INTRODUCTION

Liver fibrosis or cirrhosis is a common progressively pathological lesion of chronic liver diseases in response to various liver-damaging factors. The main mechanisms of fibrotic or cirrhotic initiation and progression at the level of cellular and molecular events have been elucidated in the past two decades[1,2]. Various causes, including hepatitis virus infections, toxification, ischemia, congestion, parasites infection, abnormal cooper or iron load, etc, result in chronic inflammation and/or wound healing responses, of which the main characteristics manifest in the absolute increase of the excessive extracellular martrix (ECM) synthesis and the relative decrease of them, leading to ECM deposit. With the stimulation of inflammation or toxins, activated hepatic stellate cells(Ito cells), injuried or regenerated hepatocytes, Kupffer cells, sinusoidal cells and natural killer (NK) cells produce certain cytokines or immunoreactive factors, which exert various biological effects on their respective target cells or organs in an autocrine or paracrine manner. These consist of the cellular basis of hepatic fibrosis advances[3,4]. It is the vital molecular event in fibrosis progression that activated hepatic stellate cell exocrine ECM components and fibrosis-implementing factors, for example, the transforming growth factor β (TGF-β), which is considered the key cytokine to accelerate cirrhotic procession[5,6]. Various factors participate in fibrosis or cirrhosis formation. They could be simply divided into the fibrosis-implementing factors, such as TGF-β, platelet-derived growth factor (PDGF), epithelial growth factor (EGF), and antifibrotic factors, such as interferon γ and interleukin-10. These cytokines play important and unique roles in the interactive complicated network. Excessive ECM deposit, disappearance of sinusoidal endothelial fenestra and subsequent capillary vascularization cause the dysfunction of hepatocytes. The unblocked progressively pathological lesions with inevitably result in, lobular reconstruction, pseudolobule formation and nodular regeneration. With the elucidation of vital cellular and molecular events, gene delivery strategies for treatment of liver fibrosis or cirrhosis emerge on the basis of gene manipulations. Our interest focuses on the recent advances of gene therapy for liver fibrosis or cirrhosis.

Effective antifibrotic treatments, including medicinal or gene therapy, should satisfy several essential criteria. First, any therapy should have a sound biological basis. Additionally, the pharmacologically active drugs or compounds should reach or reside in the liver at a high concentration and have little side effect outside the liver. Specific targeting to hepatic stellate cells were preferentially chosen. Finally, in the ideal case, a therapeutic agent should keep the regional target environment for a relatively long period[7].

BLOCKADE OF TGF-β SIGNALING

It has been demonstrated that TGF-β is of great importance in fibrogenesis, and serves as a pivot in regulation of fibrogenic and antifibrogenic mediators. TGF-β exhibits stimulatory or inhibitory properties on cellular proliferation and differentiation, and is considered to represent a fundamental regulatory molecule acting through autocrine and/or paracrine mechanism[8].

TGF-β is clearly associated with hepatic fibrogenesis and cirrhosis in experimental animal models and in human liver diseases[9,10]. It regulates the gene expression of Ito cells, which in the course of liver fibrogenesis, proliferate and transform into the myofibroblast-like cells, synthesizing large amounts of connective tissue components, and also being involved in the ECM degradation by production of matrix metalloproteinases (MMP) inhibitors of MMP (TIMP), etc[11-13]. Because of the key role of TGF-β and Ito cells in the procession of liver fibrogenesis, lots of studies focus on their

interactions. In *in vitro* studies, Ito cell cultures were found to be activated by TGF-β to increase the production of collagen type I, II, III, fibronectin, undulin and proteoglycans[14-16]. TGF-β enhanced the Ito cell transformation from resting to activated cells and inhibited Ito cell proliferation[17]. TGF-β signaling was mediated by specific receptors located on the target cell membrane. In non-activated Ito cells, type II and III were present, while in activated Ito cells, there were TGF-β/ activin receptor type I, II and III[18,20].

All the above showed clearly that anti-TGF-β intervention which could block the TGF-β signaling pathway may prevent liver fibrosis. Such interventions have come into being up to date. Qi *et al* have developed adenovirus-mediated gene transfer to rat liver for expressing a truncated type II TGF-β receptor[21]. It inhibits TGF-β activity by competing with binding of the cytokine to endogenous TGF-β receptors. The expression vector, AdCAT β-TR, was administrated via the portal vein for ensured infection and high-level expression in regional liver tissue.

Apparently, there needed a large excess of truncated receptor over the wild type full-length receptor for effective inhibition of TGF-β signaling[22,23]. Three days after AdCAT β-TR administration, two mRNAs corresponding to the truncated human receptor and the rat full-length receptor (5.5kb and 0.9kb) were detected respectively, and the former mRNA was about 20-fold that of the latter. Pathological examination showed that the extent of liver fibrosis, collagen type I, fibronectin, alpha smooth muscle actin (α-SMA), TGF-β 1 and monocytes/macrophages (ED-1) decreased significantly in AdCAT β-TR administration group. This inhibitory effect was observed in all areas of the liver. The content of liver hydroxyproline had no significant difference between AdCAT β-TR group and the intact group, while in the control group of dimethylnitrosamine (DMN)-treated persistent fibrotic rats, the amount of hydroxyproline was 3.4 times higher than that of the above two. It was evident that the activation of Ito cells and Kupffer cells was inhibited, suggesting that truncated type II TGF-β receptor gene transfer could prevent or abolish liver fibrogenesis effectively. More important, liver function of rats with AdCAT β-TR injection recovered with a marked decrease of serum hepatocyte enzyme AST and ALT[21].

Reports from Ueno *et al*[24] supported Qi *et al*'s results as well. They conducted an recombinant adenovirus expressing the entire extracellular domain of the human type ¢ò TGF-â receptor fused to the Fc portion of human immunoglobulin G (AdTβ-ExR) to produce a circulating soluble form of TGF-β receptor with remote vital organ targeting after intramuscular injection of AdT β-ExR. Soluble TGF-β receptor was detectable in circulation and its level peaked at 5-7 days after the injection. AdT β-ExR-infected COS cells secreted fused type II TGF-β receptors, which binded to TGF-β and consequently blocked the TGF-β signaling as the full-length TGF-β receptor did[24]. Injection of AdT β-ExR into the femoral muscle of DMN-induced fibrotic rats prevented hepatic fibrosis, while no side effects or complications were found either macroscopically or microscopically in the main organs including brain, heart, lung, liver and kidney. Histological examination in DMN-treated rats with i.m. injection of AdT β-ExR was essentially as the same as that in Qi *et al*'s report, which locally expressed truncated type II TGF-β receptor in the liver via the administration of AdCAT β-TR into the portal vein[21,24]. This research also disclosed that adenovirus-mediated expression of soluble TGF-β receptors exerted the binding effect to TGF-β in a TGF-β specific manner, that is, others, e.g., PDGF α-receptor and fibroblast growth factor (FGF), could not interfere with TGF-β. Although a large excess of soluble TGF-β receptor seems essential for blocking of TGF-β signaling, there was still apparent difference between specific soluble TGF-β receptor and non-receptor-specific binding proteins, e.g., decorin (would prevent TGF-β induced renal fibrosis), for blockade of TGF-β signaling[25]. Because the latter was lack of receptor specificity and selectivity when it binded to TGF-β, it may bind to other biological molecules, probably resulting in unexpected problems. More exact mechanism was also explored[26-29]. There was evidence that truncated type II TGF-β receptor may form a complex with other type TGF-β receptor and inhibit both the anti-proliferative effect of TGF-β and/or the transcriptional activation by TGF-β[30-31]. Each type of three TGF-β receptor isoforms may have its own distinct signaling pathway, each mediating a separate action setting of TGF-β[31]. Complete inhibition of TGF-β signaling was achieved via local expression of a kind of soluble TGF-β receptor in a remote area from the target organ. The fact suggested that such strategy should be applicable theoretically and therapeutically for other factors belonging to growth factor superfamily.

As a matter of fact, signaling pathways introduced by PDGF, FGF, epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), insulin, etc, could be abolished specifically by their corresponding kinase-defective mutated form of receptors[23,32-36]. This kinase-defective or kinase-truncated receptors for signal transduction blockade of their growth factor may be a useful strategy for analysis of the *in vivo* role of these growth factors, because signaling pathway was blocked at the receptor level, not at the cytokine or gene level, without affecting the normal physiological status of these growth factors or signal transfer of other receptors[21,22,37]. Although no side effects were found during the study period, special attention should be paid to the surveillance

of the possible hazards, since Shull *et al* had demonstrated that there would be multifocal inflammation and tissue necrosis in TGF-β gene disrupted mice[38]. Adenovirus displayed the high degree of hepatotrophic activity. It could also mediate the targeted expression even if it was administrated in a remote site[21,24]. Immune responses would be elicited after repeated injection of adenovirus particles, therefore may lower the effectiveness of target gene expression.

STIMULATION OF HEPATOCYTE REGENERATION

In the course of liver fibrosis, the absolute and relative volume of hepatocytes was both reduced under the direct or indirect effect of liver-damaging factors. Stimulation of hepatocyte regeneration is the essential strategy in choice of treatment. Hepatocyte growth activators include an expanding list of complete mitogen and comitogen. Complete mitogen are defined as those that are capable of stimulating DNA synthesis and mitosis of cultured hepatocytes in serum-free media. Hepatocyte growth factor (HGF), EGF, TGF-α, and keratinocyte growth factor are in this category. Comitogens enhance the stimulatory action of complete mitogens and decrease the inhibitory effect of other inhibitors, while they have no direct proliferation-enhancing effect on cultured hepatocytes, including glucagon, insulin, insulin-like growth factors, adrenal cortical hormones, vasopressin, angiotensin, thyroid and parathyroid hormones, norepinephrine, as well as calcium and vitamin D[39]. HGF was regarded as the strongest hepatocyteproliferative agent up to date. It was a pleiotropic factor with potent morphogenic, mitogenic and motogenic effects and has anti-apoptotic action on hepatocytes and other several cells in culture, exhibiting a plethora of effects in many systems and organs[40-49]. The antifibrotic effect of HGF on hepatic fibrosis was first characterized by Yasuda *et al*[50]. In their experiment, the deletion variant of hepatocyte growth factor (dHGF) which was more mitogenic than full-length HGF, was used to examine its role in preventing fibrosis induced with dimethylnitrosamine in rats. Northern hybridization and immunohistochemical staining elucidated clearly the antifibrotic effect of dHGF on DMN-treated rats. The main mechanism appeared to be suppression of Ito cell activation, as demonstrated by the reduction of mRNA of procollagen α2(I), α1(III), α1(IV), TGF-β, desmin and α-SMA. Collagen content, as measured by hydroxyproline, was also decreased. Futhermore, dHGF exerted the mitogenic and antifibrotic activities even after the hepatic fibrosis had been established with DMN[50]. Their study showed that the antifibrotic effect of dHGF is not derived from the possible effect of dHGF on cytochrome P450-dependent metabolic degradation of DMN, but from the ability of dHGF to reduce or inhibit the TGF-β mRNA level[50,51], proliferation and activation of lipocytes and to stimulate liver regeneration[50]. Burr *et al* also demonstrated the vital role of HGF in liver regeneration[52]. After treatment with anti-HGF monoclonal antibody, the serum level of immunodetectable HGF was inhibited, as well as the parenchymal proliferative response to acute CCl_4-induced liver injury. Ueki *et al* developed a novel new gene therapy approach for rat liver cirrhosis by muscle-mediated gene transfer of HGF cDNA[53]. Plasmid containing HGF cDNA was embedded in the liposome, fused to the envelope protein of hemagglutinating virus of Japan (HVJ). This HVJ-liposome complex was intramuscularly injected repeatedly to achieve therapeutically detectable expression level of HGF. Repetitive administration resulted in a sound level of human HGF and increased level of endogenous rat HGF. The number of proliferative cellular nuclear antigen (PCNA) positive cells in HVJ-liposome-HGF injection group was markedly higher than that of control group. Apoptotic hepatocytes decreased significantly as well. The c-met, HGF-specific receptor located on the surface of hepatocytes, increased considerably in HVJ-liposome-HGF treated rats and stayed at this high level even after the repeated DMN administration, meanwhile strong tyrosine phosphorylation of c-met was observed. Immunohistochemistry revealed that with the administration of HVJ-HGF-liposome, staining of TGF-β1, expressed notably in persistent cirrhotic liver, decreased, as well as desmin and α-SMA, which were indicators of activated Ito cells. It suggested that expressed HGF could inhibit activation of Ito cells, decrease the synthesis of collagen type I and TGF-β, and prevent apoptosis of hepatocytes induced by DMN administration. After several injections of HVJ-HGF-liposome, complete remission was achieved, demonstrated by histology[53]. It can be inferred that HGF not only stimulated hepatocyte regeneration, but also remodeled the disorganized cirrhotic tissue. That is the pivotal potential for HGF gene therapy of liver cirrhosis[54]. It is of particular interest that HVJ-liposome was the ideal vehicle for gene transfer, because of the high efficiency, simplicity and lack of toxicity[55]. Another aspect of HGF on promoting neovascularization in certain ischemic diseases was also focused for possible application in the treatment of liver cirrhosis. Aoki *et al* delivered HGF cDNA into the myocardial infarction region in rats[56]. It promoted the neovascularization strongly in infarcted myocardium, including capillary, small- to medium-sized vessels. As an endothelium-specific growth factor with potent motogenic activity to endothelial cells, HGF's angiogenestic activity was also confirmed by the activation and upregulation of a transcription factor-ets, which is essential for angiogenesis[56]. Immunohistochemical staining revealed positive expression of ets 1 in endothelial cells and vascular smooth muscle cells (VSMC)

around the neovascularized vessels. The ets family participated in angiogenesis regulation by activating the transcription of several genes, including collagenase I, stromelysine 1 and urokinase plasminogen activator, which are proteases involved in ECM degradation, as well as migration of endothelial cells[57]. Overexpression of exogenous HGF activated ets family, initiated auto-loop up regulation mechanism of HGF resulting in up-regulation of endogenous HGF expression[53,56], since HGF gene promoter region comprised several putative regulatory elements, such as B cell- and macrophage-specific transcription factor binding sites (PU1/ETS), besides an interleukin-6 response element (IL-6RE), a TGF-β inhibitory element (TIE), and a cAMP response element (CRE)[56,58].

Another candidate for stimulation of hepatocyte proliferation is hepatic stimulatory substance (HSS), which was first described by LaBrecque *et al* in 1975. As a heat-stable stimulator for regenerating liver with partial hepatectomy, it is considered to be the unique liver-specific stimulatory factor and is universally located in mammal embryonic liver, weanling liver and regenerating liver[59]. In 1994, Hagiya *et al* obtained a gene product in rats, called augmenter of liver regeneration (ALR) with a full-length of 1.2kb and open reading frame of 378bp[60]. The molecular weight of ALR was approximately 30kDa, as a homodimeric complex[60,61]. The recombinant ALR expressed from ALR cDNA-transduced COS cells exerted potent and dose-dependent proliferative activity tested in canine Eck fistula (portal caval shunt) model[60]. Subsequent published reports have gradually come to a common view that ALR is actually the HSS. Yang *et al* cloned the human ALR gene in 1996[62,63]. Other groups also successfully cloned the rat and human ALR cDNA subsequently[64,65]. In comparison of the ALR encoding sequences of human and rat, homology of nucleotide sequence is about 87%, and that of protein sequence was 84.8%. Rat, mouse and human ALR genes and protein products were highly conserved and preferentially expressed in the testis and the liver, probably being involved in the synthesis and stability of the nuclear and mitochondrial transcripts, especially in spermatogenesis in actively regenerative tissues. Wang *et al* demonstrated that ALR or hepatopoietin (HPO) exerted the biological activity via the high affinity receptors for HPO on the surface of rat hepatocytes and human hepatoma cells. Each of the above cells has a mean of approximate 10 000 and 55 000 receptor sites respectively, as was identified with the binding of radioisotype ^{125}I-labelled HPO to a 90kDa polypeptide[66]. Updated research by Gandhi *et al* showed a certain new aspect of ALR funtion[67]. Hepatic levels of ALR decreased for 12 hours after 70% hepatectomy in adult rats and rose with no corresponding increase in ALR mRNA transcripts, while serum ALR level increased up to 12 hours. This implied that ALR was constitutively expressed in hepatocytes in an inactive form, and appeared to be an active form after being released outside the hepatocytes in response to partial hepatectomy or other regeneration-promoting circumstances[67]. Liver-derived NK cells are important regulators for liver regeneration[68]. Francavilla *et al*[69] connected the regulation activity of ALR in liver regeneration with the novel role of NK cells. Francavilla *et al* administrated three hepatotrophic factors (ALR, insulin-like growth factor II [IGF-II] and HGF) with the surely inducing sound hepatotrophic activities to assess the *in vivo* effects on NK cells in normal rats. Results showed that NK cell cytotoxic activities were inhibited in the population of mononuclear leukocytes (MNL) in the liver (liver-resident NK cells), but not in the MNL from the spleen or peripleral blood. Results obtained *in vitro* displayed that ALR, IGF-II and HGF had no effect on NK cell function in cultured MNL from the liver, spleen or blood[69]. Results from Polimeno *et al*also verified that ALR plays a pivotal role as growth factor and as immunoregulator by controlling the mitochondrial transcription factor A expression and lytic activity of liver-resident NK cells through IFN-γ levels[70] and regulates hepatocyte proliferation through enhancing cytochrome content and oxidative phosphorylation capacity of liver-derived mitochondia[71]. Liver injuries could also be prevented with recombinant ALR injected intraperitoneally[72-74]. Gene transfer of human ALR gene into cirrhotic rat may be an meaningful tool for reversing liver cirrhosis. Interestingly, no close or stringent homology was found between ALR and other polypeptide growth factor, while ALR has both structural and functional homology compared with yeast scERV1 gene which is involved in biogenesis of mitochondria and regulation of cell cycle, which may imply ALR's evolutional conservation and essentialness to growth and development[60,66].

INHIBITION OF INTERSTITIAL INFLAMMATION

Interstitial inflammation was characterized as the main pathological changes in fibrogenesis. Those inhibiting inflammatory responses would also be the target for gene transfer to block the fibrogenic inflammation. Interleukin-10 (IL-10) is suitable for this strategy. IL-10, originally identified as a cytokine synthesis inhibitory factor, inhibits production of a variety of cytokines in various cell types. It is produced under different conditions of immune activation by the T-H 2 and TH0 subsets of helper T cells, as well as by monocytes, macrophages, B cells, keratinocytes and stromal cells[75]. Sequences of open reading frame, not 5'- or 3'- flanking regions of mouse and human IL-10 cDNA showed high homology to two viruses,

Epstein-Barr virus and equine herpes virus[76]. Acquiring a mammalian IL-10 homology and subsequent inhibitory properties of IL-10 toward macrophages may help the virus escape from the antiviral immune attacks. IL-10 exerted multiple biological activities, including inhibition of T-H1 cells and antigen-presenting cells, stimulation of mast cell proliferation, protease expression, stimulation of B cell proliferation, antibody secretion and major histocompatibility complex II (MHC II) expression[75]. IL-10 takes part in the sophisticated regulation of fibrogenesis. In IL-10 gene knockout (KO) mice treated with tetrachloride (CCl_4), there existed no difference in hepatic toxicity of CCl_4 between KO mice and wild type (WT) mice.

In CCl_4-induced acute liver injury mice, serum TNF-α and TGF-β levels were markedly high in KO mice than that in WT mice. Administration of recombinant IL-10 inhibited cultured Kupffer cells producing superoxide radicals and TNF-α *in vitro*. In CCl_4-induced chronic liver injury model, the degree of hepatic fibrosis was severer and the level of tissue TNF-α was higher than that of WT mice. IL-10 knockout also seemed to enhance monocyte infiltration [77,78]. Up-regulation of IL-10 mRNA was found in both freshly isolated quiescent and activated Ito cells. Co-transfection of Ito cells with an IL-10 expression vector and collagen reporter genes showed a 40% inhibition of α1 (I) collagen promoter activity, suggesting the *in vivo* role of IL-10 in matrix remodeling and the possibility that failure for Ito cell to sustain IL-10 expression underlied pathologic progression to liver cirrhosis[79,80]. Kupffer cell also played a pivotal role in production of IL-10. Reports from Rai *et al*[81] revealed the subtle role of IL-10 in regulating production of TNF-α, a hepatocyte proliferative factor initiated after 70% partial hepatectomy. Kupffer cell depletion induced by gadolinium chloride (GdCl) abolished induction of IL-10, then elongated half-life of TNF-α mRNA. Overexpression of TNF-α promoted liver regeneration potently after partial hepatectomy. Meijer *et al* strengthened the common point of view that Kupffer cell depletion, physically induced with dichloromethylene-diphosphonate, resulted in an imbalanced hepatic cytokine expression, thereby suppressing important growth-stimulating factors, including HGF and TNF-α[82]. Similar results were found in alcoholic cirrhosis[83]. Contraversy existed with respect to effects of IL-10 on extracellular matrix regulation, for IL-10 was likely to have different effects relying upon the differently detailed experimental materials and conditions. In general, IL-10 inhibited α1 (I) collagen gene expression [79,84] stimulated collagenase (MMP-1), stromelysin (MMP-3)[84], gelatinase (MMP-9)[85] expression and elastin promoter activity.

Antifibrotic effect of IL-10 on hepatic fibrosis was also correlated with its inhibition of TGF-β expression in fibrotic tissue, which was verified as the key fibrotic regulator as stated above. This mechanism was also verified in other experiments[82,86]. As an inhibitory regulator with pleiotropic nature, IL-10 may be used as a target gene for gene transfer in the treatment of liver cirrhosis, based on the potent capacity of suppressing production of proinflammatory cytokines[75,77,78,82,83,87-92]. Nelson *et al* showed an exciting report that IL-10 could reduce liver fibrosis and normalize serum ALT levels in IFN-γ unresponsive hepatitis C patients[93].

TELOMERE AND TELOMERASE WITH CIRRHOSIS

Telomere is a special cap-like structure at the end of eukaryotic chromosomes, composed of a tandemly (TTAGGG)-rich repeat DNA sequences and relative catalyzing proteins. Length of telomere within a certain range is essential and vital for normal mitosis, for it enhances the stability of end chromosome, prevents abnormal chromosomal rearrangement and end-end fusion, and protects against the degradation or destruction by nuclease and/or ligase. When telomere was shortened to a checkpoint range of 2-4kb, the stabilization of chromosomes would collapse. Maintenance of telomere length depends on the telomerase, which consists of RNA and two protein subsets and serves as RNA-dependent DNA polymerase to achieve complete and entire replication of chromosome. There are large amounts of evidence to demonstrate that telomerase takes part in complex regulation and plays a crucial role in cell proliferation, aging, immortalization and tumorigenesis[94]. Except for the lymphocytes of peripheral bood, hematopoietic stem cells, germ cells, embryonic somatic cells and those resident in actively proliferating tissues, for example, hair, skin and endometrium, also have telomerase activities[95]. Other tissues exert no telomerase activity.

In cirrhotic liver, evidence verified no or a variety of low activity of telomerase, while telomere length decreased commonly[96-100]. Hytiroglou *et al* found a clear cut difference in telomerase activity levels between hepatocellular carcinoma (HCC) (positive or strongly positive) and cirrhotic liver tissues (weakly positive or negative). They considered that activation of telomerase was an early event in larger nodular cirrhosis formation, and consequently exerted facilitating effect on other factors in the progression of carcinogenesis[101]. A proportion of 86% of large noncancerous nodules exhibited similar telomerase activity to HCCs, and part of it was derived from large regenerative nodules, but not dysplastic nodules[101].

The importance of maintenance of telomere length has been verified in cultured telomerase-negative human retinal pigment epithelial cells and foreskin fibroblasts, transfected with vectors

encoding the human telomerase catalytic subunit[102]. A comparison between human telomerase reverse transcriptase subunit (hTRT) gene transfer group and control group showed that with hTRT gene transfer, the telomerase-negative cells displayed normal phenotype and karyotype, as well as exceeded their normal life-span by at least 20 doublings. The fact was also demonstrated by Kiyono *et al*[103]. Results obtained from telomerase-deficient mice verified the crucial role of telomerase and maintained telomere in development, which owned the nature of progressive telomere shortening from one generation to the next, for lack of active telomerase[104,105].

Based on the elucidation of telomerase's role in senescence and tumorigenesis, Rudolph *et al* brought new insight into the mechanism of telomerase gene transfer (mTR gene) in the treatment of liver injury and cirrhosis. They adopted three systems to gauge how telomere shortening influenced hepatocyte proliferation, survival and ultimately predisposition to cirrhosis[106]. The first was the albumin-directed urokinase plasminogen activator (Alb-uPA) transgenic mouse, in which Alb-uPA expression would cause widespread hepatocytes death and fatal liver failure in newborn mice. Results showed a progressive decline in telomere length of peripheral blood lymphocytes from the first generation (G1) to the third generation (G3), with a 3.6-fold increase in apoptotic hepatocytes and a decrease in proliferative hepatocytes. The second and third system was partial hepatectomy and CCl_4 mediated liver injury, respectively. Flow cytometry verified that telomerase dysfunction inhibited mitosis of mice hepatocytes. Pathology showed abnormal mitosis and formation of anaphase bridges in G6 $mTR^{-/-}$ mice. Induced apoptosis of hepatocytes delayed the volume recovery of hepatectomized liver. Repeated administration of CCl_4, caused liver cirrhosis first in G6 $mTR^{-/-}$ mice, followed by G3 $mTR^{-/-}$ mice and finally by $mTR^{+/+}$. It suggested that with the shortening of telomere, damage-resistant capacity of parenchymal cells decreased and cirrhosis was prone to be induced.

As gene transfer vector, adenovirus revealed good hepatotrophic property (an infection rate of 85%-100%). Telomere was shortened by about 70% in G6 $mTR^{-/-}$ mice, however, after mTR gene transfer, ascites reduced with gain of body weight, and serum levels of ALT and AST improved with active proliferation of hepatocytes. Compared with $mTR^{-/-}$ mice, mTR-transferred G6 $mTR^{-/-}$ mice survived during the experimental stage with 66% decrease of mitosis index and 58% reduction of anaphase chromatin bridges. No TGF-β was detected in mTR-transferred G6 $mTR^{-/-}$ mice, implying that mTR transfer may block TGF-β signaling and/or inhibit activation of Ito cell and TGF-β secretion. Target transfer of telomerase gene into affected organ created a new strategy and also a novel pathway for the treatment of aging and certain telomerase-related chronic disease.

Before actual application, over-high activity of telomerase may induce instablility of genomic structure and tumor formation. From a clinical point of view, telomerase gene therapy may be an ideal choice of treatment for patients awaiting liver transplantation, for it could actually improve liver function and extend survival, and the eventual surgical removal of diseased organ should at most minimize the potential cancer risk [105]. Telomerase gene therapy may be regarded as an effective short-term supporting procedure for patients with end-stage liver disease before carrying out of liver transplantation[107].

Luo H, Wang LF, Imoto T, Hiji Y. Inhibitory effect and mechanism of acarbose combined with gymnemic acid on maltose absorption in rat intestine. ***World J Gastroenterol***, 2001;7(1):9-15

Abstract

AIM To compare the combinative and individual effect of acarbose and gymnemic acid (GA) on maltose absorption and hydrolysis in small intestine to determine whether nutrient control in diabetic care can be improved by combination of them.

METHODS The absorption and hydrolysis of maltose were studied by cyclic perfusion of intestinal loops in situ and motility of the intestine was recorded with the intestinal ring *in vitro* using Wistar rats.

RESULTS The total inhibitory rate of maltose absorption was improved by the combination of GA (0.1g/L - 1.0g/L) and acarbose (0.1mmol/L - 2.0mmol/L) throughout their effective duration ($P < 0.05$, *U* test of Mann-Whitney), although the improvement only could be seen at a low dosage during the first hour. With the combination, inhibitory duration of acarbose on maltose absorption was prolonged to 3 h and the inhibitory effect onset of GA was fastened to 15 min. GA suppressed the intestinal mobility with a good correlation ($r = 0.98$) to the inhibitory effect of GA on maltose absorption and the inhibitory effect of 2 mmol/L (high dose) acarbose on maltose hydrolysis was dual modulated by 1 g/L GA in vivo indicating that the combined effects involved the functional alteration of intestinal barriers.

CONCLUSION There are augmented effects of acarbose and GA,which involve pre-cellular and paracellular barriers. Diabetic care can be improved by employing the combination.

INTRODUCTION

Hyperglycemia and hyperinsulinaemia are characters of non-insulin-dependent diabetes mellitus (NIDDM). Their interaction further impairs the action and secretion of insulin in NIDDM[1]. With the aim of reducing the possibility of developing long-term various complications such as microvascular disorder or neuropathy[2], a good diet regimen and control of nutrient entry are broadly accepted as basic treatment for diabetes mellitus.

Acarbose, an alpha-D-glycosidase inhibitor, was first extracted from the culture broths of actinomycetes by Puls and his colleagues in the 1970s, and was applied in clinical studies for more than 10 years[3-5]. It reversibly inhibits alpha-glycosidases that exist in the brush-border of the small intestinal mucosa[6]. Its efficacy has been reported as a potent inhibitory effect on sucrose hydrolysis, but a weak effect on the maltose. For instance, in humans, even if high doses of 300 mg of acarbose are orally used, there is little effect on the absorption of maltose[7] and no obvious effects on body weight have been observed in most studies possibly due to its short effective duration. During daytime, blood glucose levels were hardly decreased although the postprandial blood glucose amplitudes were reduced, that also due to its short effective duration[8]. In addition, there is no interaction with the intestinal Na^+/glucose- cotransporter[9], although an inhibitory effect on glucose absorption and an osmotic stimulus-mediating glucagon-like peptide-1 secretion has been reported[10,11].

Gymnemic acid (GA)[12], a mixture of triterpene glucuronides, which was found in the leaves of the Indian plant Gymnema sylvestre, not only inhibits glucose absorption in the small intestine[13], but also suppresses hyperglycemia and hyperinsulinaemia in an oral glucose tolerance test[14]. It is especially noteworthy that the body weight gain in fat rats is suppressed by GA treatment [15]. In an ordinary human diet, carbohydrates normally represent the quantitatively greatest part and are the primary source of energy. The typical diet contains far more starch than all other carbohydrates combined. More than 80% final products of intestinal carbohydrate digestion are glucose.

Maltose is a rather important product during starch hydrolysis. In this report, the combined effect of acarbose with GA on maltose absorption in

the rat small intestines is reported. The mechanism and application in perspective are discussed.

METHODS

Animals

Male 8 - 9 weeks old Wistar rats (body weight 300 g ± 25g) obtained from Shimizu (Kyoto), were housed in an air-conditioned room at 22℃ ± 2℃ with a natural lighting schedule for 1 to 3 weeks until the experiment began. They were fed with a standard pellet diet (Oriental Yeast CO., Tokyo) and tap water. Care and treatment of the experimental animals conformed to Tottori University guidelines for the ethical treatment of laboratory animals.

Perfusion of small intestine in vivo

A modified technique as elaborated by Yoshioka[13] was used in the small intestine perfusion experiment. Animals that had fasted overnight with free access to water were anesthetized by an intraperitoneal injection of 50 mg/kg body weight sodium pentobarbital (Dainabot, Osaka). After a catheter was inserted in the trachea, the abdominal cavity was opened. The small intestine of 30 cm length from the 2 cm caudal ward of Treitz's ligament was selected. Two L-shaped cannulae were inserted into each end of the intestine and connected with a peristaltic pump (SJ-1211H, Atto, Tokyo). After the abdominal cavity was closed, the intestinal loop was rinsed with Ringer's solution (145.4 mmol/L NaCl,5.4 mmol/L KCl, 1.8mmol/L $CaCl_2$ and 2.4 mmol/L $NaHCO_3$) for 60 min. Each chemical that was dissolved in Ringer's solution was continuously perfused through the intestine at a constant flow rate of 3 mL/min. The perfusing solution was adjusted to pH 7.5- pH 7.8 with NaOH and used at 37℃.

The animals were randomly grouped and exposed to 20 mL 10 mmol/L maltose (Sigma, ST. Louis) with or without GA (extracted by ourselves from Gymnema sylvestre) and acarbose (Bayer, Osaka) by cyclic perfusion through the loops for 1h (first perfusion), then 10 mmol/L maltose only was perfused for one hour again following an intestinal rinse with Ringer's solution for 30 min (second perfusion). To compare the combined and individual effective duration, 5 groups were chosen, in which the rinse time between the two perfusions was prolonged from 30 min to 60 min, 120 min and 180 min respectively. The perfusates at the first perfusion in the 5 groups were as follows: ① control group,10 mmol/L maltose; ② acarbose group, 2 mmol/L acarbose + 10 mmol/L maltose; ③ GAa2 group, 1 g/L GA + 2 mmol/L acarbose + 10 mmol/L maltose; ④ GAa 0.2 group, 1 g/L GAa + 0.2 mmol/L acarbose +10 mmol/L maltose; and ⑤ GA group, 1 g/L GA +10 mmol/L maltose.

Measurement of maltose absorption and hydrolysis

The samples (20 μL) from perfusion fluid were taken every 15 min during 1 h perfusion period, which were kept at 0℃ until next step to prevent the possibility of further hydrolysis. The maltose hydrolyzed by over dosage of alpha-glucosidase (Funacoshi, Tokyo) and glucose in sample was measured with the glucose-B-test-kit (Wako, Osaka)[16], and by the percentages of absorption and hydrolysis of maltose in perfusate were calculated.

Recording of isometric contraction of the intestinal rings

To explain the combined effect of acarbose and GA, the effect of GA on contraction of the intestinal smooth muscle was investigated *in vitro*. Fasted animals were sacrificed by stunning and exsanguinations. The intestines at the same position as the perfusion experiments were removed, cleaned of adhering fat and connective tissues in the serous membrane, and cut into transverse rings of 1cm wide. The rings were mounted on stainless steel hooks under 5 grams of resting tension and bathed in 25 mL organ bath at 37℃ in Locke's solution containing (mmol/L) NaCl: 154, KCl: 5.6, $CaCl_2$: 2.1, $NaHCO_3$: 2.4 and Glucose: 5.6, which was saturated with 95% O_2 and 5% CO_2. Tension was recorded isometrically using a force transducer (NEC Sanei, Tokyo) through its amplifier on an ink recorder (FBR-252A, TOA, Tokyo). Tissues were allowed to equilibrate at least 90min before the experiments begun. The rings were treated with GA and the alterations of auto-rhythmic contraction were recorded.

GA extraction

Dry Gymnema sylvestre leaves were obtained from Okinawa (Japan), from which GA was extracted with water, ethanol and diethyl carbonate by a slightly modified version of Imoto's method and freeze-dried into GA powder which was confirmed at 230 nm UV with a high-performance liquid chromatography (HPLC, Shimadzu SPD-6AV, Kyoto)[12].

Statistical and pharmacological analyses

Statistical analyses were performed with the *U* test of Mann-Whitney or ANOVA, which was indicated in the result when ANOVA was used, by StatView for a Macintosh computer. $P < 0.05$ was considered to be a significant difference.

The dose-response curves were analyzed by the least-squares fitting method using Cricket Graph for a Macintosh computer. The *r* (correlation coefficient) was tested with the limit table of *r*. If the value of *r* was under $P < 0.05$, the curve and function were accepted, from which the IC_{50} s (50% inhibitory concentrations) were calculated.

RESULTS

Dose-effect relationship and effective onset

The inhibitory effects of GA and acarbose, or both

of them, on 10 mmol/L maltose absorption obtained from the intestinal loop experiments *in situ* are illustrated in Figure 1 as a function of uptake time and compared at different doses of acarbose 0.2 mmol/L (Figure 1A) and 2 mmol/L (Figure 1B), respectively. Both agents inhibited maltose absorption significantly.The first point difference between the treated and control groups in maltose absorption was considered as the onset point of the inhibitory effect on maltose absorption. The duration from GA and/or acarbose perfused to that point was regarded as the onset time. The onset time was 30 min in the GA group and 15 min in both the acarbose and combining groups, in other words the longer onset time of GA was overcome by the combined. The inhibitory rates at 60 min were 50.7% ± 3.68% (1g/L GA), 51.72% ± 2.21% (0.2 mmol/L acarbose) and 68. 97% ± 2.71% (both of them), while at the high dose of acarbose they were increased to 80.68% ± 1.81% (2 mmol/L acarbose) and 72.27% ± 2.57% (both of them) indicating that the inhibitory effects were improved by the combination only in the lower doses during the first perfusion.

Time course of the inhibition

Time-effect curves of the GA and acarbose on absorption of maltose are shown in Figure 2. Even though the intestine was rinsed for 120 min, the altered maltose absorption remained at the inhibitory level in GA, GAa2 and GAa 0.2 groups. In the case of acarbose only application, the absorption returned to almost normal after 30 min rinsing ($P > 0.05$ *vs* control). The present results suggest that the short effective duration of acarbose be overcome by the combination. The peak effect appeared during the first perfusion in GAa2 and acarbose (2 mmol/L) groups and the second perfusion following rinse for 30 min in GAa0.2 and GA groups. The altered absorption of maltose was recovered in each group to the control level after 180 min rinse with Ringer's solution.

The IC_{50}

The acarbose dose dependently inhibited the absorption of maltose with IC_{50s} of 0.65 mmol/L, 0.27 mmol/L, 0. 22 mmol/L and 0.28 mmol/L ($r >$ or $= 0.99$) during 15 min, 30 min, 45 min and 60 min perfusion, respectively. The inhibitory effects were improved when combined with GA ($P < 0.001$ ANOVA). The IC_{50} s in an hour duration decreased to about 73% and 40% of acarbose with 0.1 g/L and 0.25 g/L GA, respectively. The inhibitory effects of GA ($IC_{50} = 0.85$g/L, $r = 0.99$) were also improved by lower doses of acarbose ($P < 0.001$ ANOVA) with IC_{50} s of 0.35 g/L (0.1 mmol/ L acarbose) and 0.04g/L (0.2 mmol/L acarbose) respectively.

Augment of GA and acarbose

The amount of total maltose absorbed during the two perfusions is compared in Figure 3. The first perfusion was performed for 1 h by 10mmol/L maltose containing GA and/or acarbose and the second was performed again for 1 h by 10 mmol/L maltose only, after rinsing for 30 min. The absorption of maltose during 1 h in control group was 42.2 mg and 43.0 mg in the first and second perfusions respectively, which had no significant difference. If the total absorbed maltose in control is taken as 100%, the relative maltose absorption was 64.2% ± 5.0% and 54.0% ± 7.3% in the 0.2 and 2 mmol/L acarbose groups respectively, which was further decreased to only 26.9% ± 2.9% and 31.0% ± 2.7% respectively by the combined 1 g/L GA. In GA (1g/L) group the relative maltose absorption was 38.1% ± 4.3% but still higher than that in combined groups ($P < 0.05$). These values implied that augmented inhibitory effects are highly revealed throughout effective duration in either combined group of GA and acarbose.

Modulation of the acarbose activity by GA

The percentages of maltose hydrolysis during perfusion maltose and acarbose with or without GA are shown in Figure 4A. It is noted that the inhibitory effect of 2 mmol/L acarbose on maltose hydrolysis was time-dependently decreased by combination with 1 g/L GA in the first perfusion. The hydrolysis of maltose in GAa2 group, which was similar to that in 0.2 mmol/L acarbose, was higher than that in 2 mmol/L acarbose group at 30 min ($P < 0.05$), 45 min and 60 min ($P < 0.$ 01) except that at 15 min. On the contrary, the hydrolysis of maltose in the GAa2 group was lower than that in 2 mmol/L acarbose group ($P < 0.05$) in the second perfusion after the intestine was washed out for 120 min (Figure 4B). The hydrolyses at 15 min, 30 min, 45 min and 60 min were 15.77% ± 0.89%, 29. 44% ± 0.18%, 45.18% ± 3.20% and 59.67% ± 5.86% in the former while 21.94% ± 1.36%, 45.38% ± 2.87%, 57.52% ± 1.69% and 73.14% ± 3.92% in the latter. No significant difference was observed in lower dosages of acarbose (0.2 mmol/L) with the presence or absence of GA.

Correlation of GA's inhibitory effects on absorption and mobility of the intestine

To explain mechanism of the combination, the effect of GA on auto-rhythmic contraction of the intestinal ring was recorded isometrically using a force transducer. Although the frequency of auto-rhythmic contraction was 17.2 ± 0.77 times per minute in the intestinal rings, and the tension induced by auto-rhythmic contraction was 1406.67 mg ± 565.33 mg under normal conditions, they were dose-dependently decreased when treated with GA (Figure 5A,B). The inhibitory effects of GA on the absorption of maltose and auto-rhythmic contractions of the ring in the small intestine had a good linear correlation ($r = 0.98$, Figure 5C).

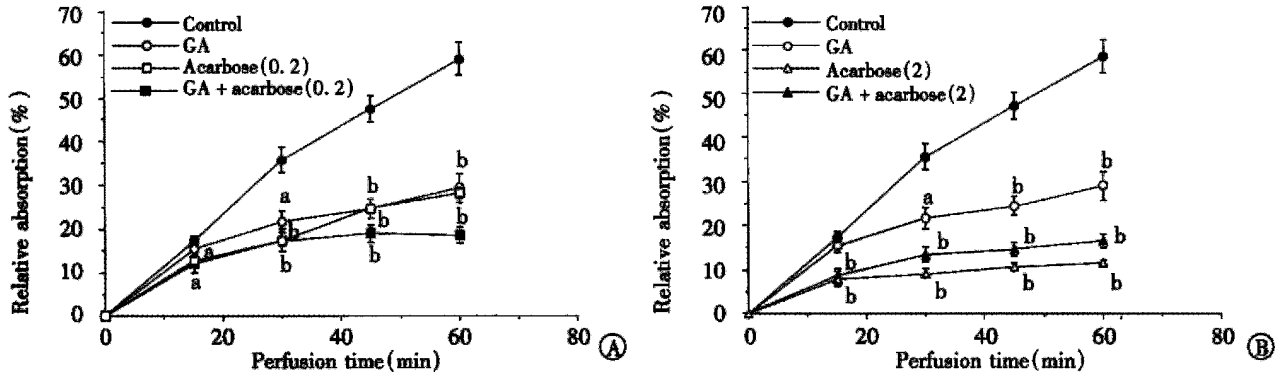

Figure 1 Inhibitory effect of GA and acarbose on maltose absorption. The intestinal loops *in situ* were perfused with 10 mmol/L maltose in the presence or absence of GA (1 g/L) and acarbose (mmol/L). The absorption of maltose is shown as percentage of maltose contained in the beginning of perfusion. Each point is expressed as mean ± SD of 5-10 determinations. ($^aP < 0.05$, $^bP < 0.01$)

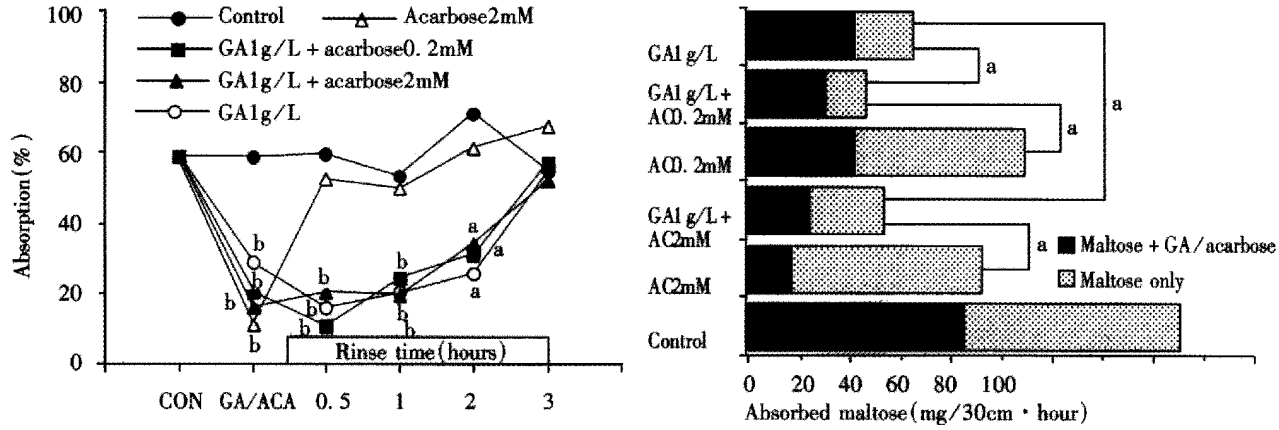

Figure 2 Alteration of maltose (10 mmol/L) absorption following application with GA and/or acarbose. Each point shows the maltose absorption during 60 min perfusion of 10 mmol/L maltose following rise with Ringer's solution after treatment of GA and/or acarbose (the second perfusion) except the points of "CON" or "GA/ACA" which shows the absorption during the first 1 hour perfusion with or without GA and acarbose (the first perfusion). The absorption of maltose is shown as percentage of maltose contained in the beginning of perfustion ($^aP < 0.05$, $^bP < 0.01$).

Figure 3 Maltose absorption during the two perfusions in the first 2.5 hours. Maltose+GA/acarbose: first perfusion, 10 mmol/L maltose containing GA and/or acarbose was perfused for 1 hour. Maltose only: after first perfusion the intestinal loops were rinsed for 30 min, then 10 mmol/L maltose only was perfused for 1 hour again. The absorbed maltose is shown as the absorption in each perfusion. There was significant difference between each treated group versus control. ($^aP < 0.05$, n = 5-10).

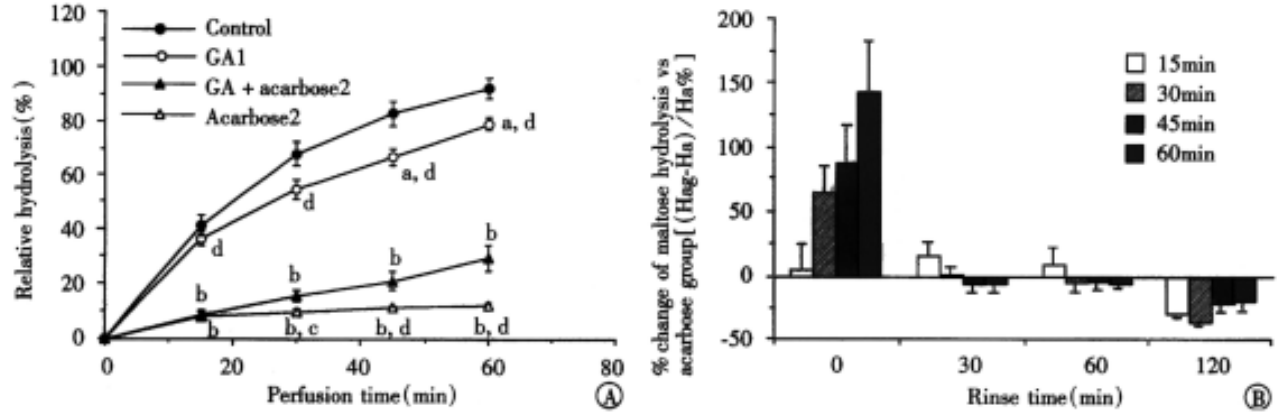

Figure 4 The dual effects of GA (1mg/mL) on the activity of acarbose during the first perfusion (A), maltose with GA and/or acarbose was presented in the perfusates. Maltose contained in the fluid at perfusion starting point was taken as 100%. $^aP < 0.05$ and $^bP < 0.01$ *vs* control; $^cP < 0.05$ and $^dP < 0.01$ *vs* GAa2. (n = 6-10) and second perfusion (B), the intestinal loops were rinsed for 30 min to 120 min, then 10 mmol/L maltose only was perfused for 1 h again. Each bar shows the percentage change of maltose hydrolysis (Hc%) in GAa2 group versus 2 mmol/L acarbose group in different perfusing times, which was calculated by the following equation: Hc% = (Hag-Ha)/Ha × 100%, where Hag and Ha represent, respectively, the hydrolyzed maltose in GAa2 group and in 2 mmol/L acarbose group. Hydrolysis of maltose in the acarbose group is believed as 100% (n = 3-10). A diminished effect in the beginning and improved effect in the end were observed.

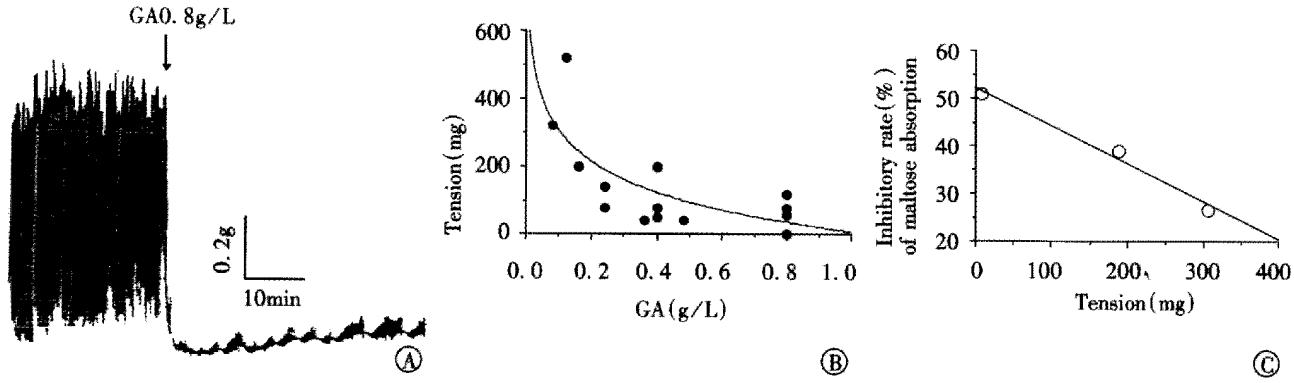

Figure 5 The relationship of GA's inhibitory effects on absorption of the maltose and on mobility of the intestinal ring. A, an example of the inhibitory effect of GA (0.8 g/L) on the intestinal auto-rhythmic contraction. B, dose-dependently inhibitory effect of GA on amplitude of the small intestinal rings which is expressed as the tension induced by the auto-rhythmic contraction in the present different doses of GA. C, correlation of GA's inhibitory effects on absorption of maltose and on tension of the intestinal ring. Each point comes from one dose of GA. The tension is calculated from the function of curve in the Figure B.

DISCUSSION

The combined effects of acarbose and GA are first reported in this paper. With the combination, inhibitory duration of acarbose was prolonged and onset time of GA was shortened, while the total inhibitory rate of maltose absorption was improved each other throughout their effective duration. Subsequently, a more effective reduction of postprandial hyperglycemia and hyperinsulinaemia could be expected by employing the combination in humans.

Acarbose is a pseudo-tetrasaccharide that is structurally similar to the typical oligosaccharides derived from starch digestion and can attach to the carbohydrate binding site of alpha-glycosidases in a competitive manner with a rank order of inhibitory potency of glucoamylase > sucrase > maltase > isomaltase. To alpha-amylase, acarbose has only a weak noncompetitive inhibitory effect[17]. In our experiment, the IC_{50} of acarbose for the 10 mmol/L (3.42 g/L) maltose absorption was 0.65 mmol/L during 15 min perfusion compared with a previous study of Krause *et al*, in which acarbose inhibits the absorption of maltose (1 g/L and 2 g/L) with IC_{50s} of 36 mg/L (0. 06 mmol/L) and 57 mg/L (0.09 mmol/L) respectively during 15 min in perfused loops[18]. The IC_{50s} and concentrations of maltose in the 3 points had a good semilog linear correlation ($r = 0.94$).

The inhibitory effects of GA on intestinal glucose absorption and oral glucose tolerance were first noticed in the 1980s[13,14], although there has been more than a century's history of treating diabetes mellitus with the leaves of Gymnema sylvestre in India [19-24]. Recently, various effects of GA including decreased body weight[15], improved hyperinsulinaemia[14] and inhibited glucose-stimulated gastric inhibitory peptide secretion[25] have been published. In a previous study in our laboratory[13], GA inhibited intestinal glucose absorption consistent with the present results, but with a difference in time (5 mmol/L glucose). Rinsed with Ringer's solution, the loops tended to recover their absorption of glucose. Those contrary results could be coming from the different effects of the unstirred layer and the tight junction on the absorption of maltose and lower concentration of glucose. In a recent study that we performed[26], GA inhibited the absorption of oleic acid and glucose (5 mmol/L) simultaneously with a time course same as the experiment of only 5 mmol/L glucose[13], which implies that the inhibitory effect of GA on the absorption of oleic acid has some relationship with the inhibitory effect of GA on glucose absorption.

Mechanism of the combination

The mechanisms for GA's actions have been considered as participating in the glucose receptor[25], Na^+/glucose cotransporter[13], ATPase[27] and insulin release[28]. In the present experiment, a new mechanism of GA's action was suggested concerned with an influence of the precellular and paracellular barriers of absorption in the intestinal brush borders.

Intestinal absorption of solute requires that the compound cross two barriers, the unstirred layer as an aqueous diffusion barrier, and epithelium which consist of enterocytes and paracellular factors[29-34]. Disaccharides are absorbed at a faster rate than monosaccharides *in vivo*, but inversely *in vitro* for the absorption of disaccharides coupled with the membrane digestion. Oligomers invariably appear in monomeric form at the serosal side of the epithelial cell or in the blood stream[35]. The concentration of glucose hydrolyzed from maltose (10 mmol/L) in the microenvironment of enterocytes and the tight junction is nearly 200 mmol/L-300 mmol/L with membrane

digestion[36], which is 10-15 times of that contained in the perfusate and is a power to drive absorption through paracellular pathway. If the tight junctions were narrowed or the membrane digestion was limited, the effect on the absorption of maltose would be more than that on the absorption of glucose.

"Membrane digestion" was defined by Ugolev and De-Laey[37] as that action of the cellular membranes on enzyme activities combined with the transport of their products of hydrolysis across membrane forms. The structural foundation of the model is presented as enterocytes projecting microvilli and the unstirred layer that is mainly formed by a glycocalyx entrapping water mixture with mucin from nearby goblet cells. Most of the disaccharidases produced by the enterocytes are binding with the membrane (under the unstirred layer) and a small amount of saliva and pancreatic amylase is in the glycocalyx. The maltose is hydrolyzed during it passes through the glycocalyx and enterocytes[38].

On the other hand, thickness of the unstirred layer (glycocalyx) largely depends on motility of the intestine, which becomes relatively thin when the intestine exhibits motility[29,37]. Suppressed by GA, the tension and intestinal auto-rhythmic contraction had un-negligible effects on unstirred layer not only, but also on the tight junction around the enterocytes. When the intestine relaxes, the paracellular pathways become narrow[36,39]. Consequently both hydrolysis and absorption could be inhibited by GA through pre-epithelium and epithelium barriers, in the latter containing transcellular (same as glucose) and paracellular factors (only for maltose or high concentration of glucose), that could be a main reason for the different time courses of GA on maltose and glucose.

It is another evidence altering the function of unstirred layer, that the activity of acarbose in the higher concentration (2 mmol/L) was decreased at the beginning and increased after rinsing by the combination with GA (Figure 4). The unstirred layer limits the diffusion of acarbose entering (at the beginning) and leaving (during rinse) the microenvironment nearest the membrane maltase resulting in the dual effects of GA on the activity of acarbose. It should be due to lower affinity[40] of acarbose with alpha-amylases, that the dual effects only appeared with higher concentration of acarbose. When the activity of alpha-amylases in the unstirred layer (glycocalyx) was inhibited, the glycocalyx digestion itself was decreased. With a combination of high concentration of acarbose and GA, the unstirred layer became thick enough to suppress the diffusion of acarbose. The glycocalyx is estimated to impede solute diffusion to the surface in a manner that is directly proportional to its solubility and inversely proportional to the square root of its molecular weight. The molecular weight of acarbose is nearly 2 times that of maltose, therefor in same condition the barrier of unstirred layer on acarbose is more effective than that on maltose. On the other hand, the solubility of GA (molecular weight about 800) was lower (about 10 g/L) than that of acarbose and maltose, which also is one of the reasons for GA's longer onset time (30 min).

The merits of combination

Tolerability should be considered when a drug is administered to a patient. Acarbose has contained in the drug list of diabetic management either type 1 or type 2 [5,40-46]. The most common adverse effect of acarbose is a gastrointestinal disturbance, which is induced by producing gas with fermentation of the unabsorbed carbohydrates in the bowel[17,43,47-50]. Acarbose has rarely been associated with systemic adverse effects, but in some case acute severe hepatotoxicity has been reported[3,51,52]. These adverse effects tend to increase with higher doses. GA not only improves the effect with a decrease in the IC_{50} of acarbose, but also inhibits the growth of anaerobia[53]. Bacterial overgrowth plays a role in the development of gastrointestinal symptoms[54], therefore the adverse effects of acarbose induced by fermentation are expected to be diminished by the combination of GA.

CONCLUSION

Acarbose inhibits maltose absorption through the inhibition of maltase under the unstirred layer and alpha-amylase in the unstirred layer. The latter is only involved at a higher dose (2 mmol/L) of acarbose. GA inhibits maltose absorption possibly by making the unstirred layer thicker and shutting the paracellular pathway, besides other reported mechanisms that are the same as glucose[13-15,25,27,28]. The effects of GA on maltose absorption and the combined effects of acarbose and GA are first reported in this paper. With the combination, the effective duration of acarbose is prolonged and the effective onset of GA is faster. Improvements in postprandial hyperglycemia, hyperinsulinaemia and insulin resistance, treatments of an overweight condition and diminishing of the adverse effects of acarbose in diabetic control by this combination are also in perspective.

Abstract

AIM To study the colon innervation of trisomy 16 mouse, an animal model for Down's syndrome, and the expression of protein gene product 9.5 (PGP 9.5) in the stenosed segment of colon in Hirschsprungs disease (HD).

METHODS Trisomy 16 mouse breeding; cytogenetic analysis of trisomy 16 mice;and PG P9.5 immunohistochemistry of colons of trisomy 16 mice and HD were carried out.

RESULTS Compared with their normal littermates, the nervous system of colon in trisomy 16 mice was abnormally developed. There existed developmental delay of muscular plexuses of colon, no submucosal plexus was found in the colon, and there was 5 mm aganglionic bowel aparting from the anus in trisomy 16 mice. The mesentery nerve fibers were as well developed as shown in their normal littermates. Abundant proliferation of PGP 9.5 positive nerve fibers was evealed in the stenosed segment of HD colon.

CONCLUSION Trisomy 16 mice could serve as an animal model for Hirschsprung's disease for aganglionic bowel in the distal part of colon. Abundant proliferation of PGP 9.5 positive fibers resulted from extrinsic nerve compensation, since no ganglionic cells were observed in the stenosed segment of the colon in HD. HD has a genetic tendency.

INTRODUCTION

The most significant pathophysiological change of Hirschsprung's disease is its characteristic abnormal enteric nervous development of colon which resulted in the regional enterospasm and narrowed lumen, loss of intestinal peristalsis and relaxing reflex of the internal enteric sphincter[1]. The physiological peristalsis of the proximal gut pushes the intestinal contents forward, leading to the second megacolon in the proximal part of the narrowed gut. Since the cause of HD is still unknown and the experiment on humans is impossible, we used protein gene product 9.5 to study the enteric nerve development of colon in trisomy 16 mice, an animal model for Down's syndrome[2,3], and the innervation of stenosed segment of the colon in HD so as to reveal the possibility of developing the congenital megacolon in trisomy 16 mice and the genetic tendency of HD in human[4-7].

MATERIALS AND METHODS

Animal stocks and breeding[8-10]

Trisomy 16 mouse embryos examined in this study were produced by crossing NMRI-female mice provided by the Experimental Center of Medical University of Lubeck, with male mice carrying the two Robertsonian (Rb) translocation chromosomes Rb (16,17) 8Lub^{wLub3} perpendicularly and Rb (11,16)2H. The day on which a vaginal plug was observed was considered to be the first embryonic day (ED).

Cytogenetic analysis

The pregnant female mice were sacrificed one hour after intraperitoneal injection of colchicine (0.02 mg/25-35 mg body weight) by dislocation of the neck. The embryos were collected by laparatomy. Small samples of liver were taken from each embryo for direct preparation of karyotypes, by using the standard technique of hypotonic treatment with 0.563% KCl and methanol : acetic acid fixation (3 : 1). Air-dried slides were observed under light microscope. Accurate ascertainment of trisomy 16 was provided by the demonstration of two Rb metecentric chromosomes and a count of 41 chromosome arms. After the defrimy of the chromosomal status, the trisomic and the normal euploid embryos of each litter could be separated (Figure 1).

Immunohistochemical methods[11]

The guts were taken from trisomy 16 embryos and

normal littermates, and fixed in a solution containing 4% paraformaldehyde and 2% picric acid in phosphate-buffered saline (PBS) for approximately 2 hours at room temperature. Fifteen pieces of narrowed HD guts were obtained from the patients aged between 18 months and 9 years. Six segments of normal colons served as controls. The diagnosis of HD was based on the case history, clinical manifestations, examination of barium enema and pressure measurement of rectum and anal. All the cases were confirmed postoperatively by pathological examinations.

Whole mount preparations of the gut were dissected out under stereomicroscopic control[12-14], and freezing sections were made at a thickness of 12 μm, then washed in 0.01 M PBS and 50% ethanol for 2 hours at room temperature. For immunohistochemistry, peroxidase-anti-peroxidase (PAP) was used in the present experiment.

The specimens were treated with 10% normal goat serum (Dakopatts × 907) for 30 min, then incubated in a primary antiserum protein gene product 9.5 (PGP 9.5) (Ultraclone RA 95101, UK) overnight at room temperature, diluted to 1 : 400 in a solution containing 10% normal goat serum, 0.01% sodium azide and 0.05% thimerosal in PBS. After three washes in PBS for 30 min, the specimens were incubated in goat anti-rabbit IgG (Dakopatts Z421) overnight at room temperature as the secondary antiserum, and diluted to 1 : 100 in the above solution. The specimens were then exposed in rabbit PAP (rabbit antibody to horseradish peroxidase and horseradish peroxidase) overnight at room temperature and diluted to 1 : 100 in a solution containing 0.1% bovine serum albumin and 0.05% thimerosal in PBS pH 7.4. 4 Cl1-naphtol or DAB was used as the chromogen for the peroxidase reaction. Control included the omission of the primary antiserum. PGP 9.5 is a cytoplastic protein composed of 212 amino acids with molecular weight of 2.45 kb. This protein only exists in the neurons and neuroendocrine cells. PGP 9.5 is a specific protein with an excellent localizing function for the neurons[15-19].

RESULTS

Development of trisomy 16 mice and their normal littermates

Owing to the abnormality of their chromosomes, the trisomy 16 mice were characterized by their small size, generalized edema and a failure of closed eyelids after embryonic day 16 (ED 16). Both the small size and lid-gap defect were attributed to the generalized growth retardation and developmental delay, leading death at the time of birth in most mice. The trisomy 16 mice in the present study were chosen from the gestational age between ED13 and ED 18. The survival rate of the trisomy 16 mice was lower with the gestational age. The lowest survival rate of trisomy 16 mice was observed at the time of their birth (Figure 2).

Development of colon innervation in trisomy 16 mice and their normal littermates

The nerve development of colon in normal littermates is a continuous process. Based on the morphology and staining degree of the PGP 9.5 positive reactions, the nerve development of colon could be divided into three stages: primary stage (ED14), juvenile stage (ED15 and ED16) and mature stage (ED17 and ED18). At ED14, scantly-distributed PGP 9.5 positive neurons were observed with light staining and round nucleus in the center of the neurons. At ED15, the distribution density of neurons increased greatly with some nervous processes, through which the neurons were connected with each other (Figure 3A). At ED16, muscular plexuses appeared with gathered neurons to form the light-stained ganglion. But the number of neurons in the ganglion was less and sparely arranged. At ED17 and ED18, the precursor cells of muscular plexuses migrated into the submucosal layer to form submucosal plexuses. The arrangement of nervous fibers in submucosal plexus was irregular, accompanied by some small-sized and sparely-distributed ganglions, while muscular plexuses were composed of primary, secondary and tertiary strands displaying a nerve meshwork with regular wide meshes and numerous large ganglia. The muscular and submucosal plexuses were further developed with much stronger PGP 9.5 staining at ED18 (Figure 4A). The increasing number of large-sized ganglions was observed with stronger immunostaining and arranged along the primary nerve strands. Numerous fine nerve strands in the gut villi were observed at ED18 (Figure 5).

When compared with the normal littermates, the developmental delay of the colon- innervation was observed in trisomy 16 mice. Some neurons appeared with a scattered distribution and light staining at ED15 (Figure 3B) and the neurons were found with some nerve processes by which irregular nervous meshwork formed at ED16. In the colon of trisomy 16 mice at ED17 and ED 18, only one plexus was visible, i.e., the myenteric plexus with a few small-sized ganglions (Figure 4B). From ED14 to ED18 there was no submucosal layer in colon, and 5mm aganglionic bowel was found at the distal end of the colon in trisomy 16 mice (Figure 6), which was revealed as a characteristic morphological evidence of the development of congenital megacolon in trisomy 16 mice. This important finding was constantly verified in all the experimental trisomy 16 mice.

The exogenous innervation of colon in trisomy 16 mice and their littermates

As early as ED14, PGP 9.5 positive nerve fibers occurred in the mesentery of both trisomy 16 mice and their normal littermates, which gradually

increased with the embryonic development. At ED17 and ED18, rich mesenteric nerve fibers were detected. In all whole mounts of PGP 9.5 nerve fibers in mesentery, they were observed regularly running in parallel and close to the blood vessels and innervated the colon in both trisomy 16 mice and their normal littermates (Figure 7). Thus, the arcades of the mesenteric vessels were clearly delineated by their immunostained perivascular plexuses.

The distribution of PGP 9.5 positive nerve fibers in the stenosed segment of HD and normal colons

The ganglions of the muscular plexus and submucosal plexus from the normal colon all revealed highly positive reaction to PGP 9.5 (Figure 8). The number of ganglion in muscular plexus was greater than that in the submucosal ones. The neurons presented a dark brown color and gathered as a mass. The adjacent neurons extended processes, by which they were connected with each other. PGP 9.5 positive nerve fibers were distributed in all intestinal layers. The richest part was in the circular muscular layer and parallel to the muscular fibers. In the proper mucous membrane, nerve network was formed around the intestinal glands. In the submucosal layer, the nerve fibers were arranged around the vessels. But in the stenosed segment of HD colon, no ganglionic cell was observed in the muscular and submucosal plexuses. At the distal end of the stenosed segment of the colon, no nerve plexus was found. Occasionally, a few neurons existed, but with abnormal morphology, while PGP9.5 positive nerve fibers were great in number in all intestinal layers. Big, strong, disordered and even twisted nerve tracts could be observed (Figure 9). Such disorderly arranged nerve fibers could also be found in the submucosal layer and proper mucous membrane layer of the colon. Some of the proliferated fibers were twisted along the vessels.

DISCUSSION

The incidence of HD is 1/5000 due to the developmental defect of enteric nervous system[20-23]. Recently, HD incidence is increasing, especially the genetic HD and Down's syndrome with congenital megacolon[24-29], which greatly aroused researchers' interest in investigating the causes. The present study was based on PGP 9.5 as primary antibody to reveal the innervation of the narrowed gut in HD and the nerve development of the colon in trisomy 16 mice.

Enough evidences have been obtained from this study that trisomy 16 mice had a significant anomaly and developmental delay in colon innervation as well as 5 mm aganglionic colon at the distal end, which was the result of the chromosome abnormality. Our present experiment, found that there was a chronological sequence in the nerve development and a clear link between the gestational age and the morphological development in colon innervation of trisomy 16 mice and their normal littermates (Table 1). At ED 14, the precursor cells of ectoderm migrated into the gut along the course of the vagus nerves; at ED 15, nerve processes were observed in the neuron migrated gut; at ED 16, the muscular plexuses and ganglions appeared in the gut; at ED17, the precursor cells in muscular layer migrated into the submucosal layer and developed into submucosal nervous plexuses; at ED 18, the relatively matured muscular and submucosal plexuses occurred, the former controls the intestinal peristalsis, and the latter manages the intestinal secretions and absorption[30, 31]. The lack of submucosal nerve plexuses of trisomy 16 mice accounted for the lower material absorption and poor intestinal secretions while the distal aganglionic colon could result in the neurotrophic and innervating disorders. It is now recognized that the intestinal nerve development begins from the cephalic part to the caudal end[32-41]. But HD was due to the stagnated development of the precursor cells. The earlier the stagnation of the precursor cells, the longer the aganglionic bowel. Since colon is the last segment of gut for the precursor cells to migrate into, colon is most likely to develop HD. The aganglionic colon in trisomy 16 mice strongly confirmed the above findings. The euchromosome 16 of trisomy 16 mice has the same sequence as the 21q22 genes of human euchromosome 21[8]. It is often used as an animal model for Down's syndrome. Besides, trisomy 16 mice have constant genetic tendency and aganglionic colon, being easy to develop congenital megacolon. Epstein and associates believed that the intestinal innervation was composed of intrinsic and extrinsic ones[42]. The well-developed mesenteric nervous system of trisomy 16 mice could be regarded as a compensation for the intrinsic nerves. When there were no ganglionic cells in the intestine, the extrinsic nerve fibers would proliferate greatly. In our experiment, considerable PGP9.5 positive nerve fibers were verified in the stenosed HD colon, which was obviously the compensative nerve proliferation to the innervation of aganglionic HD colon. Since trisomy 16 mice had severe cardiovascular abnormalities, multi-organ deformities[43-45] and could hardly survive after delivery, so in the present study, the distal colon end of trisomy 16 mice showed no such extrinsic compensating nerve proliferations.

Among all clinically verified HD cases, 20% were caused by the lack of genetic factors[46]. Trisomy 16 mice, with its constant chromosome abnormality, is a reliable animal model for studying the genetic tendency of HD. The regional microcircumstance was closely related to the changes of the genetic inheritance. Tennyson and associates have found two striking abnormalities, i.e., an overgrowth of the muscularis mucosa, particularly in the outer longitudinal layer and an extensive thickening of the basal lamina around smooth muscle cell.

These excessive accumulation of basal lamina material and muscularis mucosa interfered with normal migration of precursor cells[47-51]. Payette and associates [52] thought that the excessive accumulation of components of basal lamina material in the aganglionic region of the lethal spotted mutant mouse stopped precursor cells from migrating into the terminal bowel of lethal spotted mutant mice. Our study revealed that 5mm aganglionic bowel in length aparting from anus in trisomy 16 mice, might be caused by the change of regional micro-circumstance due to the abnormal chromosome, finally resulting in the nerve defect.

Abstract

AIM To test the hypothesis to block VEGF expression of SMMC-7721 hepatomacells may inhibit tumor growth using the rat hepatoma model.

METHODS Amplifiy the 200 VEGF cDNA fragment and insert it into human U6 gene cassette in the reverse orientation transcribing small antisense RNA which could specifically interact with VEGF165, and VEGF121 mRNA. Construct the retroviral vector containing this antisense VEGF U6 cassette and package the replication-deficient recombinant retrovirus. SMMC-7721 cells were transduced with these virus and positive clones were selected with G418. PCR and Southern blot analysis were performed to determine if U6 cassette integrated into the genomic DNA of positive clone. Transfected tumor cells were evaluated for RNA expression by ribonuclease protection assays. The VEGF protein in the supernatant of parental tumor cells and genetically modified tumor cells was determined with ELISA. In vitro and in vivo growth properties of antisense VEGF cell clone in nude mice were analyzed.

RESULTS Restriction enzyme digestion and PCR sequencing verified that the antisense VEGF RNA retroviral vector was successfully constructed. After G418 selection, resistant SMMC-7721 cell clone was picked up. PCR and Southern blot analysis suggested that U6 cassette was integrated into the cell genomic DNA. Stable SMMC-7721 cell clone transduced with U6 antisense RNA cassette could express 200 bp small antisense VEGF RNA and secrete reduced levels of VEGF in culture condition. Production of VEGF by antisense transgenea2expressing cells was 65 ± 10 ng/L per 10^6 cells, 420 ± 45 ng/L per 10^6 cells in sense group and 485 ± 30 ng/L per 10^6 cells in the negative control group, ($P<05$). The antisense-VEGF cell clone appeared phenotypically indistinguishable from SMMC-7721 cells and SMMC-7721 cells transfected sense VEGF. The growth rate of the antisense-VEGF cell clone was the same as the control cells. When S.C. was implanted into nude mice, growth of antisense-VEGF cell lines was greatly inhibited compared with control cells.

CONCLUSION Expression of antisense VEGF RNA in SMMC-7721 cells could decrease the tumorigenicity, and antisense-VEGF gene therapy may be an adjuvant treatment for hepatoma.

INTRODUCTION

Neovascularization is critical for supporting the rapid growth of solid tumors[1]. Tumor angiogenesis appears to be achieved by the expression of angiogenic agents within solid tumors that stimulate host vascular endothelial cell mitogenesis and possibly chemotaxis. One such protein, vascular endothelial growth factor (VEGF) or vascular permeability factor[2-5], is a selective endothelial cell mitogen and angiogenic agent .Many tumor cell lines secrete VEGF *in vitro*, suggesting that this diffusible molecule is a mediator of tumor angiogenesis. The clinical results showed high levels of VEGF expression in primary hepatoma, elevated levels of flt-1, the receptors of VEGF in hepatoma blood vessels, and the relationship between VEGF levels and hepatoma invasion and transfer[6]. These data indicated that VEGF and its receptors play important roles in the development of hepatoma vasculature and progressive growth of hepatoma.

In this study, we used the SMMC-7721 hepatoma cell line which has a high expression of

VEGF, as established model for human hepatoma. The strategy of exogenous expression of antisense VEGF transcribed by POL III promoter in the SMMC-7721 cell line was applied to assess the feasibility of disrupting the VEGF/VEGF receptor pathway of angiogenesis and decreasing their tumorigenicity *in vivo*.

MATERIALS AND METHODS

Materials

Bam HI, T4 DNA ligase was purchased from Promega Company. RNase A and RNase T1 were the products of MBI Fermentas, G418 was purchased from Sigma Company and SMMC-7721 cell line from Chinese Academy of Cell Biology.

Methods

Construction of vectors VEGF antisense vector to generate the VEGF anti-sense vector, a DNA fragment containing 250 bp of human VEGF cDNA, was ligated in reverse orientation in the *sal* I, *xho* I sites of the U6 cassette, and subcloned into the *Bam* H I site of pLXSN vector. Expression of the antisense molecule in pLXSN was driven by POLIII promoter of U6 cassette. The pLXSN vector also contained the G418 resistance gene driven by the simian virus (SV40) promoter. To generate infectious virions, PA317 packaging cells were transfected with pLXSN-U6-as-VEGF and selected in the culture medium containing 500 mg/L G418. Virus-containing supernatants were harvested and used to infect SMMC-7721 cells.

Genetic modification of SMMC-7721 cells The SMMC-7721 cells were incubated with the viral stock containing 8 mg/L polybrene. On the following day, the cells were split and selected in 500 mg/L G418. Cultures were added every 3-4 days with the fresh G418 supplemented media for 14 days. Resistant colonies were expanded, and subcloned and the clone which produced the reduced levels of VEGF was selected for further research.

Ribonuclease protection assay A 200bp VEGF PCR product was cloned into T7,T3 vector pBlueScript-SK, the plasmid was linearized by *Eco* R V, treated with proteinase K and purified. The α-^{32}P UTP sense VEGF RNA was generated by addition of T7 polymerase. Ribonuclease protection assays were made as follows, 20 μg of total cellular RNA was hybridized with RNA probes overnight at 45℃. The remaining single-stranded probe RNA and unhybridized RNA were digested with a mixture of RNase A and RNase T1, added yeast RNA, extracted by phenol, precipitated by ethanol, seperated on 7M urea/polyacrylamide gels, and then exposed to X-ray film.

PCR, southern blot analysis PCR was performed on genomic DNA isolated from human SMMC-7721 cells and individual clones of transfected cells using a sense primer corresponding to the U6 promoter (5'-TATACTAAGTCGACTCCTATGTGCTGG-3') and an antisense primer corresponding to the VEGF cDNA (5'-TAGAGAGGGCAGAATCATCACG-AAGTGG-3'). Using the NeoR primer, the sense primer is 5'-CAAGATGGAATTGCACGCAGG-3', the reversal primer is 5'-CCCGCTCAGAAAGAACTCGTC-3'. The PCR was performed using the following protocol: 95℃ 1min, 60℃ 1min, 72℃ 1min 30s; in the last cycle, extend 10 min at 72℃. Southern blot, 20 μg genomic DNA was digested overnight, electrophoresed on 1% agarose gels, transferred onto Hybond N nylon membrane, and hybridized with the DIG labeled NeoR probe at 68℃ for 6 h, the membrane was washed in 2 × SSC for 5 min × 2, and 0.1 × SSC for 15 min. The fragments were visualized by chemiluminescent, and exposed to X-ray film.

Quantitation of VEGF The supernatant of parental or transfected SMMC-7721 cells were measured by ELISA. To generate the conditional medium, the cells were seeded onto 3.0×10^5/well plates. The media was changed next day to MEM /0.5% bovine serum albumin/ 1% dialyzed fetal calf serum for another 24 h. The media was then replaced by the fresh MEM and cells were allowed to grow for another 48 h. The CM was generated by centrifugation at 14 000rpm at 4℃ for 15 min, then for ELISA analysis according to the manufacturer's instructions.

***In vitro* growth rate** SMMC-7721 hepatoma cells and cells transfected with antisense, and sense-VEGF were cultured at 1×10^4 and grown under standard culture conditions. Cell count was made every 24 h for a total of 144 h. The total number of cells from duplicate experiments was determined as a function of time.

Determination of *in vivo* tumor growth Subcutaneous inoculation and tumor growth measurements were carried out, 1×10^6 cells of the parental SMMC-7721 cells or antisense, sense expressing clones were injected into the flank of normal BALB/C nude mice. Tumors were measured in two dimensions every 5 days for 25 days. Tumor volume was calculated using the formula $v = l \times w^2/2$, where v = volume (mm^3), l = long diameter, and w = short diameter.

RESULTS

Construction of the antisense-VEGF RNA expression vector based on U6 POLIII promoter

All of the major transcriptional promoter elements for U6 RNA polymerase III are upstream of the transcription start, which has a potential advantage of the less exogenous RNA coding sequence. Another advantage of the U6 promoter is that U6

gene is heavily expressed in human cells. The U6 cassette contained the first 5' initial 27 nucleotides and 3' stem 19 nucleotides for transcript terminator and the U6+27 transcript was predicted to be most stable because of the γ-phosphomethyl-GTP cap. The fragment of VEGF was cloned into U6 cassette through sense or antisense direction, and verified by DNA sequence. U6 cassette containing sense or antisense VEGF was cleaved by *Hind* III, *Pst* I digestion and cloned into pBlue-SK vector, and subcloned into *Bam* HI restriction site of retroviral expression vector. The positive plasmid was verified by *Bam* HI digestion (Figure 1).

SMMC-7721 cells expressing antisense-VEGF

Following transfection by recombinant antisense VEGF or sense VEGF retrovirus, the SMMC-7721 cells were selected by antibiotic G418, the individual clones were isolated and expanded. And the selected clone expressed low VEGF for further analysis and was referred to as anti-1. This clone was evaluated for gene expression in ribonuclease protection assays. In this assay, hybridization of RNA with the complementary RNA probe protects the probe from the subsequent digestion with RNase A and RNase T1. From Figure 2, it can be seen that 200 bp antisense VEGF RNA was only expressed in SMMC-7721 transfected by pLXSN U6 antisense VEGF.

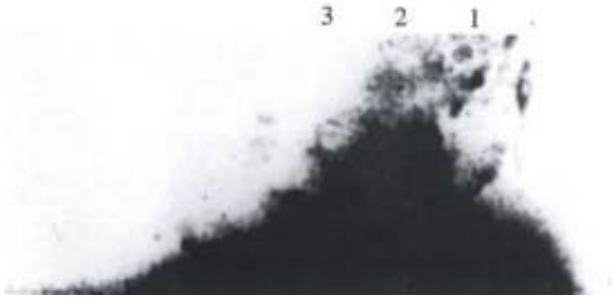

Figure 2 Detection of antisense VEGF RNA expression by RNase protection assay.
Lane 1: Hybridization with total RNA from SMMC-7721 antisense clone showed 200 bp antisenseVEGF RNA; Lane 2: Hybridization with total RNA from SMMC-7721 sense clone showed no positive band; Lane 3: Hybridization with total RNA from SMMC-7721 cells showed no positive band.

PCR analysis of DNA isolated from the antisense-VEGF, sense VEGF clones showed foreign gene integration into the genomic DNA, and the results of PCR using the specific primer, showed that the antisense VEGF U6 gene cassette had inserted the genomic DNA of SMMC-7721 cells. Southern blot analysis was performed on genomic DNA of these antisense VEGF, senseVEGF clones to verify again that there was foreign integrated cDNA (Figures 3, 4).

Diminished production of VEGF by SMMC-7721 cells transduced with antisense VEGF cDNA

In order to determine if the expression of the antisense VEGF transgene reduced production of secreted protein, supernatant from control-transduced (SMMC-7721 sense VEGF) and antisense VEGF transduced cells were assayed for VEGF by ELISA. Production of VEGF by antisense transgene-expressing cells was 65 + 10ng/L per 10^6 cells, as compared with 420 + 45 ng/L per 10^6 cells in sense group and 485 + 30 ng/L per 10^6 cells in negative control group, $P < 0.05$.

In vitro growth rate of antisense-VEGF cell lines

The antisense-VEGF cell lines appeared phenotypically indistinguishable from normal SMC-7721 cells and SMMC-7721 transfected sense VEGF cells. And growth rates of antisense-VEGF cell lines were the same as the control cells (Figure 5).

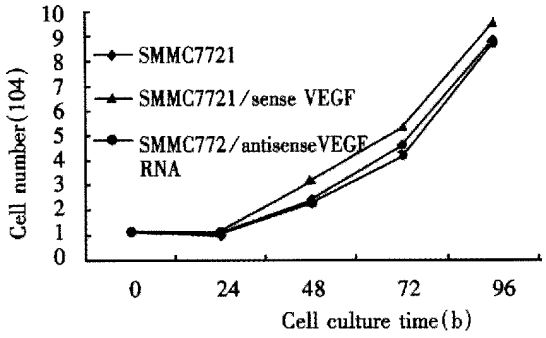

Figure 5 Proliferation curves of parental SMMC-7721 cells and antisense-VEGF, sense-VEGF cell lines.

In vivo growth of the antisense-VEGF cell lines

Control SMMC-7721 cells and antisense-VEGF SMMC-7721 cells were s.c. injected into nude mice, tumor volumes were measured every 5 days. Tumor growth was detectable and measurable for control SMMC-7721 cells 5 days post-implantation, while the antisense VEGF cell lines gave rise to tumors. Examination of mice at 25 days post-implantation revealed that the negative control SMMC-7721 group produced tumors of 630.92 ± 85 mm^3, sense-VEGF SMMC-7721 group produced tumors of 601.07 ± 52 mm^3, while the antisense VEGF SMMC-7721 group produced tumors of 76.33 ± 20 mm^3. This experiment demonstrates that the reduced tumorigenicity of antisense-VEGF SMMC-7721 cells in nude mice may be attributed to the reduced expression of VEGF (Figure 6).

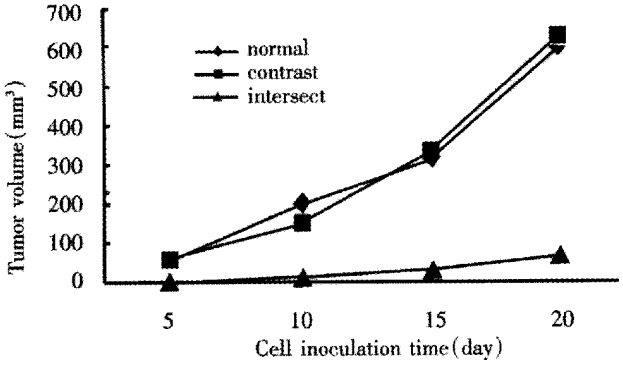

Figure 6 Tumorgenicity of antisense VEGF SMMC-7721 in nude mice.

DISCUSSION

Angiogenesis, the formation of new blood vessels , is essential for both tumor growth and metastasis [7-10]. Tumor angiogensis is a process controlled by certain chemicals produced in cancer cells. These chemicals stimulate endothelail cells to form new blood vessels. Candidates as major physiological stimulators include VEGF[11], bFGF. VEGF, and its receptors play critical roles in tumor-associated angiogenesis and represent good targets for therapeutic intervention[12-15]. VEGF was initially termed vascular permeability factor, its first function was discovered by Dvorak and colleagues[16]. There are several VEGF isoforms, in which VEGF121 and VEGF165 are readily secreted. Unlike bFGF, VEGF is a very specific mitogen for vascular endothelial cells. It also functions as a potent pro-survival factor for endothelial cells in nearby formed vessels and this may be one of its most important functions[17,18].

It is reported that VEGF is an angiogenic factor most closely associated with the neovascularization in solid tumors. VEGF is expressed by vast majority of cancers at elevated levels and blocks its activity by specific neutralizing antibodies to VEGF[19,20]. VEGF-toxin conjugates[21], aptamers[21] and small molecule VEGF receptor antagonists[22] could inhibit the growth of cancer in animal models. In human hepatocellular carcinoma, abundant tumor vascularity was observed. And vascular endothelial growth factor gene and protein expression was analyzed by means of Northern hybridization and immunohistochemistry, increased expression of VEGF has been reported in hepatocellular carcinoma cells (HCC)[23-26]. So VEGF gene expression is significantly associated with angiogenesis of HCC. Tang Zhao You *et al* studied the angiogenesis induced by liver cancer with different metastatic potentials using corneal micropocket model in nude mice. It was suggested that highly metastatic liver cancer was more angiogenic than low metastatic cancer and liver tissue[26]. In HCC with metastasis, mRNA of VEGF is closely related to the growth of HCC as well as its metastasis[27].

In China, the hepatocarcinogenesis is closely related with the hepatitis virus[28], the results of the researches showed that, after viral infection,there is abnormal expression of oncogene such as ras, bcl-2, especially P53[29-33], and there is also a possible link between oncogenes and tumor angiogenesis. Expression of mutant ras can lead to a marked induction of a potent paracrine stimulator of angiogenesis. In addition, hypoxia stimulates expression of VEGF and tumor angiogenesis[34-40]. The results of therapeutic experiments showed that the chimeric protein consisting of DT390-VEGF165 or DT390-VEGF exon7 can efficiently kill the HepG2 and gastric carcinoma cells and may kill vascular endothelial cells in the cancer[41, 42] and antiangiogenesis inhibitor TNP-470 plus lipiodol greatly decreased the hepatoma growth in animal models which depend on the reduction of microvessel density[43].

Blocking the interaction between the VEGF and its receptor can inhibit the growth of tumor through the antiangiogenesis effect[44-47]. From our

previous experiment, we found VEGF expression in hepatoma cell line SMMC-7721 cells. We there fore sought to determine if inhibition of secretion of VEGF in SMMC-7721 tumor cells would inhibit the growth of this tumor in animal model.

In order to improve the expression of the antisense VEGF RNA in the target cell, we constructed the retrovirus vector containing the human U6 promoter cassette that had the POL III promoter to transcribe the small therapeutic RNA in the nuclei of cells. Compared with other transcriptional promoters such as POL II, tRNA, there are two advantages of U6 promoter: ① high expression in human cells, and ② the therapeutic RNA contains less unnecessary RNA encoding the intragenic ptomoter. In the same time, we amplified a common VEGF cDNA and inserted reversely into U6 cassette[48-52]. U6 promoter transcribed a small antisense VEGF RNA fragment that could specifically interacted with VEGF165 and VEGF121 mRNA. Our previous results, verified that U6 cassette could effectively express antisense VEGF RNA molecules and decreased the expression of mRNA VEGF165, and VEGF121. Then U6 cassette that expressed antisense VEGF RNA was inserted into the retroviral construct. After packaging the recombinant retrovirus, this cassette was introduced into the SMMC-7721 cells. Ribonuclease protection analysis using the RNA probe specific for antisense VEGF demonstrated that there was antisense VEGF RNA expression in the SMMC-7721 cells genetically modified by antisense U6 cassette. The antisense clone selected for further study showed radical decrease in VEGF protein in supernatant compared with the sense and negative SMMC-7721 cell group. Inhibition of VEGF expression in SMMC-7721 cells resulted in severely impaired growth of this tumor *in vivo*. This may be related with the reduced levels of VEGF produced by the antisense-VEGF-transfected SMMC-7721 cell clone, and this resulted in a decrease of number of tumor blood vessels. Our findings demonstrate that the inhibition of VEGF is sufficient to control the tumor growth *in vivo*. The antisense VEGF srategy offers a way for gene therapy as an adjuvant treatment for hepatoma.

Abstract

AIM To compare the therapeutic effect and significances of multimodality treatment for hepatocellular carcinoma (HCC) with tumor thrombi in portal vein (PVTT).

METHODS HCC patients (*n* = 147) with tumor thrombi in the main portal vein or the first branch of portal vein were divided into four groups by the several therapeutic methods. There were conservative treatment group in 18 out of patients (group A); and hepatic artery ligation (HAL) and/or hepatic artery infusion (HAI) group in 18 patients (group B), in whom postoberative chemoembolization was done periodically; group of removal of HCC with PVTT in 79 (group C) and group of transcatheter hepatic arterial chemoembolization (TACE) or HAI and/or portal vein infusion (PVI) after operation in 32 (group D).

RESULTS The median survival period was 12 months in our series and the 1-, 3-, and 5-year survival rates were 44.3%, 24.5% and 15.2%, respectively. The median survival times were 2, 5, 12 and 16 months in group A, B, C and D, respectively. The 1-, 3- and 5-year survival rates were 5.6%, 0% and 0% in group A; 22.2%, 5. 6% and 0% in group B; 53.9%, 26.9% and 16.6% in group C; 79.3%, 38.9% and 26.8% in group D, respectively. Significant difference appeared in the survival rates among the groups (*P*<05).

CONCLUSION Hepatic resection with removal of tumor thrombi and HCC should increase the curative effects and be encouraged for the prolongation of life span and quality of life for HCC patients with PVTT, whereas the best therapeutic method for HCC with PVTT is with regional hepatic chemotherapy or chemoemblization after hepatic resection with removal of tumor thrombi.

INTRODUCTION

Hepatocellular carcinoma (HCC) with tumor thrombi in the main trunk or the first branch of the portal vein would be considered to be advanced stage of liver cancer[1], which often results in intrahepatic metastasis and can only be treated with conservative or non-operative methods such as per oral chemotherapy, biotherapy, traditional Chinese medicine, etc. In China, some patients even give up all the therapeutic methods for HCC. The majority of those patients usually die of liver failure or bleeding of the upper digestive tract within several months[2,3]. In recent decade, the active therapeutic measure for HCC with tumor thrombi in portal vein (PVTT) was performed at the Liver Cancer Institute of Shanghai Medical University, i. e., hepatic resection with removal of PVTT. After the operation, some patients obtained satisfactory curative effects through transcatheter chemotherapy or transcatheter hepatic arterial chemoembolization (TACE), or hepatic artery infusion (HAI) and/or portal vein infusion of chemotherapeutic agents (PVI).

MATERIALS AND METHODS

Patients

By December 1996, 147 patients with pathologically proven HCC with tumor thrombi in the main trunk or the first branch of the portal vein had been treated at the Liver Cancer Institute of Shanghai Medical University. Among them, 144 were males and 3 females, the median age was 48. 2 years (ranged from 20 to 70 years). Serum hepatitis B surface antigen was found positive in 123 cases (83.7%). Coexisting cirrhosis was found in 138

cases (93.9%): macronodular cirrhosis (cirrhotic nodule >3 mm) in 81 patients and micronodular cirrhosis (cirrhotic nodule ⩽3 mm) in 57 patients. Alpha-fetoprotein (AFP) levels were elevated (21-16 000 μg·L^{-1}) in 120 cases (81.6%). The tumors were situated in the left lobe in 53 cases, the right lobe in 61 and both lobes in 33.

Groups of patients

One hundred and forty-seven patients were divided into 4 groups. Group A: conservative treatment group, receiving only oral medications of chemotherapy or Chinese herbal decoction and supporting treatment, 18 cases; Group B: hepatic artery ligation (HAL) and/or HAI or PVI (postoperative chemotherapy through hepatic artery or portal vein, and periodical chemoembolization through hepatic artery), 18 cases; Group C: removal of HCC with PVTT in 79 cases; among them, 5 patients were lost to follow-up. The tumors and tumor thrombi were resected simultaneously or tumor thrombi were extracted from the portal vein after removal of the tumors for the HCC patients with PVTT; Group D: Intrahepatic arterial chemoembolization or chemotherapy and/or intraportal chemotherapy by catheterization or TACE were periodically performed after resection of HCC with PVTT in 32 cases; among them, 3 cases were lost to follow-up.

Location of tumor thrombi

Fifty-one cases had tumor thrombi in left branch of portal vein, 47 in right branch, 10 in both branches, 14 in left branch extending to the main portal vein, 9 in right branch extending to the main trunk of portal vein, and 16 in both branches and the main portal vein.

Comparison of clinical data in different groups in HCC patients with PVTT

These data are shown in Table 1, indicating that there were no statistical differences between groups.

Table 1 Comparison of several treatments groups for HCC with PVTT

NS: no significance statistically.

Resection of HCC and catheterization after resection

Resection of left lateral lobe was performed in 18 cases, resection of left lateral lobe and partial right hepatic resection in 3, left hemihepatectomy in 40, left trilobectomy in 9, resection of hepatic medial lobe in 3, right hemihepatectomy in 4 and right partial hepatectomy in 34. PVI was followed by resection in 5 cases, HAI in 7 and HAI + PVI in 9. The catheters were cannulated into the hepatic artery and portal vein, and the ports were completely implanted beneath the abdominal wall.

Treatment methods for PVTT

For the tumor thrombi in left branch of portal vein, the right branch of portal vein was detached at first and then ligated by using a cotton ribbon or a fine rubber tube. The purpose was to prevent spreading of cancer cells of tumor thrombi from the left branch of portal vein to the right lobe during the resection or PVTT removal. After resection of left lateral lobe or left hemihepatectomy, the tumor thrombi were taken out from the stump of left branch of portal vein and irrigation was done with physiological saline, then the stump of portal vein was sutured and the ligature of the right branch of portal vein was released.

For tumor thrombi in the right branch of portal vein, the treatment for HCC with PVTT was similar to that in the left branch.

For the tumor thrombi in both branches of portal vein, the stump of one branch of portal vein was exposed after resection of liver cancer in left or right lobe, the hepatoduodenal ligament was ligated to block the blood flow entering the liver, and then the tumor thrombi were sucked or taken out through the stump.

For the tumor thrombi in the left or right branch of portal vein extending to the main trunk, the liver cancer in left or right lobe was removed first after detaching and ligating the right or left branch of portal vein, the stump of portal vein was clipped, then the main portal vein over the duodenum was gently held by the thumb and index finger. While the stump was being loosened, the tumor thrombi would flow out with the on-going portal blood flow.

For the tumor thrombi in both branches and the main trunk of portal vein, the tumor thrombi were sucked through the stump of one branch of portal vein, while pressing the opposite branch with an index finger for preventing dissemination of tumor cells. If the tumor thrombi were difficult to be sucked or taken out, the main portal vein should be detached. A longitudinal incision of 1.5 to 2.0 cm was made on anterior or right vascular wall of the main trunk of portal vein, and then the tumor thrombi were taken out directly. After the operation, B-mode ultrasonography was performed to make out whether the tumor thrombi had been

removed completely from the portal vein.

Chemotherapy after operation

Group D: After operation, 11 patients received 1 to 3 times of TAI or TACE (median 1.5 times) and other 21 patients received 2 to 4 times (median 2.5 times) of HAI and/or PVI or hepatic arterial chemoembolization (HAE). Group B: All patients were treated by HAI or HAE and/or PVI 1 to 4 times (median 2 times). The dosages of chemotherapy in HAI or TAI and/or PVI were 5-fluorouracil (5-Fu) 1 000 mg, mitomycin (MMC) 12 to 20 mg and cisplatin or carborlatinum 80 mg, and lipoidal 5 mL in group D to 20 mL in group B of lipiodol was used in the TACE or HAE.

Statistical method

All the data were calculated with the digital Cox model and the limit of significant difference was $P<0.05$.

RESULTS

Curative effects of several therapeutic methods for HCC patients with PVTT

Among the series, the follow-up survey was lost in 8 cases. The median survival period of the 139 patients was 12 months, and the 1-, 3 and 5- year survival rates were 44.3%, 24.5% and 15.3% respectively. The median survival period and the 1, 3 and 5- year survival rates in different groups are shown in Table 2.

Table 2 Survival time and rates of patients with PVTT

Curative effects between PVTT in the main trunk and the first branch

Table 3 shows the results of multimodality treatment in patients with tumor thrombi in the main trunk and the first branch of portal vein. It indicates that the results of treatment in patients with PVTT in the first branch were better than that in patients with PVTT in the main trunk in groups C and D.

Curative effects and factors influencing the prognosis of the patients

after resection of HCC with PVTT (Table 4) The results of resection followed by chemotherapy or chemoembolization in patients with a diameter of tumor mass less than 10 cm, without tumor thrombi in the main portal vein were better than those in patients with diameter of more than 10 cm, with tumor thombi in the main portal vein and without chemotherapy or chemoembolization after resection.

Table 4 Curative effects and factors influencing the prognosis of patients after removal of HCC with PVTT

DISCUSSION

HCC with tumor thrombi in the main trunk or the first branch of the portal vein is considered to be a late stage of liver cancer, lacking in ideal therapeutic measures. The treatment was often given up in former times. As the majority of the patients with HCC have been in advanced stage when first seen, a large probortion of the patients are associated with tumor thrombi in the main trunk or the first branch of the portal vein. Therefore, it is very important to explore effective therapeutic methods for HCC with PVTT and to raise the survival rates of these patients.

Until now, the treatments for HCC with PVTT are limited. In the medical literaures about the treatments of HCC with PVTT, there were the following methods: TACE, PVI, percutaneous ethanol injection in tumor thrombi, TACE + radiotherapy and surgical removal of tumor thrombi etc. Chung *et al*[4] reported that the 1 and 2-year survival rates were 30% and 18% respectively in 110 HCC patients with PVTT by TACE. Katsumori *et*

al[5] reported that the 3-year survival rate was 44% in 9 cases of tumor thrombi in the main portal vein by hepatic arterial chemotherapy through the implanted ports beneath the abdominal wall. It was also reported that the percutaneous ethanol injection in PVTT and TACE + radiotherapy gave satisfactory curative effects for PVTT[6-8]. There were only a few papers about the resection of HCC with removal of tumor thrombi in the main trunk or the first branch of the portal vein[9,10]. Yamaoka *et al*[9] adopted 5 resection modes for PVTT. The operative mortality of 29 patients with PVTT was 11%, and the 1, 2 and 3-year survival rates after operation were 52.2%, 23. 2%, and 11.6%, respectively. Four different procedures were used for the patients with PVTT in our series, and the results revealed poor efficacy in the conservative treatment group. The median survival time was only 2 months (group A). The best curative effect was in group of removal of HCC with PVTT + HAI and/or PVI or TACE (group D). The median survival time was 16 months and the 5-year survival rate was 26.8%. For this reason, if the tumors with PVTT are limited in the left or right lobe of liver and liver function as evaluated is able to tolerate the operation, we should adopt active therapeutic procedure. The best try should be made for removal of HCC with PVTT and hepatic regional chemotherapy or chemoembolization are periodically performed after operation. This procedure can further raise the treatment efficacy and prolong the survival for the HCC patients with PVTT.

The conservative treatment (only per oral chemotherapy or Chinese herbal decoctions) can not inhibit or kill cancer cells in the HCC patients with PVTT. Rapid progression of liver cancer will result in death in a short time due to liver failure or portal hypertension, with vigorous variceal bleeding. Among 18 patients undergoing conservative treatment, 12 cases died of vigorous bleeding of upper digestive tract within 3 months and only one case had the longest survival of 13 months. Although the survival time of 18 patients treated with HAL and/or HAI were shorter, the curative efficacy was better than that of conservative treatment group. The 1-year survival rate was 22.2%. Perhaps the periodical hepatic artery chemotherapy or chemoembolization can inhibit the tumor growth in various degrees and result in partial necrosis of tumor thrombi. The results of Katsumori[5] and Ando[11] also support this viewpoint. The result in the group of removal of HCC and PVTT (Group C) was evidently better than those of Groups A and B, the median survival time being 12 months and the 1, 3 and 5-year survival rates being 53.9%, 26.9%, 16.6% respectively. If HCC is limited to one lobe and the residual liver is estimated to be functionally efficient, we should first choose surgical resections for the patients with PVTT. The residual cancer and residual tumor thrombi are primary factors influencing the survival of the HCC patients with PVTT. According to patient's conditions, periodical HAI/PVI or TACE are effective methods to improve the survival rate after operation. In the group of HAI/ PVI or TACE after resection of HCC with PVTT (group D), the median survival time was 16 months and the 1, 3, and 5-year survival rates were 79.3%, 38.9%, 26.8% respectively. The result was better than the other three groups. These results indicate that the best therapeutic method is sequential regional hepatic chemotherapy or TACE after surgical removal of HCC and PVTT. Table 3 shows curative effects in HCC patients with tumor thrombi in the main trunk of portal vein were inferior to those in patients with tumor thrombi in the first branch. The tumor thrombi in the main trunk represent the disease in advanced stage, which is often accompanied with tumor thrombi in both branches and disseminated foci in the opposite side of liver. Moreover, the resection of thrombi in the main trunk of portal vein may lead to cancer cell dissemination or incomplete extermination and rapid formation of thrombi in the main trunk after operation. The above factors cause the poor efficacy for HCC patients with tumor thrombi in the main trunk of portal vein, and poor quality of life than those with tumor thrombi in the first branch.

It has been convinced that the factors influencing curative effects for HCC with PVTT such as location of tumor thrombi (in the main trunk or the first branch of portal vein), tumor size and regional hepatic chemotherapy, etc. To our experience, the treatment methods for removal of tumor thrombi are closely related to the efficacy. Before operation, we must find out the scope of tumorthrombi with ultrasonography, CT or magnetic resonance angiography (MRA). During resection, we should block the blood flow of portal vein into liver or blood flow of the opposite branch, suck the tumor thrombi completely as far as possible and not break it. Then, we scrape off with curet the residual tumor thrombi attached on the vascular wall, and perform repeated irrigation and exsuction with physiological saline. Furthermore, anticoagulant injections through the portal vein during several postoperative days may also be an effective procedure to prevent and reduce the rapid recurrence of thrombi in the portal vein[12,13].

The therapeutic methods for HCC with PVTT are still at the investigative stage. Such patients occupy a considerable proportion in the liver cancer clinic. As PVTT is an important factor resulting in intrahepatic metastasis and recurrence after operation, it will be very valuable to study the mechanism of the PVTT formation in HCC patients and to explore more effective treatment measures for prolonging survival and improving their quality of life.

Subject headings liver neoplasms; mitogen-activated protein kinases; signal transduction; trans-activators; oncogenes; immunohistochemistry; precancerous conditions

Feng DY, Zheng H, Tan Y, Cheng RX. Effect of phosphorylation of MAPK and Stat3 and expression of c-fos and c-jun proteins on hepatocarcinogenesis and their clinical significance. ***World J Gastroenterol***, 2001;7(1):33-36

Abstract

AIM To study the effect of phosphorylation of MAPK and Stat3 and the expression of c-fos and c-jun proteins on hepatocellular carcinogenesis and their clinical significance.

METHODS SP immunohistochemistry was used to detect the expression of p42/44^{MAPK}, p-Stat3, ca2fos and c-jun proteins in 55 hepatocellular carcinomas (HCC) and their surrounding liver tissues.

RESULTS The positive rates and expression levels of p42/44^{MAPK}, p-Stat3, c-fos and c-jun proteins in HCCs were significantly higher than those in pericarcinomatous liver tissues (PCLT). A positive correlation was observed between the expression of p42/44^{MAPK} and c-fos proteins, and between pa2Stat3 and c-jun, but there was no significant correlation between p42/44^{MAPK} and p-Stat3 in HCCs and their surrounding liver tissues.

CONCLUSION The abnormalities of Ras/Raf/MAPK and JAKs/Stat3 cascade reaction may contribute to malignant transformation of hepatocytes.Hepatocytes which are positive for p42/44^{MAPK}, c-fos or c-jun proteins may be potential malignant pre-cancerous cells. Activation of MAPK and Stat3 proteins may be an early event in hepatocellular carcinogenesis.

INTRODUCTION

The regulation of cellular mitogenesis and proliferation under normal circumstances are dependent on a number of separate, yet integrated, signaling pathways responsible for the transduction of extracellular signals to the cell nucleus[1-3]. Similar to other tumorigenic cells, hepatocellular carcinoma (HCC) is characterized by the imbalance of the normal growth-promoting and growth-arresting signal transduction cascade reaction, the net result of which leads to uncontrolled hepatocyte growth [1,2]. Mitogen-activated protein kinase (MAPK) and signal transducer and activator of transcription 3 (Stat3) are important molecules in signal transduction cascades, which take part in cellular physiological growth, development, mitogenesis and differentiation, and play key roles in cellular malignant transformation[4,5]. In order to study the function of signal transduction cascade in hepatocarcinogenesis, the phosphorylation of MAPK (p42/44 MAPK, Erk1/Erk2) and Stat3 (p-Stat3), and the expression of c-fos and c-jun proteins were investigated by immunohistochemical method in HCCs and their surrounding liver tissues.

MATERIALS AND METHODS

Tissue samples

Fifty-five HCCs with pericarcinomatous tissue (PCLT) and 5 normal liver tissues were obtained by surgical resection in Xiang Ya Hospital and the Affiliated Second Hospital of Hunan Medical University, Changsha, People's Republic of China. Of 55 HCC patients, 43 were men and 12 women. The age ranged from 36 to 69 years (mean, 51.8 years). The tumor sizes were less than 3cm in diameters in 3 cases, 2.1 cm-5 cm in 32 cases, 5.1 cm-10 cm in 18, and larger than 10 cm in 2 cases. All patients were HBsAg negative. Remote metastasis was not found, and preoperative radiological or chemical therapy was nor performed in all patients. All HCCs and PCLTs were fixed in 10% formalin and embedded in paraffin. Five μm serial sections were cut. According to Edmondson's criteria[6], 10 HCCs were grade I, 21 grade II, 17 grade III, and 7 grade IV. Thirty-eight atypical hyperplasia cases were observed in 55 PCLTs.

Reagents

p42/44 MAPK(Erk1/Erk2, Thr202/Tyr204) and p-Stat3(Ser727) MAbs, were used to detect the

phosphorylation of MAPK and Stat3, and S-P detection kit were kindly donated by New England Biolab, USA. Anti-c-fos and anti-c-jun protein MAbs were purchased from GIB Com (Beijing, China).

Methods

Immunohistochemical staining Five μm tissue sections were deparaffinized, washed in 0.05 M PBS, and treated with 2% H_2O_2 for 20 min. According to the SP method, the tissues were detected with immunohistochemical technique. PBS was used as substitutes of MAbs for negative control groups[7].

Histological assessment Semi-quantity analysis was made as Formowitz described[8].

Statistical analysis

The difference between each group was analyzed by Chi-Square test and correlativity.

RESULTS

Expression of p42/44^{MAPK} and p-Stat3 proteins in HCCs, PCLTs and normal liver tissues

p42/44^{MAPK} was negative in normal liver tissues. The positive rate of p42/44^{MAPK} in HCCs (87.3%, 48/55) was significantly higher than that in PCLTs (32.7%, 18/55, $P<0.01$) (Figure 1). Positive signals were mainly located in the nucleus. The distribution of positive cells for p42/44^{MAPK} was clustered and/or diffused in HCCs (Figure 2), and scattered in PCLTs, but also clustered in atypical hyperplasia regions of some PCLTs near cancer tissues. The expression level of p42/44^{MAPK} in HCCs was higher than that in PCLTs ($P<0.01$), but it was not correlated with the differentiation degree of cancer cells (Table 1). Positive signals of p-Stat3 were of nuclear-type. Of 9 normal liver tissues, 1 case was p-Stat3 positive. The positive rate of p-Stat3 in HCC (74.5%, 41/55) was significantly higher than that in PCLTs (23.6%, 13/55) ($P<0.01$). The p-Stat3 positive cells were clustered in HCC (Figure 3), and scattered in PCLTs. The expression intensity of p-Stat3 in HCCs was also higher than that in PCLTs ($P<0.01$), but it was not correlated with differentiation degree of cancer cells ($P>0.05$) (Table 1).

