the pancreatic ducts of 5% sodium taurocholate (0.1mL/100g body wt) in rats. Results shown were the MEAN±SEM for four or more animals in each group. Asterisks indicates ^a $P<0.05$ when the positive rate of bax protein in alveolar epithelial cells at 5 hours after induction of AHNP compared with 2 and 14 hours and the positive rate of p53 protein in alveolar epithelial cells at 2 hours after induction of AHNP compared with 5 and 14 hours.

Figure 3 (PDF) The positive rate of TGFβ₁ in alveolar epithelial cells after sodium taurocholate-induced pancreatitis-associated lung injury. AHNP was induced by retrograde injections into the pancreatic ducts of 5% sodium taurocholate (0.1mL/100g body wt) in rats. Results shown were the MEAN ± SEM for four or more animals in each group. There was no significant difference among the positive rate of TGFβ₁ at 2, 5 and 14 hours after induction of AHNP.

TUNEL staining As shown in Figure 1, TUNEL selectively labeled alveolar epithelial cells nuclei. The apoptotic index of alveolar epithelial cells at 2,

5, and 14 hours after induction of AHNP were $0.33\% \pm 0.7\%$, $0.89\% \pm 0.06\%$ and $0.54\% \pm 0.08\%$, respectively. Moreover, the apoptotic index of alveolar epithelial cells at 5 hours after induction of AHNP was significantly higher than those of 2 and 14 hours ($P<0.01$).

Immunohistochemical detection of bax and p53 protein

As shown in Figure 2, the positive rate of bax protein in alveolar epithelial cells at 2, 5 and 14 hours after induction of AHNP were $0.38\% \pm 0.11\%$, $0.67\% \pm 0.13\%$ and $0.39\% \pm 0.03\%$, respectively. Similar to AI of alveolar epithelial cells, the positive rate of bax protein in alveolar epithelial cells at 5 hours after induction of AHNP was similarly markedly higher than those of 2 and 14 hours ($P<0.05$). In this study, the positive rate of p53 protein in alveolar epithelial cells at 2, 5, and 14 hours after induction of AHNP were $0.72\% \pm 0.29\%$, $0.28\% \pm 0.08\%$ and $0.32\% \pm 0.04\%$, respectively. The positive rate of p53 protein in alveolar epithelial cells significantly decreased at 5 and 14 hours after induction of AHNP compared with that of 2 hours ($P<0.05$).

Immunohistochemical detection of TGFβ₁ Immunohistochemical staining of TGFβ-1 was scarcely detected in normal lung tissues. As shown in Figure 3, although the positive rate of TGFβ-1 in alveolar epithelial cells at 2, 5, and 14 hours after induction of AHNP were $0.35\% \pm 0.14\%$, $0.39\% \pm 0.15\%$ and $0.48\% \pm 0.12\%$, respectively, no significance difference was observed among them.

DISCUSSION

Acute lung injury and adult respiratory distress syndrome (ARDS) are frequently observed during the course of severe acute pancreatitis. The pathogenesis of PALI remained unclear. Bhatia *et al*^[17] reported that neurogenic factors, such as substance P, increased release of proinflammatory mediators from the pancreas leading to increase lung injury by acting via NK1R on acinar cells. Recent studies^[18] have suggested that intercellular adhesion molecule 1 (ICAM-1) expression on pulmonary microvascular endothelial cells during pancreatitis contributed to the evolution of PALI by promoting neutrophil sequestration within the lung. Moreover, treatment with monoclonal antibodies against ICAM-1 significantly reduced the lung injury in severe acute pancreatitis^[19]. Very recently, Tsukahara *et al*^[20] noted that alveolar macrophages were activated by PLA₂, mainly by sPLA₂ type II, and produced a large amount of NO that contributed to lung injury in acute pancreatitis. Further studies had suggested that the lung injury was reduced by the administration of the PLA₂ inhibitor. Recent studies showed that the absence of T and B lymphocytes could prevent severe pulmonary injury resulting from acute pancreatitis, this indicated that

systemic lymphocyte activation modulated the systemic response, in particular, pulmonary injury caused by acute pancreatitis^[21]. Apoptotic cell death of renal tubules and hepatocytes have been reported to be involved in the mechanisms of renal failure and liver failure during severe acute pancreatitis^[22,23]. Although numerous trials had been done to clarify the mechanisms of pancreatitis-associated lung injury, there was no literature referring to involvement of apoptosis in pancreatitis-associated lung injury.