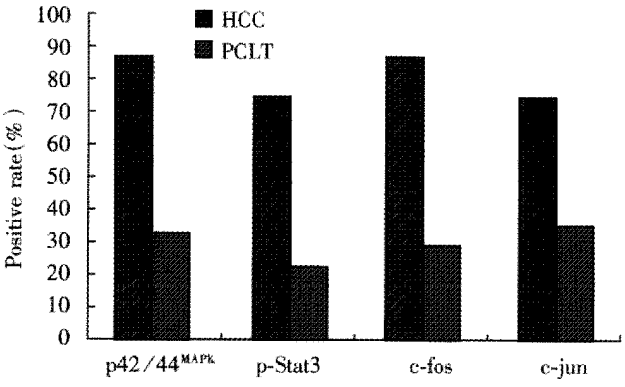

Figure 1 The positive rates of p42/44^{MAPK}, p-Stat3, c-fos and c-jun proteins in HCCs and PCLTs.

Table 1 Expressions of p42/44^{MAPK}, p-Stat3, c-fos and c-jun proteins in HCCs, PCLTs and normal liver tissues

Groups	No	p42/44^{MAPK}				p-Stat3				c-fos				c-jun

Expression of c-fos and c-jun proteins in HCCs, PCLTs and normal liver tissues

The expression of c-fos and c-jun proteins was not found in normal liver tissues. The rates of c-fos and c-jun protein expression in HCCs (76.4%, 87.3%) were significantly higher than those in PCLTs (34.5%, 29.1%) ($P<0.01$). Their positive signals were mainly of nuclear type in HCCs (Figures 4, 5) and nuclear-plasmic type in PCLTs. The positive intensity in HCCs was distinctly higher than that in PCLTs, and related to the differentiation degree of HCC cells. The poorer the differentiation of HCC cells, the stronger the expression of c-fos and c-jun proteins. The distribution of positive cells for c-fos or c-jun protein in HCCs was diffuse, and scattered in PCLTs.

Relativity of expression intensities of p42/44^{MAPK} and p-Stat3 in HCCs and PCLTs

No relationship was found between p42/44^{MAPK} and p-Stat3 signal intensities in HCCs and PCLTs (r = -0.167 and 0.0844, $P>0.05$).

Relationship between expression strength of p42/44^{MAPK} and c-fos proteins, between p42/44^{MAPK} and c-jun in HCCs and PCLTs (Table 2)

In HCCs, the expression of p42/44^{MAPK} was positively related to the expression intensities of c-fos and c-jun proteins. The stronger the expression of p42/44^{MAPK}, the higher the signal intensities of c-fos and c-jun proteins. In PCLTs, there was a positive relationship between the expression of p42/

44^{MAPK} and c-fos proteins, and no relationship between the expression of p42/44^{MAPK} and c-jun proteins.

DISCUSSION

Ras/Raf/MAPK and Janus protein tyrosine kinases (JAKs)/Stat3 cascades are two major signaling pathways of growth factors and cytokines[1,2,4,5,9,10]. The former involves transient formation of ras-GTP and activation of raf kinase at the cell membrane to activate MAPK kinase which in turn activates MAPK through dual phosphorylation on threonine and tyrosine residues[11-14]. Activated MAPK then transduces into the nucleus and phosphorylates the ternary complex factor TCF which activates the expression of immediate-early genes, such as c-fos and egr-1[14,15]. There have been a few reports concerning MAPK activation in human cancers[1,2,16-21]. It was reported that MAPK activity level in HCC was significantly higher than that in the adjacent non-cancerous lesions[1,2,18]. Our results showed that the positive signal of p42/44^{MAPK} was almost located in the nucleus, indicating that the detected MAPK is activated MAPK. The positive rate and intensity of p42/44^{MAPK} in HCCs were all distinctly higher than those in PCLTs, which is consistent with the results reported in literature. Statistical analysis found that the expression intensity of p42/44^{MAPK} in HCCs was significantly positively correlated with the expression strength of immediate-early genes (c-fos and c-jun), and the expressive intensity of p42/44^{MAPK} in PCLTs was also significantly positively correlated with the expression strength of c-fos. These findings further suggest that the imbalance of Ras/Raf/MAPK cascade components may play a key role in hepatocarcinogenesis.

JAKs associate with cytokine receptors which lack intrinsic tyrosine kinase activity and become activated upon cytokine stimulation. Activated JAKs activate Stat3 through phosphorylation of Tyr-705[22]. Phosphorylated Stat3 (p-Stat3) then

translocates into the nucleus and binds to DNA response elements and transactivates gene expression [14,23,24]. The data presented here showed that the positive signals of p-Stat3 were mainly of nuclear type, and the positive rate and strength of p-Stat3 in HCCs were significantly higher than those in PCLTs, and the signal intensity of p-Stat3 was positively correlated with the expression level of the c-jun protein in HCCs and PCLTs. These results suggest that JAKs signaling cascade may also contribute to malignant transformation of hepatocytes besides Ras/Raf/MAPK signaling pathway in hepatocellular carcinogenesis.

Results in literature were inconsistent on the correlation between Ras/Raf/MAPK and JAKs/Stat3 pathways in tumor genesis and development[14,25,26]. Chung *et al*[25] reported that MAPK activated Stat3 through phosphorylation of Ser-727. Leaman *et al*[26] found that JAKs may not be required for the activation of Stat3 by some growth factors such as EGF and PDGF. As the MAPK and Stat3 become activated upon many growth factors and cytokines, it was considered that MAPK may promote activation of Stat3, but in Jain's results MAPK may inhibit transcription activity of Stat3[14]. Our data indicated that there was no correlation between expression intensities of $p42/44^{MAPK}$ and p-Stat3 in HCCs and PCLTs. The Stat3 phosphorylation is a complex event. Because the Stat3 can be phosphorylated through different protein kinases and pathways, detecting Stat3 at different phases of signaling cascades may produce entirely contradictory results about Stat3 activity. We think that both Ras/Raf/MAPK and JAKs/Stat3 pathways may play important roles in hepatocellular carcinogenesis, but their detailed mechanisms need to be further studied.

Up to now, the characteristics of pericar-cinomatous hepatocytes has not been clear[27]. The results showed that pericarcinomatous hepatocytes, especially proliferative or atypical hyperplasia hepatocytes, strongly express $p42/44^{MAPK}$, p-Stat3, c-fos and c-jun proteins, which suggest that activation of MAPK and Stat3 may be an early event in hepatocellular carcinogenesis. It also implys that the hepatocytes which express $p42/44^{MAPK}$ and/or p-Stat3 may be potentially malignant precancerous cells. Therefore, in order to avoid local recurrence, the operative range should be as extended as possible in the resection of HCCs.

Abstract

AIM To examine the expression of activin A, a member of the transforming growth factor (TGF-β) superfamily, recently has been reported to beoverexpressed in liver cirrhosis, in the course of carbon tetrachloride-induced rat hepatic fibrosis.

METHODS Hepatic fibrosis was induced in rats by subcutaneous injections of 40% carbon tetrachloride oily solution for a period of 1 to 7 weeks. At the end of 1, 2, 3, 4, 5, 6 and 7 weeks after carbon tetrachloride injections, the rats were killed in group (6-10 rats each time) for study. The activin A messenger RNA expression and its protein localization were assessed by semi-quantitative reverse transcription polymerase chain reaction (RT-PCR) and immunohistochemistry.

RESULTS The normal rat liver expressed activin A mRNA and protein, and its expression was transiently decreased and became undetectable after carbon tetrachloride injections for 2 or 3 weeks and then increased gradually. After injection of carbon tetrachloride for 6 and 7 weeks, activin A mRNA and protein expressions were significantly enchanced in rat liver. Compared with that of the normal rat liver. Activin A mRNA expression levels in rats receiving carbon tetrachloride injections for 6 and 7 weeks were 1.6 and 2.2 times that of those in normal rat liver respectively (0.456 ± 0.094 *vs* 0.286 ± 0.0670, *P*<0.01; 0.620 ± 0.134 *vs* 0.286 ± 0.0670, *P*<0.01). Immunohistochemistry showed that activin A expressed in hepatocytes of normal liver, and its expression was decreased in rats receiving carbon tetrachloride for 2 or 3 weeks. Compared with normal liver, activin A expression distribution mode changed in fibrotic liver, being increased significantly in hepatocytes around fibrotic areas.

CONCLUSION Activin A expression was increased in late stage of hepatic fibrosis, and this may be involved in hepatic fibrosis formation in this period.

INTRODUCTION

Many researchers have tried to elucidate the pathogenesis of hepatic fibrosis[1-11]. Multiple studies have proved that cytokines play a vital role in this process, especially transforming growth factor β (TGF-β) superfamily[12-21]. Activins are newly found multifunctional proteins that belong to the TGF-β superfamily[22]. There are three kinds of activins, A(βAβA), B(βBβB) and AB(βAβB), which are hetero/homodimers closely related β-subunits of inhibin (βA and βB)[23]. Discovered by virtue of their capacity to stimulate production of follicle-stimulated hormone (FSH) from pituitary gland, activins have widespread anatomical distribution and are implicated in the regulation of many biological processes, including proliferation and differentiation of various types of cells[24]. In liver, ACT A inhibits growth of heptocytes and induces apoptosis, but promotes mesenchymal proliferation and extracellular matrix (ECM) production, and these effects are similar to those of TGF-β[25-27]. Activins and TGF-β may implicate in development of hepatic fibrosis jointly. Sugiyama *et al*[27] have demonstrated that activin A expression was significantly enhanced in cirrhotic and fibrotic rat livers induced by dimethylnitrosamine (DMN) and porcine serum. However, there has been no consensus of opinion about activin expression changing mode and its cell origins in fibrotic rats liver yet, for some researchers have got different results from those of Sugiyama. By means of RT-PCR and immunohistochemstry, we have examined the activin A expression mode in carbon tetrachloride (CCl_4) induced fibrotic rat liver.

MATERIALS AND METHODS

Animals

Adult male Sprague Dawley rats, weighing 180 g-210 g, were obtained from Shanghai Experimental Animal Institute of the Chinese Academy of Sciences. Hepatic fibrosis rat model was created by subcutaneous injections of CCl_4[28-36]. Altogether 72 rats were used. They were randomly divided into the normal control group (6 rats) and model group (64 rats). For the model group rats, CCl_4 olive solution (40% CCl_4) was injected subcutaneously at a dose of 0.4 mL/100 g twice a week. A double dose was used for the first injection. A same volume of saline was injected in normal control group animals. For study by lots every week (from the 1st to 7 th week), 72 hours after last injection of CCl_4, 6-10 model group rats were sacrificed. One portion of each liver was immediately frozen in liquid nitrogen for RNA extraction, and the remainder was fixed with 10%(vol/vol) formalin for van Gieson (VG) staining or immunostaining.

Immunohistochemistry

Deparaffinized 5 μm thick liver sections were washed three times with phosphate-buffered saline (PBS; pH 7.4), incubated in endogenous peroxidase blocking solution (Immunostain EliVision Kit, Maxim Biotech, Inc), and then treated with 0.01 M citrate buffer pH 6.0 for 10 minutes in a microwave oven at 650W. Non-specific-antibody binding was blocked by pretreatment with PBS containing 0.5% bovine serum albumin (fraction V powder, Sigma). Sections were then rinsed in PBS and incubated overnight at 4℃ with diluted monoclonal antibody against activin βA subunit (Serotic, UK) at 1:100 in PBS followed by three washes in PBS containing 0.05% Tween-20. The steps were performed using Immunostain EliVision kit according to the manufacturer's instructions. Sections were stained with 3,3'-diaminobenzidine tetrahydrochloride (DAB) as a chromogen. The slide was rinsed with distilled water, counterstained with hematoxylin, dehydrated, air dried, and mounted. The negative control slides were treated with nonspecific mouse IgG. The sections were examined under light microscopy.

Preparation of RNA

Total RNA was extracted from liver tissues according to the guanidinium isothiocyanate single-step methods (Kit from Watson Biological Inc, Shanghai).The RNA concentration of each sample was estimated by measuring the absorbance at 260 nm.

Reverse transcription and polymerase chain reaction (PCR)

Reverse transcription (RT) was performed using RT kit from Bioneer. The 20 μL reaction contains total RNA 2 μg, and oligo$(dT)_6$ 12.5pmol (Sangon, Shanghai). The first-strand cDNA sample (2 μL) was added to 25 μL of a PCR reaction mixture containing 0.5 μM gene-specific primers, 2 mM $MgCl_2$, 0.2 mM dNTP, and 1.5 units Taq polymerase, 2.5 μL 10 × buffer. Activin βA[37] sense primer: 5'-cagtcgtggacggtgcagaagt-3'; antisense primer: 5'-gcctgcggtgaggatggtctt-3'; the predicted size of the amplification products was 474 bp. The glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene (house-keeper gene) sense primer [38]: 5'-catggtctacacgttccagt-3'; antisense primer: 5'-ggctaagcagttggtggtgc-3'; the 329 bp fragment amplification product was used as a positive control of the reverse-transcriptase receation and tissue mRNA integrity. Amplification conditions included initial denaturation for 5 minutes at 94℃, 30 cycles of amplification for activinβA and 28 cycles for GAPDH, with denaturation at 94℃ for 45 seconds, annealing at 60℃ for 45 seconds, and extension at 72℃ for 1 minute. PCR products were analyzed by electrophoresis through agarose gel(2% wt/vol) and visualized by ethidium bromide staining and ultraviolet illumination. The length of PCR products was measured by comparison with standard molecular-weight marker. The signal intensity of each band was normalized by comparing it with the intensity of GAPDH.

Statistical analysis

Results were expressed as mean ± SE. To compare the mean values, ANOVA analysis was applied. Differences were considered significant if $P<0.05$.

RESULTS

Van Gieson staining

Hepatic fibrosis gradually developed with increasing CCl_4 injections. After 6-7 weeks, VG staining showed that liver from most of model group animals were forming fake liver lobuli with reticulin fibers spreading radially between the portal tracts and central veins (Figure 1).

Immunohistochemistry

Activin βA subunit was detected in normal liver. Figure 2 shows that activinβA immunoreactivity was distributed within the lobuli and localized in parenchymal cells. More staining was found in hepatocytes around central veins. No staining was found in hepatocytes around portal tracts. After CCl_4 injection for 2-3 weeks, activin βA immunostaining was decreased but still detectable, and its distribution was changed, localizing mainly in hepatocytes around fibrotic areas (Figure 3). After CCl_4 injection for6-7 weeks, activinβA immunostaining was enhanced. Many hepatocytes around fibrotic areas (around portal tracts, fibrotic septa and central veins areas) were stained positive (Figures 4,5).

PCR

ActivinβA mRNA subunit was detected in normal rat liver, but it became undetectable after CCl_4 was injected for 2-3 weeks. Four weeks after CCl_4 injections, activin βA mRNA levels increased gradually, and were significantly enhanced after 6 or 7 weeks when compared with normal rat liver (P<0.01) (Figures 6,7). Activin βA mRNA levels in rats treated with CCl_4 for 6 and 7 weeks were 1.6 and 2.1 times of those in normal rat liver respectively.

DISCUSSION

Liver cirrhosis is a final stage of various chronic liver diseases and is characterized by a marked deposition of extracellular matrix, combined with impared hepatic regeneration. Several cytokines are involved in the pathogenesis of this disease[39]. In particular, TGF-β1 is overexpressed in nonparenchymal cells of fibrotic liver of human or animals, and plays a pivotal role in the development of cirrhosis by stimulating fibroblast proliferation and ECM secretion[40-44]. Recent studies showed that activin may also be involved in the development of cirrhosis.

Activin A has mutiple effects including proliferation and differentiation of various types of cells[24]. In terms of its effects on hepatocytes, activin A inhibits DNA synthesis and induces apoptosis of hepatocytes[25,26,45]. In fibrotic or cirrhotic rat liver induced by CCl_4, De Bleser found that activin A disappeared in parenchymal cells, and it was expressed when the liver was normal. The normal hepatic stellate cells showed no activin A expression, but its expression was significantly enhanced when hepatic fibrosis had formed[17,46]. Subsequently, Sugiyama[27] found activin A expression was greatly increased in fibrotic rat liver induced by DMN and porcine serum, but it was in hepatocytes but not hepatic stellate cell that activin

A expression was significantly increased. Obviously, results from De Bleser and Sugiyama were not completely consistent with each other. Our research showed that activin A expression was increased in CCl_4-induced fibrotic rat liver, being localized in hepatocytes. These results were consistent with those of Sugiyama.

We had used the same hepatic fibrosis model as De Bleser's, but the results were different. This may be due to a difference in the period of model-making. We found that normal liver expressed activin A, but after injection of CCl_4 for 2-3 weeks, activin A mRNA became undetectable, although its protein could still be found. Four weeks later, activin A mRNA increased gradually. But it was not significantly increased until CCl_4 was injected for 6 or 7 weeks when hepatic fibrosis had formed completely. This means that most of livers have formed pseudo lobuli. Sugiyama also found that in the early period of hepatic fibrosis induced by DMN, the expression of activin βA mRNA was discreased transiently, and then increased gradually with lapse of time. However, the expression was enhanced continuously in porcine serum-induced cirrhosis. This difference may be due to serious hepatocytic damage caused by CCl_4, which is also found in the early stage of the development of DMN induced liver cirrhosis but not in porcine serum induced cirrhosis[47-50]. As activin A acts as an autocrine growth inhibitor of hepatocytes, this transient decrease in expression may promote hepatocytic regeneration. De Bleser reported that activin βA expression disappeared in parenchymal cells of CCl_4 induced cirrhosis, but we think that it might be a transient disappearance, for liver cirrhosis was not formed completely. In addition, De Bleser found that activin A expressed in activated hepatic stellate cells (HSC) of fibrotic liver, but according to our result, activin A immunostaining was mainly distributed in hepatocytes around fibrotic areas (Figures 4,5), a result also consistent with Sugiyama's reports. So it is worthy of further study to confirm whether HSC expresses activin A or not.

The expression of activin A protein was not complete in conformity with its mRNA. Its mRNA became undetectable after CCl_4 injections for 2 to 3 weeks, but activin A protein could be detected by immunohistochemistry. Sugiyama described similar phenomenon in DMN-induced cirrhosis. This may be because of the fact that the mRNA level was too low to be detected by our method. Of course, other reasons may exist and worth further studying.

In summary, our study shows that in CCl_4-induced rat cirrhosis, the expression of activin A is decreased transiently at first, and then increased gradually. Activin A may be involved in the late stage of the development of liver cirrhosis. Distribution of activin A also changes with the development of fibrosis, that is from hepatocytes around central veins to hepatocytes around fibrotic areas including central vein, connective septa and portal tracts.

Abstract

AIM To evaluate the antifibrotic effect of different doses of recombinant human Gamma-Interferon (IFN-γ) in two rat models of hepatic fibrosis, and to observe its effect on moderate chronic hepatitis B virus fibrosis.

METHODS Hepatic fibrosis was successfully induced in 150 and 196 rats by subcutaneous injection of carbon tetrachloride (CCl_4) and intraperitoneal injection of dimethylnitrosamine (DMN), respectively. Each of the two model groups was divided into: ① fibrotic model group; ② colchicine treatment group (0.1 mg/kg/day, gastrogavage for 8 weeks); ③ high-dose IFN-γ group (15 MU/kg per day, i.m. for 8 weeks); ④ medium-dose IFN-γ group (5MU/kg daily, i.m. for 8 weeks); and ⑤ low-dose IFN-γ group (1.67 MU/kg daily, i.m. for 8 weeks). Another group of 10 rats without any treatment was used as normal controls. At the end of the experiment, semi-quantitative histopathological scores of inflammation and fibrosis, liver α smooth muscle actin (α-SMA) expression level, liver hydroxyl proline content and serum hyaluronic acid levels were compared. And 47 medium chronic hepatitis B viral fibrosis patients were studied. They were given IFN-γ treatment, 100 MU/day i.m. for the first three months and 100 MU qod i.m. for the next six months. Semi-quantitative pathological scores of inflammation and fibrosis and serum hepatic fibrosis indices were compared within the 9 months.

RESULTS In animal experiment, the pathological fibrosis scores and liver hydroxyl proline content were found to be significantly lower in rats treated with different doses of IFN-γ as compared with rats in fibrotic model group induced by either CCl_4 or DMN, in a dose-dependent manner. For CCl_4-induced model, pathological fibrosis scores in high, medium and low doses IFN-γ groups were 5.10 ± 2.88, 7.70 ± 3.53 and 8.00 ± 3.30, respectively, but the score was 14.60 ± 7.82 in fibrotic model group. Hydroxyl proline contents were 2.83 ± 1.18, 3.59 ± 1.22 and 4.80 ± 1.62, in the three IFN-γ groups, and 10.01 ± 3.23 in fibrotic model group. The difference was statistically significant ($P<0.01$). Similar results were found in DMN-induced model. Pathological fibrosis scores were 6.30 ± 0.48, 8.10 ± 2.72 and 8.30 ± 2.58, in high, medium and low doses IFN-γ groups, and 12.60 ± 3.57 in fibrotic model group. Hydroxyl proline contents were 2.72 ± 0.58, 3.14 ± 0.71 and 3.62 ± 1.02, in the three IFN-γ groups, and 12.79 ± 1.54 in fibrotic model group. The difference was statistically significant ($P<0.01$). Serum hepatic fibrosis indices decreased significantly in the 47 patients after IFN-γ treatment (HA: 433.38 ± 373.00 *vs* 281.57 ± 220.48; LN: 161.22 ± 41.02 *vs* 146.35 ± 44.67; PC(r): 192.59 ± 89.95 *vs* 156.98 ± 49.22; C-I: 156.30 ± 44.01 *vs* 139.14 ± 34.47) and the differences between the four indices were significant ($P<0.05$). Thirty-three patients received two liver biopsies, one before and one after IFN-γ treatment. In thirty of 33 patients IFN-γ had better effects according to semi-quantitative pathological scores (8.40 ± 5.83 *vs* 5.30 ± 4.05, $P<0.05$).

CONCLUSION All the three doses of IFN-γ are effective in treating rat liver fibrosis induced by either CCl_4 or DMN, the higher the dose, the better the effect. And IFN-γ is effective for patients with moderate chronic hepatitis B viral fibrosis.

INTRODUCTON

Hepatic fibrosis can cause liver cirrhosis in chronic liver diseases (viral, schistosomal, alcoholic). Regardless of causes, hepatic fibrosis is characterized by a large deposition of extracellular matrix, collagen being a major component. Studies on interferon-gamma (IFN-γ) *in vitro* or *in vivo* are increasing[1-7]. Although the interferons were initially described for their antiviral properties, IFN-γ has also been found to have significant effects against hepatic fibrosis and to inhibit the synthesis

of extracellular matrix[8-14]. However, there have been few studies on the relationship between different doses and effects of IFN-γ for hepatic fibrosis. Our previous study showed that IFN-γ could lower serum hyaluronic acid levels in chronic hepatitis patients with hepatic fibrosis[15]. But no reports concerning histological changes after IFN-γ treatment have ever been found. We were prompted to systematically observe the effect of IFN-γ and investigate its effective doses on rat hepatic fibrosis induced by intraperitoneal injection of two different toxins, carbon tetrachloride (CCl_4) and dimethylnitrosamine (DMN). Once hepatic fibrosis emerged in two rat models, different doses of IFN-γ were injected intramuscularly to observe the following changes after IFN-γ treatment: pathological fibrosis scores, liver hydroxylproline content and serum hyaluronic acid levels. In the meantime, we observated 47 chronic hepatitis B patients with hepatic fibrosis who received IFN-γ treatment for 9 months. Liver biopsy and other laboratory tests were performed within the 9 months, the effect of IFN-γ was assessed.

MATERIALS AND METHODS

Animal experimental design

Sprague-Dawley rats (n = 483) weighing 200 gm-250 gm were used. They were fed with Good Laboratory Practice diet in pellets (provided by Zhejiang University Animal Study Center). Rats were maintained under 12 h light/dark cycles and allowed free access to food and water. Experiments were performed in accordance with the institutional ethical guidelines.

Hepatic fibrosis was induced by intraperitoneal injections of CCl_4 or DMN. Recombinant human IFN-γ was kindly provided by Shanghai Clonbiotech Co., Ltd (Shanghai, China, Batch Number 970521).

Rats (n = 205) were subcutaneously administered dissolved CCl_4 in olive oil (a proportion of 4:6) at 0.3 mL/kg of body weight, i.p., for 2 consecutive days a week for 16 weeks. Five rats were killed at the end of each week to examine their pathological changes.

For DMN-induced fibrosis, 278 rats were injected i.p. repeatedly, for 3 consecutive days at the first week and 2 consecutive days for the next 5 weeks. Five rats were killed at the end of each week to examine their pathological changes.

According to histological sections, hepatic fibrosis appeared at the end of the fourth week from the start of the study. One hundred and fifty rats in CCl_4 induced model and 196 rats in DMN-induced model could be used for the next study. Rats in the two models were divided into five groups: ① fibrotic model group; ② colchicine treatment group ($0.1 mg \cdot kg^{-1} \cdot day^{-1}$, gastrogavage); ③ high-dose IFN-γ group ($15 MU \cdot kg^{-1} \cdot day^{-1}$, i.m.); ④ medium-dose IFN-γ group ($5 MU \cdot kg^{-1} \cdot day^{-1}$, i.m.); and ⑤ low-dose IFN-γ group ($1.67 MU \cdot kg^{-1} \cdot day^{-1}$, i.m.). In addition, 10 rats were chosen as the normal control group. Rats in the normal control and fibrotic model groups were given 0.9% sodium chloride by intramuscular injection instead of IFN-γ.

Rats of CCl_4 induced model received 8-week treatment. At the end of the eighth week, 10 rats of each group were killed, and histological sections of their livers were evaluated by hematoxylin and eosin and Sirius red stains. α-smooth muscle actin (α-SMA) was examined with immunohistochemical technique. Liver hydroxylproline content and serum hyaluronic acid level were also detected. In the next 4 weeks, all treatments stopped. The rest of the rats were killed at the end of the sixteenth week from the start of the experiment.

Rats of DMN-induced model received 4-week treatment. At the end of the fourth week, 10 rats of each group were killed. All items performed in CCl_4-induced model were detected, too. The other rats were killed at the end of the 12 th week from the start of the study.

Histological study

Excised liver tissues from rats were fixed in 10% neutralized formaldehyde, embedded in paraffin, and then stained with hematoxylin and eosin. Alternatively, the Sirius red stain method was used to specifically stain fibrous tissue components. These sections were observed under polarization microscopy (Leica DMLB, Leica Wetalar, Germany.) to distinguish type I and III collagen[16]. Specimens were reviewed under code by a single pathologist who graded and scored the specimens according to the criteria of Scheuer and Chevallier *et al*[17,18]. In Scheuer criteria, the transformation of grade and stage was as follows: stage 0, = 2°; grade or stage 1, = 2^1; grade or stage 2, = 2^2; grade or stage 3, = 2^3; grade or stage 4, = 2^4.

Identification of activated hepatic stellate

α-SMA, a marker of activated hepatic stellate (HSC) [19,20], was detected in formaldehyde-fixed paraffin-embedded section. Briefly, liver tissue was incubated with a monoclonal IgG_2a recognizing α-SMA (Dako M851) and reactive sites were detected using the labeled streptavidin-biotin technique (Dako M680), resulting in a brown staining after incubation with Tris-buffered saline containing diammobenzidine and H_2O_2. In control slides, the primary antibody was substituted by the Tris-buffers.

Biochemical measurements

The liver was homogenated into powder and hydrolyzed with 6 mol/L HCl. The hydroxyl proline content was measured by the means of Kivirikko *et al*[21]. The routine serum biochemical tests, including serum aspartate transaminase and alanine transaminase, were performed.

Examination of serum hyaluronic acid level

Serum hyaluronic acid level was detected by radioimmunoassay technique. The kit was provided by the Shanghai Navy Medical Institute. The operations were performed according to the manufacturer's instructions.

Patients

Fourty-seven hepatic fibrosis patients with chronic hepatitis B, 37 males and 10 females, were chosen for the study. They were confirmed to have moderate hepatic fibrosis pathologically according to Scheuer and Chevallier scoring system[17,18] and had chronic hepatitis B for 6 months to 30 years. Additional criteria included: age between 18 and 65 years; presence of HBsAg in serum for at least 6 months; positive serum tests for anti-HBe documented on four occasions, at least 1 month apart, during the 6 months before entry into the study. Among four serum hepatic fibrosis indices, including hyaluronic acid (HA, upper nomal limit <110 μg/L), laminin (LN, upper normal limit <150 μg/L), type III procollagen (PCIII, upper normal limit <120 μg/L) and type IV collagen (C-IV, upper normal limit <80 μg/L), two indices were higher than upper normal limit. Patients were excluded when the haemoglobin ≤10 g/dL, platelet count ≤50 000/mL, and white cell count ≤4 000/mL. Other exclusion criteria were patients with decompensated liver disease (serum albumin <3.5 g/dL; serum total bilirubin ≥85.5 μmol/L; prothrombin time prolongation >3sec), histories of hepatic encephalopathy or ascites, esophageal or gastric varices at risk of bleeding, hepatitis delta virus, hepatitis C virus infections, causes of liver disease other than HBV, intravenous drug abuse, pregnancy, malignancy, chronic heart and/or renal failure, anti-virus therapy (such as IFN-α, lamivudine, Famciclovir and Penciolovir therapy) and immune modulation therapy (such as Thymosin α_1) within a period of 3 months, and anti-hepatic fibrosis drugs (such as colchicines, herbal recipe 861 and Extractum Semen Percise).

Study protocol

In this open label study, all the patients were given routine therapy and received rhIFN-γ (kindly provided by Shanghai Clonbiotech Co., Ltd, Shanghai, China, Batch Number 981210) at a dose of 1 MU intramuscularly daily for the first three months and every other day for the following six months. They were asked to take rhIFN-γ in local hospitals near their homes. They were visited every three months during the treatment and thereafter followed up for 3 months after the treatment stopped. At each visit, clinical and laboratory assessments were made, including serum biochemical tests, such as serum hepatic fibrosis indices, routine serum biochemical tests, such as ALT, AST and γ-glutamyl transpeptidase, alkaline phosphatase, albumin, total bilirubin and alfha fetoprotein (AFP), routine blood tests, and HBV serology. Ethical Committee of the Centers involved approved the study. All the patients were volunteers.

Histology

Liver biopsies were performed twice within the 9 months, one before the treatment and one after it. All liver biopsy specimens were stained with hematoxylin-eosin and Sirius red. A single pathologist who was blinded with respect to treatment regimen evaluated specimens according to the criteria of Scheuer and Chevallier *et al*[9,10].

Statistical analysis

Results were expressed as mean ± standard deviation and compared when appropriate, by Student's two-tailed paired and unpaired *t* test and Kruskall Wallis nonparametric one-way ANOVA.

RESULTS

Animal experiment

In normal control group, Sirius red staining showed a normal distribution of collagen in a small amount in the portal tracts and around the terminal hepatic veins.

CCl_4- induced model showed different pathological changes from DMN-induced model. In the former, besides hepatocyte necrosis, fatty degeneration was the major feature[22] while in the latter, lymphomonocyte infiltration and local hepatocyte necrosis were the main characteristics[23]. However, after 12 weeks of CCl_4 and 8 weeks of DMN treatment, all the rats in fibrotic model groups showed complete fibrotic septum, forming a pattern of micronodular cirrhosis to the parenchyma (Figure 1).

In animal treated with high-dose of IFN-γ, Sirius red staining showed a small collagen deposition in the portal tracts and lobules. Only collagen fibers around the terminal hepatic veins were observed (Figure 2). Collagen depositions in liver sections taken from animals treated with medium or low dose of IFN-γ were particularly evident but only thin bands of collagen which formed short, incomplete septum could be seen (Figures 3, 4). In colchcine treated animals, complete fibrotic septum departing from the central vein were present, and no cirrhosis could be observed (Figure 5). Tables 1 and 2 show the histological stage and grade of different groups.

In the normal control group, α-SMA positive cells were detected mainly in the portal space as elements of vascular walls or as fibroblastlike cells scattering in the connective tissue or near bile ductules. In lobule, α-SMA positive cells were present on the walls of large and medium sized terminal hepatic veins. The pattern of distribution of α-SMA positive cells was modified in CCl_4 or DMN treated animals as compared with the normal control rats. In fibrotic model groups, α-SMA positive cells were detected in portal space, sinusoid, lobule and areas where fibrotic septum appeared. Different doses of IFN-γ appeared to strikingly decrease the activation of HSC. After 8 weeks of IFN-γ treatment in CCl_4 model or 4 weeks in DMN model, only thin and incomplete parenchymal α-SMA positive septum joining thickened centrilobular veins were observed. α-SMA positive cells were mainly found in portal space and areas around fibrotic septum. Few α-SMA positive cells were present in sinusoid and lobule.

Analysis of total collagen content in liver substantiated the histological impression. Hydroxylproline evaluation in fibrotic model groups showed that the amount of Hydroxyl proline content increased approximately 5-fold (in CCl_4 model) or 6-fold (in DMN model) as compared with the normal control group, whereas, figures of different doses of IFN-γ groups were lower (<2-fold). The results in Tables 3 and 4 indicate the serum hyaluronic acid level of different groups. Except for low-dose IFN-γ group in CCl_4-induced model, other IFN-γ treatment groups had obvious decrease of serum hyaluronic acid level in both models.

Clinical study

All the 47 patients completed the 9-month treatment. Table 5 shows the changes of symptoms after the 9-month IFN-γ treatment. Except for these changes, 12 patients (12/47, 25.5%) had a better appetite than before the treatment.

Thirty-three patients were given a second biopsy after the 9-month treatment (33/47, 70.2%). According to Chevallier's criteria, semi-quantitative system score (SSS) was calculated. After the 9-month IFN-γ treatment, the SSS decreased significantly in 14 patients (14/33, 42.4%) and the SSS dropped over 2 points, increased in 3 patients (3/33, 9.1%), and remained unchanged or dropped 1 point in the remaining 16 patients (16/33, 48.5%). Table 6 shows the mean SSS change during the treatment. A significant decrease of hepatic fibrosis score in accordance with the SSS was seen at the end of the IFN-γ treatment (8.40 ± 5.83 *vs* 5.30 ± 4. 05, P<0.05). In the meantime, a decrease of inflammation score in accorda nce with the SSS was also found although the difference was not statistically significant (P>0.05). Figures 6-9 display the collagen deposition changes within the IFN-γ treatment.

Table 7 shows the mean serum hepatic fibrosis indices, including HA, LN, PCIII and C-IV, and changes during the entire study. Decreases were present in the four indices (HA: 433.38 ± 373.00 *vs* 281.57 ± 220.48; LN: 161.22 ± 41.02 *vs* 146.35 ± 44.67; PCIII: 192.59 ± 89.95 *vs*. 156.98 ± 49.22; C-IV: 156.30 ± 44.01 *vs*. 139. 14 ± 34.47) and the differences between the four indices were significant (P<0.05).

As described by Cannon *et al*[24], the main side-effects in our study during the IFN-γ treatment were: fever (25) , joint pain (13), nausea (1), myagias (18), headache (10), leukopenia (5) and platelet decreases (7). Fever presenting in some patients was temporary and only 1 person had persistent fever (about 38℃), which disappeared when the treatmentended.

We also performed other routine serum biochemical tests, including ALT, AST and γ-GT, AFP. The results showed that the mean serum ALT, AST, γ-GT levels lowered in those patients as compared with those of IFN-γ treatment. No obvious change in serum AFP level was present within the 9 months (data not shown).

DISCUSSION

CCl_4 is one of the most widely used hepatic toxins for experimental induction of liver fibrosis cirrhosis in laboratory[22,25,26]. The model was used even in 1936. But, disadvantages of the model were apparent, such as higher mort ality rate. For this reason, 205 rats were used to produce CCl_4-iduced hepatic fibrosis model in our study. By killing some animals at the end of each week, we successfully got the hepatic fibrosis model at the fourth week. A total of 150 rats were used for the following study. We used DMN-induced hepatic fibrosis model. The characteristics of this model had been described by Madden *et al* [23]. Low mortality rate, shortproduction period and easy reproduction were the main advantages. We could investigate the effect of IFN-γ on hepatic fibrosis caused by different toxins because the two models had different mechanisms of inducing hepatic fibrosis.

Earlier report on the effect of IFN-γ anti-fibrosis could be found in 1984[8]. Studies *in vitro* or *in vivo* later proved that IFN-γ had a better effect on hepatic fibrosis[9-14]. However, IFN-γ and toxins were used at the same time in these studies. In the strict sense, their results only demonstrated that IFN-γ could prevent hepatic fibrosis, but failed to prove the effect of IFN-γ. In this study, IFN-γ was used on the first day of the fifth week when hepatic fibrosis had appeared so as to observe its effect on hepatic fibrosis.

In our study, we substantiated the impression that pathological changes taking place in CCl_4-induced model were different from those in DMN-induced model[22,26]. But, all the animals in fibrotic model groups showed complete fibrotic septum, forming a pattern of micronodular cirrhosis. Treatments with different doses of IFN-γ indicated significant decreases in the SSS, liver hydroxylproline content and serum hyarunic acid level. Among the three IFN-γ treatment groups, the best effect was present in the high-dose IFN-γ group.

To our knowledge, this is the first study on the effect of IFN-γ using different doses in animals. Our results showed that the effect of IFN-γ was associated significantly with doses. The higher the dose, the better the effect (Tables 1-4). The dose of IFN-γ used for virus is as high as 600MU/day. However, in our study, the medium dose of IFN-γ (5 MU/kg/day) used in rats is equal to 100 MU/day used in human. Whether the dose of IFN-γ could be increased clinically needs further studies.

Colchicine was used as the control drug in the experiment. Its effect on hepatic fibrosis in rats was not as good as that of IFN-γ according to the pathological and biochemical examinations (Tables 1-4).

In order to complete the animal experiment, we substantiated the effect of IFN-γ on chronic hepatitis B patients with hepatic fibrosis. Fourty-seven patients conforming to the study criteria were chosen in our study. After a 9-month IFN-γ treatment, 33 patients underwent a second liver biopsy. The results showed that the SSS decreased or unchanged in 30 patients (Table 5). The mean fibrosis score in accordance with SSS decreas ed from 8.40 ± 5.83 to 5.30 ± 4.05 (Table 6). And serum indices (including HA, C-IV, PCIII and LN) strengthened the pathological impression. All the four indices decreased significantly after the IFN-γ treatment (Table 7).

It was concerned that IFN-γ would increase inflammation[27]. However, our study showed a decrease of inflammation as compared with the previous IFN-γ treatments although the difference was not statistically significant (Table 6). We chose chronic hepatitis patients for the experiment so as not to cause patients any worries at the stage of acute inflammation. The results showed that IFN-γ treatment was safe for chronic hepatic patients. In the study, we also performed routine serum biochemical tests, including ALT, AST, and γ-GT, AFP. The mean serum ALT, AST, and γ-GT level lowered in those patients as compared with those of IFN-γ treatment. No obvious change in serum AFP level was found within the 9 months.

It is well known that collagen type I is the predominant extracellular matrix protein in fibrosis and cirrhosis but few techniques could discriminate different collagens in the same section[28,29]. We used Sirius red stain to resolve the problem as described by Zhang *et al*[16]. Under Polarization microscopy, sections stained with Sirius red showed different colors, red and yellow representing collagen type I and green collagen type III.

In our previous report, decrease of serum hepatic fibrosis indices was observed[15] after 3 months of IFN-γ treatment. So, at the earlier stage of the experiment, we adopted a 6-month treatment. There were 2 patients who received a second liver biopsy. No obvious changes were found in liver sections. We considered that a 9-month IFN-γ treatment was appropriate.

In this study, we paid more attention to side-effects. Symptoms including fever, joint pain, myagias, headache, nausea, leukopenia and platelet decrease were found in the experiment. IFN-γ was first used to treatrheumatoid [30,31], for as long as 24- months[24]. No serious side-effects were reported. However, whether IFN-γ may cause any side effects when it is used to treat hepatic fibrosis needs further observations.

ACKNOWLEDGEMENT We are indebted to Prof. Pei Hui Chen from the Department of Pathology, Second Affiliated Hospital, Medical College, Zhe jiang University for his help with the pathological technique.

Abstract

AIM To investigate the anti-HBV effect of oxymatrine (oxy) *in vivo*.

METHODS HBV transgenic mice were produced by micro-injection of a 4.2 kb fragment containing the complete HBV genomes. Expression level of HBsAg and HBcAg in the transgenic mice liver was determined by immunohistochemical assay.

RESULTS Four groups (6 mice in each group) were injected intraperitoneally with oxy at the dosage of 100, 200, and 300 mg/kg or with saline once a day for 30 days. Both HBsAg and HBcAg were positive in livers of all the six mice in the control group (injected with saline), and were positive in livers of two mice in 100 mg/kg group and 300 mg/kg group. In 200 mg/kg group, HBsAg and HBcAg were negative in livers of all the six mice. Based on the results, 200 mg/kg is the ideal dosage to explore the effect of oxy at different time points. According to the oxy treatment time, mice were divided into four groups: 10 d, 20 d, 30d and 60 d (4 mice in each group). Each mouse underwent liver biopsy two weeks before the treatment of oxy. Down-regulation of HBsAg and HBcAg appeared after treatment of oxymatrine for 10 d and 20 d, Dane-like particles disappeared after the treatment of oxy for 20 d under electron microscopy, however, the expression level of HBsAg and HBcAg returned to normal 60 d later after oxy treatment.

CONCLUSION oxymatrine can reduce the contents of HBsAg and HBcAg in transgenic mice liver,longer treatment time and larger dosage do not yield better effects.

INTRODUCTION

There are about 30 million patients suffering from chronic hepatitis B in China. Patients with active liver disease carry a high risk of developing cirrhosis and hepatocellular carcinoma. At present, the most effective medicine is IFN-α, but it is too expensive for most patients. Even in the patients treated by IFN-α, the sera negative-convertion rate of HBeAg and HBVDNA is about 40%[1-3]. Previous works in our department by Cai X *et al* showed that the sera negative-convertion rates of HBeAg in patients with chronic active hepatitis B treated with oxymatrine was 61%[4]. To investigate the inhibiting mechanism of oxymatrine (oxy) on HBV replication, transgenic mice were employed as animal model to observe the changes of HBsAg and HBcAg expression in liver tissues.

MATERIALS AND METHODS

Materials

Matrine injection is the product of Ningxia Pharmaceutical Company Ltd., containing 98% oxymatrine. The restriction enzymes were purchased from PROMEGA. Taq enzyme purchased from SANGON. Immunohistochemical kits were purchased from DAKO. Primers of PCR were designed by ourselves and synthesized by GIBCO. ^{32}P labeled kit was the product of PROMEGA. Other reagents were purchased from WASON, HUAMEI and so on.

Methods

Preparation of animals HBV transgenic mice (official designation: ICR-TgN HBV adr1.2 SMMU) were produced by micro-injection of a 4.2 kb fragment containing the complete HBV genome (adr subtype)[5]. Structural analysis of the transgene revealed that at least one complete uninterrupted HBV genome was present. HBsAg and HBeAg were not detectable in the sera of the mice, but can be detected in livers by immunohistochemical assay (ABC), which was used to determine the expression level of HBV.

PCR and Southern-blot analysis Total tail genome DNA was analyzed by PCR using HBV-specific primers 5'CCCAATGGAACACTCACC[sense], 5' AGGAACCACTGAACAAATGGC [antisense]), generating a 380 bp fragment. Twenty mililiter of PCR products were analyzed by electrophoresis on a 1% agarose gel in the presence of 0.5 mg of ethidium bromide per mililiter. DNA bands were visualized by UV fluorescence. Southern-blot analysis was performed on total genomic DNA by agarose gel electrophoresis of 30 mg restricted

genomic DNA. Samples added on nylon filters were hybridized with HBV specific ^{32}P labeled DNA probes.

Histological analysis and electron microscopy were carried out as routine methods. The expression of HBsAg and HBcAg in liver tissues were assessed by immunohistochemical analysis according to Guidotti *et al*[6].

RESULTS

Effect of oxy at different doses on the expression of HBsAg and HBcAg Twenty-four age and sex-matched mice were divided into four groups. Each group was injected intraperitoneally with oxy at the dosage of 100, 200 and 300 mg/kg or with saline separately once a day for 30 days. Livers were harvested 2 hours after the last injection for immunohistochemical assay. Both HBsAg and HBcAg were positive in livers of all the six mice in the control group (injected with saline). In 100 mg/kg group, HBsAg and HBcAg were positive in two mice, while HBsAg and HBcAg were negative in the other four mice. In the 200 mg/kg group, both HBsAg and HBcAg were negative in all the six mice, none of the six mice had detectable HBV antigen in the livers. In the 300 mg/kg group, HBsAg and HBcAg were positive in two mice, and negative in the other four mice. No pathological changes were found in the transgenic mice. Based on the results, we considered that 200 mg/kg is the ideal dosage of oxy for further study.

The effect of oxy at different time on the expression of HBsAg and HBcAg

Mice were divided into four groups according to the oxy treatment time, 10d (group 1), 20 d (group 2), 30 d and 60 d (group 3 and 4). In each group, 4 mice were randomly entered. Each mouse underwent liver biopsy two weeks before the treatment of oxy (200 mg/kg). The liver samples before and after oxy treatment were collected, and immunohistochemical analysis was performed to determine the expression level of HBsAg and HBcAg. All the samples contained HBsAg and HBcAg positive cells, and the positive and negative cells were counted in 5 randomly selected high field vision, and χ^2 test was made to compare the HBV expression level before and after oxy treatment. In group 1, the number of HBsAg and HBcAg positive cells was significantly lower than before treatment of oxy in all the four mice livers. In group 2, the similar results were observed (Figures 1 and 2), and Dane-like particles could be found in the livers before oxy treatment under electron microscope and such particles could not be found after the treatment of oxy for 20 d (Figure 3). In group 3, the expression of HBV was decreased only in two of four mice. No difference was observed on the expression of HBsAg and HBcAg between the two liver samples harvested before and after the treatment of oxy in group 4.

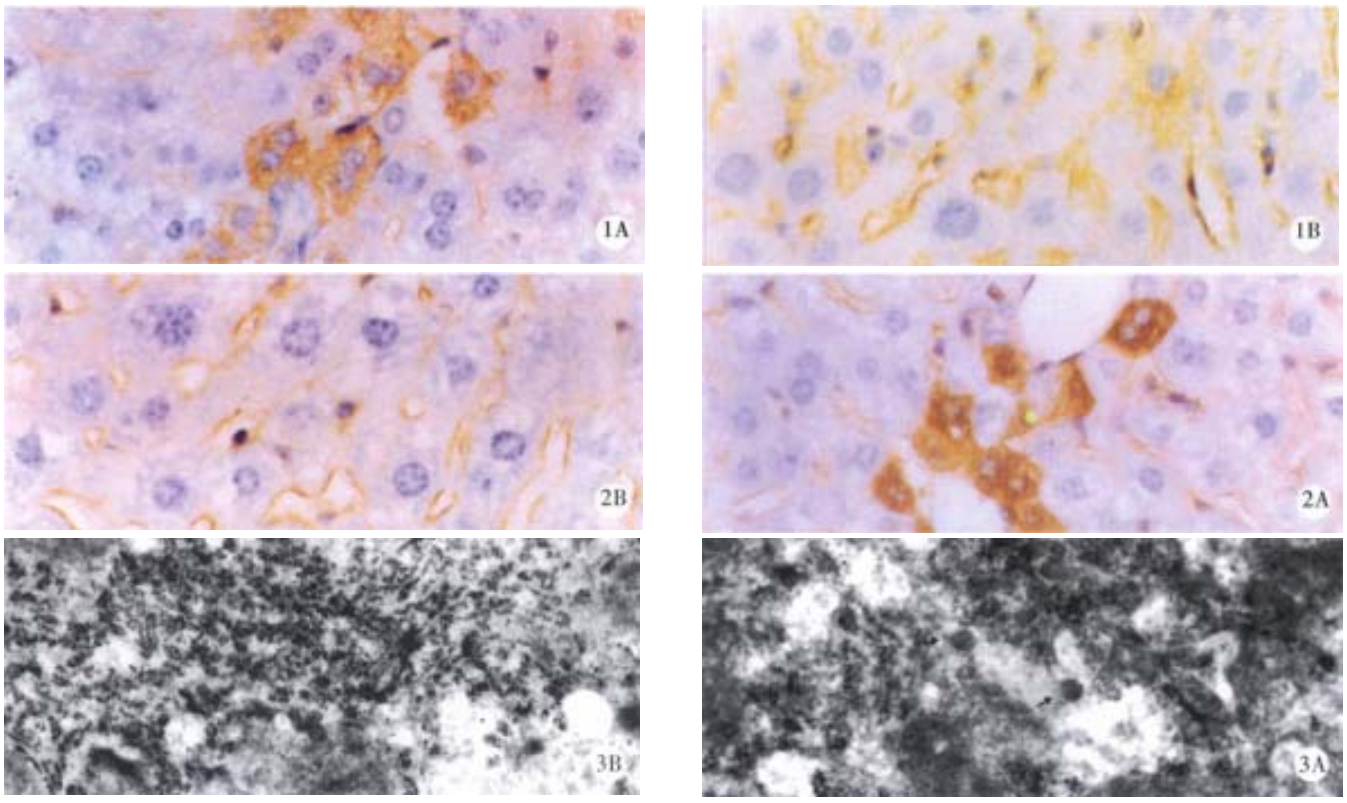

Figure 1 HBsAg in liver of the mice before (A) and after (B) treatment with 200 mg/kg oxy for 20 d.
Figure 2 HBcAg in liver of the mice before (A) and after (B) treatment with 200 mg/kg oxy for 20 d.
Figure 3 Dane's like particles can be seen in the liver of untreated mice (A) and disappeared after treatment with 200 mg/kg oxy for 20 d (B).

DISCUSSION

As a traditional Chinese medicine, *Sophra Flavescens Ait* has been used for the treatment of many diseases for thousands of years. Its extract, oxy, has long been extensively used in China. It is reported that oxy has a lot of pharmacological functions which can be divided into four classes: ① Anti-bacterial and anti-parasitic actions. It has been reported that oxy can cure acute dysentery, *Trichomonas vaginalis* and Giardia lamblia infection [7-9], but the mechanism is still unclear. ② Regulating immune reaction. Oxy can stimulate immune response at a low concentration while inhibiting immune response at a high concentration[10]. Recently, more researchers have paid attentions to the immune inhibitory effect of oxy. It has been reported that oxy has many functions such as anti-inflammation, anti-hypersensitive reactions, inhibiting histamine releasing[11-14]. The mechanism may be related to the changes of cAMP in the cell[15] and inhibiting production of cytokine[16]. ③ Inducing production of cytochrome P450. Oxy can increase the content of P450 in the rat liver significantly after treatment of oxy at the dosage of 200 mg/kg for 4d [17]. ④ Anti-virus actions. Liu JX reported that oxy could inhibit coxsackie virus B3 *in vivo* and *in vitro* [18,19]. Cai X found that the sera negative convertion rates of HBVDNA and HBeAg were 61.9% and 61.0% in chronic active hepatitis treated by oxy, while such rates in the therapy of IFN-α were 57.9% and 55.3%[4]. In our study, the content of HBV antigen in livers of transgenic mice decreased significantly after treatment of oxy for 10 and 20 d. Dane-like particles disappeared in the liver of transgenic mice after oxy treatment for 20 d. However, HBV expression level returned to normal after treatment by oxy for 60 d. We concluded that oxy can be used as an effective drug in managing HBV infection. There are two features of oxy on HBV: ① HBsAg and HBcAg was down regulated at the same time, ② longer time and larger dose did not yield better effect.

Our results strongly suggested that oxy can significantly inhibit the expression of HBV antigen in transgenic mice and the replication of HBV as well[20]. But how oxy give play to its effect can not be concluded from our experiments. However, based on the previous researches, it seems that oxy may act by two ways: ① oxy acts as an immune reaction regulator: Since HBV transgenic mice were first found by Chisari in 1985[21], *in vivo* study of HBV has become convenient and objective. Different lineage of HBV transgenic mice has also been found in our country[5,22]. A serial studies by Chisari *et al* have shown that certain soluble products of the immune response, especially IFN-γ, TNF-α, IFN-α, IL-2 and IL-12[23-28] could suppress the steady-state content of HBV messenger RNA in the hepatocytes of transgenic mice. Furthermore, these effects were found to be mediated by a post-transcriptional mechanism that selectively accelerates the degradation of cytoplasmic HBV mRNA[27]. The same events were set in motion when HBsAg-specific CTL secreted IFN-γ and induced TNF-α after antigen recognition[23,29]. The interhepatic nucleocapsid particles and replicative intermediates were also eliminated during unrelated virus infection[30,31] or during hepatocellular regeneration after partial hepatectomy[32]. Oxy is a strong immune regulator, Wang HX has reported that oxy can inhibit the competence of LAK cell killing P815 cell by about 70%-80%[33], and Shang HS reported that oxy has the same effect of marcophage on P815 cell[34], which proved that oxy may be an agonist of IL-2. Thus, IL-2 could not be the mediator of oxy inhibiting HBV. Whether other cytokines may be the mediator remains unclear. ② Oxy acts as an inducer of cytochrome P450. HBV antigen is exogenous proteins in mice hepatocytes. mRNA of HBV in hepatocytes may be degraded by cytochrome P450. Therefore, oxy can induce the production and enhance the activity of cytochrome P450[17], hence accelerating the degradation of HBV mRNA and inhibiting HBV replication. Further study is needed.

Oxy is a broad-spectrum anti virus drug, at least to HBV and coxsackie B virus 3 so far. This may give us new hope for the treatment of chronic hepatitis HBV infection including other viral infection such as HCV and HIV infection.

Cirrhosis is a servere consequence of chronic HBV infection and preventing the development of cirrhosis is very difficult[35]. Gan LW *et al* reported that oxy can inhibit the liver fibrosis induced by CCl_4 in rats[36]. Oxy can not only down-regulate HBV expression but also inhibit the liver fibrosis. Based on the two points, we concluded that oxy can be used as an effective drug in managing HBV infection. However, the exact mechanism of oxy inhibiting expression of HBV and liver fibrosis has not yet been fully understood. Further studies both basicaly and clinically are needed.

Xin Y, Li XL, Wang YP, Zhang SM, Zheng HC, Wu DY, Zhang YC. Relationship between phenotypes of cell-function differentiation and pathobiological behavior of gastric carcinomas. ***World J Gastroenterol***, 2001;7(1):53-59

Abstract

AIM To reveal the correlation between the functional differentiation phenotypes of gastric carcinoma cells and the invasion and metastasis by a new way of cell-function classification.

METHODS Surgically resected specimens of 361 gastric carcinomas(GC) were investigated with enzyme-, mucin-, and tumor-related marker immunohistochemistry. According to the direction of cell-function differentiation, stomach carcinomas were divided into five functionally differentiated types.

RESULTS ① Absorptive function differentiation type (AFDT): there were 82 (22.7%) patients including 76 (92.7%) aged 45 years. Sixty-nine (84.1%) cases belonged to the intestinal type. Thirty-eight (46.3%) expressed CD44v6 and 9 (13. 6%) of 66 male patients developed liver metastasis. The 5-year survival rate of patients in this group (58.5%) was higher than those with the other types ($P<0.01$). ② Mucin secreting function differentiation type (MSFDT): 54 (15%) cases. Fifty-three (98.1%) tumors had penetrated the serosa, 12 (22.2%) expressed ER and 22 (40.7%) expressed CD44v6. The postoperative 5-year survival rate was 28.6%. ③ Absorptive and mucin-producing function differentiation type (AMPFDT): there were 180 (49.9%) cases, including 31 (17.2%) aged yanger than 45 years. The tumor was more common in women (62, 34.4%,) and expressed more frequently estrogen receptors (ER)(129, 81. 7%) than other types ($P<0.01$). Ovary metastasis was found in 12 (19.4%) out of 62 female subjects. The patients with this type GC had the lowest 5-year survival rate (24.7%) among all types. ④ Specific function differentiation type (SFDT): 13 (3. 6%) cases. Nine (69.2%) tumors of this type derived from APUD system, the other 4 (30.7%) were of different histologicaldifferentiation. Sixty per cent of the patients survived at least five years. ⑤ Non-function differentiation type (NFDT): 32 (8.9%) cases. Nineteen (59.%) cases had lymph node metastases but no one with liver or ovary metastasis. The 5-year survival rate was 28.1%.

CONCLUSION This new cell-function classification of GC is helpful in indicating the characteristics of invasion and metastasis of GC with different cell-function differentiation phenotypes. Further study is needed to disclose the correlation between the cell-functional differentiation phenotypes and the relevant genotypes and the biological behavior of gastric carcinoma.

INTRODUCTION

Gastric carcinoma is one of the most common malignancies and has the highest mortality in China [1,2]. The most important reason causing patients' death is the metastasis to distant important organs. It was reported that 64.2% of gastric carcinomas developed distant organ metastases, among which the rate of liver metastasis was 31.8% of all patients, and ovary metastasis rate was 43.6% of the female patients[3]. As liver is the biggest parenchymatous organ in the body, the micrometastasis of it is very difficult to be diagnosed early. The same is true in ovary metastasis because ovaries lie in the bottom of abdominal cavity. There has been no good indicator so far to objectively predict the risk of liver and ovary metastases, making the diagnosis for micrometastases of these two organs very difficult. The present study put

forward a new classification of gastric carcinoma based on the cell-function differentiation features, in an attempt to reveal the relationship between the characteristics of cell-function differentiation and the local invasion and distant organ metastases of gastric carcinomas, and to clarify the causes and molecular mechanism of metastasis to the liver or ovary.

MATERIALS AND METHODS

Subjects

Three hundred and sixty-one cases of surgically resected gastric carcinomas (from Cancer Institute, China Medical University) were involved in the study, consisting of 258 men and 103 women, including 11 without metastasis, 224 with lymph node metastases, 12 with liver metastases, and 14 with ovary metastases. At least 2 blocks were cut from each primary tumor and 1 block from each metastatic tumor of any organ involved respectively.

Principle and standards of cell-functional differentiation classification

Glandular epithelial cells of gastrointestinal tract can be divided into three main groups: ① absorptive cells of the small intestine, ② mucinous cells including goblet and columnar mucous cells; and ③ cells with specific secretary function, such as parietal, chief, paneath, and APUD system cells. According to the principle that cancer cells maintain more or less the functional differentiation potential of their ancestors, a group of comprehensive indicators that could objectively reflect absorptive, mucin-secreting, and specific function differentiation were selected: indicators of absorptive function differentiation were brush border enzymes, such as alkaline phosphatase (AKP) and L-aminopeptidase (LAP); indicators of mucin secreting function differentiation were sulfomucin (HID+), sialomucin (ABpH2.5+) and neutral mucin (PAS+), and indicators of specific function differentiation were antibodies to hormones produced by APUD cells, cellular keratin and others. According to the expressions of these indicators, the gastric carcinomas were divided into five cell-function differentiation types: ① gastric carcinomas, in which more than two thirds of cancer cells expressed AKP and LAP but did not secrete mucin or hormone, were defined as absorptive function differentiation type (AFDT); ② those in which more than two thirds of the cancer cells secreted only mucin but not AKP or LAP, were defined as mucin secreting function differentiation type (MSFDT); ③ those in which more than two thirds of the cancer cells not only expressed AKP and LAP but also produced mucin, were defined as absorptive and mucin-producing function differentiation type (AMPFDT); ④ those which neither expressed AKP and LAP nor produced mucin, were defined as non-function differentiation type (NFDT); and ⑤ specific function differentiation type (SFDT) was defined as that more than two thirds of cancer cells possessed some special functions, such as the tumors from APUD system and squamous cell cancer (Table 1 and Figures 1-6).

Table 1 Standards of cell-function classification of gastric carcinoma

Type	Brush border enzyme		Mucin			Immunohistochemistry	
	AKP	LAP	HID	ABpH2.5	PAS	Ch-A	Keratin
AFDT	+	+	-	-	-	-	-
MSFDT	-	-	+	+	+	-	-
ANOFDT	+	+	+	+	+	-	-
SFDT	-	-	-	-	-	+	+*
NFDT	-	-	-	-	-	-	-

*Chosen according to practice.

Detection of cell-functional differentiations

Enzyme histochemistry[4]: alkaline phosphatase (AKP) was detected by Gomori's method, and L-aminopeptidase (LAP) by Nachal's method. Mucin histochemistry was done by the HID/ABpH2.5 / PAS method[5]; endocrine histochemistry was performed by ABC immunostaining with antibodies to hormones produced by APUD cells. The results were evaluated using the standards given in references[6,7].

Detection of tumor associated markers[8-13]

The sections from all cases were stained by ABC histochemistry using antibodies to ER and CD44v6 respectively. The ploidy of DNA patterns of the cases with liver or ovary metastasis was examined by flow cytometry (FCM). p53 and laminin expressions in the gastric carcinomas with liver or ovary metastasis were also detected immunohistochemically.

Statistics

χ^2 test was employed in this study to analyze the results of histochemistry and survival data.

RESULTS

The carcinomas were divided into five types: 82 cases classified as AFDT (22.7%); 54 MSFDT (15%); 180 AMPFDT (49.9%); 32 NFDT (8.9%) and 13 SFDT (3.6%). Tables 2 and 3 illustrate the relationship between the cell function classification and the patients' age and sex. The relationship between the cell-function classification and histological types, growth patterns, clinicopathological stages, ER expression, CD44v6 expression, ability forming laminin-positive basement membraneous structure, lymph node metastasis, liver and ovary metastases, and postoperative 5-year survival rates are shown in Tables 4-13 and Figures 1-12.

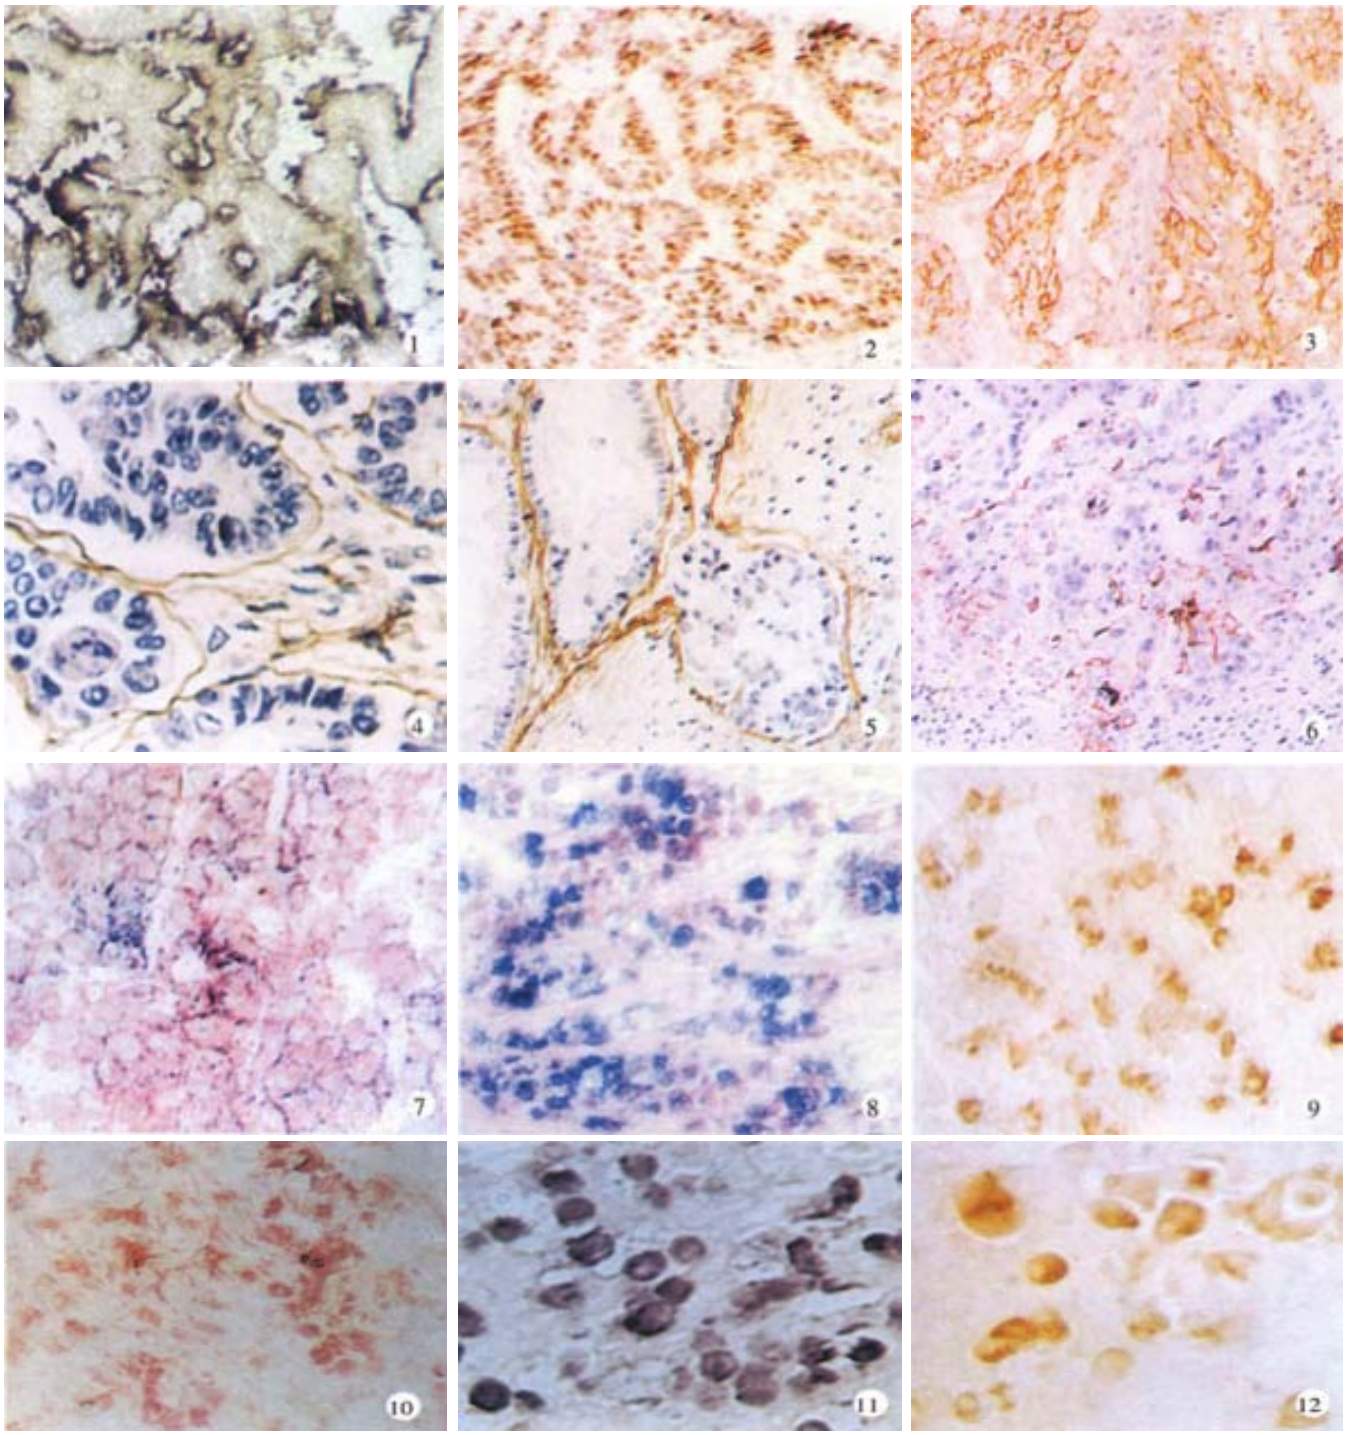

Figure 1 Primary stomach cancer of AFDT with liver metastasis. AKP was moderately positive and distributed along the free edge of cancerous papillary structure. Frozen section. ×20

Figure 2 The same case in Figure 1, Tp53 protein was expressed in most of primary cancer cells. Immunostain, ×16

Figure 3 The same case of Figure 1. CD44v6 was expressed in most of primary cancer cells. Immunostain, ×20

Figure 4 The same case of Figure 1. There was obvious basement membrane like structure with Laminin positive in the primary tumor. Immunostain, ×40

Figure 5 The same case of Figure 1. There was also obvious basement membrane like structure with laminin positive in the liver metastatic tumor. Immunostain, ×20

Figure 6 The same case of Figure 1. CD44v6 was also expressed in the liver metastatic cancer cells. Immunostain, ×20

DISCUSSION

In the light of differentiation degree, malignant tumors from epithelial cells of gastrointestinal tract may retain more or less the functional differentiation potential of their ancestors, which has effects on their biological behavior. Previous studies revealed the relationship between the morphological differentiation and the pathobiological behavior of gastric cancer[14-22], but so far there have been very few studies on the phenotypes of functional differentiation of gastric cancer cells[23-25]. We have studied simple morphological and the functional differentiation indicators of gastric carcinoma to infer its biological behavior during last fifteen years, and found that there was a correlation between the functional differentiation of gastric carcinoma cells and their biological behavior[26-32]. In this study, we investigated more cases and compared the degree of functional differentiation and morphological differentiation features of gastric carcinomas, and found no definite correlation between them. Although most well-differentiated papillary and tubular adenocarcinomas possessed absorptive functions, all signet ring cell cancers were classified as AMPFDT and carcinoid tumors as SFDT, the direction of functional differentiation of most moderately and poorly differentiated adenocarcinomas were undetermined. Most so-called undifferentiated cancers determined histologically displayed some functional differentiation, and were mostly MSFDT or AMPFDT gastric carcinomas; truly undifferentiated cancers made up only 8.3% in our study. Interestingly, 55.3% of mucinous adenocarcinomas classified by histology had mucin-secreting function (MSFDT) but the other 44.7% had absorptive and mucin-producing function (AMPFDT). Furthermore, Tumors of MSFDT were significantly different from those of AMPFDT in patient age, the serosa involvement, estrogen dependence and the CD44v6 expression. The results indicated that the cancer cells of mucinous adenocarcinoma possessed obvious heterogenicity in cell function differentiation and biological behavior, which should be paid special attention to predict the invasive and metastatic features.

The results also indicated that stomach cancers with different functional characteristics often possessed different pathobiological behavior. For example, the MSFDT tumors, constantly growing invasively, were mostly accompanied by the

serosa involvement, and were not obviously dependent on estrogen. NFDT independent of estrogen invades weakly, of which about 60% metastasized to lymph node. Among different functionally differentiated gastric carcinomas, AFDT and AMPFDT had specific clinicopathologically biological features as follows. Gastric carcinomas of ATDT were most common in the middle aged and senile (92.7%), only 7.3% were found in the young; with men (80.5%) surpassing women (19.5%), and intestinal type gastric carcinoma (84.1%) exceeding diffuse ones; and exhibited mainly "mass" or "nest" styles of growth. The invasion of this type of tumor was often beneath the serosa, which resisted local infiltration as a barrier. AFDT, whose growth was not very much dependent on estrogen, expressed metastasis-associated cell adhesion molecule CD44v6 at a higher rate than AMPFDT, and its postoperative 5-year survival rate was 58.5% revealed its best prognosis. Liver metastasis was frequently observed in patients with AFDT tumor whose biological behavior was as follows: ① mutant p53 protein positively expressed at a rate of 83.3%; ② among 75.0% of cases, DNA showed aneuploid; ③ 83.3% of this type presented positive expression of CD44v6; and ④ the thread-like basement membraneous structure containing LN was often formed. Special attention should be paid clinically to the characteristics of AFDT stomach cancer mentioned above. AMPFDT gastric carcinoma often occurried in the young aged below 45 years (17.2%) with more female patients (34.3%) than in other types, and histologically, 81.7% were diffusing invasive type and 71.7% were estrogen-dependent type, and there were more ovary metastases (19.4%) than in the other types. The 5-year survival rate of 24.7% embodied the worst prognosis. AMPFDT gastric carcinoma that grew in women with ovary metastasis had the following biological behavior: 85.7% of cases had high ER expression; mutant P53 protein displayed low expression at a rate of 21.4%; no expression of metastasis-associated adhesion molecule CD44v6; and diploid DNA occurred in 71.4% of tumors. Although the molecular mechanism of liver and ovary metastases was not clear, we should pay much more attention to the cell-function differentiation and biological behavior of gastric carcinomas mentioned above in order to help with the early diagnosis and treatment of the micrometastasis in the liver and ovary.

Much attention has been paid to the mechanism of cancer invasion and metastasis[33-42], especially to the mechanism of the liver and ovary metastases from gastric carcinomas. Several hypotheses have been proposed but cannot explain the specific organic affinity satisfactorily[43-50]. Our study found that the gastric carcinomas with liver metastasis possessed different cellular biological behaviors from those with ovary metastasis (Tables 10-12). It is thus possible to consider a new explanation of the mechanisms of the organic affinity of liver and ovary metastases: the fact that the gastric carcinoma with liver metastasis displayed absorptive function differentiation and expressed LN positive basement membrane-like structure suggested that these cancer cells may have increased the number of exposed laminin receptors. When the cells with exposed laminin receptors (LR) encounter the basement membrane of capillaries, the cancer cells can combine with the basement membrane by the specific affinity between LN and LR, making it possible for the cancer cells to invade the blood vessels. Therefore, we can hypothesize that the presence of exposed LR on the surface of cancer cells is an important precondition for the metastasis through the blood vessels. Most gastric cancers with ovary metastasis displayed disordered functional differentiation in the directions of absorption and mucin-production, and all these cancers expressed estrogen receptors (ER). This finding suggests that the specific organic affinity between the ovary and the specific type of gastric carcinomas may be related to an estrogen-estrogen receptor (E-ER) link.

In addition, our study found that gastric carcinomas exhibiting "mass" or "nest" growth pattern, all expressed thread-like structure containing LN. The reason for this phenomenon is probably that LR is polarized on the basal side of the cancer cells which grow in masses or nests, so these cancer cells can arrange in a row along basement membranes containing LN. On the contrary, the laminin receptors were absent or disordered on those cancer cells which grow diffusely, so that they cannot form a regular structure[51-53].

In summary, the findings of the study indicate that there was some correlation between the cell-function differentiation and invasion and metastasis of gastric carcinomas. A further study is necessary to make clear the genotypes of different functional phenotypes of gastric carcinomas and find out new molecular biological markers for the early diagnosis and treatment of the metastasis. Additionally, the remarkable difference between liver and ovary metastasis of gastric carcinoma in cell-function differentiation, P53 gene mutation, ploidy of DNA, CD44v6 expression and laminin expression indicates their different pathways of gene regulation.

Wu K, Shan YJ, Zhao Y, Yu JW, Liu BH. Inhibitory effects of RRR-a-tocoph eryl succinate on benzo(a)pyrene (B(a)P)-induced forestomach carcinogenesis in female mice. ***World J Gastroenterol***, 2001;7(1):60-65

Abstract

AIM To study the inhibitory effects of VES (RRR-α-tocopheryl Succinate, VES), a derivative of natural Vitamin E, on benzo(a)pyrene(B(a)P)-induced forestomach tumor in female mice.

METHODS The model of B(a)P-induced forestomach tumor was established according to the methods of Wattenberg with slight modifications. One hundred and eighty female mice (6 weeks old) were divided into six groups equally; negative control (Succinic acid), vehicle control (Succinate+B(a)P),positive control(B(a)P), high VES(2.5 g/kg.b.w+B(a)P), low VES(1.25 g/kg.b.w+B(a)P) ig as well as VES by ip (20 mg/kg.b.w + B(a)P). Except the negative control group, the mice were administrated with B(a)P ig. and corresponding treatments for 4 weeks to study the anti-carcinogenetic effect of VES during the initiation period. The experiment lasted 29 weeks, in which the inhibitory effects of VES both on tumor incidence and tumor size were tested.

RESULTS The models of B(a)P-induced forestomach tumor in female mice were established successfully. Some were cauliflower-like, others looked like papilla, even a few were formed into the ulcer cavities. VES at 1.25 g/kg.b.w, 2.5 g/kg.b.w. by ig and 20 mg/kg.b.w. via ip could decrease the number of tumors per mouse (1.7.±0.41, 1.6.±0.34 and 1.1.±0.43), being lower than that of B(a)P group (5.4.±0.32, *P*<0.05). The tumor incidence was inhibited by 18.2%, 23.1% and 50.0%. VES at 1.25 g/kg.b.w., 2.5 g/kg.b.w. by ig and 20 mg/kg.b.w. via ip reduced the total volume of tumors per mouse (54.8 ± 8.84, 28.4 ± 8.32 and 23.9 ± 16.05), being significantly lower than that of B(a)P group (150.2 ± 20.93, *P*<0.01). The inhibitory rates were 63.5%, 81.1% and 84.1%, respectively.

CONCLUSION VES has inhibitory effects on B(a)P-induced forestomach carcinogenesis in female mice, especially by ip and it may be a potential anti-cancer agent *in vivo*.

INTRODUCTION

RRR-α-Tocopheryl Succinate (referred to Vitamin E Succinate, VES) is a derivative of natural vitamin E (RRR-α-tocopheryl)[1]. The interest in this derivative of vitamin E is the fact that it can inhibit the proliferation of a variety of tumor cells *in vitro*[2]. Tumor cells responsive to VES antiproliferative effects include human monoblastic leukemia cells[3], murine B-16 melanoma cells[4], human prostatic adenocarcinoma cells[5], avian lymphoid cells[6,7], human promyelocytic cells[8], human breast cancer cells[9,10]and murine EL4 T lymphoma cells[11,12].

Although the mechanisms whereby VES inhibits the proliferation of rapidly dividing cells are not well understood, induction of cell cycle blockage[13], increasing secretion and activation of potent negative growth factors, i.e., transforming growth factor-βs and their type II- cell surface receptors [2,7,11,14], and induction of apoptosis[15-17] have been observed in VES-treated cells. Earlier studies in our laboratory using the SGC-7901 cell lines (human gastric cancer cells) as model indicated that VES has antagonistic effects on cell growth and DNA synthesis[18], and can obviously induce apoptosis of SGC-7901 cells[19,20].

To date, VES has not been extensively studied on its antitumor properties as well as its mechanism of action *in vivo*. Schwartz J and co-workers[21] found that injection of VES directly into the tumor-bearing buccal pouch of hamsters (twice a week for

four weeks at a dose of 250 μg/injection) caused chemically induced oral epidermoid carcinomas to regress. As VES is found to be a potential chemopreventive and chemotherapeutic agent, it is of interest to ascertain the manner in which tumor growth is inhibited in VES-treated mice and to better understand the relationship between the structure and the function involved. This study characterizes the ability of VES to inhibit B(a)P-induced forestomach carcinogenesis in mice, addresses the involvement of different administration ways in this experiment, and shows that VES is capable of lowering both the tumor incidence and the total tumor size. The inhibitory effects of VES may be attributed to its intact compound.

MATERIALS AND METHODS

Materials

Reagents VES (purity>98%) was obtained from Sigma Co. Ltd, 10% buffered formalin phosphate (10% formalin in neutral phosphate buffer) was purchased from Shanghai Chemical Co. (China), and B(a) P (purity>98%) from Fluka Chemical Co. Ltd (Switzerland).

Animals Female Kunming mice (4-5 weeks old) were purchased from the Animal Center of the Cancer Institute in Heilongjiang Province, China. Fifteen mice were placed in a plastic cage and the animals were maintained under the following standard conditions: 22℃ ± 2℃, 45% ± 10% relative humidity, and 12 h light/12 h dark cycles each day. All animals were fed with basic diet (purchased from the Center of Animal Experiment, Heilongjiang, China) and water.

Methods

B(a)P-induced forestomach tumorgenesis Female Kunming mice (6 weeks old) were divided into six groups, each group was composed of 30 mice. Succinic acid, B(a)P and VES were dissolved in corn oil. In group 1 (negative control) and group 2 (vehicle control), the mice were intubated with 1 g/(kg b.w.) succinic acid 4 times per week for 4 weeks. In all groups except group 1, the mice were intubated with 1mg per mouse B(a)P twice a week for 4 weeks. The mice in group 3 (positive control) were given nothing except B(a)P. Groups 4 and 5 were given 2. 5 g/(kg b.w.) or 1.25g/(kg b.w.) VES by the same way 4 times/week for 4 weeks. Group 6 was given 20 mg/(kg b.w.) VES via ip twice a week for 4 weeks. The mice were then sacrificed at week 11, 16 and 29 after the first administration of B(a) P. Buffered formalin-phosphate (10%) was immediately injected into the stomach by intubation into the mouth so that the stomach was distended and fixed. Each stomach was removed and placed on a plastic sheet and the number of tumors in each forestomach was counted. The samples were stored in 10% buffered formalin-phosphate for histological examination.

Tumor volume All tumors were examined with the aid of a magnifying lens, and tumor size was measured. As described previously[22], tumor volume was determined by measuring the three dimension size of all tumors using the average of the three measurements to calculate radium. Tumor volume was calculated with the formula: volume = $4/3\pi R^3$

Histological examination of tumors Tumors found by visual examinations were further confirmed histologically. The stomach samples were excised, fixed in 10% buffered formalin-phosphate, embedded in paraffin and processed for histologic slides with hematoxylin and eosin (HE) staining. Slides were read blindly by a pathologist and the tumors were classified according to the pathological principle.

Statistical analysis

The significance of data was determined by *t* test.

RESULTS

Establishment of B(a) P-induced forestomach tumor model On the basis of previous method with some slight modifications, the model of B(a) P-induced forestomach tumor was successfully established. Treatment of Kunming mice with 1 mg/mouse of B(a) P by ig twice a week for 4 weeks mainly resulted in four forms of tumors (Figure 1). Some bigger ones appeared cauliflower-like, the moderate tumors looked like papilloma, and the smaller ones were usually grain-like. A few tumors had broken into ulcer-like cavities.

The dynamic processes of tumorigenesis in pathology at the week 11, 16 and finally 29 were observed. Before the treatment with B(a) P, the thickness of normal gastric mucosa was uniform with all characterizstics of gastric mucosa in previous studies[23-25]. The pathological changes at week 11 after the first administration of B(a)P were mainly the hyperplasia of the gastric mucosa, just as what we said "precancerous lesions"[26], and only a few papillomas could be seen. Under this condition, the thickness of epidermins was not uniform, some positions were very thin, while others were very thick. The nuclei of hyperplastic neoplastic cells were enlarged, round or ovoid with prominent necleoli. At week 16, the dominant features were papillomas, being more serious than those at week 11, and the proportion of squamous cell carcinomas in the positive group (B (a)P) was 20%, which was more malignant than before. Tumor cells proliferated lumpy into the connective tissues and were polyhedral, with abundant cytoplasms and large nuclei, in which nucleolus was prominent and some were polynucleolar. The desmosomes were clear, the mitotic figures and a few keratinized cells could be seen. The typical pathological alterations

of B(a)P-induced forestomach tumor at the week 29 were that the number of papilloma and squamous cell carcinoma were both increased. The pathological changes of B(a)P-induced forestomach tumor are illustrated in Figure 2 and the dynamic processes of tumorigenesis in each period are shown in Table 1.

Inhibitory effects of VES on B(a)P-induced forestomach tumorigenesis The treatment with 1mg/mouse- B(a)P twice a week for 4 weeks by ig in group 3 resulted in 100% incidence of forestomach tumors. There was an average of 5.4 tumors/mouse at week 29 of the experiment (Table 2, group 3). Similar results were obtained from group 2. The results in both groups showed that the succinic acid alone had no anticarcinogenic effect. Administration of 1.25 g/(kg b.w.) and 2.5 g/(kg b.w.) VES by ig 4 times/week for 4 weeks inhibited the number of B(a) P-induced forestomach tumors per mouse by 68.5% and 70.4%, respectively (Table 2, groups 4 and 5). When 20 mg/(kg b.w.) VES was injected intraperitoneally into the mice twice a week for 4 weeks, the number of B(a)P-induced forestomach tumors was inhibited by 79.6% (Table 2, group 6). These results suggested that VES could significantly decrease the number of B(a)P-induced tumors per mouse with a dose-dependent manner.

Inhibitory effects of VES on the size of B(a)P-induced forestomach tumor Administration of 1.25g/(kg b.w.) and 2.5 g/(kg b.w.) VES by ig significantly decreased the total tumor volume per mouse by 63.5% and 81.1%, respectively. Notably, the treatment with VES via ip at a much lower dose of 20 mg/(kg b.w.) and shorter time of twice a week for 4 weeks showed even higher rate of decreasing the total tumor volume per mouse (84.1%) (Table 3).

DISCUSSION

The results of our study demonstrated that administration of VES to mice, by both ig. and ip., inhibited B(a)P-induced forestomach tumorigenesis during the initiation period. VES may be useful in the future as a chemopreventive agent of carcinogenesis. A study *in vitro* indicated that VES is able to inhibit the proliferation of tumor cells without adverse effects on non-tumor cells[27]. Kline *et al*[2] showed that VES did not inhibit the proliferation of normal murine bone marrow cells and the non-mitogen-stimulated normal avian B and T cells. They also reported that VES can retard the growth of MCF-7, a kind of human breast cancer cell, while it has no inhibitory effects on MCF-10A, a non-tumorigenic mammary cell. Since 1997, we have studied the antagonistic effects of VES on gastric cancer, and found the inhibitory effects of VES on the growth of human gastric cancer cell (SGC-7901), DNA synthesis arrest and induction of apoptosis[18,19].These findings also supported the possibilities of VES as prospective chemopreventive and chemotherapeutic agent of tumors in the future. VES given intraperitoneally was more effective than given by ig. in lowering both the number and size of B(a)P-induced forestomach tumors even at a much lower dose. Therefore, it seems that VES administrated by ig. may be decomposed by some non-specific esterases which may normally exist in stomach, thus losing its original intact structure. VES contains a succinic acid moiety attached to the chroman head structure of RRR-α-tocopherol via an ester linkage. Esterification eliminates the hydroxy moiety that mediates RRR-α-tocopherol's classical antioxidant properties that prevents VES from acting as an antioxidant, unless the esterified succinic acid moiety is removed by cellular esterases, thereby generating free RRR-α-tocopherol. After VES was proteolyzed into succinic acid and Vitamin E, succinic acid had no inhibitory effects on B(a)P-induced forestomach tumors, as shown in group 2. Previous studies have proved that the inhibitory effect of Vitamin E on

tumors was performed through its antioxidant functions, and the inhibitory effects of natural vitamin E on human promyelocytic leukemia (HL-60) cell proliferation were much weaker than that of VES *in vitro*. All these data suggest that the inhibitory effects of VES may be attributed to its intact structure, as suggested by Fariss and co-workers[27].

The mechanisms by which VES has the inhibitory effects on chemically induced forestomach tumorigenesis in mice are still unknown. VES may influence the metabolic activation and detoxification of carcinogens as well as the postinitiation phase of carcinogenesis[28-30]. B(a)P is a suspected human carcinogen and is known to cause tumors in the forestomach of mice. Singh and Hu *et al*[31-33] reported that GST plays a major role in the detoxification of the ultimate carcinogen of B(a)P (+) anti-BPDE. In our lab, VES has been found to increase the activity of glutathione S transferase (GST) which is phase II metabolic enzyme and inhibits the activity of ethoxyresorufin O-deethylase (EROD) of liver S-9 fraction in mice, a phaseIxenobiotic-metabolizing enzyme. This was the same as the results of Wu[34,35] and Seng[36]. During the developing process of cancer, the immune functions will be decreased[37-39]. Of course, this is a very complex process and it may be involved in many factors[40-42], such as IL-2, IL-4[43,44], TNF[45, 46], TGF-β[47-52] and so on. In 1993, Kline *et al*[52] found that RRR-α-tocopheryl succinate could induce IL-2 production by avian splenic T lymphocytes and murine EL-4 thymic lymphoma cells. And they suggested that VES-induced IL-2 production may involve a mechanism other than antioxidant effects of Vitamin E. In addition, administration of VES to mice increased the serum levels of IL-2 and IL-4 (unpublished data). The information indicates that the mechanisms of VES *in vivo* may be related to the activation pathway of B(a) P metabolism in liver and regulation of the immune system.

Our findings that VES can inhibit chemically induced carcinogenesis in the forestomach of mice suggest a need for further studies on pharmacology and toxicology to determine whether VES may be a useful chemopreventive agent against human gastric carcinogenesis.

ACKNOWLEDGEMENTS We would like to thank Dr. Wei Ping Yu for his technical assistance, and Dr. Dong Lai Wu for reading the pathological slides and taking the pathological photos. We are also grateful to Dr. Love for his critical review of this manuscript.

Abstract

AIM To investigate the individual and the combined effects of glutamine, dietary fiber, and growth hormone on the structural adaptation of the remnant small bowel.

METHODS Forty-two adult male Sprague-Dawley rats underwent 85% mid-small bowel resection and received total parenteral nutrition (TPN) support during the first three postoperational days. From the 4 th postoperational day, animals were randomly assigned to receive 7 different treatments for 8 days: TPNcon group, receiving TPN and enteral 20 g·L^{-1} glycine perfusion; TPN+Gln group, receiving TPN and enteral 20 g·L^{-1} glutamine perfusion; ENcon group, receiving enteral nutrition (EN) fortified with 20 g·L^{-1} glycine; EN+Gln group, enteral nutrition fortified with 20 g·L^{-1} glutamine; EN+Fib group, enteral nutrition and 2 g·L^{-1} oral soybean fiber; EN+GH group, enteral nutrition and subcutaneous growth hormone (GH) (0.3IU) injection twice daily; and ENint group, glutamine-enriched EN, oral soybean fiber, and subcutaneous GH injection.

RESULTS Enteral glutamine perfusion during TPN increased the small intestinal villus height (jejunal villus height 250 μm ± 29 μm in TPNcon *vs* 330 μm ± 54 μm in TPN+Gln, ileal villus height 260 μm ± 28 μm in TPNcon *vs* 330 μm ± 22 μm in TPN+Gln, $P<0.05$) and mucosa thickness (jejunal mucosa thickness 360 μm ± 32 μm in TPNcon *vs* 460 μm ± 65 μm in TPN+Gln, ileal mucosa thickness 400μm ± 25 μm in TPNcon *vs* 490 μm ± 11 μm in TPN+Gln, $P<0.05$) in comparison with the TPNcon group. Either fiber supplementation or GH administration improved body mass gain (end body weight 270 g ± 3.6 g in EN+Fib, 265.7 g ± 3.3 g in EN+GH, *vs* 257 g ± 3.3 g in ENcon, $P<0.05$), elevated plasma insulin-like growth factor (IGF-I) level (880 μg·L^{-1} ± 52 μg·L^{-1} in EN+Fib, 1 200 μg·L^{-1} ± 96 μg·L^{-1} in EN ± GH, *vs* 620 μg·L^{-1} ± 43 μg·L^{-1} in ENcon, $P<0.05$), and increased the villus height (jejunum 560 μm ± 44 μm in EN ± Fib, 530 μm ± 30 μm in EN ± GH, *vs* 450 μm ± 44 μm in ENcon, ileum 400 μm ± 30 μm in EN+Fib, 380 μm ± 49 μm in EN ± GH, *vs* 320 μm ± 16 μm in ENcon, $P<0.05$) and the mucosa thickness (jejunum 740 μm ± 66 μm in EN ± Fib, 705 μm ± 27 μm in ENGH, *vs* 608 μm ± 58 μm in ENcon, ileum 570 μm ± 27 μm in EN ± Fib, 560 μm ± 56 μm in EN ± GH, *vs* 480 μm ± 40 μm in ENcon, $P<0.05$) in remnant jejunum and ileum. Glutamine-enriched EN produced little effect in body mass, plasma IGF-I level, and remnant small bowel mucosal structure. The ENint group had greater body mass (280 g ± 2. 2 g), plasma IGF-I level (1450 μg·L^{-1} ± 137 μg·L^{-1}), and villus height (jejunum 620 μm ± 56 μm, ileum 450 μm ± 31 μm) and mucosal thickness (jejunum 800 μm ± 52 μm, ileum 633 μm ± 33 μm) than those in ENcon,EN+Gln (jejunum villus height and mucosa thickness 450 μm ± 47 μm and 610 μm ± 63 μm, ileum villus height and mucosa thickness 330 μm ± 39 μm and 500 μm ± 52 μm), EN+GH groups ($P<0.05$), and than those in EN+Fib group although no statistical significance was attained.

CONCLUSION Both dietary fiber and GH when used separately can enhance the postresectional small bowel structural adaptation. Simultaneous use of these two gut-trophic factors can produce synergistic effects on small bowel structural adaptation. Enteral glutamine perfusion is beneficial in preserving small bowel mucosal structure during TPN, but has little beneficial effect during EN.

INTRODUCTION

Various clinical conditions necessitate therapeutic massive small bowel resection, which is often followed by serious malabsorption, characterized by intractable diarrhea, steatorrhea, and weight loss. This malabsorptive state is defined as short bowel syndrome. Traditionally, parental nutrition (PN) is prescribed for these patients to assure adequate nutritional status and obtain enough time to wait for the remnant small bowel to undergo adaptation, with the hope of eventual transition from parental nutrition support to volitional enteral nutrition. Under this supportive therapeutic strategy, however, some patients may never achieve complete adaptation, i.e., sustaining completely on enteral nutrition, and life-long total parental nutrition (TPN) become lifesaving unless successful small bowel transplantation is conducted[1-3]. Unfortunately, long-term TPN is associated with great expense, vitamin or trace element malnutrition, recurrent catheter sepsis, and progressive cholestatic liver disease[4], whereas small bowel transplantation is still used currently as a salvage therapy for patients with severe metabolic complications, hepatic failure, or lack of venous access due to imperfect management of post-transplantational rejection[5]. Therefore, any therapy aimed at actively accelerating or enhancing the adaptive process in the residual bowel is likely to impact greatly on the patients' life style and the costs of medical care. Since 1995 Byrne *et al* have published a series of studies, which demonstrated that a combination of growth hormone, glutamine, and modified fiber-enriched diet can improve nutrient absorption, decrease stool output, and reducte TPN requirement[6-8]. These reports are the first to introduce the concept that further bowel adaptation can occur with the use of specialized nutrients and growth factors, and ushered in a new era in the treatment of short bowel syndrome. However, many questions about this therapy are to be answered, e.g., whether this therapy has enhanced the structural adaptation in the remnant small bowel and how each component of the remedy contributes to bowel adaptation.

Due to the heterogeneity in patient age, underlying diseases, and anatomy of the remnant bowel as well as ethic concerns, it is rather difficult to answer these questions directly from the patients. Consequently, we conducted this animal experiment in an attempt to assess the individual and combined effect of glutamine, dietary fiber and growth factor on the structural small bowel adaptation immediately after massive small bowel resection.

MATERIALS AND METHODS

Animals and surgical procedures

The animal protocols and procedures were approved by the Laboratory Animal Medicine Ethics Committee of Nanjing Military Area General Hospital of Chinese PLA. Male Sprague Dawley rats weighing between 220 g and 250 g (Shanghai Laboratory Animals Center, Chinese Academy of Sciences) were allowed 1 week to get acclimatized to our laboratory conditions before surgery. They were kept in individual stainless steel cages and fed a standard rat chow with free access to tap water in a room maintained at 22℃ on a 12 h day/night cycle (06:00/18:00).

The animals weighed about 260 g to 290 g at the end of acclimation period, and were fasted for 12 hours before surgery. Surgical procedures were performed using aseptic technique under anesthesia by intramuscular ketamine cocktail (ketamine, 100 $mg \cdot kg^{-1}$; and xylazine 8 $mg \cdot kg^{-1}$). Three surgeries were performed on each animal in the following sequence: placement of TPN catheter in the superior vena cava via the external jugular vein, installation of gastrotomy tube for liquid diet delivery, and 85% mid-small bowel resection. Both tubes were tunneled subcutaneously, and the dorsal cervical region exited through a spring-swivel apparatus. Normal saline was administered at 1 $mL \cdot h^{-1}$ through the TPN catheter with a minipump. Small bowel resection left the first 6 cm jejunum from the Treitz ligament and the terminal 6 cm ileum. The day when operations were performed was dated as day 0. The postoperative days were dated as day *n*.

Experimental design

After the operation, animals were placed back to stainless steel cages and supported with total parenteral nutrition (TPN), the composition of which is indicated in Table 1. TPN was administered at a half-rate of 1.25 $mL \cdot h^{-1}$ on day 1, and full-rate of 2.5 $mL \cdot h^{-1}$ on day 2 and 3. From day 4, animals were randomly allocated to seven experimental groups: ENcon group, receiving control liquid enteral nutrition (EN); EN+Gln group, receiving EN enriched with 20 $g \cdot L^{-1}$ glutamine; EN+Fib group, receiving control EN and fed with 2 g/d soybean fiber, containing 70% total dietary fiber (provided by Nanjing Military Area General Hospital of Chinese PLA, Nanjing, China), and was mixed with water to the consistency of porridge; EN+GH group, injected with control EN and 0.3IU recombinant human growth hormone (rhGH) (Saizen, provided by Laboratories Serona S.A., 1170 Aubonne, Switzerland) subcutaneously twice a day; ENint group, receiving subcutaneous injection of EN enriched with 20 $g \cdot L^{-1}$glutamine, 2 $g \cdot d^{-1}$ soy bean fiber, and 0.3IU rhGH twice a day; TPNcon group, receiving TPN, and 20 $g \cdot L^{-1}$glycine perfusion *via* gastrotomy tube; and TPN+Gln group, receiving TPN, and 20 $g \cdot L^{-1}$ glutamine perfusion *via* gastrotomy tube. Each experimental group contained 6 animals. The liquid EN was fiber-free with the compositions as indicated in Table 2, and was reconstituted with sterile water before

perfusion and used within 12 hours to avoid bacteria growth. Gastrotomy tube feeding of EN or amino acid solution was introduced gradually by the following schedule: half-strength solution at 1.25 mL·h^{-1} on day 4, full-strength solution at 1.25 mL·h^{-1} on day 5, and full-strength solution at 2.5 mL·h^{-1} from day 6-until day 12. PN was continued until full-strength EN was administered at full-rate, thus combined EN and PN to supply 251kJ calorie to the animals. Our formulas for TPN and EN supplied isocaloric and isonitrogenous nutrition to all animals, i.e., 251Kj nonprotein calories, 0. 414 g nitrogen from PN or Pepti-2000 variant, and 0. 272 g nitrogen from glutamine enrichment or glycine for control per day for each animal. Glutamine enrichment constituted 39.5% of the total nitrogen. Water was provided *ad lib* throughout the study.

Table 1 Total parenteral nutrition composition (400 mL)

Ingredients	mL
500 g·L^{-1} glucose	100.0
Fat (300 g·L^{-1} intralipid *)	67.5
Amino acid (114g·L^{-1} Novamin *)	150.0
100 g·L^{-1} NaCl	10.0
100 g·L^{-1} KCl	10.0
100 g·L^{-1} calcium gluconate	5.0
Multi-electrolytes (Addemel *)	2.5
Water-soluble vitamins (Soluvit *)	2.5
Lipid-soluble vitamins (Vitalipid *)	2.5
Nonprotein energy (kJ·mL^{-1})	4.2
Total nitrogen (g)	2.7
NPC / N (kJ·g^{-1})	620

*Provided by Sino-Swed Pharmaceutical Corp. Ltd., Wuxi, China. NPC / C: nonprotein energy per gram of nitrogen.

Table 2 Enteral nutrition composition (420 mL)

Ingredients	Control EN	Glutamine enriched EN
Pepti-2000 variant * (g)	126.0	126.0
Protein hydrolysate (g)	19.9	19.9
Nitrogen (g)	2.9	2.9
Fat (g)	4.9	4.9

Glutamine (g)	0	10.0
Nonprotein energy (kJ·mL^{-1})	4.2	4.2
NPC / N	610	610

*A commercial, nutritional complete, short-chain peptide based elemental diet (Nutricia, the Netherland). NPC / N: nonprotein energy per gram of nitrogen from Pepti-2000 variant.

Plasma and tissue isolation

Body mass was monitored every three days after surgery as an index of nutritional status. At about 12:00 am on the 12 th postoperative day, laparotomy was performed on all animals under anesthesia with ketamine hydrochloride (100 mg·kg^{-1}). Blood was obtained from the inferior vena cava and placed on ice in a heparin-pretreated tube. Plasma was then isolated by centrifugation at 4℃ and stored at -20℃ for later analysis.

The residual small intestine was rapidly resected from peritoneal and vascular connections, and the luminal content was removed. After the intestine was flushed with ice-cold normal saline, 2 cm segments from both jejunum and ileum located between 2 and 4 cm from the anastomosis were removed and fixed in phosphate-buffered neutral formalin. The animals were then killed by exsanguination.

Plasma insulin-like growth factor (IGF-I) assay and histological image analysis

Total plasma IGF-I concentrations were measured after acid-ethanol extraction with the rat IGF-I RIA DSL-2900 kit (Diagnostic Systems Laboratories, Inc., Webster, USA) in duplication, following the instruction of the manufacturer. This measurement was taken both as indicator of nutritional status and evidence of rhGH treatment.

Villus height (from villus base to villus tip), crypt depth (from crypt base to villus base), and mucosal thickness (from crypt base to villus tip) were taken as indicators of structural adaptation. Routine hematoxylin and eosin stained sections were prepared, and HPIAS-1000 True Color Image Analysis System (Tongji Qianping Image Engineering Corp., Wuhan, China) was employed to analyze the image. Fifteen intact axially oriented villi and crypts selected from each specimen were measured.

Statistical analysis

Data were expressed as $\bar{x} \pm s$. Multiple comparison tests were performed after analysis of variance with the Student-Newman-Keuls test. Differences with P value less than 0.05 were considered to be statistically significant.

RESULTS

Body mass

As shown in Table 3 and Figure 1, the initial body mass on day 0 was similar among the 7 experimental groups. The body mass on day 3 was not significantly different among the 7 groups, which reflected similar operative stress and postoperative nutritional support remedy. The overall body mass loss during the first three postoperative days averaged 26.3 g. Marked body mass difference was evident from day 6. The two TPN-supported groups had gained remarkable body mass by day 6 which was kept steady during the remainder of the experimental period, suggesting the ebbing of stress and fixed nutrition supply. No significant body mass difference was observed between the two TPN groups throughout the experiment. In ENcon, EN+Gln, and EN+GH groups, the introduction of EN resulted in further body mass loss, which was accompanied by a moderate to a large amount of liquid stool production, indicating insufficient

nutrition assimilation from the remnant small bowel. From day 6, diarrhea in these groups became increasingly milder and almost disappeared after day 9, which was associated with gradual body mass gain. Each animal in two fiber-supplied groups ate up daily fiber supply, and fiber-containing solid stool instead of large liquid stool was observed after EN introduction. Continuous body mass gain began from day 3 in ENint group, and after day 6 in EN+Fib group. From day 3, the mean body mass of ENint group maintained higher than those of the other groups, which bore statistical significance on day 6 when compared with ENcon, EN+Fib, and EN+GH groups, and on day 9 and day 12 when compared with TPNcon, ENcon, EN+Fib, and EN+GH groups. Throughout the study, ENcon and EN+Gln groups had similar body mass, which remained significantly lower than that of TPNcon on day 6 and day 9 and rose to the similar level as TPNcon on day 12. From day 6, mean body mass of EN+Fib groups began to distinguish itself significantly from ENcon, and became markedly higher than both ENcon and TPNcon on day 12. On day 9, the mean body mass of EN+GH groups was significantly higher than that in ENcon group, and on day 12 significantly higher than both ENcon and TPNcon groups.

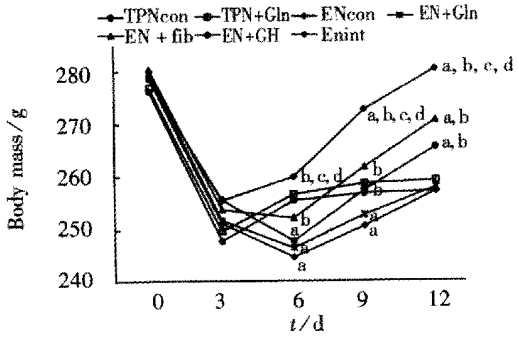

Figure 1 Body mass before and after surgery.
[a]*P*<0.05, *vs* TPNcon; [b]*P*<0.05, *vs* ENcon; [c]*P*<0.05, *vs* EN+GH; [d]*P*<0.05, *vs* EN+Fib. Day 0, refers to the day operation was performed, from which the time was dated.

Plasma IGF -I concentrations

Plasma IGF-I concentrations were similar among TPNcon, TPN+Gln, ENcon, and EN+Gln groups. Plasma IGF-I level in EN+fib group was significantly higher than that in ENcon group. GH treatment resulted in significant increase in plasma IGF-I concentration as compared with ENcon group. ENint group had the highest level of plasma IGF-I (Figure 2).

[a]*P*<0.05, *vs* Encon; [b]*P*<0.05, *vs* EN+Fib; [c]*P*<0.05, *vs* EN+GH.

Remnant intestinal mucosal structure

Compared with ENcon group, TPNcon group had significantly lower mean villus height and mucosal thickness in both remnant jejunum and ileum, and significantly shallower jejunal crypt (Figures 3 and 4). Luminal glutamine perfusion completely restored the villus height and mucosal thickness in ileum and partially restored the villus height, crypt depth, and mucosal thickness in jejunum. However, glutamine-enriched EN had a little impact on mucosal structural parameters whether in remnant jejunum or ileum when compared with ENcon group. The villus height and mucosal thickness in both remnant jejunum and ileum were more significantly increased by fiber supplementation than in ENcon group. GH treatment produced significant increase in villus height in both remnant jejunum and ileum, and mucosal thickness in remnant ileum when compared with ENcon group. Combined treatment with glutamine, fiber, and GH significantly deepened the crypt in remnant ileum as against TPNcon group, and further increased villus height and mucosal thickness in both remnant jejunum and ileum, which, when compared with EN+GH group, achieved statistical significance in villus height of both jejunum and ileum, and in mucosal thickness of ileum.

Table 3 Comparison of body mass before and after operation between each experiment groups (n = 6, $\bar{x} \pm s$, g)

Groups	Day 0	Day 3	Day 6	Day 9	Day 12

DISCUSSION

After massive small bowel resection, the structural adaptation of the remnant small bowel was characterized by mucosal hyperplasia. The villus height and crypt depth are both increased, while cell hypertrophy is considered unimportant[9]. This process is influenced by many factors, among which, both the quantity and route of nutrient intake are important regulators. Luminal nutrient supply, which is essential for structural adaptation, serves as not only energy source, but also signal for endogenous secretions and the release of various gut-trophic hormones and growth factors. On the other hand, normal nutritional status, which usually needs the facilitation of TPN to maintain, favors bowel adaptation[1]. In this study, great efforts were made to ensure strict control on the quantity and route of nutritent supply, and TPN was used immediately after bowel resection and during the period of reintroduction of enteral nutrition to improve the nutritional status. The compositions and delivery schedules for TPN and EN were set to provide isocaloric and isonitrogenus nutrition and to produce comparable overall nutritional status in animals of each experimental group. And the goal of producing comparable nutritional status was attained, which was attested by similar body mass and plasma total IGF-I concentration among TPNcon, TPN+Gln, ENcon, and EN+Gln groups. The utilization of plasma IGF-I as index of nutritional status is justified by sensitive IGF-I response to dietary intake, close correlation with body composition, short half-life, and its nycthermeral stability[10]. Thus the risk of confounding effects of variation in nutritional supplementation had been minimized.

Substantial researches have been done to modify the formulation of enteral nutrition to optimize the postresectional small bowel adaptation. Pepti-2000 variant has often been recommended as fiber-free EN to patients with short bowel syndrome in Nanjing Military Area General Hospital of Chinese PLA and has been chosen in this experiment as the EN formulation. This is justified by its compositional feature as peptide-based, polymeric nutrient-complete diet, which provide equal energy from medium-chain triglycerides and long-chain triglycerides. Polymeric diets are more trophic for intestinal adaptive hyperplasia compared with monomeric diets. Partial hydrolysation or protein facilitates amino acid absorption from peptide transporters while preserves gut trophic effect. Medium-chain triglycerides are water-soluble and are better absorbed in the presence of bile acid or pancreatic insufficiency, while long-chain triglycerides are more effective in inducing adaptation[11].

Glutamine is an essential nutrient for intestinal mucosa. Besides serving as the structural unit of protein synthesis, a precursor for synthesis of nucleotides and other micromolecules, it is the major respiratory fuel for intestinal mucosa[12]. *in vitro* studies have indicated that intracellular mitogenic signal transduction can be modified by glutamine supply and metabolism[13]. Animal studies have consistently shown that total parenteral nutrition (TPN)-induced intestinal hypoplasia can be attenuated by parenteral glutamine supplementation[14-16]. Glutamine-fortified-parent-eral or enteral nutrition has also been demonstrated to accelerate small intestinal healing and improves survival outcome after chemotherapy and radiation[17,18].

Following massive bowel resection, malabsorption occurs and patients may be intolerable to enteral nutrition and have to sustain on TPN for a certain period. Efforts made to preserve intestinal mucosal mass and absorption area during TPN will assist early reintroduction of enteral nutrition, which is essential for the initiation of intestinal adaptation. Parenteral glutamine supplementation has been shown to prevent TPN induced mucosal atrophy in the remnant small intestine after 85% resection[19]. Since enteral glutamine can be readily absorbed by small intestinal epithelium, and glutamine oxidation

stimulates enterocyte Na^+/H^+ exchange, leading to a high rate of electroneutral NaCl absorption in healthy and diseased jejunum[20], we studied the effect of enteral glutamine perfusion on the remnant intestinal mucosal structure during TPN. Because previous studies have not confirmed the beneficial effect of enteral glutmine supplementation during EN[21-25], we also studied the effect of adding extra glutamine to nutrition-complete enteral diet. Our results confirmed the existence of TPN induced intestinal hypoplasia, which was indicated by significantly lower villi in both jejunum and ileum and markedly shallower crypts in jejunum in TPNcon group compared with ENcon group. Luminal glutamine perfusion was effective to reverse TPN-induced hypoplasia in ileum and partially reverse TPN-induced hypoplasia in jejunum. In contrast, glutamine-supplemented enteral nutrition has little impact on small intestinal structural parameters. This finding is surprising, yet is similar to the results of several other studies[19-23]. The dosage ranged approximately from 2 $g \cdot kg^{-1} \cdot day^{-1}$ to 5.6 $g \cdot kg^{-1} \cdot day^{-1}$. And a dosage of more than 4 $g \cdot kg^{-1} \cdot day^{-1}$ was found effective in preventing TPN-induced intestinal hypoplasia in rats[12]. In all these studies, glutamine-fortified enteral nutrition was compared with standard rat chow or non-glutamine-containing elementary diet, or EN with insufficient glutamine due to partial hydrolysation of protein. Therefore, the lack of effect cannot be interpreted as insufficient glutamine delivered to intestine, or overload of glutamine. Different routes of administration were tried. Extra glutamine was mixed with enteral diet to form *ad lib* diet, or was administrated separately in bolus form, or administered as 24 h continuous enteral perfusion. The remnant intestines were analyzed 2, 7, 14 or 21 days after small bowel resection. The time points represent the beginning, active, and maximal remnant intestinal hyperplasia. In most of those studies, the animals gained body mass. In our study, the animals maintained the body mass lower than that of preoperation, reflecting our restrict nutrition supply. Nevertheless, despite different experimental protocols, similar results were obtained that during enteral nutrition, enteral glutamine supplementation produced little effect on remnant small intestinal morphological parameters. Therefore, the current available data raise the hypothesis that for otherwise healthy small intestine, with adequate enteral nutrition stimulation, glutamine delivered by arterial blood is sufficient for optimal intestinal growth. In consistent with this hypothesis, *in vitro* studies have shown that in a number of cell lines, maximal proliferation occurs when glutamine concentrations are maintained at 0.5 $mmol \cdot L^{-1}$ or above, a concentration approximates normal plasma concentration[26]. With the maximal mitogenic stimulation of epidermal growth factor, the optimal proliferation of IEC-6, a rat jejunum cell line, occurred at a glutamine concentration of 1.0 $mmol \cdot L^{-1}$ in the cultural medium, a concentration within the physiologic ranges of glutamine found in rat plasma[27]. Under normal nutritional status, plasma glutamine homeostasis can be maintained without nutritional glutamine supply[28]. However, in the absence of luminal nutrition stimulation during TPN, glutamine delivered by blood flow may be insufficient for optimal intestinal growth, as is attested by the fact that parenteral or enteral glutamine supplementation is effective in reducing TPN-induced intestinal hypoplasia. This insufficiency may be caused by decreased blood flow induced by TPN, or enteral nutrition can stimulate the uptake of glutamine through the basolateral membrane by modifying the activity of the transporters. However, our data do not exclude the possibility that when inadequate enteral nutrition is received, enteral glutamine may exert a trophic effect on small intestine, since minimum luminal nutrition has been found indifferent in stimulating small intestinal mucosal growth as compared with TPN[29].

Dietary fiber includes a wide variety of carbohydrates that, as a group, are resistant to enzymatic hydrolysis within the human gastrointestinal tract. The principal physiologic function of dietary fiber are regulating gastric emptying and intestinal transit time, based on the bulking action of the fiber. Insoluble fibers are minimally fermented and function almost solely as bulking agents that decrease colonic transit time and increase fecal mass. Soluble fibers are largely fermented by anaerobic gut flora, resulting in increase of the bacterial quantity, and fecal mass, and production of short-chain fatty acids (SCFAs), which are quickly absorbed by the colonic mucosa. The importance of dietary fiber in maintenance of normal colonic morphology and function has been widely acknowledged. However, its role in short-bowel syndrome has not been investigated thoroughly. Previous studies on the effect of dietary fiber on colon were mostly carried out in normal animals with intact small and large intestine. In contrast, after massive small bowel resection, the colon in continuity with the remnant small bowel will receive substantial unabsorbed carbohy drates and protein, which will undergo fermentation in colon by various anaerobic bacteria and produce SCFAs. This represents an important mechanism whereby the colon compensates some energy absorption function of the lost small intestine[30,31]. How colon with this altered environment responses to additional dietary fiber loading is not clear. Although there is the speculation that in carbohydrates malabsorption, dietary fiber supplementation seemed to be redundant in

enhancing the SCFAs production[11], available data from massive small bowel resection models showed the beneficial effect of dietary fiber supplementation on residual small bowel as well as colon adaptation[32-34]. In contrast, dietary fiber had little effect on intact intestinal function[35]. Therefore, it seems that the effect of dietary fiber is modified by the absorptive function of intestine.

We fed the animals with fiber-free enteral nutrition of 2 g soy bean fiber daily, containing about 70% total dietary fiber consisting predominantly of insoluble fiber, and found that soy bean fiber supply led to large solid fiber-containing stool, instead of large liquid stool as seen in non-fiber supplied EN groups. This indicates that fiber supply may alter the colon absorptive and moving function. Significantly improved body mass recovery was associated with this improved stool consistency. In addition, the plasma IGF-I concentration was simultaneously elevated, which implied that the improved body mass was not solely caused by colonic fiber retention. Both the residual jejunum and ileum displayed significantly greater mean villus height and mucosal thickness. The exact mechanism that soybean fiber enhanced the postresectional adaptation was not investigated in this study. Since the soy bean fiber consisted predominantly of insoluble fiber which mainly influences the intestinal transit, it is most likely that the presence of fiber in combination with unabsorbed carbohydrates and proteins in the colon had delayed the intestinal transit through direct bulk effect, hence promoting the colonic fermentation of unabsorbed carbohydrate and protein. Consequently, the secretion of colon-derived enteric hormones, such as enteroglucagon and peptide YY, might be augmented, which in turn exerted their small bowel trophic effect and stimulated further structural adaptation in small bowel.

Besides gut-special nutrients such as glutamine and dietary fiber, the possible role of many growth factors has met with intense research interest. Strong evidence has demonstrated that growth hormone (GH) is an important growth factor for intestine. Complete GH depletion due to hypophysectomy caused pronounced hypoplasia of small intestinal mucosa with decreased villus height and reduced crypt cell proliferation[36]. Simple replacement of GH can restore mucosal proliferative activity[37]. The study of the transgenic mice overexpressing the bovine growth hormone demonstrated that chronic excessive GH can produce hyperplasia in small intestinal mucosa whether food intake was *ad lib* or restricted[38]. Hypophysectomy could impair the adaptive hyperplasia in response to small bowel resection[39]. In an unpaired-fed study, exogenous GH was found to enhance mucosal hyperplasia after extensive small bowel resection[40]. Our pair-fed study revealed that exogenous GH administration significantly elevated the plasma IGF-I level, increased villus height in both remnant jejunum and ileum, and significantly increased ileum mucosal thickness. Postresectional body mass recovery was also accelerated by GH administration, suggesting the enhanced nutrient absorption. Our data further confirmed the gut-trophic property of GH. The more important findings of our study are that concomitant fiber supplementation further enlarged the villus height and mucosal thickness in both remnant ileum and jejunum, enhanced body mass gain, and increased the plasma IGF-I concentration in ENint group. These results suggest that gut-trophic growth factor, GH, can be used in combination with gut-special nutrient, dietary fiber, to bring about synergistic effect on postresectional remnant small bowel structural adaptation.

In summary, our study demonstrated that both dietary fiber and growth hormone can enhance the postresectional small bowel structural adaptation, promote bodymass-gain, and increase plasma IGF-I level when used separately. Simultaneous use of these two gut-trophic factors produced synergistic effect on structural adaptation parameters, body mass, and plasma IGF-I concentration. In contrast, the gut essential nutrient, glutamine when enterally administered with enteral nutrition, showed little beneficial effect on remnant small bowel structural adaptation, and the body mass did not alter in comparison with the control enteral nutrition. However, enteral glutamine is effective in preserving intestinal mucosal structure during TPN. These findings raise the doubt about the necessity of enteral glutamine supplementation during enteral nutrition. On the other hand, they provide the evidence favoring the combined utilization of GH and dietary fiber with enteral nutrition in patients with short bowel syndrome.

Teng GJ, Bettmann MA, Hoopes PJ, Yang L. Comparison of a new stent and Wallstent for transjugular intrahepatic portosystemic shunt in a porcine model. ***World J Gastroenterol***, 2001;7(1):74-79

Abstract

AIM To evaluate a new balloon-expandable stainless steel stent (Cordis stent) in a transjugular intrahepatic portosystemic shunt (TIPS) porcine model and compared with Wallstent.

METHODS TIPS was performed in 26 normal domestic pigs weighing 20 kg-30 kg using a Cordis stent or Wallstent (13 pigs in each stent). All pigs were sacrificed at the 14 th day after TIPS. The stent deployment delivery system, stent patency, and stent recoil after placement were evaluated.Proliferative response in representative histological sections from the center,hepatic and portal regions of the two stent designs were quantified.

RESULTS The shunt was widely patent in 4 pigs in the Cordis stent group (4/12, premature dead in 1 pig), and in 5 pigs in the Wallstent group (5/13). All remaining stents of both designs were occluded or stenotic. The mean quantified proliferation including thickness of the proliferation and the ratio of proliferation: total area in three assayed regions in Cordis stent and Wallstent was 2.18 mm² 2:00 mm, and 59.18 mm². 51.66 mm², respectively ($P<0.05$). The delivery system and mechanical properties of the Cordis stent fuctioned well.

CONCLUSION The new Cordis stent is appropriate for TIPS procedure.

INTRODUCTION

The high incidence of stenosis following transjugular intrahepatic portosystemic shunt (TIPS) remains the major barrier in this relatively new technique which is effective in controlling variceal hemorrhage secondary to portal hypertension and utilized in refractory ascites[1,2]. The exact mechanism for TIPS restenosis is not well understood and seems multifactorial. One relevant factor may be stent design. Wallstent is the most common stent currently used for TIPS procedures, but various stent designs may be effective. To evaluate a new balloon-expandable stent (Cordis stent) in TIPS, a comparative study of the Cordis stent and Wallstent was performed in a TIPS porcine model.

MATERIALS AND METHODS

TIPS was performed in 26 domestic swine weighing 20 kg-30 kg, with two stent designs: balloon-expandable stainless steel stents (Cordis Co., Miami, FL) in 13 pigs and Wallstents (Schneider, Minneapolis, MN) in 13 pigs, respectively. The Cordis stent is made up of one stainless steel wire, which is formed into a sinusoidal wave pattern, wrapped in a tubular helical fashion and held in place by a series of welded joints (Figure 1). Either Cordis stent or Wallstent with an diameter of 8 mm and 4 cm in length was used in each pig.

TIPS was performed with a 22 G, 80 cm long puncture needle with a 5-F,70 cm long coaxial Teflon catheter (AngioDynamic, Queenshury, NY), a 9 F sheath set and a 14 G metal cannula with a curved tip (Cook, Bloomington, IN).

The animals in this study had normal livers and did not have portal hypertension. All protocols were approved by the Dartmouth Animal Care and Use Committee. Animals were sedated with intramuscular Ketamine (20 mg/kg) injection, intubated and maintained with 1%-3% halothane and oxygen.

The sheath was assembled with a 9-F Teflon catheter with a tapered tip and was introduced into the IVC by a standard percutaneous Seldinger method from the right jugular vein. A 7-F NIH catheter was advanced into the right lateral hepatic vein. The sheath was then placed into the hepatic vein and followed by the metal cannula containing the coaxial puncture needle. Through the metal cannula, the puncture needle together with the coaxial catheter was advanced into the hepatic parenchyma in an anterior direction targeted toward

the right branch of portal vein. Following confirmation of suitable portal vein puncture by contrast injection, a 0.035 inch steerable guidewire (Cordis Co., Miami, FL) was advanced into the portal vein and followed by the 5-F catheter. Following portography, the floppy-tip guide wire was exchanged for an Amplatz super stiff guide wire, and a hepatic parenchymal tract was dilated using an 8 mm balloon catheter. The Cordis balloon catheter-stent delivery system was introduced into the sheath by advancing the insertion tool over the wire through the hemostasis valve, until a hand stop was reached. A stent mounted balloon was introduced through the insertion tool and advanced over the guidewire until the stent was in the desired location for deployment. The stent was deployed by inflating the balloon with a 50% saline and 50% Renografin76 solution using a standard manual technique (Le Veen balloon inflator). A 10 mm diameter balloon catheter was used with 6 atm pressure for 2 minutes with 3 repetitions. The Wallstent was deployed in a standard fashion and inflated using equivalent inflation pressures and technique for Cordis stent deployment.

Since the coagulation process is much faster in pigs than in humans based on our previous experience, 500U/kg heparin was routinely administered in each procedure. No anticoagulants or other medicines were used after the procedure.

A numerical rating system was developed in the evaluation of the following deployment factors at implantation: stent insertion through the sheath, insertion tool function, stent tracking, balloon inflation and deflation, stent expansion, ease of positioning, balloon catheter removal, and stent architecture and visibility under fluoroscopy. The rating system was scored as follows: excellent = 1; satisfactory = 2; poor = 3; and not achieved = 4.

Portal venography was performed following TIPS placement and prior to sacrifice. Plain radiography was taken and the following factors were assessed: stent migration, distortion of stent architecture and changes of diameter and length of the stent.

Animals were euthanized 2 weeks after TIPS placement by intravenous injection of 15 mL saturated KCL. All of the shunts were examined by portography via transjugular i mmediately prior to euthanasia.

Necropsy was performed i mmediately following euthanasia. The TIPS shunt and involved adjacent tissues were evaluated by gross examination at necropsy and preserved for histologic assessment. Representative crossections from the central, hepatic and portal vein regions of the stent were cut after fixation in buffered 4% formalin for at least 24 hours. The metal of Wallstent was removed before embedding while the metal of Cordis stent had to be removed using a hand saw after embedding and then reembedded in JB-4. The tissues were then cut at 5 microns and stained with modified Giemsa and basic fuchsin.

At least 3 sections in each region of stent were prepared and reviewed. Histologic quantification including thickness, the area of the proliferative response and the ratio of the proliferative area/total area of the stent was achieved using standard planimetry techniques and Nikon microscopy and Camera Lucita with Micro-Plan II Image Analysis (Laboratory Computer Systems, INC).

All quantitated data were expressed as the mean value ± SD. Stent patency and quantified proliferative reaction within the stent were compared using Chi-Square test and Student's *t* test, respectively. Statistical significance was defined as $P<0.05$.

RESULTS

TIPS was successfully performed in all pigs with both stent designs (100%). No difficulties were encountered in delivering and deploying the Cordis stents. All pigs remained healthy until the scheduled date of euthanasia except one. This pig died 2 days following Cordis stent placement from introgenic hemorrhage secondary to inadvertent gastric puncture during the TIPS procedure. This early death was excluded from the numerical results.

Patency

Stent patency was determined by venography and pathohistological examinations, 33.3% (4/12) of the Cordis stent group and 38.5% (5/13) of the Wallstent group were patent at 2 weeks post-deployment (Figure 2). This difference did not reach a statistical significance ($P>0.05$, Chi-Square test). One pig had an occluded Cordis stent because its proximal end wedged into the liver parenchyma due to its stiff property (Figure 3). Likewise, one pig had an occluded Wallstent due to longitudinal recoiling of the stent causing the distal end to withdraw from the portal vein into the liver parenchyma.

Stent deployment factors

The mean score for stent deployment factors are listed in Table 1. Stent insertion through the sheath and stent expansion were scored excellent in all procedures performed with both Cordis stent and Wallstent. Cordis stent had a higher score than Wallstent in stent tracking, positioning, and visibility by fluoroscopy. The factors of tool function, balloon in/de-flation and catheter removal which are unique to Cordis stent, were scored excellent for all procedures.

Recoiling of stents

No stent migration or stent distortion was demonstrated in either Cordis stent or Wallstent groups. Stent diameter and length i mmediately after TIPS placement and 2 weeks after TIPS are shown in Tables 2 and 3. The interval change in the Wallstent group at 2 weeks after TIPS is larger than

in the Cordis stent group. The Wallstent demonstrated an average shortening of 5.18% as compared with 0. 69% with Cordis stent.

Histopathologic characteristics

Pseudointimal proliferation (PIH) formed within the shunt with both stent designs, and histology was similar in all three assayed areas. PIH was primarily composed of myofibroblasts (Figures 2,4), organized thrombus, and collagen. Infla mmatory cells were mainly lymphocytes and mononuclear cells co mmonly located around the stent wires. Organized thrombus was characterized by palisading and herringbone deposition of the fibrin and the invasion of blood vessels (neovascularization). A single-cell lining of endothelial-like cells covering the lumen was observed only in specimens with a patent shunt. The liver tissue adjacent to the stent showed minimal injury characterized by sinusoidal dilatation, hemorrhage, focal necrosis, mononuclear infla mmation and fibrosis. There was no major difference in histological characteristics between the two groups with the different stent designs.

In 10 specimens (5 in each stent group), bile leak was identified by bile staining of thrombus. Histologic sections demonstrated extensive neo-bile duct proliferation within the PIH or on the surface of the lumen in some specimens with bile leak (Figure 4). This partially contributed to occlusion of the stent.

Quantified histological results

PIH thickness and the ratio of proliferative area/total area within both stent designs are shown in Table 4. The portal vein aspect of the stents had the highest proliferative response, the hepatic region the second highest and the middle region of the stents the least proliferative. There was no statistically significant difference among the three assayed regions between Cordis stent and Wallstent specimens (P>0.05).

DISCUSSION

Various stent designs including Palmaz stent, Gianturco-Rosch Z stent, Strecker stent and Memotherm stent have been utilized in TIPS procedures[3-6]. Wallstent is the most co mmon stent used for TIPS currently within the United States due to its flexibility which allows easy negotiation of the angles bridging a hepatic vein and a portal vein[7]. Unfortunately, TIPS stent stenosis rates are high with all stent designs, although PTFE covered stent seems to decrease the stenosis of TIPS shunt in pigs[8,9]. The mechanism and process of restenosis in TIPS remains poorly understood. However, it is well accepted that stent design including mechanical properties are important factors influencing stent patency.

Table 1 Scores of deployment factors

Stent types	Insert thru sheath	Tool function	Stent tracking	Balloon in / de flation	Stent expansion	Position	Catheter removal	Architecture & visibility
Cordis	1 ± 0.0	1 ± 0.0	1.07 ± 0.27	1 ± 0.0	1.14 ± .53	1.29 ± .61	1 ± 0.0	1.86 ± .54
Wallstent	1 ± 0.0	*	2.17 ± .84	*	1.00 ± 0.00	*	1.75 ± .87	2.42 ± .52

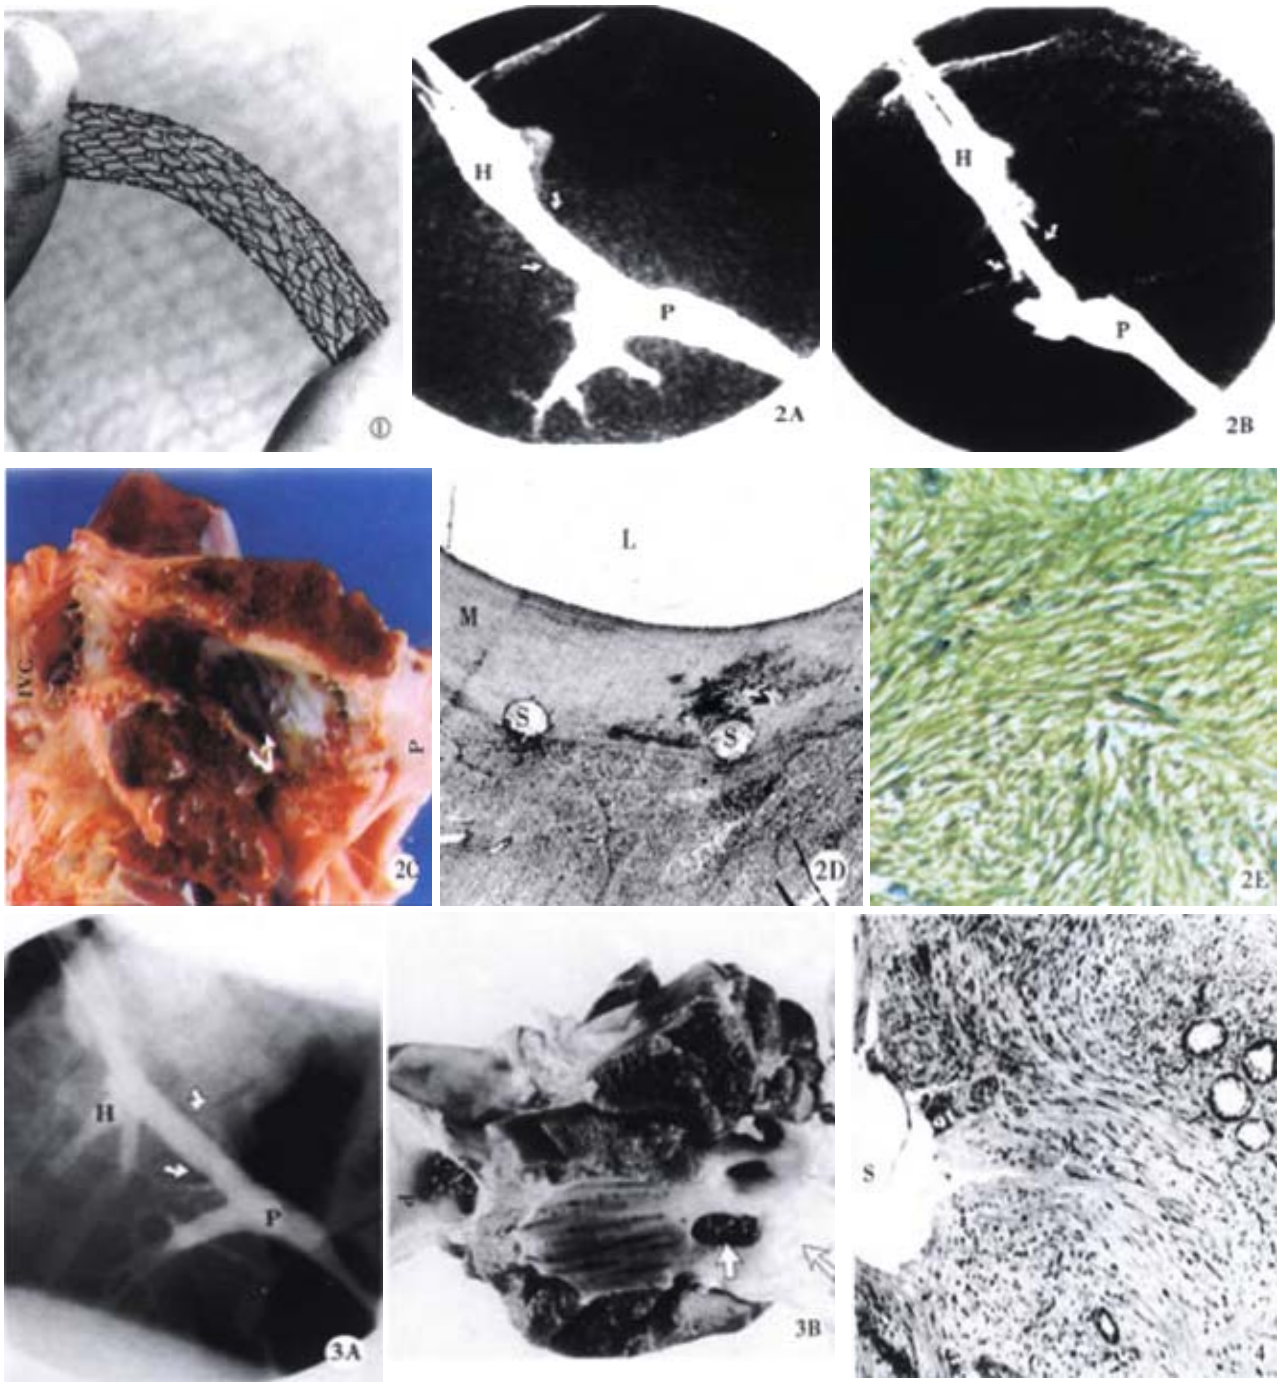

Figure 1 The Cordis balloon-expandable stent, which is constructed as a sinusoidal wave pattern by one stainless steel wire, with high rigidity.

Figure 2 a. The portal venography obtained i mmediately shows that the TIPS shunt (arrows) is well created between the hepatic vein (H) and the portal vein (P). **b.** The shunt remains patent in the portography taken i mmediately before the euthanasia at 2 weeks after stent placement. **c.** The gross examination of the specimen shows that the surface of the stent (straight arrows) is covered by a smooth and thin layer endothelia-like tissue (curved arrows) which does not extend to the ends of the stent at the IVC and the portal vein (P). **d.** Low magnification photomicrography of the TIPS reaction shows a mild myofibroblastic cell proliferation (M) under stent meshes (S) (Modified Giemsa and basic Fuchsin stain, ×3.12). **e.** The myofibroblastic cells are primarily composed of smooth muscle cells. (Anti-SMCα actin stain, ×125).

Figure 3 a. An occluded TIPS shunt from a pig using a Cordis stent. The i mmediate portal venography after TIPS shows a patent TIPS shunt (arrows). **b.** The occluded shunt was confirmed by the portography obtained i mmediately before the euthanasia in two weeks after the stent placement. The gross examination of the specimen demonstrates that the hepatic end of the stent wedges into the liver parenchyma and the proximal end of the shunt is totally occluded by the healed hepatic vein (arrows), while the portal end (P) of the stent keeps patent.

Figure 4 Photomicrography from an occluded TIPS shunt using a Wallstent shows that a massive pseudointimal proliferative tissue under the stent (S), which primarily composed of myofibroblastic cells (M). Neo-bile duct proliferation within the proliferation is also noted (arrows). Modified Giemsa and basic Fuchsin stain, ×125

Since multiple interdependent mechanical characteristics of stents may play a role in stent restenosis [10-19], the ideal stent appears to be non-existent. To produce a satisfactory stent, the following factors should be considered: stent wire material and diameter, longitudinal flexibility, hoop strength (circumferential strength), stent texture and stent surface area.

A layer of metal oxide provides the ultimate interface between stent and host following stent implantation. This is independent of metal content[10]. Similar thrombogenicity and patency rate have been observed in stented arteries using different stent metals[16,20]. Hehrlein *et al*[18] evaluated stent biocompatibility as related to surface texture and charge. Palmaz-Schatz stents were coated either by electrochemical metal deposition (platinum, gold, copper) or coated with a metallic film implanted onto the stent surface by argon ion bombardment. These stents were implanted and evaluated in a rabbit iliac arterial model. The results demonstrated that the most electropositive coating (platinum or gold) induced markedly less neointima formation than the least electropositive (copper). The authors therefore concluded that stent surface texture was the most important factor determining biocompatibility of the stent while the charge on stents appeared to be less important[18]. Strength, elasticity, and plasticity of various stents co mmonly used were recently investigated in an *in vitro* model[12,13]. The results suggested that the Palmaz stent is appropriate for insertion into highly resistant obstructions due to its superior resistance to deformation. Strecker stents and Wallstents required good wall contact to achieve adequate strength and Wallstent may not function well if implanted into eccentric stenoses of tough consistency due to its unique deformation. The Gianturco stent showed the lowest resistance and deformed more readily. We did not evaluate such criteria regarding the Cordis stent in this study. However, the higher longitudinal rigidity and hoop strength of this new stent may have merit for placement within tough and highly resistant cirrhotic liver tissue. Strong mechanical support by a stent is important to prevent proliferation as demonstrated by Ikari *et al*[17]. They demonstrated significantly higher proliferation at the articulation of Palmaz-Schats stents in stented conorary arteries and partially attributed this to lack of mechanical support in the articulation area of the stent. Surface area occupied by the metal stent mesh also influences restenosis.

A predominant difference between Cordis stent and Wallstent evaluated in this study is the rigid characteristic of Cordis stent and the flexible characteristic of Wallstent. The benefits of the Palmaz stent and Wallstent in TIPS were compared in a prospective randomized study[21]. The authors illustrated that early shunt thrombosis was more frequent with Wallstent (4/45 *vs* 0/45). Palmaz suggests that the relatively more rigid Palmaz stent could provide a stable, nonshifting surface for endothelial growth, whereas dimensional change in a prosthetic surface causes increased endothelial slough and platelet proliferation[10]. However, late observation in the same study[21] showed more frequent shunt insufficiency with Palmaz stent than Wallstent (6/45 *vs* 2/45). This indicates that the process of TIPS stenosis should be multifactorial.

Wallstent is frequently associated with unpredictable shortening in TIPS at follow-up due to the self-expanding force from elasticity[6,22]. Wallstent shortened 5.18% in our study at 2 weeks as compared with 0. 69% shortening of the Cordis stent. Stent flexibility is required to negotiate curves when delivering the stent by catheter through tortuous vessels leading to the target area. Is it possible to compromise flexibility and rigidity without the drawback of shortening like a Wallstent in TIPS Several other stent designs have been utilized in TIPS. Gianturco-Rosch stent was the first stent designed in experimental TIPS, but it seems to be unco mmonly used. Strecker stent is highly radiopaque, flexible and shortens minimally but tends to dislodge and is difficult to be recatheterized[23]. Preliminary experience in TIPS using the Memotherm stent (Angiomed, Germany) showed promising results, but the number of samples was small[6]. The new Cordis stent used in this study is relatively more flexible than the Palmaz stent, and has the added advantage of being highly radiopaque with minimal shortening. From a technical perspective, the Cordis stent deployment system consistently works well and is easy to use, compared with Wallstent. In our opinion, the Cordis stent is an appropriated compromise between the rigid Palmaz and the flexible but foreshortening Wallstent.

The similar histologic characteristics of proliferative response were observed in the two groups using different designs of stent, which is also very similar to the findings described previously by us and other authors[24-26].

To date, there are few experimental studies or clinical trials available to compare different stent designs in TIPS. It is difficult to directly compare different stent designs following deployment. For instance, although equal stent diameters and balloons with equal inflation pressures were used in our study, TIPS stent length was not equivalent following deployment. Stent diameter following TIPS completion in the Wallstent group was larger than the Cordis stent group (7.98 mm *vs* 7.40 mm). This unexpected size variation may contribute to the relative rigidity of Cordis stents compared with the relative flexibility of Wallstents and the stronger circumferential strength of Cordis stents compared with the relatively decreased hoop strength of Wallstents. Perhaps the difference in luminal diameter contributed to the increased PIH in the pigs with Cordis stents (not statistically

significant). Such an explanation is favored by our recent study (unpublished data, 1996) which demonstrated significantly thicker pseduointimal formation within the lumen (2.07 mm *vs* 1.25 mm, $P = 0.006$) when comparing a smaller diameter Wallstent (6.50 mm) to larger Wallstent (7.25 mm) in a TIPS porcine model. Nevertheless, the short-term patency rate using the Cordis balloon-expandable stainless steel stent in a TIPS porcine model in this study is comparable to that found using Wallstent.

There were interesting findings in two occluded stents in this study: one stent probably occluded because of Cordis stent rigidity, and the other probably occluded because of Wallstent longitudinal recoil. This probably reflects the inherent drawbacks of Cordis stent and Wallstent respectively. However, Cordis stent rigidity may be an advantage when deployed in stiff cirrhotic liver parenchyma in TIPS rather than in healthy, compliant normal pig livers, although Cordis stent should not be deployed where sharp curves are required to bridge the portal and hepatic veins. Use of a longer Wallstent than the exact length of the tract required in TIPS may overcome the shortening disavantage of Wallstent[22]. However, it is important to accurately place the stent in the hepatic vein to ensure patency and not to compromise future opportunity for liver transplantation[27]. The easy to use, reliable Cordis deployment system and increased radiopacity allow for accurate manipulation and precise positioning under fluoroscopy.

Therefore, our study suggests that the Cordis stent merits further investigation for potential use in TIPS patients.

INTRODUCTION

Cancer treatment situation in tumor hospitals in China has its own unique characteristics which are not found in other parts of the world. Because of the huge population and high incidence rates of esophageal and stomach cancer[1-5], the number of cancer patients waiting for admission is inconceivably large. It is estimated that there are about 1.6-2.0 million new cases per year in China. In 1999, the Hebei Tumor Hospital had 6884 carcinoma patients hospitalized, among them there were 1035 esophageal cancer and 1057 stomach cancer patients. Because of the financial problem and most peasants have not joined the medical care insurance plan. Therefore, they are not benefited by the ideal treatment regimen after being diagnosed with TNM staging.

Hebei Tumor Hospital was established in 1958 to provide medical care to cancer patients in the central and southern parts of Hebei Province. It has 621 beds. The southern part of Hebei Province around Chixian is adjacent to Linxian of Henan Province, both Chixian and Linxian counties have the highest incidence rates of esophageal cancer which are 135/100 000. Besides, stomach carcinoma is another major cancer in this region.

With a view to standardize the therapy of esophagus and stomach cancer, the authors reviewed the national and international standard treatment and recent progress in this field, and the therapeutic modalities given in this hospital from 1981 to 1997, and hope this analysis may benefit the development of standardized therapy for the above two malignances in clinical management.

MATERIALS AND METHODS

A database was constructed for esophageal and stomach cancer patients who had been hospitalized in Hebei Tumor Hospital from 1981 to 1997 by the Foxprow database management techniques. Each hospitalized patient had his or her own record in the dataset. Percentages of therapeutic modalities as surgery, radiotherapy, chemotherapy, separate or in combination were calculated by the programs written in the Foxprow language. Finally, the results were analyzed according to *Diagnosis and Treatment Criteria for Common Malignances in China* by Ministry of Health of China and *Manual of Clinical Oncology* by UICC, and recent advances in these fields so as to find out the most rational suggestions for esophageal and gastric cancer.

RESULTS AND DISCUSSION

Esophageal carcinoma

As seen in Table 1, surgery and radiotherapy are two major options for esophageal cancer. Only 2.76% of the patients were treated by chemotherapy alone, and even fewer cases had been treated by multimodality treatment regimens such as surgery + radiotherapy, surgery + chemotherapy, chemoradiotherapy, and surgery + chemoradio-therapy. Radiotherapy as a preoperative option is eligible for esophageal cancer of various locations[6]. Preor postoperative radiotherapy in addition to surgery could reduce tumor recurrence and metastasis[7,8]. Either surgery or radiotherapy alone is not satisfactory because of the high rate of recurrence and metastasis[9,10]. The rationale for preoperative radiotherapy includes cytoreduction, improved resectability and reduced chance of marginal dissemination of tumor during the surgical procedure[11]. Therefore, preoperative radiotherapy is especially beneficial to patients with middle or late stage esophageal cancer[12].

Postoperative radiotherapy had been proved to be useful in reducing recurrence and metastasis[11]. Recent trials showed that although the 5-year survival rate of esophageal cancer was still poor, it had improved somewhat from 3% 30 years ago to 10%-15% today[13]. It was reported that multimodality approaches combining surgery, radiotherapy, and chemotherapy had resulted in 5-year survival rate of 40%-75% for advanced stage patients with a complete histological response to

preoperative chemotherapy[14]. These results suggest that further improvement in multimodality treatment regimens may allow a significant increase in survival period for esophageal carcinoma patients in the future [15].

Preoperative chemotherapy has been shown in nonrandomized trials to have similar side effects and mortality rate with surgery alone. Furthermore, phase two trials have suggested higher survival rates for combination of preoperative chemotherapy and surgery than that seen in surgery alone[16]. Another randomized study of 113 patients with esophageal carcinoma found that preoperative Cisplatin and 5-Fu given concurrently with 40 Gy of radiation significantly improved 3-year survival rate (32% vs 6%)[17]. Criticism of the study included poor preoperative staging and small sample size (113 patients). However, this trial offered hope that multimodality treatment regimens may ultimately prove beneficial in improving the overall survival period in esophageal cancer.

As seen in Table 1, although the cured and improved rate on discharge was highest in patients treated by surgery + radiotherapy, the percentage was only 3.58%, far less than those with surgery alone (48.93%) or radiotherapy alone (32.87%). The percentage of multimodality treatment regimens was only 4.32%, this was because in the past, we adopted the policy of elimination of symptoms rather than eradication of the disease. Therefore, in the future, we should focus our attention on the multimodality treatment regimens and to search for the most eligible combinations.

Table 1 Treatment modalities of esophageal and stomach cancer patients from 1981 to 1997 in Hebei Tumor Hospital

Treatment modality	Esopageal cancer			Stomach cancer		
	n	%	Cured & improved(%)	*n*	%	Cured & improved(%)
Surgery	4683	48.93	92.70	5328	67.48	59.51

Total	9570	100.00	88.46	7896	100.00	84.04

Gastric carcinoma

As seen in Table 1, surgery remains the first choice as curative treatment for patients with gastric cancer, especially at the early stages[18-20]. Early intraepithelial gastric cancer without nodal metastasis by surgery alone can yield a 5-year survival rate as high as 90%-95%. These early carcinomas may also be treated by endoscopic resection or endoscopic mucosectomy[21-24]. Gastric cancer survival is clearly stage dependent and is significantly affected by lymph node involvement[25]. The 5-year survival rate for patients with early gastric carcinoma after treatment approaches 90% but only less than 5% for cancer that involves the serosa[26]. The better survival statistics among Japanese are mainly due to greater frequency of early gastric cancer. Early detection of gastric carcinoma relies upon advanced development of X-ray and endoscopies[27,28], and also upon massive screening in high risk populations.

Although surgery has been proven to be the curative therapy for early gastric cancer, unfortunately, only 10% are early cancers[29]. In fact, locoregional recurrence is also common even after curative resection[30,31], therefore adjuvant chemo and radiotherapies are absolutely necessary[32-34].

Currently, preoperative chemotherapy and intraoperative radiotherapy are used as adjuvant therapies.

The operative morbidity of gastrectomy is high. It frequently precludes patients from entering into adjuvant therapy in a timely manner. Therefore, many studies are investigating the use of preoperative therapy. Wilke *et al*[35] described 34 patients who were demonstrated at laparotomy to have locally advanced unresectable cancer, these patients received two to five cycles of etoposide, doxorubicin, and cisplatin (EAP), 70% responders were offered a second laparotomy, and 15 were without clinical evidence of local extension. Kelsen *et al*[36] reported 56 patients who underwent preoperative therapy with FAMTX combined with postoperative intraperitoneal 5-FU and Cisplatin, among whom 34 patients received a potentially curative resection. For the entire group, the median survival period was 15 months; however, for those who underwent the above preoperation chemothe rapy and surgical resection, the median survival period was 31 months. Lowy *et al*[37] reported 24 patients who responded to similar- therapy, 84% had a 5-year disease-free survival, while 30% of those who did not respond had a 5-year disease-free survival. These studies suggest an appealing potential benefit of preoperative chemotherapy by inducing positive response in some patients[38].

The largest experience with intraoperative radiotherapy (IORT) came from Japan, where it had been studied for over 20 years. Abe *et al*[39] performed a prospective randomized trial of IORT in over 200 gastric cancer patients, and a more significant survival advantage was found for patients treated with IORT and surgery over those treated by surgery alone. This 5-year survival advantage was seen in patients with stage two (84% vs 62%) and stage three (62% vs 37%). Patients with stage one disease received no benefit from IORT. In addition, the only 5-year survivors in stage four were those who received IORT. This study suggests that IORT may be able to control locoregional recurrence after resection, which alone is often a major cause of treatment failure.

According to the criteria for gastric cancer

therapy modality planning of the Diagnosis and Treatment Criteria for Common Malignances in China for early gastric carcinomas with no nodal metastasis, no adjuvant therapy is necessary following curative resection depending on whether the disease is restricted to the mucosa or submucosa, but if there is nodal metastasis, adjuvant chemotherapy should be considered. For stage two and/or stage three progressive gastric cancer patients, preoperative radiotherapy is helpful to improve resectability. Postoperative chemotherapy should be considered for all progressive gastric cancer patients whether they have undergone curative or noncurative resection, and whether there is nodal metastasis or not. Intraoperative radiotherapy should be applied for stage two or stage three patients who are undergoing curative resection[40].

As seen in Table 1, the percent of surgery alone for treatment of gastric cancer is 67.48%, surgery plus chemotherapy and surgery plus radiotherapy account for only 1.44% and 3.29% respectively. Considering only 10% of gastric cancer patients diagnosed in hospitals are early cancer and may be treated by surgery alone, all other patients present with advanced disease should be treated by multimodality regimens such as preoperative chemotherapy, pre, intra or postoperative radiotherapy etc.

CONCLUSIONS

The advent of multimodality treatment is introduced in the last decade. Pre-operational chemotherapy can eliminate micro-metastasis and post-operational radiotherapy can kill the residual cancer cells, therefore in the future surgical resection with preoperational chemotherapy and postoperational radiotherapy should be considered to achieve better results and longer-survival periods.

INTRODUCTION

Vita min E succinate (RRR-α-Tocopheryl Succinate, VES), a derivative of natural vita min E, is a compound esterified by succinic acid and 6-hydroxyl-α-tocopheryl. VES can increase the stability of á-tocopheryl and protect 6-hydroxyl from oxidation. Nowadays, this kind of vita min E has been on sale on the markets. Previous researches indicate that VES has an evident inhibitory effect on the growth of various tumor cells, but has no harm to the growth of normal cells[1-7]. The experiment *in vivo* has demonstrated that VES can cause the tumor to retrogress by regional injection[8,9]. Thus it is presumed that VES may be a potential tumor chemopreventive and chemotherapeutic agent.

Gastric cancer is one of the most common tumors in China. Up to now, most studies have focused on the preventive measures for tumors[10-13], but there has been few reports that VES inhibits the growth of gastric cancer. Our study showed that VES has an obviously inhibitory effect in the growth and DNA synthesis of human gastric cancer SGC-7901 cells[14]. The observation under electron microscope and the detection by flow cytometry and *in situ* end-labeling methods implicated that VES can induce gastric cancer cells to undergo apoptosis[15]. The exact mechanism of VES-induced growth inhibition in tumor- cells has still been unclear, but it has been reported that transforming growth factor beta (TGF-β) played a critical role in VES-induced apoptosis in tumor cells[16,17]. In addition, VES-triggered apoptosis was inhibited when c-Jun mutant was transfected into breast cancer cells[18]. The data above show that both TGF-β and c-Jun may be important factors for VES-induced apoptosis. In this study, the expression of TGF-β_1, c-Jun and c-Jun NH_2-ter minal kinase (JNK) was deter mined in SGC-7901 cells treated with VES so as to explore the mechanisms of VES-triggered apoptosis in gastric cancer cells.

MATERIALS AND METHODS

Materials

Human gastric cancer SGC-7901 cell line was obtained from the Beijing Cancer Institute and cultured in RPMI1640 medium plus 10% fetal bovine serum and routinely incubated with 5% carbon dioxide at 37℃. VES was purchased from the Sigma Corporation. Quantikine human TGF-β_1 ELISA kit was purchased from R&D Systems Company. Rabbit JNK1 polyclonal antibodies were kindly presented as a gift by Dr. Rui Hai Liu of Cornell University, USA. Rabbit c-Jun/AP_1 polyclonal antibodies were purchased from Beijing Zhongshan Biotechnical Company.

Drug treatment

VES was prepared at 5, 10 and 20mg/L by 100% ethanol. The concentration of ethanol in VES solution was adjusted to 0.1% (v/v) by 100% ethanol. Exponentially growing SGC-7901 cells were treated with VES. RPMI1640 complete condition media containing 1 μL/mL ethanol served as control.

Methods

ELISA When the cells were cultured for 12 h,18 h, 24 h and 48 h respectively, condition media was aspirated and centrifuged. The supernatant was prepared for the detection of activated TGF-β_1. Next, 500 μL culture supernatant was added into 0.1 mL 1N HCl and centrifuged for 10 min at room temperature. Then 0.1 mL 1.2N NaOH was used to neutralize the acidified samples for the detection of total TGF-β_1. Standard solution was prepared at different concentrations according to the instructions in the kit. Standard solution (200 μL per well) or activated samples were added into the 96-well plates bound with human recombinant TGF-

βs RII. Then the steps proceeded as instructed. Finally, the value of optical density (OD) of each well was deter mined at 450 nm within 30 min, using a microplate reader set to 450 nm, and corrected at 540 nm.

Western blot SGC-7901 cells were harvested, decomposed on ice and centrifuged. Total protein contents in the supernatant were detected by nucleic acid and protein analyzer. Total protein (100 μg) was used for 12% SDS-PAGE electrophoresis and transferred onto nitrocellulose membrane, which was hybridized with rabbit c-Jun/AP-1 or JNK1 polyclonal antibodies (1:1000 dilution) and then with the secondary horseradish peroxidase-labeled antibody to detect the expression of c-Jun and JNK1.

RESULTS

Effects of VES on the expression of TGF-â₁ protein

Standard curve Standard curve was created by plotting the mean absorbance for each standard on the y-axis against the concentration of TGF-β_1 on the x-axis. The linear regression equation was as follows:

$$Y = -0.037+8.559\times10^{-4}\, x \qquad r = 0.9991$$

Detection of total TGF-β_1 When SGC-7901 cells were collected following VES treatment for varying time periods, the OD value of TGF-β_1 was measured by microplate reader and converted into the concentration of total TGF-β_1 according to the regression equation above. Compared with the control, the expression of total TGF-β_1 in VES-treated cells was enhanced with a dose-time effect. After 48h treatment of VES at 5, 10, and 20 mg/L, the level of total TGF-β_1 was increased by 44.8%, 92.4% and 182. 3%, respectively (Figure 1).

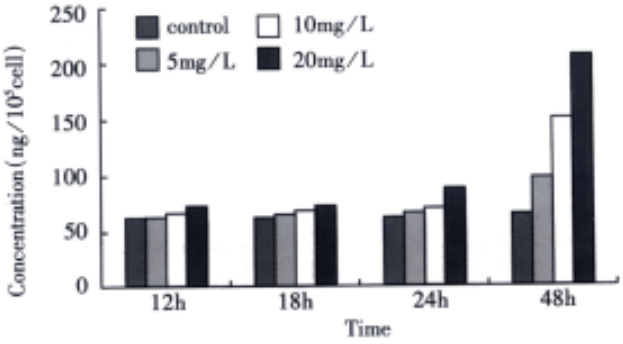

Figure 1 The effects of VES on total TGF-β_1 in SGC-7901 cells.

Detection of activated TGF-β_1 The OD value was directly measured in SGC-7901 cells harvested without acidification, and converted into the concentration of activated TGF-β_1 by means of the equation above. In comparison with the control, VES-treated cells exhibited increased level of activated TGF-β_1 in a dose-dependent manner. When the cells were treated with VES at 10 mg/L for 48 h and at 20 mg/L for 24 h and 48 h, the expression of activated TGF-β_1 was increased by 130.9%, 115.8% and 559.6%, respectively (Figure 2).

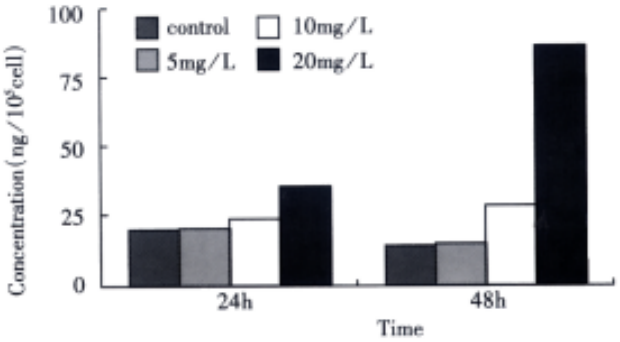

Figure 2 The effects of VES on the expression of active TGF-β_1 in SGC-7901 cells.

Effects of VES on c-Jun expression

The transferred filter membrane was hybridized with rabbit c-Jun/AP-1 polyclonal antibodies, then with the secondary antibody, colorated with DAB and imaged by digital imaging maker (Figures 3 and 4). From Figure 3, it can be seen that VES-treated SGC-7901 cells at 10 mg/L for 3 h exhibited evidently increased level of c-Jun protein. It was in a high state within 24 h and began to decrease after 24 h. Figure 4 indicates that the expression of c-Jun in VES-treated SGC-7901 cells at different concentrations at the same time was increased with a significant dose-effect relationship.

Effects of VES on JNK1 expression

The procedure was similar to that for c-Jun (Figures 5 and 6). Figure 5 shows that when SGC-7901 cells were treated with VES at 10 mg/L for 3 h, the expression of JNK1 was obviously promoted and further promotion occurred with the lapse of time within 24 h. Figure 6 implicates that the level of JNK1 expression was different in VES treated SGC-7901 cells at different concentrations at the same time. Compared with the control, the expression of JNK1 was evidently elevated in a dose-dependent manner.

DISCUSSION

Previous researches showed that induction of apoptosis in tumor cells is one of the important mechanisms by which VES inhibits tumor cell growth[15,19]. Apoptosis is the most common physiological form of cell death and occurs-during embryonic development, tissue remodeling, immune regulation and tumor regression. Thus, initiation of apoptotic signal pathway and induction of apoptosis in tumor cells will be an effective approach for treating tumors[20-23]. Apoptosis is controlled by genes. Now hundreds of regulatory factors have been identified. These factors form many apoptotic signal transduction pathways which are complex[24-28]. In this study, several apoptosis-related proteins were deter mined to investigate the possible pathways involved in VES-induced apoptosis of human gastric cancer SGC-7901 cells.

Transfor ming growth factor (TGF) is a large family of multifunctional cytokines which can regulate cell proliferation, differentiation and death[29-31]. It has been proved that TGF-β, a latent inhibitor of epidermal proliferation, plays a role in the inhibition of more than three quarters of human primary tumors (such as breast cancer[32,33], prostatic carcinoma[34], lung cancer[35,36], colic carcinoma[37] and liver cancer[38,39]). Inhibition of the activation of latent TGF-β, down-regulation or loss of the expression of TGF-β receptors and deficiency of important elements responsible for cellular message transmitting pathway cause tumor cells to escape the growth inhibition of TGF-β, resulting in cancer [40-42]. Yu *et al*[43] found that VES can improve the secretion of activated TGF-β_1 and induce apoptosis in human breast cancer MDA-MB-435 cells. When TGF-β antibody neutralization assay was applied or antisense TGF-βRII oligonucleotide was transfected into breast cancer cells, the ability of VES-induced apoptosis was blocked by 50%, which implicated that the increase of TGF-β expression was related to induction of tumor cell-undergoing apoptosis. In our study, activated TGF-β_1 was directly measured with the kit in VES-treated SGC-7901 cells and its expression was distinctly increased; yet total TGF-β_1 was detected when the samples were acidified and its expression was also clearly promoted. These facts suggested that VES can induce not only the activation of active TGF-β_1 but also an increased secretion of latent TGF-β_1. Latent TGF-β_1 is released from cells into media and activated by some enzyme outside the cell membrane.

c-Jun is an early and transient gene[44] and its response to many kinds of stimuli is rapid and transient. The expression of c-Jun can be enhanced and prolonged by many stress stimuli such as ultraviolet, irradiation, hydrogen peroxide, tumor necrosis factor α and other apoptosis-triggering factors[45,46]. As mentioned above, VES-induced apoptosis rate was obviously decreased when human breast cancer cells were transfected with antisense c-Jun oligonucleotide or c-Jun mutant[18]. Our results showed that the expression of c-Jun was elevated and prolonged in VES-treated SGC-7901 cells (usually the expression of c-Jun only lasted 3 h-4 h or even shorter), indicating that c-Jun was also involved in apoptosis of VES-treated SGC-7901

cells.

It is reported that the mainly biological roles of c-Jun are the induction of cell cycle arrest and apoptosis [47-49]. JNK can directly bind with transcription factor c-Jun and activate c-Jun through phosphorylation of serine 63/73, suggesting that the activation of JNK is the upstream events involved in phosphorylation of c-Jun. It is also known that JNK belongs to mitogen-activated protein kinases (MAPK) family whose activation can be evidently affected by TGF-β, which shows that the activation of JNK can be possibly influenced by TGF-β[50-52]. These data suggest that JNK may be involved in VES-mediated apoptosis in tumor cells. In our study, the expression of JNK protein in VES-treated SGC-7901 cells was obviously increased with a dose-dependent relationship. Therefore, we suspect that JNK1 may be involved in apoptotic signal transduction similar to TGF-β_1 and c-Jun. When SGC-7901 cells were treated with VES, the secretion and activation of TGF-β were improved, TGF-β increased the activity of JNK, JNK caused the phosphorylation of c-Jun, and finally activated c-Jun triggered apoptosis in tumor cells.

Although we presumed a signal pathway responsible for VES-induced apoptosis in SGC-7901 cells, several interrelated pathways may trigger apoptosis simultaneously owing to the fact that the mechanisms of apoptosis are complicated and precisely regulated. So the observation that the expression of these three proteins is increased is only the preli minary survey on VES. With the development of molecular biological technology, if the strategies that a point in designed signal pathway is "knockout" by different means and then the blockage of downstream events is observed can be carried out, it will be critical for further studies on the mechanisms of VES-mediated growth inhibition in tumor cells.

ACKNOWLEDGEMENTS We would like to thank Dr. Wei Ping Yu, Genetics Institute, Texas University of USA, for the technical assistance.

Peng ZH, Xing TH, Qiu GQ, Tang HM. Relationship between Fas/FasL expression and apoptosis of colon adenocarcinoma cell lines. ***World J Gastroentero***, 2001;7(1):88-92

INTRODUCTION

Fas/FasL system has been identified as a key mediator of apoptosis in tumor cells[1-4]. The occurrence and development of neoplasm are closely related to apoptosis [5-7]. Most chemotherapeutic drugs kill cancer cells mainly by inducing apoptosis[8-14]. We determined the Fas/FasL expression and apoptosis of colon adenocarcinoma cell lines induced by chemotherapeutic drugs with flow cytometry (FACScan), and studied the relation ship between Fas/FasL expression and apoptosis of colon adenocarcinoma cell lines for selection of sensitive chemotherapeutic drugs and appropriate dosage.

MATERIAL AND METHODS

Cell lines and cell culture

Colon adenocarcinoma cell lines (LS174-T cells and LoVo cells, provided by the Cell Bank of Chinese Academy of Sciences) were cultured in RPMI 1640 medium at 37℃ in a humidified 5% CO_2 atmosphere. Cells were seeded at a concentration of 1×10^6/well in 6-well plates and incubated at 37℃ in a humidified 5% CO_2 atmosphere overnight to ensure that the cells adhere to the walls, then chemotherapeutic drug of various concentrations was added and incubated again for 24 h or 48h.

Treatment with chemotherapeutic drugs

Different cell lines were treated with Cisplatin (CDDP), Mitomycin (MMC), 5-fluorouracil (5-FU) and epirubicin Hydrochloride (EPH) at concentrations of plasma peak concentration (PPC), 1/10 PPC, 1/5 PPC, 5 PPC and 10 PPC for 24 h and 48 h. The PPC of CDDP, MMC, 5-FU, EPH was 3 mg/L, 3 mg/L, 10 mg/L and 0.6 mg/L[5].

Apparatus and reagent

EPHCS-XL FACScan was purchased from Coulter Co. of America. Annexin-V-Fluos labeling reagent for identifying apoptosis was purchased from Boehringer Mannheim Co., and reagent for identifying Fas/FasL expression was purchased from Pharmingen Co..

Determination of apoptosis and Fas/FasL expression

Early apoptotic changes were identified using Annexin-V-Fluos, which binds to phosphati dylserine on the outer leaflet of apoptotic cell membranes. Propidium iodide was used for the discrimination of necrotic cells from the annexin V positively stained cell cluster. Cells were trypsinized, washed with PBS twice, centrifuged at 200×g for 5 min, and resuspended in 100mL Annexin-V-Fluos labeling solution containing Annexin-V-Fluos reagent and propidium iodide. Cells were incubated for 10-15 min and analyzed on FACScan. Percentage of apoptosis = 100% [experimental apoptosis (%)-spontaneous apoptosis in medium (%)]/[100%-spontaneous apoptosis in medium (%)][16]. For determination of Fas expression, cells were stained with anti-Fas IgG1 monoclonal antibody (mAb 1 g/mL) for 45 min at 4℃ followed by rat anti-mouse IgG1-FITC for 30min at 4℃. FII23 IgG3 antibody was used as isotype-matched antibody to control non-specific binding. For determination of FasL expression, cells were stained with FITC-conjugated rat anti-FasL mAb for 45 min at 4℃ followed by goat anti-mouse Igs-biotinylated. Rat IgG2a antibody was used as isotype-matched control antibody. Fas/FasL expression was assessed by FACScan. Fas expression = (%Fas + treated cells - %IgG1 - FITC + treated cells) - (%Fas + control cells - %IgG1 - FITC + control cells)[16]. FasL expression was calculated according to the formula as that of Fas expression. Cells were analyzed by FACScan using Cell Quest software.

DNA extration and gel electrophoresis

LS174T cells and LoVo cells of colon adenocarcinoma cell lines were added to 6-well culture plates at a concentration of 1×10^6/mL.

Cell cultures without treatment, or with treatment at different PPC of above chemotherapeutic drugs were harvested from the culture plates after 24 h or 48 h, washed twice with PBS (pH 7.4), and moved to the micro-centrifuging tube. Cells were pelleted at 300×*g* and the medium was removed by aspiration. Cell pellets were resuspended in 100 mL lysis buffer and incubated at 50℃ for 1 h, then mixed with 10 μL RNase and incubated at 50℃ for another 1 h. The DNA was resuspended in sample buffer and quantified by absorbance at 260 nm. Ten micrograms of DNA was applied to a 1.5% agarose gel in TBE buffer and resolved at 75 mA constant current for 2 h. The DNA was then visualized by ethidium bromide staining for 5 min and washed twice with distilled water. The result was observed under ultraviolet radiation (Figures 5 and 6).

Statistical analysis

Fas expression FasL expression and apoptosis percentage of each treated group were compared and checked with *F* test, and their relationship was analyzed.

RESULTS

The drug concentrations of CDDP, MMC, 5-Fu and EPH ranged between 1/10 PPC and 10 PPC[15], among which we set 1/5 PPC, PPC, and 5 PPC[17]. We treated LS174T cells and LoVo cells with chemotherapeutic drugs fo 24 h and 48 h respectively, and detected apoptosis and Fas/FasL expression with FACScan.

In untreated control group of LS174T cells, Fas expression, FasL expression and apoptosis percentage was 0.5%, 1.5% and 2.8% separately. The percentage in those treated with chemotherapeutic drug for 24 h was similar in that treated for 48 h, but figures were lower. LS174T cells treated with chemotherapeutic drugs for 48 h showed that Fas expression was upregulated when drug concentration was below 1/5 PPC or at PPC, and downregulated when drug concentration was above 1/5 PPC or at PPC (Figure 1). FasL expression was upregulated obviously when drug concentration was above PPC (Figure 2). When drug concentration of CDDP, MMC and EPH was below 1/5 PPC or PPC, apoptosis was upregulated, and downregulated at a concentration above 1/5 PPC or PPC. Apoptosis of 5-Fu group cells was upregulated with increase of drug concentration. Apoptosis in various drug concentrations in each group is shown in Figure 3.

We did not detect Fas expression of LoVo cells treated with chemotherapeutic drugs for 24 h. FasL expression was lower than that of LS174T cells. Apoptosis of 5-Fu group was upregulated with ascending drug concentration which was 54.8% when drug concentration was 10PPC. The effect of apoptosis induced by 5-Fu was the best while that induced by EPH was the worst. The results were just opposite to the results in LS174T cells. Apoptosis of CDDP group and MMC group were downregulated with ascending drug concentration (Figure 4). We could not detect Fas expression or FasL expression of LoVo cells treated with chemotherapeutic drugs for 48 h. Necrosis was found mainly in LoVo cells, apoptosis of which was lower than that of the control group.

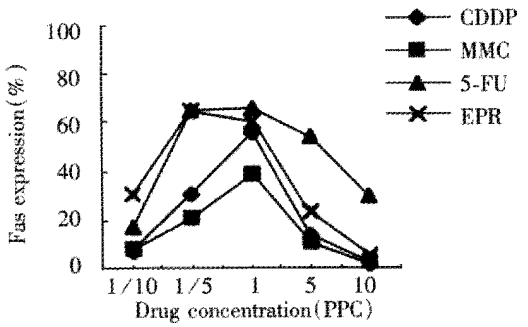

Figure 1 Fas expression of LS174T cells treated with chemotherapy drugs for 48 h.

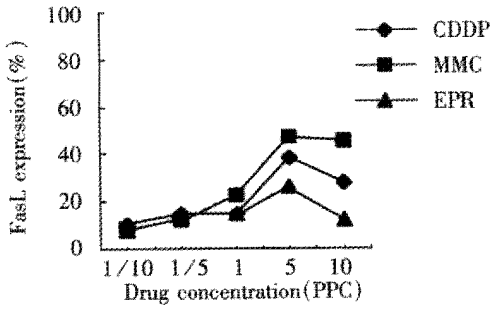

Figure 2 FasL expression of LS174T cells treated with chemotherapy drugs for 48 h.

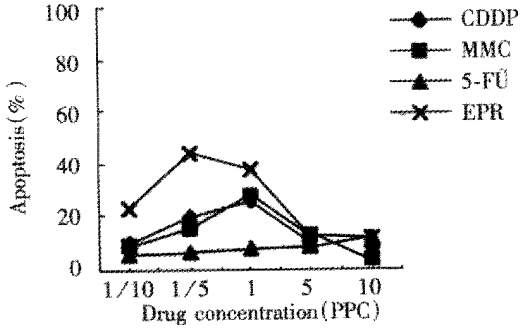

Figure 3 Apoptosis of LS174T cells treated with chemotherapy drugs for 48 h.

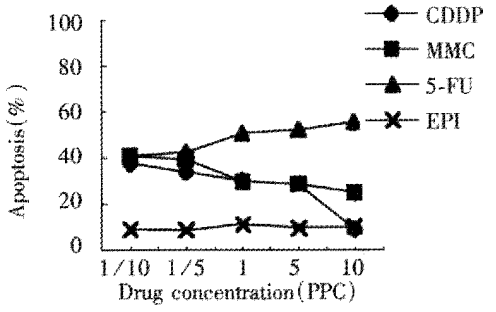

Figure 4 Apoptosis of LoVo cells treated with chemotherapy drugs for 24 h.

We abstracted DNA from the control group of cell lines and the group treated with chemotherapeutic drugs of various concentrations for 24 h and 48 h, and examined DNA ladder by agarose gel electrophoresis. The result showed that DNA ladder was remarkable in the treated group of LS174T cells when drug concentration of CDDP, MMC and EPH was 1/5 PPC or PPC, and 5-Fu concentration was 10 PPC. DNA ladder was remarkable in the treated LoVo cells when CDDP, and MMC concentration was 1/10 PPC, and 5-Fu concentration was 10PPC.There was no obvious difference among the DNA ladders at any concentration of EPH (Figures 5, 6).

DISCUSSION

Fas is a 45 kDa type I transmembrane receptor expressed by a variety of normal and neoplastic cells. It belongs to the tumor necrosis factor (TNF) receptor family. When there is no antagonistic factor in the induction of apoptosis, apoptosis of chemosensitive tumor cells is induced following cross-linking of agonistic anti-Fas antibody or FasL with functional Fas expressed by tumor cells. Chemotherapeutic drug could induce tumor cells, which did not express or weakly expressed Fas, to strongly express functional Fas. Our data by FACScan showed that the Fas expression of LS174T cells untreated with chemotherapeutic drugs was only 0.5%, but compared with the Fas expression of the control cells, the Fas expression of LS174T cells treated with CDDP, MMC, 5-Fu and EPH for 48 h was notably upregulated. Fas expression of each treated group reached its peak at 1/5 PPC or PPC, which proved that the appropriate selection of chemotherapeutic drug concentration could effectively induce functional Fas to be strongly expressed on the surface of tumor cells.

In LS174T cells, apoptosis induced by CDDP, MMC and EPH was closely related to Fas-expression. Fas expression of the four LS174T cell groups treated with chemotherapeutic drugs for 48 h and apoptosis reached their peak at 1/5PPC or PPC. Fas expression was downregulated with chemotherapeutic ascending, drug concentration, so was apoptosis. The results of DNA fragmentation studies showed that the DNA ladder was most visible when the concentration of CDDP, MMC and EPH was 1/5 PPC or PPC. Fas expression and apoptosis of CDDP, MMC and EPH groups were positively correlated by relativity analysis ($P<0.05$). In LS174T cells, Fas expression induced by EPH was most notable and apoptosis of this group was the highest of all. There was statistical significance in Fas expression and apoptosis between EPH and CDDP or MMC groups ($P<0.05$). The above data and analysis suggest that kinetics of cell apoptosis correspond to kinetics of Fas induction. We could find the hypersensitive drugs and their appropriate dosage according to apoptosis and functional Fas expression. The different apoptosis paths between LS174T cells and LoVo cells demonstrated the importance of individualized selection of chemotherapeutic drugs.

After treatment with 5-Fu, Fas expression of LS174T cells was remarkablely upregulated while apoptosis was the lowest of all. On the contrary, the anti-tumor effect of 5-Fu on digestive tract tumor is the best among the clinical chemotherapeutic drugs. This contradiction, we believed, may be caused by the different effects between *in vitro* experiment and *in vivo* treatment. *in vitro*, FasL expression of LS174T cells induced by 5-Fu was too low to effectively activate the Fas system and trigger the apoptosis cascade; *in vivo*, FasL expressed strongly on the surface of CTL or NK could mediate autocrine or paracrine chemosensitive cell death by crossing its cognate receptor. This may be the reason why the 5-Fu had best anti-tumor effect in digestive tract tumor. Our study also showed that apoptosis induced by 5-Fu increased with the concentration, which was different from other drugs used in this research.

In LS174T cells, the FasL expression of CDDP,

MMC and EPH groups reached its peak at 5PPC, and there was no significant correlation between FasL expression and apoptosis of each group (P>0.05). FasL was upregulated on the tumor surface upon drug incubation in chemosensitive tumor cells and tumor cells could mediate autocrine or paracrine to release soluble FasL (sFasL). Apoptosis could occur in tumor cells expressing FasL through suicide or fratricide, inducing Fas-mediated apoptosis of peripheral normal cells, CTL and NK which express Fas, to promote local tumor invasion or metastases [18]. Therefore, drug-induced expression of FasL in Fas-negative tumors is not effective and, could result in selective elimination of antitumor lymphocytes. The incorrect chemotherapy could cause drug resistance or immune privilege of tumor cells[19]. Therefore, the induction of FasL by chemotherapeutic drug has dual effects on tumor therapy.

FACScan determination showed that LoVo cells treated with chemotherapeutic drug did not express Fas, weakly expressed FasL, and there was no significant correlation between Fas expression and apoptosis in LoVo cells (P>0.05). However, DNA ladder of LoVo cells treated with chemotherapeutic drug was similar to that of LS174T cells, suggesting that drug-induced apoptosis of LoVo cells did not depend on FasL/Fas interaction. Drug might kill tumor cells through activating other death receptors or directly acting on the downstream factor of Fas system (such as caspases family, etc.), also might trigger apoptosis in another way[20-28]. Nita *et al*[29] used equitoxic (IC50%) doses of 5-Fu to induce apoptosis in LoVo cells and analysed Bcl-2, Bcl-XL, Bax, Bad, Bak and p53 protein expression of LoVo cells by Western blotting, and found that Bcl-XL was expressed in all the cell lines and accompanied by increased expression of Bax and Bak. We are doing further studies to find out whether the ratio of Bcl-XL to Bax is correlated with chemosensitivity of LoVo cells treated with 5-Fu.

The determination of Fas expression, FasL expression and apoptosis of tumor cells treated with chemotherapeutic drug by FACScan indicated that the induction of Fas expression and apoptosis by major chemotherapeutic drugs was the best at the concentration of PPC or below PPC. DNA ladder also proved that the selection of appropriate dosage was of great importance in chemotherapy [30-41]. We could find hypersensitive drugs and their appropriate dosage according to apoptosis determined by FACScan, partly according to Fas expression. The different apoptosis paths between LS174T cells and LoVo cells demonstrated the importance of individualized selection of chemotherapeutic drugs.

INTRODUCTION

Boanmycin (Bleomycin A6, BAM), a new antitumor antibiotic, was isolated from many components of bleomycin (BLM) produced by streptomyces pingyangensis which were obtained from a soil sample collected in Pingyang County, Zhejiang Province, China. Boanmycin has a similar chemical structure to that of BLM, but the terminal amine moiety is different [1]. Pingyangmycin (bleomycin A5), one of multicomponent bleomycin complex produced by the strain, was found to have a high activity against a wide spectrum of murine transplantable tumors, but have a relatively low pulmonary toxicity in mice[2-4]. Pingyangmycin, as a single agent, shows marked inhibition on the growth of human colon cancer, stomach cancer and nasopharyngeal cancer xenografts in nude mice[5-7]. It has been widely used clinically in the treatment of tumors since 1979 in China[8]. Because of a good antitumor efficacy of pingyangmycin as a single agent and low marrow toxicity, attempts have been made to develop new superior bleomycin derivatives[9]. BAM, a minor component of bleomycin complex, was also found to be highly active against murine tumors, human liver cancer and colorectal xenografts in nude mice, and markedly inhibit the spontaneous pulmonary metastasis of Lewis carcinoma in mice[10-14]. BAM-monoclonal antibody immunoconjugates were highly effective against related human tumor *in vivo* and *in vitro*[15-19]. BAM also reached a higher concentration and remained for a longer time in murine transplantable carcinomas as compared with other bleomycin components[3]. As observed under electron microscopy, the pulmonary toxic damage caused by BAM was less than that induced by bleomycin[20]. Phase I clinical study of BAM showed no myelosuppression and cardiac toxicity, and its major adverse reactions were fever, gastrointestinal reactions and hardening at the site of i.m. injection. All adverse effects disappeared after discontinuation of the therapy[21].

An ideal animal model for cancer is one that mimics human disease in every respect. Most tumor xenograft studies, including colorectal tumor, for the evaluation of antitumor activity of drugs used subcutaneous implantation system due to its convenience and access to direct detection and therapeutic effect. However, those models have limitations for the study of interaction of tumor cells with their relevant organ environment or organ distribution of drugs. Alteration of microenvironment surrounding tumor tissue will not only influence growth and spread of tumor but also is important for drug delivery[22-24]. Recently, use of orthotopic models for the growth of tumors in mice or rat has aroused more interest, including lung cancer, colorectal cancer, breast cancer, pancreatic cancer, etc[25-30]. However, whether such orthotopic colorectal tumor models apply to the evaluation of new anticancer agents remains unknown.

In the present study, human colorectal tumor xenograft model in nude mice and the orthotopic model of murine colon cancer were used to clarify the antitumor effect of BAM in comparison with that of mitomycin C and 5-fluorouracil, drugs commonly used in clinics against colorectal cancer. We attempted to determine the effect of BAM against colorectal cancer and whether the organ microenvironment could influence the response of a murine colon cancer to systemic therapy with BAM.

MATERIALS AND METHODS

Mice

Nude mice with a BALB/c genetic background were bred under specific pathogen-free conditions at the Institute of Laboratory Animal Sciences, Chinese Academy of Medical Sciences (CAMS). All experiments were carried out in the Institute of Laboratory Animal Sciences under specific pathogen-free conditions using laminar airflow racks. Six to seven week old male or female nude

mice weighing 18 g-22 g were used for the experiment. All food, water and bedding were sterilized.

Tumors

Two human cell lines of colorectal cancer, HT-29 and Hce-8693, transplanted into nude mice, were used. HT-29 was an adenocarcinoma of the colon established in the Memorial Sloan-Kettering Cancer Center, New York. Hce-8693 was a poorly differentiated adenocarcinoma of the cecum established in the Zhejiang Tumor Hospital, Hangzhou.

Colon tumor NO. 26 (CT-26), a murine colon adenocarcinoma, was induced in a BALB/c mouse by chemical carcinogens. Initially, CT-26 cells were serially transplanted and then established as a cell line and used in a large number of chemotherapy studies.

Drugs

Commercially available mitomycin C (MMC) and 5-fluorouracil (5-FU) were used for the experiment. BAM, a single component of bleomycin A6, was purified from bleomycin complex at Institute of Medicinal Biotechnology, CAMS & PUMC, Beijing. A 1/9 LD50 equitoxic dose for each drug, MMC 1.0 mg/kg per injection, 5-FU 27 mg/kg per injection and BAM 10 mg/kg per injection, was used for *in vivo* comparative studies[12].

Chemotherapy of human colorectal cancer xenografted in nude mice

Two human tumor fragments of about 2 mm^3 were inoculated subcutaneously into the right axillary region of nude mice. When diameter of tumor reached 3 mm-4 mm, tumor-bearing mice were randomized into test groups of 5-6 each and drug treatment was initiated. Test mouse was weighed and size of tumor was measured with sliding calipers two times weekly, and tumor weight (W) was calculated by the formula W (mg) = a(mm) × b^2(mm)/2 where a was the width and b is the length. The drugs were administered i.p., *b.i.w.*, a total of 10 injections. Next day after last treatment, mice were killed and the tumors were removed and weighed. The antitumor effect of drug was evaluated in terms of inhibitory ratio [1-(mean tumor weight of treated group - mean tumor weight of control group)] × 100%[12].

Chemotherapy of murine CT-26

Orthotopic tumor implantation Six-week-old (18 g-20 g) female BALB/c mice were anesthetized with diethylether, and the abdomen was prepared for sterile surgery. A small incision was made, the cecum was exteriorized and CT-26 cells (1×10^6/0.02 mL) were injected with a 30-G needle between the submucosa and the subserosa. The lack of extracecal leakage was the criterion for a successful injection. The cecum was returned to the abdominal cavity, and the wound was closed in one layer[7].

Subcutaneous tumor implantation CT-26 cells (1×10^6/0.02 mL) were injected into *s.c* in right axilla region. Mice were randomized into treatment and control groups based on the body weight next day after tumor cell injection. The drugs were administered *i.m.* (hindlimb), *q.o.d.*, for a total of 10 injections. Mice with *s.c* tumors and cecal tumors were killed on day 21 after tumor cell injection, and tumors were removed and weighed. The antitumor effect of drug was also evaluated in terms of inhibitory ratio [1-(mean tumor weight of treated group - mean tumor weight of control group)] × 100%[7].

Pathologic examination

Samples from untreated and drug-treated tumors were collected from subcutis or cecum and fixed in Bouin's solution, and embedded in paraffin. Sections were made, stained with H & E and observed under microscopy with a rectangular net-like micrometer. Whole area and necrosis area in tumor section was measured, and the necrosis ratio of tumors was calculated. Ten optical fields were examined along the peripheral area of the tumor and the mitotic figures were recorded[12].

Examination of nucleated cells in bone marrow

Femurs were removed and the bone marrow cavity was washed out with 3 mL white-blood-cell diluting solution. The nucleated cells per femur were counted under microscopy[12].

RESULTS

Response of colon cancer to BAM in nude mice

The results shown in Table 1 reveals the same response of the two types of human colon cancer to intraperitoneal BAM in both 10 and 15 mg/kg dose groups. Both doses exerted marked inhibition on the growth of HT-29 and Hce-8693 xenografts in nude mice.

Table 1 Inhibitory effect of BAM on the growth of human colorectal xenografts in nude mice*

Drug	Tumor	No. of mice	Dose (mg/kg)	Tumor weight (g) $\bar{x} \pm s$	Tumor growth inhibition (%)
BAM	HT-29	6		1.300 ± 0.620	
		6	10	0.138 ± 0.064	89[b]
		6	15	0.098 ± 0.074	92[b]
	Hce-8693	5		1.501 ± 1.445	
		5	10	0.154 ± 0.125	90[b]
		5	15	0.122 ± 0.154	92[b]

*Treatment was started on day 3 and day 14 after HT-29 and Hce-8693 tumor transplantation, *ip.*, twice a week, with a total of 10 injections. [b]$P<0.01$, *vs* control group.

Comparative response of colon cancer to BAM, 5-FU and MMC in nude mice

On the basis of equitoxic doses (1/9 LD50), BAM and two clinically active drugs (5-FU and MMC) were evaluated against human colon cancer HT-29 xenografts in nude mice. Table 2 shows the response of the tumor to two weekly treatments with three drugs. BAM is the most active single agent with an inhibition rate of 82% and exerted much stronger growth inhibition against HT-29 xenografts than 5-FU(P<0.01) and MMC(P<0.05). MMC had moderate activity against HT-29 xenografts with an inhibition rate of 53%. 5-FU did not arrest tumor growth throughout the experiment, and tumor increased in size at the same rate as the untreated control with an inhibition rate of 12%.

Comparative response of CT-26 growing at subcutis and cecum to BAM 5-FU and MMC

In the experiment, BALB/c mice were given injections of CT-26 cells into subcutis and cecum, which produced s.c tumor and cecum tumor. In view of the drug distribution, BAM, 5-FU and MMC were administered *i.m.* rather than *i.p.* at an equitoxic dose. In the treatment, the equitoxic dose was administered, and the antitumor activity of the three agents was compared. Table 3 shows the antitumor activity of BAM on the intracecal and *s.c* CT-26 tumor in comparison with that of 5-FU and MMC. BAM displayed a striking activity against intracecal CT-26 tumor; the inhibition of tumor growth was higher at the cecum than at the s.c site (P<0.05). The mean tumor weight after BAM treatment was less than that in the control, 5-FU and MMC groups, and the difference was statistically significant (P<0.01). On the other hand, 5-FU did not effectively suppress the tumor growth, and MMC showed mild activity.

Changes in tumor necrosis and mitosis

In contrast to the control HT-29 tumors that maintained their feature of poorly differentiated adenocarcinoma, the BAM-treated HT-29 xenografts in athymic mice presented extensive tumor necrosis and fibrosis. In areas of residual tumor, tumor cells were frequently found to have giant, bizarre-shaped pyknotic nucleoli, or prominent inclusion-type nucleoli. Xenografts treated with 5-FU and MMC showed scattered giant, bizarre-shaped nuclei and nucleolar prominence but these changes were focal and less apparent than in BAM-treated tumors. More extensive necrosis was found in tumors treated with BAM than in those treated with 5-FU or MMC. The necrotic ratio of tumors (whole necrotic area/whole tumor area) in BAM-treated group (67%) was much higher than that in 5-FU-treated (35%), MMC-treated (43%) and control groups (35%). In contrast to the tumor of the control group, the pathologic mitosis figures in BAM-treated group were reduced by 69%, which were fewer than those in 5-FU-treated, MMC-treated and control group (Table 3).

Toxicity

No death or body weight loss of more than 20% was seen in the control or treated mice during the experiment. No inhibition on bone marrow cellularity was found in HT-29-bearing nude mice and CT-26-bearing mice at therapeutic doses of BAM. There was no significant difference in nucleated cell counts of marrow between the control and BAM group. In the CT-26-bearing mice, 5-FU and MMC caused significant decrease in bone marrow cellularity (Table 4). At therapeutic doses, no pathologic changes were found in the heart, lung, liver, spleen, kidney and brain of BAM-treated mice.

DISCUSSION

Colorectal carcinomas are generally not very sensitive to the established chemotherapeutic agents; only 5-FU and MMC have shown some activity against colon carcinomas; the effects achieved, however, are of only a little value with respect to patient survival[31-41]. In the present study, we investigated the antitumor effectiveness of BAM, a new antitumor antibiotic, against human colorectal adenocarcinoma heterotransplanted to nude mice and murine colon adenocarcinoma. On the other hand, BAM, an analog of BLM that is clinically characterized by marked antineoplastic activity against carcinoma of the head and neck[42,43], showed a pronounced antitumor effect against the colorectal carcinoma used in the present study. At a 1/9 LD50 equitoxic dose, BAM exerted much stronger growth inhibition against human colon cancer HT-29 xenograft in nude mice than MMC and 5-FU. However, the tumor that remained after treatment consisted of viable cells with no degenerative changes, which were the source of early recurrence[44]. These results indicated that the effect of cancer chemotherapy should be judged not only by tumor reduction rate but also by histological changes, such as the necrotic ratio of tumors. In the present study, more extensive necrosis and fewer mitosis figures were found in tumors treated with BAM than those with MMC and 5-FU, indicating that BAM was more active against colon cancer HT-29 xenografts among three agents.

Most patients with colorectal carcinoma will die from distant metastases that are not detectable at the initiation of treatment[45,46]. Two major factors that influence the outcome of systemic therapy of cancer are heterogeneity of malignant neoplasms and *in vivo* conditions. Organ environment effects on the response of tumor to systemic chemotherapy are multifactorial, including the nutritional status of cells, the presence of organ-specific growth factors and other single-transducing agents, the degree of oxygenation, pH, extent of the vascular network and its functionality, local immunity, extracellular matrix components and drug metabolism[22-24]. The current model of orthotopic implantation of a colon carcinoma provides a unique opportunity to study a human malignancy in a context that is as close as possible to the clinical condition. Since intracecal tumors were much closer to clinical tumors than *s.c* tumors from the view of the histology of tumor growth or metastasis, this system was applicable to the evaluation of the tumor growth inhibitory effect by BAM. The present study demonstrated that murine adenocarcinoma CT-26 can successfully, using the orthotopic implantation technique, produce an aggressive tumor which retained the morphological biological characteristics of the donor tumor and metastasized to the mesenteric glands. BAM inhibited tumor growth on CT-26 implanted into the cecum and *s.c* more than 5-FU and MMC at the equitoxic dose. Moreover, the inhibitory effect of BAM on the growth of CT-26 tumor was higher at the cecum than at the *s.c* site in mice, which implicates that BAM may have the organ-specific effect. Organ-specific differences in the chemosensitivity of tumor cells have been reported by a few authors. Staroselsky et al have reported that a murine fibrosarcoma growing s.c in syngeneic mice is more sensitive to DXR than the same tumor growing as lung metastases[24]. Pratesi *et al* investigated the antitumor efficacy of flavone acetic acid against human ovarian carcinoma cells xenografted into different organ sites in nude mice, while tumors in the liver and subcutis were sensitive to the flavone, and ascites and lung tumors were resistant[22].

Since current clinical chemotherapy of colorectal cancer generally gives poor results, the finding of the present study is of interest with respect to the growth inhibiting activity of BAM against human colon carcinoma xenograft and murine colon carcinoma. However, further and extensive studies are necessary to confirm this finding and to evaluate the actual antineoplastic effectiveness of BAM against colon carcinomas.

INTRODUCTION

Although reliable assays for the detection of hepatitis C virus and E virus became available, still 10%-20% hepatitis are not caused by hepatitisA-E virus[1-3]. In 1996, two research groups isolated this agent independently and almost simultaneously and named hepatitis G virus and GB virus C, respectively[4-7]. The nucleotide and amino acid homologies between GBV-C and hepatitis G virus (HGV) were 85% and 95%[5-7]. Therefore, GBV-C and HGV were considered as two different isolates of the same virus, referred to as HGV in this paper. HGV is a single-strand, positive sense RNA virus with approximately 9.4kb in length, and classified as a member of *Flaviviridae*. HGV is mainly transmitted through transfusion and could be responsible for chronic liver infection. HGV RNA has been detected in the serum of intravenous drug users (IVDUs), volunteer and commercial blood donors, and patients with cryptogenic hepatitis[8-10]. Until now, RT-PCR is the most commonly used method for the diagnosis of HGV infection. It is necessary to develop a more convenient antibody detection assay. The baculovirus expression system is of a strong polyhedrin promoter[11], and can carry out many types of postranslation modification for a variety of proteins. Most of the expressed proteins were usually shown to be antigenic, immunological, and functionally similar to their authentic counterparts[12-16]. In this study, we used the baculovirus expression system to express HGV NS5 protein in Sf9 cells, and studied its immunogenecity.

MATERIALS AND METHODS

Materials

HGV positive sera were collected from HGV RNA positive hemodialyzed patients. The plasmid pFastBac HTa, *E.coli* DH10 Bac cell, *Spodoptera frugiperda* (Sf9) cell and recombinant plasmid HGV Iwh6 were prepared previously in this laboratory[17]. The pPROEX HTa, Lipofectin and Grace's medium were purchased from GIBCO/BRL; and expand™ Long Template PCR System was purchased from Boehringer Mannherm Company. PCR primers were designed according to HGV-Iwh6 and synthesized by Sangon Biotechnology Company. Two restriction enzyme sites *Bam* H I and *Kpn* Iwere added to the 5' end of sense and antisense primers separately. The primer sequences are sense: 5'-GCG GAT CCC TAT CGG CTG CTG TAG CTA AG-3'; antisense: 5'-GCG GTA CCT TAT TGA GCG GCC CTC TTA GC-3'.

Amplification and sequence analysis of HGV NS5 fragment

HGV NS5 fragment was amplified using HGV-Iwh6 clone as the template (PCR condition: predenature 94℃ 2 min, followed by 94℃ 30 s, 60℃ 1 min, 68℃ 2 min, 35 cycles, and extension 10 min before the ending of the reaction). The amplified fragments and pPROEX HTa were digested with *Bam* H I and *Kpn* I. Fragment and vector were recovered respectively and ligated by T4 DNA ligase to obtain recombinant plasmid pHTNS5. Sequence analysis was carried out using ABI PRISM 377 DNA sequencer (PE Company) with M13/pUC primer.

Cloning into transposing vector pFastBac HTa

pHTNS5 and transposing vector pFastBac HTa were digested with *Bam* H I and *Kpn* I, and were ligated by T4 DNA ligase. The ligation mixture was transformed into DH5α competent cell, the positive colonies were chosen on selecting agar plate (ampicillin 100 μg/mL) and identified with endonuclease digestion to obtain the recombinant plasmid pFHTNS5.

Transposon between pFHTNS5 and bacmid

Plasmid pFHTNS5 was transformed into DH10Bac competent cells containing bacmid with a mini-att Tn7 site and helper plasmid. Following hot-shock at 42℃ for 45 s, the transformation mixture was placed in a shaking incubator at 37℃ for 4 h. Recombinant

bacmid was selected on selecting plate agar containing kanamycin 50 μg/mL, gentamicin 7 μg/mL, tetracyline 10 μg/mL, X-gal 200 μg/mL, and IPTG 40 μg/mL after 24 h-48 h incubation at 37℃.

Transfection of Sf9 cells

Recombinant bacmid was extracted according to the procedure of Bac-to-Bac system. For transfection, Sf9 insect cells were grown to 60%-70% confluence. The recombinant bacmid DNA 2 μg was transfected into insect cells Sf9 with Lipofectin. After 5 d-6 d incubation at 27℃ until the morphology of the cells had obvious changes, Sf9 cells and viral supernatant were harvested respectively.

Expression of recombinant protein in insect cells and SDS-PAGE, Western-blot analysis

Twenty μL viral supernatant harvested from the transfected cells was used to infect fresh insect cells. After 5 d-6 d incubation at 27℃, the cells were harvested for protein expression analysis. The cells were washed twice with PBS and analyzed by SDS-PAGE according to the standard procedure. Western-blot was performed using HGV RNA positive sera (1:40 dilution).

RESULTS

Amplification of HGV NS5 fragment and sequence analysis

PCR product was analyzed by agrose gel electrophoresis and the length was the same as expected (Figure 1). Sequence analysis showed that the HGV NS5 fragment was cloned into the vector with correct orientation (data not shown).

Construction of recombinant transposing plasmid pFHTNS5

Figure 2 shows the construction of recombinant transposing plasmid pFHTNS5. Figure 1 shows the analysis of recombinant plasmid on agarose gel by restriction endonuclease digestion which verified that target fragment was correctly cloned into the transposing vector. The results demonstrated a successful construction of recombinant transposing plasmid pFHTNS5.

Figure 1 Analysis of recombinant plasmid by restriction endonuclease digestion.
1. λDNA / *Eco* R I + *Hind* III; 2. PCR product; 3. pHTNS5 / *Bam* H I + Kpn I; 4. pFHTNS5 / *Bam* HI + *Kpn* I.

Screening of recombinant bacmid

After transforming competent cell DH10Bac with transposing plasmid pFHTNS, the recombinant bacmid was screened by colour selection. White clones (*lacZ*$^-$) were selected as positive recombinant bacmid in a background of blue colonies (*lacZ*$^+$). The recombinant bacmid was extracted according to the procedures described in the manual of Bac-to-Bac system.

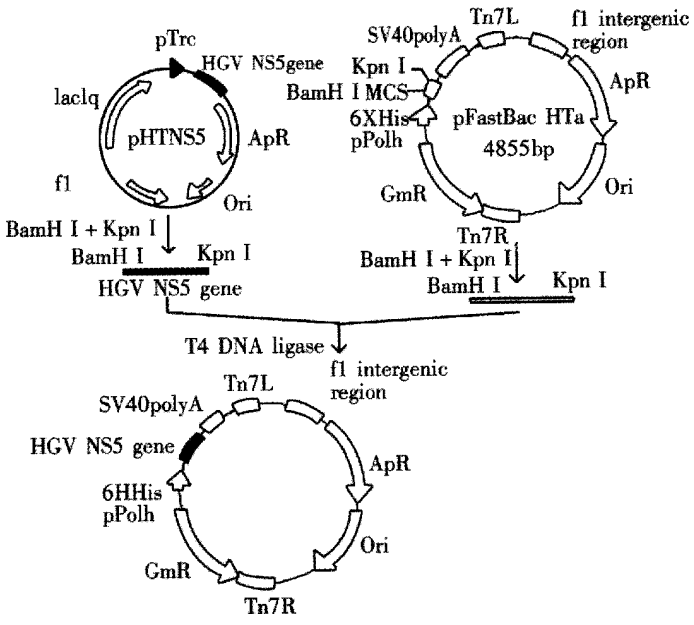

Figure 2 Construction of recombinant plasmid pFHTNS5.

Morphology of transfected or infected Sf9 cells

The morphology of Sf9 cells changed gradually after transfection or infection. The cells became big and round obviously at 4 d-5 d after transfection or infection. Cytopathic effects (CPE) were seen whereas no pathological effects were observed in normal cells (Figure 3).

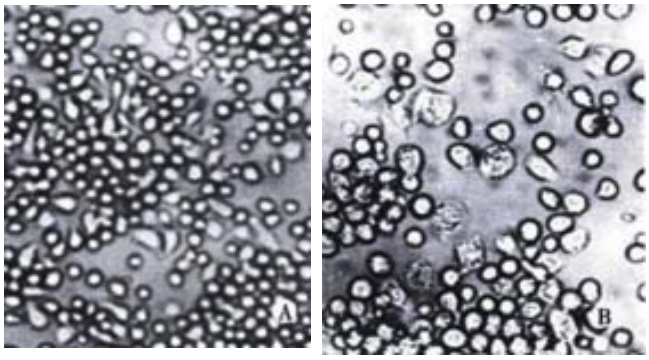

Figure 3 Morphology of uninfected, transfected and infected Sf9 cells (100×). A: Uninfected cells; B: Transfected and infected cells

SDS-PAGE and Western blot analysis of the recombinant protein

Transfected or infected Sf9 cells were harvested and analyzed on 12.5% polyacrylamide gels. Figure 4 shows the result of expressed target HGV NS5 protein with a molecular weight of M_r 41 500. Scanning results indicated that the recombinant protein amounted to 11.7% of the total proteins. Western blot results implied that the recombinant protein could react with HGV RNA positive sera (Figure 5).

DISCUSSION

Although easy and reliable assays for the clinical diagnosis of HBV and HCV infection have been established[18-26], there still existed 10%-20% parenterally and community acquired hepatitis cases of unknown cause[4,5,7]. Transmission and molecular biology of these viruses have been studied thoroughly [27-34]. Clinical studies suggest that some of these may be of viral origin. HGV is a potential aetiological agent for viral hepatitis. As a member of Flaviviridae, HGV is a single-stranded RNA virus with a genome of 9 400 bp in length which includes 5' non-coding region, structural gene region C, E1, E2, non-structural gene region NS2, NS3, NS4, NS5a, NS5b and 3' non-coding region. The genome contains a single open reading frame (ORF) which encodes a 2 900 amino acid polyprotein precursor. Many researches have been carried out since the discovery of HGV,the studies of its antigencity is one of them [17,35-39]. HGV NS5B protein functions as RNA-dependent RNA polymerase]. In addition, Pilot-Matias *et al*[40] also found that C26,C27,C28 (2047-2376 aa) of HGV NS5 gene had potential antigen epitopes. Wang *et al*[41] reported that two linear epitopes (P22, P6) might exist in HGV NS5 gene. The obtained HGV NS5 recombinant protein will provide important materials for studying its structure and function.

The Bac-to-Bac system was established by Luckow[11] in 1993, and a variety of proteins have been expressed with the control of a strong polyhedin promoter since then. It is based on site-specific transposition (transposon Tn7) of an

expression cassette into baculovirus shuttle vector (bacmid) propagated in *Escherichia coli*. After selection of blue-white clonies, recombinant bacmid DNA was extracted for the transfection of Sf9 cells. Insect cells can identify and run many modifications of post-translation and make the expressed protein close to natural protein.

In this study, HGV NS5 gene fragment amplified by PCR was confirmed by restriction enzyme and sequence analysis, and cloned into baculovirus transposing vector pFastBacHTa. Recombinant bacmid was obtained with site-specific transposition, Sf9 cell was transfected with recombinant bacmid or infected with viral supernatant. On the polyacrylamine gel, an expected protein band was seen at M_r 41 500. Western blot found that HGV NS5 recombinant protein could react strongly with HGV RNA positive sera, which implied that recombinant HGV NS5 protein could be used as antigen to detect HGV infection.

INTRODUCTION

Hepatitis B virus (HBV) is the most common etiologic agent for infectious liver diseases. It is estimated that there are more than 250 million chronic HBV carriers in the world today and there is a significant association among persistent infection, liver cirrhosis and hepatocellular carcinoma[1-3]. The control of HBV infections is thought to be mediated by both humoral and cellular immune responses involving neutralizing antibodies as well as class I and class II major histocompatibility complex (MHC)-restricted T- cells[4,5]. Among the HBV antigens, a number of studies have highlighted the importance of the human immune response against the HBcAg and HBeAg during HBV infections. During acute HBV infection, cytotoxicity T lymphocyte (CTL) specific for HBcAg and HBeAg can be detected in the circulation of the infected host. In contrast, in chronic HBV infection, HBcAg and HBeAg-specific CTL and T-helper cell activity are not readily detected. The cumulated data suggest that CTL activity may play an important role in resolving HBV infection[6-11].

DNA mediated immunization has been shown to be an novel method to induce both humoral and cell-mediated immune responses against many different antigens including HBV antigens[12,13]. We have demonstrated that the DNA vaccine based on HBV core gene has strong humoral and cellular immunogenecity in different species of mice[14,15]. In our experiments, we have further investigated the immunogenecity of this DNA vaccine in rhesus monkeys. The results show that the DNA vaccine of HBV core gene can prime obvious antigen-specific antibody and cell mediated immune responses.

MATERIALS AND METHODS

Preparation of DNA vaccine of HBV core gene

The control plasmid (pJW4303) and DNA vaccine of HBV core gene (pJW4303/HBc) were propagated by a large amount of culture of the transformed *E.coli* strain of HB101. Plasmid DNA was purified with QIAGEN Plasmid Mega Kit (QIAGEN, Germany).

Rhesus monkeys

Four rhesus monkeys (2 male, 2 female, 3 years of age) were purchased from Special Animal Breeding and Raising Center, Xingye, Henan Province, China and maintained at the animal house in Beijing Medical University. The monkeys were divided into experimental group and control group (2 monkeys in each group).

Protocols of DNA immunization

The monkeys in the experimental group were immunized with plasmid pJW4303/HBc and that in the control group were immunized with plasmid pJW4303. The plasmids were dissolved in normal saline to a final concentration of 1 g/L. Each time one monkey received 4-site intramuscular injections with a total volume of 2 mL plasmid solution containing 2 mg plasmid DNA. Three boosts with same dose were given at an interval of 2 months. The monkeys' sera before and after immunizations were collected and stored at -30℃.

Detection of anti-HBc antibody

Anti-HBc antibodies in monkeys' sera were first detected by Abbott Imx System (Abbott, USA) according to the manufacturer's instructions and end-point titers of anti-HBc antibody were then detected by an enzyme linked immunosorbent assay (ELISA). The procedures were as follows: ① The 96-well microplates were coated with recombinant HBcAg (1 mg/L) and blocked with PBS containing

10% FCS. ② Three-fold dilutions of monkeys' sera (1: 50, 1:150, 1:450 …… 1:984150) were added to triplicate wells. ③ HRP labeled rabbit anti-human IgG (Sino-American Biotechnology Co.) at the dilution of 1:3000 was used as second antibody. ④ The substrate solution (TMB) was then added to each well and reaction was stopped by 2M H_2SO_4. ⑤ The absorbence value was measured at wavelength of 450 nm by an ELISA reader. Microplate washings were performed between each step with PBST solution. The end-point of anti-HBc titer was defined as the highest serum dilution that resulted in an absorbence value two times that of non-immune or control serum.

Detection of IgG subclasses of anti-HBc

Subclasses of anti-HBc antibodies were detected in the sera of the monkeys positive for anti-HBc. The procedures were similar to the ELISA method mentioned above for detecting anti-HBc, except that serum was diluted to 1:30. 1:500 diluted sheep anti-human IgG1, IgG2, IgG3 and IgG4 (Nordic Immunological Laboratories, Tilburg, the Netherlands) were used as the second antibody, and 1:5000 diluted HRP labeled rabbit anti-sheep IgG (Jackson Immuno-Research Laboratories Inc, PA, USA) was used as the third antibody.

Detection of IFN-γ and IL-4 in PBMC culture supernatant

The procedures were as follows: ① PBMCs were separated from heparinized monkey blood by Ficoll gradient sedimentation method. ② PBMCs were resuspended with RPMI-1640 containing 10% FCS to a final concentration of 2×10^6 cells/ mL. ③ PBMC suspension 250 μL (5×10^5 cells) was added to triplicate wells in a 24-well cell culture plate, and recombinant human IL-2 (500U/well) was added as well. ④ Except for control wells, PBMCs in each triplicate wells were restimulated with recombinant HBcAg at different doses of 5 μg/well, 10 μg/well and 12.5 μg/well. ⑤ After 48 h incubation under the condition of 37℃, 5% CO_2, the supernatant was collected from each well and stored at once at -70℃. ⑥ IFN-γ and IL-4 concentrations were detected by the ELISA kits (Jinmei Biotechnology Co., Shenzheng, China).

PBMC proliferation assay

The procedures were similar to that for detecting IFN-γ and IL-4 in PBMC culture supernatant, except that ① PBMCs were incubated for 72 h; ② 0.5 μCi ^{3}H-TdR was added to each well and followed by another 4h incubation; PBMCs were then collected onto filter membrane which were then backed 2 h at 80℃; and the radioactivity (CPM) was determined by a beta-scintillation counter (Beckman). The PBMC proliferation activity was expressed by Stimulation Index (SI), which was calculated according to the following formula: (SI = CPM of HBcAg stimulated well/CPM of non HBcAg stimulated well). SI value greater than 2 was generally considered as having antigen specific PBMC proliferation.

RESULTS

Anti-HBc IgG and its end-point titer in monkey's sera

The results of anti-HBc IgG and its end-point titer in monkey's sera are shown in Table 1.

Table 1 Anti-HBc in sera of experimental and control monkeys

Monkey No.	Group	Anti-HBc antibody					End-point
		0 month	2 month	4 month	6 month	8 month	
1	Experimental	N[a]	P[b]	N/D[c]	N/D	N/D	1:36450
2	Experimental	N	N	P	P	P	1:109350
3	Control	N	N	N	N	N	1:150
4	Control	N	N	N	N	N	1:150

[a] N: negative

[b] P: positive (in Abbott Imx System, the detected value less than 1. 00 was considered positive for anti-HBc).

[c] not detected because of death.

Subclasses of anti-HBc IgG in sera of experimental group of rhesus monkeys

Subclasses of anti-HBc IgG (IgG1, IgG2, IgG3 and IgG4) were detected in the experimental monkeys (No.1 and No.2), which were found to be positive for anti-HBc in the previous tests. The results are shown in Table 2.

Table 2 Subclasses of anti-HBc IgG and IgG1/IgG2 ratio in rhesus monkeys' sera

Monkey No.	IgG1	IgG2	IgG3	IgG4	IgG1/IgG2
1	0.61 + 0.01[a]	1.02 + 0.08	0.32 + 0.02	0.12 + 0.01	0.60
2	0.61 + 0.04	1.05 + 0.04	0.40 + 0.01	0.18 + 0.03	0.58

[a] The values indicated $\bar{x} \pm s$ of triplicate wells.

IFN-γ and IL-4 levels in culture supernatant of PBMCs stimulated with recombinant HBcAg

IFN-γ and IL-4 levels were detected in monkey No.2 (experimental group) and monkey No.3 (control group). Monkey No.1 and No.4 died before this test was performed. The results are shown in Table 3.

Table 3 IFN-γ and IL-4 values in culture supernatant of PBMCs

Monkey No.	Group	IFN-γ (ng/L)	IL-4 (ng/L)
2	Experimental	15.63	6.25
3	Control	<3.13	6.25

HBcAg specific PBMCs proliferation activity in experimental and control groups of rhesus monkeys

HBcAg specific PBMCs proliferation activities were measured in monkey No.2 and No.3 by the time of 12 months after first immunization. The results are listed in Table 4.

Table 4 HBcAg specific PBMC proliferation activity*

Monkey No.	Group	HBcAg dose for stimulation (μg/well)			
		0	5	10	12.5
2	Experimental	354.4 ± 64.5	984.9 ± 105.4[a] (2.74)	1364.9 ± 47.9[a] (3.83)	890 ± 155.6[a] (2.12)
3	Control	198.4 ± 3.9	274.5 ± 33.2 (1.37)	261.5 ± 28.2 (1.32)	250 ± 70.0 (1.24)

*The values in the table refer to CPM ($x \pm s$ from each triplicate well), the values in the brackets indicate stimulation index (SI). [a]$P<0.05$ *vs* control monkey.

DISCUSSION

DNA-mediated immunization refers to the induction of an immune response to antigen expressed *in vivo* subsequent to the introduction of DNA carrying the protein coding sequences and the regulatory elements needed to express them[16,17]. An important feature of DNA-based immunization is the *in situ* production of the expressed protein (s), mimicking a viral infection. The endogenous synthesis should allow presentation of antigens by class I molecules of MHC, resulting in the induction of CD8 + cytotoxic T lymphocytes (CTL)[18]. There have been several experimented reports in which recombinant plasmid DNA was used to induce immune responses to particular pathogens, including malaria[19], herpes simplex virus (HSV)[20], influenza A[21], rabies virus[22], simian immunodeficiency virus (SIV)[23], human immunodeficiency virus type I (HIV)[24] and hepatitis B virus (HBV)[25-32].

In our earlier work, the HBV core gene fragment, which was modified to assure the high level expression of HBcAg[33], was successfully cloned into the plasmid pJW4303, the vector containing CMV immediate early promotor. This recombinant plasmid was named pJW4303/HBc. The DNA immunization using pJW4303/HBc among Balb/c (H_2d) and C57BL/6 (H_2b) mice showed that this recombinant could induce strong humoral (antibody) and cellular (CTL) immune responses[34].

When evaluating the immunogenecity and safety of potential DNA vaccine for eventual use in humans, the nonhuman primate models should be considered. The best nonhuman primate candidate would be those closest to humans on a phylogenetic basis. However, cost and other considerations may preclude studies in hominoid species, such as chimpanzee, orang utans, gorillas, and gibbons. Based on the cost and availability, nonhominoid primate species including rhesus monkeys, represent the alternative candidate nonhuman primate species for pre-clinical immunogenecity studies[35,36].

Townsend *et al*[37] observed the specific immune responses in mouse and rhesus monkeys after genetic immunization with retrovirus vectors expressing different forms of the hepatitis B virus core and e antigens. Their results showed that intramuscular injections with 10^8 CFU of the the LHBc-Neo retrovirus vector into rhesus monkeys induced HBc/eAg-specific antibody production and CD8 + CTLs. The CTL response is long-lasting, and being detectable as late as 16 weeks after immunization.

We used the plasmid as the vector to carry HBV core gene for DNA immunization in rhesus monkeys, which was different from the observation above the reason for that is that the safety of the vector for retrovirus vector was integratable to the host genome.

In our experiments, all 4 monkeys were negative for anti-HBc before DNA immunization. After intramuscular immunization of pJW4303/HBc and pJW4303, the monkeys in the experimental group all developed anti-HBc antibody while the monkeys in the control group all negative for this antibody, indicating that this DNA vaccine could induce antigen specific humoral response in rhesus monkeys. We also found that the monkeys in the experimental group could show different antibody response profiles. Monkey No.1 became positive for anti-HBc (1:36450) after the first immunization while monkey No.2 was not negative for anti-HBc until the second immunization and the antibody titer became higher (1: 103 950) as late as the total four immunizations were accomplished. This different antibody production profiles might indicate the individual difference in response to DNA immunization.

In human and other hominoid primates, the serum IgG exhibited four subclasses, i.e., IgG1, IgG2, IgG3 and IgG4. The relative concentrations of these IgG subclasses were 60%-70% for IgG1, 15%-20% for IgG2, 5%-10% for IgG3, and 1%-7% for IgG4. When looked into the antigen specific IgG antibodies the concentration of IgG1 and IgG2 and its ratio IgG1/IgG2 could reflect the response profiles of helper T cells (T-H1 type or T-H2 type) to some extent. Generally speaking, IgG1/IgG2<1 or IgG1/IgG2>1 reflected T-H1 type or T-H2 type immune responses. The previous data showed that T-H1 type response was beneficial for the clearance or eradication of chronic infected viruses while the T-H2 type- response was usually correlated to the exacerbation of immunopathogenic damage of host tissues[38]. Feltquate *et al* had found that intramuscular immunization of DNA vaccines was prone to induce T-H1 type of immune response, thereby facilitating the recovery of the host from chronic viral infection[39]. Our results also

demonstrated that two monkeys intramuscularly immunized with HBV core DNA vaccine all exhibited T-H1 type of immune response based on the fact that their IgG1/IgG2 ratios were all less than 1 (0.60 and 0.58, respectively).

The profiles of cytokine production were another indicators of helper T cell responses[40-44]. IFN-γ, IL-2, TNF-α and GM-CSF were usually considered as T-H1 type cytokines, while IL-4, IL-5 and IL-10 were T-H2 type cytokines. IFN-γ and IL-4 were chosen in this experiment to observe helper T cell responses after DNA immunization of HBV core gene in rhesus monkeys. IFN-γ level was significantly higher in the culture supernatant of PBMC from the monkeys immunized with HBV core DNA vaccine than that from monkeys injected only with control plasmid (15.63 ng/L *vs* <3.13 ng/L). At the same time, IL-4 levels in both monkeys with injections of pJW4303/HBc or PJW4303 were similar (6.25 ng/L *vs* 6.25 ng/L). The results indicated IFN-γ prominent cytokine profile in the monkey immunized with HBV core DNA vaccine. This result combined with the result of IgG1/IgG2 ratios mentioned above further confirmed the T-H1 type immune responses in the monkeys of the experimental group.