Apoptosis was initially confirmed as a specific form of cell death that served to eliminate excessive or unwanted cell types during embryogenesis and normal tissue growth^[24], but had been recently clarified to be induced in cellular injury with inflammatory disease^[25]. It was generally believed that apoptosis was a genetically regulated form of cell death, and pyknotic nuclei and formation of apoptotic bodies were the typical features of apoptosis^[26,27]. In the current work, we selected two apoptosis-regulated gene bax and p53, which were confirmed to be involved in the control of apoptosis. Proapoptotic gene bax, one of the members of apoptosis-regulated gene bcl-2 family, was a dominant inhibitor of bcl-2 and promoted cell apoptosis^[28-30]. Tumor suppressor gene p53 was a special related gene with activation of cell-cycle arrest and apoptosis^[31,32]. A very important role of normal or wild type p53 as a "guardian of the genome" was capable of inducing apoptosis upon DNA damage. Recent studies suggested that activation of NF-kappa B activity augmented p53-induced apoptosis^[32]. On the contrary, mutant p53 failed to initiate apoptosis process, so mutant p53 was thought to have effect on apoptosis inhibition. More recently, Buckley *et al*^[33] demonstrated that apoptosis via induction of p53, p21, and bax proteins was seen in alveolar epithelial cells cultured from hyperoxic rats, and apoptosis might be a protective mechanism that limits lung injury^[34].

TGF β family in mammalian cells was comprised of at least three homologous polypeptides that could regulate a variety of cellular functions, including proliferation and differentiation processes^[35,36]. Recently, some investigators reported that TGF β_1 could induce apoptosis in normal and malignant cells^[37,38]. It was demonstrated that the induction of apoptosis by TGF β_1 was due to the regeneration of reactive oxygen species in the cells, the involvement of caspase family proteases^[39-41], induction of p53 and bax^[37], or expression of TIEG (TGF β inducible early gene)^[42-44]. In this study, we sought to explore the potential relationship between TGF β_1 and apoptosis of alveolar epithelial cells in pancreatitis-associated lung injury.

We found that the apoptotic index of alveolar epithelial cells at 5 hours after induction of AHNP was significantly higher than those of 2 and 14 hours

($P < 0.01$), and the positive rate of bax protein in alveolar epithelial cells at 5 hours was markedly higher than those of 2 and 14 hours after induction of AHNP ($P < 0.05$). Interestingly, the positive rate of bax protein in alveolar epithelial cells was paralleled to the AI of alveolar epithelial cells in pancreatitis-associated lung injury. The positive rate of p53 protein in alveolar epithelial cells dramatically decreased at 5 and 14 hours after induction of AHNP compared with 2 hours ($P < 0.05$). Similarly, the positive rate of p53 protein in alveolar epithelial cells was intended to parallel to the AI of alveolar epithelial cells in PALI. Immunostaining of TGF β_1 was detected at 2, 5 and 14 hours after induction of AHNP, no significant difference was observed among them. Our data demonstrated that apoptosis of alveolar epithelial cells might be mediated by apoptosis-regulated gene bax and p53, but TGF β_1 was not implicated in apoptosis of alveolar epithelial cells.

In summary, apoptosis of alveolar epithelial cells might be involved in PALI, and the mechanisms of apoptosis probably correlates with the expression of apoptosis-regulated gene bax and p53 but is not related with the expression of TGF β_1 . Recent studies^[45] have suggested that mild pancreatitis was found to be associated with extensive apoptotic acinar cell death while severe pancreatitis was noted to involve extensive acinar cell necrosis but very little acinar cell apoptosis. More recently, some investigators^[46-48] have found that induction of apoptosis in pancreatic acinar cells attenuates the severity of experimental acute pancreatitis. Furthermore, Kaiser *et al*^[45] have demonstrated that inhibition of apoptosis by administration of cyclohexamide could enhance the severity of pancreatitis. These data have led to the concept that pharmacological induction of apoptosis in pancreatic acinar cell injury to reduce inflammatory reaction provides a new therapeutic strategy for the treatment of acute pancreatitis. Very recently, we found that the mechanisms of SSA in treating acute pancreatitis might be induction of apoptosis in pancreatic acinar cell injury to reduce inflammatory response^[49].

Future studies for clarifying the initiators, regulators, genetic control and signal transductal pathway of apoptosis of alveolar epithelial cells, would be able to reveal the pathogenesis of PALI, and further elucidate the role of apoptosis of alveolar epithelial cells in PALI.