Cell-mediated immune response is critical for the termination of chronic HBV infections[45-47]. Antigen specific lymphocyte proliferation assay is an alternative for the CTL assay to evaluate the cell-mediated immune response[48]. In this experiment, the HBcAg specific PBMC proliferation activity was seen in the monkey immunized with pJW4303/HBc but not in the monkey injected with pJW4303 ($P<0.05$). After stimulation with three different doses of HBcAg, the stimulation index (SI) was all >2 in the experimental monkeys but all <2 in the control monkeys, which strongly indicated that DNA vaccine of pJW4303/HBc could induce antigen-specific cell-mediated immune response in rhesus monkeys.

Sallberg *et al* reported that DNA immunization of HBV core gene using retrovirus as vector could markedly decrease the HBV DNA level in the sera of experimental chimpanzees, and even induce the seroconversion of HBeAg to anti-HBe[49]. Our results showed that using plasmid as vector the DNA vaccine could also stimulate the immune responses in nonhuman primate rhesus monkeys, which was obviously helpful and beneficial for the host to inhibit and eventually eradicate chronically infected virus, including hepatitis B virus. As the designer vaccines for the 21st century, DNA vaccines demonstrated its feasibility of inducing specific cellular immunity in humans[50]. We believed that DNA vaccine of HBV core gene may become a potential therapeutics for the treatment of chronic HBV infection in humans in the near future.

INTRODUCTION

Hepatitis B viral infection, one of the most-prevalent liver disorders in China and Korea, is a serious infectious disease as it has the potential of progressing into liver cirrhosis and primary hepatic carcinoma. China and Korea both belong to high-risk endemic regions of viral hepatitis[1]. The HBsAg positive rates in China ranged from 6.9%-17.9% by age, race and test methods[2-5]. In Korea, they were 6.5%-13.3% in all age groups[6-9], and 3.9%-5.9% in childhood groups[10-11]. There have been few comparative studies on Korean-Chinese and other Chinese. Considering the high mortality rates of liver cirrhosis or hepatoma among Korean-Chinese, HBsAg positive rate of Korean-Chinese must be higher than that of other Chinese. The positive rates of Korean-Chinese in Yanji and Longjing cities of Yanbian area by RPHA method were 7.5% and 7.1% respectively, which were higher than 6.2% and 4.7% in Han-Chinese respectively[12].

In regard to the possible reasons of such differences, some studies have laid special emphasis on social, economic and demographic variables such as age, sex, life style, and environment.

This study was conducted in order to assess the pattern of hepatitis B infection prevailing among Han-Chinese, Korean-Chinese, and Koreans. For collection of data, two serological surveys were carried out in 1996 in Korea and China respectively.

MATERIALS AND METHODS

Study areas

Study areas were Yangpyung County of Kyonggi Province in Korea and Helong County of Yanbian, a Korean Autonomous Prefecture in China. In Helong County, the proportion of residents by ethnicity were 55% for Korean-Chinese and 44% for Han-Chinese[13]. To compare the prevalence of hepatitis B between Korea and China, we carefully considered the characteristics of selected areas. In both areas, 70% of the residents were farmers. But the pattern of age distribution was different; the majority residing in Yangpyung County in Korea were more than 50 years old, while those in Helong County in China were over 40 years old.

Study subjects

Study subjects among ethnic groups were 556 Korean (male 41.7%, female 58.3%, $P<0.05$), 541 Korean-Chinese (male 51.6%, female 48.4%) and 261 Han-Chinese (male 39.5%, female 60.5%, $P<0.05$). These distributions by gender were statistically significant in Korean and Han-Chinese. Age distributions by ethnic groups were also significantly different; and the Koreans had older age and the Chinese had younger age. Age distributions by gender were not different between Korean and Korean-Chinese, but they were significantly different in Han-Chinese (Table 1). Therefore, this study showed the results with age-adjusted rates by gender.

Table 1 Characteristics of subject by ethnic groups[d]

Ethnic groups	Age (years)	Gender		Total
		Male	Female	
Korean-Chinese[b,c]	20-39	103	117	220
	40-49	89	77	166
	50-	87	68	155
Total		279	262	541
Han-Chinese[a,b,c]	20-39	42	103	145
	40-49	30	44	74

Questionnaires

The questionnaire survey gave direct interviews, including the relative factors on hepatitis B infection such as demographic characteristics, life style, vaccination and disease history.

Serologic tests

Serological markers on hepatitis B virus (HBsAg, anti-HBs and anti-HBc) were tested by EIA (enzyme immunoassays). Sera were stored in a deep freezer, at -30℃ until this test. The serologic tests were all done in Korea.

Statistical analysis

For comparison by ethnic groups, age-adjusted rates by direct method were used. The statistical significance was determined using χ^2 test or Mantel-Haenszel's χ^2-test on SPSS or EPISTAT.

RESULTS

There were no vaccinees on hepatitis B among Chinese, but the vaccination rate among Koreans was 32.4% (36.5% for males and 29.0% for females). The vaccination rate was 44.2% for the age group of 20-39 years, 45.4% for the age group of 40-49 years, and 24. 4% among those aged 50 and over (Table 2). In order to compare hepatitis B virus markers among ethnic groups, the vaccinees were excluded.

HBsAg positive rate of males was higher than that of females in the three ethnic groups. Age-adjusted HBsAg positive rates were 7.2%, 12.0% and 4.1% in Han-Chinese, Korean-Chinese, and Korean respectively (P<0.05). This order was same in both genders. But, the difference was statistically significant only in males (P<0.05). Anti-HBs positive rates of males were higher than those of females in Korean-Chinese and Korean, but the differences were not statistically significant. There was also no difference by gender in the Han-Chinese. The age-adjusted anti-HBs positive rate of Korean (62.5%) was the highest, of Korean-Chinese was 57.6%, and of Han-Chinese 49.2%. This order was true in males and females, but the differences among the three ethnic groups were not significant. Anti-HBc positive rates of males were higher than those of females in all three groups, but these differences were not significant. Age-adjusted anti-HBc positive rate was 69.7%, the highest in Korean-Chinese, 60.9% in Korean and 54.0% in Han-Chinese. This order was also found by gender, and these differences were all statistically significant (P<0.05).

The definition of hepatitis B infection was determined as cases that have any hepatitis B virus markers among HBsAg, anti-HBs and anti-HBc. The infection rate was higher in males than in females among the three ethnic groups. But the difference was significant only in Koreans (P<0.05). Age-adjusted infection rates were 78.6% in Korean, 77.0% in Korean-Chinese and 60.7% in Han-Chinese. These differences among the three ethnic groups were significant (P<0.05) in males, females and the total.

In Koreans, the HBsAg positive rate was lower than that of Korean-Chinese, but the HBV infection rate was not different from Korean-Chinese, and was higher than that of the Han-Chinese. In Korean-Chinese, the HBsAg positive rate and HBV infection rate were higher than those of the Han-Chinese. In the Han-Chinese, the HBV infection rate was the lowest and the percentage of those who are susceptible was the highest (Table 3).

We classified the serologic profiles into 8 types by 3 HBV markers, which are HBsAg, anti-HBc and anti-HBs. Mushahwar *et al* (1981)[21] used 15 classifications by 5 HBV markers including HBeAg and anti-HBe, to determine the HBV infectivity. We used 8 types for the description of HBV serologic profiles in the cross-sectional study. Type I of our classification means those susceptible who have all three negative markers. These percentages of those susceptibles were higher in females than in males in all three ethnic groups. The percentage was 18.6% for Koreans or Korean-Chinese, and 36.7% for Han-Chinese. In females, the percentage was 40.5% for Han-Chinese, 29.6% for Korean, and 23.7% for Korean-Chinese. Among HBsAg positive serologic profiles, type VII was dominant. But, varied types such as V, VI and VIII were found only in Korean-Chinese and Han-Chinese excluding Koreans. Koreans had only one type VII, among HBsAg positive profiles. The percentage of HBsAg negative combination (HBsAg- and anti-HBs+ and/or anti-HBc+), were 78.5% and 65.5% for Korean, 67.5% and 67.6% for Korean-Chinese and 53.1% and 52.1% for Han-Chinese. Among these profiles, type IV was dominant in all three ethnic groups (Table 4).

DISCUSSION

Since 1980, China has produced hepatitis B vaccines and by regulations, children must be vaccinated. However, vaccination against HBV was not mandatory in adults. Therefore, none of study subjects in China were vaccinated, while in Korea, 32.4% were vaccinated. It implies that the circumstances of HBV infection and transmission were different between China and Korea. Age-adjusted HBsAg positive rate of Korean-Chinese was 12.0%, higher than the 10% previously reported in China as a whole[14]. Moreover, the rate was higher than the 8.0% for the Korean-Chinese in Yanbian area during the 1980s[12]. The rate for Han-Chinese (7.2%) was less than the national level (10%) in China, and the same or less than that of other reports[2-5]. However, no other reports were found from Yanbian area, the differences did not reflect the chronological change. In Koreans, the rate for non-vaccinees was 4.1%, which was less than other reports (6.5%-13.3%)[6-10,15,16].

Korean and Korean-Chinese are the same race, but HBsAg positive rates were different and increased with time for Korean-Chinese and decreased with time for Koreans. The difference between Korean and Korean-Chinese seems to be caused mostly by vaccination. Other factors such as socioeconomic status, sanitary status and medical support appear to influence HBV infection and transmission[6,7,11,17]. The difference between Korean-Chinese and Han-Chinese resulted from cultural difference such as life style, food habits and susceptibility[6,7,11,17]. The rate for Korean-Chinese was more similar to the Han-Chinese than to Koreans, which suggests that environmental factors are more important than genetic factors on HBV.

Positive anti-HBc is difficult to determine definitely. Type IV (anti-HBs+, anti-HBc+, and HBsAg-) and VIII (anti-HBs+ anti-HBc+, and HBsAg+) are in recovery phases caused by the positive anti-HBs. But type III (anti-HBs-, anti-HBc+, and HBsAg-) and VII (anti-HBs- anti-HBc+, and HBsAg+) mean acute or chronic infection. The order of high anti-HBc positive rates among the three ethnic groups was Korean-Chinese, Korean and Han-Chinese. This order was too

difficult to interpret like the anti-HBc.

Positive anti-HBs means having immunity against HBV. Age-adjusted anti-HBs positive rate for Chinese (57.6% for Korean-Chinese and 49.2% for Han-Chinese) was higher than that of other reports[2-5], however, in Korean (the 62.5%) it was higher[8,18] or lower than that of other reports[7,19]. Even though the difference among the three ethnic groups was not statistically significant, the reason why the anti-HBs positive rate for Korean (62.5%) was the highest, can be explained by the different serological profiles. Among the anti-HBs positive Koreans, 20.9% was type II (anti-HBs+, anti-HBc-, and HBsAg-), which indicates remote past infection, but, 10.3% and 9.5% among Korean-Chinese and Han-Chinese. Other types like IV (anti-HBs+, anti-HBc+, and HBsAg-), VI (anti-HBs+, anti-HBc-, and HBsAg+) and VIII (anti-HBs+, anti-HBc+, and HBsAg+) indicate the recovery phase of acute infection as a whole (IV, recovery phase of HBV infection; VI, unknown; and VIII, circulating immune complex of HBsAg or reinfection with different HBsAg subtype or process of seroconversion from HBsAg to anti-HBs). Therefore, positive anti-HBs Koreans had more remote infections than Korean-Chinese and Han-Chinese, which could be also applied to the exploration of HBV infection rates. HBV infection was determined by having had any one of the positive HBV markers among HBsAg, anti-HBs and anti-HBc. The order of high HBV infection rates among the three ethnic groups was the same as anti-HBs, Korean, Korean-Chinese and Han-Chinese. The difference was statistically significant ($P<0.05$).

HBV infection rates in Korean-Chinese were 81.4% in males and 76.3% in females, which were 80.8% in males of Hunan area and 75.5% in female of Guangxi of China[5]. The rates for Koreans were 81.4% in males and 70.4% in females. Therefore, even if the HBsAg rates have been decreasing as compared with that of the 1980s, HBV infection rate did not drop. According to Maynard *et al*[20]. 70%-90% of the population were infected with HBV in the highly endemic areas. Hence, Korea and Yanbian were included in the endemic area.

The fact that HBV infection rates for Korean-Chinese and Koreans were higher than those of the Han-Chinese seems to be caused by susceptibility and cultural factors such as life style and dining habits. Ahn *et al*[19] reported the association between HBV infection and behavioral characteristics such as life style, dining habit and sanitary status. Therefore, to determine the reason for the higher rate of HBV in Koreans and Korean-Chinese, more studies dealing with genetic factors and behavioral factors are needed.

In regard to positive HBsAg rate, the results showed difference by ethnic groups in the same area. Consequently, for each of the areas and the ethnic groups, the HBV infection and transmission must be differentiated[21]. For the clarification of the natural course on HBV, more detailed immigration studies and follow-up efforts should also be made.

INTRODUCTION

Hepatitis B virus (HBV) belongs to the group of hepatovirus, a major pathogen of human acute and chronic hepatitis B[1-4], which has a very close association with human hepatocellular carcinoma (HCC)[5-8]. For example, a statistical data from a hospital in Shanghai showed that 80% of HCC patients were positive for HBsAg (personal communication). The published data reported that people infected with HBV have a 200-fold greater risk of developing HCC than age-matched population not infected with HBV[9-11]. So HBV infection, including its consequences, is one of the key problems for the human health in the world. Since HBV only infects human beings and a few kinds of higher primates[12-14], the lack of culture cell and animal model impede the study of biological characteristics of HBV and human hepatitis B in the laboratory[15,16]. In 1985, the first transgenic mouse carrying HBV genes was generated[17], and thereafter the transgenic mouse system was applied in HBV studies[18-26].

HBV prevailing in the world has at least 4 subtypes[27-30], ayw, adr, ayr and adw, among which subtype adr is the most prevailing in China[31,32]. The complete genome of subtype adr has been cloned and analyzed from HBV infected population in China. It was identified that subtype adr was different from other 3 subtypes in DNA and protein sequence[33]. In order to produce the animal model for exploring adr subtype of HBV associated biomedical issues, we generated transgenic mice harboring complete genome from subtype adr of HBV by microinjection method, in which the HBsAg gene and HBeAg gene could be expressed, and the genomic DNA of HBV could be replicated and packed into complete virus particles. This model will be very useful for examination of many aspects of HBV and its associated biomedical issues *in vivo*.

MATERIALS AND METHODS

HBV genome of *adr* subtype was obtained from plasmid -padr-1-dimer. C57 mouse strain was bought from Animal Center of Shanghai Birth Control Research Institute. PCR primers for identification were designed by ourselves according to S region of HBV genome, primer 1: 5'CCCAACCTCCAATCACTCACC3', primer 2: 5'ACGAACCACTGAACAAATGGC3', synthesized by GIBCO BRL company (USA). The themostable DNA polymerase was bought from Sangon Co. (Canada), antigen-antibody ELISA kit of HBV was the product of Sino-American Bio-Engineering Co. (China). Primera gene Labeling System kit was bought from Promega Co. (USA). Antibodies for immunohistochemistry assay were products of Dako Co. (USA). Reagents for transmission electron microscopy were standard ones (China).

Preparation of HBV DNA and microinjection

padr-1-dimer has two copies of intact HBV (adr subtype) genome head to tail, cloned in BamHI site of plasmid pBR322 (Figure 1). Restriction enzymes *Sal* I and *Cla* I were used to digest *Padr*-1-dimer, followed by 7 $g \cdot L^{-1}$ agarose gel electrophoresis of the digested products, the 7.0 kb band was retrieved, purified and dissolved in TE buffer for microinjection. Microinjection and embryo manipulation were performed according to the methods described in References[34-36].

PCR and Southern-blotting of integrated transgenes

Genomic DNA from tail tissue of transgenic mice and normal mouse were prepared, and amplified with primers in S region according to the cycling program: 94℃, 30s; 60℃, 40s; 72℃, 45s; run 35

cycles in 50 μL reaction system. Fifteen μL of PCR products were loaded on 15 $g \cdot L^{-1}$ agarose gel in the presence of 0.5 μg ethidium bromide per mL. 380 bp band was visualized by UV fluorescence. Southern blot was performed on genomic DNA by agarose electrophoresis of 30 μg restricted DNA with *Bam* HI. Nylon filtrates were hybridized with the probe including HBV genome labeled with α-P^{32}-dATP for further characterization of the transgenic mice.

HBV gene expression in transgenic mice

HBV gene expression in serum Venous blood in eye sockets of mice was collected, serum was isolated by centrifugation, and then used for HBsAg and HBeAg ELISA or RIA.

HBV gene expression in tissues The distribution of HBsAg and HBcAg was assessed by the labeled-avidin-biotin detection procedure. Briefly paraffin-embedded sections were treated for 10 min at 37℃ with 30 $mL \cdot L^{-1}$ hydrogen peroxide and washed with PBS. Rabbit anti-HBsAg primary antiserum at 1:100 dilution, and goat anti-HBcAg primary antiserum at 1:200 dilution were applied over night at room temperature. After washing with PBS, a secondary antiserum consisting of biotin-conjugated goat anti-rabbit IgG and rabbit anti-goat IgG was applied at 1:200 dilution for 40 min at 37℃, and then washed with PBS. Then the preparation was treated with 1:100 dilution ABC complex stained with DAB, and finally counterstained with hematoxylin.

Assay of serum antibody of transgenic mice

Fifty μL of the serum from transgenic mouse was assayed for anti-HBsAg, anti-HBeAg and anti-HBcAg by ELISA according to the Kit protocol.

Pathological findings analysis

Serum ALT and AST Serum ALT and AST were tested with auto-biochemical analyzer.

Histopathological study The specimens of liver, kidney, heart, spleen from transgenic mice were fixed in formalin, paraffin embedded, sectioned and stained with HE.

Examination of HBV Dane's particles in liver tissue from transgenic mice under TEM Several immunohistochemically HBV-positive mouse liver specimens were fixed over night at 4 ℃ in 40 $mL \cdot L^{-1}$ paraformaldehyde and 1 $g \cdot L^{-1}$ glutaradehyde in PBS. They were then postfixed in 10 $g \cdot L^{-1}$ OsO_4 in cacodylate buffer for 1hr at room temperature, dehydrated in gradient ethanol, and embedded in epoxy resin. This sections were cut on an LKB Ultratome III, mounted on copper grids, stained in uranyl acetate and lead citrate, and examined with electron microscope.

RESULTS

Microinjection and embryo manipulation

Hundreds of molecules of target fragment were microinjected into male pronuclei of fertilized eggs. Of 355 fertilized eggs microinjected, 262 of manipulated eggs survived; the survival rate was 73.8%. Thirteen of female recipient mice were transplanted with microinjected eggs through one of the ovarioles, and 2 of the transplanted mice were pregnant; the pregnant rate was 15.4%. Six small mice were born and all of them survived; the survival rate was 100%.

Founder mice and the identification of HBV DNA integration in transgenic mice

PCR and Southern-blotting results indicated that 4 mice were positive. So four founders were obtained. The founder mice were named HB *adr* dimer-*x*. The positive rate was 66%. Then the founders were mated with the normal mice of the same line. 27 F_1 offspring of the founder mice were born. In 14 of them PCR showed positive genomic DNA PCR. The offspring of F_1 were 56 mice, 28 of them were positive, and the positive rate was 50%. The exogenous genes can be transmitted through the germ line (Figure 2).

HBV genes expression in transgenic mice

HBV gene expression in serum The HBsAg and HBeAg were detected in the serum with ELISA and RIA. And the expression level of HBsAg was higher than that of HBeAg, and the gene expression was different in different founders (Table 1). The concentration of HBsAg in the serum was about 3000 $IU \cdot L^{-1}$.

Table 1 The ELISA result of founder mice and normal mice (A450)

Antigen	Control		Transgenic mice			
	Negative	Positive	HB-2	HB-3	HB-4	HB-5
HBsAg	0.01	1.42	0.17	0.06	0.26	0.23
HBeAg	0.01	1.56	0.06	0.06	0.08	0.09

Distribution of HBsAg and HBcAg in transgenic mice Immunohistochemical study of liver and kidney tissues from transgenic mice indicated that the distribution of positive hepatocytes was uneven, HBsAg-positive particles were located mainly in cytoplasm of hepatocytes. HBsAg expression level was weaker in kidney than in liver; the products of immune reactions of HBcAg-positive were not very certain, and mainly emerged in a few nuclei of hepatocytes from the individuals that were invariably HBsAg-positive (Figure 3). No obvious product of immune reaction from HBsAg and HBcAg positive mice was found in spleen, skin, testis and other detected tissues.

Serum antibody in transgenic mice The ELISA test indicated that there was no significant positive result of HBV antibodies in HBV transgenic mouse serum.

Figure 4 Dane's particles under electron microscope.

HBV Dane's particles in liver in transgenic mice under TEM HBsAg particles (spherial and filamental) were found in the endoplasmic reticulum of some hepatocytes, a few of in renal tubule-epithalia, and the cytoplasm of a few Kupffer cells (Figure 4).

Histopathological findings in transgenic mice

Histopathologic observation in transgenic mice tissues Mice have been monitored histologically for over 1 year without evidence of pathological changes in any organ, especially the liver and kidney. The serum ALT and AST assays indicated that there was no significant difference between the transgenic mice and the normal ones.(P>0.05) (Table 2).

Table 2 Aminotransferase in the transgenic mice (n = 12, $x \pm s$)

Mice	ALT(nkat·L^{-1})	AST(nkat·L^{-1})
Normal	698.5 ± 471.8	3597.4 ± 7669.9
Transgenic	708.5 ± 491.8	4349.2 ± 7248.1

DISCUSSION

The HBV transgenic mice show replication of the HB virus in the hepatocytes, but have no evidence of cytopathology of the liver and other organs or tissues.

In theory, HBV genes microinjected are complete in structure, and can be expressed and replicated in their bodies[37,38], because we have purposefully prepared the fragment which contains two copies of intact HBV (*adr* subtype) genomes head-to-tail to make it sure that all of four open reading frames of HBV genome are complete in structure. Four of the founders all showed serum HBsAg-positive, but the expression level is different. We think this is due to the different integrated site of HBV DNA. In general, the exogenous gene will be integrated into multi-sites in transgenic mice. This is similar with the other reports[39,40].

Immunohistochemical assays of several tissues from transgenic mice revealed that HBV gene tissue-dependent expressions were tissue-dependent, and the genes were mainly expressed in the liver and kidney, but the expression level was different; this is similar to HBV-infection in nature. Examination of liver and kidney tissue from transgenic mice under transmission electron microscope revealed the existence of Dane's particles and HBsAg particles in hepatocytes, which confirmed the ability of HBV genome replication in the transgenic mice.

Serum anti-HBs, anti-HBc and anti-HBe detected by ELISA were negative in all of the transgenic mice, and suggested that these mice were tolerant to HBsAg, HBcAg and HBeAg; this result was consistent with that of other author's reports[41]. Now, we obtain the F_3 generation positive mice. The HBV DNAs were able to be transmitted through the germ line of the mice from one generation to another.

The results of our experiments shows that HBVgenome introduced by microinjection is integrated into the mouse genome, and the HBV genes can be expressed, replicated and packaged. So these lines of HBV transgenic mice may be used as the animal model for the study on HBV and its associated biomedical issue. And it can also be applied in the selection of anti-HBV drugs and vaccine[42,43]. It is also useful for exploring the mechanism of HBV infection.

INTRODUCTION

Liver fibrosis is a dynamic course leading to cirrhosis from a various chronic liver diseases. The pathological basis of fibrosis is the disturbance of production and degradation of the extracellular matrix (ECM), which causes accumulation of ECM in the liver[1,2]. The deposition of collagen is derived primarily from collagen types I and III in liver fibrosis[3]. The main sources of ECM are the hepatic stellate cells (HSCs)[4,5], especially when HSCs are activated by hepatic injury[6,7]. One of the important methods for preventing liver fibrosis is the inhibition of proliferation and activation of HSCs so as to reduce production of collagen. Glycyrrhetinic acid (GA) has been clinically used in the treatment of liver diseases. It has anti-injury[8-10] and anti-viral[11-13] effects on hepatic diseases. The clinical trials have shown that GA could lower the serum aminotransferase level both in Asian[14,15] and European patients[16] with chronic hepatitis. Our previous studies also indicated that GA could down-regulate mRNA expression of types I and III procollagen in NIH3T3 cells[17] and in fibrotic livers of rats induced by alcohol and CCl_4[18]. However, the effect of GA on HSCs mRNA expression of types I and III procollagen is unclear. In this study, the effects of GA on HSCs mRNA expression of procollagen types I and III and collagenase were investigated and deposition of types I and III collagen in different stages of fibrotic livers in rats was also observed.

MATERIALS AND METHODS

Animal model of liver fibrosis and drug treatment

Adult SD rats weighing 250 g-300 g were selected. They were distributed as the normal group, the model group, and the GA group. Each group contained the early (2 weeks), middle (6 weeks), and late stage (9 weeks) subgroups. There were 30 rats in each group and 10 rats in each subgroup. The liver fibrosis model was induced by the administration of CCl_4 and alcohol. Potenlini, an injectable compound whose active component is GA, was administered intraperitoneally in the GA group with 3 mL per rat three times a week, begining at 2 weeks prior to sacrifice. Rats were killed by the end of 2, 6 and 9 weeks respectively.

Isolation and culture of HSCs

HSCs were isolated from rat liver as described by Hu[19] with slight modifications. The HSCs showed a typical stellate-like shape containing fat droplet in cytoplasm. During the culture period, HSCs became larger and contained less amounts of fat droplet. By the end of 2 weeks, HSCs looked like myofibroblast. Cells were seeded in culture flask and maintained in DMEM media supplemented with 20% FCS and antibiotics. The media was changed every 48 h. After 2 weeks, when cell confluence was attained, they were harvested by the trypsinized method and applied to further studies or stored in liquid nitrogen.

Identification of HSCs

Freshly isolated HSCs could be distinguished by its autofluoresence characteristic of vitamin A in the lipid droplets at 328 NM. Immunohistochemistry showed that desmin and α-SMA were positive in 99% of cells after 2 weeks of culture. Besides, transmission electron microscopy confirmed the existence of lipid droplet in cytoplasm and revealed a purification of about 90% in freshly isolated cells.

^{3}H-TdR and ^{3}H-proline incorporating test

After two weeks of culture, the HSCs were collected and seeded on 96-well culture plates at a density of 1 × 10^5 cells/mL cultured media. Forty-eight hours later, GA (i.e.potenlini) was added into wells at a final concentration of 1.0, 0.5, 0.25, 0.125 and 0.0625 mg/L, respectively, and incubated for 4 h, 24 h or 48 h, then ^{3}H-TdR or ^{3}H-Proline at a density of 18.5 KBq/per well were added and incubated for 24 h. The cells were then harvested with trypsin and the adhered cells were placed into glass fiber filter by multiple cell collector. The cells were baked at 80℃ for 2 h, scintillation fluid was added and the radioactivity in the cells was determined using scintillation counter.

Plasmid amplification and probe labeling

Plasmid pUCAU1U (containing procollagen type I cDNA fragment)[20], pHFS3 (containing procollagen type III Cdna fragment)[21], and pUC19A (containing collagenase cDNA fragment)[22], were amplificated in LB culture media. The plasmid DNA was extracted with a plasmid extracting kit (QIAGEN Incorporation, Germany). Plasmid was cleaved with restriction endonuclease and the target cDNA fragment was retrieved and phenolized. The cDNA fragment was labeled with DIG high primer technique (Boehringer Maannheim Incorparation,Germany). The probe was further purified by ethanol precipitation. Finally, the efficiency of probe labeling was determined using pseudo-hybridization, the optimal probe concentration of procollagen types I and III and collagenase was found to be 25, 35 and 25ìg/L respectively.

RNA extraction and Northern blot

HSCs RNA was extracted with a Rneasy mini-kit (Boehringer Maannheim Incorparation, Germany). Total RNA 5 μg was electrophorized on a 1% agarose/ 3% formadehyde gel. The RNA samples were stained with ethidium bromide and transferred overnight by capillary blotting in 20 × SSC to nylon membrane. The RNA was immobilized by baking for 30 min, at 120℃. Membranes were prehybridized (2 h) and hybridized (overnight) at 60℃ in high SDS solution. The membranes were washed at a stringency of 2 × SSC with 0.1% SDS at room temperature for 30 min and 0. 1 × SSC with 0.1% SDS at 68℃ for 30 min. The hybridization band was obtained by the chemoiluminescent method after film exposure for 5-10 min and then quantified by the scanning laser densitomitry.

Dot blots of types I and III collagen

The types I and III collagens were isolated by limited pepsin digestion. The livers were minced and homogenized thoroughly in cold distilled water and then centrifuged at 12 000rpm for 20 min. The precipitate (5 g) was suspended in 0.5M acetic acid and digested with pepsin for 24 h at 4℃ with stirring, and then centrifuged. The supernatant was incubated with NaCl (1.0M) overnight. The precipitate contained types I and III collagen which were purified by salt fractionation and their concentration was estimated by ultraviolet spectroscopy. Twenty μL of each sample was loaded on PVDF membrane and was blocked with 10% BSA for 60 min. The polyclonal antibodies (1:250 dilution) of types I and III collagen were added and incubated overnight. The membrane was then washed with PBST 3 times and blocked again with 10% BSA for 30 min. It was then incubated with the secondary antibody for 2 h at room temperature. After washing with 50mM Tris-HCl, the dot was obtained 5-10 min after incubation with DAB. The dot intensity was quantified by scanning laser densitomitry.

Statistical analysis

Data were expressed as mean ± SD. One way ANOVA and *t* test were applied for data analysis.

RESULTS

Histological examination and identification of HSCs

Histological examination (H&E and collagen specific staining) revealed the successful establishment of the rat liver fibrosis models at different stages. Two weeks after CCl_4 and ethanol treatment, denaturation and necrosis were the main microscopic changes in liver. By 6 weeks, except for denaturation, connective tissues began to enlarge and extend. By 9 weeks, pseudo-nodules formed and bands of connective tissues were found in the portal areas. The yield of HSCs was 1.6-1.8 × 10^7 cells per liver. The result of transmission electron microscopy, fluorescence microscopy (Figure 2) and immnohistochemical staining all showed that the purity of HSCs was high, which met the demand of further studies.

^{3}H-TdR and ^{3}H-proline incorporating test

Compared with the control group, GA had an inhibitory effect on cultured HSCs on incorporation of ^{3}H-TdR and ^{3}H-proline at 4 h, 24 h, and 48 h (Table 1), with a time dependent relationship. This inhibitory effect was significant in a dose-dependent manner when the concentration of GA was above 0.25 mg/L (^{3}H-TdR), and 0.125 mg/L (^{3}H-proline), respectively (Table 2).

Table 1 Effect of GA treatment with different duration on ^{3}H-TdR and ^{3}H-proline incorporation of HSCs

Drug	Duration (hrs)	^{3}H-TdR incorporation		^{3}H-proline incorporation	
		cpm	Inhibition rate(%)	cpm	Inhibition rate(%)

	1.0	1027 ± 121	33[b]	220 ± 63	59[b]

[a]Compared with control values, $P<0.05$; [b]Compared with control values, $P<0.01$.

Plasmid amplification and probe labeling

The purity of extracted plasmid DNA was high, and the ratio OD260/OD280 was over 1.6. The DNA yield of three kinds of plasmid all exceeded 130 μg. Electrophoresis showed that the yield of DNA fragment, which was cleaved with restriction enzyme, was satisfactory. On the other hand, the probe concentration of type I and III procollagen and collagenase was determined to be 15 mg/L, 35 mg/L and 100 mg/L, respectively.

The effect of GA on HSCs mRNA expression of types I and III procollagen and collagenase

At the end of 2, 6 and 9 weeks after the induction of rat liver fibrosis, HSCs mRNA expression of types I and III procollagen in the model group was higher than in normal group ($P<0.05$). However, HSCs mRNA expression of types I and III procollagen in GA group was lower than that in the model group, but was higher than the normal group (GA group vs model group and GA group vs normal group, $P<0.05$). HSCs mRNA expression of collagenase in the model group was higher than in normal group at each stage of liver fibrosis ($P<0.05$). And at the end of 9 weeks, the mRNA expression of HSCs showed a dropping tendency. HSCs mRNA expression of collagenase in GA group was also higher than in normal group, but there was no difference between the GA and the model group (Figure 1).

The effect of GA on liver deposition of types I and III collagen

At the end of the 2nd, 6th and 9th week, the liver deposition of types I and III collagen in the model group was higher than in normal group ($P<0.05$). The liver deposition of types I and III collagn in GA group was lower than in model group ($P<0.05$), but was still higher than in the normal group. In addition, the density of type I and III collagen in treatment groups were closer to the model group at the end of the 9th week than at the 2nd and 6th weeks (Figure 2).

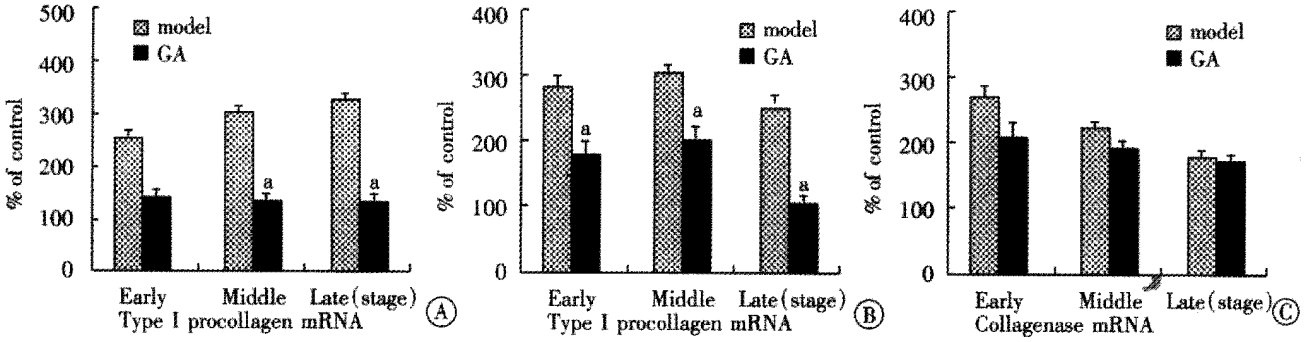

Figure 1 Densitometric analysis of collagenase, type III and I procollagen mRNA Northern blot. The result of Densitometric analysis after normalization against hybridization signals for normal groups was expressed as mean percentage ± SD of the control values ($n = 5$). The level of types I and III procollagen mRNA expression of HSCs in GA groups was lower than in model groups ([a]$P<0.05$). For the collagenase mRNA expression of HSCs, there was no significant difference between GA groups and model groups.

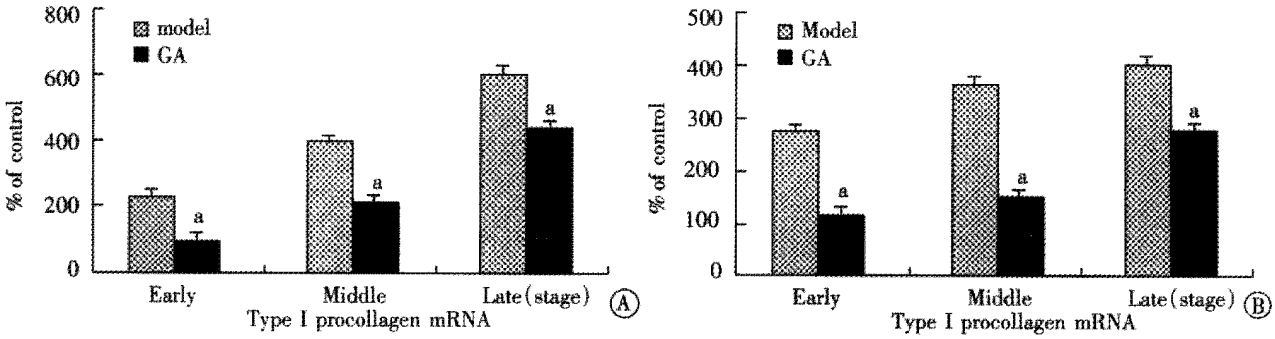

Figure 2 Dot blot densitometric analysis of types I and III collagen. The result of densitometric analysis after normalization against hybridization signals for normal groups was expressed as mean percentage ± SD of the control values ($n = 5$). The level of types I and III collagen densitometric values in GA groups was lower than in model groups ([a]$P<0.05$).

DISCUSSION

In normal livers, HSCs are situated in the Disse£§s spaces, separating hepatocytes from sinusoidal endothelium and being rich in fat drips. It has been well known that HSCs are responsible for the excessive production of ECM[23-25]. The central event in liver fibrosis is the activation of HSCs and subsequent transformation from quiescent vitamin A-rich cells to proliferative, fibrogenic and contractile myofibroblasts[26]. *In situ* hybridization demonstrated the specific transcript of procollagen[27,28]. It is rationale to choose HSCs as a target for pharmacological therapies for anti-fibrosis of liver. In this study, we observed that GA had an inhibitory effect on proliferation and collagen production of HSCs *in vitro*, which could be associated with the inhibition of activation of HSCs. The activation of HSCs is a pleiotrofic process. It involves a series of gene transcriptions. Finally, HSCs display a shape that is similar to myofibroblast-like cells while addition of GA delayed the transformation of HSCs into myofibroblast-like cells. It suggests that GA could serve as a proximal segment modulator to decrease the activation and collagen production of HSCs in culture.

It has been proved that the expression of type I and III procollagen is up-regulated in hepatic fibrosis [29,30]. In this study, we demonstrated that the expression of types I and III procollagen of HSCs increased in hepatic fibrosis of rats. At the end of the 2nd, 6th and 9th week, the expression of types I and III procollagen was down-regulated in GA treated group, but still higher than in normal group, which indicates that GA only decreases the expression of types I and III procollagen partially. We have previously reported that GA inhibits nuclear factor-κB (NF-κB) binding activity[31]. NF-κB is a pleiotropic transcription activator[33] that exists in many kinds of cells[32]. It binds NF-κB inhibitors (IκB) in the cytoplasm as an inactive form. A wide spectrum of cellular stimulating signals, including mitogen, cytokines, bacterial lipopolysaccharides, viruses and viral proteins, and oxidative injury, could induce the activity of NF-κB[34]. Inducers of NF-κB activity resulted in phosphorylation, ubiquitination and degradation of IκB proteins, thus releasing free NF-κB for its translocation into the nucleus to activate transcription. We presume that by this way, GA can down-regulate the expression of types I and III procollagen of HSCs. In normal liver, the production of collagen is relatively static, and only with moderate expression of mRNA of type III and IV procollagen and laminin. The mRNA expression of type I procollagen increased significantly in the formation of hepatic fibrosis. The ratio of type I:III was about 4:1[35] as observed in our study.

Recently, it has been found that the activity of interstitial collagenase is elevated in the early stage of hepatic fibrosis[23]. However, in the development of fibrosis, the activity of collagenase decreased[36-40]. In our study, the activity of collagenase increased at the early and middle stage of fibrosis, i.e. 2 or 6 weeks after CCl_4 treatment. At the end of the 9th week (late stage), it dropped to the level similar to that of normal groups. It could be due to the overexpression of tissue inhibitor of metalloproteinase in late stage of hepatic fibrosis[41,42]. GA reduced the mRNA expression of types I and III procollagen of HSCs, but not elevated the mRNA expression of collagenase of HSCs, which indicates that GA decreases the deposition of types I and III collagen by reducing the production of collagen, instead of dissolving the collagen. Therefore, at the end of the 9th week, GA was unable to obviously decrease the deposition of collagen. It suggested that the treatment for hepatic fibrosis with GA should begin at the early stage of fibrosis.

Based on the well-known mechanism of fibrosis, the treatment of fibrosis should include the following elements: removing the injurious stimuli; suppressing the hepatic inflammation; down-regulating the stellate cell activation and promoting the matrix degradation[26]. As we know, the major etiological factor of cirrhosis in patients in China is chronic hepatitis B. Histological improvement was found in the patients responding to antiviral therapy with lamivudine for HBV[43]. The result of a long-term follow-up study suggested that the proliferation of fibrous tissues was reversible[44]. Sun *et al*[45] indicated that antifibrotic therapy is important even in cirrhotic stage in which the fibrogenesis is still active. The results of our studies indicated that the effects on antifibrosis of GA might be exerted by down-regulating the binding activity of NF-κB and HSC activation, and by suppressing the hepatic inflammation. Our previous study also showed that the effect of GA on serum conversion of HBeAg[14]. Sato *et al*[46] reported that GA could inhibit the release of HBsAg from the infected hepatocytes. Therefore, GA appears to function at multiple phases of hepatic fibrogenesis. Furthermore, the more exciting report is that GA treatment could inhibit the occurrence of hepatocellular carcinoma[47]. It has been also reported that long term (2-16 years.) treatment by GA in chronic hepatitis C patients had no side-effect and was effective in preventing liver carcinogenesis[48].

Other Chinese herbal recipes have shown their features in antifibrosis. Varieties of recipes or herbal extracts, such as Xiao Chaihu Tang[49], Recipe 861[50], Yiganxian[51], Ganyanping[52], and Matrine[53] have been shown to be effective in prevention and treatment of liver injury and fibrosis with different mechanism and pathway. It implies that the clinical application using the combination of glycyrrhetinic acid with these medicines is an

interesting area for further investigations.

In conclusion, GA inhibits the proliferation and collagen production of HSCs in culture, down-regulates the mRNA expression of type III and I procollagen, and reduces the deposition of type III and I collagen in fibrotic liver. It can be a very useful drug for anti-fibrotic treatment in patients with chronic liver disease.

ACKNOWLEDGEMENTS The authors would like to thank Dr. EdgarLiu (Dept. of Pharmacology, Hong Kong University) and Dr. Xia Hua Xiang (Dept. of Medicine, Queen Mary Hospital, Hong Kong University) for their review of the mamuscript.

INTRODUCTION

The increased expression of ICAM-1 on a wide range of cells and in the sera of patients with malignancies, chronic liver diseases and inflammation diseases has been described since the late 1980s[1-22]. Recently rapid progress in studies on expression of ICAM-1 in patients with hepatocellular carcinoma (HCC) have been achieved, including clinical and experimental researches [23-31]. It is well known now that ICAM-1 expressed in two ways in HCC: ① membrane-bounded ICAM-1 on the surface of HCC cells (mbICAM-1), which did not express in normal liver cells, and ② soluble ICAM-1 (sICAM-1) in sera of the patients, the concentration of which is well correlated with the progress and prognosis of the disease[32]. However, little is known about whether sICAM-1 is a diagnostic marker for early detecting HCC and monitoring its postoperative recurrence. It has been demonstrated that measurement of sICAM-1 might be of clinical values for early diagnosis and monitoring recurrence of HCC, particularly in patients with normal or low serum level of α-fetoprotein (AFP)[33-37]. Another controversy in this field is what is the main source of high levels of circulating sICAM-1 in HCC patients. It was reported that there were two forms of sICAM-1: HCC-specific circulating form of ICAM-1 shedding from HCC cells, and inflammation-associated ICAM-1 upregulated by several cytokines, of which interferon-gamma (INF-gamma) was the main cytokine trigger for ICAM-1 expression[38]. To solve the two problems mentioned above has become the key to the study. For this purpose, we have further confirmed the clinical values of sICAM-1 detection in HCC compared with benign liver diseases and normal control, analyzed the serum levels of AFP and sICAM-1 in HCC; observed mbICAM-1 expression in different regions of HCC tissues with the immunohistochemistry, and measured the expression of ICAM-1 mRNA in tissue samples by reverse transcriptase polymerase chain reaction (RT-PCR).

MATERIALS AND METHODS

Patients

Between January 1997 and July 2000, 151 patients with pathologically proven HCC either by surgical resection of liver tumors or by liver biopsies (131 men and 20 women; aged from 14 to 80 years, median 49) were treated in our department. Tumor was less than 5 cm in diameter in 21 patients,less than 10 cm in 43 and more than 10 cm or with extrahepatic metastasis in 87 cases. Liver cirrhosis was found in 137 patients. Hepatitis B surface antigen (HBsAg) was positive in 129 patients. Hepatitis C antibody was positive in 14 patients. The serum concentration of AFP was measured in all cases by radioimmunoassay (RIA) and its reference ranges were classified as follows: >200 μg/L as positive in 93; 20 μg/L-200 μg/L as questionable positive in 33 and <20 μg/L as negative in 25[35]. Treatment included surgical procedures (in 90 cases), interventioanl radiology (IR in 46) and percuteneous ethanol injection (PEI in 15). Among the surgically-treated patients, tumor resection was performed in 75, including radical resection in 42, nonradical in 33 due to intrahepatic vascular invasion on the resected margin pathologically or intrahepatic metastasis of tumor found intraoperatively. Laparotomy cathterization of the hepatic artery was undertaken in 15. The 46 patients underwent IR therapies including transcatheter arterial embolization (TAE) in 30 and transcatheter arterial infusion (TAI) in 16.

Follow-up of the patients undergoing hepatectomies

The patients undergoing hepatectomies were followed up monthly in the first year and once every two months in the second year postoperatively. During the follow-up, serum concentration of AFP and sICAM-1, liver function and image

examinations including BUS, CT or selective hepatic angiography were undertaken. Tumor recurrence was confirmed when intrahepatic lesion or portal vein tumor thrombi were found by liver image, and pathological diagnosis was established by reoperation or biopsy of the tumor.

ELISA for sICAM-1

Concentrations of sICAM-1 were measured with an enzyme-linked immunosorbent assay kit (Biosource Europe, Fleurus, Belgium) as described previously[31-37]. In all HCC patients, sICAM-1 levels were compared with their levels of serum AFP. As controls, serum levels of sICAM-1 were measured in 62 patients with chronic hepatitis B (CH), 60 with liver cirrhosis (LC) and 50 healthy blood donors.Immunohistochemistry of liver tissues -Tissues from tumor and adjacent region were obtained from 52 patients with surgical resection. Histologically normal liver tissues were obtained from 3 patients with liver hemangioma. To demonstrate the presence of ICAM-1 in the resected liver tissues, each fresh specimen was cut at -20℃ with the cryostat (4 μm- thick), mounted on sialinized adhesion microscope slides, dried overnight at room temperature, fixed with cold acetone (-20℃) for 10 min and chloroform for 20 min. Anti-human ICAM-1 mouse monoclonal antibody (Clone HA58, Pharmigen) was used. The slides were washed twice in TRIS/0.2% BSA and then incubated with sheep-anti-mouse-Ig (DAKO, Copenhagen, Denmark). And then the staining reaction was developed with a streptavidin-biotinylated-alkaline-phosphatase-complex (DAKO),slides were counterstained with hematoxylin, and nonreacting monoclonal antibody of IgG-1-isotype (DAKO) was used as negative control.

RNA extraction and DNA amplification

The total RNA was isolated from the fresh resected liver tissues by the acid guanidium thiocynate-phennol-chloroform method[39](Gstract, Maxim Biotech, Inc., San Francisco, USA). The concentration of RNA was determined from absorption at 260nm, and A 260: -80 ratios were > 1.7. RNA (10 μg)was subjected to electrophoresis in 1.5% agarose gels. The PCR primer for ICAM-1 and GAPDH were designed according to Vigano *et al*[40]. The following four primers presented by Dr. Shraven were used: ① (105) 5'-TGATGACATCAAGAAGGTGGTGAAG-3'; ② (1047)5'-TCCTTGAGGCCATGTGGGC-CAT-3'; ③ (825) 5'-GTCCCCTCAAAAGTCATCC-3'; ④ (1064) 5'-AACCCCATTCAGCGTCACCT-3'. The primer set was used to amplify an intron-spanning region of the human glyceraldeyde-3-phosphate dehydrogenase (GAPDH) gene. The latter gene provided a constitutively expressed internal control for complementary DNA contamination. The presence of ICAM-1 and GAPDH mRNAs was demonstrated by amplifying respective target sequences using PCR according to the instruction provided with the Technical Bulletin Kit (Promega). In brief, 3 μL (2.5 mM) RNA, and 50 pmol/L primers for ICAM-1 or GAPDH were added to each reaction mixture respectively, which included 0.4mM dNTPs 2 μL, 3 μL (1.5 mM) $MgSO_4$, AM V reverse transcriptase 1 μL (5U), TfI DNA polymerase 1 μL (5U), and AMV/TfI 5 × buffer 10 μL. The final reaction volume was 50 μL and was covered with 20 μL mineral oil. Then with PCR thermal cycle(Hema 480, China), RT-PCR reaction was run in the following procedures: ① 48℃ for 45 min, 1 circle; ② 94℃ for 2 min, 1 circle; ③ 94℃ for 30s, 60℃ for 1 min, 38℃ for 2 min, 30 circles; and ④ 68℃ for 7min, 1 circle. Five μL PCR product was placed on 1.5% agarose gel and observed by EB staining under UV light, the electrophoresis photo was transformed into computer, and ICAM-1 intensity was analyzed with MPIAS500 image system, while the GAPDH band intensity was subtracted as an internal standard.

Statistical analysis

Groups were compared by the Kruskal-Wallsi test and the *t* test.

RESULTS

sICAM-1 measurement

The concentrations of sICAM-1 measured in different groups are illustrated in Figure 1. The levels of sICAM-1 in the patients with CH (median -462 μg/L), LC (median-587 μg/L) and HCC (median -1120 μg/L) were significantly higher than that in the normal control (median -285 μg/L) (P<0.01). The levels of sICAM-1 in HCC group was also significantly higher than those in CH and LC groups (P<0.01).

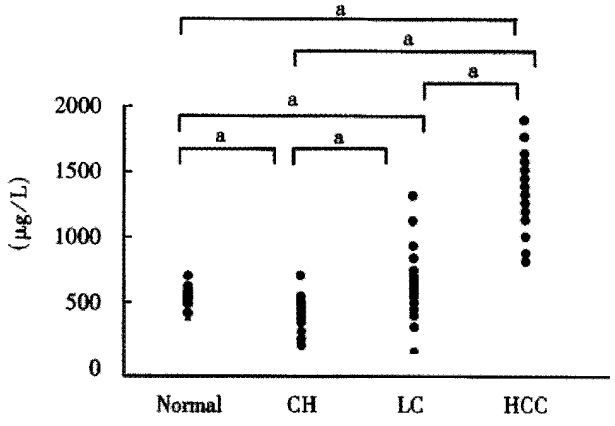

Figure 1 Serum concentration of sICAM-1 in normal controls (n = 50), in patients with chronic hepatitis (CH, n = 62), cirrhosis (LC, n=60), and hepatocellular carcinoma (HCC, n =151). ^aP<0.05, ^bP<0.01.

Comparative analysis of the serum values of sICAM-1 and AFP in HCC patients is listed in Table 1. There were 93 (62%) patients with positive serum AFP, and 58 (38%) with questionable and negative (33 and 25). However, the median values of sICAM-1 in these patients were 1597, 1456 and 1271 μg/L respectively. Statistical analysis showed no significant differences. In addition, analysis of ranges of sICAM-1 of HCC patients showed that 129 (85.4%) patients had a serum concentration exceeding 1000 μg/L, which was higher than the positive rate of serum AFP in the group of same patients.

Table 1 Comparative analysis of serum levels of sICAM-1 and AFP in HCC patients

Group	Number of patients	sICAM-1(μg/L)	AFP(μg/L)
AFP<20 μg/L	25	1271	18
AFP 20-200 μg/L	33	1456	121
AFP>200 μg/L	93	1597	26280

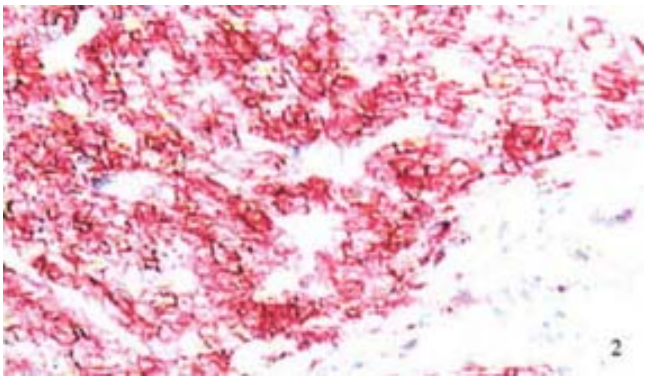
During the postoperative follow-up period of 6-61 months, tumor recurrence was confirmed in 41 patients. The median level of sICAM-1 of the patients was 1051 μg/L and 30 (73.2%) cases had a value higher than 1000 μg/L. On the other hand, there were 25 (60%) patients with serum AFP positive (>200 μg/L). In 6 patients with negative AFP, tumor recurrence was not detected by liver image until their serum levels of sICAM-1 had exceeded 2-4 times higher than before for 1-4 months.

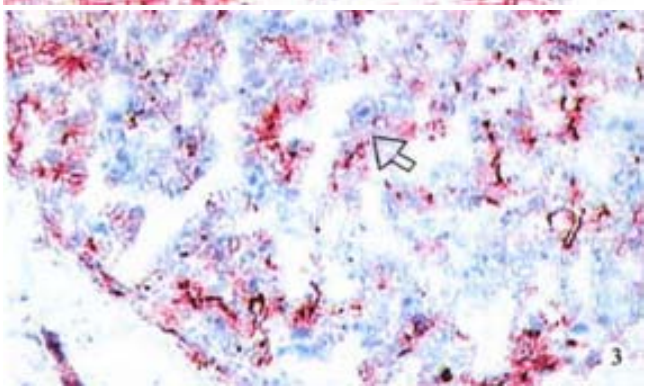
Immunohistochemical staining

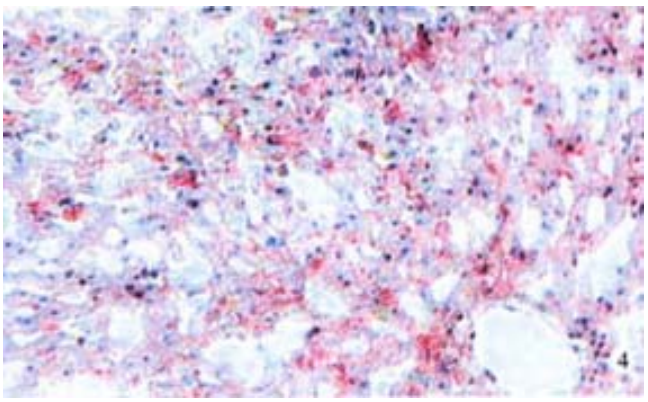
In all HCC samples, cancerous regions showed positive membrane staining for ICAM-1 with a honeycomb pattern (Figure 2). Parts of plasma of HCC cells showed strong positive reactions. In contrast to the cancerous areas, in noncancerous adjacent areas (Figure 3), the expression of ICAM-1 was negative, except those hepatocytes in severe cirrhotic areas. Normal liver tissue showed negative or very weak staining of the vascular endothelial cells and hepatocyts for ICAM-1 (Figure 4).

RT-PCR detection of ICAM-1

ICAM-1 mRNA in HCC tissues was detected by RT-PCR analysis (Figure 5). The result showed that freshly aspirated liver tissues expressed the gene coding for ICAM-1 because RT-PCR generated a DNA fragment corresponding to the predicted length, 943bp, of the ICAM-1 amplification product. In each tissue sample, all GAPDH amplification products were of 240bp length. The results revealed that the expression of ICAM-1 was stronger in the carcinomatous tissues of 28/43 cases (65.1%) than that in the paracacinomatous tissues of 13/43(30.2%) cases. Thirty-two of 43 cases had the levels of sICAM-1 >1000 μg/L.







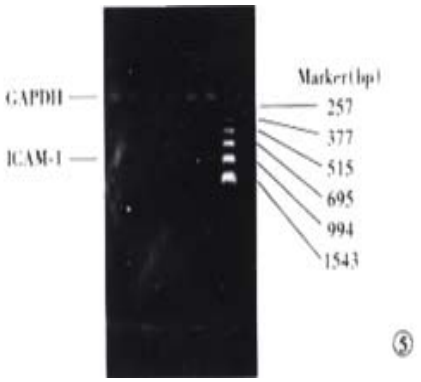


Figure 2 Immunohistochemical staining of ICAM-1 in hepatocellular carcinoma tissue is positive on the surface of tumor cells and in a honeycomb pattern.
Figure 3 Increased expression of ICAM-1 in paracancerous tissue was shown with severe cirrhosis by immunohistochemical staining.
Figure 4 ICAM-1 expression was negative in normal liver tissue by immunohistochemical staining (AEC method).
Figure 5 RT-PCR product gel electrophoresis. Three ìL RT-PCR products of ICAM-1 and GAPDH run on 1.5% agarose gel stained with EB. Lane 1 and Lane 4: the control for ICAM-1 and GAPDH. Lane 2 and 5: paracarcinomatous tissue for ICAM-1 and GAPDH. Lane and 6: HCC tissues for ICAM-1 and GAPDH.

The clinicopathological analysis of ICAM-1 mRNA and HCC is shown in Table 2. In the patients with serum levels of sICAM-1 above 1000 μg/L, the expression rates of ICAM-1 mRNA in HCC and adjacent tissues were 75.0% and 34.4%, respectively (P<0.01), however, in group with sICAM-1 lower than 1000 μg/L, the expression rate in those tissues were 36.4% and 18.2%, respectively (P>0.05). It is noticed that the expression rate of ICAM-1 mRNA was related to the severity of liver cirrhosis and intrahepatic metastasis of tumor. However, the expression rates of ICAM-1 mRNA were not correlated with the serum levels of AFP, differentiation of tumor and tumor sizes.

Table 2 Clinicopathological analysis of ICAM-1 mRNA and HCC %(n)

Clinical data	Cases	Positive tumor ICAM-1 mRNA	Positive paratumor ICAM-1 mRNA
Serum AFP>400 μg/L	25	68.0 (17/25)	32.0(8/25)
Serum AFP<400 μg/L	18	61.1(11/18)	27.8(5/18)
sICAM-1>1000 μg/L[a]	32	75.0(25/32)	34.4(11/32)
<1000 μg/L	11	36.4(3/11)	18.2(2/11)
Severe cirrhosis[a] Yes	30	80.0(24/30)	36.7(11/30)
No	13	30.8(4/13)	15.4(2/13)
Differentiation High	15	66.7(10/15)	33.3(4/15)
Low	28	64.3(18/28)	32.1(9/28)
Tumor size >5 cm	31	66.7(8/12)	25.0(3/12)
<5 cm	12	64.5(20/31)	32.3(10/31)
Intrahepatic metastasis[b] Yes	15	86.7(13/15)	40.0(6/15)
No	28	46.4 (13/28)	25.0(7/28)

DISCUSSION

HCC is one of the malignancies, which inflicts Chinese population severely. The prognosis of the disease is still dismal due to a delayed diagnosis, low resected rate and high recurrence rate of the tumor. Thus early diagnosis and effective postoperative monitoring are important to improve the surgical effectiveness for HCC[41]. The present study further confirmed our previous observations and other reports, in which elevated serum sICAM-1 was found in HCC, which was significantly higher than in benign liver diseases and the normal controls (Figure 1). As described by Shimizu *et al*[42], a sICAM-1 level above 1000 μg/L is a determinant for prognosis and progression of HCC. In our 151 patients with HCC, 129 (85.4%) cases had a high serum concentration of ICAM-1 above 1000 μg/L, which suggested that the positivity of sICAM-1 was higher than that of serum AFP. Although the serum levels of AFP in the HCC patients were different (Table 1), the sICAM-1 levels in the same group of patients showed no significant differences, particularly in cases with low levels of or negative AFP, indicating that measurement of sICAM-1 might be of diagnostic value for HCC.

Another interesting finding from our study is that in patients with AFP negative or questionable positive, sICAM-1 is a more sensitive serum diagnostic marker than AFP and other procedures, including BUS, CT, etc. In 41 patients with tumor recurrence detected during the postoperative follow-up, 73.2% patients had a high level of sICAM-1 above 1000 μg/L, however, the proportion of positive serum AFP in the same cases was only 60%. Moreover, in 6 of the 41 patients with negative AFP, tumor recurrence was diagnosed 1-4 months earlier by sICAM-1 than by liver image examination. We believe that sICAM-1 is not only a useful marker for predicting the progression and prognosis of the disease, but also a sensitive marker for diagnosing and monitoring HCC and its recurrence, especially for patients with low serum concentrations of AFP when the serum level of sICAM-1 was above 1000 μg/L[32-36].

As mentioned above, our clinical observations strongly supported that sICAM-1 might be of diagnostic value for HCC. However, it is unknown what is the main source of high level of sICAM-1 in HCC: HCC- specific ICAM-1 shedding from mbICAM-1 or inflammation-associated ICAM-1[38]. To distinguish the two forms of ICAM-1 is the ultimate goal of the study in this field[38]. Clinically, we have got the evidence that sICAM-1 is derived from HCC tumor cells, because we found in non-radical resected patients, the sICAM-1 concentrations maintained at a high level after the operation compared with those who underwent a radical resection of tumors, whose sICAM-1 levels would be decreased to the normal within 1-2 months postoperatively. This suggested that circulating sICAM-1 in HCC may originate mainly from tumor cell itself[36,37].

To verify our clinical findings that sICAM-1 is mainly derived from the HCC cells, we investigated the expression of ICAM-1 in HCC and its adjacent tissues with immunohistochemistry. The results showed that ICAM-1 expressed strongly in all specimens of HCC, but did not express in noncancerous regions, which reflected such a fact that high serum sICAM-1 levels of HCC patients might be attributable to tumor cells and a malignant transformation of hepatocytes. Our inference was supported by other authors[24,30,43,44]. Torri and Momosaky reported a high expression rate of ICAM-1 in HCC (80%-96%). Although three possible mechanisms for the expression of ICAM-1 were considered, Torri *et al* hold that malignant transformation of liver cells appeared to be the most important mechanism for the ICAM-1 expression in HCC. Thus they concluded that examination of ICAM-1 might yield significant information on the process of malignant transformation of hepatocytes[41,43]. In the nude mouse liver cancer metastasis model, Sun JJ *et al* demostrated that tissue ICAM-1 and sICAM-1 could indicate the stage

of HCC, potential of hepatoma cells for invasion and metastasis[45]. In addition, *in vitro* study by Momosaky *et al* showed that HCC cell itself markedly secreted soluble ICAM-1 into the culture supernantant in tumor cell lines[43]. On the other hand, no soluble ICAM-1 was shed from normal mouse hepatocytes regardless of the presence or absence of cytokine stimuli[43]. According to the observations from the present and other studies mentioned above, we think that high levels of sICAM-1 in HCC patients might be released mostly from the tumor cells.

After the clinical and immunohistochemical studies, we have recently investigated the correlation between serum levels of sICAM-1 and expression of its mRNA in HCC tissues. The results (Table 2) suggested that hepatocytes transformation may be the essential cause for strong expression of ICAM-1 mRNA, as in carcinomatous tissues of the 43 patients, the positive rate of expression was 65.1% (28/43). However, that in non-carcinomatous tissues was only 30% (13/43), which was quite different from the HCC tissues ($P<0.01$), and in normal liver tissues expression of ICAM-1 mRNA did not exist. Furthermore, the same correlation between the expression of ICAM-1 mRNA and the serum concentrations of sICAM-1 was observed. In patients with serum levels of sICAM-1 above 1000 μg/L, the expression rates of ICAM-1 mRNA in HCC and adjacent tissues were 75% and 34.4%, respectively, however, in group with sICAM-1 lower than 1000 μg/L, the expression rates were 36.4% and 18.2% respectively, which indicated that the expression of ICAM-1 protein was controlled by its correlative gene at the level of transcription regulation.

The expression rate of ICAM-1 mRNA was also related to the severity of liver cirrhosis and intrahepatic metastasis of tumor. Particularly in the later circumstances, the expression rate was much higher in metastatic patients (86.7%) than those without metastasis (53.6%), which suggested that the expression of ICAM-1 mRNA may play an important role in tumor intra and extrahepatic spread. These results were identical to our clinical observations, in which the proportion of sICAM-1 level >1000 μg/L was higher than that of AFP (73. 2% vs 60%) and sICAM-1 level was more sensitive than liver image examinations in indicating tumor recurrence.

Based on our studies on expressions of ICAM-1 and its mRNA in serum and tissues of HCC, we concluded that: ① Serum levels of sICAM-1 in HCC were significantly higher than that in benign liver diseases and normal controls, which indicated that it is useful to measure sICAM-1 to differentiate HCC from other benign lesions when the level of sICAM-1 is higher than 1000 μg/L. ② The high expression level of sICAM-1 might result from the strong expression of ICAM-1 in HCC tissue, which was controlled by its related gene. The source of sICAM-1 in HCC was originated mainly from HCC cells. ③ In HCC with intrahepatic metastasis, the expression of ICAM-1 mRNA was significantly high, which suggested that detecting sICAM-1 is of important value in predicting tumor recurrence after surgery. ④ With understanding of the mechanism of ICAM-1 expression and its origination, we believe that measurement of sICAM-1 may be of diagnostic value for HCC, particularly in patients with low levels of serum AFP.

ACKNOWLEDGEMENT We gratefully acknowledge Prof. Meuer for his cooperation, Dr. Shraven for the primers of PCR; and Yong Ming Liu, and Si En Zen for their excellent works in this study.

Liu F, Li JX, Li CM, Leng XS. Plasma endothelin in patients with endotoxemia and dynamic comparison between vasoconstrictor and vasodilator in cirrhotic patients. ***World J Gastroenterol***, 2001;7(1): 126-127

METHODS

We measured the concentration of endothelin in plasma using radioimmunoassay in 121 patients with cirrhosis and compared these values with 50 age- and sex-matched control subjects, and evaluated systemic endotoxemia. At the same time, perioperative plasma vasoconstrictor and vasodilator were clinically observed in 30 portohypertensive cirrhotic patients undergoing portosystemic shunt.

RESULTS

Plasma endothelin levels were higher in cirrhotic patients with ascites than in those without ascites. Femoral venous plasma endothelin levels averaged 90 ± 23 ng/L in cirrhotic patients versus 34 ± 8 ng/L in controls (P = 0.000), and that of cirrhotics with ascites was higher than those without 106 ± 17 ng/L *vs* 90 ± 23 ng/L(P = 0.002). Moreover, plasma endothelin levels increased in proportion to the severity of endotoxemia (r_s = 0.61, P = 0.034). Both the levels of plasma vasoconstrictors (ET, TX-) and of the vasodilator (PGI_2) were higher in portohypertensive cirrhotic patients (ET: 107.8 ± 25.9 ng/L*vs* 48.1 ± 9.4 (P = 0.000); TX-: 349.7 ± 198.4 ng/L *vs* 156.3 ± 54 (P = 0.000); PGI_2: 463.1 ± 108.3 ng/L *vs* 227.2 ± 46 (P = 0.000), and their concentrations decreased significantly in patients after portosystemic shunt (P = 0.002).

DISCUSSION

These results suggest that endothelin has significant influence on the portal vascular resistance of cirrhotic liver *in vivo* and may play an important role in the pathogenesis of portal hypertension[25-28]. Endotoxin may lead to the increased synthesis and release of endothelin. It could be that a dynamic balance between levels of vasoconstrictor and vasodilator in plasma exists in the pathophysiology of portohypertensive cirrhotic patients after portosystemic shunt.

INTRODUCTION

Portal hypertension is a common clinical syndrome characterized by an abnormal increase in portal blood to the systemic circulation, bypassing the liver. Recent studies have reported that humoral substances play an important role in the pathogenesis of portal hypertension, either by increasing vascular resistance at both the intrahepatic and porto-collateral sites or affecting splanchnic vasodilation with a concomitant increase in parto-collateral blood flow[1-6].

Endothelin (ET) released by endothelial cells is a 21-amino acid peptide with potent vasoconstrictor action. Endothelin comprises a family of four homologous isopeptides in human and animals (ET-1, ET-2, and ET-3, VIC)[7-14]. Most reported data are related to ET-1, which is the most powerful vasoconstrictor. Owing to a variety of reasons, reports concerning endothelin levels in cirrhotics are not consistent with each other. Endothelin concentrations in plasma have been reported to be increased in some studies and normal or reduced in others[15-20]. Present evidence suggests that endothelin may play an important role in modulating intrahepatic vascular resistance[21-24]. However, the relationship between vasoconstrictor (ET, TX-) and vasodilator (PGI_2) during portosystemic shunt has not been documented.

INTRODUCTION

Multiple organ dysfunction syndrome (MODS) is thought to be a frequent consequence of sepsis[1-3]. Despite substantial advances in our knowledge and understanding of the basic pathophysiologic mechanisms[4-7], in critically ill patients infections and sepsis are still associated with a high mortality[8,9]. There is evidence that the development of tissue damage in sepsis and shock is closely associated with the release of an ever increasing number of mediators and accumulation of neutrophils at the sites of infection or injury[10,11].

The endothelium is an intimal layer of simple squamous cells which provides a continuous, fluent surface for circulating blood. It is not the passive, metabolically inert barrier that it was once thought to be, and it is now known to be a metabolically and physiologically dynamic tissue with multiple functions. On the basis of recent discoveries in the field of endothelial cell biology (such as endothelium-derived mediators and the expression of adhesion molecules), end othelial cells are now thought to be not only target cells of injury, but also actively involved in inflammatory reactions and subsequent organ damage[12,13].

Polymicrobial sepsis induced by cecal ligation and puncture (CLP) is a model of sepsis which reproduces many of the inflammatory and pathological sequelae that are observed clinically. Following CLP, animals develop bacteremia, hypothermia, hypotension, and damage to multiple organ systems[14]. The present study was designed to observe the gene expression of adhesion molecules and proinflammatory cytokines in hepatic sinusoidal endothelial cells with a CLP model, in order to investigate the role of endothelial cells in tissue damage during sepsis.

Institute of Surgical Research , General Hospital of PLA, Beijing 100853, China

Dr. Rong Qian Wu, graduated from General Hospital of PLA as a M.D. in 1999, now attending surgeon of general surgery, major field of research in sepsis and MODS, having 15 papers published.

MATERIALS AND METHODS

Animal model and CLP

NIH mice were obtained from the animal center of the General Hospital of PLA. The mice were randomly divided into 2 groups: CLP group and sham group. Sepsis was induced in the CLP group by CLP. The mice were anesthetized, and the cecum was ligated below the ileocecal junction: intestinal continuity was maintained. The cecum was punctured twice with a 20-gauge needle and a small amount of cecal contents was expressed through the punctures. The incision was closed and 1 mL of normal saline was administered subcutaneously. Sham-operated mice underwent the same surgical procedure, but without CLP. The mice were sacrificed at 3 or 12 h after the procedure.

Isolation and purification of hepatic sinusoidal endothelial cells

Hepatic sinusoidal endothelial cells were isolated by collagenase perfusion of the liver, isopyknic sedimentation in a two-step percoll gradient, and selective adherence [15]. The purified sinusoidal endothelial cells were identified by staining with anti-von willebrand factor (vWF, factor VII I-related antigen). Flow cytometric analysis showed a purity greater than 85% in hepatic sinusoidal endothelial cells.

Analysis of adhesion molecules and proinflammatory cytokines mRNA by reverse transcription-PCR

Total RNA was extracted from endothelial cells. We used a phenol-chloroform extraction method reported by Chomczynski. The RNA was then quantitated spectrophotometrically. Total RNA from experimental samples was used to synthesize cDNA using AMV reverse transcriptase. β-actin and β_2-MG were used as internal control primers. The primers for the adhesion molecules and controls were as follows: β- actin (478bp), 5'AGG GAA ATC GTG CGT GAC ATC AAA 3', 5'ACT CAT CGT ACT CCT GCT TGC TGA 3'; β_2-MG (300 bp), 5'GGC TCG CTC GGT GAC CCT AGT CTT T 3',

5'TCT GCA GGC GTA TGT ATC AGT CTC A 3'; VCAM-1 (442bp), 5'CCT CAC TTG CAG CAC TAC GGG CT 3', 5' TTT TCC AAT ATC CTC AAT GAC GGG 3'; ICAM-1 (326bp), 5'TGC GTT TTG GAG CTA GCG GAC CA 3', 5' CGA GGA CCA TAC AGC ACG TGC AG 3'; E-selectin (435bp), 5'CCT GAA CTG CTC CCA CCC GTT CG 3', 5' GTG AAG TTA CAG GAT GAC TTA AAC GCA 3'; TNF-α (349 bp), 5'TTC TGT CCC TTT CAC TCA CTG G3', 5'TTG GTG GTT TGC TAC GAC GTG G 3' IL-1β (441bp), 5'ATT AGA CAG CTG CAC TAC AGG CTC 3', 5'AGA TTC CAT GGT GAA GTC AAT TAT 3' IL-6 (156bp), 5'TGG AGT CAC AGA AGG AGT GGC TAA G 3', 5'TCT GAC CAC AGT GAG GAA TGT CCA C 3'. Polymerase chain reactions were performed in a 25 μL reaction volume. A hot start was applied for 5min at 95℃. The amplification cycle (denaturation step at 94℃ for 30s, an annealing step at 55℃ for 30s and an extension step at 72℃ for 90s) was repeated 30 times and followed by a final extension for 10 min at 72℃. Amplified products were separated by electrophoresis in ethidium bromide-stained 1.5% agarose gel and visualized with UV illumination. The bands representing reaction product on the film were scanned by densitometry. A normalization quotient (Q) was calculated between the integrated optical density values (IOD) for the adhesion molecules and the β-actin or β_2-MG bands (Q = IOD, adhesion molecules band/internal control band). The level of adhesion molecules mRNA were expressed as the quotient of the integrated optical density values for the adhesion molecules and the β-actin or β_2-MG bands.

Statistical analysis

All data were reported as means ± SD. Data were analyzed by *t* test for comparisons between the two groups. A *P* value of less than 0.05 was deemed significant.

RESULTS

Adhesion molecules mRNA expression in hepatic sinusoidal endothelial cells

E-selectin mRNA levels markedly increased at 3 h after CLP in hepatic sinusoidal endothelial cells, and returned to baseline at 12 h after CLP. Increases in ICAM-1 mRNA level was found at 3 h after CLP, and this level became higher at 12 h after CLP. VCAM-1 mRNA expression in hepatic sinusoidal endothelial cells increased significantly 3h after CLP but declined at 12h after CLP (Table 1).

Table 1 Adhesion molecules mRNA expression in hepatic sinusoidal endothelial cells ($x \pm s$)

	E-selectin		ICAM-1		VCAM-1

[b]$P<0.01$ *vs* sham group.

Proinflammatory cytokines mRNA expression in hepatic sinusoidal endothelial cells

A significant increase in TNF, IL-1 and IL-6 gene expression was observed at 3 and 12 hours after CLP. The level of TNFα and IL-1β at 3 hours was higher than 12 hours, and the level of IL-6 gene expression at 12 hours was higher than 3 hours (Table 2).

DISCUSSION

The liver, with its rich supply of blood and sinusoid, is directly exposed to bacteria and endotoxins drained from the GI tract[16-19]. Previously, researchers in our institute have reported that the liver is the most susceptible and vulnerable organ during sepsis and multiple organ failure [20].

Vascular endothelial cells form an interface between tissues and inflammatory cells. This unique location allows localization of the inflammatory reaction to the site of injury while protecting adjacent healthy tissue. Endothelial cells mediate the local inflammatory response through modulation of vascular tone, vascular permeability and stimulation of leukocyte extravasation[21,22]. The role of neutrophil extravasation and accumulation has been emphasized in recent years[23,24]. This is mediated by the induced expression of multiple cell adhesion molecules on the surface of neutrophils and endothelial cells[25,26]. These include the selectins which are a group of surface glycoproteins essential to leukocyte margination and rolling along the vascular endothelium. Specifically, endothelial E- and P- selectin and L-selectin are expressed on neutrophils[27]. Another group of cell adhesion molecules involved in endothelial cell-leukocyte interaction is the immunoglobulin supergene family. This group comprises intercellular adhesion molecules-1 and 2 (ICAM-1, ICAM-2), vascular cell adhesion molecules-1 (VCAM-1)[28]. The most well studied of these molecules is ICAM-1, which play a critical role in events subsequent to initial leukocyte margination. In this study, we found that the up-regulation of the expressions of adhesion molecules in liver sinusoidal endothelial cells is a crucial step for the migration of leukocytes to and accumulation at the site of inflammation. Although neutrophils are important for killing microorganisms, activation of recruited neutrophils coupled with excessive release of oxygen metabolites and proinflammatory mediators may induce tissue injury which can lead to organ dysfunction[29,30].

Cytokines are polypeptides or glycoproteins of low molecular weight. Most cytokines are not stored as preformed molecules, hence their production requires new gene transcription and translation. Unlike mediators derived from the classical endocrine system, cytokines are produced. The production of cytokines at various tissue sites depends, in part, on the proximity of the site to the injurious stimulus. In this study we assessed the gene expression of proinflammatory cytokines in hepatic sinusoid endothelial cells. Recent discoveries in the field of endothelial cell biology have shown its capability of production cytokines[31-33], but the role of endothelial cell-derived cytokines in sepsis induced tissue injury was largely ignored. Proinflammatory cytokines TNF and IL-1 are known to play predominant roles in the normal inflammatory response. Exaggerated endogenous production is likely responsible for the complications associated with sepsis such as tissue injury and ultimate organ failure[34-36]. We observed a significant increase in TNF and IL-1 gene expression shortly after the induction of sepsis. This indicates that endothelium is an important source of cytokines during sepsis, and may play a role in sepsis induced organ dysfunction. The consensus of the concept of systemic inflammatory responses has brought about a likely promising approach in the treatment of SIRS/MODS[37] -anti-inflammatory instead of anti-infection[38,39]. Various approaches aimed at interrupting the cascade of host inflammatory responses have been tested. These include interventions targeted at the inflammation effector cells as monoclonal antibodies or receptor antagonist to pro-inflammatory cytokines. However, many of these seemingly effective measures in experimental study failed when moved from the laboratory bench to clinical ward [40-44].

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common human malignancies world wide[1,2], and is closely associated with infection of HBV and HCV and contamination of aflatoxin B1[3-6]. Although the molecular mechanisms of hepatocarcinogenesis remain poorly understood, an increasing number of genetic abnormalities have been recognized[7-10], for example, the *p*16 gene[11,12] the p53 gene[13-18], the E-cadherin gene[19], and the c-myc gene[20]. In relevance to HCC, inactivation of a tumor suppressor gene *p*16, which is important in the regulation of cell cycling, has recently been described in a significant proportion of patients with HCC[11]. An important mechanism of gene inactivation is aberrant methylation in the promoter region of the gene[11,21,22]. Evidence of p16 hypermethylation has also been documented in several human cancers[21-26]. However, to our knowledge, there were few studies on the *p*16 gene in HCC. 5-Aza-2'-deoxycytidine (5-Aza-cdR) is thought to act by inhibiting DNA methyltransferase that methylates cytosine residues in eukaryotic DNA[27]. Cedar *et al*[28] even took it as an experimental tool for demethylation. This drug appears to incorporate into the cellular DNA where it acts as a noncompetitive inhibitor of the maintenance methylase[29]. Methel moieties are thus passively removed when the DNA undergoes replication, and indeed, numerous inactive cellular and viral genes can be turned on following exposure to 5-Aza-cdR[30]. In order to determine whether *p*16 hypermethylation is involved in hepatocarcinogenesis, we determined the *p*16 gene protein, mRNA expression and methylation status in HCC cell line HepG2 before and after treatment with 5-Aza-cdR, and observed the growth change.

MATHERIALS AND METHODS

Cell line culture

Human hepatocellular carcinoma cell line HepG2 was obtained from the Laboratory of Gastroenterology, Southwest Hospital. It was cultured in RPMI 1640 supplemented with 100 mL/L fetal bovine serum, 100KU/L penicillin/ streptomycin and 5% sodium pyruvate at 37℃ in humidified atmosphere of 50 mL/L CO_2.

5-Aza-CdR treatment

Cells (approximately 1×10^5/mL) were plated in the vial, and treated with 5×10^{-7}M 5-Aza-cdR (Sigma Co.) for 24 h. The medium was changed after 24 h drug treatment and cultured for 9 days, to ensure complete recovery from the immediate toxic effects of 5-Aza-cdR[31]. Untreated cells were analyzed under similar conditions as a control.

Determination of cell cycle profile

Cells (2×10^6/100 mL vial) were plated and treated with 5×10^{-7} M 5-Aza-cdR. Cells were fixed after 7 days with 700 mL/L ethanol, and stained with propidium iodide (50 mg/L: Crze Co.). DNA content at each cell cycle stage was determined via flow cytometry.

Effects of 5-Aza-CdR on tumorigenicity

HepG2 cells (2×10^6) were injected into the right flank of 4-week-old Balb/c male nude mice 11 days after treatment with 5-Aza-cdR. Untreated cells were injected into the left flank under the same condition as a control. Tumor sizes were measured 4 weeks after injection.

Immunohistochemistry

Cells (1×10^6/3 cm dish) were cultured onto acid-washed 0.8 × 0.8 (mm) coverslips. The cells were fixed in 4% parafomaldehyde for 30 min at room temperature. The slides were washed in phosphate-buffered saline (PBS) three times for 3 minutes. The endogenous peroxidase activity was quenched by 10 minute incubation in methanol with 3% hydrogen peroxide (Zhongshan Chemical Co.). The fixation slides were then cleared with PBS. Nonspecific binding was blocked by applying normal goat serum in humidity chamber in a dilution of 1:10

for 30 minutes. Slides were blotted, and the anti-entire-human p16 antibody (Zhongshan Chemical Co.) (ready to use) as a primary antibody was applied for 1 hour at 37℃ in a humidity chamber. Secondary antibody (rabbit anti-mouse IgG) (Zhongshan Chemical Co.) diluted with PBS and normal human serum (40 μL rabbit anti-mouse antibody, 50 μL normal human serum, and 910 μL PBS) was applied for 1 hour at 37 ℃ in a humidity chamber. Finally, peroxidase-antiperoxidase conjugate diluted 1:100 in PBS was applied for 1 hour at 37℃ after washing with PBS. Slides were kept in diaminobenzidine tetrahydrochloride for 10 minutes (50 mg in 200 mL PBS with 25 μL of 30% H_2O_2) (DAB; Zhongshan Chemical Co.) . The manufacturer provides the presence (+) and absence (-) controls. The expression of p16 gene was observed under the light microscope and analyzed by the figure analysis method.

RT-PCR

RNA was isolated using Tripure isolation reagent (Boehringer Mannheim Co.). RNA was reverse transcribed according to the manufacturer's instructions of the access RT-PCR system (Promega Co.). cDNA was amplified using primers specific for both the p16 gene and GAPDH gene, the latter being used as a control. The primers used for *p*16 amplifications were located in exon 1 and exon 2 of the gene. Their sequences were 5'-AGCCTTCGGCTGACTGGCTGG-3'(sense) and 5'-CTGCCCATCATCATGACCTGGA-3'- (antisense). (Shanghai Sheng Gong Chemical Co., PAG pure). Standard PCR reaction was performed in total volume of 25 μL reaction mixture, including dNTP 0.2mM, 1 mM each primer 1 (sense) and Primer 2 (antisense), 1 mM $MgSO_4$, 0.1 U/mL of reverse transcriptase AMV, 0.1U/mL of Taq DNA polymerase and 100ng RNA. Conditions for *p*16 amplifications were 94℃ for 2 min, 40 cycles of 94 ℃ for 30s; 60℃ for 45s; and 68℃ for 90s , followed by incubation at 68℃ for 7 min. RT-PCR amplification product is 428 base pair[bp]. Primers for the GAPDH gene were 5'-CCACCCATGGCAAATTCCATGGCA-3' (sense), and 5'-TCTAGACGG CAGGTCAGGTCCAC-3'. (antisense) Conditions for GAPDH amplifications were 94℃ for 2 min, 40 cycles of 94℃ for 30s , 60℃ for 40s and 68℃ for 60s, followed by incubation at 68℃ for 7min. The amplification product is 598 bp. RT-PCR products were resolved on 2% agarose gel by figure analysis method.

PCR-based methylation assay

DNA was isolated with the Tripure isolation reagent. A PCR assay relying on the inability of some restriction enzymes, e.g. Hpa II or *Msp* I, to cut methylated sequences was used to analyze the methylation status of the second exon of the *p*16. DNA digests were performed according to the manufacturer's directions (Boehringer Mannheim Co.). DNA (1 μg) was digested for 2 h with 10 units of enzyme/μg of DNA. 200 ng of the digested DNA were amplified with primers flanking the restriction sites. The primers set used for methylation analysis of *p*16 exon 2 were 5'-CTGCTTGGCGGTGAGGGGG-3'(sense) and 5'-CCTCACCTGAGGGACCTTC-3'(antisense). The amplifiction products was 402 bp. Conditions were: 94 ℃ for 3 min, 35 cycles of 94℃ for 1 min, 57℃ 30s, and 72℃ for 40s, followed by incubation at 72℃ for 1 min. PCR products were resolved on 2% agarose gel. To rule out the possibility of incomplete restriction, all samples were digested twice with each of the enzymes in independent experiments. PCR ampifications from each of the duplicate digests were repeated at least twice to ensure reproducibility of the results.

Statistical analysis

t tests were used for statistical analysis. Significance was defined as $P<0.05$.

RESULTS

Cell cycle arrest after treatment with 5-Aza-cdR

HepG2 cells treated with 5-Aza-cdR were analyzed by flow cytometry to identify any change in its cell cycle profiles. The treated cells showed an increase in the proportion in G1,from 79.4% to 82.2% and a decrease in S, from 11.9% to 6.4%. Apoptotic rate increased from 6. 5% to 14.5%. These results indicated that 5-Aza-cdR may induce cancer cell division and apoptosis.

Effects of 5-Aza-cdR on tumorigenicity

Tumors induced via the injection of untreated HepG2 cells were approximately 1.32 cm^3 in size, whereas the tumors induced by HepG2 cells treated with 5-Aza-cdR averaged 0.98 cm^3 in size. These demonstrated that the growth-inhibitory effects of 5-Aza-cdR treatment *in vivo* were still recognizable.

Effect of 5-Aza-cdR on P16 protein expression

The positive 5-Aza-cdR-treated cells showed intense

homogenous brown staining of their nucler. After treatment with 5×10^{-7} M 5-A2a-cdR, HepG2 showed a higher expression of P16 protein than untreated cells. We observed under light microscope 5 fields in every slide at random, measured the staining degree of every 124 positive cells by the figure analysis method, IOD was 212.81 ± 62.56 and 495.89 ± 52.12 respectively in the untreated group and the treated group. This showed a significant difference (P<0.05). Although *P*16 protein expression alternations are very complicated and still undefined, our data showed that *P*16 protein expression could be silenced by hyper methylation of *p*16 gene (Figures 1,2).

Effect of 5-Aza-CdR on p16 mRNA expression

Figure 3 shows that expression level of *p*16 mRNA in HepG2 cells was increased after treated with 5×10^{-7} M 5-aza-cdR. The *p*16 gene, was selected for this study, because it was known to frequently undergo *de novo* methylation during tumorigenesis and because 5-Aza-cdR might be highly effective in inducing the expression of the gene inappropriately silenced by *de novo* methylation[18]. These results demonstrated a strong correlation between hypermethylation of the *p*16 and transcriptional silencing of this gene.

Effect of 5-Aza-CdR on p16 gene methylation status

Before 5-aza-cdR treatment the *p*16 exon2 showed hypermethylation, and therefore could not be deaved by loth HpaII and *Msp* I. It has been known that only the DNA indigested with *Hpa* II or *Msp* I can be amplified. After treated with 5-aza-cdR, the *p*16 gene became demethylated, then could be deaved by loth of the enzymes, and this failed to be emplified. Our experiment demonstrated that after hypermethylation in the *p*16 exon2 and 5-aza-cdR could enhance demethylation (Figure 4).

DISCUSSION

HCC is one of the most frequent human malignances worldwide. A number of tumor suppressor genic abnormalities are being recognized involving in the development of HCC[7-20]. The tumor-suppressor gene, p16,coding for an inhibitor of cyclin-dependant kinase (cdk) 4, was isolated and mapped to chromosome 9p21 [32,33], a locus frequently lost in diverse malignancies [34]. The *p*16 gene product p16 protein was originally isolated as a protein that was associated with cdk complexes[35] and thought to exert a negative type of control on cell proliferation through its binding to cdk4, thereby preventing cdk4 from forming an active complex with cyclin D protein[36]. As one of cancer-associated genes, the p16 gene abnormalities is arousing more and more attention. Germ-line mutations of the p16 gene have been identified in hereditary melanomas[37]. In addition,the gene is homozygously deleted or mutated in uncultured tumors of diverse origin[38], including pancreatic adenocarcinomas[39], melanomas[37], esophageal carcinomas[40,41], gliomas [42]lung cancer[43] and hepatocellular carcinoma[44]. Recently, it has been reported that inactivation of the *p*16 gene is frequently associated with aberrant DNA met hylation in all common human cancers[26]. However, there have been relatively few studies on expression of *p*16 in HCC.

Sun *et al*[45] found that DNA methyltransferase (MTase) mRNA levels were significantly higher in HCC and HCC cell lines (including HepG2 cell line), but they did not study the related genic methylation. Wong *et al*[46] demonstrated that aberrant methylation of the p16 gene occurred in 73% of HCC tissues. Hui *et al*[44] studied six HCC cell lines and found no p16 mRNA and protein in only one of them. After ruling out mutation and homozygous deletion of the p16 gene, they guessed that the silence of p16 gene might be associated with enhanced methylation of p16 gene, although the methylation status was not tested. However, p16 mRNA was detected in the other five HCC cell lines, and they thought that the lack of p16 gene transcription was not a frequent event in HCC cell line. The absence of p16 protein and presence of p16 mRNA expression strongly suggested that inactivation of p16 gene function could occur at the posttranscriptional level, but, the presence of expressions of both *p*16 mRNA and protein in HepG2, could not be explained. Boyes *et al*[47] discovered that the inhibition of gene transcription correlated with density of DNA methylation and the length of the promoter region. Hsieh[48] also found that the expression of gene transcription depended on CpG island methylation density; lower levels of methylation yielded a 67% to 90% inhibition of gene expression, higher levels of methylation extinguished gene expression completely. Numerous investigations described reactivation of genes by 5-Aza-cdR by acting on various loci of the inactive X chromosome[49], the VHL gene[50], the E-cadherin gene [51], the estrogen receptor gene[52] and the p16 gene[31]. In order to detect similar methylation changes in HepG2 cell line, we also used 5-Aza-cdR.

In this study, HepG2 cells treated with 5-Aza-cdR, showed demethylation of the p16 gene. The p16 mRNA and protein were all increased dramatically, cell cycle was arrested in G1, apoptototic rate increased and implanted tumor grew more slowly. According to our results, we thought that: p16 hypermethyla tion is associated with HCC cell line; MTase is increased in HepG2 cell line; 5'CpG island of p16 promoter was not methylated completely in this HCC cell line; p16 gene can be reactivated by inhibiting the activities of MTase; p16 methylation may be a common event during the establishment of the cell line *in vitro*; and p16 gene encodes a cell cycle regulatory protein that belongs to the cyclin-dependent kinase inhibitory protein family and regulates the G1/S phase cell cycle transition, and therefore, reactivated p16 may affect the growth of the HCC cell line. Xiao *et al*[53,54] found that 17p13.3 CpG island, PYN22.1, Rb gene all showed hypermethylation, we guess that 5-Aza-cdR may reactivate those genes.

The induction of p16 activation by 5-Aza-cdR *in vivo* and the decreased tumorigenicity in animal experiment suggest the chemotherapeutic potential of 5-Aza-cdR in the management of cancer.

INTRODUCTION

The mechanism that DNA hypomethylation leads to activation of oncogene and occurrence of malignant neoplasm is being increasingly recognized by researchers. Normal DNA methylation plays important role in stabilizing the phenotype of cell. DNA methylation status reduction and/or pattern alteration are related to activation and abnormally high expression of some oncogenes and cellular malignancy [1-6]. c-fms oncogene encodes for colony stimulating factor 1 receptor (CSF-1R)[7], c-fms/CSF-1R was highlyexpressed in hepatocellular carcinoma (HCC) tissue, but the mechanism remained obscure[8,9]. In this study, restrictive endonucleases *Hpa* II/*Msp* I digestion and Southern blot were used to study methylation status alteration of c-fms oncogene in HCC tissue and matching circum-cancer liver tissue, meanwhile the relationship between the alteration and clinical pathology of HCC was investigated. The gist of this study was to clarify the mechanism leading to c-fms oncogene high expression in hepatocellular carcinogenesis.

MATERIALS AND METHODS

Subjects

Thirty HCC patients were verified with pathological examination (25 males and 5 females, age range 32 -76 years, mean 55 years). Fresh hepatic tissue of HCC focus and circum-tissues 2 cm from HCC focus were cut off, normal control was from HBV negative hepatic tissue of renal transplantation donor. All the tissues were washed with physiological saline and put in freezing tube, and then they were put in liquid nitrogen for storage.

Main reagents

Restrictive endonucleases *Hpa* II/*Msp* I were purchased from Japan TaKaRa Bio-Company. DIG random labeling and detection kit were purchased from Boster Bio-Company. Nylon transfer membranes used for Southern blot were purchased from Shanghai Bio-Company. c-fms plasmid was kindly provided by academician Gu Jianren in the National Laboratory for Oncogene and Related Genes, Shanghai Cancer Institute.

METHODS

DNA extraction About 0.5g hepatic tissue was triturated in mortar, and a dissolvent (10 mmol/L Tris-Cl pH 8.0,10 mmol/L EDTA pH 8.0, 0.5% SDS) 500 μL was added. The preparation was digested with proteinase K and RNase, then it was extracted twice with saturated hydroxybenzene and once with chloroform isoamyl alcohol (chloroform:isoamyl alcohol = 24:1), and at last 2.5 volumes of absolute alcohol and 0.1 volume of 3 mol/L sodium acetate (pH 5.2) were added to precipitate the DNA. The extracted DNA was dissolved in TE buffer (pH 8.0), and DNA concentration was detersmined with an ultraviolet spectrophotometer.

Probe labeling

Plasmid extraction, restrictive endonucleases digestion, reclamation and purification were performed as the methods recorded in Molecular Cloning. The probe was labeled with DIG random labeling and detection kit.

Southern blot

Genome DNA 10 μg was digested with restrictive endonucleases Hpa II and *Msp* I 50U each for 12 hours respectively. Digested DNA was examined with 0.8% agarose electrophoresis. The buffer used for electrophoresis was 0.5 × TBE. Electrophoresis was ended when 2 kb marker shifted to the middle of the gel. Photo was taken under ultraviolet ray transmission. The gel was immersed in 0.25 mol/L

Department of Gastroenterology, Zhujiang Hospital, The First Military Medical University, Guangzhou 510282, Guangdong Province, China
Jun Cui, graduated from North China Coal Medical College in 1994 and got bachelor degree, graduated from China Medical University in 1997 with master degree, worked in Yantai Yu Huang-Ding Hospital, came to the First Military Medical University in 1998 to continue the study of doctor degree. Now physician-in-charge, lecturer, specialized in the genetic diagnosis and therapy for hepatocellular carcinoma, having 10 papers published.

HCl for 10 minutes, washed with distilled water for 20-30 minutes, and then immersed in denaturalizing liquid twice for 15 minutes each time. The gel was again washed twice with distilled water, and then it was immersed into neutralizing liquid twice for 15 minutes each time. A piece of nylon membrane of the same size as the gel was cut, it was immersed into 2 × SSC for 20 minutes. Transfer was performed for 18 hours at room temperature by the capillary transfer method. Then the nylon membrane was taken out and washed several times with 2 × SSC. After this, it was fixed for 20 minutes under long wave ultraviolet radiation. The transferred nylon membrane was sealed in a plastic bag and then pre-hybridizing reagent was perfused into the bag. The bag was put in a 42℃ water bath for 2 hours, and then pre-hybridizing reagent was decanted off. The bag was sealed, after the hybridizing reagent containing the DIG-labeled probe had been put in. The bag was put into a 42℃ water bath and hybridized for 20 hours. After hybridization the nylon membrane was taken out, and showed coloration according to the instruction of the DIG random labeling and detection kit.

Pathological examination and classification

The tumors were variously classified into unifocal or multifocal, and massive or nodular (a main tumor mass with satellites). The size and inner-condition of the tumors were recorded. The histological grading was based on Edmondson standard I-IV scale.

RESULTS

Southern blot of HCC tumor tissue and circum-cancer liver tissue

Hpa II and *Msp* I are isoschizomers. Both can digest CCGG sequence, but when the sequence is methylated into C-mCGG, only *Msp* I can digest while *Hpa* II can not. Methylation status of the gene may thus be determined by relying on such a difference. The data in this study showed that after digestion with *Hpa* II, hybridizing bands of less than 6.5kb in size were observed in 36.7%(11/30) of HCC tissue and 13.3%(4/30) of circum-cancer liver tissue, which resembled those of the hybridizing bands digested with *Msp* I. The results indicated that the methylation status of c-fms oncogene in the tissue was decreased (Figures 1,2).

Methylation status comparison of c-fms oncogene in HCC tissue and circum-cancer liver tissue

Hypomethylation rate of c-fms oncogene in HCC tissue and circum-cancer liver tissue was compared, the difference was determined, the result is shown in Table 1.

Table 1 Methylation status of c-fms oncogene (number of patients)

Methylation status	HCC tissue	Circum-cancer liver tissue
Normal methylation	19	26
Hypomethylation	11	4

Note: χ^2=4.36, P<0.05, hypomethylation rate of c-fms oncogene in HCC tissue was higher than that in circum-cancer liver tissue.

Relationship between hypomethylation of c-fms oncogene and clinical pathology

The relationship between hypomethylation of c-fms oncogene in hepatic tissue and the sex, age and pathological Edmondson scale of patients was analysed; the results are shown in Table 2.

Table 2 Relationship between hypomethylation of c-fms oncogene and clinical pathology

Item		Total number	HCC tissue		Circum-cancer liver tissue	
			Number	%	Number	%
Sex	Male	25	10	41.0	3	12.0
	Female	5	1	20.0	1	20.0
Age(yrs)	<60	22	7	31.8	2	9.1
	⩾60	8	4	50.0	2	25.0
Edmondson	I-II	14	2	14.3	1	7.1
scale	III-IV	16	9	56.3[b]	3	18.8

[b]P<0.05, *vs* Edmondson I-II.

Chi-square test showed that there was no significant relationship between hypomethylation of c-fms oncogene and sex and age of patients (P>0.05). There was significant relationship between Edmondson scale and hypomethylation of c-fms oncogene in HCC tissue (χ^2=5.66, P<0.05), while there was no significant relationship between Edmondson scale and hypomethylation of c-fms oncogene in circum-cancer liver tissue(P>0.05).

DISCUSSION

In the process of cellular carcinogenesis, genetic and epigenetic mechanism contributes to abnormal expression of gene. The genetic mechanism involves the mutation and chromosome rearrangement, with which genetic products of abnormal molecular structures can be produced[10-19]. The epigenetic mechanism mainly refers to an altered methylation status of 5'-cytosine in the DNA sequence, which leads to an abnormal expression of gene in quantity, but no change in DNA sequence and genetic product [20-24]. In the process of cellular carcinogenesis, the methyl groups in CpG islands of DNA are lost gradually. Although the accurate mechanism between DNA hypomethylation and cellular carcinogenesis remains obscure, some data showed that DNA hypomethylation could affect chromatin condensation in the middle stage, which led to a change and/or rupture of chromosome[25-31]. DNA hypomethylation is a kind of molecular structure leading to abnormal expression of gene; it facilitates a high expression of gene[32]. Highly specific DNA methylation types exist in human genomes, and are reflected in genetic characteristics of DNA, such as transcription, duplication, recombination, transposition and mutation. One biological function of human genome DNA methylation is to keep promoter of gene in silent status for long. 5' methyl-cytosine in special DNA sequence can mediate the specific combination and interaction between DNA and some functional proteins. As the interactions locate in the core region which regulates biological function of gene, sequence-specific methylation of DNA can affect cellular function[33-39]. Furthermore, DNA methylation depends on combining special proteins, and it directly or indirectly induced conformational alterations of DNA. DNA methylation is a kind of modificatory mode of cellular DNA at transcription level. In human genome, CpG islands in house keeping genes including a great number of oncogenes are in the form of methylation. Transcription and expression of the methylated genes especially oncogenes are limited. Decline of DNA methylation status at special sites of oncogene induces abnormal expression of the gene[28,40-43].

c-fms oncogene locates at 5q 33.3 of human chromosome and encodes CSF 1R, which has tyrosine kinase activity[44]. c-fms/CSF-1R is highly expressed in hepatocellular carcinogenesis, and its expressing level in HCC tissue is higher than that in circum-cancer liver tissue. Through the mechanism of signal transduction, CSF-1R stimulates the growth and development of HCC [45-50]. The whole length of c-fms oncogene is 43kb, in which there are 49 CCGG sites. The data in this study indicated that the hypomethylation rate of c-fms oncogene in HCC tissue was higher than that in circum-cancer liver tissue, while no hypomethylation of c-fms oncogene in normal hepatic tissue was observed. So hypomethylation is an important activating mechanism of c-fms oncogene in hepatocellular carcinogenesis. The data also showed that the hypomethylation rate of c-fms oncogene in Edmondson III-IV HCC was higher than that in Edmondson I-II HCC. All the evidence indicated that hypomethylation of c-fms oncogene might be an important late genetic incident in hepatocellular carcinogenesis. HCC with hypomethylation of c-fms oncogene may show the characteristics of higher malignancy and rapid development, and provide a clinical guide in the selection of surgery, radiotherapy and chemotherapy, and also in judging the prognosis of patients.

c-fms/CSF-1R is abnormally high-expressed in hepatocellular carcinogenesis at a late stage, meanwhile hypomethylation of c-fms oncogene occurs, and the hypomethylation rate of c-fms oncogene in HCC tissue is higher than that in the circum-cancer liver tissue. These data indicate that hypomethylation of c-fms oncogene is a kind of molecular mechanism leading to abnormally high CSF-1R expression and promoting the occurrence and development of HCC. So blocking the process of hypomethylation of c-fms oncogene, consequently decreasing a high expression of CSF-1R may have great clinical significance in decreasing malignant phenotype of HCC and improving prognosis of patients.

INTRODUCTION

Crypt epithelial cells in normal small intestine proliferate at a high speed. But they are very difficult to culture *in vitro* and passage stably. A lot of studies have been done [1-16]. Some domestic labs isolated and cultured crypt cells from embryonal intestines and aseptic animal intestine, but failed. We introduced normal rat epithelial cell line IEC-6 from the USA and its living condition for stable passage was successfully established after trials. The cell line was testified to be the small intestinal epithelial cell by electron microscopy, immunihistochemistry and enzymatic-histoch-emistry. It has been applied to some related research work[17-21]. It was found that many factors were involved in the culture system. Our present study focuses on the culture method and the influencing factors on IEC-6.

MATERIALS AND METHODS

Reagents

Dulbecco's modified Eagle Medium (DMEM), HEPES from Sigma Cooperation, ^{3}H-TdR with the radioactive concentration of 37 MBq/mL and activity ratio of 740GBp/mL is the product of the Chinese Nuclear Science Institute.

Apparatus

Carbon dioxide culture case, Model Queue 2721, USA; automatic liquid scintillation counter, Model 1217, Sweden; cell harvester, Model 2T-II, Zhejiang Province; and microplate, Japan.

Institute of Combined Injury, PLA, School of Preventive Medicine, Third Military Medical University, Chongqing 400038, China
Dr. Xin Ze Ran, graduated from Third Military Medical University in 1980, now engaged in the research of combined radiation injuries for 20 years and having 40 papers published.

Cell line

Intestinal epithelial cell line, No. 6, IEC-6 was provided by the General Hospital of Massachusetts, Boston, USA.

Culture liquid medium

Liquid DMEM/L was made up according to the protocol supplemented with HEPES 10 mmol, penicillin 10^5U, streptomycin 100 mg, sodium carbonate 3.7 g and fetal bovine serum 100 mmol. L-glutamine 200 mmol/L was added before use.

Establishment of cell passage and detection of activity

IEC-6 cell line was immediately put into 40℃ water bath to thaw after being taken from liquid nitrogen, centrifuged for 10 minutes at 1000r/min. Liquid medium was added per bottle after the supernatant was deserted. Then the bottle was put into the carbon dioxide case (10% CO_2, 18.6% O_2 100% relative humidity, 37℃). After the cells adhered to the wall, change the liquid once, then passage on the 5th day. When the cell was passaged or the activity was detected, the liquid medium was deserted and 0.02% EDTA 8 mL was added for digestion of 30 minutes at 37℃. The incompletely digested cells were scraped softly with curved tube, passed into centrifuge tube and centrifuged for 8 minutes at 1000r/min. Supernatant was deserted and the liquid medium was added to a certain concentration. The cells were then seeded onto 96-well plates and cultured for 72 hours. ^{3}H-TdR, 1.5uCi per well, was added at the 12th hour before the culture was stopped. At the end of the culture, the cells were digested with 0.02% EDTA, harvested on the glass fiber filter membrane, and heated at 80℃. When the membrane cooled down to the room temperature, 8 mL scintillation liquid was added, Cpm was measured with automatic liquid scintillation counter.

Scintillation liquid contained POPOP 0.4 g, PPo 4 g, xylene 1000 mL.

RESULTS AND DISCUSSION

Effect of IEC-6 density

IEC-6 cells at various densities in microplate wells were labeled with ^{3}H-TdR 18.5kBq and cultured for 72 hours to investigate its effect on proliferation. Table 1 shows that at a certain range of densities, ^{3}H-TdR incorporation increased with the IEC-6 amount, the peak was at 10×10^4/well. Positive

correlation was found between cell density (X) and ^{3}H-TdR incorporation (y) at the range of 1.25×10^4-10×10^4/well with the correlation coefficient $r = 0.956$ and regression equation $y = 2177X+3575$(min^{-1}). When the cell density was more than 11.25×10^4/well, there was negative correlation ($r = 0.986$, y) = 36782-1253 X), possibly due to the limit amount of nutrition, liquid evaporation and subject to changes of culture condition[22].

Table 1 Effect of density on ^{3}H-TdR incorporation in culture cell ($\bar{x} \pm s$)

Density ($\times10^4$/well)	n	Min^{-1}	Density ($\times10^4$/well)	n	Min^{-1}
1.25	18	3547 ± 681	11.25	20	23648 ± 1398
2.50	20	9941 ± 413	12.50	18	20593 ± 2245
5.00	18	17931 ± 2051	13.75	20	19812 ± 2310
7.50	18	19825 ± 2135	15.00	18	17638 ± 959
10.00	24	23789 ± 2536	17.50	22	14874 ± 881

Effect of culture time

Incorporation of ^{3}H-TdR was different after IEC-6 was cultured for 6, 12, 24, 48, 72 and 96 hours (Table 2). Within 72 hours, incorporation increased from 1846 ± 146 to 25727 ± 4006 (min^{-1}) along with the time prolongation and it reached its peak at 72 hour. But when the culture time extended to 96 hours, the incorporation decreased. This may be caused by the activity inhibition of some IEC-6 under non-physical conditions.

Table 2 Effect of culture time on IEC-6 cell proliferation ($\bar{x} \pm s$)

Culture time (h)	n	Min^{-1}	Culture time (h)	n	Min^{-1}
6	24	1846 ± 146	48	24	21258 ± 1240
12	26	4038 ± 363	72	24	25727 ± 2006
24	24	6367 ± 588	96	24	24355 ± 2079

Effect of different ^{3}H-TdR dosage

In this study, different dosage of ^{3}H-TdR was administered in the IEC-6 culture system. A linear correlation was found between the ^{3}H-TdR incorporation and dosage when the dose was below 55.5KBq/well. When larger dosage was used, the incorporations slightly increased or decreased (Table 3). The radioactive damage to cells and consequent inhibition of DNA synthesis by high concentration of ^{3}H-TdR contributed to the incorporation decrease. Generally, the dosage of 18.5 KBq/well ^{3}H-TdR to 10×10^4 cell yielded a satisfactory result of incorporation 2.5×10^4.

Table 3 Effect of ^{3}H-TdR dosage on IEC-6 cell proliferation ($\bar{x} \pm s$)

^{3}H-TdR dosage (kBq/well)	n	Min^{-1}	^{3}H-TdR dosage (kBq/well)	n	Min^{-1}
0.00	20	139 ± 29	27.75	21	27555 ± 1637
2.31	22	1333 ± 118	37.00	21	37235 ± 1485
4.62		10136 ± 1083	46.25	22	41874 ± 1213
9.25	24	16880 ± 1447	55.05	24	48072 ± 1676
18.50	24	24890 ± 1623	74.00	20	42430 ± 1735

Effect of pH in lipid medium

pH of culture medium is one of the most important factors in cell culture. To optimize the culture condition, the pH value was set at 6.0, 6.6, 7.26, 7.6, 8.0 and 8.8, and ^{3}H-TdR incorporation was measured respectively (Table 4). The incorporation was the highest at pH 7.26, lower pH at 6.6 and 7.6, and the lowest at pH 6.0 and 8.0. In the common sense, cells can survive when pH ranged from 6 to 8. Variant cells and animal species do not have the same optimal pH. It is believed that optimal pH has an effect on the survival of cells *in vitro* by adjusting the intracellular enzymes and proliferation factors. We therefore set the optimal pH 7.26 in IEC-6 culture medium.

Table 4 Effect of pH of culture medium on ^{3}H-TdR incorporation ($\bar{x} \pm s$)

pH	n	Min^{-1}	pH	n	Min^{-1}
6.0	20	4528 ± 660	7.6	28	12897 ± 1301
6.6	24	18771 ± 920	8.0	20	1305 ± 146
7.26	24	22510 ± 1448	8.8	20	636 ± 102

Effect of insulin and concentration of fetal bovine serum

Fetal bovine serum is one of the essential factors in cell culture *in vitro*. If the concentration of fetal bovine serum is too low, cells will die or have proliferation prohibited. When the concentration is too high, the osmotic pressure in culture medium will change and it will influence the survival of cells. In this study, we found that 10% of fetal bovine serum was optimal in culture medium. Content of glucose in DMEM was high (4500 mg/L) and insulin can speed up glucose oxygenolysis and transportation through cell membrane, so the use of glucose was accelerated in the cells. The results showed that incorporation of ^{3}H-TdR was higher in cells treated with insulin than in the cells (Table 5) without insulin treatment.

Table 5 Effect of insulin and concentration of fetal bovine serum on IEC-6 cell proliferation ($\bar{x} \pm s$)

Fetal bovine serum(%)	n	Min^{-1}	
		Insulin group	Control group
0.0	18	476 ± 22	510 ± 101
2.5	20	13111 ± 978	1901 ± 580
5.0	22	14756 ± 1094	9097 ± 1069
7.5	22	20262 ± 2012	14569 ± 1136
10.0	24	23666 ± 1114	18775 ± 1361
15.0	20	22743 ± 1728	17645 ± 1289
20.0	18	22590 ± 1603	16965 ± 1147

Repeatability measurement

To investigate the experimental method, stability and the researcher's error, repeatability was measured by dividing the same culture system of IEC-6 into 30 parts. The incorporation of ^{3}H-TdR was 24327 ± 808 (min^{-1}). The value ranged from 23921 to 24733 when P<0.01 and coefficient of variation was 3.32%.

Effect of ionizing radiation on IEC-6

Intestinal epithelial cells are sensitive to ionizing radiation. The changes of incorporation of ^{3}H-TdR showed the damage of ionizing radiation on cells which reflected the cell biological characteristics. When IEC-6 was not exposed to radiation, the incorporation was 24327 ± 808. Incorporation after 4Gy, 8Gy, 16Gy, 2Gy and 26y irradiation were 31.8%, 24.1%, 15.2%, 11.2% and 8. 3% of control. Significantly negative dose-effect relation was found with the relative coefficient r = -0.970 (Table 6).

Table 6 Effect of ionizing radiation dosage on ^{3}H-TdR incorporation in IEC-6 cell ($\bar{x} \pm s$)

Dosage(Gy)	Min^{-1}	(%)	Dosage(Gy)	Min^{-1}	(%)
0	13427 ± 803	100.0	16	3698 ± 371	15.2
4	7736 ± 765	31.8	18	3381 ± 235	13.9
6	7249 ± 472	29.8	20	3041 ± 327	12.5
8	5863 ± 594	24.1	22	2725 ± 348	11.2
10	4865 ± 586	20.0	24	2481 ± 263	10.2
14	4136 ± 424	17.0	26	2019 ± 154	8.3
			r = -0.970		

In summary, methods of IEC-6 culture, passage and activity detection established in this study have the advantage of easy handling, being reliable in results, using less amounts of cells and a good repeatability. Subjective error can be avoided in measurement of epithelial proliferation with radioactivity. These will provide an ideal method for the research[23-35] on intestinal epithelimm[36-42].

Liu B, Staren E, Iwamura T, Appert H, Howard J. Effects of Taxotere on invasive potential and multidrug resistance phenotype in pancreatic carcinoma cell line SUIT-2. ***World J Gastroenterol***, 2001;7(1):143-148

INTRODUCTION

Development of drug-resistance to chemotherapy and subsequent metastasis of tumor are primarily responsible for treatment failure and the death from cancer. There have been many previous studies on the relationship between expression of multidrug resistance (MDR) phenotype P-glycoprotein (P-gp) and the malignant properties of tumors, but the results are often conflicting[1-8]. The difference in tumor types or MDR phenotype induced by specific agents might account for this discrepancy. Taxotere (TXT), a member of the family of taxanes, has antitumor activity through its effect of promoting the polymerization of tubulin[9,10]. Since microtubules are involved in many respects of cell functions, such as cell movement, intracellular protein translocation, an altered invasive ability has been confirmed in *in vitro* invasion assay[11-14] and *in vivo* metastasis assay[15] in tumor cells treated with taxane. Taxane has also been found to down-or up- regulate the expressions of metastasis-associated proteins or genes, such as metallo-poteinase[13,16-18], urokinase-type plasminogen activator[18], and E-cadherin[19]. Our previous work demonstrated that the intrinsic and acquired resistance to TXT in pancreatic adenocarcinoma (PAC) cell line SUIT-2 was mediated mainly by P-gp[20]. This study demonstrated that the invasive ability of TXT-resistant cells S2/TXT was not significantly greater than that of SUIT-2. However, S2/TXT cells have increased resistance to the anti-invasion effects of TXT as compared with their parental cells, SUIT-2.

MATERIALS AND METHODS

Reagents

Taxotere, obtained from Rhone-Poulenc Rorer Pharmaceuticals Inc., was stored as 10mM stock solution in absolute ethanol at -20℃. This solution was further diluted in the medium and used in the cell culture immediately before each experiment. MTT (3-[4, 5dimethylthiazol-2-yl]-2,5-diphenyltetrazoliumbromide) was dissolved in phosphate buffered saline (PBS) at a concentration of 5 g/L and filtered. The MTT solution was stored in the dark at 4℃ before use.

Cell cultures

Human pancreatic cancer cell line SUIT-2 was established by Iwamura *et al*[21]. This cell line was derived from a metastatic liver tumor of human moderately differentiated pancreatic carcinoma. Its sublines including S2-007, S2-013, S2-020 and S2-028 were cloned by soft agar culture and showed different metastatic potential[22]. Cells were cultured in plastic flasks with McCoy's modified medium supplemented with 10% fetal bovine serum (FBS) (Sigma) and 1. 25% penicillin-streptomycin solution (Sigma) (designated as "culture medium" below) and maintained at 37℃ in humidified atmosphere containing 5% CO_2.

Development of TXT resistant SUIT-2 cell line (S2/TXT)

A SUIT-2 TXT resistance derivative was developed by growing the parental cell line SUIT-2 in increasing concentration of TXT. Initially, the cells were grown as monolayers in culture medium at 37 ℃ in 5% CO_2 humidity atmosphere and exposed to 0.1nM TXT with addition of fresh culture medium and drugs every 3 days. After 2 weeks, the cells were exposed sequentially to stepwise increasing concentration of the drug until a TXT concentration of 2 nM was achieved. These cells were maintained in a drug-free culture medium for at least 3 weeks before used in experiments.

MTT colorimetric assay

The MTT colorimetric assay was performed as described by Page *et al*[23]. Briefly, SUIT-2 and S2/TXT cells were grown within 96well microtitre plates (Costar) at 2×10^4 cells/100 μL of culture medium per well and acclimated for 6 hours. Various concentrations of drugs (100 μL) diluted in culture medium were added. Five duplicate wells were used for each determination. The plates were incubated at 37℃ in 5% CO_2 for 72 hours when the control cells reached 90% confluence, and 30 μL of MTT solution was then added to each well and the plates were incubated at 37℃ for another 4 h. The medium and MTT solutions were then aspirated and 150 μL of dimethyl sulfoxide (DMSO) (Sigma) was added. The plates were agitated on the shaker for 15 minutes and read on Bio-Tek Microplate reader EL 800 (Bio-Tek Instruments, Inc.) with DeltaSoft 3 software. Fraction of cell proliferation was defined as the ratio of optical density volume to that of controls. The IC_{50} was defined as the concentration of the drugs required to reduce the optical density by 50% in treated cells to that of the controls.

Reverse transcription-polymerase chain reaction (RT-PCR)

The isolation of total RNA was based on the method of Chomczynski and Sacchi[24]. After the SUIT-2 and S2/TXT cell lines grew to 90% confluence, the total RNAs were extracted from the cell lines using Trireagent (Biotechnique, Molecular Research Center, Inc.). The total RNA was also isolated from the SUIT-2 cells incubated with 0.4 nM of TXT for 24 h. The messenger RNA was quantitated by measuring its absorbance at 260 nm. Equal amounts of RNA were reversed transcribed using SuperScriptTM One-stepTM RT-PCR System (Life Technologies). The 25 μL PCR mixed in each tube containing 0.5 μL RT/Tag Mix, 3 μL of 5 mM $MgSO_4$, 5 μL diethy pyrocarbonate (DEPC, Sigma) treated distilled water, 3 μL mixed primer pairs, 12. 5 μL 2X reaction mix and 1 μg template RNA in DEPC water. After an initial denaturation in a programmable thermocycler at 94℃ for 2 minutes, PCR was carried out for 30 cycles with the thermal profile: denaturing at 94℃ for 30 seconds, annealing at 55℃ for 30 seconds and extension at 72℃ for 1 minute with an extra 10 minutes extension for the last cycle. After completion of the amplification cycles, 5 μL of each PCR product was electrophoresed at 60V for 1.5 h on a 1.2% agarose gel (GIBCOBRL) in Trizma base and glacial acetic acid EDTA buffer, together with a 100-bp DNA (GIBCOBRL). The specific primers for mdr1 used in this study were sense 5'-CCC ATC ATT GCA ATA GCA GG-3', antisense: 5'- GTT CAA ACT TCT GCT CCT GA-3'. The metastasis of the carcinoma involved many kinds of genes. The primers used to detect the metastasis-related genes in this study were MMP-2: sense 5'-GAG CTG AAG GAC ACA CTA AAG AAG A-3'; antisense 5'-TTG CCA TCC TTC TCA AAG TTG TAG G-3', MMP-9: Sense 5'-CAC TGT CCA CCC CTC AGA GC-3'; antisense 5'-GCC ACT TGT CGG CGA TAA GG-3', Intigrin α5: sense 5'-CAT TTC CAA GTC TGG GCC AA-3'; antisense 5'-TGG AGG CTT GAG CTG AGC TT-3', intigrin β1: sense 5'-TGT TCA GTG CAG AGC CTT CA-3'; antisense 5'-CCT CAT ACT TCG GAT TGA CC-3' and E-Cadherin: sense 5'-GTG ACT GAT GCT GAT GCC CCC AAT ACC-3'; antisense 5'-GAC GCA GAA TCA GAA TAA GAA AAG CAA G-3'. β-actin was used as controls. Its sense primer was: 5'-TGA CGG GGT CAC CCA CAC TGT GCC CAT CTA-3'; antisense primer was: 5'- CTA GAA GCA TTT GCG GTG GAC GAT GGA GGG-3'.

Flow cytometry for Rhodamine-123 (Rho-123) accumulation assay

SUIT-2 and its subline S2/TXT cells were harvested in logarithmic growth phase with 0.25% trypsin and resuspended in phenol red-free DMEM medium at 1×10^6 cells/mL. For Rho-123 accumulation assay, aliquots of 1 mL cell suspension were preincubated with or without 5 μM Verapamil for 45 minutes at 37℃. Rho-123, 200 μg/L dissolved in DMEM, was added and incubated for 40 minutes at 37℃ in the dark. After incubation, cells were washed twice with and resuspended in ice-cold Rho-123 free DMEM with 5 μM Ver. The accumulation of Rho-123 in cells was analyzed with flow cytometry. Ten thousand cells per sample were analyzed. The fluorescence was measured on a logarithmic scale of 4 decades of log. These cell lines, which had not been exposed to Rho-123, were used to determine the background of autofluorescence under this condition.

Fibroblast conditioned medium (FCM)

The FCM was obtained by incubating NIH 3T3 cells (ATCC) in a serum free medium. Briefly, after NIH 3T3 cells grew to 70%-80% confluence in 10% FBS McCoy's medium, the medium was changed to DMEM containing ascorbic acid (50 mg/L), the cells were then incubated at 37℃ for 24 h. The medium was collected after spinning down the cells and stored at -80℃[25].

Cell invasion assay

Matrigel invasion ability of cells was assayed using a Transwell cell culture chamber[25] with an 8 μm pore size polyvinylpyrrolidone-free polycarbonate filter (Costar, Cambridge, MA). At first, the filter was coated with 200 μL Matrigel (Invitrogen, 0.25 μg/μL) and allowed to air-dry overnight. The Matrigel was reconstituted the following day with

200 μL DMEM at room temperature for 30 minutes. SUIT-2 and S2/TXT cells were harvested by trypsinization and resuspended in the culture medium at concentration of 2×10^5 cells/mL. Single cell suspension (400 μL) were placed in the upper chamber of the Transwell in the presence or absence of 0.4 nM of taxotere. The lower chamber contained 1 mL conditioned medium. After the cells were incubated at 37℃ for 24 h, the cells on the upper surface of the filter were removed by wiping with a cotton swab. The filter was fixed with 3% glutaraldehyde, stained with Hematoxylin. Cells which had invaded to the lower surface of the filter in five microscopic fields of 150 × magnification, were counted in each filter. Triplicate samples were conducted. The data were expressed as the average cell number of 15 fields.

Statistics

The significance of different invasion ability between SUIT-2 and S2/TXT, before and after treatment with TXT, was analyzed with Student's *t* test. Values were expressed as mean ± SD.

RESULTS

The sensitivity of SUIT-2 and S2/TXT cells to TXT

The acquired TXT resistant cell line S2/TXT was established from SUIT-2 by culturing with stepwise increasing concentrations of TXT as described in the Materials and Methods. Its IC_{50} (8.1 nM) was 9.5 folds that of its parental cell line SUIT-2 (IC_{50}: 0.85 nM). No change of sensitivity to TXT was found in this cell line during 4 months of study. The doubling time and morphology were similar to that of its parental cell line SUIT-2.

Expressions of mdr1 and other metastasis related genes

The expressions of the major drug transporter pump gene *mdr1* were studied by RT-PCR. There were strong expressions of *mdr1* in TXT-resistant cell line S2/TXT and SUIT-2 cells treated with 0.4 nM TXT for 24 h, and no expressions in the parental cell line SUIT-2, which were sensitive to TXT. Expression of metastasis-related genes in S2/TXT, including MMP-2, MMP-9, Integrin α5, Integrin β and E-Cadherin, was different from the parental cell line SUIT-2. Incubated with 0.4 nM of TXT for 24 h, TXT did not up- or down-regulate these metastasis-related gene expressions (Figure 1).

Rho-123 accumulation assay

Transporter activity of P-gp in S2/TXT cells was assayed by accumulation and efflux of Rho-123 tested with flow cytometry. The accumulation of Rho-123 in SUIT-2 cells is much higher than that of S2/TXT cells. The addition of 5 μM Ver significantly elevated the intracellular Rho-123 level in the TXT-resistant SUIT-2/TXT cells but not in the TXT-sensitive SUIT-2 cells.

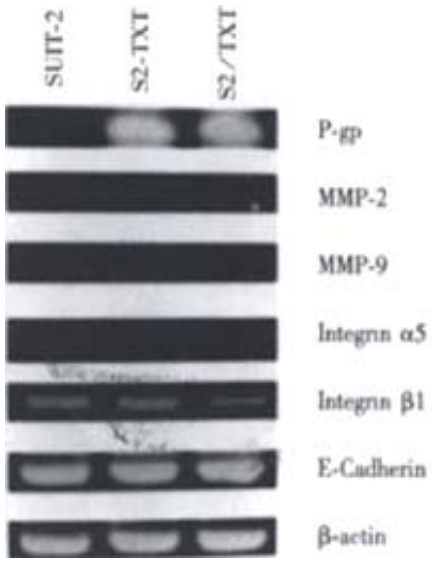

Figure 1 Reverse transcription-polymerase chain reaction (RT-PCR) analysis of drug resistance gene messenger RNA *mdr1* in SUIT-2 and S2/TXT cell lines. RT-PCR was performed with 30 cycles of PCR amplification. The β-actin gene RT-PCR products confirms that intact mRNA is equally present in each of the cell lines. This figure shows that there were strong expressions of *mdr1* in TXT-resistant cell line S2/TXT and SUIT-2 cells treated with 0.4 nM TXT for 24 h, no expressions in the parental cell line SUIT-2. Metastasis-related gene expressions had no difference in these cells.

Invasion assay

The effects of TXT on the *in vitro* invasion ability of SUIT-2 and S2/TXT were examined using an invasion assay system with reconstituted Matrigel membrane. The invasion ability of S2/TXT, which expressed P-gp, was not significantly different from that of SUIT-2 (83 ± 28 *vs* 71 ± 22 cells per field, $P>0.05$). Treatment of the cells with 0.4 nM of TXT for 24 h significantly inhibited the cell invasion of SUIT-2 through the Matrigel basement membrane (71 ± 22 *vs* 17 ± 5 cells per field, $P<0.01$). However, the TXT, in the concentration tested, had no effect on invasion of drug resistant cell line S2/TXT (83 ± 28 vs 68 ± 24 cells per field before and after TXT treatment, $P>0.05$).

DISCUSSION

Pancreatic adenocarcinoma (PAC) currently remains one of the leading causes of cancer death throughout the world. Most patients are surgically unresectable at the time of diagnosis. For those who were resected, the risk of recurrence was extremely high[26]. Consequently, chemotherapy is an important approach for most patients with PAC. Taxane as a promising antitumor agent has been widely used in treatment of cancers. Unfortunately, the initial response to this agent may be hampered by the development of multidrug-resistant cells[27] and possible enhancement of malignant potential[28]. Taxane resistance of tumor cells may involve many mechanisms, but were most often

related to the expression of P-gp[20]. In this study, examination of the TXT effect on the *in vitro* proliferation capacity of SUIT-2 and S2/TXT cells revealed a higher sensitivity of SUIT-2 when compared to the S2/TXT variant. TXT challenge of the initially drug sensitive parental SUIT-2 cell lines resulted in the development of multidrug resistance together with simultaneous expression of P-gp. Active drug transporter pump P-gp in these TXT^{a2}resistant cells was confirmed by Rhodamine accumulation assay. However, in a study by Dumontet *et al*, only 44% of resistant clones were found to express the *mdr1* gene, and studies with labeled paclitaxel (Taxol, PTX) did not show altered accumulation in *mdr1* negative clones[29]. Other studies on the mechanisms of Taxane-resistance included the composition and the mutations in β-tubulin isotypes[29,30]. The different expression of P-gp or tubulin mutation might be related to the means by which the resistant cells were selected [31]. Multi-step selected cells often present a high level of Taxane-resistance mediated by P-gp, while single-step selection yields a low level Taxane-resistance cells with tubulin mutations[31]. Since severe tubulin mutations are very likely to affect cell survival, these cells will generally be lost during the selection.

As shown in this study, TXT had marked inhibitory effects on tumor cell invasion. These effects were also found in other tumor cells treated with taxol[11-13,32]. The basic effects of Taxane on tumor cell promoted the polymerization of tubulin and stabilizing microtubule assembly, thereby blocking cell replication in the late G2 mitotic phase of the cell cycle[10,33,34]. Since microtubules are also important components of cell motility and intracellular transport [19,35,36], it is possible that TXT inhibits the invasive and migratory ability through interference with the function of the fundamental part of the cytoskeleton, such as inducing rearrangements or changes of the microtubules, which might interfere with their functional ability to mediate cell movement and protease vesicle transports and secretions of the gelatinase[13]. Direct observation by microinterferometry demonstrated that taxol can suppress the mean area of protrusion and retraction of cells and reduced the spread of cell translocation [35]. The prevention of microtubule depolyme rization by taxol can freeze the cell in a spread conformation, thereby blocking motility[37]. In some cell types, microtubules are known to serve as tracks to transport vesicles and organelles[38]. Mark *et al* reported that relatively low levels of taxol can inhibit secretion of the M_r 72 000 and M_r 92 000 type IV collagenases plus an M_r 57 000 glatinase by blocking the cytoplasmic processing and packaging of the protease and completely inhibit cell attachment to matrigel, type IV collagen and plastic substrates *in vitro*. This has been shown to contribute to the reduced *in vitro* invasive ability and the establishment, growth and long-term survival of prostate tumor cells in SCID mice[13]. TXT did not, however, increase Integrin-mediated cell adhesion and cell spreading, which are attributable to microtubule depolymerization induced by microtubule disrupting agents[39].

Like other neoplasms, this pancreatic carcinoma cell line SUIT-2 is heterogeneous and consists of multiple subpopulations of cells with different invasive and metastatic properties[22]. These cells may be heterogeneous with regard to their sensitivity to chemotherapeutic agent and may contain different expressions of drug resistant phenotypes. Our previous studies have shown that the most TXT-resistant cell line in SUIT-2 and its subline (S2-007, S2-013, S2-020, S2-028) was S2-020 with strong expression of P-gp[21]. Although an *in vitro* study showed that S2-020 was also the most invasive toward Matrigel among these cell lines[22], there was no direct evidence that the expression of P-gp in this cell lines is responsible for its high invasive potential. On the contrary, it has been demonstrated that type I and IV collagenolytic activities are related to the malignancy of these cell lines[22,40].

The existence of different subpopulations in tumor increases the chance that cells with a high probability of survival will be selected when environmental conditions change. When SUIT-2 cell lines were treated with TXT, the highly invasive S2-020 with positive P-gp expression would be selected. However, the morphology of S2/TXT is totally different from that of S2-020 and *in vitro* invasive ability and morphology are similar to that of SUIT-2. Therefore, the expression of P-gp in S2/TXT was not due to the selection effect of TXT but to creation of TXT-resistant clone caused by potential of genetic mutation of TXT. In addition to the development of MDR, exposure tumor cells to some chemotherapeutic agents can cause activation or inactivation of genes with altered behavioral phenotype[41]. There was, however, no evidence that this occurred in this specific cell line treated with TXT, as shown by analysis of a number of metastasis-related genes. Thus, TXT appears capable of inducing the expression of P-gp without changing the intrinsic malignant characteristics of SUIT-2 cells.

In contrast to the study by Belotti *et al*, which show the PTX inhibits the motility of parental and PTX resistant cells equally[11], TXT did not inhibit the invasiveness of the TXT-resistant cell SUIT-2. This difference might be related to the mechanisms of taxane-resistance. Although the effect of PTX on cell motility and invasiveness is independent of

its effect on cell proliferation[11], these effects might still be based on the intracellular concentration of the drug. Studies have shown that the tumor cells can present TXT-resistance with normal intracellular concentration of TXT. This kind of resistance usually is mediated by changes of beta tubulin isotypes[31]. In such cases, the normal intracellular drug concentration in the TXT-resistance cell can be reached as in the TXT sensitive cells. In the S2/TXT cell line, which expresses active drug transporter pump P-gp, the intracellular concentration of TXT might not be high enough to act on microtubule and to inhibit cell invasion. It indicates that the resistance to the cytotoxic activity of TXT also confers resistance to the anti-invasion of the drug in the cell line SUIT-2. Therefore, the collateral anti-tumor effects of chemotherapeutic agents, as proposed by other studies[13], will disappear in this TXT-resistant cell line when treated with taxotere.

The relationship between P-gp expression and tumor malignancy is controversial. Although some studies have found that the expression of P-gp is casually related to a less aggressive pheno-type[4,42,43], in numerous cases, metastases exhibit a multidrug resistant pattern. Clinical and *in vitro* studies have also provided correlative results concerning the changes of metastatic potential following acquisition of the MDR phenotype[2,3,8,44]. To date, there has been no direct evidence showing that P-gp is involved intumor malignant potential. The invasive ability in the P-gp-positive S2/TXT cell line was not different from its P-gp-negative parental cell line SUIT-2, suggesting that TXT has no direct effect on increasing tumor malignant potential related to the induction of P-gp expression in this PAC cell line. The higher malignant potential associated with positive P-gp expression found in the other studies might be due to other invasive or metastatic related gene expressed simultaneously with P-gp.

From this study, we conclude that P-gp is primarily responsible for TXT resistance in PAC cell lines SUIT-2. However, expression of P-gp does not confer a more malignant invasive potential in this cell line with TXT resistance. Furthermore, TXT can inhibit the invasive ability of drug-sensitive cells but not drug-resistant cells.

Hobsley M, Tovey FI. *Helicobacter pylori*: the primary cause of duodenal ulceration or a secondary infection? ***World J Gastroenterol***, 2001;7(2): 149-151

INTRODUCTION

It is generally accepted that *Helicobacter pylori (H. pylori)* infection has a role in duodenal ulceration. Eradication of *H. pylori* accelerates healing compared with placebo in the absence of control of gastric secretion and reduces ulcer recurrence. There is increasing evidence, however, that it may not be the primary cause of duodenal ulceration, but that it may be a secondary factor in a number of cases. This possibility is supported by four sets of observations:

1 *Geographical distribution*

In India and China there is a difference in prevalence of duodenal ulceration between the rice eating areas of the south and the drier wheat and millet eating areas of the north despite a similar high prevalence of *H. pylori* infection[1-3]. There is a similar situation along the West Coast of Africa. In the coastal area in the south where there is a diet of yams, sweet potato, manioc, plantains, rice and some white flour, the prevalence of duodenal ulceration is higher than in the northern savannah regions where much of the diet is millet. Both areas have a similar prevalence of *H. pylori* infection[4,5]. Again in Fiji the Indian population adhering to their traditional diet has twice the incidence of duodenal ulceration compared to the Fijian population despite similar *H. pylori* infection rates[6,7].

2 *H. pylori-negative duodenal ulceration*

There are many reports of *H. pylori*-negative duodenal ulceration unrelated to non-steroidal anti-inflammatory drugs (NSAIDs) varying in prevalence between 14% and 72% (Table 1)[8-26]. The figures from more developed countries suggest that *H. pylori*-negative duodenal ulceration occurs more frequently in areas where the overall prevalence of *H. pylori* infection in the community is low[20,27]. A paper from Greater Rochester, New York[11], reports a 48% prevalence of *H. pylori*-negative in white patients and 15% in non-white, with an overall prevalence of 39%. Parsonnet[28] has conducted a world-wide survey of reports and gives a figure of 40% *H. pylori* negative duodenal ulcers. Kurata *et al*[27] calculated that only between 48% and 64% of peptic ulcers are *H. pylori*-positive.

3 *Early cases of duodenal ulceration may be H. pylori-negative*

Dres Pest[29] from Argentina found a 78% incidence of *H. pylori* infection in patients with a history of chronic ulceration and only 41% in patients with a short history. He suggests that many patients with a short history may be free from *H. pylori* infection.

4 Recurrence after eradication

Laine *et al*[30] from N. America have done a meta-analysis of seven trials subjected to strict criteria and report a recurrent duodenal ulcer rate of 20% within 6 months of *H. pylori* eradication in patients not on NSAIDs. Two other reports[31,32] excluding NSAIDs give figures of a 6% endoscopic recurrence within 3 years and of 18.9% clinical relapse within 7 years after eradication in patients remaining *H. pylori*negative. There are many other reports of recurrent ulceration in patients remaining *H. pylori* negative after eradication in which NSAID users have not been excluded.

DISCUSSION

The above findings strongly suggest that *H. pylori* infection is not a prerequisite for duodenal ulceration and that *H. pylori* infection when it occurs may be only a secondary factor.

It has been suggested that the differences mentioned in the geographical distribution of duodenal ulcer may be due to the higher prevalence of Cag A and Vac A virulent strains of *H. pylori* in these areas, but there is no evidence to support this[33-39].

The long held concept that duodenal ulceration is the result of a combination of increased acid output together with factors such as reduced bicarbonate in the duodenum reducing the ability of the duodenum to cope with the presenting acid level still remains valid. There may be other factors-smoking, genetic or dietary. Smoking has a chronic effect of increasing the ability to secrete acid[40]. There is convincing evidence that the differences in geographical or ethnic distribution of duodenal ulceration may be diet related[41,42]. Duodenal ulceration is less common in areas where unrefined wheat, certain pulses and millets form the staple diet and more common in areas where rice, refined maize or wheat flour, yams, manioc, plantains or sweet potatoes are the staple foods. Experiments in our laboratory on animal peptic ulcer models have confirmed the protective action against ulceration of the lipids present in certain food from areas of low duodenal ulcer prevalence and have shown that stored milled white rice and its oil are ulcerogenic[43-46]. There are several reports[47-62] showing the protective effect of certain dietary essential fatty acids, phospholipids and phytosterols against peptic ulceration in several experimental animal models.

In conclusion, the findings suggest that duodenal ulceration does occur independently of *H. pylori* infection and that *H. pylori* infection which may be coincidental or be acquired subsequently contributes to the chronicity of the ulceration. Subsequent infection is more likely to occur in areas where the prevalence of *H. pylori* infection is high. Treatment reducing acid secretion and raising the pH may contribute to *H. pylori* infection in ulcer patients.

This is presented as a paper for discussion and it is hoped that readers will respond with their points of view in the correspondence section of the journal.

INTRODUCTION

Hepatic encephalopathy (HE) is a frequent complication of chronic liver disease. It is defined as a characteristic functional and reversible alteration of the mental state, due to impaired liver function and/or increased portosystemic shunting.

In the brain of HE patients, neurons appear morphologically normal, but astrocytes show signs of Alzheimer type II degeneration, i.e. nuclear enlargement, peripheral margination of chromatin and prominent nucleoli. Ammonia is generally considered to play a central role in the pathophysiology of HE[1]. In HE, selective alterations of blood-brain barrier permeability, changes in cerebral energy metabolism, an increased GABA-ergic tone, changes in neurotransmitter systems and alterations of gene expression. e.g. of monoamine oxidase, peripheral-type benzodiazepine receptor (PTBR) and neuronal NO synthase are found (reviewed in[1-10]. The reversibility of HE symptoms and the reason for its precipitation by a variety of different factors has not been sufficiently explained yet (Table 1). Central insights into the etiology of HE have arisen from recent *in vitro* work with astrocytes. Astrocytes are important constituents of the blood-brain barrier, and uptake of substances from the blood into the brain is achieved by transastrocytic transport. Astrocytes communicate directly with neurons[11], regulate neurotransmitter processing and ionic milieu and provide substrates for neurons[12,13]. In brain, astrocytes are the only cells containing glutamine synthetase[14] and represent the major site of cerebral ammonia detoxification. Upon exposure to ammonia, cultured astrocytes develop Alzheimer type II changes. These findings prompted the idea that HE is a disorder of glial cells with a consecutive neuronal dysfunction[7,15,16].

Although the symptoms of HE in *acute or chronic* liver failure are different, there are good reasons to assume that the pathophysiology of both conditions is similar, but may involve different kinetics. In acute liver failure, astrocytes swell and brain edema develops[17]. HE in chronic liver disease is not accompanied by clinical signs of cerebral edema, but evidence for increased cell hydration has been given, as described later. A disturbance of astrocyte hydration is apparently a major pathophysiologic event in both forms.

MRS FINDINGS IN HE

MR-spectroscopy (H-MRS) studies in human brain initiated the idea that a disturbance of astrocyte cell volume homeostasis could be decisive for development of chronic HE[18-20]. ^{1}H-MRS can be used to study metabolic abnormalities in the human brain *in vivo* and allows a myo-inositol signal to be picked up, which represents an osmosensitive myo-inositol pool[18] of predominantly glial origin[21]. Myo-inositol is an organic osmolyte in astrocytes[22-24]. Such organic osmolytes play a decisive role in cell volume regulation: upon shrinkage, they accumulate inside the cells, in response to cell swelling they can be released from the cells via osmoregulated membrane channels[25,26]. Consistently, *in vivo* ^{1}H-MRS studies on the brain from cirrhotic patients with HE show a depletion of myo-inositol which is accompanied by an increase in the glutamine/glutamate signal[18,19,27-30], as shown in Figure 1. On the other hand, in cirrhotic patients, the implantation of transjugular intrahepatic-stent-shunt (TIPS) may lead to an aggravation of ^{1}H-MRS changes (Figure 2)[18] and a normalization of MRS findings after transplantation has been described[30]. *In vitro* studies from the rat have shown similar alterations after portocaval shunting[28]. There is a good correlation between the extent of these ^{1}H-MRS changes and the clinical severity of HE[18,19,29,30]. An increased glutamine/glutamate signal, together with adecrease of inositol signal, is observed in patients after TIPS implantation[18], as depicted in Figure 2. A high sensitivity and specificity of the myo-inositol signal for the diagnosis of HE cirrhotics has been reported[29,30], but these changes have also been reported in asymptomatic stages of hepatic encephalopathy[18,19,29,30].

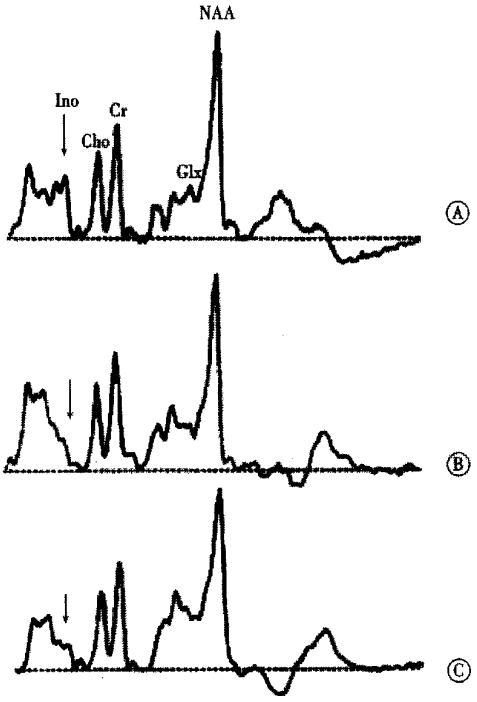

Figure 1 Parietal ^{1}H-MNR spectra from (A) a healthy person, patients with posthepatitic cirrhosis and latent (subclinical) HE (B) and manifest grade I-II HE (C). An increase in the glutamine/glutamate signal (Glx) and a decrease of the inositol signal (Ino) is observed. Further abbreviations: Cho, choline; Cr, creatine; N-acetylaspartate (NAA)[18].

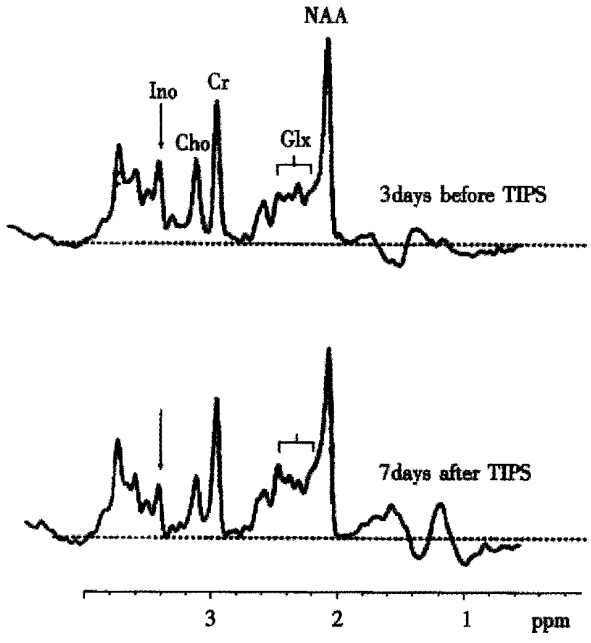

Figure 2 Parietal ^{1}H-MNR spectra from a 47-year-old patient with alcoholic cirrhosis 3 days before and 7 days after implantation of TIPS, showing an increased Glx signal and a decreased Ino signal. For abbreviations see Figure 1[18].

IMPAIRED CELL VOLUME HOMEOSTASIS IN HE AND FUNCTIONAL CONSEQUENCES FOR ASTROCYTES

The MRS findings in HE make an impaired cell volume homeostasis in brain likely and suggest that cellular non-cytotoxic edema[31] is present in hepatic encephalopathy. This edema is the result of an osmotically active intracellular accumulation of glutamine in response to hyperammonemia and a consecutive depletion of releasable myo-inositol and probably other osmolytes. Astrocytes swell in presence of ammonia[7,32]. Ammonia induces brain edema and intracranial hypertension in the portocaval shunted rat *in vivo* in a largely methionine sulfoximine-sensitive way[33]. PET studies with ^{15}N-ammonia on human brain from encephalopathic patients showed an increased cerebral metabolic rate for ammonia, suggestive of enhanced cerebral uptake of ammonia in HE and a stimulation of glutamine synthesis[34]. Astrocyte swelling also occurs *in vitro* under the influence of hyponatremia[35,36], some neurotransmitters[35,37], TNF-α[38] and benzodiazepines[7,37]. Apart from myo-inositol, recent data suggest that other organic osmolytes, such as taurine[21,22] and α-glycerophosphorylcholine[22,39], are depleted in order to counteract astrocyte swelling in HE. Small increases in astrocyte water content, as may occur in HE, could already have important functional consequences despite the absence of clinically overt increased intracranial pressure. Cell hydration is an independent signal which regulates cell function and gene expression, reviewed in[40-43] and a variety of different osmosignalling pathways linking cell hydration and cell function have been identified [44]. Extensive work from this laboratory has described the impact of cell hydration on cell function, cytoskeleton and gene expression[45], mainly in liver. In brain, cell hydration is also considered a key trigger of cell function. Swelling of astrocytes in culture activates via phosphatidylinositol-3-kinase extracellular regulated protein kinases (Erks)[36], i.e. members of the MAP kinase family with multiple functions, elevates intracellular calcium concentrations[46] and upregulates the peripheral type benzodiazepine receptor (PBR, reviewed in[47]) at the level of agonist binding[48] and mRNA (D. Häussinger and R. Fischer, unpublished results). Further, astrocyte swelling increases the pH in endocytotic vesicles[49] in an Erk-dependent osmosignalling pathway (R. Fischer and D. Häussinger). Several key findings in HE can thus partially be explained by an increase of astrocyte hydration. The endosomal alkalinization following astrocyte swelling could affect receptor densities and neurotransmitter processing and swelling-induced changes of the activity of plasma membrane transporters may underlie the selective changes in "blood-brain barrier" permeability of HE. Cell swelling stimulates glycogen synthesis and inhibits

glycogenolysis[45,50] and the increased deposition of glycogen in astrocytes in animal models of chronic HE[7] may reside on cell swelling. Astrocyte swelling leads to an increased expression of PBR and augments the synthesis of neurosteroids, which are potent modulators of neuronal $GABA_A$ activity [7]. Thus the interaction between astrocyte swelling, PBR expression and increased neurosteroid synthesis may explain the increased $GABA_A$-ergic tone in HE[9,51].

ASTROCYTE SWELLING AS AN INTEGRATIVE SIGNAL OF HE

An increase in astrocyte hydration, i.e. a low-grade cerebral edema, is a major pathogenetic event in the development of HE and induces a profound alteration of astrocyte function[20]. Altered astrocyte function may eventually lead to a disturbance of glioneuronal communication and present as the clinical syndrome of HE. Bleeding, infection, sedatives or electrolyte imbalance may precipitate HE in the cirrhotic patient (Table 1). Apart from ammonia, an increase of astrocyte hydration is also induced by hyponatremia, benzodiazepines and cytokines. Multiple factors could thus obviously result in a common pathogenetic endpath, i.e. glial swelling with its functional consequences. The osmolyte systems for counteraction of cell swelling are intact in non-cirrhotics and the precipitating conditions are well tolerated. In cirrhosis, however, organic osmolyte depletion is observed in order to compensate for glial glutamine accumulation and further challenges of cell volume can hardly be counteracted. The ^{1}H-MRS findings in nonencephalopathic cirrhotics could represent an early stage of a largely compensated disturbance of astrocyte volume homeostasis, where only few consequences yet for astrocyte hydration and function are observed. In response to HE-precipitating factors, a dysequilibrium of astrocyte volume results and hydration-dependent alterations of glial function will become clinically apparent. This unstable situation may explain the rapid kinetics of HE episodes and why severe brain edema with fatal outcome can occasionally develop in endstage cirrhotics[52].

DIAGNOSIS AND GRADING OF HE

Usually, HE is due to extensive porto-venous collateral shunting together with a decrease in hepatic function, resulting in increased cerebral ammonia load and diminished ammonia detoxification. Fulminant hepatic failure (FHF) means acute liver failure accompanied by hepatic encephalopathy. Sometimes, HE may be the result of metastatic liver disease[53], portal vein thrombosis[54], congestive heart failure[55] or constrictive pericarditis[56]. Even in the absence of overt liver disease, portosystemic shunting can induce HE[57], reviewed in[58]. Pre-TIPS encephalopathy is an important predictor of death during follow-up after placement of TIPS[59].

The symptoms of encephalopathy in all of these circumstances are characteristic, but unspecific. They range from subtle neuropsychologic derangements to coma. The diagnosis is made be the recognition of an appropriate hepatic disorder and the presence of encephalopathy in the absence of any other likely non-hepatic causes.

Foetor hepaticus and an increased blood ammonia concentration may contribute to the diagnosis.

For study purposes, an exact quantification of HE is required and defined by the West Haven Criteria [60,61]. The PSE index comprises the mental state, asterixis, number connection test results, electroencephalography and arterial blood ammonia concentrations. Subclinical hepatic encephalopathy (SHE) can only be diagnosed by subtle neuropsychological testing[62]. Preliminary results show that hepatic retinopathy, as detected by neurophysiological testing, very sensitively reflects the degree of HE (G. Kircheis and D. H-ussinger, unpublished observation) and responds to HE therapy. At the bedside, HE grade I is characterized by desorientation, whereas grade II HE shows spontaneous or inducible asterixis. In HE grade III, the patient is somnolent, grossly desoriented and precomatose, whereas grade IV represents coma.

THERAPY OF HE

Treatment of HE focusses on the pathogenetic events present in the individual patient. The most important therapeutic approach is to identify the precipating factors (Table 1) and to treat them vigorously. The required measures for precipitating factors are: therapy of GI bleeding together with bowel cleaning by lactulose, antibiotic treatment of concurrent infection, protein restriction, parenteral nutrition by an i.v. line and discontinuation of any diuretic therapy or sedatives. In patients with deterioration of HE after TIPS implantation, a

reduction stent may sometimes be necessary[63,64]. Apart from treatment of precipitating factors, additional therapeutic measures interfere with ammonia generation/disposal. In placebo-controlled studies, conflicting data exist on the efficacy of most therapeutic substances. Administration of lactulose is considered as gold standard in the treatment of HE, even for subclinical encephalopathy[65], but the beneficial effect of lactulose has not been precisely shown versus placebo, reviewed in[66]. In a recent randomized crossover trial, plasma ammonia and nitrogen balance were significantly better on vegetable protein diet as compared to an isonitrogenousanimal protein diet[67]. Neomycin is equally effective as lactulose, but a placebo-controlled trial on neomycin showed little effectivity[68]. Intravenous ornithine aspartate has proven its effectivity[69,70]and the benefit of orally administered ornithine aspartate is currently evaluated. Most studies on oral branched-chain amino acids (BCAA) showed clinical improvement of latent or low-grade HE and of protein tolerance[71], but studies on i.v. BCAA have not led yet to definite results. Benzodiazepine receptor antagonists have been reported to be of value in HE[72,73] but, to date with only modest success in some patients. In experimental cirrhosis, zinc supplementation reduces blood ammonia and increases liver ornithine transcarbamlyase activity[74] and a positive effect of zinc supplementation has also been shown in clinically overt HE[75].

MOLECULAR PHYSIOLOGY OF HEPATOCELLULAR TRANSPORT PROTEINS

Basolateral transport systems

Na^+-dependent bile salt uptake Uptake of bile salts into the liver was first characterized in experimental models such as the isolated perfused rat liver[1], isolated hepatocyte cultures and basolateral plasma membrane vesicles[2-4]. These studies indicated that more than 80% of taurocholate uptake but less than 50% of cholate uptake into hepatocytes is sodium-dependent[5-11]. Whereas unconjugated bile salts are uncharged molecules that can traverse membranes by passive nonionic diffusion, conjugation with glycine or taurine decreases their pKa values and necessitates the presence of a specific carrier protein for hepatocellular uptake[12].

The chief uptake system for conjugated bile salts in mammalian liver was isolated by expression and molecular cloning strategies and has been called the Na + - taurocholate cotransporting polypeptide (gene symbol: SLC10A1)[13-16]. Rat Ntcp consists of 362 amino acids with an apparent molecular mass of 51 kD[17,18] and is expressed exclusively at the basolateral membrane of hepatocytes (Figure 1)[17]. Ntcp mediates sodium-dependent uptake of taurocholate and other bile salts when expressed in stably transfected COS-7, Chinese hamster ovary (CHO) and hepatoblastoma (HepG2) cells or in cRNA injected *Xenopus laevis* oocytes, with apparent Km values between 17-42 μmol/L[10,13,17,19,20]. The only non-bile salt substrates that are transported by Ntcp are selected sulfated steroid conjugates such as estrone-3-sulfate[21] and dehydroepiandrosterone sulfate (DHEAS) [20]. In human liver, NTCP represents a 349-amino acid protein[14]. NTCP is structurally related to the intestinal bile salt transporter (IBAT), that also mediates the Na^+-dependent uptake of bile salts[22]and that is expressed not only in ileum, but also in the kidney[23] and in cholangiocytes[24].

Na^+-dependent taurocholate uptake is reduced in experimental models of cholestasis such as bile duct ligation[25], endotoxinemia[26,27] and partial hepatectomy[28], is reduced in primary hepatocyte cultures[29] and is absent in various hepatoma cell lines [30,31]. These changes in hepatic Na^+ dependent bile salt uptake correlate with expression levels of Ntcp. Thus, Ntcp mRNA and protein levels are decreased in bile duct ligation[25,32], endotoxinemia[26,33] and ethinyl estradiol induced cholestasis[34]. In patients with a diagnosis of extrahepatic biliary atresia and clinical evidence of cholestasis, NTCP mRNA levels are also decreased[35].

Na^+-independent hepatic uptake of amphipathic substrates: the organic anion transporting polypeptide family (OATP) Whereas uptake of conjugated bile salts into the liver is largely a Na^+-dependent process mediated by Ntcp, numerous other endogenous and xenobiotic compounds including non-bile salt organic anions and drugs are cleared from sinusoidal blood by carrier-mediated uptake into hepatocytes. Following hepatocellular uptake, many of these compounds are biotransformed in two phases. Phase I is mediated by cytochrome P450 enzymes and prepares the drug for conjugation by creating polar groups. Phase II conjugates drugs with a glucuronate, sulfate, glycine or methyl group and represents a detoxification step. The conjugates can then be excreted into bile or urine.

Na^+-independent hepatocellular uptake of bile salts and non-bile salt amphipathic compounds cannot be attributed to the function of a single transport protein, but is mediated by a family of transport proteins called the "organic anion transporting polypeptides" (Oatps) (Figure 1). In rat hepatocytes, at least three members of the Oatp

family have been identified, called Oatp1 (Slc21a1) [36], Oatp2 (Slc21a5)[37] and Oatp4 (Slc21a10)[38]. Oatp1 is a 670 amino acid protein with an apparent molecular mass of 80 kDa that is localized at the basolateral membrane of hepatocytes[39-41] and at the apical membranes of kidney proximal tubular cells[39] and choroid plexus epithelial cells[42,43]. Many of the functional characteristics of Oatp1 indicate that it could represent the "multispecific bile acid transporter" identified in previous experimental models[3,44]. Thus, studies in numerous heterologous expression systems have shown that Oatp1 mediates the hepatocellular uptake of bile salts, bromosulphophthalein (BSP), conjugated steroids, thyroid hormones, leukotriene C_4, bilirubin monoglucuronide, ouabain, ochratoxin A, the anionic magnetic resonance imnaging agent gadoxetate (Gd-EOB-DTPA), the angiotensin-converting enzyme inhibitors enalapril and temocaprilat, the HMG-CoA reductase inhibitor pravastatin, and even oligopeptides including the thrombin inhibitor CRC-220, the endothelin antagonist BQ-123 and the opioid receptor agonists [D-penicillamine-2,5]enkephalin (DPDPE) and deltorphin II (for detailed review of the substrate specificities of Oatps/OATPs see reference[45]). The driving force for Oatp mediated substrate transport is not fully understood, although it has been shown that Oatp1 can mediate bidirectional transport of BSP[46] and anion exchange of taurocholate/HCO_3^-[47]. An important driving force for organic anion uptake via Oatp1 appears to be countertransport of reduced glutathione[48].

Oatp2 is a 661 amino acid protein with an apparent molecular mass of 92 kD at the basolateral plasma membrane of hepatocytes[41]. Oatp2 has also been detected in the retina[49], in endothelial cells of the blood brain barrier[43] and at the basolateral plasma membrane of choroid plexus epithelial cells[43]. Oatp2 is a close homologue of Oatp1 and transports bile salts, the cardiac glycosides ouabain and digoxin, and cyclic peptides[37,41]. An important difference between Oatp1 and Oatp2 is their acinar localization in the liver. Whereas Oatp1 is distributed homogeneously within the liver acinus [41,50], Oatp2 exhibits a heterogeneous lobular distribution with predominant expression in perivenous hepatocytes excluding the innermost 1-2 cell layers surrounding the central vein[41,51]. Interestingly, treatment of rats with phenobarbital, a known inducer of microsomal drug metabolizing P450 enzymes[52] and of hepatocellular ouabain, digoxin and thyroxine uptake[53-57], resulted in a significant increase in Oatp2 expression and in the appearance of positive immunofluorescence signals even in the innermost layer of perivenous hepatocytes[58].

Oatp4 (Slc21a10) can also mediate Na^+-independent uptake of bile salts in rat hepatocytes and represents a full-length isoform of the so-called "liver-specific transporter 1" or rlst-1[38,59]. Oatp4 transports numerous organic anions including taurocholate, BSP, conjugated steroids, prostaglandin E-2, leukotriene C_4, the thyroid hormones T_3 and T_4, and gadoxetate[38]. Oatp4 is 43% and 44% identical on the amino acid level with Oatp1 and Oatp2, respectively.

In human liver, at least four OATPs have been identified to date, called OATP-A (SLC21A3), OATP-B (SLC21A9), OATP-C (SLC21A6) and OATP8 (SLC21A8). OATP-C (also called OATP2 and LST-1)[60-62] and OATP8[63] are exclusively expressed at the basolateral membrane of hepatocytes and exhibit 80% mutual identity. The closest homologue expressed in rat liver is Oatp4, which is 64% and 66% identical with OATP-C and OATP8, respectively. Accordingly, the substrate specificities of human OATP-C and OATP8 and rat Oatp4 are very comparable[38,64]. Transport substrates of OATP-C include taurocholate (Km ~ 14-34 μM)[60,61], bilirubin monoglucuronide, DHEAS, estradiol-17β-glucuronide (Km~ 8 μM)[62], estrone-3-sulfate, prostaglandin E_2, thromboxane B_2, leukotriene C_4, leukotriene E_4, T_3 (Km~3 μM), T_4 (Km~3 μM)[60], pravastatin (Km~35 μM)[61] and BSP (Km~0.3 μM)[64]. OATP8 exhibits a closely overlapping substrate specificity compared with OATP-C but additionally transports the cardiac glycoside digoxin (similar to rat Oatp2) and is particularly efficient in transporting the oligopeptides BQ-123 (endothelin receptor antagonist), DPDPE (opioid receptor agonist) and cholecystokinin (Km~11 μM)[64,65].

OATP-B (SLC21A9) is also strongly expressed in human liver, with additional expression in spleen, placenta, lung, kidney, heart, ovary, small intestine and brain[64]. OATP-B is a 709 amino acid protein with an apparent molecular mass of 85 kDa that is localized at the basolateral plasma membrane of hepatocytes[64]. Compared to OATP-C and OATP8, OATP-B exhibits a limited substrate specificity for the organic anions BSP (Km~0.7 μM), estrone-3-sulfate (Km~6 μM) and DHEAS.

The fourth OATP known to be expressed in hepatocytes, albeit at relatively low levels, is OATP-A (SLC21A3)[66].Although OATP-A was originally isolated from human liver, it is predominantly expressed in human cerebral endothelial cells[67]. OATP-A is a 670 amino acid protein that transports bile salts, BSP (Km~20 μM), estrone-3-sulfate (Km~59 μM)[68], DHEAS (Km~6.6 μM)[69], the magnetic resonance imaging agent Gd-B 20790[70], the opioid receptor agonists DPDPE (Km~202 μM) and deltorphin II (Km~ 330 μM)[67], the antihistamine fexofenadine[71],

and the amphipathic organic cations APD-ajmalinium, rocuronium, N-methyl-quinine (Km~5 μM) and N-methyl-quinidine (Km~26 μM)[72]. Thus, in contrast to the preference of OATP-B, OATP-C and OATP8 for organic anions, OATP-A additionally transports amphipathic organic cations indicating that it can mediate substrate uptake into hepatocytes charge independently. Overall, the Oatp/OATP family of transporters plays a central role in hepatocellular organic anion and drug clearance.

Na^+-independent hepatic uptake of hydrophilic organic anions and organic cations: the organic ion transporter family (OAT/OCT) In addition to NTCP and OATPs, the basolateral hepatocyte membrane possesses a third family of transport proteins mediating substrate uptake, called the organic anion transporter (OAT) family[73]. This family comprises the OAT, the organic cation transporter (OCT)[74,75] and the organic cation transporter novel type (OCTN)/carnitine transporter families[73]. Whereas Oat1 is expressed only in rat kidney[76,77], Oat2 is expressed exclusively[78] and Oat3 predominantly[79] in rat liver. In human liver, only OAT2 (SLC22A7) has been isolated (Figure. 1). Oat2 mediates sodium-independent transport of α-ketoglutarate and salicylates, whereas Oat3 transports para-aminohippurate (PAH), estrone-3-sulfate, and the cationic compound cimetidine.

The first organic cation transporter, called OCT1, was cloned from rat kidney[80] and is expressed at the basolateral membrane of hepatocytes, small intestinal enterocytes and cells of the renal proximal tubule S1 segment[74]. In man, hOCT1 (SLC22A1) is expressed specifically in the liver (Figure 1) and mediates the hepatic clearance of small type I cations such as tetraethylammonium, N-methylnicotinamide, dopamine and choline[81,82]. No studies investigating the role of the OAT/OCT/OCTN transporter family in human liver disease have been performed to date.

Basolateral efflux pumps The basolateral membrane also possesses several members of the multidrug resistance protein family (MRPs) belonging to the superfamily of ATP-binding cassette (ABC) transporters (Figure 1). MRP1 (ABCC1) mediates the ATP-dependent efflux of glutathione S-conjugates[83], leukotriene C_4, steroid conjugates such as estradiol-17β-D-glucuronide and glucuronidated or sulfated bile salt conjugates[84]. MRP1 is normally expressed at very low levels in hepatocytes, but expression levels are increased in human hepatoblastoma HepG2 cells and SV40 large T antigen-immortalized human hepatocytes[85]. MRP3 (ABCC3) is expressed at the basolateral hepatocyte membrane[86] and mediates basolateral efflux of the organic anions estradiol-17β-D-glucuronide and S-(2,4-dinitrophenyl) glutathione, the anticancer drugs methotrexate and etoposide [87,88] and even of monovalent bile salts[89]. MRP5 (ABCC5) appears to be an anion transporter, however its expression level in the adult liver is very low[90]. MRP6 (ABCC6) is localized at the lateral membrane of hepatocytes and transports the cyclic pentapeptide and endothelin antagonist BQ-123[91-93]. Interestingly, mutations in the *MRP6* gene have been shown to be the cause of pseudoxanthoma elasticum[94].

Canalicular transport systems

Bile salt excretion Canalicular excretion represents the rate-limiting step in the overall secretion of bile salts from blood into bile. Whereas bile salt concentrations within the hepatocyte are in the micromolar range, canalicular bile salt concentrations are more than 1000fold higher, necessitating active transport across the canalicular hepatocyte membrane. Characterization of ATP-dependent taurocholate transport in canalicular membrane vesicles indicated the presence of a specific carrier system for monovalent bile salts[95,96], with an apparent Km for ATP-dependent taurocholate transport of ~ 2-20 μM[95-98].

The chief transport system that mediates the canalicular excretion of monovalent bile salts is the so-called "bile salt export pump" or Bsep (ABCB11), first cloned from pig[99] and subsequently from rat [100] and mouse liver[101,102]. Rat Bsep is a 1321 amino acid protein with 12 putative membrane-spanning domains, four potential -N-linked glycosylation sites, a molecular mass of ~ 160 kDa and with the structural features of the ABC-transporter superfamily[100]. The amino acid sequence is more homologous with the MDR family of transporters (~50%) than with MRPs. In membrane vesicles from transfected Sf9 insect cells, rat Bsep transports taurocholate with a Km of ~5 μM which is comparable to ATP-dependent transport in canalicular rat liver plasma membrane vesicles[100]. Bsep is expressed on the surface of canalicular microvilli as indicated by electron microscopic studies. In addition to taurocholate, rat Bsep also mediates ATP-dependent transport of glycocholate, taurochenodeoxycholate (Km ~ 2 μM) and tauroursodeoxycholate (Km ~ 4 μM).

The locus of the mouse Bsep gene on chromosome 2, band 2C1.3[101], corresponds to the locus of human BSEP on chromosome 2q24[103]. This region has been linked to the *Lith1* gene near D2Mit56 that confers genetic gallstone-susceptibility in the C57L/J mouse strain[104-106]. These mice overexpress Bsep[107] and exhibit relative hypersecretion of cholesterol into bile with subsequent cholesterol supersaturation[108]. The exact significance of overexpression of Bsep in these

mice is unclear, since it has been shown that functional ATP-dependent taurocholate transport activity in canalicular membrane vesicles is approximately 3fold lower compared to AKR/J gallstone-resistant mice, despite 3fold higher protein levels[109]. The functional decrease in canalicular bile salt excretion could be the cause of increased gallstone susceptibility in C57L/J mice.

The human *BSEP* gene locus has been identified as the positional candidate for progressive familial intrahepatic cholestasis type 2 (PFIC2), a progressive liver disease characterized by low biliary bile salt concentrations[103]. In PFIC2, BSEP is absent from the canalicular membrane and biliary bile salt concentrations are less than 1% of normal[110].

Excretion of non-bile salt organic anions The excretion of non-bile salt organic anions into bile is mediated by the canalicular multidrug resistance protein 2, MRP2[111]. MRP2 (ABCC2) has a molecular mass of 190 kD and the human protein exhibits 46% amino acid identity to human MRP1. Both rat and human MRP2 are expressed predominantly in the liver with exclusive localization in the canalicular membrane (Figure 1)[112-115]. The spectrum of organic anions transported by MRP2 is qualitatively similar to that of MRP1[84] and includes glutathione conjugates, glucuronides, leukotriene C_4 and divalent bile salts, but not monovalent bile salts[114,116]. A role for MRP2 in the canalicular excretion of reduced glutathione (GSH), a major driving force for the maintenance of bile salt-independent bile flow, has also been demonstrated[117]. Various structurally and functionally unrelated xenobiotics such as probenecid, glibenclamide, rifampicin, vinblastine, indomethacin and cyclosporin A were shown to inhibit excretion of the anionic fluorescent dye carboxy-2',7'-dichlorofluorescein (CF) by primary human hepatocytes, thus suggesting that organic anion excretion by human liver may be impaired by various drugs[118]. Mutations in the *MRP2* gene that lead to the synthesis of a truncated, non-functional protein, have been identified as the pathogenetic basis of hereditary chronic conjugated hyperbilirubinemia, discussed further below.

Phospholipid excretion The major lipid that is cosecreted into bile with cholesterol is phosphatidylcholine (PC). The constant replenishment of PC molecules from the inner to the outer hemileaflet of the canalicular membrane is mediated by the concerted action of ATP-dependent[119] and ATP-independent[120-122] PC "flippases". The ATP-dependent flippase has been identified as a class III multidrug resistance (MDR) P-glycoprotein, Mdr2 in mice and MDR3 in humans (ABCB4) (Figure 1)[123-125], a 170 kD canalicular protein. Mouse Mdr2 and human MDR3 are present in high concentrations in the canalicular membrane of hepatocytes. Mice lacking this protein are unable to secrete phosphatidylcholine (PC) into bile[123]. Conversely, in fibroblasts from transgenic mice expressing the human *MDR3* gene under a vimentin promoter, the transfer of radiolabeled PC from the inner to the outer leaflet of the plasma membrane is stimulated [124]. In addition, expression of mouse Mdr2 in secretory vesicles from the yeast mutant sec6-4, results in a time- and temperature-dependent enhancement of PC translocation to the inner leaflet of the membrane[126]. These data indicate that both mouse Mdr2 and human MDR3 function as physiological phospholipid translocators.

Copper excretion The liver is the central organ of copper homeostasis with a great capacity to store and excrete this metal. The degree of biliary copper excretion is directly proportional to the size of the hepatic copper pool, indicating that hepatocytes can sense the copper status in the cytoplasm and regulate copper excretion into bile accordingly[127]. The biliary excretion of heavy metals such as copper is an important detoxifying mechanism of the liver. Copper excretion is mediated by a copper transporting P-type ATPase called ATP7B that is expressed predominantly in the liver[128-130] (Figure 1). This 160 kD protein is localized to the trans-Golgi network[131] where it mediates the incorporation of copper into cuproenzymes such as ceruloplasmin. A truncated 140 kD isoform of ATP7B is localized to mitochondria[132], possibly explaining the abnormalities of mitochondrial morphology in Wilson's disease. Immunohistochemical studies in human liver indicate additional weak staining of ATP7B at the canalicular membrane[133]. A green fluorescent GFP-ATP7B fusion construct transfected into human hepatoma Huh7 cells localizes neither to the trans-Golgi network nor to the canalicular membrane, but to so-called late endosomes [134]. Copper incorporated into late endosomes is probably transported to lysosomes and subsequently excreted into bile by a process known as biliary lysosomal excretion[134].

Copper is presumably taken up into human hepatocytes via the copper transporters hCTR1 and hCTR2[135]. As the copper concentration of the hepatocyte increases, ATP7B redistributes from the trans-Golgi network to a cytoplasmic vesicular compartment[131] and to pericanalicular vacuoles[136] (Figure 1). After copper depletion, ATP7B returns to the trans-Golgi network. Thus copper can induce trafficking of its own transporter from the trans-Golgi network to the apical membrane, where it may mediate biliary copper excretion. Copper-induced redistribution of ATP7B may provide a mechanism to preserve copper when it is scarce and to prevent copper toxicity when levels become too high.

ROLE OF HEPATOCELLULAR TRANSPORTERS IN LIVER DISEASE

Hereditary defects of hepatocellular transporters

Progressive familial intrahepatic cholestasis Progressive familial intrahepatic cholestasis (PFIC) describes a group of autosomal-recessive disorders. The onset is usually during the first months of life, with severe and progressive intrahepatic cholestasis, proceeding to cirrhosis by the second decade. Diagnosis is based on the following criteria: ① progressive intrahepatic cholestasis and liver cell failure, after the exclusion of other causes of liver disease; ② lack of bile duct pathology (intrahepatic and extrahepatic); ③ a normal number of interlobular bile ducts[137]. Other signs and symptoms include pruritus, jaundice, hepatomegaly, wheezing and nosebleeds, cough, fat-soluble vitamin deficiency, cholelithiasis, short stature and delayed sexual development[138].

Three types of PFIC have been described[139] (Table 1). PFIC type 1 (PFIC1, Byler's disease) is caused by a mutation in the coding sequence of the *FIC*1 gene (*ATP*8*B*1, chromosome 18q 21-22)[140], that is expressed predominantly in liver and small intestine. The FIC1 gene product is a P-type ATP-ase putatively involved in the transport of phosphatidylserine and phosphatidylethanolamine from the outer to the inner leaflet of plasma cellular membranes[141]. Patients with a defective FIC1 protein encounter bouts of jaundice that later become permanent, severe pruritus, chronic watery diarrhea, high serum bile salts, but normal γ-GT and cholesterol levels in serum. Histologically, cholestasis is found with progression to cirrhosis, but without ductular proliferation.

PFIC type 2 (PFIC2, Byler syndrome) is caused by mutations in the *BSEP* gene (located on chromosome 2q24)[142] that lead to an absence of the bile salt export pump from the canalicular hepatocyte membrane[110]. Defective canalicular bile salt excretion results in an accumulation of bile salts within the hepatocyte and toxic damage. PFIC2 resembles PFIC1 clinically, biochemically and histologically, although the initial presentation is more severe with permanent jaundice from onset, and liver failure occurs more rapidly.

PFIC type 3 (PFIC3) is caused by homozygous mutations in the *MDR3* gene[143], that lead to an absence of the phospholipid export pump MDR3 from the canalicular membrane and to an absence of the major biliary phospholipid, *phosphat*-idylcholine, from bile. This results in toxic bile salt induced injury of the biliary epithelium. PFIC3 is characterized by elevated serum γ-GT levels, ductular proliferation, and an inflammatory infiltrate in the early stages which progresses to biliary cirrhosis[143,144]. Mice with a homozygous disruption of the *Mdr2* gene (which corresponds to *MDR3* in man) represent an animal model of PFIC3[123]. Overall, the analogy between the murine knockout model and human cholestatic liver disease indicates that the nonsuppurative cholangitis observed in Mdr2/MDR3 deficiency is caused by the high luminal concentration of free bile salts that are not sequestered in mixed micelles in the absence of phospholipids.

The appearance of lipoprotein X in the plasma of cholestatic mice has been attributed to the function of Mdr2. Bile duct ligation in control mice induced a dramatic increase in plasma cholesterol and phospholipid concentrations, mainly as lipoprotein X[145]. In bile duct ligated Mdr2 - / - mice, cholesterol and phospholipid concentrations were also increased but plasma fractionation revealed a complete absence of lipoprotein X. Plasma levels of cholesterol and phospholipid during cholestasis correlated very closely with the expression level of Mdr2, indicating first that the shift of hepatocellular lipid secretion from bile to plasma during cholestasis depends upon the formation of lipoprotein X, and second that the concentration of lipoprotein X is modulated by the activity of Mdr2. Thus, the elevation of serum cholesterol that is a common feature of cholestasis in man, could also be dependent upon the function of MDR3.

Benign recurrent intrahepatic cholestasis (*BRIC*) is also caused by a mutation in the *FIC*1 gene (ATP8B1) (Table 1). It is characterized by recurrent bouts of cholestasis in the adult, with symptom-free intervals lasting from months to several years. Unlike PFIC1, BRIC is not associated with progressive liver damage. Serum bile salt concentrations are elevated as the earliest markers of cholestasis. FIC1 is also expressed in the small intestine, where it appears to play a role in intestinal bile salt absorption. It is of interest that in non-symptomatic BRIC patients, fecal loss of bile salts due to intestinal malabsorption is increased[146].

Dubin-Johnson syndrome The Dubin-Johnson syndrome is an autosomal recessive disorder that is caused by impaired biliary excretion of certain cholephilic organic anions such conjugated bilirubin (Table 1). It is characterized by conjugated hyperbilirubinemia, increased urinary excretion of coproporphyrin I, deposits of a black pigment in centrolobular hepatocytes, and prolonged BSP retention[147]. In contrast to PFIC, hepatic function is preserved. The syndrome is produced by the absence of MRP2 protein from the canalicular hepatocyte membrane[148] due to mutations of the *MRP2* gene (ABCC2)[111,147,149]. Recently, the MRP2Delta(R,M) mutation, which describes the deletion of Arg1392 and Met1393, was shown to cause disturbed maturation and trafficking of the protein from the ER to the Golgi complex and impaired sorting of this glycoprotein to the apical membrane[150]. Absent MRP2 function may be compensated for by increased expression of MRP3

at the basolateral hepatocyte membrane, as suggested by immunofluorescence studies on liver sections from a Dubin-Johnson patient[86].

Wilson's disease Wilson's disease is an autosomal recessive disorder characterized by copper accumulation in the liver, brain, kidney and cornea secondary to inadequate biliary copper excretion. Under physiologic circumstances, biliary excretion represents the sole mechanism for copper excretion, and thus affected individuals have progressive copper accumulation in the liver. When the capacity for hepatic storage is exceeded, cell death ensues with copper release into the plasma, hemolysis, and tissue deposition [127]. The age at onset ranges from 3 to 40 years, with highly variable clinical manifestations. Hepatic dysfunction is the most common initial presentation in childhood, progressing from mild elevation of serum transaminases in asymptomatic individuals to chronic active hepatitis and cirrhosis. In some cases, severe chronic liver disease or fulminant hepatic failure may be the initial manifestations. The laboratory diagnosis of Wilson's disease is confirmed by decreased serum ceruloplasmin, increased urinary copper content, and elevated hepatic copper concentration.

Wilson's disease results from the absence or dysfunction of the ATP7B gene product, a copper transporting P-type ATPase encoded on chromosome 13. Molecular genetic analysis is complex, as more than 100 unique mutations have been identified and most individuals are compound heterozygotes. A database of Wilson's disease mutations can be retrieved online at *http://www.medgen.med.ualberta.ca*. Of these mutations, the H1069Q mutation accounts for more than 40% of the alleles in affected Northern European patients, whereas the *A778L* mutation is observed in 30% of alleles of Oriental patients[127]. Expression of the *H1069Q* mutant in a copper transporter-deficient cell line reveals that this mutation causes a defect in protein folding that results in mislocalization to the ER and rapid degradation[151]. The histidine residue at amino acid position 1069 appears to be essential for trafficking from the *trans* Golgi network in response to copper[151] (Figure 1).

Acquired defects of hepatocellular transporters

Extrahepatic cholestasis Extrahepatic cholestasis is produced by an obstruction of the hepatic or common bile duct secondary to cholelithiasis, neoplasms, or sclerosing cholangitis. A major risk factor for hepatocellular injury during bile duct obstruction is the increased intracellular concentration of potentially toxic bile salts[152]. This can be partly counteracted by the decrease in Ntcp expression that occurs in bile duct ligated rats[25, 32]. The human NTCP mRNA is also downregulated in cholestasis, as evidenced in 23 patients with a diagnosis of extrahepatic biliary atresia[35]. At the canalicular pole, the expression of the bile salt export pump, Bsep, is reduced to 50% of controls on the protein and to 32% on the RNA level[153]. Bsep expression is thus preserved relatively well compared to the marked decrease in expression of the canalicular multispecific organic anion transporter Mrp2[154]. The relative preservation of Bsep expression during bile duct ligation serves to maintain the canalicular efflux of bile salts that has been demonstrated experimentally[155].

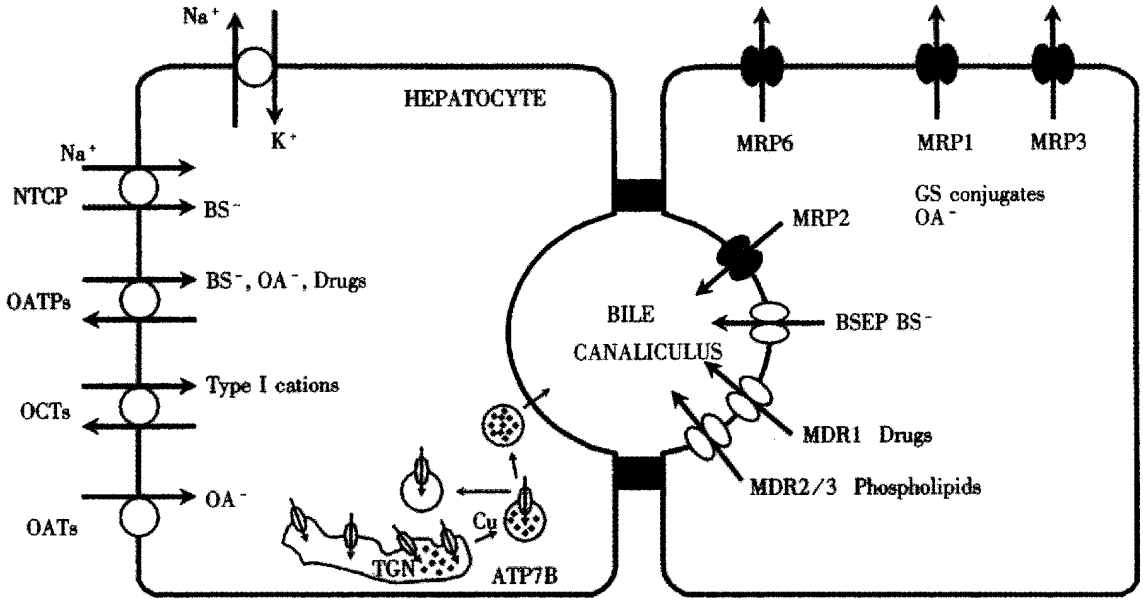

Figure 1 Hepatocellular transport proteins involved in bile salt, drug and organic substrate clearance by human liver.
Abbreviations: NTCP, Na^+-taurocholate cotransporting polypeptide; OATPs, organic anion transporting polypeptides; OCTs, organic cation transporters; OATs, organic anion transporters; ATP7B, Wilson ATPase; TGN, *trans*-Golgi network; MRP, multidrug resistance protein; MDR, multidrug resistance gene product; BSEP, bile salt export pump; BS, bile salts; OA, organic anions; GS, glutathione.

Table 1 Role of hepatocellular transport proteins in the pathogenesis of liver disease

Species	Transport protein	Gene symbol	Physiologic function	Alteration in liver disease
Basolateral transport proteins				
Rat / human	Ntcp / NTCP	SLC10A1	Na^+ dependent bile salt uptake	Decreased Ntcp expression in rat models of cholestasis[25,26,34] Decreased NTCP expression in human cholestatic liver disease[35]
Rat	Oatp1	Slc21a1	Multispecific uptake of organic anions and amphipathic compounds	Decreased Oatp1 expression in bile duct ligation[32] and in ethinyl estradiol induced cholestasis[34]
	Oatp2	Slc21a5	Multispecific uptake of organic anions and of cardiac glycosides (digoxin)	Not yet investigated
	Oatp4	Slc21a10	Multispecific uptake of organic anions and amphipathic compounds	Decreased Oatp4 expression in bile duct ligation and sepsis[59]
Human	OATP-A	SLC21A3	Multispecific uptake of organic anions and amphipathic compounds	Increased mRNA levels in primary sclerosing cholangitis (PSC)[180]
	OATP-B	SLC21A9	Multispecific uptake of organic anions and amphipathic compounds	Not yet investigated
	OATP-C	SLC21A6	Multispecific uptake of organic anions and amphipathic compounds	Decreased mRNA levels in primary sclerosing cholangitis[181] Not yet investigated
	OATP8	SLC21A8	Multispecific uptake of organic anions and amphipathic compounds	
Rat / human	rOCT1 / hOCT1	SLC22A1	Uptake of small hydrophilic organic cations (TEA, MPP, choline, dopamine)	Not yet investigated
Rat	OAT2	SLC22A7	Uptake of glutarate, salicylates, methotrexate, PGE_2 and PAH	Not yet investigated
Rat	OAT3	SLC22A8	Uptake of PAH, estrone-3-sulfate, ochratoxin A, cimetidine	Not yet investigated
Rat / human	Mrp1 / MRP1	ABCC1	Efflux of cytotoxic cations and non-bile salt organic anions	Increased expression in hepatoma cells[85] and sepsis[182]
Rat / human	Mrp3 / MRP3	ABCC3	Efflux of organic anions, bile salts and anticancer agents	Increased Mrp3 expression in Eisai Hyperbilirubinemic Rats and in bile duct ligation[91] Increased MRP3 expression in Dubin-Johnson syndrome and primary biliary cirrhosis[86]
Rat / human	Mrp6 / MRP6	ABCC6	Efflux of BQ-123	Not yet investigated
Canalicular Transport Proteins				
Mouse / rat / mBsep / Bsep / BSEP Human		ABCB11	Canalicular efflux of bile salts	Mutations in the BSEP gene and absence of the protein in patients with PFIC2, characterized by low γ-GT levels and reduced biliary bile acid excretion[103,110] *Cis*-inhibition by cholestatic drugs such as cyclosporine A[172] *Trans*-inhibition by the cholestatic estrogen metabolite estradiol-17β–D-glucuronide[172,175] Increased mBsep expression in C57L / J gallstone-susceptible mice, despite reduced bile salt excretory capacity[107,109]
Mouse / rat /	Mdr2 / Mdr2 / MDR3	ABCB4	Biliary excretion of phospholipids	Mdr2 -/- knockout mice exhibit an absence of phospholipids in bile and develop progressive liver disease with portal inflammation, bile duct proliferation and fibrosis[123] PFIC3, characterized by high γ-GT levels and absent lipoprotein X in serum, is caused by mutations in the *MDR3* gene (chromosome 7q21)[143] MDR3 mutations in PFIC3 are associated with intrahepatic cholestasis of pregnancy[171]
Rat / human	Mrp2 / MRP2	ABCC2	Canalicular excretion of organic anions	Decreased Mrp2 mRNA and protein levels in bile duct ligation and endotoxinemia[154,183] Decreased canalicular density of Mrp2 transporter molecules in endotoxinemia[183], taurolithocholate cholestasis[184] and bile duct ligation[154] Mutations in the rat *Mrp*2 gene cause hereditary conjugated hyperbilirubinemia[112] Mutations in the human *MRP*2 gene cause the Dubin-Johnson syndrome with absent protein expression[147,149] MRP2 function is inhibited by anabolic 17á-alkylated steroids[185,186] Decreased MRP2 mRNA but unchanged protein levels in PBC[187] Decreased MRP2 mRNA levels in PSC[181]
Human	FIC1	ATP8B1	Putative aminophospholipid translocator	P-type ATPase, positional candidate in genetic linkage analysis of PFIC1 (Byler's disease) and BRIC[141]
Human	AE2	SLC4A2	Canalicular Cl- / HCO_3^- exchange	Decreased AE2 expression on the luminal surface of cholangiocytes in PBC (increased expression secondary to UDCA treatment)[188]

Abbreviations: Ntcp / NTCP, rat / human Na^+-taurocholate cotransporting polypeptide; Oatp / OATP, rat / human organic anion transporting polypeptide; rOCT1 / hOCT1, rat / human organic cation transporter 1; OAT, organic anion transporter; Mrp / MRP, rat / human multidrug resistance protein; mBsep / Bsep / BSEP, mouse / rat / human bile salt export pump; Mdr / MDR, rodent / human multidrug resistance gene product; FIC1, familial intrahepatic cholestasis protein; AE2, anion exchanger 2; PSC, primary sclerosing cholangitis; PFIC, progressive familial intrahepatic cholestasis; PBC, primary biliary cirrhosis; BRIC, benign recurrent intrahepatic cholestasis; UDCA, ursodeoxycholic acid.

The molecular basis of reduced Ntcp expression in cholestasis has not been resolved. The *Ntcp* gene promoter appears to contain a response element for the farnesoid X receptor (FXR), a nuclear receptor that is responsive to bile salts[156-159]. This is suggested by recent studies in FXR knockout mice, which are unable to decrease Ntcp mRNA levels in response to bile acid feeding[160]. Since intracellular bile salt levels are elevated in bile duct ligation, decreased Ntcp expression is probably caused by suppression of Ntcp transcription via a cascade involving FXR. In the case of cholesterol 7á-hydroxylase (CYP7A1), the rate-limiting enzyme in cholesterol catabolism to bile salts, repression of gene transcription by bile salts has been extensively studied (for review, see reference[161]). Elevated intracellular bile salts activate FXR. This decreases levels of Ntcp and increases those of Bsep[160]. FXR also induces expression of the "short heterodimer partner" SHP, a nuclear receptor that suppresses bile acid synthesis by antagonizing the function of "liver receptor homolog-1" or LRH-1, an orphan receptor required for expression of CYP7A1[161]. Decreased expression of rat Oatp1 in bile duct ligation may also be mediated by FXR, since in FXR knockout mice bile acid feeding induces expression of (mouse) Oatp1[160]. These elaborate autoregulatory cascades ultimately serve to maintain hepatic cholesterol catabolism, and coordinate regulation of bile acid transporters and synthesizing enzymes is likely.

Sepsis-associated cholestasis Septic patients frequently exhibit cholestasis, the primary clinical manifestation of which is hyperbilirubinemia. In animal models of sepsis, reduced hepatic clearance of bile acids and organic anions is found[27,33,162]. The key mediators of sepsis induced cholestasis are inflammatory cytokines such as tumor necrosis factor alpha (TNF-α) and interleukin-1β. These are liberated in response to endotoxemic stimuli, which can be induced experimentally by application of bacterial lipopolysaccharide (LPS). Both Na^+ dependent basolateral and ATP-dependent canalicular bile salt transport is reduced in hepatocyte plasma membrane vesicles isolated from LPS treated rats[27,33]. Direct administration of either LPS, TNF-α or interleukin-1β causes a decrease in Ntcp mRNA levels[26]. The decrease in Ntcp expression can be explained by decreased binding activity of ① the nuclear transcription factor hepatocyte nuclear factor 1 (HNF1) and ② a heterodimeric complex consisting of the retinoic acid receptor (RARα) and the retinoid x receptor (RXRα), to the *Ntcp* gene promoter[163, 164]. In the case of the human NTCP, dependence of gene transcriptional activity upon the CCAAT/ enhancer binding protein, the α form of which is reduced in sepsis[165], has been shown[166].

The reduction in bile flow that follows LPS administration is caused primarily by an 86% decrease in GSH secretion and a 25% decrease in HCO_3^- secretion [167], two major driving forces of bile salt independent bile flow. GSH is a substrate of Mrp2[117], the mRNA and protein levels of which are also reduced following treatment of rats with LPS[154]. The mechanism of decreased Mrp2 expression appears to be similar to Ntcp, since reduced binding of the RXRα:RARα complex to the rat *Mrp2* promoter secondary to IL-1β has been shown[164].

Cholestasis of pregnancy Intrahepatic cholestasis of pregnancy (ICP) has a high prevalence in Sweden and Chile and is characterized by pruritus and biochemical cholestasis. It is the clinical correlate of estrogen induced cholestasis. The familial clustering, the higher prevalence among relatives of patients with ICP and the susceptibility to oral contraceptive-induced cholestasis in families with a history of ICP implicates genetic factors in the pathogenesis[168-170]. Mutations of the *MDR3* gene in women with PFIC type 3 seem to predispose to ICP, although not all women with the mutation develop cholestasis[143,171].

The susceptibility to ethinyl estradiol in patients with a history of ICP suggests a role for estrogen metabolites in the pathogenesis. The cholestatic estrogen metabolite estradiol-17β-D-glucuronide (E-217G) has been shown to inhibit Bsep transport function[172]. E-217G, which is an Mrp2 substrate[173], probably *trans*-inhibits Bsep function from within the canalicular lumen, since Mrp2-deficient rat strains that are unable to secrete E-217G into the bile canaliculus do not develop cholestasis[174]. A recent study has confirmed that intact Mrp2 function is a prerequisite for the development of $Es_2$17G induced cholestasis [175]. The possible role of as yet unidentified genetic polymorphisms of the *BSEP* gene in the development of estrogen-induced cholestasis is currently under investigation.

Drug-induced cholestasis The liver is the major site of drug metabolism and elimination from the human body. The importance of drugs as hepatotoxins lies not in the overall number of cases, which is relatively small, but in the severity of some reactions and in their potential reversibility provided the drug etiology is promptly recognized. The most common causative agents include NSAIDs, antibiotics, newer antihypertensive agents, H_2-receptor blockers and psychotropic drugs. Drug induced hepatotoxicity can be divided into the three categories cholestatic, hepatocellular or mixed type injury, depending upon serum biochemistry. Cholestasis with hepatitis is seen with many drugs, notably chlorpromazine, psychotropic agents, erythromycins, clavulanic acid and NSAIDs. Pure cholestasis without hepatitis is observed most

frequently with estrogens, oral contraceptive steroids and 17α-alkylated androgenic steroids and less frequently with cyclosporine A, tamoxifen, griseofulvin, glibenclamide and others. Steroid jaundice caused by methyltestosterone and other C17-alkylated anabolic steroids is dose-related but is also dependent upon the individual susceptibility of the recipient. Whereas hepatic dysfunction is seen in most recipients of steroids, jaundice in seen in only few. A minor degree of hepatic dysfunction in women taking oral contraceptives which contain C-17 ethinyl estrogen and progesterone derivatives is relatively frequent. As mentioned above, women with a personal or family history of cholestatic jaundice of pregnancy are particularly prone to develop jaundice when taking oral contraceptives.

The following alterations of hepatocellular transporter function can be held responsible for the development of drug induced cholestasis. Selective interference of a drug or its metabolite with bile secretory mechanisms has been shown for C17-alkylated ethinylated steroids, the cholestatic bile acid lithocholic acid, and experimentally for icterogenin. *Cis*-inhibition of Bsep mediated [^{3}H]-taurocholate transport by cyclosporine A, rifamycin SV, rifampicin and glibenclamide is the likely mechanism for itrahepatic cholestasis caused by these agents[172]. Parenteral administration of cyclosporin A in rats inhibits both bile salt excretion and bile salt-independent bile flow, resulting in cholestasis[176]. In addition, bile salt synthesis decreases by about 50% and the total bile acid pool is reduced in rats following orthotopic liver transplantation. Selective interference with the sinusoidal -uptake of substances such as bilirubin and bromosulphophthalein has been shown for the tuberculostatic agents rifamycin SV and rifampicin. Both are mainly eliminated by hepatic uptake, metabolism and excretion into bile. Rifampicin increases serum bile salt concentrations in 72% of patients after the first dose[177], suggesting acute interference with sinusoidal uptake of bile salts. In the Xenopus laevis-oocyte expression system, rifampicin was shown to inhibit Oatp2 but not Oatp1 mediated taurocholate uptake. Both Oatp1 and Oatp2 were inhibited by 10 μmol/L rifamycin SV, whereas significantly higher concentrations of rifamycin SV and rifampicin were required to inhibit Ntcp[178].

The nonsteroidal anti-inflammatory agent sulindac, an established hepatotoxin, may also cause cholestasis by interference with the canalicular excretion of bile salts. Sulindac has been shown to follow the "cholehepatic shunt" pathway and induce choleresis[179]. However, when coinfused with taurocholate in the isolated perfused rat liver, sulindac causes cholestasis by reducing taurocholate secretion. Sulindac appears to be secreted into the bile canaliculus in unconjugated form via a canalicular bile salt export system and is passively absorbed by the bile duct epithelium, thereby inducing a bicarbonate-rich choleresis. Due to continuous cycling within the cholehepatic shunt pathway, high local concentrations of sulindac could be reached within the hepatocyte that cause cholestasis by inhibition of canalicular bile salt efflux[180-188].

Schepke M, Sauerbruch T. Transjugular portosystemic stent shunt in treatment of liver diseases. ***World J Gastroenterol***, 2001;7(2):170-174

INTRODUCTION

More than 10 years ago, an interventional technique for the creation of an intrahepatic decompressive shunt between a branch of the portal vein and a main hepatic vein using expandable metallic stents has been introduced for the treatment of portal hypertension[1,2]. This transjugular portosystemic intrahepatic stent shunt (TIPS) functions as a side to side shunt, similarly to surgical shunts. During the last decade, TIPS has become one of the major therapeutic options for patients suffering from the most common complications of liver cirrhosis, namely recurrent intestinal bleeding and refractory ascites. At present it is probably the most frequently performed portosystemic shunt procedure. TIPS insertion does not require abdominal surgery and has a lower procedure related mortality than conventional surgical shunts. In specialized centers, the rate of procedure related deaths is not higher than 1% as compared to 3%-15% reported for surgical shunts [3,4]. Thus, critically diseased or elderly patients who are not can didates for surgical shunts may be considered for TIPS insertion. However, every portosystemic shunt procedure has the potential disadvantage that the portal liver perfusion is reduced or completely stopped which may deteriorate liver function. Therefore, TIPS has to be compared with both surgical shunts and the non-shunt treatment alternatives, namely endoscopic treatment for bleeding varices and paracentesis for the treatment of refractory ascites.

In addition to the technical expertise required to perform intrahepatic stent placement, the proper selection of patients and indications remains a crucial issue. Numerous controlled clinical trials published within the last years help us weigh the role of TIPS among the different treatment options and to select the patients, who are most likely to benefit from this procedure.

INTESTINAL BLEEDING

Bleeding from esophageal or gastric varices in patients with portal hypertension is still associated with a high mortality of about 30%-50%[5]. Prior to the first bleeding episode, medical treatment with unselective betablockers is the therapeutic standard in patients with a high bleeding risk, shunt procedures are not indicated for the primary prevention of bleeding[5]. Once a patient has survived the first episode of intestinal bleeding, the rebleeding rate without treatment is about 50%-70% within two years[6]. Thus, the application of therapeutic strategies for the prevention of rebleeding is mandatory.TIPS versus endoscopic treatment for the prevention of rebleeding from varices

The first line treatment for bleeding varices at most centers is endoscopic injection sclerotherapy or banding ligation. These procedures have proved effective in both treating the acute bleeding episode and preventing rebleeding[5]. Within the past years, numerous studies demonstrated that banding ligation is superior to sclerotherapy with respect to local side effects (treatment induced ulcers and bleeding), efficacy of variceal eradication, and rebleeding rate. Thus, endoscopic variceal ligation is considered to be the best established endoscopic treatment for patients with bleeding varices[7].

However, endoscopic procedures do not reduce portal pressure and thus, even after effective variceal eradication, recurrent varices may occur or patients may develop bleeding from extraesophageal varices. Since TIPS does reduce the portal pressure by about 50%, it was assumed to be more effective for the prevention of rebleeding. To date, eight controlled trials comparing TIPS with endoscopic therapy and two meta-analyses have been published[8-17].

Overall, according to the pooled data in the most recent meta-analysis[15], the results of the other meta-analysis published earlier are not substantially different[17]. TIPS is superior to endoscopic treatment with respect to rebleeding. The overall rebleeding rate within 13 and 33 months

was 21% in the TIPS-group as compared with 52% for endoscopic treatment. The number of patients needed to be treated by TIPS instead of endoscopic treatment to prevent one rebleeding episode was 3.3 (95% CI 2.6, 4.4). It was argued that the rebleeding rate in the endoscopically treated patients was rather high in these trials, probably because the centers that performed these trials are specialized in TIPS rather than in endoscopic treatment. Indeed, in trials comparing different endoscopic techniques for the prevention of rebleeding, the rebleeding rates for both sclerotherapy and banding ligation were lower (approximately 40%)[7]. However, since the pooled rebleeding rate for TIPS was only 21% in the published trials, and it may even be better today because of improved patients' surveillance, it can be concluded that TIPS is more effective than endoscopic treatment for the prevention of rebleeding. On the other hand, TIPS significantly increased the encephalopathy rate (31% versus 19% after endoscopic treatment). When 4-10 (95% CI) patients are treated by TIPS instead of endoscopic treatment, one more encephalopathy rate occurs. Only one trial that had been included in the meta-analysis in abstract form but has recently been published in full text demonstrated a significant reduction of mortality after TIPS[16]. In the meta-analysis, mortality was not significantly different between the TIPS and endoscopic groups. The most common cause of death among those patients treated with TIPS was liver failure, whereas variceal rebleeding was the most common cause of death in endoscopically treated patients[15]. Thus, with respect to bleeding related mortality, there was a trend in favor of TIPS, which, however, was not statistically significant[15].

In conclusion, TIPS is more effective for the prevention of rebleeding as compared to endoscopic treatment. This does, however, not translate into a reduction of mortality, most likely because TIPS may deteriorate liver function in some patients as indicated by a higher encephalopathy rate. Most centers prefer endoscopic banding ligation as first line treatment of bleeding esophageal varices and insert a TIPS when the endoscopic treatment fails (rebleeding despite endoscopic treatment). The clinical decision to change the therapeutic strategy from endoscopy to TIPS requires an exact evaluation of the patient's bleeding history and liver function. The severity of bleeding episodes, the prior endoscopic treatment and the site of bleeding have to be taken into account, e.g., one might change earlier from endoscopic treatment to TIPS in patients bleeding from gastric varices since they are more difficult to treat endoscopically and often bleed more severely than esophageal varices. Furthermore, TIPS is also effective in patients with ascites. In patients with recurrent variceal bleeding and concomitant severe ascites, it is reasonable to insert a TIPS earlier since these patients may also benefit with respect to ascites.

However, patients with a decompensated liver disease (bilirubin >85.5 μmol/L, Child's class C, a history of hepatic encephalopathy unrelated to bleeding) are likely to further deteriorate after TIPS insertion as compared to patients with a preserved liver function. These patients are not candidates for elective *TIPS*-insertion.

TIPS versus propranolol for the prevention of rebleeding

Propranolol effectively reduces portal pressure and related risk of rebleeding. Studies comparing unselective beta-blockers with TIPS for the prevention of rebleeding are lacking. Thirty to 40 percent of patients do not respond to propranolol with an adequate decrease of portal pressure. In a meta-analysis of nine randomized trials endoscopic sclerotherapy (which is inferior to ligation) has been shown to be more effective than propranolol to prevent variceal rebleeding[18] and TIPS is more effective than endoscopic treatment for this indication[15]. Thus, although there are no controlled trials on this topic, one may indirectly conclude that TIPS must be more effective for the prevention of variceal rebleeding than unselective beta-blockers.

Emergency TIPS for the treatment of uncontrolled bleeding

Uncontrolled acute variceal bleeding despite adequate first-line endoscopic treatment with or without vasoactive drugs continues to be a major clinical problem. The prognosis of these patients is poor and only the early diagnosis and treatment of an uncontrolled bleeding or an early rebleeding may improve the outcome.

Once the diagnosis of an uncontrolled bleeding despite adequate first-line treatment is made (which should be based on the Baveno criteria[19], emergency TIPS is recommended as second line treatment[20] since it is effective in both reducing portal pressure and arresting bleeding in >90% of patients[21]. However, since these critically ill patients frequently develop severe complications (e.g., sepsis, pneumonia, respiratory failure, hepatorenal syndrome) although the bleeding is controlled after TIPS, only about 50% of patients survive for more than two months after emergency TIPS insertion according to most series[21].

TIPS for bleeding extraesophageal collaterals

Some patients with portal hypertension bleed from

ectopic collaterals like duodenal or rectal varices[22]. These patients can also be effectively treated by TIPS insertion. However, atypically located varices occur more often in patients with portal hypertension due to a prehepatic obstruction like portal vein thrombosis. These patients are not candidates for TIPS, especially in patients with ectopic varices, the patency of the portal vein has to be proved prior to TIPS insertion.

TIPS for bleeding from hypertensive gastropathy

Since hypertensive gastropathy is associated with an elevated portal pressure and chronic or-*rarely*-acute bleeding from the gastric mucosa in these patients is difficult to treat with drugs or endoscopic procedures, TIPS has been evaluated for this indication. The largest recently published study found a beneficial effect of TIPS insertion with respect to rebleeding and endoscopic findings both in mild and severe hypertensive gastropathy and concerning transfusion requirements in patients chronically bleeding from severe hypertensive gastropathy[23]. This study emphasizes the importance to differentiate between patients with a real severe hypertensive gastropathy and patients with a gastric (antral) vascular ectasia (G(A)VE syndrome) because the former responds to TIPS insertion whereas the latter does not. Prior to TIPS-insertion, G(A)VE should be ruled out in these patients by endoscopy or-if necessary-by biopsy.

REFRACTORY ASCITES

The elevated portal pressure plays an important role in the pathogenesis of refractory or recurrent ascites. This clinical situation indicates a severe impairment of liver function. Thus, these patients should be evaluated for liver transplantation. If liver transplantation is not available or applicable, repeated large-volume paracentesis, implantation of a peritoneovenous shunt or TIPS insertion are the remaining treatment options.

Peritnoneovenous shunting is no longer routinely performed in most specialized centers since the occlusion and infection rate is high and some studies demonstrated an even increased death rate as compared to paracentesis[24]. Repeated paracentesis is effective and safe[24,25] but is associated with some disadvantages, e.g., the risk of bacterial peritonitis or local bleeding due to frequent punctures, adverse effects of high-dose diuretic treatment, intermittent tense ascites and risk of hepatorenal syndrome.

The majority of preliminary, uncontrolled studies that applied TIPS for the treatment of refractory ascites are promising[26-30]. A recently published, larger-scale controlled randomized trial comparing TIPS with repeated paracentesis for the treatment of refractory ascites demonstrated that TIPS is very effective for this indication[31]. Following TIPS insertion, 61% of patients had no ascites after three months as compared with 18% in the paracentesis group. In this study treatment with TIPS was independently associated with a better transplant-free survival in the mulitvariate analysis (one/two year transplant-free survival: 69%/58% in the TIPS group versus 52%/32% in the paracentesis group). In contrast, the only controlled randomized small study investigating the role of TIPS for the treatment of refractory ascites reported a significantly worse survival in the Child's class C patients treated with TIPS as compared to those treated with paracentesis[32]. However, since the mean baseline serum bilirubin was 30.8 μmol/L in the patients included in the first study[31], this discrepancy might be due to the fact that the patients in the latter study[32] had a more severe hepatic impairment. It must be stressed, that the number of patients included was relatively small in both studies[25,32] and 60[31] patients, respectively. Thus, larger studies with a higher statistical power are needed, in particular to determine the role of TIPS with respect to survival in those patients. However, it can be concluded from these two trials that TIPS is effective for the treatment of refractory ascites in patients with moderately impaired liver function (Child's class B or "good" C, serum bilirubin <51. 3 μmol/L). In patients with a more severe liver impairment TIPS may even accelerate the progression of liver failure and worsen the prognosis.

Hepatorenal syndrome

Patients with refractory ascites are at risk to develop a hepatorenal syndrome. This syndrome is characterized by renal insufficiency in patients with decompensated liver cirrhosis without preexistent kidney disease[33]. Especially the rapidly progressive form, in the literature commonly referred to as hepatorenal syndrome type I, has a very poor prognosis: 90% of patients died within a few weeks after diagnosis, the median survival was only two weeks[34]. Liver transplantation is the only definitive treatment for patients with hepatorenal syndrome, but many patients are not elegible for transplantation. Furthermore, due to the rapid course of this disease, even candidates for transplantation may die while waiting for a donor organ. A recent uncontrolled study evaluated TIPS in 41 non-transplant cirrhotic patients with hepatorenal syndrome (21 type I, 20 type II)[35]. The results were very promising. Even in the group of patients with type I hepatorenal syndrome, 50% of patients treated with TIPS were still alive

after six months as compared with 14% in the non-TIPS control group. TIPS cannot be recommended as an established treatment for hepatorenal syndrome before controlled randomized trials are published, but preliminary results indicate that TIPS is probably effective as a bridge to transplant for this serious condition.

SELECTION OF PATIENTS FOR TIPS

As it has been outlined, TIPS is an effective treartment for some severe complications of liver cirrhosis. However, like every portosystemic shunt procedure, TIPS may deteriorate liver function by reducing portal liver perfusion. Thus, most studies failed to demonstrate a survival benefit in patients treated with TIPS. Especially in patients with refractory ascites, a symptom of an at least moderate to severe hepatic impairment, selection criteria have to be evaluated very carefully. For clinical practice, the serum bilirubin has proved to be an important tool for this decision. In patients with a bilirubin >51.3 μmol/L TIPS should be inserted only in life threatening conditions like uncontrolled variceal bleeding. In the elective situation, patients with such a severe hepatic impairment may rather benefit from non-shunt treatment alternatives. In patients with a cholestatic liver disease, higher baseline bilirubin levels may be tolerable prior to TIPS insertion. Recently, two different scoring systems for the prediction of survival after TIPS based on pre-TIPS parameters have been published[36,37]. Both scoring systems contain the serum bilirubin. In addition to serum bilirubin levels, these studies identified the following risk indicators for poor prognosis after TIPS insertion. Pre-TIPS hepatic encephalopathy unrelated to bleeding, TIPS as emergency treatment for uncontrolled hemorrhage, alanin aminotransferase levels of >100U/L[36], impaired renal function, prolonged prothrombine time and viral or other non-alcoholic, non-cholestatic etiology of liver cirrhosis[37].

SUMMARY

During the last years, TIPS has definitely gained an important role within the different therapeutic options for patients with complicated liver cirrhosis. TIPS can be recommended as second-line treatment for gastroesophageal varices that bleed despite adequate endoscopic treatment and is also beneficial in many patients with refractory ascites. TIPS insertion is recommended as emergency treatment of otherwise uncontrolled variceal bleeding. Furthermore, although controlled trials are lacking, TIPS is probably also effective in more rare conditions like hepatorenal syndrome, hepatic hydrothorax and Budd-Chiari syndrome. However, TIPS insertion may also deteriorate liver function by reducing the portal perfusion and thus, patients have to be selected carefully.

As compared to surgical shunts, TIPS has the clear advantages of being less invasive and probably having a lower procedure related mortality. However, as indicated by the only randomized controlled trial directly comparing TIPS with a surgical shunt[38] (portocaval H-graft shunt), the relatively high TIPS-dysfunction rate due to thrombosis or endothelial hyperplasia remains a clinical problem requiring a careful follow-up of patients and should be addressed in the future development of this technique.

Kirsner JB. Historical origins of current IBD concepts. ***World J Gastroentero***, 2001;7(2):175-184

INTRODUCTION

The "nonspecific" inflammatory bowel diseases, ulcerative colitis and Crohn's disease, represent a group of heterogeneous inflammatory and ulcerative diseases of the small and large intestines of unknown etiology, associated with many gastrointestinal and systemic complications. Appearing initially as isolated cases in Great Britain and northern Europe during the 19th and early 20th centuries, they have steadily increased numerically and geographically and today are recognized worldwide.

ULCERATIVE COLITIS

Matthew Baillie's 1793 *Morbid Anatomy of Some of the Most Important Parts of the Human Body* strongly suggests that patients were dying from ulcerative colitis during the latter part of the 18th century[1]. The first "impact" description of "ulcerative colitis" by Samuel wilks[2] of London in 1859 concerned a 42 year old woman who died after several months of diarrhea and fever. Autopsy demonstrated a transmural ulcerative inflammation of the colon and terminal ileum, originally designated as "simple ulcerative colitis", but a century later identified as Crohn's disease[3]. The 1875 case report of Wilks and Moxon[4] describing ulceration and inflammation of the entire colon in a young woman who had succumbed to severe bloody diarrhea was an early instance of ulcerative colitis.

In 1902 R.F. Weir[5] performed an appendicostomy in a patient with ulcerative colitis to facilitate colonic irrigation with potassium permanganate for a presumed infection. J. P. Lockhart-Mummery[6] of London in 1907, aided by the then new electrically illuminated proctosigmoidoscope, discovered carcinoma of the colon in seven of 36 patients with ulcerative colitis. By 1909, 317 patients had been admitted to seven London hospitals with an inflammatory and ulcerative disease of the colon[7]. Many had died from perforation of the colon, peritonitis, hemorrhage, sepsis and pulmonary embolism. Into the 20th century similar instances of "ulcerative colitis" were being reported in Europe and in the United States. Etiologic speculation included food and pollen allergy and a psychogenic disorder. Treatment later with sulfonamides (1938) and then antibiotics, beginning with penicillin (1946), re-emphasized the possibility of a bacterial infection. The favorable responses to ACTH and adrenal steroids during the 1950s[8] stimulated interest in immunological mechanisms as discussed later.

Pathology Initial pathologic descriptions of ulcerative colitis recognized the diffuse mucosal/submucosal involvement, beginning in the rectum and rectosigmoid, and advancing proximally to involve the entire colon in a diffuse inflammation of the mucous membrane with chronic inflammatory cells, lymphocytes, plasma cells, and eosinophiles, vascular congestion, goblet cell depletion, and crypt abscesses [9]. In 1933 Buie and Bargen[10] implicated vascular "thrombotic phenomena" as the patholgical basis for ulcerative colitis and in 1954 S. Warren and S. Sommers[11] described an inflammatory necrosis of arteries, veins, or both, leading to vascular occlusions and infarction of the colon in some patients with ulcerative colitis. A 1949 review implicated an etiologic agent in the fecal stream[12], as had been proposed by P. Manson-Bahr in 1943 and earlier by B.Dawson[13] in 1909.

"Natural" and experimental colitis Veterinarians long had been aware of inflammatory diseases of the small intestine and colon in animals (dogs, cat, horse, cattle, sheep, swine, rodents), attributable to bacteria, parasites, or viruses. However, despite morphologic similarities, none duplicated human IBD. Only the colitis in cotton top tamarins (saguinus oedipus) from colombia, housed in the United States, resembled human ulcerative colitis in its clinical and histologic features and response to sulfasalazine.

Many attempts to reproduce ulcerative colitis in animals (rabbit, guinea pig, hamster, dogs, mice, rats) during the 1920s-1960s[14] included nutritional depletion (vitamin A, pantothenic acid, pyridoxine), the local application of Shiga and staphylococcal toxins to colonic explants, the vasoconstriction induced by adrenalin

intraperitoneally in dogs, the intravenous injection of staphylococcus toxin in rabbits, enzymes (collagenase, lysozyme) intrarectally and intraarterially and carrageenan orally[15]. Topically (colonic) applied compounds (4%-10%) acetic acid, trinitrobenzene sulfonic acid in 50% alcohol), orally administered drugs (indomethacin, mitomycin-c), and inhibition of fatty acid oxidation[16] caused temporary colonic injury.

CROHN'S DISEASE

In 1612 Gullielmus Fabricius Hildenus (Wilhelm Fabry)[17] (1560-1634) noted at autopsy in a boy who had died after persistent "abdominal pain" and diarrhea that "the ulcerated cecum (was) contracted and invaginated into the ileum". G.B. Morgagni[18] (1682-1771) in his 1769 "De Sedibus et Causis Morborum" described ulceration and perforation of an inflamed distal ileum and enlarged mesenteric lymph nodes in a young man of 20 with a history of diarrhea and fever culminating in death after 14 days. Similar cases were reported by Combe and Saunders[19] and by Abercrombie[20]. Abraham Colles[21] of Dublin in 1830 described Crohn's disease among children and the complicating perianal, rectovaginal and rectovesical fistulas. In 1889 Samuel Fenwick[22], in a 27 year old woman with a history of diarrhea and weight loss, at autopsy observed "adherent loops of intestine with a communication between the cecum and adherent small intestine…" The lower end of the ileum was dilated and hypertrophied and the ileocecal valve was contracted to the size of a swan's quill. Early in the 20th century, case reports from Europe documented the occurrence of a similar condition associated with lower abdominal (inflammatory) masses, assumed to be "malignant" and, at a time of limited abdominal surgery, arbitrarily dismissed as "untreatable"[23].

The classic 1913 paper by T.Kennedy Dalziel[24], including 13 patients, antedated Crohn's contribution by nearly 20 years. The first patient had experienced bouts of cramping abdominal pain and diarrhea since 1901, progressing to intestinal obstruction and death. At autopsy, the entire small intestine was chronically inflamed and the mesenteric lymph nodes were enlarged. Dalziel attributed his "chronic interstitial ileitis" to Johne's mycobacterial intestinal disease of cattle.

By 1920 American physicians were reporting instances of hyperplastic, granulomatous lesions of the intestinal tract, originally identified as "hyperplastic intestinal tuberculosis." The clinical features were similar: young patients (children, teenagers, and young adults) often operated upon for "appendicitis", symptoms of fever, abdominal cramps, diarrhea, and weight loss. The disease usually involved the terminal ileum or ileocecal area. In a 20 year old man, three bowel resections were required within 18 months for recurrent intestinal obstruction[25]. In some countries (United States, England, Sweden) but not in others (Denmark, Norway), Crohn's disease was more commonly reported among Jewish people (Ashkenazi rather than Sephardic) regardless of native birth, immigrant history or orthodoxy.

Immediately preceding the paper by Crohn *et al*[26] in 1932, F.J. Nuboer[27] of Holland and M. Golob [28] of New York (1932) and in 1934 A. D.Bissell[29] of the University of Chicago reported instances of a similar disease. In 1936 Crohn *et al*[30] described 9 patients with combined ileitis and right-sided colitis. Fone[31] of Australia, noted that 40 of 41 patients had had at least one abdominal operation. Despite early European and American descriptions of colonic involvement by Crohn's-like inflammatory lesions[32, 33], the concept was not completely accepted in America until the 1959 and 1960 reports of Lockhart-Mummery *et al*[34,35].

Etiologic speculation included bacteria, viruses, abdominal trauma and impaired vascular and lymphatic circulation. In 1943, Tallroth[36], noting many eosinophils in histologic sections, termed the disease "ileitis allergica". The concept of an endolymphangitis provided the rationale for the 1936 experiments of Reichert and Mathes[37] who injected fine sand and the sclerosing solution of 26% bismuth oxychloride with Esch. Coli into the cannulated mesenteric lymphatics of dogs, producing an edema of the ileocecal area. Chess [38] in 1950 fed dogs silica and talc; and kalima *et al*[39] (1976) injected formalin solution into the mesenteric lymphatics, producing an endolymphangitis but not regional enteritis. Van Patter *et al*[40] in 1954 suggested that "the causative agent may be found in the fecal stream" entering the lymphatic system and causing lymphatic obstruction, dilatation and lymphoid hyperplasia but this possibility again went unnoticed.

Pathology of Crohn's disease In 1938 Coffey[41] emphasized the subacute or chronic, granulomatous inflammatory process, the tendency to intestinal stenosis and the fistula formation. In 1939 G. Hadfield[42] of England noted thickening of the ileum, fistulas from bowel to abdominal wall and to the urinary bladder, the giant-cell systems in the submucosa and in regional lymph nodes and the lymphedema of the submucosa. Warren *et al*[43] described the process as: "A progressive sclerosing granulomatous lymphangitis, probably a reaction to an irritative lipid substance in the bowel content." Rappaport's[44] 1951 study of 100 cases included 85

bowel resections and 15 autopsies; in 72 instances, sections from mesenteric lymph nodes, and in 35 appendices, documenting the gross features of Crohn's disease: adherent mesentery, thickened distal small bowel, enteric fistulas, intestinal narrowing, aphthous and linear serpiginous ulcers, a cobblestone appearing mucosa, and an asymmetrical distribution of disease. The tiny slit-like ulcer, located precisely over the M cell in the epithelium overlying lymphoid follicles in Peyer's patches[45], the granulomas, the focal distribution and the lymphoid prominence conveyed as "pathogenetic" histologic features of Crohn's disease.

EPIDEMIOLOGY

An epidemiological approach to inflammatory bowel disease was not feasible until the 1950s. Melrose [46] in 1955 collected information on 1425 patients with chronic idiopathic ulcerative colitis for the years 1946 to 1950 and proposed an incidence of 10.9% per 10 000 general admissions. The rate of 6.9% for the five Scottish towns in contrast to 15. 5% for the London hospitals was early recognition of the urban: rural IBD incidence differential. Houghton *et al*[47] in 1958, on the basis of 170 patients with ulcerative colitis and 32 with ileitis in Bristol, England for 1953, 1954, and 1955, estimated annual incidence rates of 0.85 per 1000 for ulcerative colitis and 0.14 per 1000 for regional ileitis. Ustvedt[48] of Norway in 1958, for the ten year period 1945-55, noted a mean annual rate of 1.2 per 100 000 population. Acheson[49] in 1960 analyzing data for 2320 male veterans discharged from U.S. Veterans Administration hospitals with diagnoses of regional ileitis, ulcerative colitis, or nonspecific enteritis, observed a fourfold increase of Jewish patients, over a sample of all discharges. Acheson[50] also noted a twentyfold increase in the incidence of ankylosing spond ylitis among U.S. veterans with IBD.

In the first population study of 231 patients with ulcerative colitis (excluding proctitis), Iversen *et al*[51], in Copenhagen county (Denmark) for the period 1961-1966, reported a disease incidence averaging 7.3 per 100 000 per year. A population study of Crohn's disease in two counties in central Sweden for the period 1956-1967[52] revealed a mean incidence of 2. 5/100 000 for the first six years of the 12 year span and 5.0 during the second six year period, a rising trend observed subsequently in other geographic areas.

Epidemiologic studies by Mendeloff *et al*[53-55] in the Baltimore area during the 1960s documented the rising incidence of ulcerative colitis during the first half of the 20th century, exceeding Crohn's disease in a proportion of 4 to 5:1. Mendeloff characterized the IBD population as follows: ① Males and females nearly equally affected; ② patients more commonly western than oriental, much more often of northern European origin; ③ more often urban than rural dwellers; ④ more often caucasian than colored; ⑤ more common among Jews (Originating often in northern Europe and North America) than among non-Jews, but not common among Israelis; and ⑥ more common in families than expected. For the period 1960 to 1979 Calkins and Mendeloff[55], comparing their first and second analyses, noted an increase in the age adjusted rate for Crohn's disease over ulcerative colitis, for whites of both sexes and for non-white females. Subsequent epidemiologic surveys[56] documented the worldwide distribution of IBD, the initially increased and now stabilizing incidence of ulcerative colitis, the rising incidence of Crohn's disease, appearing also in formerly "lagging" countries (Brazil, South Korea) and the unexpectedly high incidence of inflammatory bowel disease (especially Crohn's disease) in such areas as the North Tees Health District of England.

The implication of foods in the etiology of Crohn's disease during the 1960s-1970s, especially concentrated sugars, margarine, and fats, never attained scientific credibility.

Smoking and IBD The relationship between ulcerative colitis and non-smoking, especially the occurrence of ulcerative colitis among former smokers, was first reported by S.M. Samuelsson[57] in a 1976 thesis (Uni versity of Upsala). Rhodes *et al*. of Cardiff, Wales[58] in a 1982 mail questionnaire confirmed the hitherto recognized infrequency of cigarette smoking in patients with ulcerative colitis and the excess of cigarette smoking in Crohn's disease: eight percent of the ulcerative colitis series were current cigarette smokers compared with 42% of the group with Crohn's disease and 44% of controls. Forty eight percent of the ulcerative colitis group had never smoked compared with 30% for Crohn's disease and 36% for controls. The negative association between ulcerative colitis and cigarette smoking, especially among ex-smokers and the reverse relationship between smoking and Crohn's disease, subsequently was reaffirmed in studies from other geographic areas. The biologically complex tobacco-ulcerative colitis relationship is not exclusive to inflammatory bowel disease and is present also in patients with Parkinson's disease[59], and Alzheimer's disease.

PSYCHOGENIC RELATIONSHIP

Scientific recognition of the physiologic responses of the body to emotional stress originated with the classic obser vations of Cabanis (1796)[60],

Pavlov[61], and Cannon[62] (early 1900s). Psychogenic factors were "formally" implicated in ulcerative colitis in the reports of Murray[63] (1930) and Sullivan[64] (1935), who had been impressed with a chronological relationship between emotional disturbances and the onset of bowel symptoms in men and women with significant emotional disturbances involving their marriage, home life and interpersonal relationships.

Psychiatric precepts during the 1930s, 1940s, and 1950s emphasized an "ulcerative colitis personality", described as "immaturity of the patient, indecisiveness, over-dependence, and inhibited interpersonal relationships," together with critical emotional events including the loss of a loved one, feelings of social rejection, and "maternal dominance". The 1947 experiments of Almy *et al*[65], demonstrating the physiological effects of emotional stress upon the normal colonic mucosa (hyperemia, vascular engorgement , increased secretion of mucus, and augmented colonic motor activity) and, more pronounced in the ulcerative colitis colon, appeared consistent with the psychogenic hypothesis.

Psychotherapy (conventional and *psycho*-analytical) was an important part of medical treatment during the 1930s-1950s. In 1954 Grace, Pinsky, and Wolff[66] reported lower operability rates, fewer serious complications, and lower mortality rates in 34 patients with ulcerative colitis treated by stress-control therapy. However, in a series of 70 patients with severe ulcerative colitis treated by psychoanalytically oriented psychotherapy for three months, no specific value was observed in preventing surgical intervention on severe recurrences. Feldman *et al*[67] found no evidence of a psychogenic causation in a controlled study of 34 patients with ulcerative colitis.

Early clinical reports implicating emotional difficulties in ulcerative colitis had originated in retrospective reviews of often incomplete hospital records and in uncontrolled clinical observations. Later controlled clinical and critical studies did not support the concept[68,69]. A. Karush *et al*[70] in 1977 summarized the prevailing psychiatric view: "We do not claim that ulcerative colitis is'caused' by unusual reactions of the mind alone, we claim only that these reactions almost always play a vital role in the interaction of the four etiological determinants, genetic endowment, constitutional vulnerability, intrapsychic processes, and the external environment." Today, the role of emotions and stress in human disease has extended to the realm of the neurosciences[71], perhaps involving neuroimmune interactions as the basis of the emotional contributions to IBD. Emotional disturbances were less emphasized in Crohn's disease. Blackburn in 1939 considered a majority of 24 patients "abnormally introspective". Grace [72] and others were impressed with the relationship between stress and the onset or relapse of Crohn's disease. On the other hand, kraft and Ardali[73] and Crockett[74] regarded the psychological difficulties as consequences of chronic, recurrent, and frustrating illness and this view predominates today.

MICROBIAL ASPECTS—ULCERATIVE COLITIS

Bacterial causes of ulcerative colitis attracted attention during the early 20th century when bacterial origins of intestinal disease were first being identified, including bacillus coli (1909), streptococci (1911), and B. Coli communis (1913). None fulfilled Koch's postulates, yet, bacterial possibilities influenced the treatment of ulcerative colitis for many years. Hurst[75] administered a "polyvalent anti-dysenteric serum" intravenously, Leusden[76] an autologous vaccine of fecal bacteria and later sulfonamides and antibiotics were used extensively.

Focal infection (e.g. dental infection) was a popular cause of disease in the United States during the 1920s and encouraged the extensive removal of teeth, gallbladders and appendices. The occurrence of ulcerative colitis in a patient following removal of an abscessed tooth encouraged J.A. Bargen[77] to pursue the problem, experimentally and clinically. In 1925, Bargen *et al*[78] reported positive cultures from the rectal ulcerations in 80% of 68% ulcerative colitis patients and the occurrence of colonic lesions in rabbits injected intravenously with broth containing diplostreptococci. Cook[79] and Mayo microbiologist Edward Rosenow, in 1931, injected rabbits with diplostr eptococci cultured from abscessed teeth of patients with active ulcerative colit is and described a "diffuse hemorrhagic infiltration" of the colon. Cook also inoculated artificial cavities created in the teeth of dogs with a diplostreptoc occus isolated from the teeth of patients with ulcerative colitis. Diarrhea developed in seven of 15 animals and colonic ulcerations were observed proctoscopically for months. Bargen then treated patients with an autologous vaccine of diplostreptococci, with limited success. Studies by M. Paulson[80] and by Mones *et al*[81] had failed to confirm the experiments of Bargen and the diplostreptococcus concept soon lost scientific credibility.

Other bacteria implicated and similarly discarded for lack of decisive evidence included: the anaerobe spherophorus necrophorus[82], bacillus Morgagni, pseudomonas aeruginosa, hemolytic and non-hemolytic Esch. Coli, and viruses (e.g. lymphopathia venereum). Serological evidence of unusual response to known viruses (influenza,

mumps, measles, herpes, Cocksackie A, B, Echo, E-B, Adenovir us) in ulcerative colitis has been negative. The occasional increased titers of cytomegalovirus (CMV) have been in malnourished, secondarily immunodeficient patients. In the 1940s, studies of a possible etiologic relationship with lymph opathia venereum[83] proved negative[84].

Bacterial viral causes—Crohn's disease The many bacteria implicated in Crohn's disease included Boeck's sarcoid , mycobacteria (Kansasii [1978], paratuberculosis), anaerobic organisms (including Eubacteria strains Me_{46}, Me_{47}, B. Vulgatus, peptostreptococcus, aerobacter aerogenes, coprococcus, bifidobacteria), Campylobacter fetus ssp. Je juni, Yersinia enterocolitica, Chlamydia trachomatis), mycobacterial variant (Mycobact-erium Linda)[85], bacterial components[86] (lipopolysaccharides, peptidoglycans, *oligo*-peptides), metabolic products (toxins, necrosins) and viral protein elements (virions, prions); none achieved etiologic status. Serological studies of Epstein Barr, Echo A, B adenovirus, rotavirus, and Norwalk virus, as in ulcerative colitis, also was negative. Today, the possible role of an antecedent exposure to measles is under investigation.

Specific infections of the terminal ileum and colon in animals have been associated with tissue changes resembling Crohn's disease, including an enterocolitis in cocker spaniels (1954), mycobacterial paratuberculosis infection of the terminal ileum in cattle (Johne's disease) (1913), a terminal ileitis in swine, and a granulomatous colitis of Boxer dogs[87]. However, none of the animal diseases duplicated Crohn's disease.

IMMUNE MECHANISMS

Edward Jenner[88] in 1801 wrote that infection can alter the body in a manner that will cause its tissues to react with increased intensity to subsequent contact with the infective agent." More than 100 years elapsed before the important role of the gastrointestinal tract in the immune homeostasis of the body was demonstrated[89]. In 1919, Besredka[90] showed that oral "immunization of rabbits protected against otherwise fatal Shiga bacillus infection." In 1922 Davies[91] documented the presence of fecal antibody in the stools of patients with bacillary dysentery before serum antibody appeared. Subsequent observations by Heremans[92] (1960), Tomasi *et al*[93] (1965), and Bienenstock, among others, identified the IgA class of immunoglobulins and their role in the emerging field of mucosal immunity of the gastrointestinal tract. In 1938 I. Gray *et al* [94] induced an allergic reaction to a specific protein in the passive ly sensitized rectal mucosa of human subjects and the rhesus monkey and in the mucosa of the ileum and the colon in man (1940)[95,96]. The concept of an altered gut mucosal immune system in the pathogenesis of inflammatory bowel disease[97] developed in the context of a temporary interest in hypersensitivity (allergy) of mucous membranes of the gastrointestinal tract to foods, pollens, and other allergens[98,99].

Immune mechanisms in the late 1940s were implicated in various diseases of unknown etiology (e.g. rheumatoid arthritis). Several clinical events during the 1930 s and 1940s suggested to me the potential involvement of immune mechanisms in ulcerative colitis[100]. These included the abrupt onset of severe ulce rative colitis in a young woman who, with many others, had developed acute food poisoning at a family picnic in New York state; everyone recovered within 24 to 48 hours except for the patient, who developed ulcerative colitis from which she died several years later; the association of ulcerative colitis with other immune diseases (e.g. autoimmune hemolytic anemia); the ulcerative colitis developing years later in individuals who had experienced an acute amebic dysentery (1933-1934), the familial occurrences of inflammatory bowel disease, and the beneficial therapeutic effects of ACTH and the adrenal corticosteroids.

The immunologic resources and responses of the gastrointestinal tract, despite earlier observations, had not been fully appreciated. Kirsner and Palmer[101] wrote in 1954: "…Perhaps future studies should include the concept of vulnerability of the host, a person more susceptible to ulcerative colitis because of tissue hyper-reactivity." In 1956, utilizing the 1920 Auer [102] principle of local autosensitization to foreign protein, Kirsner and Elchlepp[103] produced immune complexes to crystalline egg albumin in rabbits and localized the complexes to the distal bowel via the rectal instillation of a non-inflammatory solution of very dilute formalin. An ulcerative colitis promptly developed in the same areas of the left colon demonstrated immunologically to contain the immune complexes and nowhere else. The Auer-Kirsner phenomenon was reproduced in 1963 by Callahan *et al*[104]. In colon-sensitized inbred mice. Kirsner and Goldgraber, inducing the cla ssic Arthus and the Shwartzman reactions in the rabbit colon, in 1958-1959 reconfirmed the immunologic responsiveness of the bowel.

Studies by Kirsner*et al*[105], O. Broberger *et al*[106] and by Bernier *et al*[107] had demonstrated heterogeneous hemaggluti nating and precipitating "antibodies" reacting with antigens of human colon mucosa in the sera of children and adult patients

with ulcerative colitis. Shorter[108] (1972), in recognition of the infant's more permeable in testine and immature intestinal defenses permitting the entry of bacteria and other antigens into the bowel, suggested an early "priming" of the gut mucosal immune system as "preparing" the bowel for the later development of an inflammatory bowel disease; a sequence of events similar to the earlier instances of food poisoning. Immunological interest in IBD increased and by the 1960s focused upon "autoimmunity", intestinal antigens, anti-colon anti bodies, abnormal serum immunoglobulins and an experimental immune colitis. The methodology was crude; the "antigens" and "antibodies" were inadequately characterized and a relationship to IBD was never established.

Though immune mechanisms are involved in IBD, immunologic studies, after approxi mately fifty years, have not yet demonstrated an antecedent vulnerability in patients or in healthy members of IBD families. Most of the immunologic phenomena described in IBD thus far, appearing and disappearing with the activity and quiescence of ulcerative colitis or Crohn's disease, represent secondary even ts, reflections of an over-active malfunctioning gut mucosal immune system. Nevertheless immunologic interest continues in the gut-associated mucosalimmune system, antigen-access M and dendritic cells of the intestinal epithelium, T cell antigen receptors and transgenic animal models[109]. Interest also is developing in the identification of antigen(s) (probably components of the intestinal flora) recognized by the serum anti-neutrophil cytoplasmic antibodies found in ulcerative colitis. The present view for ulcerative colitis emphasizes increased responsiveness of the gut muscosal immune system, involving Th1 T cells in Crohn's disease and Th2 T cells in ulcerativ e colitis in genetically vulnerable individuals. For Crohn's disease, immunological mechanisms also are involved in association with the intestinal inflammatory reaction probably involving a component of the intestinal flora.

M cell Two additionally important elements of the immune response in IBD are the intestinal (antigen access) M cell and the role of lymphokines / cytokines. The M (membranous) cell is a specialized epithelial cell characte rized by lumenal surface microfolds rather than microvilli overlying the gut- associated lymphoid tissues (also present in the colon and the appendix), which facilitates the selective uptake and transport of bacterial, viral, or food antigens from the intestinal lumen to the gut mucosal immune system. The membran ous (M) cell of the intestinal epithelium was identified in 1923 when Kumagai[110] demonstrated the uptake of ink, carmine dye, powdered erythro cytes, and living mycobacteria from the intestinal lumen into the rabbit appendi x and/or Peyer's patches, via specialized cells in the intestinal epithelium. In 1965 Schmedtje[111], studying the epithelium of the rabbit appendix, designated such cells overlying lymphoid follicles as "lympho-epithelial cells". Owen *et al*[112] (1974) coined the term M cells.

Inflammation, lymphokines, cytokines Cytokines are small to medium-sized proteins elaborated by "producer" cells responding to disease- inducing stimuli (injury or antigenic stimulation), influencing the behavior of particular target cells via specific surface receptors. Lymphokines is the arbitrary term applied to cytokines produced by cells involved in the immune system. Cytokines participate in the regulation of the immune response and help orchestrate the complex process of inflammation. The interrelationship of the immune response in IBD with the inflammatory process and the regulatory role of lymphocytes and cytokines are extremely important in understanding the nature of IBD.

Interest in the biology of inflammation and its involvement in immune reactions dates back nearly 100 years to the observations on cellular immunity (i. e. phago cytosis) by Elie Metchnikoff[113] in 1883, on humoral immunity by Paul Ehrlich[114] (1908), and in the 1930s and 1940s to the biochemical studies of inflammation by Valy Menkin[115]. McCord *et al*[116] in 1969 were the first to discover the enzyme superoxide dismutase (SOD) and proposed that the free radical is produced in mammalian systems. Babior[117] first demonstrated that activated polymorphonuclear cells produce large quantities of the superoxide anion radical. The possible role of reactive oxygen metabolites in intestinal injury or inflammation was first reported by Neil Granger *et al*[118] who demonstrated that post-ischemic microvascular injury in the small bowel could be attenuated by the intravenous administration of superoxide dismutase. M.B. Grisham *et al*[119] also suggested the possibility that immunologically-activated phagocytic leukocytes (e.g. PMNs, eosinophils, and macrophages) could be important contributors to the mucosal injury characterizing intestinal inflammation. In 1975, Gould[120] of England found increased levels of the cyclooxygenase derived prostaglandins (PGE_2) in the stools of patients with ulcerative colitis. Sharon *et al*[121] also noted elevated levels of prostagland ins in the colonic mucosa and the serum of patients with ulcerative colitis. The prostaglandins subsequently were identified as cytoprotective agents.

Interest in lymphokines/cytokines dates to the

1972 discovery of a factor produc ed by macrophages stimulating T cell responses to antigens, later designated as interleukin-1 (IL-1)[122] (perhaps known in the 1940s as endogenous pyrogen)[123] and to the discovery of interleukin-2 (IL-2) by Paetkau *et al*[124] and by Chem *et al*[125] in 1976. Sharon and Stenson demonstrated a 50-fold increase in the leukotriene LTB4 in the colonic mucosa of ulcerative colitis and postulated a pro-inflammatory role for LTB4 in both ulcerative colitis and Crohn's disease. Investigation of the important role of cytokines in the tissue reaction of ulcerative colitis and of Crohn's disease today is one of the most active research areas in IBD.

GENETIC ASPECTS OF INFLAMMATORY BOWEL DISEASE-EARLY OBSERVATIONS

The first published instances of familial IBD from the 1909 London symposium: (a) brother and sister, (b) father and sibling, and (c) father and siste r of a third patient, were considered "coincidences", and this view prevailed for more than 50 years. Reports of "familial" inflammatory bowel disease appeared in the 1960s and subsequently increased, indicating a genetic relations hip in IBD[126-129].

Ulcerative colitis In 1936 Moltke[130] described 5 fam ilies with ulcerative colitis. Sloan *et al*[131] (1950) noted 26 positive family histories among 2000 patients, kirsner and Palmer (1954) reported 6 family occurrences, and Banks, Korelitz, and Zetzel (1957), 9 families among 244 patients. Schlesinger and Platt (1958) obtained a family history of ulcerative colitis in 17% of 60 children with ulcerative colitis. An unusual sequence involved two brothers, who developed ulcerative colitis and succumbed to carcinoma of the colon within 15 years after onset of the disease[132]

Crohn's disease Crohn[133] in 1934 described regional ileitis in a brother and sister. Familial instances of regional enteritis subsequently were reported by other observers[134,135]. In the family described by Kuspira *et al*[136], six members were affected spanning three generations.

Familial patterns Familial distributions of IBD involved first-degree relatives (parent, child, or siblings) more often than second-degree or third-degree relatives (aunts, uncles, nieces, and nephews) in accord with a polygenic inheritance. In the 1963 Chicago study for ulcerative colitis, 50 of the 89 family members were brothers, sisters, and cousins, approximately the same generation as that of the probands and 11 were grandparents. For Crohn's disease, 15 of 22 family members involved brothers, sisters, and first- cousins. De Matteis[137] (1963) summarized 5 reports on ulcerative colitis comprising 20 parent-child combinations; mother and child were involved in 16 and father and child in 4. Among 32 reports on Crohn's disease involving 72 familial instances, mother and child were affected in 7 instances and father and child in 3.

The occurrence of IBD in three or more members of the same family, very strong support of a genetic relationship, included Spriggs (1934): ulcerative colitis in 2 brothers and a sister; Moltke (1936): brother, sister, and maternal aunt; B rown and Schieffley (1939): 2 sisters and 1 brother; Jackman *et al*[138] (1942): (a) mother, son, and mother's brother; (b) mother and 2 daughters with ulcerative colitis and nephew with regional enteritis; and Bacon (1958): tw in brothers and a sister.

Thayer's[139] (1972) family included a 21-year-old male with ulcerati ve colitis since the age of 8 who developed a carcinoma of the descending colon. A maternal aunt developed ulcerative colitis at the same time. One year after the death of the index patient, his brother, 2 years younger, developed ulcerative colitis and required colectomy and ileostomy. Within a year after this operation the boy's father developed ulcerative colitis and after 5 years of medical treatment, he also underwent a colectomy and ileostomy. The 8 members of the Morris family (1965) represented 3 generations, all with ulcerative colitis, 4 males and 4 females. The 7 affected members of the Ashkenazi Jewish f amily studied by Sherlock *et al* (1963) included 5 with Crohn's disease and 2 with ulcerative colitis. Seven IBD uninvolved relatives of the same family had varying degrees of deafness.

Intermingling of diseases-twins-genetic associations Ulcerative colitis was more likely to occur than Crohn's disease among the fami lies of probands with ulcerative colitis and a similar relationship held for probands with Crohn's disease. However, in approximately 25% of families, the dise ase incidence was mixed, suggesting a similar genetic susceptibility profile. The association of ulcerative colitis and Crohn's disease with genetically- mediated conditions, such as for ulcerative colitis: ankylosing spondylitis and Turner's syndrome; and for Crohn's disease: psoriasis and the Hermansky-Pudla k syndrome, added to the evidence. The survey of monozygotic twins demonstrated moderate concordance for ulcerative colitis and strong concordance for Crohn's disease; discordance was more common for ulcerative colitis than for Crohn's disease.

Early genetic surveys revealed an association between HLA-DR2 phenotype and ulcerative

colitis, between DR1, DWQW5 or B44C-W5 phenotypes with Crohn's disease, and HLA-DQB-1 genotype with Crohn's disease in children. Recent genetic linkage studies have identified gene loci in chromosomes 6 (possibly for ulcerative colitis), chromosome 16 (definitely for Crohn's disease), loci for chromosome 1 in the Chaldean patient population relocated near Detroit and a trend toward common genes for Crohn's disease and ulcerative colitis.

CONCLUDING COMMENT

The chronological events described for ulcer ative colitis and for Crohn's disease reveal diseases at least several centuri es old. The changing epidemiological patterns; the increases during the 19th century, especially in northern Europe and England, extending to the United States in the early 20th century; the prominence of ulcerative colitis during the first half and of Crohn's disease during the second half of this century; their frequency in the industrialized countries contrasting with under-developed cou ntries; their appearance in previously lagging, increasingly industrialized are as (e.g. Japan, Brazil), all are consistent with widespread environmental etiolo gic contributions (bacteria, viruses, and parasites, cytotoxic food additives, industrial, atmospheric, and water pollutants, chemicals, "stress", etc.) not exclusive to any particular geographic area or to any ethnic group, affecting genetically-vulnerable individuals in immune and genetically mediated complex tissue reactions.

The study of ulcerative colitis and Crohn's disease today involves many expandi ng scientific disciplines, including the biology of the intestinal epithelium, the molecular basis of inflammation, genetic, geographic epidemiology, molecular microbiology, intestinal immunology, molecular genetics and gastrointestinal neuro-endocrinology. The challenge for the next century will be to utilize these scientific advances in coordinated interdisciplinary research towards the ultima te understanding and control of two of the most intriguing diseases in medicine[140].

Chen QP. Enteral Nutrition and acute pancreatitis. ***World J Gastroentero***, 2001;7(2):185-192

INTRODUCTION

Acute pancreatitis (AP) is a common severe illness of the digestive tract with variable involvement of other regional tissues and/or remote organ systems[1-3]. Mild disease is associated with minimal organ dysfunction and rapid recovery, while severe disease is associated with multiple organ system failure and local complications such as necrosis, abscess, fistulas and pseudocyst formation [4-6]. Mild attacks account for 80% of hospital admissions for this condition and usually resolve in 5 to 7 days. Twenty percent of patients with severe acute pancreatitis (SAP) tend to have a more protracted hospital course with higher mortality, and are more likely to require a multidisciplinary treatment that includes Nutritional support[7-9]. Nutritional support in the patients with AP is both very critical and more complex. In the past years, parenteral Nutrition (PN) was recommended for patients with AP[10,11], but recently, significant progress has been achieved in the field of enteral Nutrition (EN)[12,13]. Clinical research has shown that early delivery of Nutrition via the gastrointestinal tract after severe injury can reduce septic morbidity in critically injured patients [14-18]. Enteral diets have been reported to decrease Gut permeability and maintain mucosal immunity and Gut-associated lymphatic tissue (GALT)[19-21]. These observations provide new insights into the use of EN. Therefore, more and more clinicians have begun to use this technique for patients with AP. This review examines metabolic alterations of AP and effects on pancreatic secreration of EN, evaluates the indications, feeding access and formulas of EN, and assesses the clinical role of EN in AP.

Department of Heptobiliary Surgery, The Affiliated Hospital of Binzhou Medical College, Binzhou 256603, Shandong Province, China
Dr. Qiang Pu Chen, graduated from Binzhou Medical College in 1983 and received his MS degree from Nantong Medical College in 1989. He is director of the Department of Heptobiliary Surgery, the Affiliated Hospital of Binzhou Medical College, and a member of the editorial board of the World Chinese Journal of Digestology. He is majoring in hepatobiliary surgery and clinical nutrition and has published 60 papers and 8 books.

METABOLIC ALTERATIONS AND AP

The metabolism of AP is very similar to sepsis, and is characterized by hyperdynamic changes, hypermetabolism, and catabolism. The hyperdynamic changes include increased cardiac output, decreased systemic vascular resistance, and an increase in oxygen consumption[22]. Hypermetabolism is seen in the majority of the patients[23] and is associated with increases in measured resting energy expenditure (REE) as high as 139% of that value predicted by the Harris-Bennedict equation (HB). Bouffard *et al* demonstrated that total energy expenditure was 1.49 times of the predicted resting energy expenditure using the Harris-Benedict equation in patients with SAP[24]. A variety of factors affect the REE from one patient to the next, or even the same patient during his or her hospital course. Sepsis N complicating pancreatitis may independently raise energy expenditure further. In one study, development of sepsis led to an increase in mean measured REE from 105% to 120% of the HBREE[23]. However, this is not a uniform finding of the hypermetabolism across the entire patient population. Dickerson *et al*[23] found that 38% of a group of pancreatitis patients were normometabolic (measured REE = HBREE±10%), and 10% were actually hypometabolic (measured REE<90% of the HBREE). With the variation of REE between patients with AP and with so many factors that can affect ultimate cumulative energy expenditure, indirect calorimetry may be useful to the clinician to measure caloric requirement accurately[23,24]. Catabolism is another important metabolic alteration in AP. Isotope techniques have been used to demonstrate that patients with SAP have a significantly higher urea production compared with controls, indicating both increased protein catabolism and diminished muscle protein synthesis. The resultant negative nitrogen balance is, therefore, a net effect of both of these changes[25]. Catabolism and proteolysis of skeletal muscle protein raises concentrations of aromatic amino acids, decreases levels of branched-chain amino acids, and accelerates ureagenesis. Nitrogen levels (from urea) in urine may increase up to 20-40 $g \cdot d^{-1}$[26]. Overall, the circulating pool of amino acids decreases to as low as 40% of normal levels. Circulating glutamine levels in the serum may drop to as low as 55% of normal levels, while levels in skeletal muscle may drop to as low as 15% of normal levels[26]

Errors in carbohydrate and fat metabolism also occur with AP, and may or may not be associated with underlying chronic pancreatitis. This may result from increased cortisol and catecholamine

secretion in the stressed state (which leads to an increase in the glucogen/insulin ratio), impaired beta-cell function, and insulin resistance. Gluconeogenesis is increased, while glucose clearance and oxidation are diminished. In AP, glucose intolerance occurs in 40%-90% of cases, and insulin is required in as many as 81% of patients. Isotope techniques have been used to demonstrate that patients with severe disease have an impaired ability to oxidize glucose compared with controls. Exogenuos glucose infusion causes almost complete suppression of gluconeogenesis from protein in normal subjects, but not in patients with AP. These changes are consistent with a state of hepatic insulin resistance, and are similar to those observed in patients with sepsis[27,28]. Micronutrient and vitamin deficiencies (such as hypocalcemia, hypomagnesmia,lower zinc levels, and thiamine and folate deficiencies), may also be present on admission or develop during hospitalization. Hypocalcemia occurs most often in as many as 25% of patients, presumably related to decreased parathyroid hormone secretion, increased stimulation of calcitonin, hypomagnesemia, and hypoalbuminemia[22-31]. The effects of increased metabolic demands are compounded by an inability or reluctance to maintain an adequate oral intake, so that patients become malnourished during the course of their illness. MalNutrition may be especially apparent in those who have an acute outbreak of chronic pancreatitis, because some patients with chronic alcoholic pancreatitis may also have suffered nutrient deficiencies.

In recent studies, the disease and its complications and metabolic changes have been associated with the release of cytokines and other mediators of inflammation, such as interleukin-1 (IL-1), IL-6, IL-8, tumor necrosis factor α (TNF-α) and platelet-activating factor[32-36]. In addition, researchers have reported activation of the complement cascade, release of oxygen-derived free radicals and nitric oxide, and generation of prostaglandin E_2 and thromboxane A_2 from the metabolism of arachidonic acid[37,38]. These cytokines and mediators may cause systemic inflammatory response syndrome (SIRS), which in turn promotes a series of metabolic alterations and multiple organ failure[39]. If prolonged and combined with starvation, these changes can lead to a rapid loss of lean body mass, associated morbidity, and death[40]. Increased intestinal permeability in animals[41-44] and humans[45], along with anassociated impaired Gut barrier function, may lead to translocation of bacteria and endotoxins from the Gut lumen into systemic circulation[46], which contributes to the release of cytokines and systemic inflammatory responses. Experimental animal work has indicated that EN may prevent bacterial translocation in AP[47].

EFFECTS OF EN ON PANCREATIC SECRETION

The key pathological mechanism of AP is autodigestion of the pancreas and peripancreatic tissues by pancreatic enzymes. Oral and nasogastric feeding increases pancreatic secretion by stimulation of the cephalic and gastric phase, and it is suggested that early oral feeding may lead to recurrence of symptoms, elevations of serum amylase and lipase, and delayed complications[48,49]. In a study of 8 patients with AP, it was found that the interdigestive secretions of the exocrine pancreas were not different, within 72 h of the onset of mild to moderate disease, from those in 26 normal controls. Based on this evidence, the authors propose early inhibition of pancreatic secretion with somatostatin in the acute phase of the illness[50]. Animal studies[51,52] show that "pancreatic rest" reduces pancreatic synthetic activity and basal proteolytic and bicarbonate secretions, but evidence from human studies is less certain. A retrospective study suggests that early oral feeding predisposes patients to major peripancreatic infections, while prolonged nasogastric suction reduces the incidence of these infections[53]. However, randomized controlled studies[54] in patients with mild to moderate AP have, failed to establish the value and efficacy of putting the pancreas to rest by avoiding exocrine secretion. The definition of the pancreatic rest is variable. There are three main fluid volumes of pancreas juice: protein enzymes, and bicarbonate, which have different functions and reactions to stimulations. Of them, protein enzyme output is thought to be responsible for the autodigestion of the gland and perpetuation of the inflammatory process. One study showed that reducing the protein enzyme output from pancreas while sitimulating fluid volume and bicarbonate output put the pancreas to rest. From the available studies, in spite of some controversies, the reduction of pancreatic secretion or "putting the pancreas to rest" is necessary when dealing with the patients with AP in clinical practice.

The issue of whether or not the EN can successfully put the pancreas to rest is considerably more complex and controversial. In an early study in dogs, Ragins *et al*[55] demonstrated that intragastric delivery of nutrients (Vivonex) caused an increase in the volume, and protein content, and bicarbonate content of pancreatic secretions compared with those in saline-infused controls. Intraduodenal feeding only increases the volume of pancreatic secretions, but does not affect protein or bicarbonate secretion. In contrast, jejunal infusion showed no increase in any of the three components of pancreatic secretion. Other studies of dogs[56,57] also show that the intraduodenal delivery of elemental diets or pure amino acid solutions significantly increases pancreatic secretions, suggesting that the amino acid content of elemental diets is responsible for the stimulatory effects. In contrast, intrajejunal administration of nutrients is not associated with a significant change in the volume, protein content, or bicarbonate content of pancreatic secretions compared with controls.

Keith[58], in a study of two patients with chronic pancreatitis, reported changes in volume and amylase output in response to the intrajejunal infusion of an elemental formula. Keith concluded that bypassing the stomach, thereby minimizing acid secretion, played an important role in keeping the pancreas at rest. In direct contrast, other studies showed stimulation of pancreatic enzyme secretion in response to jejunal feeds[59,60].

Another factor affecting pancreatic secretion is the kind of feeding formulas. A study[59] on volunteers fed either an elemental diet or a food homogenate (via a nasoenteral tube placed at the duodenojejunal flexure) indicates that the latter has a greater stimulatory effect on the secretion of pancreatic lipase and chymotrypsin than the former. The authors suggest that this difference might be related to the greater nitrogen content of the food homogenate. Grant *et al*[61] demonstrated the effect of jejunal infusion of a formula with long-chain fat in a postoperative patient with an isolated duodenal fistula. Infusion of Osmolite into the jejunum resulted in a significant increase in lipase output, but no changes in amylase, bicarbonate, or fluid volume. Infusion of either Vinonex or Criticare, which are nearly fat-free, showed no significant increase in any component of pancreatic secretion. Similarly, Cassim and Allardyce[62], using a dog model, showed that an intact protein blended diet infused into the jejunum increased volume enzyme output, while an elemental formula increased only volume and bicarbonate with no change in protein enzyme output. Bodoky *et al*[63] randomized 12 patients undergoing pylorus-preserving pancreaticoduodenectomy for chronic pancreatitis. The patients received either EN via a needle catheter feeding jejunostomy (7 patients) or PN (5 patients). A catheter placed during operation in the pancreatic duct was used to collect pancreatic secretions. The authors found that evidence of the disease was mainly apparent in the pancreatic head and that the function of the pancreatic remnant was near normal. They did not find any difference in the volume of pancreatic secretions or the content of bicarbonate, protein, chymotrypsin or protein amylase between the two groups. Recently, a study[64] compared the effects of an elemental diet with an immune-enhancing formula administered by a jejunal route on pancreatic secretions after Whipple pancreaticoduodenectomy. The authors found a small but significant increase in pancreatic enzyme and bicarbonate secretion after jejunal feeding compared with the fasting state, but there was no significant difference in pancreatic enzyme output when the effects of the elemental and immune-enhancing feeds were compared.

Summarizing available evidence from both human and animal studies, one may conclude that oral, intragastric and intraduodenal feeding produce a significant stimulation of pancreatic secretions. In contrast, intrajejunal feeding has a smaller stimulatory effect. Elemental formulas (with individual amino acids and nearly fat-free) clearly cause less stimulation than standard formula with intact protein and long-chain fat. Therefore, intrajejunal feeding is the rational route of EN for patients with AP.

EN NECESSITY AND AP

Eighty percent of patients admitted for AP exhibit mild signs of symptoms of the disease, which usually has a self-limiting hospital course and is managed by intravenous fluid resuscitation and analgesia. These patients are likely to return to an oral diet within 7 days. The remaining 20% of patients admitted with SAP tend to have a more protrated hospital course, these patients have a more prolonged gastroduodenal atony, an increased risk for complications, and require surgical operations. This latter group is more likely to require Nutritional support by the enteral and/or parenteral route. Thus, it is necessary to identify the severity of AP before recommending enteral feeding. A variety of scoring systems has been devised to determine severity of AP and may actually be more accurate than clinical assessment. The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system[65] and Ranson criteria[66,67] are two of the more useful scoring systems. Patients with a Ranson score of 2 or less or an APACHE IIscore of 9 or less are identified as having mild pancreatitis. In these cases, Nutritional support is considered unnecessary unless complications develop or the score begins to increase. In contrast, patients who score 3 or greater on the Ranson criteria scale or 10 or greater on the APACHE II scale, may be identified as having SAP and should be considered for Nutritional support particularly if the score increase in the first 48 h. The intrajejunal route of enteral feeding is the best, unless patients present with shock, massive bleeding of the gastrointestinal tract, intestinal obstruction, jejunum fistula or severe enteroparalysis.

ENTERAL ACCESS AND AP

There are three main categories of enteral access for patients with AP: ① nasojejunal tube, ② percutaneous gastrostomy/jejunostomy tube and ③ surgical jejunostomy with gastrostomy[68,69]. The choice of the route depends upon the phase of the disease and available expertise. During the early phase, resuscitation is the priority, and obtaining the access at this time must be weighed against the risk. Once the patient is believed to be stable, initial attempts at enteral feeding are probably reasonable. The first choice should be placement of a nasojejunal tube, because this technique is not invasive and easy to perform. The tube can be placed by using blind, pH, fluoroscopic and endoscopic-assisted techniques[70]. However, the endoscopic technique is a more popular method in clinical practice. One distinct advantage of endoscopic placement is that it can be performed at the bedside. An endoscopic placement method for

long nasojejunal tubes was described by Berger and Papapietro[71]. In 24 patients with AP, 28 tubes were placed using this method. In 15 patients with brain damage, traditional nasojejunal feeding tubes were placed without endoscopy. The position of both types of tubes was determined by fluoroscopy with the aid of contrast media. The results showed that the endoscopic placement method was simple and the tube was placed beyond the ligament of Treitz in all patients. No traditional tube was placed in the jejunum and contrast media filled the duodenum in all cases. The authors suggest that nasojejunal tubes can be easily placed beyond the ligament of Treitz with endoscopic aid and can be used for enteral feeding in patients with AP. Recently, Salasidis *et al*[72] introduced an air insufflation technique for placing the nasojejunal tube, reporting successful placement in 32 patients. This technique can also be used at patients' bedside[73].

Patients with gastroparesis and high nasogastric tube outputs may be good candidates for a combined gastric decompression / nasojejunal feeding tube. However, this kind of tube is more difficult to place and can be easily dislodged.

Patients who develop complications (pneumonia, ARDS) with protracted needs for enteral support may be candidates for percutaneuos enteral access. For most patients with AP, a combination of percutaneuos endoscopic gastrostomy and jejunostomy should be used for simultaneous gastric decompression and jejunal feeding[74]. The percutaneuos gastrojejunostomy can also be performed by radiologically-guided method, which has a higher success rate and fewer complications[75]. In some patients, a direct percutaneuos endoscopic jejunostomy technique[76], which allows placement of tubes directly in the jejunum with a success rate of around 85% and a minimal complications, is also a choice for enteral feeding.

Surgical jejunostomy is indicated for the patients requiring operations. There are many techniques used for jejunostomy: Witzel, Stamm, Marwedel, open gastrojejunostomy, needle catheter technique, and laparoscopy[12,77]. Among them, needle catheter jejunostomy is attractive for short-term (<4-6 wk) use. Myers JG *et al*[78] studied this technique in 2022 cases and reported a rate of 1. 55% for technique complications. For long-term use, the Witzel or Marwedel jejunostomy with 14, 16 or 18F catheters is the most (it more than 3) popular technique. One advantage of the large-bore tube is the easy administration of both enteral feedings and medications. Also, once the tube has been in place for approximately a week, it can be easily replaced should it become occluded or inadvertently dislodged[21]. No matter which kind of jejunostomy technique is used, it is necessary to perform a gastrostomy, allowing simultaneous gastric decompression and jejual feedings.

ENTERAL FORMULAS AND AP

Numerous enteral formulas are available today to meet various needs. They are generally classified as elemental (monomeric), semi-elemental (oligomeric), polymeric or specialized formulas[12]. All of these formulas contain varying concentrations of proteins, carbohydrates, and fats, depending on the patient's disease state. A number of factors such as paralytic ileus, glucose intolerance, fat intolerance with hypertriglyceridemia, and pancreatic enzyme deficiency, should be considered when selecting the enteral products for the patients with AP. In view of the metabolic features of AP, elemental diets (so-called chemically defined diets) should be considered as the first option. Although there is some variation among products, most elemental diets are lactose-free, are nearly fat-free (only 2%-3% of calories are derived from long-chain fat), and contain protein almost entirely in the form of individual amino acids. Examples include Precision HN (Sandoz, 1.3% calories as fat), Criticare HN (Mead Johnson, 3% calories as fat), and Vivonex High Nitrogen (Norwich Eaton, 0.87% calories as fat). These diets cause less stimulation of pancreatic exocrine secretion than standard formulas, and can lower pancreaticactivity, which is beneficial for treatment of the AP.

There is rational for use of a second category of formulas for patients with AP, that of seminelemental diets. One advantage of these diets is that the nutrients are more easily absorbed in the absence of digestive enzymes. An animal study on a ligated model of the pancreatic duct[79] and a human study with cystic fibrosis patients[80] have shown that protein in the form of small peptide chains may be absorbed more efficiently than individual amino acids. Although seminelemental formulas usually contain a higher percentage of fat calories than the elemental diets, only a small percentage is composed of long-chain fat. Most of the fat is in the form of medium-chain triglycerides (MCT), which can be directly absorbed across the small intestinal mucosa into the portal vein in the absence of lipase or bile salts. The enteral products such as Criticare HN (Mead Johnson, 5% of calories as fat, MCT), Pepti-2000 (Nutricia, 10% of calories as fat, MCT), and Vital HN (Ross, 11% of calories as fat, MCT) are all seminelemental formulas, and can be used effectively in clinical practice[12].

Another category of formulas is polymeric diets, which contain 50% to 55% carbohydrates, 15% to 20% intact proteins, and 30% fats. These diets are frequently used in patients with functional gastrointestinal tracts. Many polymeric diets have recently been added to the novel nutrient substrates, such as glutamine, arginine, ω-3 fatty acids, nucleotides, and fiber, which play important roles in some critically ill patients in the maintenance of mucosal integrity and immune status[12,81-83]. A recent study reported that, an average critically ill

patients who received a glutamine-enhanced enteral feed required a shorter stay in the hospital than patients who were fed a standard isocaloric isonitrogenous enteral feed[84]. The authors also documented a significant reduction in postintervention costs; the cost per survivor was 30% less in the glutamine fed group. The beneficial effects of immune-enhancing formulas have also been observed in critically ill patients[12,21,85-89]. Randomized, controlled studies reported that patients who received immune-enhancing enteral feeds containing arginine, nucleotides and ω-3 fatty acids (fish oil) after operation and trauma had a lower rate of postoperative infections and wound complications compared with patients receiving isocaloric, isonitrogenous control feeds[88,89]. Two recent meta-analyses of randomized controlled trials[86,87] comparing patients receiving standard EN with those receiving commercially available immune-enhancing feeds reported that, although immuno Nutrition has no effect on mortality rate, there is a significant reduction in infection rates, ventilator duration and length of hospital stay in these patients. At present, there are no available reports on the clinical effects of immune-enhancing diets on patients with AP. But recently, there was a case report[90] comparing the pancreatic output with respect to different feeding regimens in a patient who underwent a partial pancreatectomy for carcinoma. There was no difference in pancreatic exocrine secretion when the patient was fed jejunally with a polymeric immune-enhancing formula or supported with two different formulations of TPN. The authors suggest that jejunal feeding of polymeric immune-enhancing diet may be safe to administer patients with AP. Therefore, considering the above advandages, polymeric diets, particularly those containing glutamine, arginine, ω-3 fatty acids, nucleotides, and fiber, may be used in AP patients, but the beneficial effects require further study.

CLINICAL EXPERIENCES WITH EN

The use EN as therapy for patients with AP goes back to the 1970s when Voitk *et al*[91] demonstrated the beneficial effects of an elemental diet in 6 patients with complicated pancreatitis, reporting both positive nitrogen balance and weight gain. Since then a number of reports in the literature described successful use of enteral feeding in patients with pancreatitis without exacerbating the disease process. Most of the studies describe patients within whom the inflammatory process had peaked and begun to resolve, and the enteral feeding were used as transitional feedings.

Since the end of the 1980s, there is now renewed interest in early enteral feeding for AP. One large series[92] described the early use of EN within 48 hours of onset of AP. Among 83 patients with no evidence of ileus on admission for AP, 92% tolerated their enteral infusion well. Kudsk *et al*[93] reviewed an experience of feeding jejunostomies in 11 patients who underwent exploratory laparotomy for complications of pancreatitis. Two died, but the remaining 9 patients gradually improved on enteral feeding with none showing exacerbation of their diseases. No catheters were lost and mild diarrhoea was encountered only during the first week of therapy. This study indicates that prolonged jejunal feeding may be provided safety in patients with SAP without aggravating the disease. Parekh *et al*[94] showed similar beneficial effects of EN in 9 patients with AP in whom enteral feeding was commenced at a mean of 11 days after admission and continued for a mean of 16 days. This not only improved Nutritional status but was also accompanied by successful resolution of complications in 7 of the 9 patients. The authors suggest that stable patients who are unable to benefit from EN. Simpson *et al*[95] retrospectively reviewed nasoenteral feeding in 5 patients with acute alcoholic pancreatitis with a mean Ranson score of 1.8. None needed PN and the disease and its complications resolved in all 5. Nakad *et al*[96] described a study of early EN with SAP patients using double-lumen nasogastrojejunal tube within 60 h after admission. Severity was established by a mean Ranson score of 3.57. No patient developed a relapse, hypertriglyceridaemia or abnormalities of liver function, indicating that jejunal feeding can be used safely in SAP patients without reactivation of the inflammatory process.

Pupelis *et al*[97] reported 29 patients who had been operated on for SAP. They were randomized to receive either EN and conventional intravenous fluids postoperatively (n = 11) or conventional intravenous fluid alone (n = 18). Seventeen additional patients who had major abdominal operations for other conditions were also given EN and intravenous fluids and comprised the control group. Nutritional intake, duration of stay in the intensive care unit (ICU), hospital morbidity, mortality, and outcome were observed. Ten of the 11 patients given EN combined with conventional intravenous fluids survived, whereas 5 of the 18 given fluids alone died. The pattern of bowel transit in the fed group did not differ from that in the control group. The authors suggest that postoperative EN seems to be safe and effective in patients with SAP and may improve survival. However, another randomized, controlled study of EN *vs* conventional therapy (i.e. no Nutritional support) in patients with SAP provided no evidence of improved outcome in patients receiving Nutritional support in terms of organ dysfunction score or inflammatory markers such as antiendotoxin core antibody, IL-6, TNF receptor 1 and CRP[98]. Patients receiving enteral feeding had significantly worse abnormal intestinal permeability on the 4th day of therapy. However, this trial involved a total of only 27 patients and a median of 1.8 MJ/day was delivered over the first 4 d by EN,

which constituted 21% of daily caloric requirements. So, the results may be deliberated. Chen and Zhu[99] compared the effect of early EN and late EN. Thirty-eight patients were divided into an early group (start EN 3 to 4 days after operation) and a late group (start EN 7 days after operation). All patients received PN at first, and then were transferred to EN. The results indicated that patients tolerated the therapy well in both groups. In addition, early correction of hypoalbuminemia with more quickly improved serum albumin was observed in the group of early enteral feeding.

EN VS PN AND AP

Although there have been a number of studies comparing the clinical effects of EN and PN in postoperative, injured, burned, cancer, or critically ill patients[16-18,100-106], only three articles have been published that compare EN with PN in AP patients[107-109]. McClave *et al*[107] performed the first prospective, randomized trial comparing early EN with PN in 30 patients with mild, or acute chronic pancreatitis. EN was via nasojejunal tube and PN was via a central or peripheral line, both within 48h of admission. Efficacy was measured by the percentage of goal energy intake ($25kcal \cdot kg^{-1} \cdot d^{-1}$) achieved, days to oral diet and length of hospital stay. Although enterally fed patients lagged 1 day behind the other group in achieving energy goals, this difference disappeared by the fourth day. Mean Ranson, APACHE III and multiple organ failure scores decreased in the EN group and increased in the PN group, but these differences were not statistically significant. Patients in the latter group had significantly higher stress-induced hyperglycaemia over the first 5 days. There was a statistically insignificant trend towards earlier normalization of serum amylase, progression to oral diet, and decrease in hospital and intensive therapy unit stay in the EN group compared with the PN group. The mean cost of parenteral feeding was 4 times higher than that of enteral feeding. The authors suggest that EN for AP is not only safe and effective, but also significantly less costly than PN. Compared with PN, EN may promote more rapid resolution of the toxicity and stress response to pancreatitis. In another prospective randomized trial[108], comparing parenteral with enteral feeding in 38 consecutive patients with severe necrotizing pancreatitis, there was no statistically significant difference between the two groups with regard to intensive therapy unit support, use of antibiotics, hospital stay and number of days of Nutritional support. Nitrogen balance improved equally in both groups, but severe hyperglycaemia requiring insulin therapy was twice as frequent in the PN group compared with the EN group. Total complications and septic complications were significantly more common in the PN group, suggesting that EN should be the preferred method for Nutritional support in patients with SAP.

Windsor *et al*[109] recently published a randomized controlled trial of EN versus PN in 34 consecutive patients with AP who had a mean Glasgow score of 2 and APACHE II score of 8. After 7 d of Nutritional support, the EN group became better than the PN group with respect to CRP concentrations and APACHE II scores. Furthermore, the serum level of immunoglobulin M and endotoxin core antibodies increased in the PN group whereas it remained unchanged in the EN group. The total antioxidant capacity also fell in the former group and increased in the latter. There was a reduction in the requirement for intensive care, incidence of intra-abdominal sepsis, multiple organ failure, need for operative intervention, and mortality rate in the enterally fed group compared with the parenterally fed group. There was, however, no difference in hospital stay. The authors conclude that EN is not only feasible, but may modulate the inflammatory and sepsis response, reduce disease severity and improve clinical outcome and physiological parameters compared with PN. Erstad[110] reviewed the literature of both PN and EN in patients with AP from 1966 to 1999. The results show that the duration of AP and time to oral feedings is similar whether patients receive EN (i.e., jejunal tube feedings) or PN. Additionally, complications, length of stay, and costs are either similar or decreased with EN versus PN, suggesting that the EN rather than PN should be used to provide Nutrition to patients with AP. PN should be reserved for patients in whom nasojejunal feeding is not possible.

CONCLUSIONS

Patients with AP have a hypermetabolic and hypercatabolic state, resulting in mal Nutrition. Nutritional support for patients with AP is needed, particularly in SAP patients. Jejunal feeding is well tolerated and, unlike gastric and duodenal feeding, does not stimulate pancreatic secretions. EN by the jejunal route is feasible and safe, even in the early stage of AP. The elemental or semi-elemental formulas should usually be used. Although there is no definite evidence that EN support alters clinical outcome or the natural history in most patients with AP, at present, the beneficial effects of EN towards improving the Nutritional condition, protecting Gut barrier function, reducing translocation of bacteria and endotoxins, modulating the inflammatory and septic response, and decreasing the cost have been observed. Therefore, the EN rather than PN should be used to provide nutrional support for patients with AP. PN should be reserved for the patients in whom jejunal feeding is not possible. Furthermore, larger sample multi-center trials are needed to identifly the effects of EN on clinical outcome and the natural history in patients with AP, and the beneficial effects of formulas containing the novel nutrient substrates also require further study in the patients with AP.

Subject headings putrescine/metabolism; Caco 2 cells/ metabolism; polyamines/metabolism; biological transport

Milovic V, Turchanowa L, Stein J, Caspary WF. Transepithelial transport of putrescine across monolayers of the human intestinal epithelial cell line, Caco-2. ***World J Gastroenterol***, 2001;7(2):193-197

Abstract

AIM To study the transepithelial transport characteristics of the polyamine putrescine in human intestinal Caco-2 cell monolayers to elucidate the mechanisms of the putrescine intestinal absorption.

METHODS The transepithelial transport and the cellular accumulation of putrescine was measured using Caco-2 cell monolayers grown on permeable filters.

RESULTS Transepithelial transport of putrescine in physiological concentrations (>0.5 mM) from the apical to basolateral side was linear. Intracellular accumulation of putrescine was higher in confluent than in fully differentiated Caco-2 cells, but still negligible (less than 0.5%) of the overall transport across the monolayers in apical to basolateral direction.EGF enhanced putrescine accumulation in Caco-2 cells by four fold, as well as putrescine conversion to spermidine and spermine by enhancing the activity of S adenosylmethionine decarboxylase. However, EGF did not have any significant influence on putrescine flux across the Caco- 2 cell monolayers. Excretion of putrescine from Caco-2 cells into the basolateral medium did not exceed 50 picomoles, while putrescine passive flux from the apical to the basolateral chamber, contributed hundreds of micromoles polyamines to the basolateral chamber.

CONCLUSION Transepithelial transport of putrescine across Caco-2 cell monolayers occurs in passive diffusion, and is not influenced when epithelial cells are stimulated to proliferate by a potent mitogen such as EGF.

INTRODUCTION

Polyamines putrescine, spermidine and spermine are small aliphatic cations necessary for cell growth. If the cells are deprived from their polyamines they will stop dividing, resuming their proliferation rates after restoration of normal polyamine levels[1,2]. Polyamine content in the cell is tightly regulated: in addition to synthesis (via ornithine decarboxylase, synthesising putrescine from ornithine; and S-adenosylmethionine decarboxylase, an aminopropyl donor, synthesising spermidine and spermine), all mammalian cells are equipped with an efficient polyamine uptake system, regulated by mitogens[3-6] and capable of supplying the rapidly proliferating cells with increasing amounts of polyamines from the extracellular space.

Intestinal lumen is the main exogenous source of polyamines for the body. The prevailing polyamine in the intestinal lumen, putrescine, is present in human diet in high amounts[7,8]. In particular, food of plant origin contain excessive amounts of putrescine, while meat and meat products are rich in other two polyamines, spermidine and spermine. Postprandial putrescine concentrations in the duodenal and jejunal lumen can reach millimolar levels[9]. However, not longer than 2 h after meal, luminal polyamine content returns to baseline. Luminal putrescine is rapidly converted to metabolically active spermidine already in the intestinal wall[10,11]. However, surprisingly little is known about absorption mechanisms of luminal putrescine and its final metabolic fate, in spite of the findings that outlined the importance of luminal putrescine (and other polyamines) in both normal and neoplastic growth throughout the body. Luminal polyamines were found to support tumor

growth[12], and are found to accumulate in tissues of high demand, i.e., high proliferation rate, such as neoplasia[13,14] or skeletal muscle stimulated to grow by clenbuterol[15].

To elucidate the mechanisms of putrescine absorption from the intestinal lumen, we used Caco-2 cells grown on permeable filters as an experimental model. Caco-2 cells originate from human colonic adenocarcinoma, but after two weeks in culture, spontaneously differentiate into an enterocyte-like phenotype[16]. These cells form monolayers with well-developed tight junctions[17], and have been evaluated in detail as a model to study both transcellular and paracellular transport of nutrients and drugs in the gut[17-20].

MATERIALS AND METHODS

Materials

EGF (human recombinant, expressed in S. cerevisiae), unlabelled putrescine, spermidine and spermine were purchased from Sigma Chemie (Deisenhofen, Germany). [^{3}H]-putrescine was obtained from Amersham Buchler (Braunschweig, Germany). Cell culture media and supplements were purchased from Gibco BRL (Eggenstein, Germany).

Methods

Cell culture Caco-2 cells were obtained from the German Cancer Research Centre, Heidelberg. Cells of passage number 49-56 were used. The cells were maintained in Dulbecco's modified Eagle medium (DMEM) containing 4.5 g/L glucose and 25 mM Hepes, supplemented with 10% foetal calf serum, 100 U/mL benzylpenicillin and 10 mg/L streptomycin. The medium was changed every second day. The cells were routinely checked for Mycoplasma in monthly intervals.

For the experiments, the cells were expanded in tissue culture flasks (225 cm^2 growth area), detached by treatment with 0.5 g/L trypsin and 0.2 g/L EDTA in PBS, and, to allow monolayers to be formed and uptake to be studied in conditions closely resembling this in the human intestinal epithelium, reseeded to 10 cm^2 cell culture filters (ANOPORE; Nunc, Roskilde, Denmark); 2×10^6 cells were seeded to each plate. After 24 h, 1.5 mL of the medium was replaced with fresh medium and further maintenance was done as described above.

Putrescine uptake studies Cells were monitored for confluence by phase contrast microscopy. Confluence was reached at average after 6 or 7 days of culture. Confluent (day 7) or differentiated (day 14) Caco-2 cells were washed twice with PBS and synchronised in serum-free DMEM overnight. The studies on polyamine uptake into Caco-2 cells were done by adding 50 μM of each polyamine (0.1 μCi/mL) to the cell culture wells. After the desired period uptake was terminated by washing the cell monolayers twice with cold PBS to remove non-absorbed radioactivity from the cell surface. The filters were then removed by cutting using a sterile scalpel, and the cells were permeabilised with 1N NaOH, neutralised with 1 N HCl and the radioactivity was measured by standard liquid scintillation counting. In the experiments where a known enhancer of polyamine uptake into the cells, EGF was used, the procedure was carried out by the same manner except that the cells were incubated with 100 μg/L EGF for 12 h prior to the uptake experiments. Because EGF receptors in both confluent and differentiated Caco-2 cells are localised predominantly at the basolateral side [21], EGF was routinely added only to the basolateral chamber.

Permeability of putrescine across Caco-2 cell monolayers Transport studies using radiolabelled putrescine were performed on Caco-2 cells cultured on permeable filters. All experiments were carried out at 37℃ in serum-free DMEM under 'sink' conditions, as described by Artursson[18-20], using Caco-2 monolayers which were 14 days old. Transepithelial resistance was routinely measured using Millicell TER chamber (Millipore, Eschborn, Germany), and the value of 250 Ohm × cm^2 was considered sufficient to allow permeability studies.

In brief, all solutions were preheated to 37℃ and the experiments were performed at 37℃ ± 1℃ on a custom-built heating plate. The cell monolayers were washed with preheated DMEM and equilibrated in the same medium for 20-25 minutes prior to the transport experiments. The filters were then transferred to wells containing 1.2 mL fresh preheated DMEM. One millilitre DMEM containing radiolabelled test substance was added to the apical ("donor") chamber. The [^{14}C]-mannitol (MW 182, comparable to molecular weight of putrescine - 161.1) was used as a marker molecule to assess the integrity of the monolayers during the experiment. Radioactivity was used at concentrations of 10 000 or 20 000 Bq/mL for Caco-2 monolayers. Samples were taken from the apical solutions in order to measure the initial donor concentration. At four regular time intervals, the inserts were moved to new wells and samples were taken from the basolateral solution. All samples were analysed directly as described below.

The possible effect of putrescine adhesion to permeable supports was investigated by comparing the diffusion of [^{14}C]-putrescine across cell-free supports. No retarded diffusion of [^{14}C]-putrescine was observed, which showed that possible adhesion of putrescine to extracellular material could be neglected.

Analytical methods S-adenosylmethionine -decarb oxylase activity in Caco-2 cells was assayed as described

before[22], by measuring the amount of $^{14}CO_2$ liberated from S-adenosyl (carboxy ^{14}C)-L-methionine. The final volume of incubation medium consisted of 50 mM Tris-HCl pH 7.2, 0.2 mmol/L S-adenosyl (carboxyl ^{14}C)-L-methionine, 0.05 mmol/L pyridoxal-5-phosphate, 2.5 mmol/L DTT, and 0.1 mmol/L EDTA. The incubation period at 37℃ was 60 minutes. Radioactive samples were analysed using a liquid scintillation counter (Packard Instruments 1900CA TRI-CARB®; Canberra Pacard Instruments, Downers Grove, IL). Protein was measured by Coomassie blue assay, by kits obtained from Biorad Laboratories GmbH (Munich, Germany).

Calculations The apparent permeability coefficient (P_{app}, cm/s) was determined according to the following equation[18-20]:

$$P_{app} = \frac{K \cdot Vr}{A}$$

where K is the steady state rate of change in concentration in the receiver chamber (C_t/C_0) versus time (s), C_t is the concentration in the receiver compartment at the end of each time interval, C_0 is the initial concentration in the apical chamber at each time interval (mole/mL), Vr is the volume of the receiver chamber (mL) and A is the surface area of the filter membrane (cm^2).

Statistics The results were expressed as mean values ± SEM of four to six experiments. One-way ANOVA was used to compare means. A 95% probability was considered significant.

RESULTS

Basal and EGF-stimulated putrescine uptake in Caco-2 cells

Caco-2 cell monolayers were incubated with and without 100 μg/L EGF for 12 hours and then with 50 μM radiolabelled putrescine for different time intervals. Uptake rate of putrescine increased rapidly and was significantly higher in confluent than in differentiated Caco-2 cells (Figure 1). In confluent, 7 days old cells, EGF-induced putrescine uptake was significantly higher than in differentiated 14 days old cells, basolateral uptake being markedly higher than apical uptake when the cells were stimulated with EGF.

Transepithelial permeability of putrescine

The transepithelial resistance in Caco-2 cell monolayers reached a plateau of 234 ± 12 Ohm × cm^2 after approximately one week in culture and maintained this value for at least 40 days in culture, which was in agreement with previous findings[18-20]. Such monolayers of Caco-2 cells transported [^{14}C]-mannitol with P_{app} of 22 ± 4 × 10^6 cm/s, which was another proof of their well developed tight junctions and full functional integrity. When physiological amounts of putrescine (100 μM; 0.1 μCi/mL) was added to the apical chamber and flux into the basolateral chamber measured over time, transport was linear. Almost the entire applied concentration diffused to the basolateral chamber within a 60 min experimental period (Figure 2).

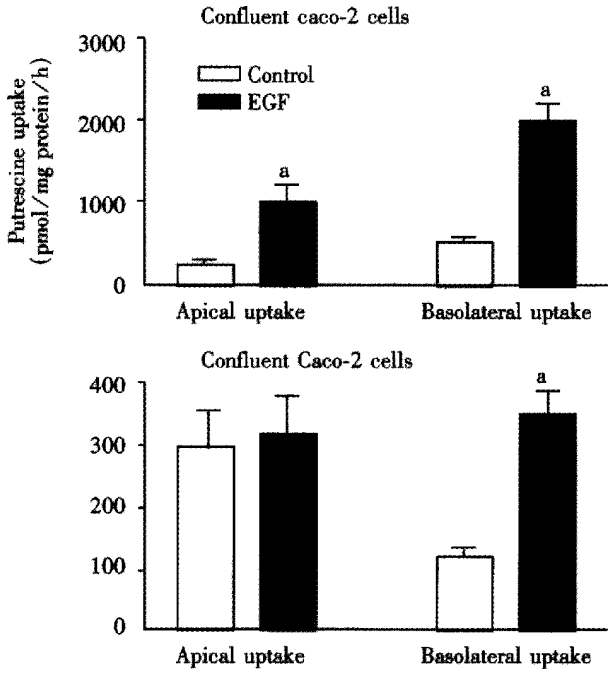

Figure 1 Apical *vs*. basolateral uptake of putrescine in confluent (day 7) and differentiated (day 14) Caco-2 cells in culture. The experiments were carried out as indicated in the Methods section. EGF (100 μg/L) was added to the basolateral chamber, and the cells were incubated for 12 h. Mean ± SEM, N = 4. $^aP<0.001$ *vs* control.

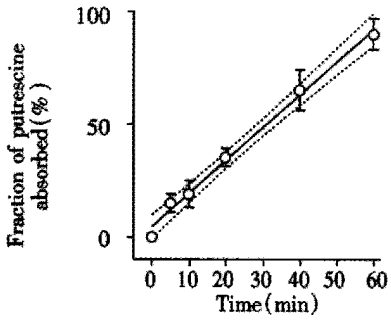

Figure 2 Transepithelial permeability of putrescine across Caco-2 cell monolayers. The experiments were done as described in Methods section, with 100 μM (0.1 μCi/mL) putrescine added to the apical chamber and incubation time 60 min. Mean ± SEM, N = 4.

Apparent permeability constants (P_{app}) for putrescine was in the range of 18-35 × 10^6 cm/s, which was similar to Papp of the standard marker for paracellular permeability, mannitol (Figure 3). There was no change in P_{app} values when the cells were incubated in a balanced salt solution without glucose (data not shown).

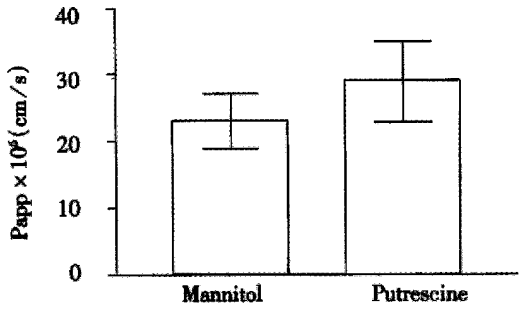

Figure 3 Apparent permeability coefficients for mannitol and putrescine. Each bar represents mean ± SEM of six experiments. Differences between the values are not statistically significant.

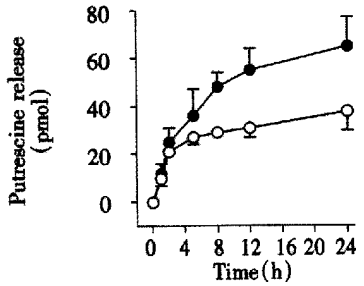

Figure 4 Putrescine release from Caco-2 cells pre-loaded with physiological concentrations (100 μmol / sample) putrescine ± EGF. Each data point represents mean ± SEM of six experiments.

Transcellular component of putrescine transport across the intestinal epithelium: putrescine uptake and release in Caco-2 cell monolayers

A 12 h incubation with 100 μg/L EGF stimulated not only putrescine uptake in CaCo-2 cells (Figure 1), but also its conversion to spermidine and spermine. This conclusion was based on the finding that EGF stimulated the activity of S-adenosylmethionine decarboxylase, the enzyme responsible for conversion of putrescine to spermidine and spermine by approx imately 90% (control: 114 ± 9 pmol CO_2/mg protein, *vs* EGF: 201 ± 8 pmol CO_2/mg protein, $P<0.01$). To investigate whether an increase of putrescine uptake in the intestinal epithelium can be more profoundly increased by a potent growth stimulus such as EGF (and therefore its general absorption influenced), we preloaded control and EGF-treated Caco-2 cell monolayers with physiological concentrations of putrescine (100 μmol), allowed to incubate for 2 h (time period previously shown to be sufficient for maximal uptake)[5], then washed the monolayers with PBS to remove non-absorbed radioactivity, and transferred to radioactivity-free cell culture wells. Release of the radioactivity originating from exogenous putrescine to the basolateral chamber in both control and EGF-treated cells was initially rapid, reaching plateau not earlier than after 6 h incubation (Figure 4). Up to 24 h only minute amounts of the radioactivity was released across the basolateral membrane, the values not exceeding 45 pmol; EGF did not have major influence on putrescine release.

DISCUSSION

Our results indicate that putrescine transport through the intestinal epithelial barrier is linear, the levels taken up by the epithelial cells not exceeding 0.5% of those passively transported across the intestinal epithelium. Treatment with EGF, known to up-regulate putrescine uptake in Caco-2 cells, did enhance putrescine accumulation in Caco-2 cells, but this had no overall impact on net transport of putrescine across the intestinal epithelium, in concentrations shown to exist postprandially in the intestinal lumen[9]. In spite of all limitations of the model used (i.e., absence of subepithelial tissue, inability to measure possible rapid metabolisation of absorbed putrescine in the intestinal wall), our data lead to the conclusion that, in the gut, putrescine is absorbed exclusively by passive diffusion.

A number of studies done in different experimental models show that polyamines rapidly disappear from the intestinal lumen after meal and are rapidly distributed in the body, being directed to tissues with highest demand, i.e. with the highest proliferation rate[23]. Our data may provide an explanation about the possible mechanism for the rapid disappearance of dietary putrescine from the gut lumen. At physiological pH putrescine is fully charged. Small, charged and hydrophilic molecules are usually absorbed via the paracellular pathway, and their transport is additionally facilitated by solvent drug[24]. Indeed, in our experimental model, permeability constant for putrescine did not significantly differ from this of a distinct paracellular marker sized similar to putrescine, mannitol (Figure 2).

The presence of several hundreds of micromoles putrescine in the postprandial duodenal and jejunal lumen, while its concentration in blood and tissues hardly exceeds tens of micromoles, clearly rises a need to offer an explanation for such a high supply and low utilisation of this polyamine in the body. Excess luminal putrescine has recently been attributed as an instant energy source in the gut[25]. Furthermore, endothelial cells in the gut are rich in diamine oxidase, the enzyme able to degrade excess putrescine to succinate and GABA[26]. In the only study of this kind done in humans, disappearance of putrescine from the human intestinal lumen was found to be linear; however, the amounts of putrescine itself, shortly after the putrescine-rich test meal, showed that no free putrescine was detectable in blood. Instead, its acetylated derivative was rapidly and markedly increased, while the amounts of spermidine and spermine increased less rapidly but progressively[27]. All these data may fit well into the hypothesis that putrescine, as well as other two polyamines, cross the intestinal epithelial barrier passively, and that they are then both rapidly metabolised in situ and

used as an instant energy source, or, also rapidly, metabolised into spermidine and spermine and then transported throughout the body.

Apart from transport across the intestinal epithelium, small amounts of putrescine in our study were also taken up by enterocyte-like Caco-2 cells. Putrescine uptake was also stimulated by EGF. Perhaps surprisingly, this uptake was higher across the basolateral then the apical membrane, and the difference was further increased after stimulation with EGF. The role of basolateral polyamine uptake when the gut is stimulated to grow has been described before[28-30], and putative polyamine transporters at the basolateral membrane of the enterocyte has been well characterised at the biochemical level[31,32]. Our data might also additionally confirm an interesting hypothesis that polyamines, via local circulation in the intestinal wall, do reach the enterocyte via their basolateral membranes rather than directly, via the brush border membrane of the enterocyte[33].

In conclusion, our data show that putrescine crosses the intestinal epithelial barrier passively, while only minor amounts are taken up by intestinal epithelial cells. Our data provide an explanation for a known rapid disappearance of dietary polyamines from the intestinal lumen, and their rapid distribution in the body, where they then exert their known growth-related actions.

ACKNOWLEDGEMENTS The data were presented in part at the European Intestinal Transport Group meeting in Lecce (Italy), in May 1995. The authors are indebted to Professor Per Artursson (Department of Pharmaceutics, Uppsala University, Sweden) for his help in establishing the Caco-2 cell model, to Dr Gerard M. Murphy and Professor R. Hermon Dowling (UMDS, Guy's Hospital, London, UK) for critical discussions, and Caroline von Sch¢ippenthau (born Deubner) for help in experimental work. The study was supported by a postdoctoral research fellowship of the Alexander von Humboldt Foundation (to Dr Vladan Milovic).

Abstract

AIM To assess potential contributions of biliary IgA for crystal agglomeration into gallstones, we visualized cholesterol crystal binding of biliary IgA.
METHODS Crystal binding biliary proteins were extracted from human gallbladder bile using lectin affinity chromatography. Biliary IgA was isolated from the bound protein fraction by immunoaffinity chromatography. Pure cholesterol monohydrate crystals were incubated with biliary IgA and fluoresceine isothiocyanate (FITC)conjugated anti IgA at 37 ℃. Samples were examined under polarizing and fluorescence light microscopy with digital image processing.
RESULTS Binding of biliary IgA to cholesterol monohydrate crystals could be visualized with FITC conjugated anti IgA antibodies. Peak fluorescence occurred at crystal edges and dislocations. Controls without biliary IgA or with biliary IgG showed no significant fluorescence.
CONCLUSION Fluorescence light microscopy provided evidence for cholesterol crystal binding of biliary IgA. Cholesterol crystal binding proteins like IgA might be important mediators of crystal agglomeration and growth of cholesterol gallstones by modifying the evolving crystal structures *in vivo*.

INTRODUCTION

Cholesterol gallstone formation involves multiple steps including hepatic secretion of lithogenic bile[1,2] and nucleation and growth of cholesterol crystals within the gallbladder[3]. Besides cholesterol supersaturation[4] and gallbladder hypomotility[2,5], kinetic protein factors that promote or inhibit cholesterol crystallization have been suggested to play key roles in cholesterol gallstone pathogenesis[6,7]. During the past decade, model bile studies indicated that several promoter or inhibitor proteins influence cholesterol crystallization *in vitro*[8-14]. Immunoglobulins were also identified as nucleating proteins in the gallbladder bile of patients with cholesterol gallstones[15,16]. However, the significance of individual protein factors for the pathogenesis of the human disease remains controversial[17,18].

By preparing crystal adsorbed proteins via sucrose density gradient centrifugation and gel electrophoresis, we identified a subgroup of human biliary proteins that bind to cholesterol crystals, modify crystal morphology and inhibit cholesterol crystallization[19]. We demonstrated that secretory immunoglobulin A (IgA) is a major constituent of this group of cholesterol crystal-binding proteins[20]. To assess the importance of biliary IgA for cholesterol crystal agglomeration into gallstones *in vivo*, we now visualized and characterized the binding of biliary IgA to the cholesterol crystal surface.

MATERIALS AND METHODS

Chemicals and analytical procedures

Cholesterol was obtained from Eastman Kodak Co. (Rochester, NY, USA) and its purity was verified by HPLC to be >99%[21]. Sodium taurocholate was obtained from Sigma Chemical Co. (St. Louis, MO, USA). *Concanavalin A* and *Helix pomatia*-lectin-sepharose were purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). All other chemicals were reagents or HPLC grade quality (Sigma Chemical Co.; Merck AG, Darmstadt, Germany).

Isolation of biliary IgA by immunoaffinity chromatography (Figure 1A)

Gallbladder bile from patients with cholesterol

gallstones was obtained by needle aspiration during cholecystectomy. The protocol was approved by the ethical committee of RWTH Aachen. To remove insoluble constituents, bile samples were ultracentrifuged at 100 000 × *g* for 1h. Biliary protein fractions were isolated by affinity chromatography using -Concanavalin A and Helix pomatia- lectin, as described[19,20].

Biliary IgA was isolated from the bound protein fraction by immunoaffinity chromatography[20]. Briefly, affinity columns were prepared by coupling rabbit polyclonal antibodies against the human immunoglobulin á-chain (Sigma Chemical Co.) to Aminolink coupling gel (Immunopure- Immoblization Kit, Pierce Chemical Co., Rockford, IL, USA). After washing the column with 1 M NaCl and equilibration with Tris-buffered saline (TBS; 20 mM Tris/HCl, pH 7.4, 200 mM NaCl, 3 mM NaN_3), biliary proteins (2 - 3mg) were applied to the affinity column overnight. The column was washed extensively with TBS containing 10 mM sodium taurocholate to remove any unbound material and residual lipids. Afterwards, the bound IgA was eluted from the column with 10 Lm 0.1 M glycine/HCl (pH 2.5) into a tube containing 500 µL 1 M Tris/HCl (pH 9.5), and dialyzed against 25 mM ammonium bicarbonate. All steps were carried out at 4℃.

Immunofluorescence studies (Figure 1B)

Cholesterol monohydrate crystals were prepared by recrystallization from 95% (v/v) ethanol according to Igimi and Carey[22]. Five grams cholesterol was dissolved in 400 mL ethanol at 60℃ and cooled slowly to room temperature. To obtain predominantly small, intact crystals, the solution was stirred at 30 rpm. The cholesterol crystals were harvested by filtration through a 0.45 µm micropore filter (Millipore Corp., Bedford, MA) and checked under light microscopy.

Cholesterol monohydrate crystals were resuspended in phosphate buffered saline (PBS; 9.6 mM phosphate, pH 7.2, 2.7 mM KCl, 137 mM NaCl, 3 mM NaN_3) containing 1% (w/v) bovine serum albumin (BSA) to reduce non-specific crystal binding. Samples were incubated at 37℃ for 1 h and shaken at 100 rpm. After washing the crystals three times with PBS containing 0.1% (w/v) BSA (PBS/BSA), IgA was added in PBS/BSA to a final concentration of 200 µg/L. The sample was incubated for 2 h at 37℃ with rapid agitation (100 rpm). After another four washes with PBS/BSA, fluoresceine isothiocyanate (FITC)-conjugated anti-human IgA (Sigma Chemical Co.) was added in PBS/BSA (dilution 1 : 10). The sample was incubated for 1 h at 37℃. After two final rinses, the suspension was taken up in 1mL PBS/BSA. Samples without IgA or with human IgG (Sigma Chemical Co.) served as controls.

Small specimen (25 µL) were examined under polarizing and fluorescence light microscopy (Leica DM RB, fluorescence filter I3). Microphotographs (Minolta 9000) were processed with Corel Photopaint™ (Version 7.0; Corel Corporation, Dublin, IL).

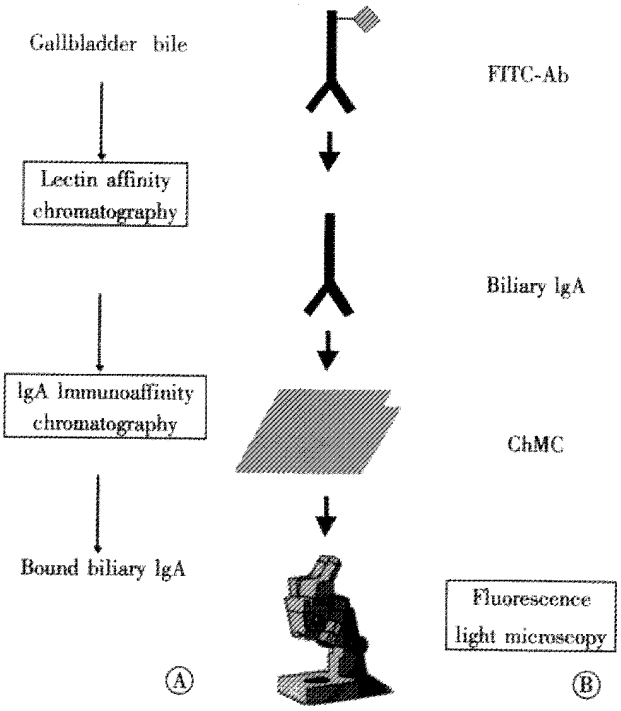

Figure 1 (A) Biliary IgA was isolated from human gallbladder bile by lectin affinity in sequence with immunoaffinity chromatography. (B) Cholesterol crystal binding of biliary IgA to cholesterol monohydrate crystals (ChMC) was visualized microscopically with fluoresceine isothiocyanate-conjugated anti-human IgA antibodies (FITC-Ab).

RESULTS

Utilizing the information on the identity of cholesterol crystal-binding proteins[20], we isolated biliary IgA by lectin affinity chromatography and immunoaffinity chromatography. The isolation procedure yielded electrophoretically homogeneous preparations of biliary IgA, as judged by silver-stained sodium dodecyl-sulfate polyacrylamide gel electrophoresis and immunoblotting (not shown), thus confirming the results of our previous study[20].

The immunofluorescence studies clearly demonstrate significant binding of biliary IgA to cholesterol monohydrate crystals. After incubation of the cholesterol crystal suspension with biliary IgA, followed by the secondary antibody conjugated to FITC, fluorescence is observed dispersed on the surface of the crystals. The left, middle and right panels of Figure 2A and Figure 2B display two representative cholesterol crystals by light, polarizing and fluorescence light microscopy,

respectively. The basic unit is the plate-like cholesterol monohydrate crystal, which shows an euhedral triclinic form with straight edges and a smooth surface (Figure 2A). In addition, the crystals tend to aggregate and to form more irregular structures (Figure 2B). The two right microphotographs of Figure 2A and Figure 2B show how the specific yellow FITC fluorescence is distributed on the crystal surface: Peak fluorescence signals occur at crystal edges as well as screwed and stepwise dislocations, consistent with crystal binding sites with a high affinity to IgA.

Figure 3 displays control samples with IgG (A) and without IgA (B). The crystals exhibit no or only little spotted fluorescence, with blank crystals set off against the green background activity.

Separate experiments were carried out to reduce residual non-specific binding by pre-incubation with BSA (data not shown), and 0.1% (w/v) BSA was used throughout the experiments. This is consistent with recent immunofluorescence studies demonstrating that albumin binds to randomly located little spots on the crystal surface[23], although albumin is not a crystal-binding protein *sui generis* and does not modulate cholesterol crystallization in model bile[24].

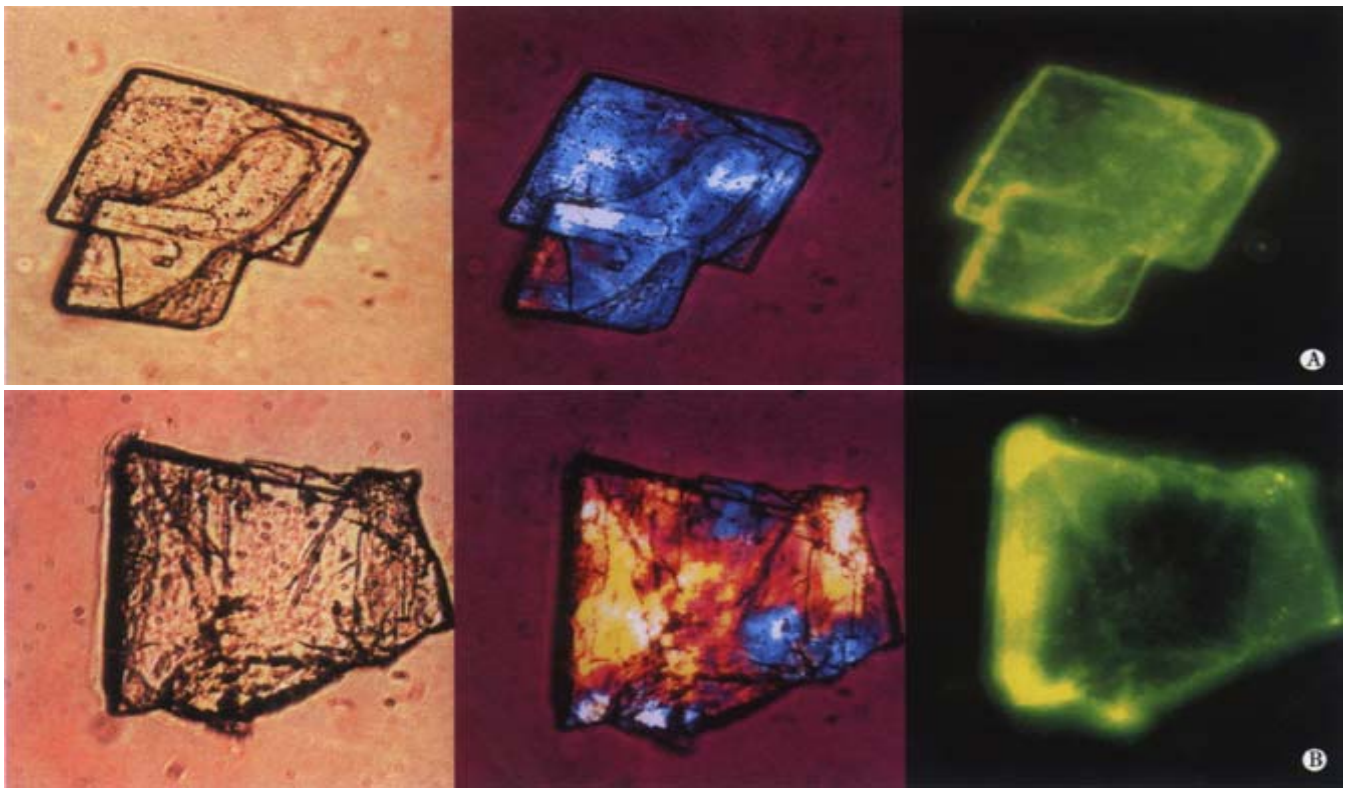

Figure 2 Binding of biliary IgA to cholesterol monohydrate crystals. Crystals were treated with biliary IgA, followed by FITC-Ab (see Figure 1). Left, middle and right panels of show light, polarizing and fluorescence light microphotographs, respectively.

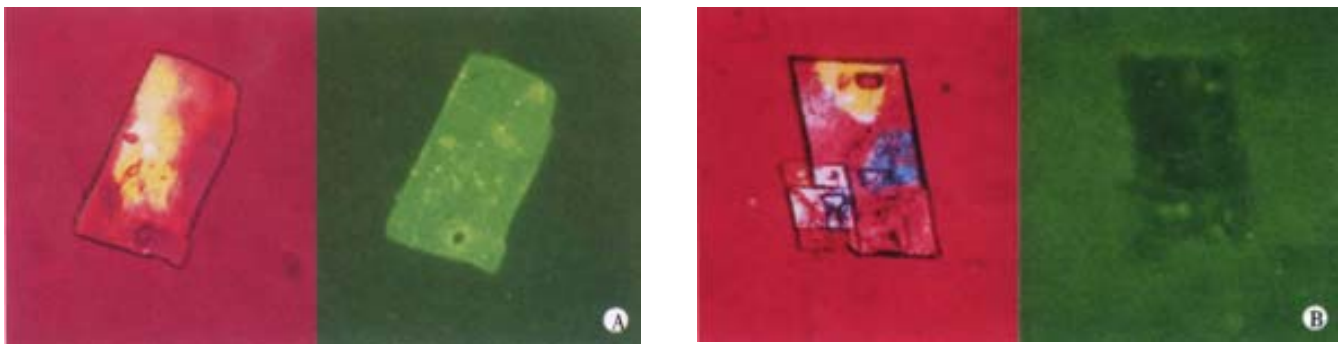

Figure 3 Cholesterol monohydrate crystals with IgG and FITC-Ab incubation (see Figure 1). Cholesterol monohydrate crystals without IgA incubation (FITC-Ab only). Left and right panels show polarizing and fluorescence light microphotographs, respectively.

DISCUSSION

Gallbladder bile contains several proteins that exhibit promoting or inhibiting effects on cholesterol crystallization *in vitro*. Besides physical-chemical determinants[4] and hypomotility of the gallbladder, these kinetic protein factors are assumed to modulate cholesterol gallstone formation[7,25]. Because systematic studies in reconstituted supersaturated human bile (cholesterol saturation index >1.6) did not affect cholesterol crystallization sequences or crystal detection times[17], biliary proteins might predominantly affect subsequent cholesterol crystal agglomeration and growth into mature stones[26].

Bile formation is a means of delivering immunoglobulin into the biliary system and the intestine. The major biliary immunoglobulin is IgA, which enhances the immune protection of mucus membranes and epithelial cells by binding injurious agents or toxins[27]. In humans, polymeric IgA is the predominant class of biliary immunoglob ulins[28,29]. It is secreted by the liver and the gallbladder[30] as complex (secretory IgA), consisting of IgA monomers and the secretory component that is necessary for the endocytotic path way of IgA across the biliary epithelial cells. Our previous studies demonstrated that secretory IgA inhibits cholesterol crystallization in supersaturated model bile in a dose-dependent manner; maximum crystal growth rate and final crystal concentration were significantly reduced even below physiological concentrations[20]. Furthermore, the presence of IgA and other crystal-binding proteins changed crystal morphology, favoring compact and regular microcrystals. However, direct visualization of IgA binding to the crystal surface was not demonstrated.

The interaction between biliary IgA and cholesterol monohydrate crystals could not be visualized by immunoelectron microscopy using anti-human IgA labeled with colloidal gold (mean particle size 4 nm), because the crystal structures were unstable under the conditions tested. We therefore employed immunofluorescence, which was successfully applied in parallel studies that investigated the protein contents of cholesterol gallstones[31] and biliary sludge[23]. Our fluorescence light microscopy studies confirmed cholesterol crystal binding properties of biliary IgA. These findings are in line with localization of IgA in biliary sludge where it was clearly associated with aggregations of cholesterol crystals, which resemble the concentric cholesterol layers at the periphery of stones[23]. These findings support the hypothesis that crystal-binding IgA might be an important modulator of cholesterol crystal agglomeration into stones and stone growth *in vivo*.

The interaction between IgA and cholesterol crystals could not only depend on the distinct immunoglobulin class but might predominantly rely on the variable ends of the light chains. This hypothesis is supported by the synthesis of specific antibodies against cholesterol upon injection of cholesterol-rich liposomes in rabbits and mice[32,33]. These antibodies recognize non-oxidized crystalline cholesterol[32], and analyses by solid-phase ELISA revealed that human sera contain varying levels of naturally occurring autoantibodies to cholesterol[34]. Similarly, humans might synthesize and secrete specific IgA antibodies to cholesterol into bile. This would explain why biliary IgA inhibits cholesterol crystal growth, in contrast to IgA from colostrum[20] and other immunoglobulins, which promote cholesterol crystallization in various experimental settings[15,35]. Using a modified ELISA technique for rapid, precise measurement of protein binding to cholesterol crystals[33], we have recently shown that binding of purified biliary IgA is more than 10-fold increased compared to colostrum IgA (Südfeld S, Lammert F, Busch N, Matern S; unpublished observations).

We speculate that crystal growth inhibitors like biliary IgA attach to the most rapidly growing sites like spiral and edge dislocations on the thermodynamically stable monohydrate crystals, thus changing crystal morphology, retarding crystal growth and decreasing final crystal concentration[19]. This concept applies to many crystal growth inhibitors in biomineralization. Concerning formation of other stones in humans, Nakagawa *et al*. reported a glycoprotein that prevents formation of urinary calcium oxalate stones in healthy persons[36]. From human pancreatic calculi, a small acidic glycoprotein could be isolated that inhibits calcium carbonate precipitation[37]. Other glycoproteins regulate the precipitation of calcium salts in bone and dentin[38,39]. Additional examples of crystal growth inhibiting glycoproteins are found in sera of polar fish and insects, whose 'antifreeze' proteins prevent freezing by adsorbing to ice crystal surfaces[40,41]. These examples illustrate that the concept of crystal growth inhibition by crystal binding probably applies to all inhibitor proteins in biomineralization.

Abstract

AIM An increased viscosity of gallbladder bile has been considered an important factor in the pathogenesis of gallstone disease. Besides lipids and proteins, mucin has been suggested to affect the viscosity of bile. To further clarify these issues we compared mucin, protein and the lipid componEnts of hepatic and gallbladder bile and its viscosity in patients with gallstones.

METHODS Viscosity of bile (mPa.s) was measured using rotation viscosimetry in regard to the non Newtonian property of bile at low shear rates.

RESULTS Biliary viscosity was markedly higher in gallbladder bile of patients with cholesterol (5.00 ± 0.60 mPa.s, mean ± SEM, *n* = 28) and mixed stones (3.50 ± 0.68 mPa.s; *n* = 8) compared to hepatic bile (0.92 ± 0.06 mPa.s, *n* = 6). A positive correlation between mucin and viscosity was found in gallbladder biles (*r* = 0.65; *P*<0.001) but not in hepatic biles. The addition of physiologic and supraphysiologic amounts of mucin to gallbladder bile resulted in a dose dependent non linear increase of its viscosity. A positive correlation was determined between phospholipid concentration and viscosity (*r* = 0.34, *P*<0.005) in gallbladder biles. However, no correlation was found between total protein or the other lipid concentrations and viscosity in both gallbladder and hepatic biles.

CONCLUSION The viscosity of gallbladder bile is markedly higher than that of hepatic bile in patients with gallstones. The concentration of mucin is the major determinant of biliary viscosity and may contribute by this mechanism to the role of mucin in the pathogenesis of gallstones.

INTRODUCTION

Gallbladder mucin, a high molecular weight and densely glycosylated protein secreted by gallbladder epithelium, is the principal organic constituent of gallbladder mucus and biliary sludge[1-3]. It appears to play an important role in different stages of cholesterol or mixed gallstone formation[4]. Gallbladder mucin hypersecretion and accumulation in the gallbladder as a viscoelastic gel precedes the formation of gallstones in animals[5,6] and in humans[7,8]. Furthermore, the highly viscous gel on the luminal side of the gallbladder epithelium and the soluble mucin in bile are believed to enhance the residence time of lithogenic bile in the gallbladder, allowing the growth of cholesterol crystals and, thereby, serving as a nidus for gallstone formation[2,9]. In fact, an association between hexosamine concentrations in bile which derive mostly from soluble mucin and the viscosity of bile has been already described by Bouchier *et al*[10] many years ago. In a more recent study, capillary viscosimetry like Bouchier biliary viscosity at 37℃ was correlated closely with total protein concentration and hexosamine concentration in bile[11]. Few further studies dealing with bile viscosity are available, and in these studies capillary viscosimeters were also used[12-14]. According to these studies, bile behaves essentially as a Newtonian fluid at high shear rates. A Newtonian fluid has a constant viscosity, whereas a non-Newtonian fluid shows a disproportionate increase in viscosity at a low flow velocity. However, capillary viscosimeters lack standardization and are unable to measure the viscosity at low shear rates, at which bile shows a non-Newtonian behaviour. We used the Contraves LS-30 coaxial rotation viscosimeter to eliminate this problem. This

viscosimeter is very sensitive and has a wide measurement range, from 0.01 s^{-1} to more than 100 s^{-1} covering the range of both Newtonian and non-Newtonian flow.

Our study included bile samples from both hepatic and gallbladder biles from patients with mixed or cholesterol stones. The viscosity of bile was compared with the quantitatively most important constituents to investigate which component of bile affects its viscosity.

METHODS

Patients and collection of bile

Thirty-six patients, 25 women (mean age 40 ± 10.5 years) and 11 men (mean age 48.5 ± 11.4 years), who underwent laparoscopic surgery because of symptomatic gallstone disease and six patients with T-drainage after cholecystectomy were also included in the study. Gallstones were visualized by ultrasonography and reasonable gallbladder function was confirmed by determining that at least 30% of the fasting volume was emptied after the administration of a liquid test meal. Patients shown to have severely impaired gallbladder function or a loss of the gallbladder reservoir or cystic duct obstruction were excluded from the study. All patients gave informed consent after a detailed explanation of the procedure required for intraoperative bile collection. During laparoscopic surgery, the gallbladder was punctured with a 16-G needle and the bile was aspirated as completely as possible because of the known stratification of human gallbladder bile[15]. Stones were removed, washed with distilled water, dried, weighed and ground to a powder. The cholesterol content of the stones was measured chemically after extraction with organic solvent and expressed as percentage of dry weight[16]. T-tube hepatic bile was collected from 6 patients (3 women and 3 men) by gravity drainage within 24 hours after cholecystectomy.

Microscopy of bile and crystal observation time

After the collection, bile samples were mixed thoroughly and one drop was immediately examined under polarized light microscopy for cholesterol crystals. Four mL of gallbladder bile was centrifuged in polycarbonate tubes with a 50 Ti rotor at 37℃ for 1 hour at 100 000 × *g* in a Beckman L5-65 ultracentrifuge (Beckman Instruments, Fullerton, CA) to precipitate biliary "sludge". The supernatant was microscopically free of cholesterol crystals. Aliquots were incubated at 37℃ and examined daily under polarized light microscopy for up to 21 days[17].The time taken for cholesterol microcrystals to appear was defined as the crystal observation time and measured in days.

Analysis of bile composition

For the analysis of bile composition, duplicate aliquots were stored at -30℃ prior to determination. Cholesterol was determined colorimetrically with the Liebermann-Burchard reaction after double extraction of 1 mL methanolic bile sample with petroleum ether[18]. Phospholipids were measured as total biliary phosphate after hydrolysis at 150℃ with sulfuric acid, using the colorimetric assay of Fiske-Subbarow, and total bile salts were determined by a modified 3-α-hydroxysteroid dehydrogenase method [19,20]. The saturation index of each sample was calculated in native bile by dividing the cholesterol concentration with the maximum cholesterol solubility according to Carey and was corrected for the total lipid content of each individual bile[21]. Total protein was analysed using the Lowry assay after purification of biliary proteins[22]. This method has been validated extensively by adding known amounts of different serum proteins (albumin or γ-globulin) to samples of gallbladder bile with unknown protein content. In contrast to the fluorimetric assay which underestimates the amount of added protein, protein recovery was determined quantitatively by the Lowry assay.

Biliary mucin concentration was determined according to an assay recently described[23]. The assay is a modification of the classical method of Pearson *et al*[24] and Harvey *et al*[25]. Briefly, fresh gallbladder bile was diluted 1:1 (v/v) with 0.1 mol/L Tris-HCl buffer (pH 7.5) containing 0.44mol/L potassium thiocyanate and 0.02% NaN-3. The formation of lipid aggregates in vesicular form was avoided by addition of sodium cholate to this buffer (final concentration 12.5 mmol/L). The mixture was shaken overnight and centrifuged at 12 000 × g for 10 min. One mL of the supernatant was fractioned on a Sepharose 2B column (40 cm × 1.0 cm, Pharmacia AB, Uppsala, Sweden) at a constant flow of 0.3 mL/min. As for elution buffer, we used 20 mmol/L Tris, 140 mmol/L NaCl, 3 mmol/L NaN-3, pH 8.0 buffer containing 25 mmol/L sodium cholate. Column fractions of 1mL were collected and analyzed for glycoprotein by periodic acid/Schiff (PAS) assay[26]. The excluded PAS-positive glycoprotein fractions were further pooled and dialyzed for 12 h against distilled water to remove bile acids. Mucin concentration was measured in this fraction by the periodic PAS-assay using purified human gallbladder mucin standard.

Determination of viscosity

The rheologic measurements were carried out on a calibrated Contraves Low Shear-30 rotation viscosimeter, using a coaxial-cylinder system with a gap width of 0.5 mm (Contraves AG, Zürich, Switzerland). The rotation viscosimeter allows accurate measurements of viscosity of both Newtonian and non-Newtonian fluids. Programming

of measurements and the processing of the measured data were done utilizing the Contraves Rheoscan 30. To obtain a rapid standardized measurement within the entire range of shear rates (0.1 to 118s^{-1}), a computer program was used to enable measurements in one sample within 5 min[27]. These were repeated twice after an interval of 60s each. Thus, the final result of biliary viscosity represented the mean value of a total of 30 determinations. The viscosity was measured within 3 hours after the collection of the bile sample at laparoscopic cholecystectomy. One mL of the bile sample was taken for any viscosity assay and all measurements were performed at 37℃. All samples were centrifuged for 2 min at 12 000 × *g*, to eliminate sediment that could interfere with the determinations.

To study the effect of mucin on the rheological properties of human bile, purified mucin from porcine stomach (0.24-2.24 g/L) was added to gallbladder bile and the viscosity measured as shown above.

Statistical analysis

Values of each group of parametric data are expressed as means ± SEM. Non-parametric data (crystal observation time) are expressed as median and range. Group comparison was performed for parametric data using unpaired Student's *t* test and for non-parametric data using the Mann-Whitney U test. Spearman's correlation coefficient were calculated between variables and expressed as significant at the $P<0.05$ level.

RESULTS

Individual and total lipids, CSI, crystal observation time, protein, mucin and viscosity in gallbladder bile of patients with cholesterol and mixed stones and in hepatic bile are shown in Table 1. As expected, protein, mucin and lipid concentrations and viscosities were markedly higher in gallbladder bile compared to hepatic bile. A positive correlation between mucin and viscosity was found in gallbladder biles (Figure 1) but not in hepatic biles ($r = 0.01$;n.s.). Figure 2 shows the effect of adding physiological and supraphysiological amounts of mucin to gallbladder bile in relation to the viscosity. There was a dose dependent non linear increase of its viscosity by adding external mucin to native gallbladder bile at three different shear rates including the prestatic region (shear rate 0.1s^{-1}) in this experiment.

Furthermore, a positive correlation was determined between phospholipid concentration and viscosity ($r = 0.34$, $P<0.05$) in gallbladder biles (Figure 3). However, no significant correlation was found between total protein (Figure 4) or the other lipid concentrations and viscosity in both gallbladder (Table 2) and hepatic biles.

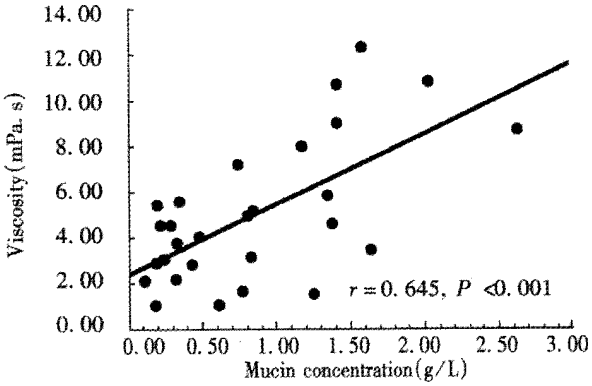

Figure 1 Correlation of viscosity and mucin concentration in 36 gallbladder biles from patients with gallstones.

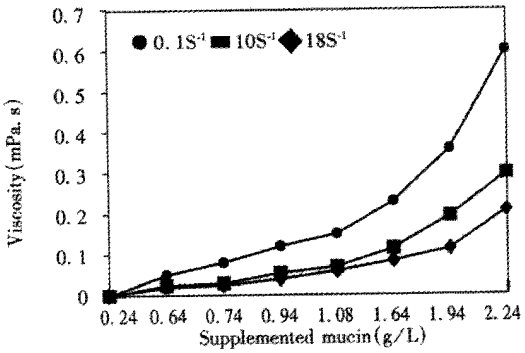

Figure 2 Increase of viscosity at 3 different shear rates including the prestatic region after supplementation of gallbladder bile with purified porcine mucin.

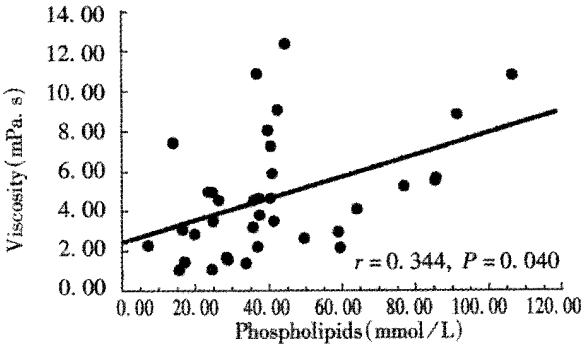

Figure 3 Correlation of viscosity and phospholipid concentration in 36 gallbladder biles from patients with gallstones.

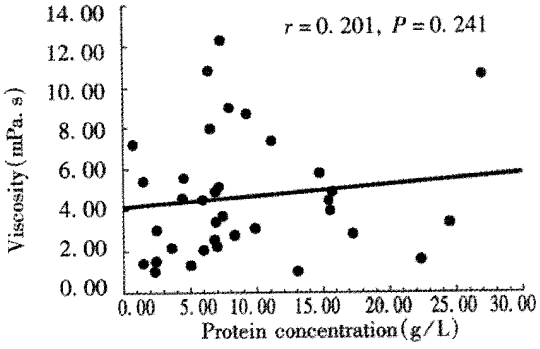

Figure 4 Correlation of viscosity and total protein concentration in 36 gallbladder biles from patients with gallstones.

Table 1 Cholesterol, phospholipids, bile acids, total lipids, CSI, protein, mucin, viscosity (mean ± SEM) and crystal observation time (median and range) in gallbladder bile of patients with gallstones and in hepatic bile

	Cholesterol stones (n = 28)	Mixed stones (n = 8)	Hepatic bile (n = 6)
Cholesterol (mmol / L)	21.1 ± 2.2	12.8 ± 1.7	1.9 ± 1.1
Phospholipids (mmol / L)	46.0 ± 4.7	26.6 ± 4.7	3.4 ± 1.3
Bile acids (mmol / L)	141.2 ± 15.1	65.9 ± 7.7	13.7 ± 7.4
Total lipids (g / dL)	11.3 ± 1.1	5.7 ± 0.7	1.0 ± 0.5

Table 2 Correlation coefficients between viscosity and mucin, protein, lipids and CSI in gallbladder bile of 36 patients with cholesterol or mixed gallstones

Viscosity (mPa·s)	Correlation coefficient (r)	Significance level
Mucin (g / L)	0.645	P<0.001
Total protein (g / L)	0.201	P = 0.24
Total lipids (g / dL)	0.238	P = 0.16
Cholesterol (mmol / L)	0.223	P = 0.19
Phospholipids (mmol / L)	0.344	P = 0.04
Bile acids (mmol / L)	0.161	P = 0.34
CSI	-0.141	P = 0.41

DISCUSSION

The aim of this study is to elucidate the relationship between viscosity and the main constituents of gallbladder and hepatic bile of patients with gallstones.

A major finding of our study is that mucin concentration is positively correlated to the viscosity of gallbladder bile. Similar results were obtained by Shoda *et al*[11], using a capillary viscosimeter, who determined a positive correlation between biliary viscosity and hexosamine concentration of gallbladder bile. In contrast to this report, we did not find a significant correlation between viscosity and the total protein concentration in gallbladder bile of patients with gallstones. These discrepancies might be explained by the different methods of protein determination in both studies. As stated above, the fluorescamine method used in the study of Shoda *et al*. might underestimate the total amount of protein in bile. The use of capillary viscosimeter instead of rotation viscosimetry in the study of Shoda is unlikely to explain the different findings, since bile behaves over a wide range of shear rates like a Newtonian fluid.

A further finding of our study was the positive correlation between phospholipids and viscosity in gallbladder bile. This correlation might be affected by the degree of concentration of gallbladder bile, although the other lipid components bile acids and cholesterol were not positively correlated to the viscosity. Furthermore, higher ratios of phospholipid to bile acids would favor the development of higher molecular weight micelles or vesicles which could favor a higher viscosity of bile. Although further studies have measured bile viscosity in patients with biliary drainage[28,29], the number of studies concerning gallbladder bile is very limited. This is astonishing, since an increased viscosity may play an important role in the formation of cholesterol crystals in gallbladder bile. According to Poiseuille's law bile flux through the cystic duct is inversely correlated to bile viscosity. Thus, increases in bile viscosity may lower the emptying of the gallbladder, thereby allowing more time for cholesterol crystal growth. Mucin has been shown to hydrophobically bind cholesterol in vesicles, promoting nucleation of solid cholesterol monohydrate crystals[30-32] and may also contribute thereby to an increase of the viscosity of gallbladder bile.

We investigated further the relation between viscosity and mucin concentration in human bile by adding purified porcine stomach mucin (range between 0.24 and 2.24 g/L) to native gallbladder bile. A non-linear increase of viscosity with the addition of mucin at 3 different shear rates including the prestatic region was observed. Particularly, after reaching a mucin concentration above 2 g/L, a greater increase in viscosity was found. Cholesterol crystal growth was promoted by already physiological concentrations of bovine gallbladder mucin and appeared to be maximal at 4 g/L [33]. Very high mucin concentrations (up to 20 g/L) have been found in mucin gels and sludge[34] and it has been proposed that crystal growth occurs within the mucin gel that is freqently seen before gallstone formation[2]. The concomitant increase in viscosity may contribute further to the retention of crystals in the gel phase of biliary mucin.

In summary, the most relevant finding of this study suggests that the concentration of mucin is the major determinant of biliary viscosity. Thus, an increased secretion of mucin by the gallbladder epithelium might contribute to a vicious cycle by inhibiting the emptying of the gallbladder and by this mechanism favoring the formation of gallstones.

Abstract

AIM To conduct a cohort study of 101 patients with hepatocellular carcinoma (HCC) presenting to a tertiary care medical referral center in Germany between 1997 and 1999.

METHODS AND RESULTS Data were retrospectively analyzed by chart review. In 95 cases (72 males and 23 females) sufficient data were available for analysis. Twenty five (29%) of 85 patients were HBsAg or anti HBc positive, 21/85 (25%) were anti HCV positive, and 6/85 (7%) were positive for both HBV and HCV-markers. Age was significantly lower in HBV positive patients than in the other two groups. Thirty one (34%) of 90 patients had histories of alcohol abuse. In 79/94 (84%) patients, cirrhosis was diagnosed. Of these cirrhotic patients, 29/79 (37%) belonged to Child Pugh's group (CHILD) A, 32/79 (40%) to CHILD B, and 18/79 (23%) to CHILD C. AFP was elevated in 61/91 (67%) patients. A single tumor nodule was found in 38/94 (40%), more than one nodule in 31/94 (34%), and 25/94 (26%) had a diffusely infiltrating tumor, i.e. the tumor margins could not be seen on imaging procedures. Portal vein thrombosis was present in 19/94 (20%). Imaging data consistent with lymph node metastases were found in 10/92 (11%), while distant metastases were found in 8/93 (9%). According to Okuda 28/94 (30%) were grouped to stage I, 53/94 (56%) were grouped to stage II, and 13/94 (14%) were grouped to stage III. Survival data were available for 83 patients. The Kaplan-Meier estimate for median survival was 84 months. Factors influencing survival were the Okuda score, the presence of portal vein thrombosis, and the presence of ascites. The presence of non complicated liver cirrhosis by itself, distant metastases, or infection with hepatitis viruses did not influence survival. AFP positivity by itself did not influence survival, though patients with an AFP value greater than 100 μg/L did experience shortened survival. Treatment besides tamoxifen or supportive care was associated with prolonged survival. The influence of therapy on survival was most pronounced in Okuda stage II patients. There was longer survival in those Okuda stage II patients who were treated with percutaneous ethanol injection.

CONCLUSION Even in a low incidence area such as Germany, the majority of HCC is caused by viral hepatitis and therefore potentially preventable. Reflecting the high proportion of advanced stage tumors in our patients, the median survival was poor. Patients who received active therapy had a longer survival.

INTRODUCTION

Hepatocellular carcinoma (HCC) was responsible for the death of an estimated 609 000 individuals 1998 representing 1.1% of total mortality in WHO member states[1]. The incidence varies with geographic[1] area since factors predisposing to HCC development are unevenly distributed across continents and sometimes even within countries or within populations[2,3].

The incidence of HCC is clearly linked to the rate of chronic HBV infection[4,5]. A large percentage of HCC patients show serological or histological markers of past contact with HBV[3]. Prospective studies have demonstrated that men

chronically infected with HBV and expressing hepatitis B surface antigen (HBsAg) are about 70-fold more likely to develop HCC than their seronegative counterparts. Furthermore, even HBsAg-negative patients often exhibit serologic evidence, such as anti-HBc positivity, of past HBV-infection. Molecular mechanisms that account for that association are interaction of HBVproteins with signal transduction pathways, apoptosis, transcriptional machinery, and DNA repair[6]. Likewise, HCV infection predisposes to HCC[7]. While the molecular mechanisms of this association are not well understood at present, HCV proteins seem to interact with functions of the host cell in ways partially comparable to HBV proteins[8-12]. Examples include the capacity of HCV proteins for transactivation and their influence on apoptosis. The main difference between HCV and HBV related hepatocarcinogenesis is the lack of genomic integration of HCV sequences. It is interesting, however, that HCV frequently produces HCC only after liver cirrhosis has developed. This and the acquisition of HCV at a more advanced age may partially explain the older age at diagnosis and worse liver function compared to HBV-related liver cancer[13,14]. Therefore, HCC might be prevented by early antiviral therapy[15-17]. Besides hepatitis virus infection is associated with a large number of cases of HCC[18-23], liver cirrhosis itself regardless of etiology is a predisposing factor for HCC development[24,25]. In fact, most cirrhotics in Japan die from HCC[26]. Certain industrial[27], behavioral [28], or familial factors[29,30] also contribute to HCC development.

HCC can be cured by liver transplantation or liver resection[31-33]. However, due to the multifocal nature of the disease as well as coexisting conditions, only a small minority of patients can be treated surgically. This proportion of surgically treatable patients is likely to increase after institution of screening programs [34,35] that are based on the recognition of high risk groups[36] for the development of HCC. This is very important as the outcome of non-treatable patients remains poor[37,38].

While there is much data on the clinical characteristics and the outcome of patients with HCC in high risk countries in which the majority of HCC are viral hepatitis and/or aflatoxin-related[20-22,39], we know little about predisposing factors, clinical characteristics, and factors influencing outcome in low incidence areas such as northern Europe. Some of the data are contradictory with regard to factors predisposing to HCC development[18,40-43]. As incidence of HCC in many low-risk areas is rising albeit with local differences[44], presumably due to an increase in hepatitis virus-related liver cancer[45,46] and possibly rising rates of HCC development in women[47,48], an analysis of the present situation is needed to serve as a baseline for future refinements. The present study summarizes the data on a cohort of patients admitted to a hepatology unit at a tertiary medical referral center in Germany.

PATIENTS AND METHODS

Our institution is an academic tertiary care center located in the western part of Germany that receives the majority of patients as referrals from other hospitals. Using computer based searching for patients that presented for the first time with a diagnosis of hepatocellular carcinoma between 1997-1999, we identified 101 patients. Their charts were retrospectively reviewed. In 95 patients enough data were available for comprehensive analysis. These cases were further analyzed.

Diagnosis of HCC was made either by biopsy, postmortem examination or by diagnosing a new liver lesion in the proper clinical context in the absence of a demonstrable extrahepatic tumor and observing the clinical course. Liver cirrhosis was diagnosed by histology or by clinical evidence (signs of portal hypertension on endoscopic examination or characteristic imaging features on ultrasound examination).

A diagnosis of alcohol abuse was made using the criteria of Kubicka *et al*[40]. In brief, alcohol abuse was defined as a chronic alcohol consumption of more than 60 g/day for both sexes or when a history of alcohol abuse was noted in the patients' records.

Anti-HCV, HBsAg, Anti-HBc were measured using commercially available 2nd/3rd generation ELISA-based assays (Abbott Laboratories, Wiesbaden, Germany). Ultrasound examinations, CT scans, and chest X-rays were analyzed for the number of lesions, the size of the largest lesion, the approximate amount of liver volume taken up by the tumor, and the presence of extrahepatic lesions. The Okuda-score was calculated from imaging results and laboratory parameters. Patient survival was recorded by contacting the patients' primary care physician by mail or telephone.

For statistical analysis data were described by median and range. The number of patients with a specific trait was listed along with the number of patients for whom enough data was available to asses the absence or presence of this trait. Comparisons of continuous data between groups were performed using the Mann-Whitney-U-test (two groups) or the Kruskal-Wallis-test (more than two groups). Relationship between groups of nominal/ordinal data were explored using the chi-squared test, if necessary in its modification as the Fisher's exact test. To analyze survival data Kaplan-Meier-analysis was performed and survival differences between groups tested using the Log-rank-test. The Kaplan-Meier estimate for median or mean survival was reported depending on patient number.

RESULTS

Patient characteristics

Patient characteristics are summarized in Tables 1 and 2. Median patient age was 63 years (Range: 31-85 years) for men and 67 years (Range 42-83 years) for women. There was no statistically significant difference in age between men and women (U-test). The three most frequent concomitant diseases were diabetes mellitus in 32/95 (34%), arterial hypertension in 16/95 (17%) and nephrolithiasis in 6/95 (6%) patients. Apart from nephrolithiasis that was only diagnosed in men there was no predominance of one sex in these associated conditions. There was no difference in body mass index between those patients who suffered from diabetes and those who did not have diabetes. 24/32 (75%) Patients with diabetes suffered from liver cirrhosis.

Table 1 Patient characteristics: risk factors for HCC

Variable	Number/Total	Percentage
Sex		
Male	72/95	76%
Female	23/95	24%
Markers of past or present HBV infection		
Yes	25/85	29%
No	60/85	71%
Markers of HCV infection		
Yes	21/85	25%
No	64/85	75%
Markers of both HBV and HCV-infection		
Yes	6/85	7%
No	79/85	93%
History of alcoholism		
Yes	31/90	34%
No	59/90	66%
Cirrhosis

No	15/94	16%
Child score (only cirrhotics)		
A	29/79	37%
B	32/79	40%
C	18/79	23%
AFP elevated		
Yes	61/91	67%
No	30/91	33%

Table 2 Patient characteristics: age and clinical chemistry results

Variable	Median (Range)
Age	64 (31-85) years
GPT	32 (10-244) U/L
AP	214 (2-1490) U/L
Bilirubin	1.5 (0.4-14.4) mg/dL
Prothrombin time acc. to Quick	83 (25-122)%
Albumen	3.4 (1.9-4.6) g/dL
AFP	38 (0.9-831000) μg/L

Specific predisposing factors to HCC development

Hepatitis viruses Twenty-five/85 (29%) of HCC patients had markers of past or present HBV infection. Another 21/85 (25%) were infected by the hepatitis C virus (HCV), while 6/85 (7%) of patients had markers of infection with both viruses. There was a significant difference in age in patients with HBV, HCV, HBV/HCV coinfection, and those without hepatitis ($P<0.01$, Kruskal-Wallis-test). The median age (55 years, range 31-76 years) of patients with markers of HBV-infection was more than ten years lower than the median ages of patients without hepatitis (66, range 42-82 years), with HCV-infection (66, range 38-83 years), or with HBV/HCV-coinfection (69, 57-75 years). This is depicted in Figure 1. Interestingly, only 1/21 patients with HCV infection and none of the patients with HCV/HBV coinfection did not suffer from liver cirrhosis, while 2/24 patients with HBV-infection and 7/33 patients without hepatitis did not have cirrhosis.

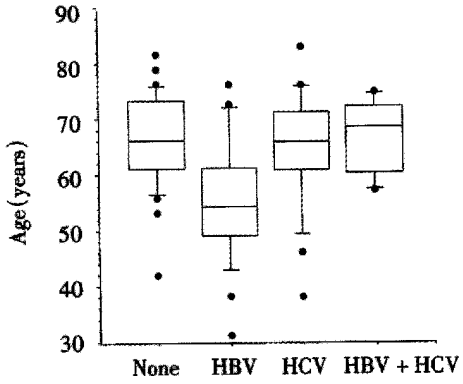

Figure 1 Box plots showing the patients' age according to hepatitis status. Patients with HBV-infections have a lower median age compared to patients with no hepatitis (None, n = 33), HBV-infection (HBV, *n* = 25), HCV Infection (HCV, *n* = 21), or HBV/HCV co-infection (HBV+HCV, *n* = 6).

Alcoholism Thirty-one/90 (34%) of HCC patients in our cohort were alcoholics. Age of alcoholics was not statistically different than that of patients with HCC from other causes ($P>0.05$, U test). Comparing the presence of alcoholism with the presence of viral markers, there was no apparent positive correlation between the presence of alcoholism and presence of markers indicating past or present HBV or HCV-infection. Indeed, only 9/81 patients were both alcoholics and had markers of hepatitis B or C, while 21/81 patients were alcoholics without markers of hepatitis and 39/81 patients had hepatitis but no alcoholism. 12/81 patients suffered neither from hepatitis nor alcoholism. Therefore it seems likely that a negative association between hepatitis and alcoholism exists in our cohort. This is confirmed by a borderline significant Fisher's exact test ($P<0.05$) for this inverse relationship.

Cirrhosis Seventy-nine/94 (84%) of HCC patients suffered from liver cirrhosis. The biggest percentage (40%) of these patients could be classified as CHILD-Pugh B, while 37% and 23% could be classified as CHILD A and C respectively. Age of cirrhotics was identical to that of non-cirrhotic patients ($P>0.05$, U test).

Tumor characteristics Tumor characteristics are listed in Table 3. 61/91 (67%) of patients had a positive AFP-test. The diameter of the largest tumor nodule in AFP positive tumors was significantly larger ($P<0.05$, *U*-test) than that of AFP negative tumors. A single tumor nodule was observed in 38/94 patients, while the remaining tumors were multinodular, with a diffuse growth pattern in 25/94. 20/89 tumors were smaller than 3 cm, 31/89 were between 3 and 5 cm, and 38/89 were larger than 5 cm. An involvement of both liver lobes was noted in 49/93 cases. In 19/94 cases an associated portal vein thrombosis was diagnosed. Ascites was seen during ultrasound in 43/95 patients. It was not possible to further classify ascites as malignant or due to liver cirrhosis retrospectively. Lymph node metastases were seen in 10/92 patients, while distant metastases (mainly lung metastases) were diagnosed in 8/93 patients.

Table 3 Tumor characteristics during initial presentation

Variable	Number / Total	Percentage
Type of tumor growth		
One nodule	38 / 94	40%
>1 Nodule	31 / 94	34%
Diffuse	25 / 94	26%
Size of largest nodule		
<3 cm	20 / 89	22%
3 cm-5 cm	31 / 89	35%
>5 cm	38 / 89	43%
Involvement of both liver lobes

Yes	43 / 95	45%
No	52 / 95	55%
Tumor stage according to Okuda		
I	28 / 94	30%
II	53 / 94	56%
III	13 / 94	14%

Outcome and factors influencing outcome

Survival data were available for 83 patients. The Kaplan-Meier estimate for median survival for all patients was 8.4 months. Survival curves according to Okuda stage are shown in Figure 2. There is a highly significant ($P<0.001$, Log-rank-test) relationship between tumor stage according to Okuda and patient survival. Kaplan-Meier-estimates for mean survival were 13.8 months for Okuda stage I, 9 months for Okuda stage II, and 1 month for Okuda stage III. By survival analysis other single factors influencing survival could be demonstrated: A significant ($P<0.02$, Log-rank test) influence on survival could be shown for the presence of portal vein thrombosis. The Kaplan-Meier estimate for mean survival in the absence of portal vein thrombosis was 10 months while the estimate for mean survival in the presence of portal vein thrombosis was 2.4 months. Likewise, patient survival was significantly shorter ($P<0.004$, Log-rank test) if ascites was present. The Kaplan-Meier estimates for median survival were 13 months in the absence and 3.8 months in the presence of ascites (Figure 3). The CHILD score was significantly correlated with survival of cirrhotic patients: CHILD A patients ($n = 27$) survived a median time of 14 months, CHILD B patients ($n = 29$) survived a median time of 6.6 months, while CHILD C patients ($n = 13$) survived a median time of 0.7 months. This influence of CHILD stage on survival was significant ($P<0.01$, Log-rank-test). CHILD stage was significantly correlated to Okuda score ($P<0.01$, Chi-squared test).

No difference in survival could be found for patients with or without hepatitis ($P = 0.8$, Log-rank test), AFP-positive versus AFP-negative patients ($P = 0.11$, Log-rank test), the presence of distant metastases ($P = 0.22$, Log-rank test), and for the presence or absence of liver cirrhosis ($P = 0.95$, Log-rank test).

While AFP positivity by itself was not associated with lower survival, AFP-levels greater than 100 ug/L ($n = 33$) were associated with a median survival of 3 months, while lower AFP-levels ($n = 46$) were associated with a survival of 12.5 months ($P<0.01$, Log-rank test).

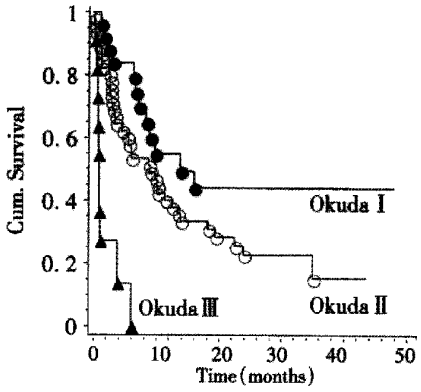

Figure 2 Kaplan-Meier-analysis of patient survival according to Okuda stage. Significant differences between groups ($P<0.001$, Log-rank test) can be seen.

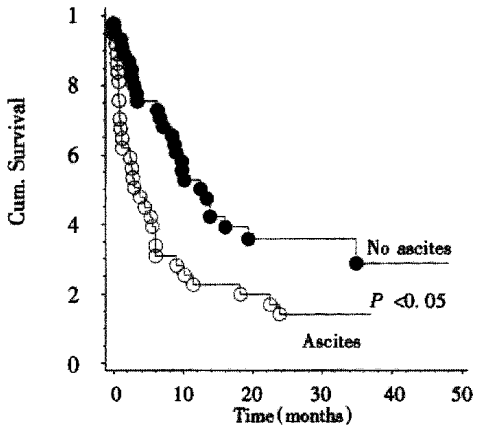

Figure 3 Kaplan-Meier-analysis of survival in relation to the presence or absence of ascites. Treated patients (open circles) lived significantly longer ($P<0.05$, Log-rank test) than their untreated counterparts (filled circles).

To investigate the influence of therapy on survival, the patients were divided in a group that received active therapy (17 percutaneous ethanol injection, 8 transarterial chemoembolisation, 11-I-131-Lipiodol administration, 2 resection, 2 octreotide for more than 4 weeks) and a group that received either supportive care (n = 36) or tamoxifen treatment (n = 13), that has recently been shown to yield no survival benefit compared to placebo. These patients were then stratified according to Okuda score. Only Okuda stage I or II patients were included. When survival was compared between both stratified groups overall there were significant differences (P<0.04, log-rank test) in survival between treated and untreated patients. For Okuda stage I the Kaplan Meier estimate for mean survival in the treatment group (n = 13) was 9 months, while the estimate for mean survival in the untreated group (n = 12) was 12 months. For Okuda stage II the Kaplan-Meier estimate for mean survival for the treatment group (n = 19) was 19 months while the estimate for mean survival for the untreated group (n = 27) was 7 months (Figure 4). While the use of percutaneous ethanol injection was not significantly related to increased survival overall(P = 0.18, Log-rank test); in Okuda stage II tumors there was better survival for patients receiving this treatment modality (P<0.02, Log-rank test). When only patients were analyzed who received either supportive therapy (n = 36) or tamoxifen treatment (n = 13), no difference for survival times could be found between tamoxifen treated patients and those who received supportive therapy.

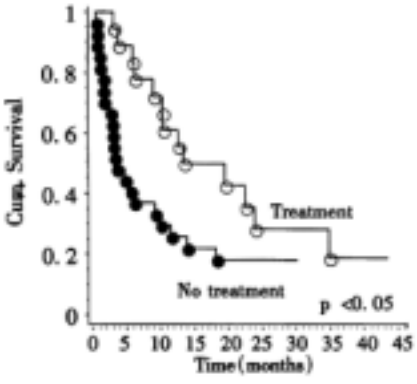

Figure 4 Kaplan-Meier-analysis of Okuda stage II patients in relationship to treatment. Patients with ascites (open circles) lived for a significantly shorter (P<0.05, Log-rank test) time than their counterparts without ascites (filled circles).

DISCUSSION

Patient characteristics

The age and sex distribution of our patient cohort closely reflected published data from other series. Interestingly, there was a high prevalence of diabetes mellitus in our patients. Other studies on HCC also reported a high prevalence of diabetes mellitus[49-51]. The body mass index of diabetic patients was similar to that of their non-diabetic counterparts as was the number of subjects with liver cirrhosis. The high prevalence of diabetes mellitus in our series can be interpreted as a consequence of the high prevalence of liver cirrhosis in HCC patients overall. Cirrhosis is associated with impaired glucose tolerance and diabetes in 20%-30% of cases[52,53].

Predisposing factors to HCC development

The presence of liver cirrhosis in 84% of our patients is well within the range of cirrhosis rates reported in the literature (Table 4). All but three of the patients with viral hepatitis were cirrhotics. The other HCCs can most likely be explained by the high prevalence of alcoholism in our patients. As alcoholism was not associated with viral hepatitis in our patients, alcohol abuse may have been an independent risk factor for HCC development. Liver cirrhosis was fairly advanced in most of our HCC patients as evidenced by the high proportion of CHILD B and CHILD C liver cirrhosis.In our study 29% of HCC had evidence of past or present HBV-infection, 25% had evidence of HCV-infection, and 7% had evidence of both HBV and HCV-infections. This is comparable to infection rates in northern Europe and some more recent studies from southern Europe (Table 4) that show that a rising proportion of hepatocellular carcinoma is HCV related. This is similar to Asian countries where one can also observe a clear relationship of HCC and hepatitis B and C (Table 4). The lower age of HCC-patients with HBV infection compared to that of HCC-patients with HCV-infection and HCC-patients without HBV/HCV-infection or with HBV/HCV-coinfection may be explained by two hypotheses: Firstly, HBV may have been acquired earlier in life than HCV. Secondly, HBV might be a more potent oncogenic stimulus than HCV. There is some evidence to support this latter hypothesis: HBV has been identified as a risk factor for HCC in individuals that are not cirrhotic. This may mean that the many interactions of HBV proteins with the host cell[6] and especially the transactivating function of HBV proteins coded by integrated viral sequences[54-56] can cause cancer regardless of cirrhosis development. Indeed, two of our 24 patients with HBV infection did not have cirrhosis. The older age of HBV/HCV coinfected patients compared to patients with HBV monoinfection might also be related to specific modes of transmission that occur only at an older age. It is a very interesting observation that the majority of HCC even in a low-risk area for viral hepatitis such as Germany are related to viral hepatitis and, therefore, potentially preventable. An important

factor in preventing liver cancer in Germany will be an effective reduction or eradication of HBV infection through general vaccination programs. This approach has already proved successful in Asia. Another possibility of preventing HCC could be interferon treatment of HCV infection. Although there is still some controversy if this may prevent HCC development, it seems very likely that successful interferon therapy can prevent progression to liver cirrhosis and will therefore reduce HCC incidence. HCV-related HCC occurs following the development of liver cirrhosis in the majority of cases. In our patients there was only one patient with HCV infection but without liver cirrhosis.

Tumor characteristics

Two thirds of our patients had a positive AFP-test. This is similar to the results of other German studies[41,43] and illustrates that other tumor markers are needed to detect early HCC in AFP-negative cases. This is emphasized by significantly larger tumor nodules in AFP positive cases. Patients with large tumor nodules may not be good candidates for liver transplantation or resection, the only curative therapies available for HCC.

As detailed in Table 3, most of the tumors were in an advanced stage at presentation. 70% of tumors were Okuda stage II or III. Involvement of both liver lobes was predominant in this study. there was also a high rate of portal vein thrombosis. The tumor stages in our patients were more advanced than the tumor stages in other German series, in which the percentage of Okuda stage II and III tumors ranged from 43% to 61%[40,41,57].

It is surprising, however, that despite locally advanced tumors, we detected only a relatively small rate of nodal or extranodal metastases. This may indicate that extrahepatic tumor spread in HCC does not generally present a major problem although it may become highly relevant in individual cases especially after liver transplantation.

Outcome and factors influencing outcome

Overall outcome was poor. Reflecting the large number of advanced tumors and the minuscule number of surgically treated patients in our study, the Kaplan-Meier estimate for median survival was only 8.4 months. This is similar to German results reported by Petry *et al*[41] and within the scope of survival results for medically treated patients reported by other authors[38,58]. Other authors had also observed the clear-cut relationship of survival to the Okuda stage of the tumor.

AFP positivity was not related to survival. However, when only tumors with AFP levels greater than 100 ug/L were compared to tumors with lower or negative AFP levels, survival was shortened for the patients with the higher AFP levels. This may reflect a larger tumor burden in the patients with higher AFP levels as evidenced by significantly larger tumor nodules in AFP positive patients. This relationship of decreased survival in patients with an AFP level greater than 100 ug/L had also been described by others[57]. The relation of CHILD stage to survival was expected since the CHILD stage reflects some of the same variables that are measured by the Okuda score. The disappointing survival of CHILD C cirrhotics with HCC (median survival of less than one month) might suggest that these patients are not treated but offered symptom-targeted supportive care. However, this has not been tested prospectively.

Comparing survival of tamoxifen treated patients to patients receiving supportive therapy, there was no survival benefit for tamoxifen treated patients. This matches results from prospective studies[59,60] that proved tamoxifen to be ineffective in HCC. Therapy other than tamoxifen was related to increased survival. As small tumors in cirrhosis have a relatively good prognosis[61], it was therefore important to assess the influence of therapy on survival without the confounding effect of Okuda stage. The analysis of treatment groups stratified by Okuda stage confirmed that treated Okuda stage II patients survived longer. Ethanol injection (PEI) was associated with improved survival in Okuda stage II patients. A favorable impact of PEI on survival was previously reported in the literature[62].

One has to be cautious in interpreting retrospective data such as ours. It may be possible that patients were offered therapy because they were in a better clinical state, even though their Okuda stages were identical. Prospective studies must address the effectiveness of therapy in HCC.

As HCC is mostly a problem confined to the liver, with most patients dying from liver related complications such as liver failure or variceal bleeding, an effective approach to HCC treatment may consequently be any therapy aimed at local tumor control such as PEI, high-frequency

thermocoagulation, or laser induced thermocoagulation[63,64] to prevent portal vein thrombosis and parenchymal displacement.

CONCLUSIONS

Our data show the majority of HCC seen at our institution to be related to viral hepatitis. Therefore, to reduce the incidence of HCC, the prevalence of viral hepatitis must be controlled through vaccination programs and possibly through antiviral treatment. As only about two thirds of HCC were AFP positive, additional tumor markers must be sought to identify patients with HCC early in their disease when they might still benefit from curative surgical interventions. Survival was poor, but therapy (in our series mostly TACE, ethanol injection, and ^{131}I-Lipiodol treatment) was associated with improved survival.

ACKNOWLEDGEMENTS We thank Profs. Dr. Dr. F. Bidlingmaier and Klingmüller, Institute for Clinical Biochemistry, University of Bonn, for help in obtaining some of the AFP measurements. We are also indebted to Prof. Dr. B. Matz, Institute of Medical Microbiology, Section of Virology, University of Bonn, for his help in obtaining the hepatitis status for some of our patients.

Abstract

AIM To prepare the conjugate of staphylococcal enterotoxin A (SEA) protein which is a bacterial SAg and the F(ab')2 fragment of mAb HAb18 against human hepatocellular carcinoma (HCC), and identify its activity in order to use SAg in the targeting therapy of HCC.

METHODS MAb HAb18 was extracted from the abdominal dropsy of Balb/c mice, and was purified through chromatography column SP 40HR with Fast protein liquid chromatography (FPLC) system. The F(ab')$_2$ fragment of mAb HAb18 was prepared by papainic digestion method. The conjugate of mAb HAb18 F(ab')$_2$ fragment and SEA was prepared with chemical conjugating reagent N succinimidyl 3 (2pyridyldithio) propionate (SPDP) and purified through chromatography column Superose 12 with FPLC system. The molecular mass and purity of each collected peak were identified with SDS-PAGE assay. The protein content was assayed by Lowry's method. The antibody activity of HAb18 F(ab')$_2$ against HCC in the conjugate was identified by indirect immunocytochemical ABC method, and the activity of SEA in the conjugate to activate peripheral blood mononuclear cells (PBMC) was identified with MTT assay.

RESULTS The IgG mAb HAb18 was extracted, and purified successfully. Immunocytochemical staining demonstrated that it reacted with most of HHCC cells of human HCC cell line. There were two peaks in the process of purification of the prepared HAb18 F(ab')$_2$ SEA conjugate. SDS-PAGE assay demonstrated that the molecular mass of the first peak was about 130 ku, and the second peak was the mixture of about 45 ku and a little 100 ku proteins. The immunocytochemical staining was similar in HAb18 F(ab')$_2$ SEA conjugate and HAb18 F(ab')$_2$, i.e.the cytoplasm and/or cell membranes of most HHCC cells were positively stained. The MTT assay showed that the optical absorbance (A) value at 490 nm of HAb18 F(ab')$_2$ SEA conjugate was 0.182 ± 0.012, that of negative control was 0.033 ± 0.009, and there was significant difference between them ($P<0.05$).

CONCLUSION SPDP is a good protein conjugating reagent and can be used in preparing protein conjugate. The conjugate of mAb HAb18 F(ab')$_2$ fragment and SEA protein was prepared successfully in present study and can be used in the experimental study of HCC targeting therapy with the conjugate of SAg and anti HCC mAbs or their fragments.

INTRODUCTION

Superantigen (SAg) is a group of proteins which can conjugate with some Vβ fragments of the α or β region of T lymphocytic receptor (TcR) when submitted by major histocompatibility complex (MHC) II molecules. SAg can activate T lymphocytes efficiently and make them release a lot of cytokines[1-5]. SAg has great potential anti-tumor effect, but single SAg has some severe side effects to normal cells expressing MHCII molecules[6]. Using the conjugates of SAg and anti-tumor monoclonal antibody (mAb) or their fusion proteins to treat tumor is a focus in tumor targeting therapy research currently[7-21]. There has been no report about anti-hepatoma with mAb-SAg conjugate until now. The conjugate of SAg - Staphylococcal enterotoxin- A (SEA) and the F (ab')$_2$ fragment of mAb HAb18 against human hepatocellular carcinoma (HCC) was prepared with heterotype bifunctional conjugating reagent N-succinimidyl-3-(2-pyridyldithio) propionate

(SPDP), and the activities of the F(ab')$_2$ fragment of mAb HAb18 against HCC and SEA's activating peripheral blood mononuclear cells (PBMC) in the conjugate of HAb18 F(ab')$_2$ and SEA was identified in this study, laying an experimental base for the research of HCC targeting therapy with mAb-SAg conjugate.

MATERIALS AND METHODS

Cells, animals and main reagents

The hybridoma cells which secrete mAb HAb18 against HCC-associated antigens was established by our department[22]. This hybridoma was prepared by taking the cell suspension of some fresh human HCC tissue as antigen, and the cells were fused according to normal procedures for mAb preparation. Human HCC cell line HHCC was purchased from Shanghai Institute of Cell Biology, Chinese Academy of Sciences (Shanghai, China). Balb/c mice (body weight of 20 g-25 g) that were used to prepare the abdominal dropsy of mAb HAb18 were provided by the Experimental Animals Center of our university. Papain, mitosis promoter PHA, Methabenzthiazuron (MTT) and dithiothreitol (DTT) were the products of Serva Co. (USA). SPDP was synthesized and kindly provided by Prof. Wen Xue Wang, Department of Toxicology of our university. SEA protein and rabbit mAb against the F(ab')$_2$ fragment of mouse IgG were purchased from the Academy of Military Medical Sciences (Beijing, China). Immunohistochemical ABC kit was the product of Vector Laboratories Inc. (USA). Dimethyl benzidine (DAB) and dimethyl sulfoxide (DMSO) were the products of Sigma Chemical Co. (USA).

Extract of mAb HAb18 and preparation of its F (ab')$_2$ fragment

Extract and purification of mAb HAb18 The hybridoma cells which secrete mAb HAb18 (its immunoglobulin type is IgG), was cloned and selected again. The abdominal dropsy of the antibody was prepared by injecting 1×10^6 hybridoma cells into the cavum abdominis of every Balb/c mouse and collected at the aseptic environment. After pretreated with 0.01 mol·L^{-1} phosphate-buffered saline (PBS) (pH 7.5), the collected abdominal dropsy was purified through chromatography column SP-40HR (column volume was 2 cm × 18 cm, and velocity of flow was 10 mL·min^{-1}) with Fast protein liquid chromatography (FPLC) system (Waters 650E, Waters Co., USA), and the IgG part was collected. Then 227 g·L^{-1} solid ammonia sulfate was added at 4℃, agitated for 15-20 min, stood at 4℃ for more than 1 h, and centrifuged at 1 500 rpm for 5 min. The supernatant was aborted, while the deposit was dissolved in 0.01 mol·L-1 PBS (pH 7.4) and dialyzed with the same buffer for 12 h-20 h.

Identification of mAb HAb18 The antibody specialty of mAb HAb18 was identified by normal immunocytochemical ABC method. The procedures were as follows: ① HHCC cells were cultured in 6-well culture plates which contained some coverslips in RPMI1640 medium containing 150 mL·L^{-1} new born bovine serum at 37℃ until the cells grew into log phase; ② the cells were fixed in 950 mL·L^{-1} ethanol for 15 min; ③ 7.5mL·L^{-1} H_2O_2 was added and incubated at 37 ℃ for 10 min; ④ normal sheep serum was added and incubated at 37℃ for 30 min; ⑤ MAb HAb18 was added, while PBS was used as negative control, and incubated at 37℃ for 1h; ⑥ biotin-labeled sheep anti-mouse IgG mAb was added and incubated at 37℃ for 30 min; ⑦ ABC complex was added and incubated at 37℃ for 30 min; ⑧ the color was developed with DAB for 10-20 min; ⑨ the slides were counterstained with hematoxylin, dehydrated, cleared and mounted.

Preparation of the F(ab')$_2$ fragment of mAb HAb18

The F(ab')$_2$ fragment of mAb HAb18 was prepared by papainic digestion method. The procedures were: ① MAb HAb18 was dialyzed with 1 mol·L-1 NaAc (pH 5.5) for 12 h; ② papain was dissolved in NaAc buffer containing 3 mol·L-1 EDTA and 2 mol·L-1 DTT; ③ the dissolved papain whose mass was about 5% of the pre-digested mAb, was added into the mAb solution and incubated at 37℃ for 10 h; ④ the same concentration of papain was added again and incubated at 37℃ for 10 h-12 h; ⑤ 2 mmol·L-1 iodinate acetamide was added to terminate the reaction; ⑥ at last, the proteins were dialyzed with 0.01 mol·L-1 phosphate buffer (PB) (pH 7.5).

Preparation and purification of HAb18 F(ab')$_2$-SEA conjugate

SEA protein and mAb HAb18 F(ab')$_2$ purified through chromatography column with FPLC were respectively dissolved and dialyzed in 0.1 mol·L-1 PB (pH 7.5, containing 0.1 mol·L-1 NaCl). Then they reacted with SPDP, which was dissolved in DMSO and whose molecular value was twice that of HAb18 F(ab')$_2$ or SEA protein, for 30 min. SEA was dialyzed again in 0.1 mol·L-1 PB (pH 7.5, containing 0.1 mol·L-1 NaCl), and HAb18 F(ab')$_2$ was dialyzed again in 0.1 mol·L-1 PB (pH 4.6, containing 0.1 mol·L-1 NaCl). DTT whose final concentration was 50 m mol·L-1 was added into HAb18 F(ab')$_2$. Thirty min later, they were dialyzed in 0.1 mol·L^{-1} PBS (pH 7.5) in nitrogenous environment and at room temperature. Finally, the complex of SPDP and SEA was mixed with the reductive complex of HAb18 F(ab')$_2$ and SPDP, and they were stirred for 24 h. The conjugate was purified through chromatography Superose 12 column (column volume was 1 cm × 65 cm, and velocity of flow was 0.2 mL·min^{-1}) with FPLC system. The molecular

mass and purity of the protein of each collected peak were identified with SDS-PAGE assay (the concentration of separation gel was 120 $g \cdot L^{-1}$). The protein content was assayed by Lowry's method.

Identification of the activity of HAb18 F(ab')$_2$ in the conjugate

The antibody specialty of HAb18 F(ab')$_2$-SEA conjugate against HCC was identified by indirect immunocytochemical ABC method. The procedures were: ① HHCC cells were cultured in 6-well culture plates which contained some coverslips in RPMI1640 medium containing 150 $mL \cdot L^{-1}$ new born bovine serum at 37℃ until the cells grew into log phase; ② the cells were fixed in 950 $mL \cdot L^{-1}$ ethanol for 15 min; ③ 7.5 $mL \cdot L^{-1}$ H_2O_2 was added and incubated at 37℃ for 10 min; ④ normal sheep serum was added and incubated at 37℃ for 30 min; ⑤ HAb18 F(ab')$_2$-SEA conjugate was added, while HAb18 F(ab')$_2$ and PBS was respectively used as positive and negative controls, and incubated at 37℃ for 1 h; ⑥ rabbit anti-mouse IgG F(ab')$_2$ mAb was added and incubated at 37℃ for 30 min; ⑦ biotin-labeled sheep anti-rabbit IgG mAb was added and incubated at 37℃ for 30 min; ⑧ ABC complex was added and incubated at 37℃ for 30 min; ⑨ the color was developed with DAB for 10-20 min; ⑩ the slides were counterstained with hematoxylin, dehydrated, cleared and mounted.

Identification of the activity of SEA in the conjugate to activate PBMC

PBMC was extracted from fresh human peripheral blood that had been treated with anticoagulant reagent heparin by Ficoll's density gradient centrifugation method, and $2 \times 10^5 \cdot well^{-1}$ PBMC were added into 96-well flat-bottom culture plates. Then 0.1 $mg \cdot L^{-1}$ HAb18 F(ab')$_2$-SEA conjugate was added, while RPMI1640 medium containing 150 $mL \cdot L^{-1}$ new born bovine serum was used as negative control, 0.1 $g \cdot L^{-1}$ PHA and 0.02 $g \cdot L^{-1}$ SEA as positive controls. Six wells were used for each group of cells. They were cultured in CO_2 incubator at 37℃ for 60 h, then MTT (2 $g \cdot L^{-1}$, 50 $\mu L \cdot well^{-1}$) was added and incubated continually at 37℃ for 4 h. The medium was centrifuged and discarded, and 100 $\mu L \cdot well^{-1}$ DMSO was added. The culture plate was shaken for 10 min and the optical absorbance (*A*) value at 490 nm was detected with Bio-Rad ELISA instrument. The obtained data was statistically analyzed with Student's *t* test.

RESULTS

Extract and identification of mAb HAb18

After dialyzed, the abdominal dropsy of IgG mAb HAb18 was purified successfully with chromatography column SP-40HR (Figure 1). Immunocytochemical staining showed that the positive signal was brown, and located mainly within the cytoplasm and/or on the cell membranes. Most of the HHCC cells were positive. There was no detectable positive signal in negative control.

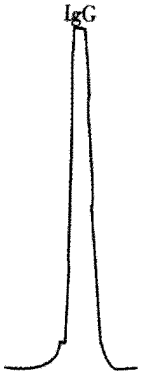

Figure 1 Chromatography for the purification of mAb HAb18.

Purification of HAb18 F(ab')$_2$-SEA conjugate

There were two peaks in the process of purification and elution of the prepared HAb18 F(ab')$_2$-SEA conjugate (Figure 2). SDS-PAGE assay demonstrated that the relative molecular mass of the first peak was about Mr. 130 and it was HAb18 F(ab')$_2$-SEA conjugate. The second peak was the complex of Fab whose relative molecular mass was about 45 and a little F(ab')$_2$ whose relative molecular mass was about 100 (Figure 3).

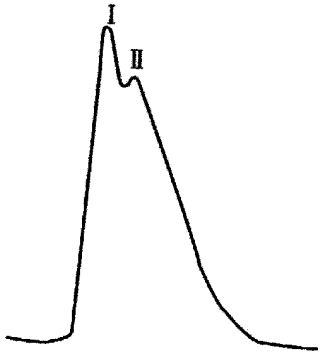

Figure 2 Chromatography for the purification of HAb18 F(ab')$_2$ SEA conjugate.

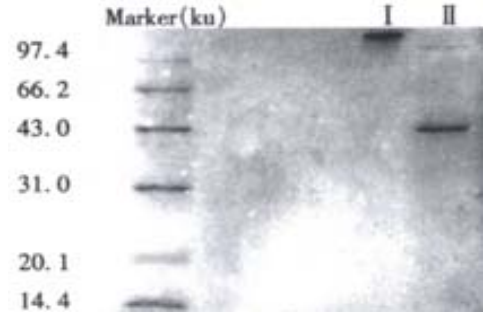

Figure 3 SDS-PAGE assay of the relative molecular mass of purified HAb18 F(ab')$_2$-SEA conjugate.

Identification of antibody activity of HAb18 F(ab')$_2$-SEA conjugate

The result of immunocytochemical staining was similar in HAb18 F(ab')$_2$-SEA conjugate and HAb18 F(ab')$_2$, i.e., the cytoplasm and/or cell membranes of most HHCC cells were positively stained, and no detectable positive signal was found in negative control (Figure 4).

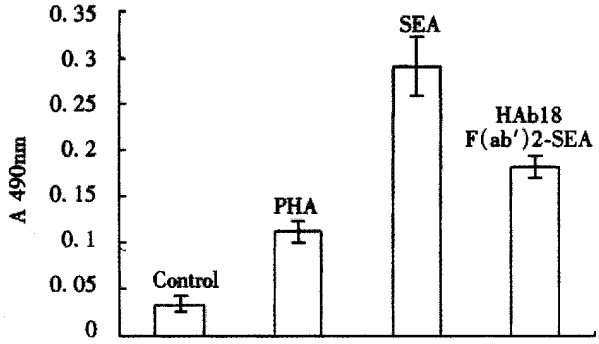

Figure 4 Distribution of HAb18 F(ab')$_2$ SEA conjugate in human hepatoma HHCC cells. ABC, ×400

Experimental observation on HAb18 F(ab')$_2$-SEA conjugate activating PBMC

The result of MTT assay showed that the *A* value at 490 nm of HAb18 F(ab')$_2$-SEA conjugate was 0.182 ± 0.012, those of PHA and SEA were respectively 0.112 ± 0.012 and 0.291 ± 0.032, that of negative control was 0.033 ± 0.009. The data of HAb18 F(ab')$_2$ SEA conjugate, PHA and SEA were all significantly higher than that of negative control (P<0.05, Figure 5).

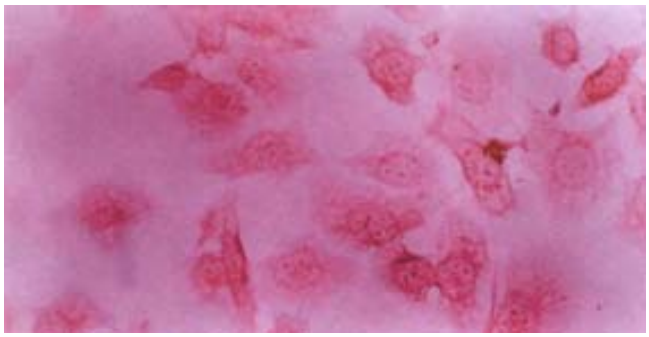

Figure 5 The MTT assay result of HAb18 F(ab')$_2$-SEA conjugate stimulating PBMC to proliferate.

DISCUSSION

HCC is a common malignant tumor, and there has been no effective treatment up to date[23,24]. Besides the 3 conventional therapeutics, i.e., surgical operation, chemotherapy and radiotherapy, targeting diagnosis and therapy of HCC with anti-HCC mAb have been studied extensively, giving a hopeful prospect to HCC treatment[25-36]. Targeting therapy is a common means of tumor immunotherapy, and is called "biological missile"[37-47]. The "warheads" of" "biological missiles" are usually radioactive nuclides, chemotherapeutants or toxins. Because of the radioactive pollution, "warheads" falling off and other side effects to normal tissue *in vivo*, the conjugate of mAb and radioactive nuclides, chemotherapeutants or toxins have limited effects and can not be used widely. SAg is a new "warhead" of "biological missiles". It can kill tumor cells through activating esoteric T lymphocytes, and make the activated T lymphocytes release much useful cytokines. The anti-tumor effect of mAb-SAg conjugate is significantly greater than that of bispecial mAb-mediated cytokines or mononuclear-microphage[8]. Dohlsten *et al*[7-9] have respectively prepared the chemical conjugates of SEA and anti-colon carcinoma mAb C215, C242, and the fusion proteins of SEA and the Fab fragment of mAb C215, C242 are prepared by gene engineering method. The cytotoxic experiment indicates that these conjugates or fusion proteins do not lose the ability of activating T lymphocytes. RT-PCR assay shows that SEA-activated monocytes express the mRNAs of many cytokines such as IL-1α, Il-1β, IL-2, IL-6, TNF-α, TNF-β and TNF-γ. Ihle *et al*[10] have prepared the fusion protein of SEA and staphylococcal protein A (SPA) which has a special affinity to IgG, and the conjugates of SEA and anti-CD7 mAb (IgG2a), anti-CD38 mAb (IgG1) respectively, and the cytotoxic experiment to MHCII negative acute T lymphocytic leukemia cells was performed. The results are excellent. The targeting treatment to severe combined immune deficiency (SCID) mice bearing intraperitoneally growing colon carcinoma colo205 cells using fusion protein SEA-C242 Fab shows that human T lymphocytes must be planted into SCID mice before treatment, indicating that SEA-C242 Fab needs to activate T lymphocytes to develop its anti-tumor effect[11]. Litton *et al*[12] have observed the reaction of tumors and their spherical tissues to fusion protein SEA-C242 with immunohistochemical staining and computer-assisted image analysis, and the results demonstrate that the T lymphocytes and monocytes concentrate in all the tumor tissues just several hours after the SEA-C242 Fab was injected. The main cytokines produced are TNF-α, IL-2, IL-4, IL-5, IL-10, IL-12, IFN-γ, GMSF and TGF-β. The authors consider that apoptosis in tumor cells happens because of the production of cytokines, T lymphocytes infiltration and CD95 (Fas) receptor expression. That is followed by obvious reduction of tumor mass, which is seen within 24 h after the SEA-C242 Fab infusion. In the previous studies of SAg treatment for tumors mAb-SAg conjugates or their fusion proteins were used. mAb-targeted SAg

was mainly used in the studies of anti-tumors including colon carcinoma, melanoma, lymphoma, neuroblastoma, etc. There have been some clinical reports about treating tumors with mAb-SEA conjugate[48,49]. Compared with complete mAb, the main advantages of mAb F(ab')$_2$ fragment are: ① Its volume is smaller, and easy to penetrate through tumor tissues; ② the human anti-mouse antibodies reaction is milder, and suitable for repeated treatments; ③ It does not conjugate with the Fc receptors on non-tumor cells, and can increase T/NT ratio *in vivo*. Therefore, in the present study, we used the F(ab')$_2$ fragment of mAb HAb18, but not intact mAb, and prepared the conjugate of the F(ab')$_2$ fragment of anti-HCC mAb HAb18 and SEA protein so as to use it in the experimental study of SAg anti-HCC in the future.

In the previous reports, the F(ab')$_2$ fragment of mAb is usually prepared by pepsic digestion method, and the papainic digestion method is mostly used to prepare the Fab fragment of mAb. The productive rate of preparing IgG fragments with papainic digestion is higher than those of other traditional methods and it is helpful in preserving the antibody activity. When an mAb is digested with papain, the F(ab')$_2$ fragment can be obtained at pH 5.5, and the Fab fragment can be obtained at pH 8.0[50]. The HAb18 F(ab')$_2$ prepared in this experiment contained a small amount of Fab, which can not be removed because of the limited conditions of purification. The second peak produced during purification of HAb18 F(ab')$_2$-SEA conjugate was the complex of HAb18 F(ab')$_2$ and Fab, but the amount of F(ab')$_2$ was significantly less than that of Fab. These results indicated that most F(ab')$_2$ had conjugated with SEA protein, whereas Fab seemed not prone to conjugate.

During the preparation of protein conjugate by SPDP method, the reagents with moderate reacting activity should be used, and the reacting conditions should be mild, such as at room temperature, in neutral pH value and water bath, so as to avoid denaturalization of proteins and loss of biological activity. SPDP is a commonly-used protein conjugating reagent. It can introduce sulfhydryl into protein molecules, and then make the protein molecules conjugate with other protein molecules with sulfhydryl exchange or sulfhydryl addition reactions. There are few side effects of this conjugating reaction, but SPDP also has some shortcomings, such as being prone to inactivate because of deliquescence, and there are many other influencing factors during the operating process. The results in present study suggested that the protein conjugate of mAb HAb18 F(ab')$_2$ and SEA can be prepared by SPDP method successfully, while the activity of proteins can be kept well.

Because the F(ab')$_2$ fragment of mAb HAb18 used in this study did not contain Fc fragment, mouse anti-human intact IgG antibodies can not react with it effectively, so the antibody activity of HAb18 F(ab')$_2$-SEA conjugate can not be identified by normal immunocytochemical method. In our experiment, the activity of mAb F(ab')$_2$ fragment in HAb18 F(ab')$_2$-SEA conjugate can be identified effectively by indirect immunocytochemical ABC method, in which rabbit anti-mouse IgG F(ab')$_2$ mAb was used as the second antibody.

SAg has a strong mitogenetic effect on PBMC because it can activate T lymphocytes effectively[51]. The A value of HAb18 F(ab')$_2$ SEA was significantly higher than that of negative control in this study ($P<0.05$), which indicated that the prepared HAb18 F(ab')$_2$ SEA conjugate had a significant effect on stimulating the proliferation of PBMC and can be used in the experimental study of HCC targeting therapy with mAb-SAg conjugate.

Wietzke Braun P, Meier V, Braun F, Ramadori G. Combination of "low-dose"ribavirin and interferon alfa-2a therapy followed by interferon alfa -2a monotherapy in chronic HCV infected non responders and relapsers after interferon alfa-2a monotherapy. ***World J Gastroenterol***, 2001;7(2):222-227

Abstract

AIM **To report on the efficacy, safety and tolerability of interferon alfa-2a combined with a "low dose" of ribavirin for relapsers and non-responders to alpha interferon monotherapy.**

METHODS **Thirty four chronic hepatitis C virus infected non responders to interferon alfa-2a monotherapy (a course of at least 3 months treatment) and 13 relapsers to interferon alfa-2a monotherapy (a dose of 3 to 6 million units three times per week for at least 20 weeks but not more than 18 months) were treated with the same dose of interferon alfa-2a used before (3 to 6 million units three times per week) and ribavirin (10 mg/kg daily) for 6 months. In complete responders, interferon alfa-2a was administered for further 6 months at the same dose used before as monotherapy.**

RESULTS **Seven (20.6%) of 34 non responders stopped the combined therapy due to adverse events, including two patients with histological and clinical Child A cirrhosis. In 17/27 (63%) non responders, the combined therapy was stopped after three months because of non response. Ten of the 27 non responders completed the 12 month treatment course. At a mean follow up of 28 months (16-37 months) after the treatment, 4/10 (15%) previous non responders still remained complete responders. All 13 previous relapsers completed the 12-month treatment course. At a mean follow up of 22 months (9-36 months) after treatment, 6/13 (46%) the previous relapsers were still sustained complete responders.**

CONCLUSION **Our treatment schedule of the combined therapy for 6 months of interferon alfa-2a with a low dose of ribavirin (10 mg/kg/day) followed by 6 months of interferon alfa-2a monotherapy is able to induce a sustained complete response rate in 15% of non responders and 46% of relapsers with chronic hepatitis C virus related liver diseases comparable to those obtained with the standard doses of ribavirin 1000 - 1200 mg/day. Randomized prospective controlled trials using lower total amounts of ribavirin in combination with interferon should be performed.**

INTRODUCTION

The hepatitis C virus (HCV) is the most common infectious agent associated with post-transfusion and community-acquired non-A-non-B hepatitis and cryptogenic cirrhosis[1]. Up to 85% of patients with acute HCV infection will develop chronic liver disease and spontaneous viral elimination is rare[2]. In studies with a follow up of 10-20 years, cirrhosis secondary to chronic HCV infection develops in 20%-30%[2,3] and is the most common indication for liver transplantation worldwide[4]. Patients with cirrhosis secondary to chronic HCV infection also have an increased risk for development of hepatocellular carcinoma, estimated to be between 1%-4% per year[5]. The introduction of alpha interferon (IFNα) for the treatment of HCV infection is an outstanding revolution in antiviral therapy[6]. However, alpha interferon monotherapy strategies can only induce a sustained response in 8%-21% of the patients with chronic HCV-related liver disease[7]. Thus, new therapeutic strategies were needed for chronic HCV infection in order to increase the sustained response rate in naive patients and patients in whom the

response to standard alpha interferon monotherapy was ineffective, in particular the relapsers and non-responders.

Systemic ribavirin (1-β-D-ribofuranosyl-1, 2, 4-triazole-3-carboxamide), a broad-spectrum oral purine nucleoside analogue, has been used for the treatment of a variety of viral diseases[8]. In children with viral diseases, ribavirin is usually given orally at a dosage of 10 mg/kg daily[8]. In adult human immunodeficiency virus (HIV)-infected patients, ribavirin plasma levels between 6 and 12 μmol/L are required to achieve viral inhibition with acceptable toxicity[9]. Daily oral doses of 600 (1200) mg ribavirin resulted in a mean peak plasma concentration of 5.0 (11.1) μmol/L at the end of the first week. Clinical and hematologic toxicities were not noted at a ribavirin dosage of 600 mg/d for 2 weeks, but a dosage of 1200 mg/d for 2 weeks resulted in moderate to severe clinical and hematological adverse events (hematocrit decrease) [9]. Furthermore Glue *et al*. reported similar ribavirin pharmacokinetics comparing pediatric and adult patients[10].

In patients with chronic HCV infection, ribavirin monotherapy has been found to improve serum levels of hepatic transaminases and liver histology by decreasing hepatic inflammation and necrosis[11-13]. In 1991, oral ribavirin treatment in a dosage of 1000 mg/d for chronic HCV-infected patients weighing less than 75 kg and 1200 mg/d weighing more than 75 kg for 12 weeks was evaluated in a pilot study [14]. In 1994 and 1995, the first promising reports[15-18] on the combined therapy with alpha interferon and ribavirin in a dosage of 1000-1200 mg/d orally according to Reichard *et al*[14] were obtained in relapsers and non-responders as well in naive patients with chronic HCV infection. Therefore, we started a combination treatment with interferon alfa-2a (IFN) in non-responders and relapsers to IFN monotherapy. However, we used a lower dosage of oral ribavirin (10 mg/kg body weight daily) according to that used in child[8] and adult[9] HIV-infected patients and to pharmacokinetic studies performed in healthy volunteer and patient populations[10]. Duration of the combined therapy was 6 months, followed by a 6-month treatment with IFN monotherapy for responders to combined therapy in chronic HCV-infected patients who were previous non-responders or non-sustained responders (relapsers) to IFN alone. The results of safety, tolerability and virological efficacy during and after treatment are reported.

PATIENTS AND METHODS

Patients

Fourty-seven chronic HCV-infected patients (15 female, 32 male, mean age 48 years) with histological mild chronic hepatitis (n = 17), moderate chronic hepatitis (n = 18), severe chronic hepatitis (n = 5), cirrhosis (n = 5) and unknown histology (n = 2) received antiviral therapy. HCV genotypes were classified in 10 patients as I (1a), in 30 as II (1b), in 2 as IV (2b), in 4 as V (3a), and one was unclassifiable according to Okamoto[19] and Simmonds[20]. The cause for HCV transmission could be identified as lood-transfusions (n = 13), injection drug use (n = 3), occupational (n = 2), sexual/household (n = 1) and unknown (n = 28). All patients had been previously treated with IFN. Thirty-four patients had not responded. Non-response to the first IFN therapy was defined as the persistence of at least 3 abnormal aminotransferase activities during a course of at least 3 months of IFN treatment with monthly control and after IFN discontinuation, and by PCR which remained positive [21]. Thirteen patients had an initial response to a dose of 3-6 million units three times per week for at least 20 weeks but not more than 18 months[22], followed by relapse. The IFN treatment was discontinued for at least 3 months before the combination therapy was started. All patients had persistent elevations of serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST), a positive third-generation anti-HCV test using an immunoblot procedure (CHIRON RIBA HCV 3.0 SIA, Ortho Diagnostic Systems Inc., Raritan, USA) and positive serum HCV RNA by reverse transcriptase/polymerase chain reaction (RT/PCR). Patients with decompensated liver disease, autoimmune disorders, thyroid gland alterations, active alcohol or injection drug abuse, history of major psychiatric disease, pregnancy, significant anemia (hemoglobin <12 g/dL), leukocytopenia (<3000 μL) or thrombocytopenia (<50000 μL) were not included. Active hepatitis A virus, HIV, hepatitis B virus, cytomegalovirus or Ebstein-Barr virus infections were excluded by convential laboratory tests. Informed consent was obtained in all treated patients.

Treatment

Combination therapy was given for 6 months with IFN and ribavirin. The IFN dose was adjusted to the previous IFN treatment. Twenty-two of 34 previous non-responders were treated with 6 MU subcutaneous (s.c.) t.i.w. and 12/34 with 3 MU t.i. w.. Eleven of 13 previous relapsers were treated with 6 MU t.i.w. and 2/13 with 3 MU t.i.w.. To improve virological efficacy and tolerability instead of using ribavirin at a dose of 1000-1200 mg/day, we administered ribavirin at 10 mg/kg body weight daily in three divided doses orally. This dose was chosen in accordance to the tolerability data obtained in HIV-infected children[8] whose pharmacokinetic data are similar to those obtained in adults[10] and in HIV-infected adults[9]. Patients who responded to the combination therapy were

treated for another 6 months with IFN monotherapy with the same preceeded dose (3 or 6 MU s.c. t.i.w.). After 12 months of treatment, the patients were followed up for at least 9 months.

Monitoring

Clinical examination, total blood cell counts, routine biochemical tests and detection of serum HCV RNA by RT/PCR were performed before and at monthly intervals during and after 6 months treatment, thereafter every 3 months.

Detection of serum HCV-specific RNA by RT/PCR

RNA was extracted from serum samples (140 μL) using the QIAamp viral RNA KIT (Qiagen, Hilden, Germany) according to the manufacturer's protocol. One-fifth of the extracted material from serum was subjected to a nested RT/PCR procedure essentially as described[23].

Determination of HCV genotypes

HCV genotypes were determined according to Okamoto *et al*[19] using RT/PCR with a type-specific primer of the core region. Genotypes determination was then confirmed by restriction enzyme digestion analysis as described previously[24].

RESULTS

Response to previous IFN monotherapy, combination therapy with IFN and ribavirin, subsequent IFN monotherapy for responders to combination therapy and outcome during follow-up for previous non-responders is depicted in Figure 1 and for previous relapsers in Figure 2.

Drop-outs

Seven of 34 non-responders to previous IFN monotherapy (20.6%) stopped the combination therapy because of insulin dependent diabetes mellitus ($n = 1$), sarcoidosis ($n = 1$), lichen ruber oris mucosae ($n = 1$), severe fatigue ($n = 1$) or depression and fatigue ($n = 3$). Two of seven drop-out patients had a histological and clinical Child A cirrhosis. During combination therapy and after withdrawal, transaminases remained unchanged at elevated levels and serum HCV RNA was still positive in all patients. There were no drop-outs in the 13 relapsers to the previous IFN monotherapy.

Outcome of combination treatment (6 months)

Twenty-seven non-responders to previous IFN monotherapy continued on the 6-month course of combination therapy. At the end of the 3 months, 17/27 (63%) patients did not respond to the combination therapy with unchanged elevated transaminases and positive serum HCV-RNA, so therapy was stopped. Ten of 27 (37%) had a complete response with transaminases in the reference ranges and negative serum HCV RNA.

All 13 relapsers to previous IFN monotherapy completed the 6-month course of combination therapy. At the end of 6 months, 13/13 (100%) patients had a complete response with transaminases in the reference ranges and negative serum HCV RNA.

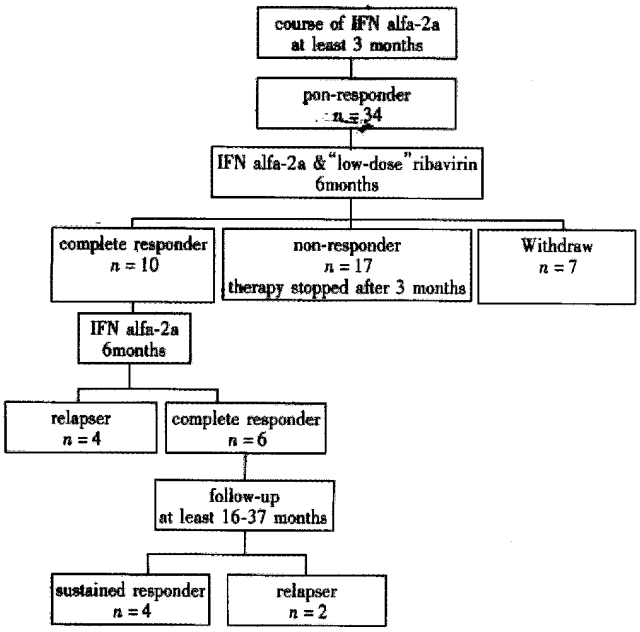

Figure 1 Outcome of 34 HCV infected non-responders to IFN monotherapy, including response to combined therapy with IFN and "low-dose" ribavirin for 6 months, response to followed IFN monotherapy for 6 months for complete responders to combined therapy and outcome during follow up after 12 months treatment.

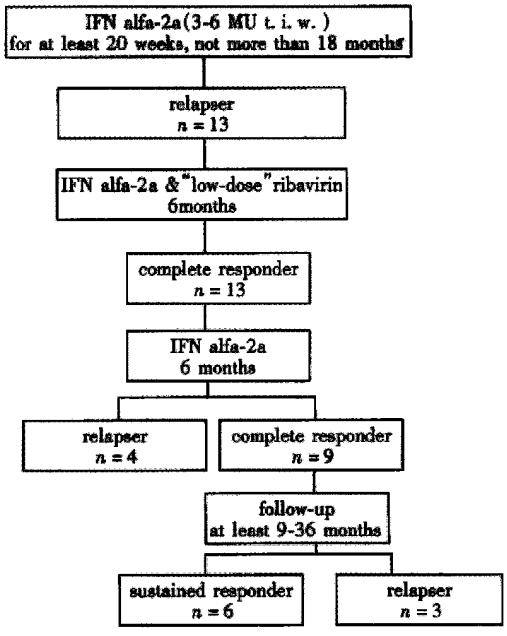

Figure 2 Outcome of 13 HCV-infected relapsers to IFN monotherapy, including response to combined therapy with IFN and "low-dose" ribivirin for 6 months, response to followed IFN monotherapy for 6 months for complete responders to combined therapy and outcome during follow-up after end of 12 months treatment.

Outcome of complete treatment (12 months)

The 10 non-responders to previous IFN monotherapy, who had a complete response at the end of combination therapy were treated with the same dose of IFN used before as monotherapy for a further 6 months. During the 6-month course of IFN monotherapy, 4/10 (40%) patients had a relapse within 6-months after the end of ribavirin treatment. Six of ten (60%) patients still had a complete response at the end of 12-month treatment course with transaminases in the reference ranges and undetectable serum HCV RNA.

All 13 relapsers to previous IFN monotherapy had a complete response at the end of combination therapy and were treated with the same dose of IFN used before as monotherapy for a further 6 months. During the 6-month course of IFN monotherapy, 4/13 (31%) patients had a relapse within 6 months after ribavirin treatment. Nine of 13 (69%) patients still had a complete response at the end of 12-month treatment with transaminases in the reference ranges and undetectable serum HCV RNA.

Follow-up (at least 9 months)

At the end of the 12-month treatment, 6 non-responders to previous IFN monotherapy became complete responders. At a mean follow-up of 28 months (16-37 months), 2/6 (33%) patients relapsed, 4/6 (67%) were sustained responders, including one patient with genotype II (1b) and cirrhosis.

At the end of 12-month treatment, 9 relapsers to previous IFN monotherapy became complete responders. At a mean follow-up of 22 months (9-36 months), 3/9 (33%) patients relapsed, 6/9 (67%) were sustained responders with transaminases in the normal range and undetectable serum HCV-RNA.

In summery, 4/27 previous non-responders (15%) and 6/13 previous relapsers (46%) are sustained responders.

Side effects

Combination therapy with IFN (3-6 MU s.c. t.i.w.) and "low-dose" ribavirin (10 mg/kg body weight) was well tolerated. Monitoring of side effects by questioning and clinical examination revealed arthralgia in 77%, fatigue in 27% and loss of weight in 19% of the patients. The most prominent side effects of combination therapy were alterations in total blood cell counts. Mild leukocytopenia (minimal 2000/μL in a patient without cirrhosis and 1400/μL in a patient with cirrhosis) and thrombocytopenia (minimal 79 000 μL in a patient without cirrhosis and 35 000 μL in a patient with cirrhosis) were generally seen. Decreases in hemoglobin is shown in Figure 3. Of 40 patients who continued on combination therapy 7 patients were withdrawn. There was no need of transfusion or drug dose reduction. All side effects were completely reversible within one month after treatment.

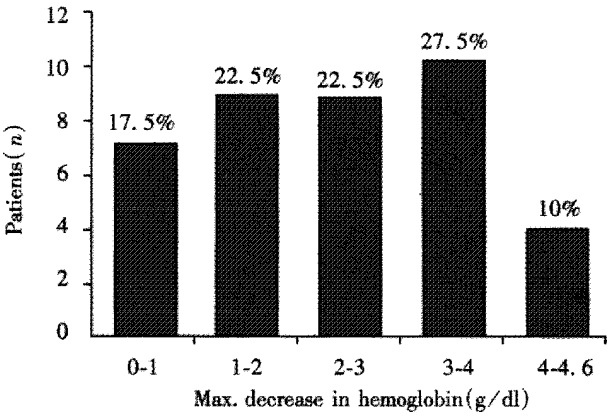

Figure 3 Decrease of hemoglobin of 40 patients (34 non-responders and 13 relapsers to IFN monotherapy) who continued on combination therapy with IFN and "low-dose" ribavirin.

DISCUSSION

In this retrospective uncontrolled analysis, we report on our experience of 47 chronic HCV-infected patients who received a combination treatment of IFN and "low-dose" ribavirin after previous failure to IFN monotherapy. Of the 47 patients, 34 were non-responders and 13 relapsers to the initial IFN monotherapy. Seven of 34 (20.6%) non-responders to the previous IFN monotherapy (two with histological cirrhosis), did not complete the 6 months course of combination therapy due to various side effects, but none of the 13 relapsers to previous IFN monotherapy. In comparison to our results, a meta-analysis of individual patient data from European centers revealed that about 10% of patients withdrawn from treatment[25]. Although our results have the drawback of being obtained under uncontrolled conditions, they have the advantage of being more realistic as every day experience is often different from that obtained under controlled study conditions.

In our patients, we found that a 6-month course of combined therapy with "low-dose" ribavirin induced a complete response at the end of treatment in 10 (37%)of 27 initial non-responders. In a similar retrospective analysis, 2 (12.5%) of 16 non-responders to IFN monotherapy were complete responders at the end of combination therapy and both patients relapsed during the follow-up period[26]. From our initial 13 relapsers to IFN monotherapy, 13 (100%) were complete responders at the end of 6-month combination treatment with "low-dose" ribavirin, in contrast to the multicenter study from Davis *et al*, who found 77% complete responders at the end of 6-month combination treatment with ribivarin in a dose of 1000-1200 mg per day depending on body weight[22].

Previous publications had suggested that duration of therapy longer than 6 months may reduce the number of relapsers[16,27]. Therefore, the 23 complete responders (10 initial non-responders and 13 relapsers to IFN monotherapy) at the end of 6-month combined therapy continued with IFN alone for another 6 months. Eight of 23 (35%) complete responders at the end of combined therapy with "low-dose" ribavirin (4 initial non-responders and 4 relapsers to IFN monotherapy) relapsed under IFN monotherapy within 3 months, suggesting that in a subgroup of patients a longer course of combined therapy could leed to sustained response.

During the follow-up period, 5 of 15 (33%) complete responders at the end of 12 months treatment (2 initial non-responders and 3 relapsers to IFN monotherapy) relapsed within 3 months. Also, these patients represent a subgroup who may benefit of a longer period of combined therapy. However, 4/27 (15%) initial non-responders (including one with histological cirrhosis and genotype I (1b) and 6/13 (46%) relapsers to IFN monotherapy were still complete sustained responders (16-37 months follow-up for initial non-responders and 9-36 months for initial relapsers to IFN monotherapy) after 12 months treatment.

A combined therapy with IFN and "low-dose" ribavirin for 6 months followed by 6 months of IFN monotherapy in those patients who responded to the combination therapy can induce sustained response not only in relapsers to IFN monotherapy, but also in some non-responders, among whom, one patient had histological sign of cirrhosis and genotype I (1b). This result is noteworthy as the monotherapy course was performed with a total amount of IFN which was previously shown to be effective in a large number of patients[27]. This suggests that retreatment with a higher dose of IFN for a longer period[28-30] is less promising than the combination therapy. Our experience also shows that a further 6 months of IFN monotherapy after combination therapy may help reduce the number of relapsers and that on the other hand the duration of the combination therapy of 6 months may not be sufficient for some patients. The results of this retrospective analysis are difficult to compare with those recently published by Sostegni *et al*[31], Davis *et al*[22], Pol *et al*[21] and by Milella *et al*[32] obtained treating patients who were non-responders to[21,31,32] or relapsed after[22,32] interferon alfa monotherapy with a combination therapy for 6 months, because the number of non-responders and relapsers we treated is small. However, it is also noteworthy that the lower dose of ribavirin we used seems to allow response rate may similar to those recently published in controlled studies[21,22,31,32]. This strategy received support in a recently presented abstract[33] where a ribavirin dose of 600 mg/day was as effective as 1000 mg/day as for as week 12 HCV RNA levels concerns during alpha interferon and ribavirin therapy in chronic HCV-infected patients. This is also of economic relevance as the ribavirin released into the market recently increases the costs of about 1000 Dollars per month. Our results may stimulate a prospective study where complete responders under combination therapy are treated for further 6 months with alpha interferon alone as has been recently suggested by Perasso *et al*[34].

In conclusion, combination therapy with "low-dose" ribavirin may represent a therapeutic alternative for at least some non-responders and relapsers.

ACKNOWLEDGMENT We like to thank Dr. S. Mihm for determination of HCV genotypes and detection of serum HCV RNA, Mrs. Gogoll for assistance in collecting the data, the colleagues of our department for co-operation in treating patients, and Prof. V. W. Armstrong for reading the manuscript.

Meier V, Mihm S, Wietzke Braun P, Ramadori G. HCV-RNA positivity in peripheral blood mononuclear cells of patients with chronic HCV infection: does it really mean viral replication? ***World J Gastroenterol***, 2001;7(2):228-234

Abstract

AIM To analyze the association of HCV-RNA with peripheral blood mononuclear cells (PBMC) and to answer the question whether HCV-RNA positivity in PBMC is due to viral replication.

METHODS HCV-RNA was monitored in serum and PBMC preparations from 15 patients with chronic HCV infection before, during and after an IFN-α therapy using a nested RT/PCR technique. In a second approach, PBMC from healthy donors were incubated in HCV positive plasma.

RESULTS In the IFN-α responding patients, HCV-RNA disappeared first from total RNA preparations of PBMC and then from serum. In contrast, in relapsing patients, HCV-RNA reappeared first in serum and then in PBMC. A quantitative analysis of the HCV-RNA concentration in serum was performed before and after transition from detectable to non detectable HCV-RNA in PBMC-RNA and vice versa. When HCV-RNA was detectable in PBMC preparations, the HCV concentration in serum was significantly higher than the serum HCV-RNA concentration when HCV-RNA in PBMC was not detectable. Furthermore, at no time during the observation period was HCV specific RNA observed in PBMC, if HCV-RNA in serum was under the detection limit. Incubation of PBMC from healthy donors with several dilutions of HCV positive plasma for two hours showed a concentration dependent PCR positivity for HCV-RNA in reisolated PBMC.

CONCLUSION The detectability of HCV-RNA in total RNA from PBMC seems to depend on the HCV concentration in serum. Contamination or passive adsorption by circulating virus could be the reason for detection of HCV-RNA in PBMC preparations of chronically infected patients.

INTRODUCTION

Hepatitis C virus (HCV) is an enveloped singlestranded positive-strand RNA virus of the Flaviviridae family[1]. It is the major agent responsible for parenterally transmitted non-A, non-B hepatitis[2]. Acute infection with HCV is often clinically asymptomatic and the majority of patients develop a chronic hepatitis[3]. Treatment with interferon α (IFN-α) in combination with ribavirin, a synthetic guanosine analogue, is now the regimen of choice for patients chronically infected with HCV[4,5]. During drug administration, HCV-RNA may disappear both in serum and in peripheral blood mononuclear cells (PBMC)[6], but the proportion of patients responding to this therapy in terms of a sustained virological response varied around 40%. About 15%-20% of HCV infected patients progress to end-stage liver disease with cirrhosis and also hepatocellular carcinoma[7-10]. After orthotopic liver transplantation, reinfection of the graft with HCV is the rule[11,12]. It has been hypothesized that virus replication takes place at extrahepatic sites. Possible sites are the different cell fractions (PBMC, granulocytes or red blood cells/pellets) of the peripheral blood[13,14] or tissues like lymph nodes, pancreas, adrenal gland thyroid, bone marrow or spleen[15]. In particular, PBMCs have been suggested to function as an important extrahepatic reservoir or as a possible site for extrahepatic HCV replication[16-19]. This assumption was based on the demonstration of negative-strand HCV-RNA, the replicative intermediate of HCV, in association with PBMC from HCV infected patients in whose sera negative-strand HCV-RNA was not detected. The presence

of negative-strand HCV-RNA in extrahepatic compartments based on PCR detection assays has been suggested in many reports with very significantly different detection rates (from 0% to 100%). An extensive artefactual detection of negative-strand HCV-RNA due to self-priming and mispriming events is possibly responsible for these differences. This is especially true when a 5'-noncoding-region primer pair is used[20,21].

Other authors have also shown that the presence of HCV sequences in PBMC is compatible with passive virus adsorption via specific receptors or with contamination by circulating virus[22,23]. HCV has been found to bind to low density lipoproteins (LDL) and therefore, enter the PBMC via LDL-receptor[24-26]. Pileri and colleagues demonstrated the binding of HCV to CD 81, a 25-kD molecule of the tetraspanin superfamily expressed in various cell types including hepatocytes and B-lymphocytes[27].

The present study aims to analyse the association of HCV-RNA with PBMC and to answer the question whether HCV-RNA positivity in PBMC is really due to viral replication. Therefore, HCV-RNA detectability was serially monitored in both the serum and PBMC preparations from 15 patients with chronic HCV infection before, during and after IFN-α therapy. In a second approach, PBMC from healthy donors were incubated for a short time in HCV-RNA positive plasma to investigate the possibility of an attachment of HCV to PBMC.

MATERIALS AND METHODS

Patients

A total of 15 patients (8 women and 7 men; mean age 57.0 years; age range 41-79 years) (Table 1) infected with HCV as diagnosed by the presence of anti-HCV antibodies and HCV-RNA in serum were studied consecutively. All were anti-HCV and HCV-RNA positive for at least six months. The degree of the liver injury was estimated histopathologically according to established criteria [28,29]. Patients with active hepatitis B virus or human immunodeficiency virus infection and those with continued alcohol or drug abuse were excluded. The patients received an IFN-á therapy (3×10^6 to 6×10^6 IU IFN-α_{2a} three times weekly to 6×10^6 IU IFN-α_{2a} daily, Roferon A, Hoffmann La Roche, Basel, Switzerland; doses were adapted individually based on well-being and response parameters) over a period of 6 to 17 months. Blood samples were taken twice before the therapy, monthly during therapy and after therapy. Serum samples and PBMC preparations were stored at -80℃. Additionally, blood samples were collected from three healthy donors (VM, NN and BS) for isolation of HCV negative PBMC and from three untreated patients (EZ, SG and UP) with chronic HCV infection for isolation of HCV positive plasma. The study was approved by the local ethics committee of the Georg-August-University, G-ttingen, Germany.

Preparation of PBMC

Human PBMCs were isolated from peripheral blood by Ficoll density gradient centrifugation[30]. Residual red blood cells were hypotonically lysed and cells were washed three times with phosphate buffered saline (PBS) pH 7.3. Cell preparations were routinely assessed for viability (>95%) by trypan blue dye exclusion. Typically, a PBMC preparation consisted of >98% lymphocytes and monocytes and <2% granulocytes as determined by morphology of cells stained according to Pappenheim.

Isolation of total cellular RNA

PBMCs obtained from approximately 30 mL peripheral blood were taken up in 3 mL guanidinium isothiocyanate (GTC) buffer[31]. The material was subjected to shearing forces by drawing it rigorously through a capillary needle. Subsequently, total cellular RNA was isolated by cesium chloride (CsCl) density gradient centrifugation[32] and the RNA concentration was determined photometrically.

Detection and quantification of serum HCV RNA

HCV specific RNA was extracted from serum samples (140 μL) using QIAamp viral RNA Kit (Qiagen, Hilden, Germany) according to the manufacturer's protocol. For qualitative determination of HCV specific RNA one fifth of the extracted material was subjected to a nested RT/PCR procedure essentially as described[33]. For the quantitative measurement of HCV viral RNA the Amplicor HCV Monitor Test Kit (Hoffmann-La

Roche AG, Grenzach-Wyhlen, Germany) was used according to the manufacturer's protocol. Test results less than 600 copies/mL are below the lower limit of quantification of the test and should be reported as "HCV detected, less than 600 copies/mL".

Detection of HCV RNA in PBMC by nested RT/PCR-procedure

For the qualitative detection of HCV specific RNA in PBMC 100 ng of total cellular RNA were subjected to a HCV specific nested RT/PCR procedure essentially as described[33].

Incubation of HCV-RNA negative PBMC in HCV-RNA positive plasma

Blood samples were obtained from the three healthy donors (VM, NN and BS) for preparation of HCV-RNA negative PBMC and from the three patients (SG, EZ and UP) chronically infected with HCV for isolation of HCV-RNA positive plasma samples. The PBMCs were isolated as described before. The plasma samples were obtained by centrifugation (10 minutes, 14 000 rpm and 4℃) of the HCV-RNA positive blood samples. The HCV concentration was then measured in these samples using the Amplicor Monitor Test Kit. Afterwards each of the three different plasma samples were diluted 1:4, 1:16 and 1:64 with HCV-RNA negative plasma from a healthy donor to reduce the virus concentration; one undiluted sample was also used.

PBMC isolated from donor VM were then incubated with the plasma samples from patient UP, from donor NN in the plasma samples of patient EZ and from donor BS in the plasma samples of patient SG. Incubation was performed for 2 hours at 37℃ in an air incubator. After incubation the PBMCs were washed three times in PBS as described above. The total cellular RNA was then isolated by CsCl density gradient centrifugation and the HCV-RNA was detected with HCV specific nested RT/PCR technique as described.

RESULTS

HCV-RNA detectability in sera and in total RNA preparations of PBMC from patients with chronic HCV infection before, during and after an IFN-α therapy

The detectability of HCV specific RNA was monitored regularly before, during and after an IFN-α therapy in sera and in total RNA preparation of PBMC in 15 patients with chronic HCV infection by a nested RT/PCR procedure. HCV-RNA was below the detection limit in 102 serum samples taken during the IFN-α therapy. In none of these cases could HCV-RNA be observed in PBMC. In contrast, HCV specific RNA was only detectable in PBMC when HCV-RNA in serum was above the detection limit.

In patients who completely responded to the IFN-α therapy, the number of HCV-RNA copies decreased progressively until they became undetectable in serum samples. HCV-RNA in PBMC fell below the detection limit before positivity disappeared from the serum. In the patients relapsing after cessation of IFN-α therapy, HCV-RNA reappeared first in serum and later in PBMC. Serum HCV-RNA concentrations were measured quantitatively before and after transition from detectable to non-detectable HCV-RNA in PBMC preparation and vice versa. The transition from detectable to non-detectable HCV-RNA in PBMC during drug therapy was associated with a strong and significant decrease of serum HCV-RNA concentration (Table 2 and Figure 1). Vice versa, the transition from non-detectable to detectable HCV-RNA in PBMC, in the case of a breakthrough under therapy, or when the therapy was stopped and a relapse was observed, was associated with a marked and significant increase of serum HCV-RNA concentration (Table 2 and Figure 1). HCV-RNA was undetectable in PBMC if HCV-RNA concentration in serum fell below 2263 copies/mL and became detectable when the HCV-RNA level in serum was higher than 4708 copies/mL (Table 2).

In one patient (pt #15) after therapy and in four patients (pt #3, pt #4, pt #9 and pt #14) relapsing after cessation of therapy, the blood samples taken during these period did not include the moment, when HCV-RNA was detectable in serum and undetectable in PBMC.

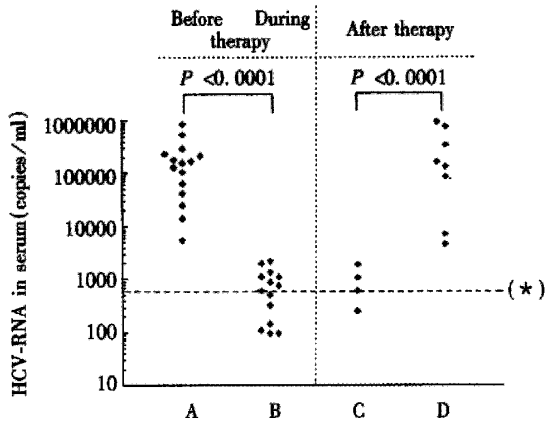

Figure 1 HCV-RNA concentration (copies / mL) in sera from patients with chronic HCV infection with regard to HCV-RNA detectability in PBMC before, during and after an IFN-α therapy. The transition from detectable to non-detectable HCV-RNA in PBMC during drug therapy was associated with a strong and significantly decrease of serum HCV-RNA concentration. Vice versa, the transition from non-detectable to detectable HCV-RNA in PBMC, in the case of a breakthrough under therapy, or when therapy was stopped and a relapse was observed was associated with a marked and significantly increase of serum HCV-RNA concentration. Columns A and D: HCV-RNA concentration, if HCV-RNA in serum and in PBMC was detectable. Columns B and C: HCV-RNA concentration, if HCV-RNA in serum was detectable and in PBMC undetectable. (*) Test results less than 600 copies / mL are below the lower limit of quantification of the test and should be reported as "HCV detected, less than 600 copies / mL".

Incubation of HCV-RNA negative PBMC from healthy donors in HCV-RNA positive plasma from patients infected chronically with HCV

The results of the measurement of the HCV concentrations in the undiluted positive plasma samples of each patient with chronic HCV infection using the Amplicor HCV Monitor Test Kit were as follows: patient SG 119271 copies/mL, patient UP 337539 copies/mL and patient EZ 77518 copies/mL. The virus concentration of the dilutions steps in each patient is shown in Table 3. The results of incubation of PBMC from healthy donors in HCV-RNA positive plasma with different virus concentration are summarized in Table 3. After a two-hour incubation at 37℃, all PBMC samples incubated in the undiluted plasma samples were HCV-RNA positive. When PBMCs from donor BS were incubated in plasma samples from patient SG, the HCV-RNA was detectable only in the undiluted sample (119271 copies/mL, Table 3). After incubation of PBMC from donor VM in plasma samples of patient UP, the HCV-RNA was detectable in dilution step 1:16 (21096 copies/mL, Table 3). On incubation of PBMC from donor NN in plasma samples of patient EZ, the HCV-RNA was detectable in dilution step 1:4 (19290 copies/mL, Table 3). These results indicate a possible correlation between the detectability of HCV-RNA in PBMC and the HCV concentration in the plasma, since no HCV-RNA could be detected in PBMC when the HCV titer was below 19290 copies/mL.

Table 3 Detectability of HCV-RNA in PBMC of healthy donors after incubation with different dilutions of HCV-RNA positive plasma

Patients	HCV concentration (copies/mL)				PMBC of healthy donor	Detectability of HCV-RNA in PBMC of healthy donors	
	Undiluted sample	1:4	1:16	1:64		Before incubation	After incubation dilution step (copies/mL)
SG	119 271	29 818	7454	1863	BS	n.d.	Undiluted (119271)
UP	337 539	84 385	21 096	5274	VM	n.d.	1:16 (21096)
EZ	77 518	19 290	4822	1206	NN	n.d.	1:4 (19290)

DISCUSSION

In all cases of orthotopic liver transplantation, an HCV reinfection of the graft occurs[11,12]. Persistence of HCV at extrahepatic sites is considered to be responsible for the reinfection. Therefore, any extrahepatic association of virus, e.g., by productive replication or simply by adhesion to outer membrane structures, appears to be relevant. One important extrahepatic reservoir is possibly the whole blood, which consists of a liquid component (plasma) and different cell fractions (PBMC, granulocytes and red blood cells/platelets). In the literature it has been suggested that PBMC can function as an important extrahepatic reservoir and a possible site for HCV replication. The evidence for this assumption was based on the demonstration of negative-strand HCV-RNA in association with PBMC from HCV infected patients by a RT/PCR technique[16-19]. Other possible extrahepatic reservoirs were described by Laskus and colleagues in chronically HCV infected patients, additionally infected with the acqured immunodeficiency syndrome. HCV-RNA negative-strand could be detected by a Tth-based reverse transcriptase polymerase chain reaction in lymph nodes, pancreas, adrenal gland, thyroid, bone marrow and spleen[15]. The value of these findings is however controversial, since the presence of negative-strand HCV-RNA in extrahepatic compartments based on RT/PCR techniques has been described in many reports with a very large range of detection rate (from 0% to 100%). In fact, by using synthetic as well as biological templates, an extensive artefactual detection of negative-strand HCV-RNA, due to self-priming and mispriming events could be documented. This is especially true when a 5' noncoding region primer pair is used[20,21]. The

mispriming artefacts were directly correlated to the titer of positive strand and depend on the RT/PCR technique used[21]. Therefore, in this study no experiment was performed for the detection of negative-strand HCV-RNA in PBMC preparations.

In this work, the presence of HCV-RNA was qualitatively analysed in serum and in total RNA preparations of 15 patients infected chronically with HCV, before during and after an IFN-α therapy. During the observation period after beginning IFN-α therapy, it was noted that HCV-RNA disappeared first from total RNA preparations of PBMC and then from serum. In the case of a breakthrough under therapy or of a relapse at the end of therapy, HCV-RNA reappeared at first in serum and then in the total RNA preparation of PBMC. Therefore, we performed a quantitative analysis of the HCV titer at these points of transition, and obtained the following results: (a) HCV specific RNA in total RNA preparations of PBMC was only detectable when HCV-RNA in serum was above the detection limit of the assay; (b) the transition from detectable to non-detectable HCV-RNA in PBMC during drug administration was associated with a marked decrease of serum HCV-RNA concentration; (c) the transition from non-detectable to detectable HCV-RNA in PBMC in the case of a breakthrough or a relapse was associated with a marked increase in serum HCV-RNA concentration; (d) when HCV-RNA in PBMC was detectable, the HCV concentration in serum was significantly higher than when HCV-RNA in PBMC was not detectable (Figure 1): and (e) it was possible to contaminate PBMC of healthy donors with HCV by incubation for a short time (2 hours) at body temperature (37℃) in HCV positive plasma samples. These results are in agreement with those published by Cribier and colleagues (1998). These authors could show that HCV-RNA become detectable in the PBMC of healthy donors after an incubation of the cells with HCV-RNA positive serum with high virus concentration[34].

HCV-RNA in PBMC become undetectable in the *in vivo* study when HCV-RNA concentration in serum falls below 2263 copies/mL (Table 2) and in the *in vitro* experiments when the HCV-RNA level falls below 19290 copies/mL (Table 3). One explanation for this discrepancy could be that for the *in vitro* experiments we choose a short period of incubation, which however, better shows the adherence of HCV to blood cells.

These findings support the assumption that the presence of HCV sequences in total RNA preparations of PBMC is probably compatible with passive virus adsorption, with endocytosis of the virus or with contamination by circulating virus[22,23]. In 1992 Thomssen and colleagues described a possible mechanism of how HCV could bind to the surface of PBMC. They found, that HCV could bind to β-lipoprotein (LDL) and therefore possibly adhere in this form to specific lipoprotein-receptors on PBMC[25,26]. Recently, Agnello and colleagues demonstrated that HCV can enter the cells via the LDL-receptor[24]. The endocytosis of HCV by the LDL receptor was mediated both by VLDL or LDL and directly by HCV binding to the cell surface. Three kinds of cell lines (Hep G2, G4 and Daudi cells) were used in this study. After an incubation in HCV positive HCV-RNA serum positive-strand was detectable in each cell line by *in situ* hybridiziation. HCV-RNA negative-strand, as evidence for replication, was detected in the Hep G2 and Daudi cells, but not in the G4 cells, a B-lymphocyte cell-line[24]. These findings are in agreement with our results, that no replication occurs in PBMC. Another possibility for adherence of HCV to PBMC has been shown by Pileri and colleagues, who demonstrated the binding of HCV to CD 81, a 25-kD molecule of the tetraspanin superfamily, expressed in various cell types including hepatocytes and B-lymphocytes[27]. Fluorescence *in situ* hybridization of HCV-RNA in PBMC showed signals on the cytoplasmatic membrane of the cells. However, this could also be an indication for passive viral adsorption via a specific receptor or for a contamination by circulating virus. Other fluorescent signals appeared in granules in distinct submembrane areas or diffuse in the cytoplasm[35,36]. A possible explanation for these findings may be the ingestion of virus particles by phagocytosis particularly in macrophages or by endocytosis via the LDL-receptor.

HCV-RNA was not only detected in PBMC but also in other cell fractions of the whole blood such as granulocytes and red blood cells or platelets. Schmidt and colleagues have investigated the distribution of HCV in whole blood and in the different cell fractions. Whole blood contained significantly more HCV-RNA than pasma, which contained more HCV-RNA than PBMC, the lowest level of HCV-RNA was found in granulocytes and in red blood cells/pellets[13,14]. In the case of granulocytes, the virus may simply be ingested by phagocytosis and in the red blood cells or pellets. The HCV may be present because virus or virus-protein complexes could also adhere to specific receptors on the cell surface. Bronowicki and colleagues described the SCID mouse model as a possible *in vivo* model to analyse the issue of HCV-RNA persistence in mononuclear cells[37]. In their study, they injected PBMC from patients infected chronically with HCV into SCID mice. To exclude the possibility that just virus contamination and not true infection of the cells occurred, they incubated as a control sheep PBMC and human fibroblasts in HCV-RNA positive serum and injected them into

SCID mice. After injection of human PBMC, HCV-RNA was detected in 30% and 23% of blood cells and serum samples respectively of SCID mice. On the other hand, in the control mice, HCV-RNA sequences were not detectable either in serum samples or in PBMC. Therefore, they postulated the possibility of a replication of HCV in PBMC. In fact, the detection of no HCV-RNA in the control mice would argue against an adsorption of virus particles. The hypothesis was strengthened by detection of HCV negative-strand in two cell fraction samples of two SCID mice. However, no data were available showing that the sheep PBMC or human fibroblasts become HCV-RNA positive after the incubation in HCV-RNA positive serum.

Taken together, our findings could be explained as follows. During the IFN-α treatment, the HCV level is lowered by the inhibition of the hepatic virus replication. When the virus concentration decreases below a not yet exactly known upper limit, contamination of the PBMC becomes undetectable. At this time point, HCV is only detectable in serum for a short period and then disappears. On the other hand, it is also possible that IFN-α inhibits virus replication in both PBMC and the liver, and consequently, the HCV concentration in serum decreases in parallel with that of PBMC, although in lower amounts, the HCV-RNA continues to be detectable in the serum even when PBMC are negative. This indicaties that liver is the major site of replication. This could also explain that in the case of a relapse, the virus replication goes on in the liver and that the virus become detectable in the serum and then in the PBMC. The only approach to prove a true virus replication in PBMC is the detection of non-structural proteins (proteases, helicase or RNA-dependent RNA polymerase), which are important for virus replication, but this topic has not yet been investigated.

Our *in vitro* study, however, suggests that HCV-RNA positivity in PBMC may be due to the binding of the virus to blood cells and not to the true virus production. This would mean that PBMCs do not function as an extrahepatic reservoir for HCV when the diseased liver is explanted. In these cases, small amounts of HCV-RNA may still be present in the serum or attached to blood cells and be responsible for reinfection of the graft. This could happen even in the patients who are complete responders under IFN-α therapy immediately before transplantation.

ACKNOWLEDGMENTS The authors thank the physicians of the Division of Gastroenterology and Endocrinology, who were involved in care and control of the patients under investigation, for their kind cooperation. The authors also wish to thank Mrs. H. Dörler and H. Keller for technical assistance and acknowledge Prof. Dr. Rer. Nat. V. Armstrong for critical reading of the manuscript.

Reshetnyak VI, Sharafanova TI, Ilchenko LU, Golovanova EV, Poroshenko GG. Peripheral blood lymphocytes DNA in patients with chronic liver diseases. ***World J Gastroentero***, 2001;7(2):235-237

Abstract

AIM Of this investigation is to reveal the damage to peripheral blood lymphocytes (PBL) DNA in the patients with chronic liver diseases.

MATERIALS AND METHODS Sixteen-nine patients with chronic liver diseases (37 patients with chronic viral hepatitis, 2 patients with liver cirrhosis of mixed etiology (alcohol + virus G), 30 women with primary biliary cirrhosis-PBC) were examined. The condition of DNA structure of PBL was measured by the fluorescence analysis of DNA unwinding (FADU) technique with modification. Changes of fluorescence (in %) reflected the DNA distractions degree (the presence of DNA single-stranded breaks and alkalinelabile sights).

RESULTS AND CONCLUSION The quantity of DNA single-stranded breaks and alkalinelabile sights in DNA in all patients with chronic viral hepatitis didn't differ from the control group, excluding the patients with chronic hepatitis (CH) C + G. Patients with HGV and TTV monoinfection had demonstrated the increase of the DNA single-stranded breaks PBL quantity. This fact may be connected with hypothesis about the viruses replication in white blood cells discussed in the literature. Tendency to increase quantity of DNA PBL damages in the patients with primary biliary cirrhosis (PBC) accordingly to the alkaline phosphatase activity increase was revealed. Significant decrease of the DNA single-stranded breaks and alkalinelabile sights in the PBC patients that were treated with prednison was demonstrated. Probably, the tendency to increase the quantity of DNA single stranded breaks and alkalinelabile sights in lymphocytes of the PBC patients was depended on the surplus of the blood bile acid content.

INTRODUCTION

The last years investigations demonstrated that chronic viral hepatitis are the systemic infections[1,2]. The replication of viruses hepatitis B (HBV), C (HCV) was revealed in mononuclear blood cells, bone marrow, lien and other organs. This fact accounts for polymorphism clinical signs of these infections and sometimes-unsuccessful treatment with interferon's therapy.

The role of recently revealed hepatitis G virus (HGV) for the autoimmune processes development is being discussed[3]. Phenomenon of viral immune supervision "avoid" is associated with disturbances of infected lymphocytes and monocytes immune control functions. Viral replication in blood cells with nucleuses may lead to the damage of lymphocytes genetic apparatus and the beginning of immunopathological reactions.

The immunocompetent cells condition plays significant role in the development of autoimmune process in the patients with PBC.THE AIM of this investigation is to reveal the damage to peripheral blood lymphocytes (PBL) DNA in the patients with chronic liver diseases.

MATERIALS AND METHODS

We studied 69 patients with chronic liver diseases: 43 females and 26 male, mean age ± SD: 40.8 ± 17.7 years (range 16-77 years). The study group consisted of 37 patients with chronic viral hepatitis, 2 patients with liver cirrhosis of mixed etiology (alcohol + virus G), 30 woman with PBC. Control group was formed of 10 healthy volunteers (5 females and 5 males).

The liver functional state was estimated with cytolysis enzymes activity (alanine and asparagine aminotransferases), indexes of cholestasis syndrome (activity of alkaline phosphatase, gammaglutamiltranspeptidase, and contents of cholesterol, bilirubin).

Hepatitis B markers (HBsAg, HBsAb, HBeAg, HBeAb, HBcAbsum, HBcAb IgM, HBV DNA),

hepatitis C markers (HCVAb IgG, HCVAb IgM, HCV RNA) hepatitis G markers (HGV RNA) and hepatitis TTV markers (TTV DNA) were revealed with immunoferment analysis method (IFA) and with polymerase chain reaction (PCR). The immunoglobuline's levels (IgM, IgG, IgA) were determined with IFA.

The liver biopsy was done to all patients with PBC and the main part of the patients with chronic hepatitis.

Lymphocytes were obtained from 20 mL of peripheral blood (obtained by venepuncture from healthy donors and patients with chronic liver disease) by centrifuge with the presence of Fikoll-pak solution during 30 minutes with 400 × *g*.

The condition of DNA structure of PBL was measured by the fluorescence analysis of DNA unwinding (FADU) technique as indicated by Birnboim H.C. and Jevcak J.J. (1981) with modification[4,5]. Method was created for alkalinelable sights and DNA single-stranded breaks registration. Suspension with 2 × 10^6 cells/mL was lysised. Lysate was treated with ethidium bromide, which selectively binds to double-stranded (ds) DNA. Ethidium bromide with DNA formed fluorescence complexes.

Each lysate was divided equally into 3 sets of tubes: ① a sample (P) used for evaluating total fluorescence of native DNA; ② a blank sample (B) in which DNA was completely unwound by alkaline and mechanical destruction; ③ a sample (T) used to estimate alkalinelabile sights and DNA single-stranded breaks which was obtained by alkaline. The percentage of dsDNA (D) was determined from the fluorescence of tubes P, B and T by equation: D = (P-B)/(T-B) × 100%.

The fluorescence was read with excitation wavelength 520 nm and an emission wavelength of 590 nm, and slit width 8 nm by a Jasco FP-550 spectrofluorimeter.

Changes of fluorescence (in %) reflected the DNA distractions degree (the presence of DNA single-stranded breaks and alkalinelabile sights).

Statistical methods

Conventional methods were used for calculation of means and standard deviations (SD). Results are shown as means ± SD. For skewed variables, non-parametric tests were used for comparisons between the groups (Mann-Whitney *U*-test), whereas Student's *t*-test was used for normally distributed variables. In all cases, *P* values less than 0.05 were considered significant.

RESULTS AND DISCUSSION

There were 37 patients with chronic viral hepatitis in our study. Chronic hepatitis B was revealed in 5 patients, chronic hepatitis C in 11 patients, chronic hepatitis B + C-in 1 patients, chronic hepatitis G-in 8 patients, chronic hepatitis TTV-in 4 patients, chronic hepatitis B + G-in 2 patients, chronic hepatitis C + G-in 3 patients, and chronic hepatitis B + C + G-in 3 patients.

Cirrhosis of mixed etiology (alcohol+virus G) was revealed in 2 of 69 studied patients. Replication of viruses was revealed in all patients with chronic viral hepatitis and liver cirrhosis with mixed etiology.

PBC was determined in 30 of 69 studied patients. The 1st-2 nd stage of PBC determined in 10 patients, the 3 rd stage of PBC was revealed in 14 patients and the 4th stage of PBC was revealed in 6 patients (accordingly to morphological H.Popper's classification, 1970)[6].

The percentage of $_{ds}$DNA, D, in control group was 83.5 ± 3.2. PBL DNA damages in patients with CH and PBC did not significantly differ from control group (Figure 1).

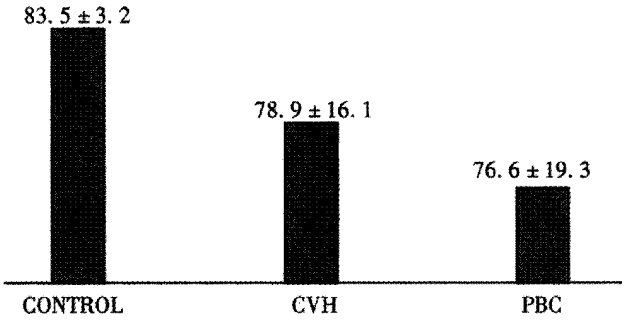

Figure 1 Percentage of double strained DNA in the blood lymphocytes (CVH: chronic viral hepatitis; PBC: primary biliary cirrosis).

The tendency to the increase of alkalinelabile sights and DNA single-stranded breaks in the patients with chronic liver diseases was determined.

Figure 2 shows diagram of DNA PBL content in the patients with viral CH. The quantity of DNA single-stranded breaks and alkalinelabile sights in all patients of this group didn't differ from the control group, excluding the patients with CH C+G ($\bar{x} \pm s$: D = 65.3% ± 12.9%, P<0.05).

Apparently the viruses C and B didn't possess a significant destructive effect on DNA PBL of the patients with chronic disease. But the patients with HGV and TTV monoinfection had demonstrated the tendency of increase of the DNA single-stranded breaks PBL quantity. This fact may be connected with hypothesis about the viruses replication in white blood cells discussed in the literature[3].

Increase of the HGV destructive effect on the DNA was revealed in the patients with chronic hepatitis of mixed (HCV + HGV) etiology (quantity of alkalinelabile sights and DNA single-stranded breaks is increased) (Figure 2).

Percentage of $_{ds}$ DNA in group of the patients with mixed HBV + HCV + HGV infections was decreased (D = 63.5 ± 20.7). Correlation between DNA structure change and hyperfermentemia degree was not revealed in the patients with different activity of chronic hepatitis.

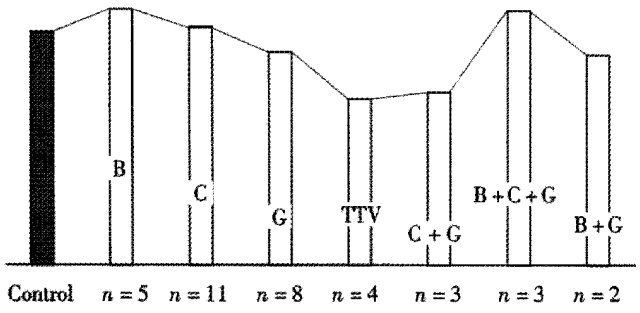

Figure 2 Percentage of double strained DNA in the blood lymphocytes of patients with chronic viral hepatitis (HBV: hepatitis B virus; HCV: hepatitis C virus; HGV: hepatitis G virus; TTV: TT virus).

So, monoinfection with HBV and HCV didn't significantly influence on PBL DNA structure in the patients with chronic disease. Monoinfection with HGV and TTV leads to increase of DNA single-stranded breaks in human PBL. Possibly, HCV increases virus G destructive effect on lymphocytes DNA structure.

Content of $_{ds}$ DNA in PBL in depending on cholestasis degree (activity of alkaline phosphatase, content of cholesterol and bilirubin), degree of histological process and used treatment was examined in the patients with PBC. Tendency to increase quantity of DNA PBL damages in the patients with PBC according to the alkaline phosphatase activity increase ($D_{aph<500un/}$ = 81.9% ± 15.2%, n = 11; $D_{aph>500un/L}$ = 74.8% ± 21.8%, n = 19) (Figure 3) was revealed.

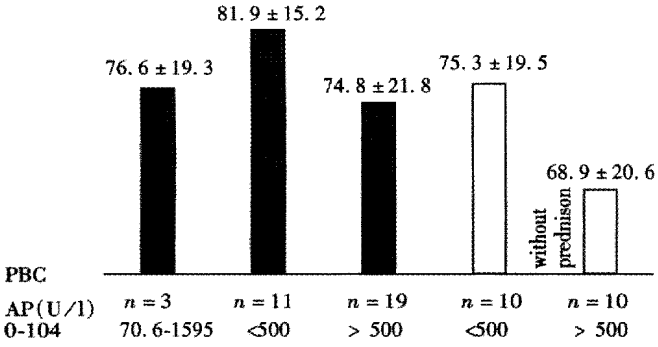

Figure 3 Percentage of double strained DNA in the blood lymphocytes of patients with PBC (PBC: primary biliary cirrosis; AP: alkaline phosphatase [normal range 0-104 u/l]).

The same data was demonstrated in 20 PBC patients without prednison treatment: percentage of $_{ds}$ DNA was 75.5% ± 19.5% in 10 PBC patients with alkaline phosphatase activity <500 u/L, and D = 68.9% ± 20.6% in 10 PBC patients with alkaline phosphatase activity >500 u/L (Figure 3). Dependence on $_{ds}$ DNA content according to other indexes of cholestasis and degree of histological changes was not demonstrated.

All PBC patients were divided into 4 groups according to the treatment methods: 6 patients were treated with prednison, 14 patients were treated with ursodeoxycholic acid (UDCA), 4 patients were treated with prednison and UDCA simultaneously, and 6 patients were treated with metabolic drug. The UDCA was not increased of D (Figure 4). Significant decrease of the DNA single-stranded breaks and alkalinelabile sights in the PBC patients, that were treated with prednison ($\bar{x} \pm s$: D = 94.5% ± 13.5%, n = 6, P<0.05, versus control D = 72.2% ± 19.9%, n = 20, P<0.05) was revealed (Figure 4).

The percentage of $_{ds}$ DNA, D, in lymphocytes in the PBC patients that were treated with prednison and UDCA simultaneously was 79.2% ± 5.3% (Figure 4).

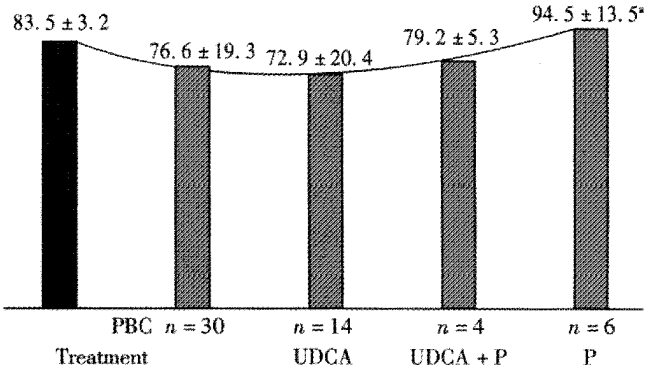

Figure 4 Percentage of double strained DNA in the blood lymphocytes of patients with PBC (PBC: primary biliary cirrosis; UDCA: urodesoxicholic acid; P: prednison; *P<0.05 *vs* control and all PBC patients).

Index D in the patients that were treated with UDCA, prednison and prednison with UDCA simultaneously had testified the suppression by bile acids the DNA reparation that was depended on prednison.

Probably, the tendency to increase the quantity of DNA single-stranded breaks and alkalinelabile sights in lymphocytes of the PBC patients was depended on the surplus of the blood bile acid content.

Immunohistochemical study of hepatic oval cells in human chronic viral hepatitis

Xiong Ma, De Kai Qiu and Yan Shen Peng

Subject headings hepatitis, viral, human; liver regeneration; oval cell; immunohistochemistry; colony stimulating factors

Ma X, Qiu DK, Peng YS. Immunohistochemical study of hepatic oval cells in human chronic viral hepatitis. ***World J Gastroenterol***, 2001;7 (2):238-242

Abstract

AIM To detect immunohistochemically the presence of oval cells in chronic viral hepatitis with antibody against c-kit.

METHODS We detected oval cells in paraffin embedded liver sections of 3 normal controls and 26 liver samples from patients with chronic viral hepatitis, using immunohistochemistry with antibodies against c-kit, π class glutathione S-transferase (π-GST) and cytokeratins 19 (CK19).

RESULTS Oval cells were not observed in normal livers. In chronic viral hepatitis, hepatic oval cells were located predominantly in the periportal region and fibrosis septa, characterized by an ovoid nucleus, small size, and scant cytoplasm. Antibody against stem cell factor receptor, c-kit, had higher sensitivity and specificity than π-GST and CK19. About 50%-70% of c-kit positive oval cells were stained positively for either π-GST or CK19.

CONCLUSION Oval cells are frequently detected in human livers with chronic viral hepatitis, suggesting that oval cell proliferation is asso ciated with the liver regeneration in this condition.

INTRODUCTION

Although essentially a quiescent organ, the normal adult liver can fully regenerate following surgical resection or injury. Liver regeneration is usually achieved by the entry of normally proliferatively quiescent, differentiated hepatocytes into the cell cycle, but, when hepatocyte regeneration is defective, oval cells can migrate outward from the portal tracts and then differentiate into hepatocytes[1-3]. The term oval cells described as small cells with oval nuclei that arise in the periphery of the portal tracts in rat models of hepatocarcin ogenesis and injury[4-7]. These cells are thought to have both clonogenic and bipotential capacity, i.e., the ability to proliferate and differentiate into cells of either hepatocyte or biliary epithelial cells[8]. There is also evidence that under certain conditions, oval cells can be induced to differentiate into non-hepatic lineages including intestinal and pancreatic epithelium[9]. The origin of oval cells and their precise location within the liver have remained enigmatic[10]. The aim of this study is to detect immunohistochemically the presence of oval cells in chronic viral hepatitis with antibody against c-kit.

MATERIALS AND METHODS

Tissue samples

Formalin-fixed, paraffin-embedded liver biopsy specimens from 26 patients with chronic liver diseases were obtained from the Department of Histopathology at Shanghai Institute of Digestive Diseases (Renji Hospital). Patient age ranged from 23 to 71 years, with mean age of 54 years. Twenty-six patients had been diagnosed having chronic viral hepatitis (twenty-one chronic hepatitis B; five chronic hepatitis C) with various degree fibrosis. There were mild fibrosis ($n = 5$), moderate fibrosis ($n = 8$), severe fibrosis ($n = 6$), and hepatic cirrhosis ($n = 7$). Three specimens of grossly normal liver tissues from the area surrounding benign angiomas were used as references. Specimens were fixed immediately in 10% neutral formalin and embedded in paraffin.

Primary antibodies

To highlight the presence of oval cells, three primary antibodies were used. The antibody against stem cell factor receptor, c-kit, was purchased from Oncogene Research Products. c-kit (Ab-1) is a purified rabbit polyclonal antibody raised against the

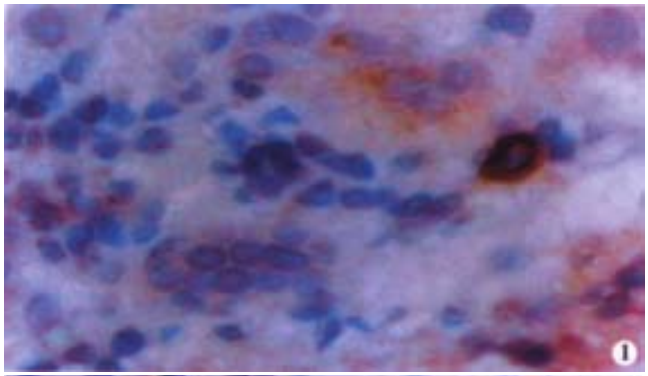
peptide (GSTASSSQPLLVHDDV), a sequence found at the Carboxyterminus corresponding to residues 961-976. Antibodies against π-class glutathione S-transferase (π-GST, clone 353-10) and cytokeratins 19 (CK19, clone BA17.1) were purchased from Dako Co, Denmark.

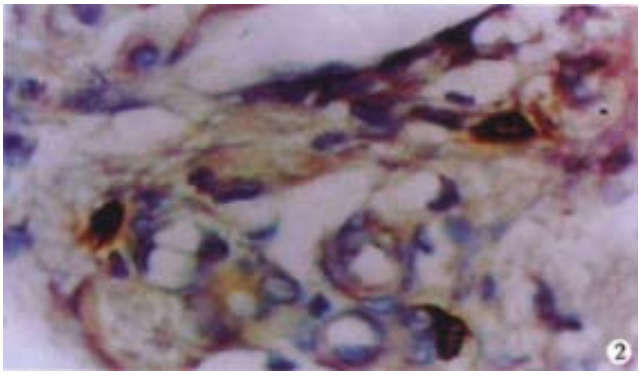
Immunohistochemistry

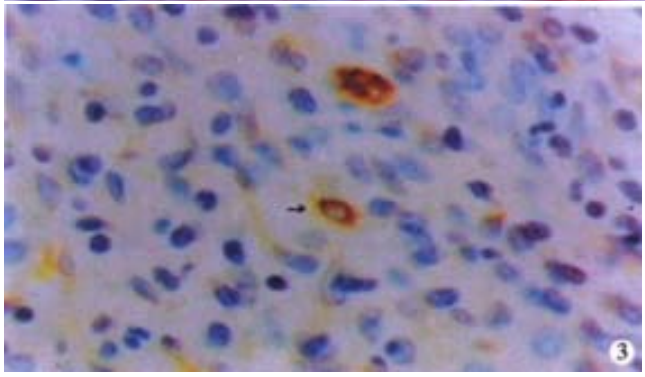
Immunohistochemical staining was performed on serial sections at room temperature, using the alkaline phosphatase method. The sections were deparaffinized in xylene and rehydrated through graded alcohol. The sections were boiled in 6M urea at 95℃ for 10 min for c-kit staining. Endogenous peroxidases were inactivated by immersing the sections in hydrogen peroxide for 10 minutes, then were incubated for 10 minutes with normal swine serum in Tris-buffered saline to block non-specific binding. The sections were subsequently incubated overnight at 4℃ with relevant antibodies (1:100 dilution respectively). The following day, the sections were incubated with biotinylated anti-mouse or anti-rabbit IgG (1:50 dilation, Maxim Biotech Inc., USA) for 45 minutes, followed by peroxidase-conjugated streptavidin (1:50 dilation, Maxim Biotech Inc.). The chromogenic reaction was developed with diaminobenzidine for 10 minutes, and all sections were counterstained with hematoxylin. Controls consisted of omission of the primary antibody.

RESULTS

Oval cells were not detected in normal liver tissue, but were detected in most liver tissues from patients with chronic viral hepatitis. Oval cells were characterized by ovoid nuclei from 7 μm × 9 μm to 12 μm×17 μm, small size, and scant cytoplasm (Figure 1). They were located predominantly in the periportal region (Figure 2) in hepatic cirrhosis, and were often found in close association with inflammatory cells in chronic active hepatitis (Figure 3). There were "transitional cells" in the parenchyma with size and structure between those of human oval cells and mature hepatocytes. They were moderately stained by CK19 antibody, had round nuclei, more cytoplasm, and were smaller in size than mature hepatocytes (Figure 4). c-kit antibody had higher sensitivity and specificity than π-GST and CK19. About 50%-70% of C-kit positive oval cells were stained positively for either π-GST or CK19. Some mature hepatocytes also expressed π-GST. Most mature bile ducts also expressed CK19.







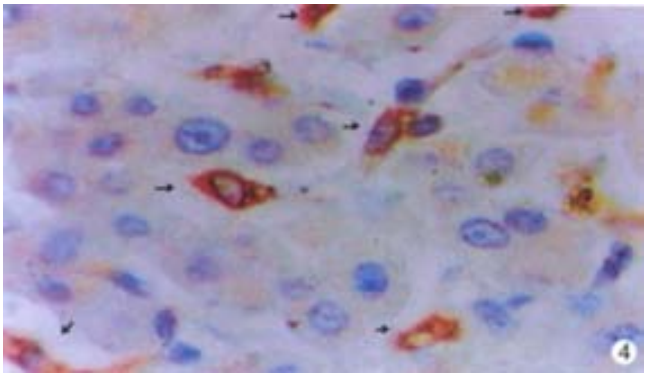


Figure 1 Oval cell identified by c-kit staining (Immunohistochemistry ABC method; original magnification: × 400)

Figure 2 Oval cells were located predominantly in the periportal region in hepatic cihrrosis (Immunohistochemistry ABC method; stained by c-kit; original magnification: × 400)

Figure 3 Oval cells were often found in close association with inflammatory cells in chronic active hepatitis (Figure 3). (Immunohistochemistry ABC method; stained by π-GST, original magnification: × 400)

Figure 4 "Transitional cells" from a patient with hepatic cirrhosis (Immunohistochemistry ABC method; stained by CK19; original magnification: × 400)

DISCUSSION

Hepatic oval cells proliferate under certain conditions, mainly when hepatocytes are prevented from proliferating in response to liver damage, and may be stem cells of hepatocytes and bile duct cells or the intermediate progeny of a hepatic stem cell[2]. Oval cells in animals are activated following administration of a variety of toxins and carcinogens alone or combined with other surgical or dietery regimens[11-19]. One of the models studied most is acetylaminofluorene treatment followed by partial hepatectomy, and an array of cytokines and growth factors have been shown to be an up-regulatory mechanism, is being delineated, for example interferon γ is implicated in orchestrating the process[20]. The oval cell itself however, probably represents the activated progeny of a dormant stem cell compartment although oval cells are readily identified in injury liver, one area of great controversy is the question of where these putative stem cells reside in the normal liver[3]. One suggestion is that they are present in the canals of Hering, that is the region where cells are transitional between the periportal hepatocytes and the biliary cells lining the smallest terminal bile duct[21]. Others suggest that there are cells which are located in the portal tracts, in the periductular region, or even that periportal hepatocytes have stem cell or metaplastic properties[2].

Oval cells are of great clinical interest since they may be the progenitor cells of both hepatocellular carcinomas and cholangio-carcinomas. Furthermore, they could be useful vehicles for *ex vivo* gene therapy for the correction of metabolic liver diseases[2]. However, identifying stem cells or their progeny in human liver has been a challenge. Oval cells, similar in morphology and antigenic profile to those seen in rodents, may be associated with many liver diseases in humans. These include submassive necrosis, focal nodular hyperplasia, primary biliary cirrhosis and primary sclerosing cholangitis, alcoholic hepatitis and cirrhosis, hepatoblastoma and HBV-associated hepatocellular carcinoma, genetic hemochro-matosis, and hepatitis C[22-30]. We detected the presence of hepatic oval cell in patients with chronic viral hepatitis. The human oval cell has a distinct morphology, with oval-shaped nuclei, small size and scant cytoplasm, and thus can be distinguished from the mature hepatocytes and inflammatory cells[1]. Oval cells express a wide variety of antigens that can be detected immunocytochemically. Although by no means specific for oval cells, many antibodies are very highly expressed, and can be used to highlight the presence of oval cells in histological sections[2].

Stem cell factor (SCF), a cytokine with structural similarity to the colony stimulating factors, was first isolated from conditioned medium of Buffalo rat liver cells[31]. Since then, it has become clear that SCF is critically important for early epithelial stem cell differentiation in hematopoiesis[32] or gamaetogenesis[33]. The corresponding receptor for SCF is encoded by the proto-oncogene c-kit, and exhibits a tyrosine kinase activity facilitated by its intracellular domain[34]. Target cells for SCF, which express c-kit, include mast cells[35], hematopoitic progenitor cells[32], and germ cells[33]. Recent studies suggest that SCF and c-kit may be involved in early growth and development of hepatic progenitor cells. Up-regulation of SCF and c-kit has been described in AAF-treated, partially hepatectomized rats, in which the carcinogen treatment inhibits the replication of hepatocytes and the induction of oval cells may be observed[19,36]. A similar increase of SCF and c-kit, accompanied by oval cell proliferation, has also been reported in bile duct-ligated rat[37]. Baumann U *et al* suggests that c-kit-positive cells may represent a hepatic progenitor cell population in normal and diseased pediatric liver[38]. In our study, we observed that some c-kit-positive cells with an oval-like morphology were present in human livers with chronic viral hepatitis, and that antibody against c-kit is useful in detecting the oval cells. We detected π-GST as a fetal GST in the majority of oval cells, supporting the view that oval cells display characteristics which resemble fetalhepatocytes or liver stem cells[29,39]. CK19n positive staining suggests that oval cells have characteristics of biliary epithelium[40]. The combined use of these antibodies and the knowledge of morphology allows us to reliably identify oval cells.

As hepatitis develops, hepatocyte necrosis is followed by an attempted secondary proliferation response of mature hepatocytes, but this proliferation response is often impaired in chronic liver diseases. Thus, oval cells may have a chance to proliferate and differentiate into hepatocytes or biliary epithelium cells[41]. We observed that oval cells were located predominantly in the periportal region, and were found in close association with fibrosis septa and inflammatory infiltrates. This location suggests that cytokines or other factors associated with the development of inflammation and fibrosis may be required to stimulate oval cell proliferation, differentiation and migration[42]. The matrix in fibrotic and cirrhotic livers is the binding site for both epidermal growth factor[43,44] and hepatocyte growth factor[45], whose receptors have been shown to be involved in proliferation of oval cells[46]. Additionally, the presence of “transitional

cells" may be evidence that oval cells are progenitors of hepatocytes.

While the debate on the source and location of hepatic stem cells is ongoing, two recent papers add a new dimension and offer a challenging alternative hypothesis to explain the origin of oval cells. By transplanting rat bone marrow into lethally irradiated recipients and following the fate of syngeneic cells using various markers, Petersen BE *et al*[47] reported striking changes in the livers of animals induced to regenerate following 2-AAF and CCl_4 treatment. Male donor marrow cells were visualized in female recipients. In a second model, marrow from dipeptidyl peptidase IV positive animals was transplanted into dipeptidyl peptidase IV deficients. In both cases, evidence was presented to suggest that the donor cells migrated into the livers of recipient animals and subsequently underwent differentiation to become hepatocytes, although it was less clear whether ductular cells of biliary phenotype developed[47]. A second recently published study describes a similar approach comprising a mouse marrow transplant model which, interestingly, did not include a liver injury step[30]. This new report provides confirmatory evidence that bone marrown derived haematopoietic stem cells can indeed give rise to hepatocytes[48]. The ability to identify and exploit a human hepatic clonal stem cell could have important clinical implications, since generating large numbers of differentiated and therefore fully functional human hepatocytes has enormous potential[49,50].

In conclusion, the presence of oval cells in human livers with chronic viral hepatitis indicates that oval cell proliferation may be one of the mechanisms in liver regeneration in this condition. The origin, growth, and differentiation of this cell is worth investigating further.

Abstract

AIM To test the hypothesis that *Helicobacter pylori* eradication alone can reduce the incidence of gastric cancer in a subgroup of individuals with an increased risk for this fatal disease.

METHODS It is a prospective, randomized, double blind, placebo controlled multinational multicenter trial. Men between 55 and 65 years of age with a gastric cancer phenotype of *Helicobacter pylori* gastritis are randomized to receive a 7 day course of omeprazole 2 × 20 mg, clarithromycin 2 × 500 mg, and amoxicillin 2 × 1 g for 7 days, or omeprazole 2 × 20 mg plus placebo. Follow-up endoscopy is scheduled 3 months after therapy, and thereafter in one-year intervals. Predefined study endpoints are gastric cancer, precancerous lesions (dysplasia, adenoma), other cancers, and death.

RESULTS Since March 1998, 1524 target patients have been screened, 279 patients (18.3%) had a corpus dominant type of *H. pylori* gastritis, and 167 of those were randomized (58.8%). In the active treatment group (n = 86), *H. pylori* infection infection was cured in 88.9% of patients. Currently, the cumulative follow-up time is 3046 months (253. 38 patient years, median follow up 16 months). So far, none of the patients developed gastric cancer or any precancerous lesion. Three (1.8%) patients reached study endpoints other than gastric cancer.

CONCLUSION Among men between 55 and 65 years of age, the gastric cancer phenotype of *H. pylori* gastritis appears to be more common than expected. Further follow up and continuing recruitment are necessary to fulfil the main aim of the study.

INTRODUCTION

Gastric cancer is the second most common fatal malignancy in the world being responsible for at least 750 000 deaths annually[1]. Even though the incidence of gastric cancer is steadily decreasing in Western industrialized countries, the absolute number of diagnoses and deaths is likely to increase due to population growth and changing age structure of populations[2,3]. Following the first epidemiological reports of an association between *H. pylori* infection and gastric cancer in 1991[4-6], the International Agency for Research on Cancer, sponsored by the World Health Organization, categorized *H. pylori* infection as a definite human carcinogen in 1994[7]. Six years after that decision, the causal role of *H. pylori* in gastric carcinogenesis is still poorly understood, and the epidemiological data vary depending on the background prevalence of the infection and the design of the studies[8,9].

As suggested by an economical analysis based on the US data, a screen and treat strategy for *H. pylori* infection, even under conservative assumptions, may be a cost-effective strategy for gastric cancer prevention comparable to the costs of breast mammography screening programms[10]. This

strategy would become more cost-effective among populations at a higher background risk of gastric cancer [11]. However, valid prospective data on the benefit of *H. pylori* eradication for gastric cancer prevention are lacking. A non-randomized Japanese study on 132 *H. pylori* positive patients with early gastric cancer who had undergone endoscopic resection showed that after additional *H. pylori* eradication therapy there were no new occurrences of early gastric cancer during 2 years. However, among those who remained infected, there was a 9% recurrence rate of early gastric cancer[12]. Whether *H. pylori* eradication can lead to regression of gastric atrophy and intestinal metaplasia, histological risk markers for gastric cancer is still controversial[13]. The quality of endoscopic-bioptic follow-up studies of these parameters is often limited due to the confounding factor of sampling error, and due to a considerable lack of consensus among pathologists concerning the assessment of atrophy[14]. Decisive evidence that takes full account of all benefits and risks of preventive *H. pylori* eradication therapy could be derived only from adequately designed clinical trials with clearly defined study endpoints.

Recently, a corpus-dominant distribution of *H. pylori* gastritis has been recognized as a histological gastric cancer risk marker, which is frequently found not only in patients with gastric cancer at various clinical stages of disease[15,16], but also in healthy relatives of gastric cancer patients[17]. Based on histological studies, patients with a corpus-dominant *H. pylori* gastritis have an about 9-fold increased risk for gastric cancer[16]. This corpus-dominant gastritis has been termed as gastric cancer phenotype of *H. pylori* gastritis, and is the basis for the so-called "gastric cancer risk index" which has been suggested as a screening marker for *H. pylori* infected individuals in Germany being at an increasing risk for gastric cancer[18,19]. The major advantage of this screening marker is the homogenous distribution of the inflammatory response within antral or corpus mucosa which makes it less susceptible to sampling error.

In the present study, we are using this corpus-dominant phenotype of *H. pylori* gastritis as histological inclusion criteria to identify individuals with a clearly increased compared to the normal population. The aim of the present study is to investigate whether *H. pylori* eradication alone can reduce the incidence of gastric cancer in subjects with an individual high risk for gastric cancer.

PATIENTS AND METHODS

Recruitment and evaluation of patients

Gastroenterologists in hospitals and private practice in Austria, Czech Republic and Germany were asked to participate in the preparation of the study. Those who were interested were asked to obtain gastric biopsies for histological screening from all patients of the target age group who present for upper endoscopy, and to send these biopsies to one of the participating institutes of pathology.

At each endoscopic examination, two biopsies each from the antrum and the corpus were obtained according to the updated Sydney System[20]. In addition, one biopsy from the antrum and one from the corpus was taken for the rapid urease test (HUT-Test). At follow-up endoscopies, additional biopsies were obtained from macroscopically suspicious areas such as focal erythema, erosions or polyps.*H. pylori* colonization is detected by Warthin Starry. Hematoxilin & Eosin stain was used for assessment of gastritis according to the updated Sydney System[20], including the following parameters: grade and activity of gastritis, atrophy, intestinal metaplasia, lymphocytic aggregates, and degeneration of surface epithelium.

The first follow-up endoscopy was performed 3 months after treatment to determine successful eradication, and to increase the probability to detect preneoplastic changes or early gastric cancer which may have been overseen at the screening examination. Thereafter, follow-up endoscopies are scheduled in one-year intervals.

Inclusion criteria

Men between 55 and 65 years of age are eligible for inclusion in the study if they give informed consent to participate, if *H. pylori* is detected, and if the following histological criteria are present: ① grade of gastritis in the corpus $\geqslant$ grade of gastritis in the antrum; ② grade of activity of gastritis in the corpus $\geqslant$ grade of activity of gastritis in the antrum[18]. The grade and activity of gastritis in the corpus is required to be at least moderate or high according to the updated Sydney System[20].

Patients are not eligible for participation if one of the follwing criteria is present: *H. pylori*-associated diseases with strongly recommended indication for anti *H. pylori* therapy[21], type-A gastritis, a history of partial stomach resection, contraindications for biopsy sampling, present or history of malignant disease, expected residency in Germany, Austria or Czech Republic for the following five years, severe chronic disease with a survival expectancy of less than five years, benigne neoplastic lesions (adenoma, dysplasia) or early gastric cancer at the 3-month endoscopy, known allergy against the study medication.

Randomization and intervention

The randomization was carried out by the study secretariats at the University Hospitals in Dresden, Vienna and Brno. Patients receive either omeprazole 2 × 20 mg, clarithromycin 2 × 500 mg, and amoxicillin 2 × 1000 mg given for 7 days with meals[22], or omeprazole 2 × 20 mg and identically looking placebos. In case of allergy against penicilline, patients received either omeprazole 2 × 20 mg, clarithromycin 2 × 250 mg, and metronidazole 2 × 400 mg, or omeprazole plus

placebo. The trial was conducted in a double-blind fashion. Patients who did not agree to randomization received open anti *H. pylori* therapy, and were asked to return to regular follow-up endoscopies.

Statistics and ethics

The main study end points are benign neoplastic lesions (dysplasia, adenoma) in two subsequent examinations, gastric cancer, cancer of other origin, and death. The analysis is based on the intention-to-treat principle. *Chi*-square tests were used to compare categorial variables. The study was approved by the Ethics Committee of the University of Magdeburg, and by all Regional Ethics Committees in Germany, Austria and Czech Republic where patients were recruited.

RESULTS

In preparation of the trial, about 1300 gastroenterologists in Germany were informed by mail and invited to participate in the study. In addition, multiple information seminars were held in various regions of the country to explain organisatory matters, and to discuss critical questions. At initiation of the study in Germany, 500 gastroenterologists (232 in hospitals, 268 in private practice) and 201 pathologists stated interest and announced to participate in the study. However, during the first two years only 239 (47.8%) gastroenterologists became active by screening and recruiting at least one patient. Among those were 157 gastroenterologists in hospitals, and 82 doctors in private practice. Thus, between April 1998 and Dezember 2000, 1526 men at the age between 55 and 65 years were endoscopic-histologically screened, 749 in hospitals and 777 in private practice. The histological inclusion criteria was identified in 279 (18.3%) patients. Of these patients, 167 (58.8%) agreed to participate in the study, 86 were randomized to receive therapy to eradicate *H. pylori* (omeprazole plus antibiotics), while 81 were assigned to receive omeprazole plus placebo. One patient (1.2%) of the active treatment group prematurely discontinued treatment due to severe allergy. Otherwise no adverse side effects occurred leading to discontinuation of therapy. Of the 112 patients who declined randomisation and received open anti-*H. pylori* therapy, 109 stated to return to follow-up endoscopies in one to two-year intervals. Thus, 276 patients are currently under follow-up.

In the active treatment group, 54 (62.8%) patients have returned to control examinations so far. Among those, *H. pylori* infection has been cured in 48 (88.9%) patients. Those patients who did not become *H. pylori* negative did not receive a second course of anti-*H. pylori* therapy so far.

At present, 105, 50 and 24 patients have passed the 3-month, one-year, and two-year control endoscopy. Until January 2001, the cumulative follow-up time of all randomized patients was 3046 months (253.8 patient years). The median follow-up period of these patients was currently 16 months (range 3-35 months). So far, none of the patients developed gastric cancer or any preneoplastic lesion in the stomach. Three (1.8%) patients reached study endpoints other than gastric cancer. One patient of the active treatment group developed malignant melanoma 8 months after anti-*H. pylori* therapy. Two patients who were randomized to the placebo group died of myocardial infarction 6 and 7 months after therapy, respectively. Both patients had known coronary heart disease but were in stable condition at randomisation. Two patients of the placebo group received anti-*H. pylori* therapy, one of them due to active duodenal ulcer, the other patient due to persistent functional dyspepsia. Both patients, however, will continue the follow-up. Another 2 patients received cardiac surgery, one aortic valve replacement and one coronary bypass. Both patients will continue follow-up.

Table 1 Current status of the PRISMA study (initiation April 1998)

Endoscopy-histologically screened men between 55 and 65 years of age	Cases (n = 1526)	%
Presence of histological inclusion criteria	n = 279	18.3
Patients randomized	n = 167	58.8[a]
Non-randomized patients continuing follow-up	n = 109	39.1[a]
Patients with study endpoints	3	1.8[b]
Cumulative follow-up (months / years)	3046 / 253.8	

[a]Percentage of those who meet all inclusion criteria
[b]Percentage of all randomized patients.

Table 2 Currently conducted *H. pylori*-gastric cancer intervention trials with cancer endpoints

Name	Country	Target group	Age group	Sample size	Main endpoints
SCISC	China	Population	30-65	2400	Gastric cancer
NCI	China	Population	35-69	3400	Gastric cancer , dysplasia
JITHP	Japan	Population	20-59	5000	Gastric cancer
BUPA	U.K.	Population	35-69	56000	Gastric cancer
PRISMA	Germany Austria Tchech Republic	Male subjects with Corpus dominant gastritis	55-65	3000	Gastric cancer dysplasia,adenoma

DISCUSSION

Reliable epidemiological evidence on *H. pylori* and gastric cancer is still relatively sparse. Until today, only 10 seroepidemiological prospective have investigated the prevalence of *H. pylori* in a total of 800 gastric cancer cases. A combined analysis of these studies yielded a risk ratio of 2.5 for gastric cancer in people seropositive for *H. pylori* antibodies[9]. It may well be that the role of *H. pylori* in gastric cancer has been underestimated by these studies due to methodological reasons, such as poor sensitivity and specificity of serological tests available in the late 80s, or geographic variation of *H. pylori* antigens. In contrast, more recent studies indicate a much higher risk for gastric cancer in *H. pylori* infected individuals[23,24]. For example, a histology-based prevalence study in our patient

population has shown a *H. pylori* prevalence of more than 90% in patients with early gastric cancer, and a much higher relative risk for gastric cancer calculated after exclusion of other precancerous conditions such as type A gastritis[23]. Moreover, histological studies of our group have described a corpus-dominant pattern of mucosal inflammation, which is found in most *H.pylori* infected gastric cancer patients irrespective of the clinical stage[15,16], and also significantly higher in healthy relatives of gastric cancer patients compared to individuals without of family history of gastric cancer[17]: the so-called "gastric cancer risk index" which was developed on the basis of this gastric cancer phenotype of *H. pylori* gastritis[18] serves as histological inclusion criteria for the present study. A major advantage of this inclusion criteria is that it can be used to identify individuals with an increased gastric cancer risk independent of the presence of intestinal metaplasia which is always prone to sampling error. This gastric cancer risk index has recently been investigated in a Japanese patient population. In this study, a high prevalence of the gastric cancer phenotype of *H. pylori* gastritis was found in gastric cancer patients, but also with a similar frequency in control subjects[25]. In the study by Meining *et al*[18] duodenal ulcer patients were chosen as control group, because these patients rarely develop gastric carcinoma, and therefore probably would show histopathological features different from those of gastric cancer patients. In contrast, the Japanese study used gastritis patients without clinical relevant disease as control group, and were therefore unable to reproduce our previous findings.

To calculate the gastric cancer risk for target group in our study, we started from an average incidence of gastric cancer of about 62/100 000 per year in men aged 55 to 65 years[26]. Based on our data in patients with early gastric cancer[23], we calculated an incidence of 143/100 000 for *H. pylori*-positive men in this age group can be calculated. Under consideration of the histological inclusion criteria used in the present study which are found in 72% of early gastric cancer patients and in only 9% of *H. pylori* infected individuals without disease, we expect an incidence of gastric cancer as high as 1200/100 000 in our target patient group. In the present study, we observed that at least in men in the age group 55 to 65 years, the prevalence of a corpus-dominant pattern of *H. pylori* gastritis was higher than in the average population of infected individuals. By the selection of this high risk group for gastric cancer, we hope to be able to decrease the follow-up time of the study population and the number of recruited patients.

The key question is whether gastric cancer can be prevented by *H. pylori* eradication. It is worth mentioning that development of gastric cancer several years after *H. pylori* eradication has already been reported. For example, patients of the German MALT Lymphoma Trial which started in 1993 still remain under long-term endoscopic-histological follow-up[27,28]. Until today, 3 of these patients have developed early gastric cancer approximately 4 years after *H. pylori* eradication and complete remission of their lymphoma[29]. In addition, the extended follow-up of Japanese early gastric cancer patients who were treated with endoscopic mucosal resection and *H. pylori* eradication has shown that a metachronous gastric cancer may be inhibited to a great extent. However, one of these patients so far has developed a second gastric cancer four years after *H. pylori* eradication[30]. Although these reports suggest that gastric cancer may still occur after *H. pylori* eradication, they can not be transferred to the general population since those patients already had a gastric malignancy.

Relevant studies addressing the question of gastric cancer prevention by *H. pylori* eradication can be divided into those with precancerous lesions and those with gastric cancer as major study endpoint[13]. The latter studies vary considerably in their study design, but have in common that they require a much larger number of recruited patients and a longer follow-up compared with the studies using precancerous lesions as endpoints. Three of these trials are being conducted in Asian populations, while two studies, Including ours, are conducted in European populations (Table 2). The Asian studies are recruiting subjects from the general population in an area with a high population risk of gastric cancer following an endoscopy. One of the Chinese studies is also recruiting subjects to receive antioxidant micronutrients such as vitamins C and E, and therefore will be able to investigate the interaction between *H. pylori* eradication and dietary intervention in reducing the cancer risk. The British study aims to recruit the largest number of subjects with the longest follow-up, since the study is performed in a population with a relatively low gastric cancer risk. Men and women undergoing routine medical examination are randomized to testing for *H. pylori* and subsequent treatment if positive, or no testing. In contrast, the PRISMA study will assess the benefit of *H. pylori* eradication in patients with a high individual risk within a population of relatively low gastric cancer risk. By selection of a particular high-risk group it was expected to be able to reduce the necessary samplesize and the follow-up time. During the first two years of the study, however, we had to learn that at least in Germany the recruitment of subjects for this particular study-despite tremendous efforts by the principlal investigators[31-34] is extremely affected by the concerns of both patients and doctors regarding the possibility of being randomized to the control group. In our opinion, these concerns are mainly caused by the relatively broad knowledge about the association of *H. pylori* and gastric

cancer which has already been distributed by both professional and general media. Therefore, many patients expect and receive antimicrobial therapy if the infection has been diagnosed, despite the absence of strongly recommended indications for anti *H. pylori* therapy[21], and although the effect on cancer prevention is unproven. On the other hand, the certain benefit of regular control endoscopies which is the only measure to detect malignancy at a curable stage, and which would be provided by participation in the PRISMA study seems to be regarded as not acceptable or inconvenient for many patients and physicians. Due to these obvious difficulties in the recruitment of patients, it is currently planned to modify the study design and to continue without a placebo group. Although this measure will reduce the power of the study to a certain extent, it is believed that the key question can still be answered.

ACKNOWLEDGEMENTS The PRISMA Studies are supported by the Deutsche Krebshilfe e.V. (Project Nr. 70-2345-Ba I), and by the Onkologischer Arbeitskreis Bayreuth e. V. We thank the following pharmaceutical companies for providing the study medication: AstraZeneca, Wedel, Germany; Abbott GmbH, Wiesbaden, Germany, Ratiopharm GmbH, Ulm, Germany. We also thank our study secretary assistant Ms. R. Beckmann for her valuable support.

Abstract

AIM To report 3 of 120 patients on the German MALT lymphoma trial with *H. pylori* associated gastric MALT lymphoma who developed early gastric cancer 4 and 5 years, after complete lymphoma remission following cure of *H. pylori* infection.

PATIENTS AND RESULTS Three patients (two men, 74 and 70 years; one women, 77 years) with *H. pylori*-associated low-grade MALT lymphoma achieved complete lymphoma remission after being cured. Surveillance endoscopies were performed twice a year in accordance to the protocol. Four years after complete lymphoma remission in two patients, and after 5 years in the other, early gastric adenocarcinoma of the mucosa-type, type II a and type II c, respectively, was detetcted, which were completely removed by endoscopic mucosa resection. In one patient, the gastric cancer was diagnosed at the same location as the previous MALT lymphoma, in the other patients it was detected at different sites of the stomach distant from location of the previous MALT lymphoma. The patients were *H. pylori* negative during the whole follow-up time.

CONCLUSION These findings strengthen the importance of regular Long term follow-up endoscopies in patients with complete remission of gastric MALT lymphoma after cure of *H. pylori* infection. Furthermore, gastric adenocarcinoma may develop despite eradication of *H. pylori*.

INTRODUCTION

Primary gastric low-grade marginal zone B-cell lymphoma of MALT type is a distinct disease entity with a characteristic histological presentation and clinical behaviour[1]. The role of chronic *Helicobacter pylori (H. pylori)* infection in the pathogenesis of gastric MALT lymphoma has become increasingly recognized. Thus MALT in the stomach is formed as an immunologic defense-system to control local infection caused by *H. pylori*. It is composed of antigen specific-reactive T-cells, plasma cells, some B-cells, and antigen-presenting, follicular, dendritic cells, and thus mimicing the lymphoid follicles known from other intestinal sites. Data were emerging to indicate that in fact low-grade MALT lymphomas in the stomach are a result of genetic changes probably affecting B-cells which clonally evolve from *H. pylori* related chronic gastritis[2]. There has been major progress in this area, including improvement of biopsy diagnosis, and especially, the start of a revolution in the treatment of low-grade gastric MALT lymphoma by eradicating *H. pylori* that lead to a complete remission in about 80% of cases[3-8].

Despite decreasing numbers of gastric cancer in western countries, it is still the second most common cause of death due to a malignant disease world wide[9]. Serological investigations in 1990 revealed that a high prevalence of anti *H. pylori* IgG antibodies is associated with a high incidence of gastric cancer in South America and China[10,11]. Thereafter, many case control studies reported on a 3-6 fold increased risk for gastric cancer in *H. pylori* positive individuals[12-15]. Since there are many other factors that are important for the development of gastric cancer, i.e. low vitamin C

level, gastric mucosal atrophy or hypergastrinaemia with an increase of nitroso compounds, the role of *H. pylori* is currently under investigation, thus the question if early eradication of the infection in high risk patients can prevent the development of gastric cancer[16,30].

Among the literature reviewed, only a few reports describe the development of synchronous gastric adenocarcinoma and primary gastric lymphoma[17-19]. However, only one report mentioned the probable co-factor *H. pylori* and the role of minimal invasive methods such as eradication therapy in the case of the lymphoma and endoscopic treatment for early gastric carcinomas[20]. The association of gastric lymphoma and the subsequent development of gastric adenocarcinoma is an exceptional finding, and has only been reported once with a gastric lymphoma of immunocytoma type in 1990 by a Spanish group[21].

In this paper, we reported 3 patients with *H. pylori* associated gastric MALT lymphoma who developed early gastric cancer 4 and 5 years, respectively, after complete lymphoma remission following cure of *H. pylori* infection.

PATIENTS AND METHODS

As reported earlier[5,7,22], 120 patients with primary gastric low-grade B cell MALT lymphoma in an early stage EI and *H. pylori* infection were included in the German MALT lymphoma trial starting from 1993. Cure of the infection leads to complete lymphoma remission in 79%, and partial remission in 10% of cases. Eleven percent of patients did not respond to antibiotic treatment.

Of the patients achieving complete lymphoma remission (n = 95; 79%) three developed an early gastric adenocarcinoma 4 and 5 years, respectively, after complete remission detected during routine follow-up endoscopy. Patient 1 (#1), a 74-year-old male, was included in the trial in March 1995 presenting with a gastric ulcer in the antrum and was treated in accordance to the protocol receiving antibiotic medication[5]. Four weeks later, the infection was cured, and after another 8 weeks, the patient achieved complete lymphoma remission. During the first year of follow-up, the patient was endoscoped every 3 months. Biopsy specimens were obtained each time and examined for continuous complete lymphoma remission and absent *H. pylori* colonization. Endoscopic controls were then performed twice a year. In June 1999, 4 years after complete lymphoma remission, routine control endoscopy showed a small flat elevation at the same location of the stomach where the MALT lymphoma ulcer was diagnosed 4 years earlier. Biopsies obtained from this area revealed an tubular adenoma partially transformed into a well-differentiated early gastric adenocarcinoma of the mucosa-type (m-type), 4mm in diameter, type IIa, intestinal type in accordance to the Laurén classification[23], UICC Ia (pT1G1pN × M × R0). *H. pylori* could not be detected either in the antrum or corpus mucosa. The early gastric adenocarcionoma was removed by endoscopic mucosa resection (EMR). Staging procedures revealed an adenocarcinoma of the left colon that was removed by surgery.

The second patient (#2), a 77-year-old woman, entered the MALT lymphoma trial in December 1995. Thirteen years earlier, the woman was diagnosed suffering from nodal Hodgkin's disease stage II b that was initially successfully treated with chemotherapy. In 1994, the Hodgkin's disease relapsed and the patient received another course of chemotherapy. In December 1995 she presented with a gastric ulcer at the angulus. Biopsy specimens revealed an early stage *H. pylori*-associated low-grade MALT lymphoma and she was enrolled in the study receiving antibiotic treatment. As described in patient #1, she underwent routine endoscopic control examinations after achieving complete lymphoma remission. Four years later, surveillance endoscopy revealed a complete erosion, 6 mm in diameter, opposite the ulcer scar where the MALT lymphoma was diagnosed with *H. pylori* negative. Biopsy specimens showed a well-differentiated tubular adenocarcinoma of the mucosa-type (m-type), 6 mm in diameter, type II c (according to the Japanese classification), intestinal type based on the Laurén classification[23], UICC I a (pT1G1pN × M × R0) that was removed by EMR (Figure 1).

The third patient (#3), a 70-year-old man, was diagnosed having an *H. pylori* associated low-grade MALT lymphoma in the upper corpus region in October 1994. He received antibiotic treatment and achieved complete lymphoma remission 12 months after cure of the infection. The patient was followed up in accordance to the protocol[5], and surveillance endoscopy 5 years after complete remission of the gastric MALT lymphoma revealed three flat elevations in the prepyloric antrum mucosa, approximately 5-6 mm in diameter. Endosonographic ultrasound revealed a mucosa-type tumor, and biopsies obtained during gastroscopy showed infiltrates of an intestinal type (Laurén) early gastric adenocarcinoma type II a and II c (Japanese classification), UICC Ia (pT1G1pN × M × R0). EMR was performed as well as additional argon plasma coagulation.

All histological evaluations were done by one central pathologist (M.S.). Sections were stained with H&E to grade gastritis, and Warthin-Starry stain to detect and grade colonization with *H. pylori*. Grading of the varibles of gastritis was done using the Sydney system[25], with slight modifications characterized by using a scoring system ranging from 0 = none to 4 = severe, and including the degree of replacement of foveolae by regenerative epithelium as an additional variable[26].

RESULTS

Briefly, 120 patients with primary gastric low-grade B cell MALT lymphoma in an early stage EI and *H. pylori* infection were included in the German MALT lymphoma trial starting in 1993. Cure of the infection leads to complete lymphoma remission in 79% (n = 95), and partial remission in 10% (n = 12) of cases. Eleven percent of patients (n = 13) did not respond to antibiotic treatment probably because of more advanced stages that were initially undergraded, or high-grade tumor components that were undetected[22]. Nine patients showed a lymphoma relapse, 8 local and 1 distant, 128 to 481 days after complete remission all but 1 *H. pylori* negative. The median follow-up time was 32 months.

Within the group of patients achieving complete lymphoma remission (n = 95; 79%) three patients aged 70-77 years, two men and one man, developed an early gastric adenocarcinoma 4 and 5 years, respectively, after complete remission detected during routine follow-up endoscopy, comprising an incidence rate of 3.15%. Based on the median follow-up time of 48 months, the annual risk for the development of a gastric adenocarcinoma following complete remission of gastric MALT lymphoma is 0.78%. In all patients, minimal invasive methodssuch as eradication therapy in lymphoma, diagnosed early and endoscopic treatment for early gastric carcinoma was employed (Figure 1). Endoscopic treatment of the carcinoma with EMR resulted in R0 resection of the cancer, and a follow-up examination 6 months after EMR in patients #1 and #2 revealed no remnant carcinoma infiltrates.

At the time of diagnosis of gastric adenocarcinoma, none of the patients showed *H. pylori* infection. In two patiens, the carcinoma was diagnosed near an area with intestinal metaplasia and signs of focal atrophy (Figure 2).

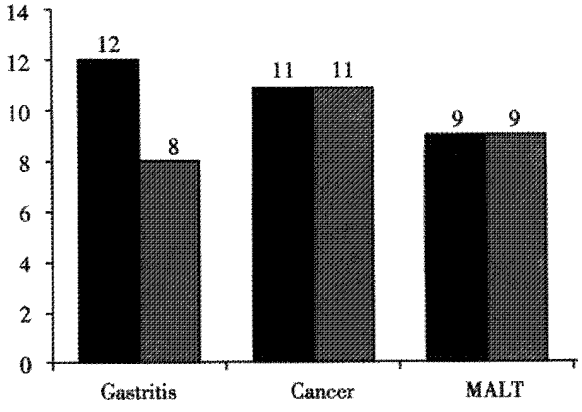

Figure 2 Medians of the summed gastritis score in antrum and corpus, formed by adding together the respective values of grade and activity of gastritis, replacement of foveolae by regenerative epithelium, and density of *H. pylori* colonization as presented in Reference 24.

DISCUSSION

The association of primary gastric MALT lymphoma and the subsequent development of gastric adenocarcinoma is an exceptional finding. In the review of the literature, we have found only 1 case of this subsequent association with an immunocytoma type gastric lymphoma[21]. The patient was treated with subtotal gastrectomy and adjuvant radiotherapy and developed an adenocarcinoma of the gastrojejunal anastomosis. As no one looked for *H. pylori* infection at that time the implicated factors in the development of this association are gastric resection and radiotherapy, and as it was also speculated, the non-Hodgkin's lymphoma itself. Reports on simultaneous MALT-type lymphoma and early adenocarcinoma of the stomach are more frequent[17-20]. It was speculated for a long time that patients with Hodgkin's disease and nodal non-Hodgkin's lymphoma seem to have an excess risk for other cancers, and a high incidence of other cancers (20%) has also been found in some series of patients with gastric MALT lymphomas[27]. Montalbán and co-workers[28]were able to show that in patients with gastric MALT lymphoma, other cancers do occur, but that there is no increase in risk above the background population. Among 136 patients with gastric MALT lymphoma, other cancers were detected in 11.7%, either prior to the diagnosis of MALT lymphoma, concomitantly or after diagnosis. Of all 136 patients investigated, only 53 had not received chemotherapy, radiotherapy or surgery as implicated factors, and of those, 2 (3.7%) patients developed a gastric adenocarcinoma. This cumulative incidence is in line with the cumulative incidence we report in this paper, that is 3.15% (3/95 patients).

The observation of concurrent or subsequent gastric adenocarcinoma and MALT lymphoma is of interest as both are etiologically related to *H. pylori*. For gastric MALT lymphoma, the causative association with this chronic stimulus is well established, and cure of the infection can lead to complete remission of early lymphoma in about 80% of cases[5,7,8]. As indicated earlier, serological investigations demonstrated a high prevalence of anti *H. pylori* IgG antibodies in an area with a high incidence of gastric cancer[10,11], and many case control studies reported on a 3-6 fold increased risk for gastric cancer in *H. pylori* positive individuals[12-15]. In one report analysing synchronous adenocarcinoma and low-grade B-cell MALT lymphoma, *H. pylori* was seen in 7 (78%) of 9 cases which is consistent with an etiological role for this organism in both tumors in the stomach[18].

Primarily on the basis of this epidemiological evidence, *H. pylori* has been classified as a definite human carcinogen in 1994[29]. Although several pathophysiological mechanisms have been identified which may contribute to the development of gastric carcinoma, the role of *H. pylori* eradication for disease prevention is currently under investigation[16, 30]. The aim of these studies is to test the hypothesis that *H. pylori* eradication alone can reduce the incidence of gastric cancer in a subgroup of individuals with an increased risk for developing gastric adenocarcinoma. A non-randomized Japanese study on 132 *H. pylori* positive patients with early gastric cancer who had undergone endoscopic mucosa resection showed that after additional *H. pylori* eradication therapy, no new early gastric cancer occurred during 2 years. Another 2 years later, i.e. 4 years after eradication therapy, one of these patients so far has developed a second gastric cancer. However, among those who remained infected, there was a 9% recurrence rate of early gastric cancer[33, 34]. Whether *H. pylori* eradication can lead to regression of gastric atrophy and intestinal metaplasia, histological risk markers for gastric cancer, is still controversial[16]. Based on all these evidences and, hence, the idea of a possible prevention of the development of gastric adenocarcinoma by curing chronic *H. pylori* infection, it is surprising that 3 patients within our MALT lymphoma trial developed gastric carcinoma despite eradication of the bacterium 4 and 5 years earlier in the scope of treating the gastric MALT lymphoma. These data may indicate that *H. pylori* eradication alone might not be sufficient to prevent cancer. However, it might have been successful, if cure of the infection probably occurred earlier in life. The timing of treatment might be crucial for the determination if the development of gastric adenocarcinoma can be prevented by *H. pylori* eradication alone. Although our report suggests that gastric cancer may still occur after *H. pylori* eradication, these data can not be transferred to the general population since those patients already had a gastric malignancy.

Based on the findings that MALT lymphoma patients, in fact, do not have an increased risk of additional neoplasms, there is no need to invoke or be concerned about general genetic instability of the host as a possible underlying mechanism for lymphoma-and/or carcinogenesis. Differences in the characteristics of *H. pylori* strains as well as different environmental factors in the infected hosts seem also being involved in the variable outcome of the infection[31,32]. Recently, a corpus-dominant distribution of *H. pylori* gastritis has been recognized as a histological gastric cancer risk marker, and studies concerning the degree and distribution of *H. pylori* have shown significant differences among *H. pylori* associated diseases[24]. As it was demonstrated by Meining *et al*[24], in both malignant diseases investigated, gastric

adenocarcinoma and gastric MALT lymphoma, the extent of gastritis was equal in the corpus and in the antrum mucosa. Thus both malignant diseases differ from the benign gastritis only in the extent of the gastritis in the antrum and corpus part of the stomach. Furthermore, the overall extent of gastritis in MALT lymphoma patients was not as severe as in patients who had a carcinoma or gastritis only. Gastric atrophy was much more frequent in gastric cancer patients than in MALT lymphoma patients (42% vs 6% in the antrum mucosa, 18% *vs* 4% in the corpus mucosa)[24]. The three patients with gastric adenocarcinoma presented here also have a gastritis equally expressed in the corpus and antrum mucosa but of a milder degree. The carcinomas diagnosed were found near or within intestinal metaplasia in two cases of consecutive atrophy, the histological risk markers for early gastric cancer. The exact reasons for the differences in distribution and degree of gastritis in different *H. pylori* associated diseases have not yet been fully understood. It seems possible, that patients developing a minimal to mild gastritis, equally distributed in the antrum and corpus mucosa are likely to have a higher risk of developing a gastric MALT lymphoma.

Our study population included 56 men and 64 women with a median age of 65 years (a range of 29-88 years). The three patients developing a gastric adenocarcinoma were 70, 74, and 77 years old, respectively. The incidence of cancer in the general population increases continuously with age, affected by changing patterns of population screening and intensity of attempts at cancer detection, and is about 120 for men and 50 for women in this age group in Germany. The relatively high median age in our MALT lymphoma study group is therefore, independently of other risk factors, associated with a high cumulative incidence of cancers. Appreciating the apparent increase in cancer incidence brought about by better screening methods and earlier detection, and comparing our results to a defined general population with accurately known cancer incidences, there is still to state that the association of primary gastric MALT lymphoma and the subsequent development of gastric adenocarcinoma is an exceptional finding, and that *H. pylori* gastritis must be considered to be associated with the development of these two malignancies with an approximately 6-7 fold increase of the overall incidence.

All cancers of our three patients were detected during routine surveillance endoscopy. Endoscopy was performed in each patient twice yearly in accordance to the MALT lymphoma protocol since these patients have achieved complete lymphoma remission after cure of *H. pylori* infection. Early gastric adenocarcinoma was detected 4 and 5 years after complete remission of lymphoma. Due to the early stage diagnosis of the gastric cancer, endoscopic therapy (mucosal resection = EMR) was successfully performed in each case. In contrast to most cases of synchronous MALT lymphoma and gastric carcinoma, the definite diagnosis of gastric lymphoma and carcinoma was obtained preoperatively. As it has been also stated by Müller *et al*[20], this seems to be in future times an essential prerequisite for employing minimal invasive methods such as eradication therapy in the case of the diagnosed early lymphoma and endoscopic treatment for early gastric carcinomas. This management of the diseases seems to be benefical and effective especially with regard to the life quality of the patients. However, to apply this treatment strategy, it is important to perform regular long-term follow-up endoscopies in patients with complete remission of gastric MALT lymphoma after cure of *H. pylori* infection.

She FF, Su DH, Lin JY, Zhou LY. Virulence and potential pathogenicity of coccoid *Helicobacter pylori* induced by antibiotics. ***World J Gastroenterol***, 2001;7(2):254-258

Abstract

AIM To explore the virulence and the potential pathogenicity of coccoid *Helicobacter pylori* (*H. pylori*) transformed from spiral form by exposure to antibiotic.

METHODS Three strains of *H. pylori*, isolated from gastric biopsy specimens of confirmed peptic ulcer, were converted from spiral into coccoid from by exposure to metronidazole. Both spiral and coccoid form of *H. pylori* were tested for the urease activity, the adherence to Hep 2 cells and the vacuolating cytotoxicity to Hela cells, and the differences of the protein were analysed by SDS-PAGE and Western blot. The mutation of the genes including ureA, ureB, hpaA, vacA and cagA, related with virulence, was detected by means of PCR and PCR-SSCP.

RESULTS In the coccoid *H. pylori*, the urease activity, the adherence to Hep 2 cells and the vacuolating cytotoxicity to Hela cells alldecreased. In strain F44, the rate and index of adherence reduced from 70.0% ± 5.3% to 33% ± 5.1% and from 2.6 ± 0.4 to 0.96 ± 0.3 ($P<0.01$), respectively. The invasion of coccoid *H. pylori* into Hep 2 cell could be seen under electronmicroscope. SDS-PAGE showed that the content of the protein with the molecular weight over Mr 74 000 decreased, and the hybridiotional signal in band Mr 125 000 weakened, while the band *M*, 110 000 and Mr63 000 strengthened in coccoid *H.pylori* as shown in Western blot. The results of PCR were all positive, and PCR-SSCP indicated that there may exist the point mutation in gene hpaA or vacA.

CONCLUSION The virulence and the proteins with molecular weight over Mr74 000 in coccoid *H.pylori* decrease, but no deletion exists in amplification fragments from ureA, ureB, hpaA, vacA and cagA genes, suggesting that coccoid *H.pylori* may have potential pathogenicity.

INTRODUCTION

Helicobacter pylori is an important pathogen that causes chronic gastritis and peptic ulcer and may be a risk factor for gastric carcinoma[1-9]. The organism exists in two forms, a spiral form and a coccoid form. The coccoid *H.pylori*, which can be induced by increased oxygen tension, extended incubation and exposured to antibiotics[10-14], is nonculturable but alive [12,15-17], and could be induced to revert to a virulent spiral form *in vivo*[11]. Therefore, the coccoid *H. pylori* has been suspected to play a role in the transmission of the bacteria and to be partly responsible for recrudescence of infection after antimicrobiol treatment. However, the pathogenesis of coccoid *H.pylori* remains unclear. In this study, three strains of coccoid *H.pylori* transformed from spiral form by exposure to metronidazole, were tested for the urease activity, the adherence to Hep-2 cells and the vacuolating cytotoxin activities to Hela cells, the differences of the protein were analysed by SDS-PAGE and Western blot, and mutation of the genes involving ureA, ureB, hpaA, vacA and cagA was detected by means of PCR and PCR-SSCP, in order to explore the virulence and the potential pathogenicity of coccoid *H.pylori*.

MATERIALS AND METHODS

Bacterial strains

Three strains (F_{44}, F_{45} and F_{49}) of *H.pylori* were isolated from gastric biopsy specimens of confirmed peptic ulcer patients. The isolates were spiral shape, positive for catalase, oxidase, urease, and cagA and vacA gene. Stock cultures were maintained in defatted milk at -80℃.

Cells

The Hep-2 cells and Hela cells were maintained in

1640 medium supplemented with 10% fetal calf serum, 200 IU/mL penicillin and 50 μg/mL streptomycin at 37℃ in 5% CO_2-95% air, and recultivated once or twice a week.

Cultivation of H.pylori and induction of coccoid forms

The stored strains of *H.pylori* were cultivated on Brucella agar with 5% sheep blood at 37℃ for 2-3 days under microaerophilic conditions (5% O_2; 10% CO_2; 85% N_2). After subculturing, the bacteria were harvested and suspended in Brucella broth with 10% fetal calf serum, and the suspension was divided into two parts, one as spiral *H.pylori*, the other added with metronidazole at a concentration of 1/2 of MIC values (MIC = 32 mg/L-64 mg/L) at 37℃ under the microaerophilic conditions for a few days until coccoid forms reaching 100%(about 2-3 days).

Examination of urease activity

According to the manufacturer's instructions of the kit detecting fastly urease activity (Sanqiang Company), the suspension of *H.pylori* (10^{10} cfu/mL) was added into the testing well in volume of 5 uL, and on the basis of reacting colors, the urease activity was divided into five grades ("+++ +" "+++", "++","+"and "-").

Assay for adherence to Hep-2 cells

To assay bacterial adherence, Hep-2 cells were grown to confluence on coverslips in culture flask, and the suspension of *H.pylori* (10^8 cfu/mL) were added in a total volume of 0.5mL for Hep-2 cultures and allowed to adhere for 3.5 h at 37℃ in 5% CO_2 95% air. Cultures were washed and stained with Wright-Giemsa stain, and both the amount of cells adhereed by bacteria and bacteria adhereing to cells were counted among one hundred cells under the light microscope. In addition, the culture with strain F_{44} was scraped using a glass club, centrifuged, and the pellet was embedded in Epoxy 618, then the ultrathin sections were cut and examined under a Hu-12A transmission electron microscope.

Assay for cytotoxicity to Hela cells

To assay vacuolating cytotoxicity of *H.pylori*, Hela cells were grown to confluence in 96-well plates (2×10^4 cells/well at the time of infection), the suspension of bacteria were swung, centrifuged, and the cell-free supernatants were concentrated 20-fold using polyethylene glycol M_r 20 000, then sterilized by passage through a 0.25 μm pore-size filter. The concentrated supernatants at the consistency shown in Table 4 were added in a total volume of 0.1 mL to Hela cells, and Brucella broth served as a negative control. After incubation for 48 h, cells were stained and observed under phase microscope. Wells, in which 50% or more cells were vacuolated, were defined as showing a cytotoxic effect[18].

SDS-PAGE of whole cell proteins

The suspension of *H.pylori* (6×10^{10} cfu/mL) were centrifuged, washed once with 0.5 mol/L Tris (pH 7.4), and the pellets were suspended in extraction buffer consisting of 0.75% Tris, 2% sodium dodecyl sulfate, 5% dithiothreitol, 10% glycerol and 0.1% bromophenol blue. The homogenate was heated for 5 min in a boiling water bath and frozen at -20℃ until use. According to Sambrook J *et al*[19], the protein solutions (10 μL) were electrophoresed on SDS-polyacrylamide gels with the stacking and the separating gels containing 5% and 10% acrylamide, respectively, and the gels were stained with Coomassie blue.

Western blot

According to Sambrook J *et al*[19], after SDS-PAGE, the proteins were blotted onto a nitrocellulose membrane under a constant current of 100 mA for 7 h, and the antigenic profiles were studied by Western blotting using serum from the patients infected with strain F_{44} (diluted at 1/50).

PCR and PCR-single-strand conformational polymorphism (PCR-SSCP)

PCR primers and the size of the corresponding PCR products are shown in Table 1[20-22]. The suspension of bacteria were centrifuged, and the pellets were resuspended in distilled water(10^5 cfu/mL), heated in a boiling water bath for 1min to obtain the DNA template, which was added into PCR reaction system in volume of 1/5. PCR was performed as follows: denaturation at 95 for 5 min, followed by 30 cycles of denaturation (94℃ for 0.5 min);annealing (52℃ for 1 min); and extension (72℃ for 1 min), and final extension at 72℃ for 7 min. The PCR products were electrophoretically separated on 0.2% agarose gel, and stained with ethidium bromide.

Table 1 Oligonucleotide primers used for PCR reactions

Gene amplified	Primer sequence	Size of PCR product
ureA	HPU_1:5'-GCCAATGGTAAATTAGTT-3'	411bp
	HPU2:5'-CTCCTTAATTGTTTTTAC-3'	
ureB	HPU_{55}:5'-AATTGCAGAAATATCAC-3'	115bp
	HPU_{17}:5'-ACTTTATTGGCTGGTTT-3'	
hpaA	$HPYLO_1$:5'-GAATTACCATCCAGCTAGCG-3'	375bp
	$HPYLO_2$:5'-GTAACCTTGACAAAACCGGC-3'	
vacA	VA_1F:5'-ATGGAAATACAACAAACACAC-3'	259bp
	VA_1R:5'-CTGCTTGAATGCGCCAAAC-3'	
cagA	F_1:5'-GATAACAGGCAAGCTTTTGAGG-3	349bp
	B_1:5'-TCTGCCAAACAATCTTTTGCAG-3'	

ureA: urease gene A; ureB: urease gene B; hpaA: *H.pylori* adhesin gene A; vacA: vacuolating cytotoxin geneA; cagA: cytotoxin-associated gene A.

SSCP was performed as follows: the mixture consisting of 5 μL of PCR product and 3 μL of loading buffer (95% formamide, 200 mmol/L EDTA, 0.05% bromophenol blue, and 0.05% xylene cyanol) was heated at 100℃ for 5 min to denature double-stranded DNA and then plunged into ice for 5 min, and electrophoresed on 50% polyacrylamide gel under a constant voltage of 300v for 7 h, the gel was stained with 0.2% silve nitrate.

Statistical analysis

Analysis of data was performed using the Student *t* test. A value of $P < 0.05$ was regarded as statistically significant.

RESULTS

Urease activity

As shown in Table 2, the urease activity of coccoid *H. pylori*, which was transformed from spiral form by exposure to antibiotic in subinhibitory concentrations, decreased.

Table 2 Urease activity of*H.pylori*

Strain	Urease activity	
	Spiral form	Coccoid form
F_{44}	++++	+
F_{45}	++++	++
F_{49}	++++	+

Adherence to Hep-2 cells

According to the following formula, the rate and the index of adherence were calculated:

The rate of adherence = the amount of cell adherenced by bacteria/100×100%

The index of adherence = the amount of bactria adhereing to cells/100

For each coverslip five-fields (one field containing of one hundred cells) were counted, and the mean of all fields is shown in Table 3. As compared with the spiral forms ($P < 0.01$), the adherence of coccoid forms to Hep-2 cells decreased. In addition, invasion of coccoid *H. pylori* into cell could be seen under electron microscope (Figure 1).

Vacuolating activity to Hela cells

As shown in Table 4, vacuolating activity of coccoid *H. pylori* to Hela cell impaired after Hela cells were incubated with different concentrations of supernatants of coccoid *H.pylori* for 48 h.

Table 3 Adherence test of *H.pylori* to Hep-2 cells

	Rate of adherence			Index of adherence		
	F_{44}	F_{45}	F_{49}	F_{44}	F_{45}	F_{49}

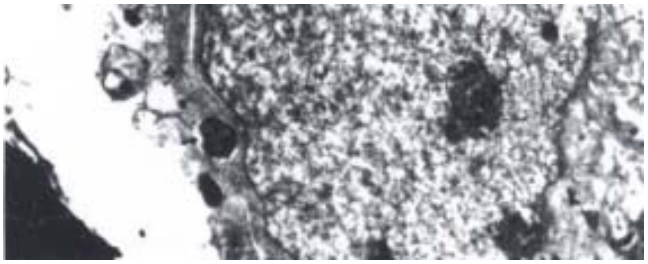

Figure 1 Invasion of coccoid *H.pylori* into Hep-2 cell. Transmission electron microscope, × 15 000

SDS-PAGE and Western blot

SDS-PAGE patterns are illustrated in Figure 2A. The content of the proteins with molecular weight over Mr 74 000 decreased, especially the band at Mr 125 000 was presented with deletion in coccoid *H. pylori*. The protein patterns of the three strains of coccoid *H. pylori* were similar. Western blot patterns showed that the hybridiotional signal in band M_r 125 000 weakens, meanwhile, strengthens in band M_r 110 000 and M_r 63 000 in all coccoid *H. pylori* as illustrated in Figure 2B.

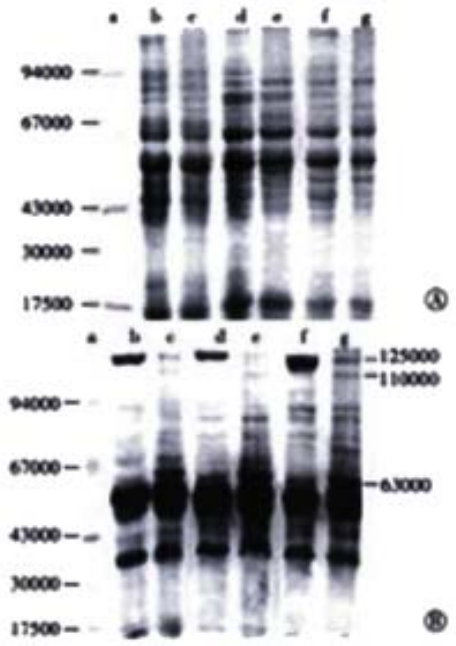

Figure 2 A. SDS-PAGE pattern of whole cell proteins of *H. pylori*, B. Western blot pattern of the proteins of *H. pylori*.

PCR and PCR-SSCP

The result of PCR for strain F_{44} is illustrated in Figure 3. The genes detected by PCR, which included ureA, ureB, hpaA, vacA and cagA, were all positive in both spiral and coccoid *H.pylori*. The patterns of SSCP showed that there could exist point mutation in vacA gene of strain F_{44} and F_{45}, as well as in hpaA gene of strain F_{49} in coccoid forms. The pattern of SSCP for strain F_{44} is illustrated in Figure 4.

DISCUSSION

H.pylori can convert into coccoid forms after induced by antibiotics *in vitro* or *in viro*[12,23,24]. It has been reported that coccoid *H.pylori* is able to colonize and to produce gastric alterations in the suitable animal model[11]. Costas M *et al*[25]compared the pre-with post-treatment isolates of *H.pylori* from the same patients by using 1-D SDS PAGE of proteins and considered that recurrent patients were not reinfected with a different strain but that there was recrudescence of the pre-treatment strain. Thus, it is reasonable to suppose that the viability of the coccoid form may account for the wide number of relapses in patients. However, as yet, the pathogenesis of the coccoid form remains unclear.

The putative pathogenic determinants of *H.pylori* can be divided into two major groups[26]: maintenance factors, which allow the bacterium to colonize and remain within the host, and virulence factors, which contribute to the pathogenetic effects of the bacterium. Both urease activity and adherence to epithelia cells of *H.pylori* are important maintenance factors[27-30]. In this study, It is shown that both urease activity and adherence to Hep-2 cell of coccoid *H.pylori* decreased, suggesting that virulence related to colonization in coccoid *H.pylori* reduced. Vacuolating cytotoxin produced by about 50%-60% of *H.pylori* strains[18,31-33] is one of the important virulence factors[34]. Infection with cytotoxin-producing *H.pylori* strains was more prevalent among patients with peptic ulcer disease[35-37]and gastric carcinoma[18,38-42] than among patients with gastritis alone. In our study, the decrease of vacuolating cytotoxicity in coccoid *H. pylori* was found, which may be related with the reduction of the volume of M_r 87 000 VacA and M_r 125 000 CagA proteins determining vacuolating cytotoxicity [34,43] by SDS-PAGE. These findings indicate that the coccoid *H.pylori* is less efficient in the colonizational virulence and vacuolating cytotoxicity,which may make it unlikely to induce an inflammatory response. Thus the alleviation of clinical symptom of the patients after antimicrobiol treatment does not necessarily mean eradication of *H.pylori*, it may also result from the convertion to coccoid form. As shown in the assay for adherence, a few coccoid *H.pylori* still adhered to Hep-2 cells, even invated into them, which indicates that coccoid *H.pylori* is likely to sustain in the host, thus making the recrudescence of infection possible.

In order to display the hereditary background of coccoid *H.pylori*, the genes related with virulence mentioned above (involving ureA, ureB, hpaA, vacA and cagA) were detected by PCR and PCR-SSCP. No deletion was in these genes, but there only existed the point mutation in genes hpaA or vacA. These data demonstrate that the coccoid *H.pylori* may revert into an infectious spiral form under the appropriate conditions and result in recudescence of infection, suggesting that coccoid *H.pylori* may have potential pathogenicity.

According to the features of coccoid *H.pylori*, it may escape the techniques usually applied for their detection such as cultivation and assay for urease activity. Because of no deletion in genes mentioned above in coccoid *H.pylori*, we can use PCR to detect these genes instead of conventional methods to determine whether the bacteria have been completely eliminated after treatment.

Some studies showed that the synthesis of some proteins of coccoid *H.pylori* increased such as 62KDa and >94KDa proteins[16,44,45]. In this study, the results of Western blot showed that the antigenic fraction with molecular weight in M_r 110 000 and M_r 63 000 was detected more intensively in all three strains of coccoid *H.pylori*, as compared with

spiral *H.pylori*. The fractions may be the one degraded from a high-molecular-mass antigen. Further studies are required to determine whether these antigenic proteins have special functions.

Abstract

AIM To examine the role of p38 during acute experimental cerulein pancreatitis.

METHODS Rats were treated with cerulein with or without a specific JNK inhibitor (CEP1347) and/or a specific p38 inhbitor (SB203580) and pancreatic stress kinase activity was determined. Parameters to assess pancreatitis included trypsin, amylase, lipase, pancreatic weight and histology.

RESULTS JNK inhibition with CEP1347 ameliorated pancreatitis, reducing pancreatic edema. In contrast, p38 inhibition with SB203580 aggravated pancreatitis with higher trypsin levels and, with induction of acinar necrosis not normally found after cerulein hyperstimulation. Simultaneous treatment with both CEP1347 and SB203580 mutually abolished the effects of either compound on cerulein pancreatitis.

CONCLUSION Stress kinases modulate pancreatitis differentially. JNK seems to promote pancreatitis development, possibly by supporting inflammatory reactions such as edema formation while its inhibition ameliorates pancreatitis. In contrast, p38 may help reduce organ destruction while inhibition of p38 during induction of cerulein pancreatitis leads to the occurrence of acinar necrosis.

INTRODUCTION

Acute pancreatitis is a common gastrointestinal disorder but remains enigmatic in its unpredictable clinical course ranging from mild to very severe, and life threatening pancreatitis. Due to our limited understanding of its underlying pathophysiology, the treatment of acute pancreatitis is still confined to general supportive measures with no causal approach. In order to better understand the pathophysiology of pancreatitis, we characterized the molecular mechanisms of the pancreatic stress response.

Members of the mitogen-activated protein kinase (MAPK) cascade are considered to play key roles in signal transduction pathways activated by a wide range of stimuli[1]. The three best characterized members of this growing family of serine/threonine kinases are extracellular signal-regulated kinase (ERK), c-jun N-terminal kinase (JNK) and p38. While ERK responds vigorously to growth factors and certain hormones, JNK and p38 are rather activated by stress stimuli and are widely believed to be part of the cellular stress response machinery[1-5]. Activation of these kinases requires phosphorylation of both tyrosine and threonine residues by upstream dual specific kinases. Active MAPK are responsible for the phosphorylation of a variety of effector proteins including several transcription factors[1].

In the pancreas, it has been shown that hyperstimulation with the cholecystokinin (CCK) receptor agonist cerulein, which induces acute pancreatitis in rats, can activate JNK in rat pancreas[6,7]. We and others have recently found that p38 is also expressed in the pancreas and rapidly activated by cerulein[8-10]. Due to the pattern and time course of activation in response to a variety of different secretagogues, JNK has been proposed as an important mediator early during cerulein-induced pancreatitis[6,10]. In addition, we have also shown that treatment with CEP1347, a specific inhibitor of the JNK pathway[11,12], ameliorates cerulein pancreatitis[13].

However, no data on the effects of p38 inhibition on the course of experimental pancreatitis is available so far. There is evidence that p38 may actually promote the protection through influencing HSP27 phosphorylation and actin stabilization[8,14]. Therefore, we have studied the effects of p38 inhibition with SB 203580 on the course of cerulein

pancreatitis, and compared the effects of p38 inhibition to those of JNK inhibition as well as inhibition of both kinases simultaneously. Our data show that both kinases influence pancreatitis differentially in that JNK inhibition ameliorates pancreatitis while p38 inhibition aggravates cerulein pancreatitis, resulting in the development of necrosis.

MATERIAL AND METHODS

Chemicals and antibodies

Sodium dodecyl sulfate (SDS), polyacrylamide, molecular weight and isoelectric focusing standards were products of BioRad (Hercules, CA, USA); nitrocellulose membranes were obtained from Schleicher and Schuell (Keene, NH, USA). All other chemicals were from Sigma (St. Louis, MO, USA). CEP-1347 was kindly provided by Cephalon Inc (West-Chester, PA, USA).

Preparation and treatment of pancreatic acini

Acini were prepared as previously described[15]. Briefly, pancreata from white male Sprague Dawley rats were digested with purified collagenase and dispersed by pipetting through polypropylene pipettes of decreasing orifice, followed by filtration through a 150 μm nytex screen. Acini were purified by centrifugation through 4% bovine serum albumin (wt/vol) and then preincubated for 30 min at 37℃ in N-2-hydroxyethyl-piperazine-N'-2-ethane-sulfonic acid (HEPES)-buffered Ringer solution (HR), pH 7.4, supplemented with 11.1 mM glucose, minimal Eagle's medium amino acids, 5 g/L bovine serum albumin, and 0.1 g/L soybean trypsin inhibitor. Buffers were gassed with 100% O_2. Acini were then kept resting at room temperature for 2 hours with and without 20 μM CEP-1347 and/or 50 μM SB203580. Incubation at 37℃ was then continued and acini stimulated with the indicated concentrations of cerulein. After 30 min stimulation, acini were pelleted and homogenized for assessement of MAPK, JNK and p38 activity in kinase/IP buffer, containing 50 mM glycerophos-phate, 2 mM Na_3V0_4, 1 mM each of NaF, EGTA, EDTA, DTT, PMSF, benzamidine, 10 mg/L each of aprotinine and leupeptin, 0.1% β-mercaptoethanol (v/v), 0.03% Brij 35 (w/w), 5% glycerol in phosphate buffered saline (pH 7.4, 150 mM NaCl, 16 mM $Na_2HPO_4 \cdot 2H_2O$ and 4 mM $NaH_2PO_4 \cdot 2H_2O$). Supernatants were used for measurement of amylase release, expressed as % total amylase content.

In vivo experiments

Rats were anesthetized by intraperitoneal injection of pentobarbital (50 mg/kg). Following insertion of a tail vein catheter, rats were then treated with a hyperstimulatory dose of cerulein (10 μg/kg i.v.). Controls received isotonic saline only. To assess the effects of stress kinase inhibition on cerulein-induced pancreatic stress kinase activation, rats were treated with 30 mg/kg CEP-1347, SB203580 or both, dissolved in Solutol (Boehringer Mannheim), by subcutaneous (s.c.) injection 4 h prior to cerulein injections. Controls received solutol alone. The rats were then sacrificed 30 min after cerulein injection and pancreata homogenized in stress kinase/IP buffer. This time point was chosen since it is known that pancreatic ERK, JNK and p38 are all strongly activated 30 min after cerulein hyperstimulation *in vivo*[6-10]. Pancreatic wet weight and trypsin activation as well as serum lipase and amylase were also determined.

To assess effects of cerulein and SB203580 on p38 Map kinase *in vivo*, activation of pancreatic MAPKAP kinase 2 was assessed following immunoprecipitation in an *in vitro* assay using recombinant HSP27 as substrate as described[13,16].

SDS-PAGE

One-dimensional gel electrophoresis was performed according to Laemmli, as previously described[17]. Five μg of protein were loaded per lane.

Light microscopy and histological evaluation

For histological evaluation, freshly removed pancreata were formalin (4%) fixed, ethanol dehydrated and, embedded in paraffin. Six micrometer slices were then stained with H&E and subjected to conventional light microscopy.

Serum amylase and lipase measurements

Measurement of serum amylase and lipase activity was performed using commercially available kits (Boehringer Mannheim) following the manufacturers instructions.

Measurement of trypsin activity

After incubation with or without cerulein, acini were pelleted (10 000 × *g*, 1min). Pellets were resuspended in 1mL HEPES buffer without BSA and sonicated. After a second centrifugation step (20 000 × *g*, 2 min), the supernatant was then analysed. Trypsin activity was measured fluorometrically using BOC- Glu-Ala-Arg-MCA as the substrate, according to the method of Kawabata[18] To allow quantification and comparison between experiments, a standard curve with known amounts of trypsin was generated by plotting trypsin concentration (0-100pg) against flouresence intensity (380lEx/460lEm). Trypsin content in individual samples was then normalized to total protein content (BioRad) using BSA as a standard and expressed as pg trypsin per mg protein.

Statistical analysis

Analysis was done using standard software (Sigma Plot, Systat). Data were compared by Student's *t* test, $P<0.05$ was considered significant.

RESULTS

Effects of CEP1347 and SB203580 on acinar stimulus secretion coupling and trypsin activity

We have previously shown that JNK inhibition does not influence acinar stimulus secretion coupling[13]. We, therefore, investigated effects p38 and/or JNK inhibition on cerulein-induced acinar amylase release (Figure 1A). Cerulein induced a dose dependent secretory response including the typical biphasic inhibition with hyperstimulatory amounts (●). Neither JNK nor p38 inhibition apparently altered the secretory dose response to cerulein. Thus, treatment with either 20 μM CEP1347 (▽), 50 μM SB203580 (▼) or both agents given simultaneously (○) did not alter maximal amylase release not the biphasic dose response. We also measured the effects of stress kinase inhibition on cerulein-induced acinar trypsin activation (Figure 1B). Active trypsin could be found even in unstimulated acini, but treatment with cerulein led to a dose dependent increase of acinar trypsin activity (●). Interestingly, using CEP1347 (▽), we observed a tendency towards reduced trypsin activation while SB203580 (▼) appeared to increase trypsin activation. However, in isolated acini, this effect was not statistically significant.

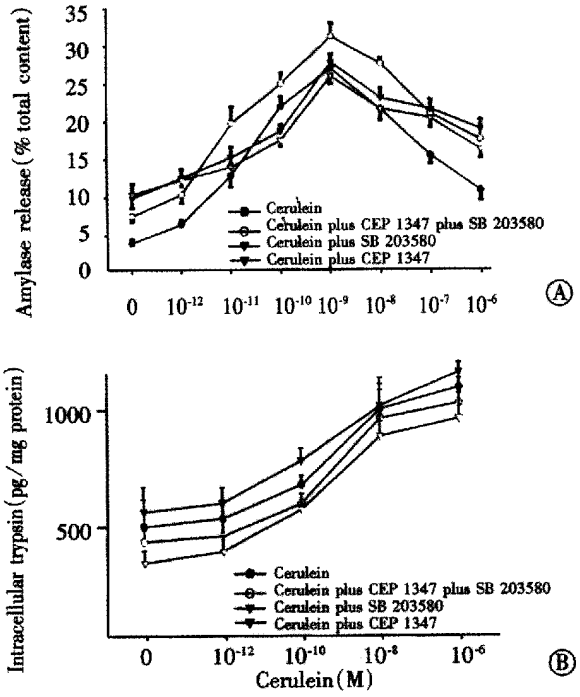

Figure 1 Effects of CEP1347 and SB203580 on acinar stimulus secretion coupling and trypsin activation. Acutely isolated acini were incubated with the indicated amounts of cerulein for 30 min (●). Acini were also treated with 20 μM CEP1347 (▽), 50 μM SB203580 (▼) or both agents simultaneously (○). A: Amylase release into the supernatant was determined and expressed as % of total content. Stimulus secretion coupling was not significantly altered by stress kinase inhibitors. B: Active trypsin was measured in acinar homogenates and expressed as pg / mg protein. Although SB203580 treated acini had a tendency towards higher amounts of active trypsin, this effect was not statistically significant.

SB203580 inhibits cerulein-induced p38 kinase activation in vivo

In order to compare the effects of JNK and p38 inhibition *in vivo*, we tested whether *in vivo* inhibition of pancreatic p38 activity could be accomplished. In contrast to JNK[9,10], p38 is constitutively active in the pancreas (Figure 2, lane 1). Treatment with 30 mg/kg cerulein resulted in strong p38 activation (lane 2). Treatment with 3 mg/kg SB203580 reduced cerulein-induced p38 activation by half while 30 mg/kg SB203580 suppressed cerulein-induced p38 activation almost completely (Figure 2, lanes 3 and 4). However, even the highest SB203580 dose could not reduce pancreatic p38 kinase activity below basal levels (Figure 2, lane 4). SB203580 had no apparent effect on cerulein-induced activation of JNK or ERK (not shown).

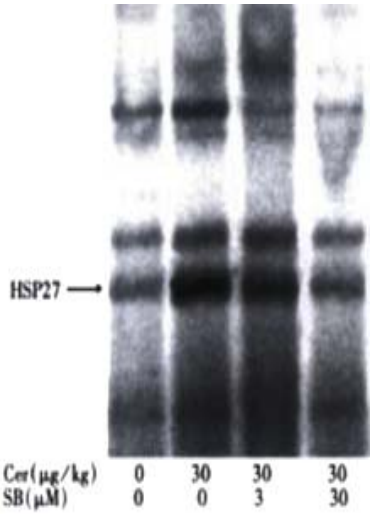

Figure 2 SB203580 inhibits cerulein-induced p38 kinase activation *in vivo*. Animals were treated with the indicated amounts of SB203580, sc, 2 h prior to cerulein hyperstimulation. *In vitro* phosphorylation of HSP27 following immunoprecipitation of MAPKAPK2 was used as read-out of p38 activity. 30 mg SB203580 almost completely abolished cerulein-induced pancreatic p38 activation.

Effects of CEP1347 and SB203580 on biochemical parameters of pancreatitis

According to our previous results, we used 30mg of either CEP1347[13] and/or SB203580 (Figure 2) given sc 4h prior to cerulein. In accordance to the results on acinar stimulus secretion coupling (Figure 1), both agents failed to alter the increase of serum amylase and lipase levels following pancreatitis induction (Figure 3A and B). As reported previously[13], treatment with CEP1347 to inhibit JNK activation significantly increased the dry to total pancreatic weight ratio after cerulein hyperstimulation, indicating reduced edema formation (Figure 3C). In contrast, SB203580 treatment to inhibit p38 kinase activation had no apparent effect on the cerulein-induced increase of pancreatic water content. However, when given simultaneously, SB203580 treatment abrogated the

effects of CEP1347 on the dry to total pancreatic weight ratio. Thus, animals pretreated with both CEP1347 and SB203580, apparently developed similar edema compared to rats treated with cerulein alone.

We also measured the pancreatic trypsin activity *in vivo* (Figure 3D). Compared to acini, pancreata from untreated rats contained very little active trypsin and trypsin activity was strongly induced following cerulein hyperstimulation. Thus, freshly isolated acini on average contained 500 pg active trypsin/mg protein while whole pancreata from untreated control animals on average contained only 15 pg/mg protein (Figure 1B and 3D). Accordingly, the fold increase of active trypsin after cerulein hyperstimulation was much higher *in vivo* (5 fold) rising to 72 pg/mg protein, compared with acini in which cerulein hyperstimulation induced only a 2-2.5 fold increase. The higher basal active trypsin content in acini may possibly be explained by the mechanical stress of the acinar preparation.

As in acini, CEP1347 given *in vivo* did not alter cerulein-induced pancreatic trypsin activation. In contrast, SB203580, interestingly, further increased pancreatic trypsin activation in response to cerulein. This effect was much more pronounced compared to isolated acini, possibly due to lower basal trypsin activity *in vivo*. Thus, SB203580 pretreated animals had significantly higher pancreatic trypsin levels following cerulein hyperstimulation when compared to animals pretreated with CEP1347 (Figure 3D). Again, when given simultaneously, CEP1347 treatment abrogated the effect of SB203580 on pancreatic trypsin activation.

SB203580 treatment leads to necrosis development during cerulein pancreatitis

In order to better compare the effects of CEP1347 and SB203580 on cerulein pancreatitis, histological assessment was also performed (Figure 4). Control pancreata showed regular acinar structure with polarized acinar cells grouped around a ductal lumen and lobules were separated by thin septi (Figure 4A). Cerulein induced the typical morphological changes of edematous pancreatitis including widened interstitial spaces and vacuole formation but without necrosis (Figure 4B). In accordance to previous results[13], JNK inhibition through CEP1347 pretreatment strongly reduced edema formation while vacuolisation was still visible (Figure 4C). Interestingly, inhibition of p38 with SB203580 without concomitant JNK inhibition aggravated cerulein pancreatitis with focal areas of necrosis (Figure 4E and F). Effects of either compound alone on cerulein pancreatitis were mutually abolished when both JNK and p38 were inhibited through simultaneous treatment with CEP1347 and SB203580 (Figure 4D) and no major difference in cerulein pancreatitis without any stress kinase inhibition was seen (compare panel B and D).

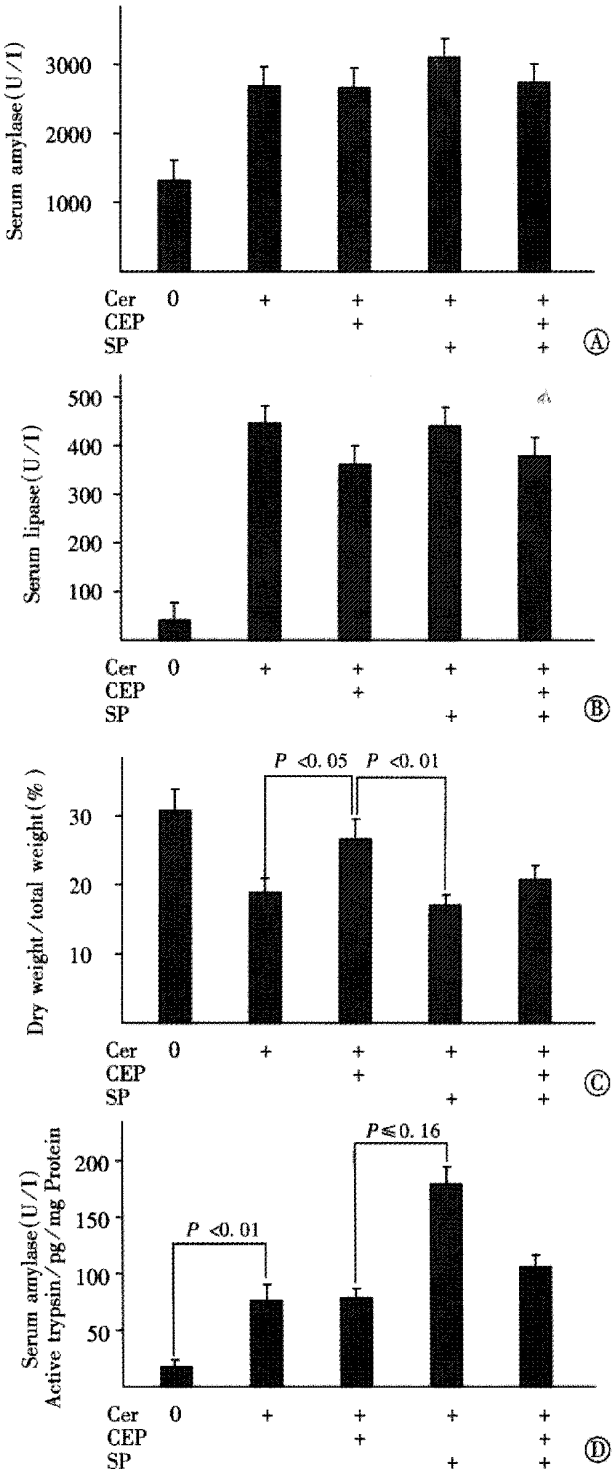

Figure 3 Effects of CEP1347 and SB203580 on biochemical parameters of pancreatitis. Animals were treated with 10 μg/kg cerulein iv and sacrificed 2 h later. As indicated rats were also pretreated with 30 mg/kg CEP1347 and/or SB203580 4 h prior to cerulein injections. Serum amylase levels (A), serum lipase levels (B), dry to pancreatic total weight ratio (C) and pancreatic active trypsin content (D) were determined after sacrifice. Kinase inhibitors had no apparent effect on the cerulein-induced increase of serum digestive enzyme levels. However, CEP1347 reduced the cerulein-induced increase of pancreatic water content and this effect was blocked by simultaneous treatment with SB203580. SB203580 further increased cerulein induced pancreatic active trypsin content and this effect was blocked by simultaneous treatment with CEP1347.

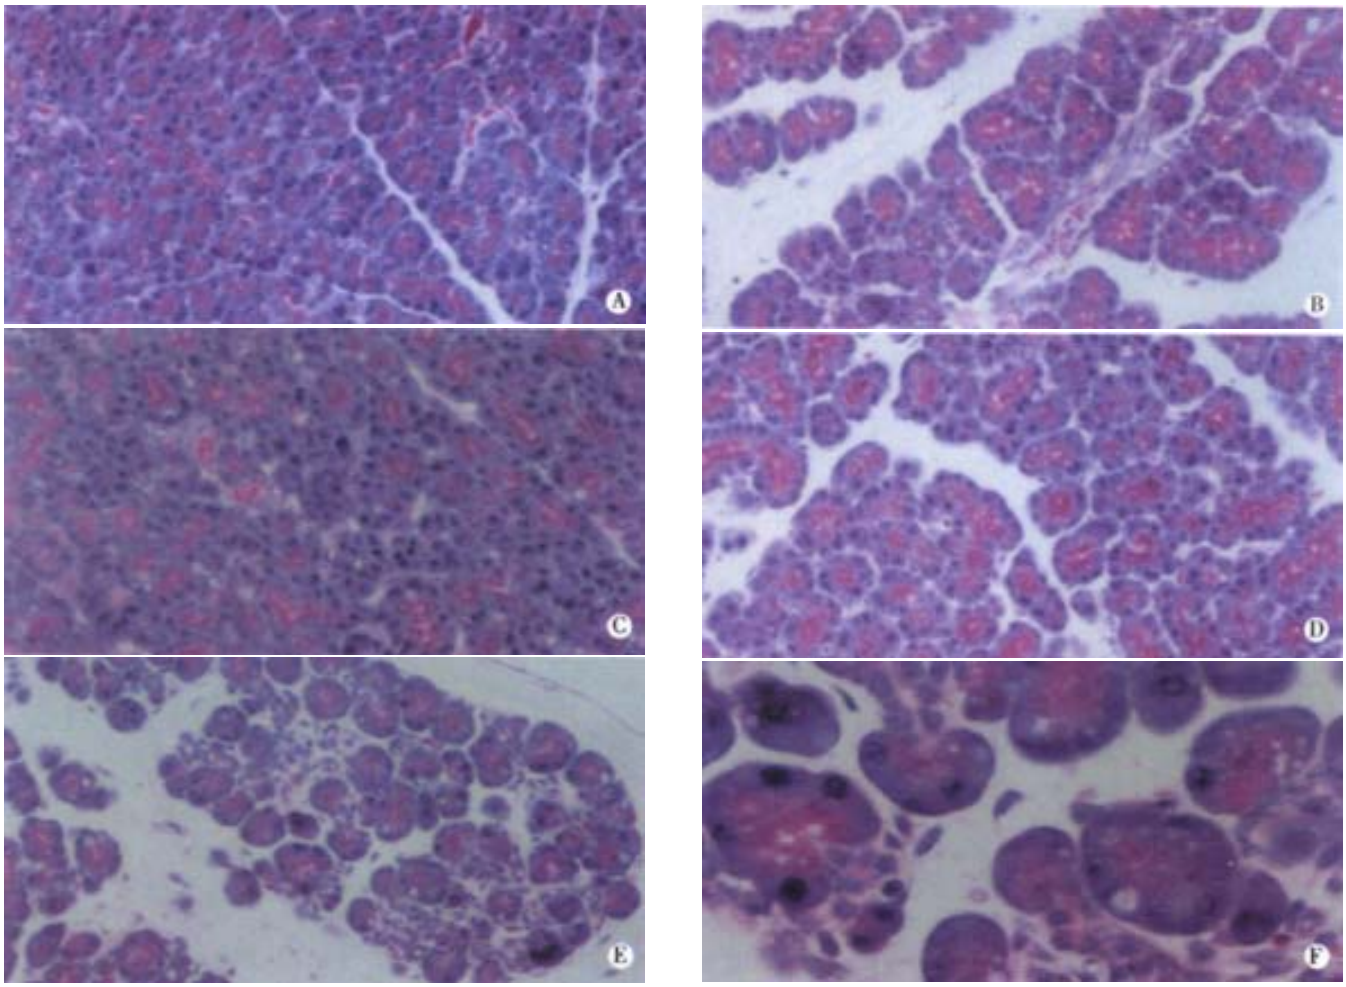

Figure 4 SB203580 treatment leads to necrosis development during cerulein pancreatitis. Animals were treated as in Figure 3. Pancreata were then removed and tissue sections HE stained for light microscopy. untreated control, cerulein alone, 30 mg/kg CEP1347 4 h prior to cerulein, 30 mg/kg CEP1347 and SB203580 prior to cerulein, and 30 mg/kg SB203580 prior to cerulein. Original magnification 50 fold (A-E). Panel F shows a higher (150-fold) magnification of panel E.

DISCUSSION

In our study, we investigated the effects of p38 kinase inhibition on cerulein pancreatitis in comparison to JNK inhibition. We used CEP1347 and SB203580 as tools to specifically inhibit JNK and p38 kinase, respectively. Previously we used CEP1347 for inhibition of pancreatic JNK[13]. CEP 30 mg/kg had no effect on other members of the ERK family. In addition, it has been shown that CEP1347 exhibits between 10-200 fold greater potency towards inhibition of the JNK pathway as compared with other kinases such as protein kinase C, protein kinase A, trk tyrosine kinase, myosin light chain kinase and phosphatidyl inositol 3 kinase[12,13]. We, therefore, believe that CEP1347 can safely be used as a tool to characterize the function of JNK during pancreatic stress. SB203580 has been extensively characterized and widely used as p38 inhibitor and is known to specifically inhibit p38 isoforms α and β but not γ and δ[19]. Nothing is known about pancreatic expression of p38 isoforms, but we (Figure 2) and others[8] have shown that the cerulein-induced p38 activation can be almost completely blocked through SB203580. This indicates that SB203580 is a useful tool to assess the role of p38 kinase in the pancreatic stress reaction early during pancreatitis induction. It is interesting to note that basal p38 kinase activity in the pancreas could not be suppressed by SB203580. This indicates that SB203580 insensitive p38 isoforms may be expressed in the pancreas while only those isoforms inhibitable by SB203580 may be responsive to hyperstimulation stress.

From our data it is clear that neither JNK nor p38 play any role in acinar stimulus secretion coupling, which is in agreement with previous reports by us and others[8,13]. However, our data provides further evidence that stress kinases play an important role early during pancreatitis. Although the exact roles of JNK or p38 for cellular stress responses are still not clear, it has been suggested that these pathways may at least in part be

redundant and may substitute each other[20]. Interestingly in our system, p38 and JNK pathways did not appear as redundant systems. JNK inhibition clearly ameliorated cerulein pancreatitis, reducing pancreatic edema formation following cerulein hyperstimulation. This indicates that JNK activation may promote pancreatic injury. Accordingly, JNK activation has been widely reported to induce cellular damage such as apoptotic or necrotic cell death[20].

In contrast, p38 inhibition aggravated cerulein pancreatitis, indicating that p38 activation may support protection of the pancreas against damage through hyperstimulation stress. Recent evidence from other systems indicates that p38 activation can indeed be protective. Thus, p38 is reportedly important for protection observed after ischemic precondition in myocardial cells and it is evidenced that p38 may exert protective effects via its substrate MAPKAPK2 (MAPK activated protein kinase 2)[14,21].

Our investigation does not allow definitive conclusions about the mechanism of SB203580 actions on the course of cerulein pancreatitis. Based on theoretical considerations, some speculations about mechanisms are possible, however. The deletorious effect of p38 inhibition was apparent biochemically with higher pancreatic levels of active trypsin following cerulein hyperstimulation *in vivo* and, most importantly, histologically with the appearance of necrosis. Premature intracellular trypsin activation has long been thought to play a key role in pancreatitis development[22-24]. Recent evidence to support the importance of active trypsin for the development of pancreatitis came from two sources. First, the discovery of the underlying genetic defect of hereditary pancreatitis showed that, trypsin mutations are sufficient to induce pancreatitis[25,26] second, acinar cells respond to secretory hyperstimulation with rapid conversion of the inactive zymogen precursor trypsinogen to its active form, trypsin[27-29]. Our data could, therefore, be interpreted that p38 kinase inhibition increases pancreatic active trypsin content, allowing necrosis to occur. Our model does not allow us to distinguish whether the active trypsin was mainly present intracellularly or in the pancreatic interstitial space.

Interestingly, it has also been reported that large amounts of trypsinogen are released into the interstitial space during cerulein pancreatitis and that activation of interstitial trypsinogen through concomitant infusion of enterokinase induces necrosis in that model[30]. It is believed that digestive enzymes accumulate in the interstitial space during pancreatitis induction due to missorting of zymogen granules to the basolateral rather than the apical membrane and that missorting is at least in part related to disturbances of the acinar cytoskeletal organization. In the pancreas, it has been demonstrated that secretagogues can activate the p38-MAPKAPK2 pathway[8,10], which has further indicated that secretagogues induce HSP27 (heat shock protein 27) phosphorylation via the p38-MAPKAPK2 pathway[8]. HSP27 phosphorylation via the p38-MAPKAPK2 pathway has further been shown to stabilize the acinar actin cytoskeleton against the effects of secretagogue stimulation[8]. In addition, there is evidence that the p38-MAPKAPK2-HSP27 pathway may be important for organ protection in the pancreas.

Although speculative, it appears possible that during cerulein pancreatitis induction, p38 activation may help reduce acinar damage through its action on MAPKAPK2-HSP27 with increased cytoskeletal stability and less accumulation of active trypsin in the interstitial space. In this model, interruption of the p38-MAPKPAK2-HSP27 pathway through SB203580 could then allow necrosis to occur after cerulein hyperstimulation. The exact mechanism of SB203580 action will have to be determined through additional studies.

In conclusion, we have demonstrated that stress kinases play no role in acinar stimulus secretion coupling. We have also shown that inhibition of JNK and p38 kinase oppositely influences the course of cerulein pancreatitis. SB203580 increases pancreatic active trypsin content and also induces necrosis following cerulein hyperstimulation although necrosis is typically not a feature of cerulein pancreatitis. Our current working hypothesis is that p38 kinase activation may stabilize the actin cytoskeleton via the p38-MAPKAPK2-HSP27 pathway. Inhibition of p38 kinase then might increase missorting of secretory granules with higher amounts of trypsinogen/trypsin secretion into the interstitial space and concomitant development of necrosis.

Abstract

AIM To explore relationships between human carcinomas and mycoplasma infection.

METHODS Monoclonal antibody PD4, which specifically recognizes a distinct protein from mycoplasma hyorhinis, was used to detect mycoplasma infection in different paraffin embedded carcinoma tissues with immunohistochemistry. PCR was applied to amplify the mycoplasma DNA from the positive samples for confirming immunohistochemistry.

RESULTS Fifty of 90 cases (56%) of gastric carcinoma were positive for mycoplasma hyorhinis. In other gastric diseases, the mycoplasma infection ratio was 28% (18/49) in chronic superficial gastritis, 30% (14/46) in gastric ulcer and 37% (18/49) in intestinal metaplasia. The difference is significant with gastric cancer (χ^2 = 12.06, P<0. 05). In colon carcinoma, the mycoplasma infection ratio was 55.1% (32/58),but it was 20.9% (10/ 49) in adenomarous polyp (χ^2 = 13.46, P<0.005). Gastric and colon cancers with high differentiation had a higher mycoplasma infection ratio than those with low differentiation (P<0.05). Mycoplasma infection in esophageal cancer, lung cancer, breast cancer and glioma was 50.9% (27/53), 52.6% (31/ 59), 39.7% (25/63)and 41% (38/91), respectively. The mycoplasma DNA was successfully amplified with the DNA extracted from the cancer tissues that were positive for mycoplasma infection (detected with antibody PD4).

CONCLUSION There was high correlation between mycoplasma infection and different cancers, which suggests the possibility of an association between the two. The mechanism involved in oncogenesis by mycoplasma remains unknown.

INTRODUCTION

Mycoplasma is one of the smallest living organisms isolated from nature, and can be cultured in a special medium. Mycoplasmas spread widely at the cell membrane of many types of mammaliane cells. Some can enter these cells[1-3]. As a conditional pathogenic organism, mycoplasmas have been associated with many diseases[4-11]. Experimental data indicates that some mycoplasmas cause chromosomal changes and cell transformations *in vitro* through progressive chromosomal loss and translocations[12-17], but the association between mycoplasmas and cancer remains unclear. Monoclonal antibody (MAb) PD4 was prepared with human gastric cancer cell line MGC803 as immunogen[18]. The antibody specifically reacted with an antigen associated with some tumor cell lines[19]. Western blot analyses indicated that molecular weight of this antigen (P40) was about 40 kilo-Daltons. Our previous study indicated that MAb PD4 could inhibit the growth of Rat 3-3 and GCM3T3 cells, as well as the tumorigenicity in nude mice[20]. Recently, the antigen P40 was identified with N-terminal sequence analysis. The 16 amino acids at the N-terminus of P40 are identical with the N-terminus of P37, which originated from Mycoplasma hyorhinis, and the PD4 reacted with mycoplasma hyorhinis strongly (unpublished). These results indicate that MAb PD4 is an antibody raised to mycoplasma, not to tumor cells. We then used PD4 detecting mycoplasma infections in paraffin-embedded gastrointestinal carcinoma tissues and other cancers. Here we report the detection results which show a strong association between mycoplasma infections and different human carcinomas.

MATERIALS AND METHODS

Specimen selection

The examined specimens were selected according to the results of hematoxylin-eosin (H&E) staining evaluated microscopically. There are 90 samples of

archived gastric carcinoma tissues and 44 samples of archived normal tissue around carcinoma for comparison, 67 samples are from men and 28 samples are from women. The pathologic grand I-II, II-III and III were 23, 18 and 49 cases, respectively, in the 90 tumor specimens. We selected 47 cases of superficial gastritis, 46 cases of gastric ulcer, and 49 cases of intestinal metaplasia to serve as controls. Fifty-eight cases of colon carcinoma and 49 cases of adenomarous polyp were chosen for detection. Besides the gastrointestinal samples, 53 cases of esophageal carcinoma, 59 cases of lung carcinoma, 63 cases of breast carcinoma, and 91 cases of glioma were also detected. Except the specimens of glioma, which were from 307th Hospital of the People's Liberation Army, all of the samples were kindly provided by the Department of Pathology of the First Affiliated Hospital of Jiangxi Medical College of China.

B-SA immunoperoxidase stain

Tissues embedded in paraffin were microtome-sectioned into 4 μm slices. The slices were floated onto a tissue flotation bath and mounted on 3-aminopropyltriethoxysilane (APES)-treated slides. Sections were heat-immobilized in an oven at 60℃ for 30 minutes, deparaffinized with three changes of xylene, sequentially dehydrated in different concentrations of ethanol, and rinsed in distilled water. Endogenous peroxidase activity was blocked by immersing sections in 0.3% H_2O_2 for 5-10 minutes, followed by sequential rinsing in distilled water and in phosphate buffered saline (PBS). The primary antibody, mouse anti-mycoplasma hyorhinis monoclonal antibody PD4 (described above prepared by our laboratory, diluted to 10 mg/L) was applied to the slices. Unspecialized mouse IgG was used as a negative control. After being incubated for 1 hr at 37℃ or overnight at 4℃, the slices were rinsed three times in PBS for 5 minute each. The slices were stained with B-SA kit (Biogenex) according to the manufacturer's instruction. The results were evaluated by two investigators independently. (-) means no yellow staining was observed in cells, (+) means some cells were observed to be lightly stained, but less than 50%, and (++) indicates that over 50% were observed to be stained, or the staining was strong.

Extraction of DNA from tissues embedded in paraffin

Human gastric cancer tissues embedded in paraffin were microtome-sectioned into 10 μm slices. Two or more slices from each sample were placed into individual sterile autoclaved microcentrifuge tubes. Sterility was maintained at all times and the microtome blade was cleaned completely with ethanol between sectioning to prevent cross-contamination. Digestion buffer, consisting of 0.5% Tween-20, 50mM Tris (pH 8.5), 1mM EDTA, and 200 mg/L proteinase K (Sigma Chemical Co), was added into each tube and incubated overnight. The DNA was successively extracted with equal volumes of Tris-saturated phenol (pH 8.0), 1:1 phenol/chloroform (vol/vol) and then chloroform. one/10 volume of 10M ammonium acetate was added to each sample and the DNA was precipitated by the addition of 2.5 volumes of 100% percent cold ethanol. The DNA was incubated at -20℃ overnight and centrifuged for 20 minutes at 4℃, 12 000 rpm. The DNA was washed with 70% ethanol, and suspended in distilled water.

Mycoplasma infection detected by PCR

Primers used to amplify conserved mycoplasma 16sr DNA were synthesized by Shengong Co. (Shanghai) and the sequences are as follows: forward primer: 5'-TACGGGAGGCAGCAGTA-3'; reverse primer: 5'-TCAAGATAAAGTCATT-3'. The PCR program consisted of 35 cycles at 94℃ for 30 seconds, 48℃ for 30 seconds, and 72℃ for 20 seconds, and 72℃ 10 minutes for final extension[21,22]. The PCR products were analyzed with agar gel electrophoresis.

Statistical analyses

The data were analyzed using the χ^2 test implemented in a commercially available computer program. A value of $P \leqslant 0.05$ was considered significant.

RESULTS

Mycoplasma infection in gastric carcinoma tissues and other gastric diseases

The results indicate that the gastric carcinoma tissues with high differentiation had a higher mycoplasma infection ratio than that of low differentiation gastric carcinoma tissues ($P<0.005$, Table 1). Seven samples exhibited different levels differentiation in the same specimen. The mycoplasma infection in the atypical hyperplasia was higher than that in the carcinoma tissue; the mycoplasma infection was positive in the gastric adenocarcinoma or in the papilloma, but was negative in the gastric mucoid carcinoma.

Table 1 Mycoplasma infection in different grades of gastric carcinoma

Grades of differentiation	Total number of cases	Infection of mycoplasma				
		Negative cases (-)	Positive cases (+)	Positive cases (++)	Total positive cases	Ratio of positive (%)
I-II	23	3	12	8	20	87
II-III	18	7	9	2	11	61
III	49	30	14	5	17	39
Total	90	40	35	14	50	56

In other gastric diseases, the total mycoplasma infection ratio was 31.5% (45/142). This ratio was significantly lower than that observed in the cancer tissue ($\chi^2 = 12.06$, $P<0.05$, Table 2).

Table 2 Comparison of mycoplasma infection in gastric carcinoma and in the other gastric diseases

	Infection of mycoplasma			
	Negative cases	Positive cases	Total number of cases	Ratio of positive (%)
Chronic superficial gastritis	34	13	47	28
Intestinal metaplasia	31	18	49	37
Gastric ulcer	32	14	46	30
Gastric carcinoma	40	50	56	56
Total number of cases	137	95	50(mean)	40(mean)

Mycoplasma infection in colon carcinoma and adenomarous polyp tissues

In the 58 cases of colon carcinoma, the total infection ratio was 55%. As in the gastric carcinoma described above, the colon carcinoma tissues with high differentiation had a higher mycoplasma infection ratio than that of low differentiation colon carcinoma tissues (Table 3, $P<0.05$).

In the 49 cases of adenomarous polyp, there were 10 cases with mycoplasma infection. The positive ratio was 20.4%. The difference between the infection ratio of colon carcinoma and that of adenomarous polyp was significant ($\chi^2 = 13.46$, $P<0.005$).

Table 3 Mycoplasma infection in different grades of colon carcinoma

	Infection of mycoplasma					
Grades of differentiation	Total number of cases	Negative cases (-)	Positive cases (+)	Positive cases (++)	Total positive cases	Ratio of positive (%)
I-II	42	15	15	12	27	64
II-III	8	5	2	1	3	37
III	8	6	2	0	2	30
Total	58	26	19	13	32	55 (mean)

Mycoplasma infection in other carcinoma tissues

Beside the gastriointestinal carcinomas, other cancer tissues from human esophagus, lung, breast and brain were also analyzed (Table 4).

Table 4 Mycoplasma infection in other carcinoma tissues

	Infection of mycoplasma					
Types of carcinoma	Total number of cases	Negative cases (-)	Positive cases (+)	Positive cases (++)	Total positive cases	Ratio of positive (%)
Esophagus	53	26	21	6	27	50.9
Lung	59	28	23	8	31	52.6
Breast	63	38	17	8	25	39.7
Glioma	91	53	27	11	38	41.0
Total	266	145	88	33	121	45.5

Some immunoperoxidase stainings of different carcinoma are shown in Figure 1. The low differential gastric cancer (ring cell cancer) was negative reacted with PD4 (A), but the gastric adenocarcinoma was positive (B).

Detection of mycoplasma DNA in positive specimen by PCR

We selected 3 positive and 3 negative specimens detected by immunochemistry for mycoplasma DNA amplification. The specimen DNA was extracted and PCR was carried out by using mycoplasma 16srDNA primers. The mycoplasma hyorhinis DNA was used as control. The analysis of agar gel electrophoresis showed that mycoplasma DNA was amplified from all three positive specimens, as well as from the positive control of mycoplasma DNA, but there was no mycoplasma DNA amplified from negative tissues, which should be 142bp in size (Figure 2). This result corresponded with that of immunohistochemical detection.

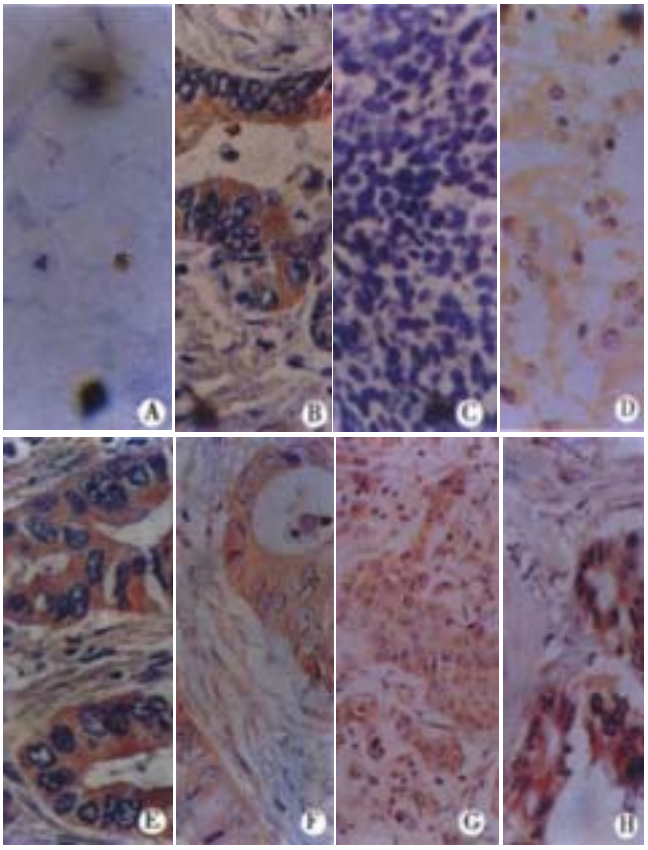

Figure 1 Immunoperoxidase stainings of different carcinoma tissues reacted with monoclonal antibody PD4 (× 400). Both A and B were gastric carcinomas. A (singnet-ring cell carcinoma) was negative, B (adenocarcinoma) was positive. C (glioma) indicated the negative reaction, D (glioma), E (lung cancer), F (esophagus cancer), G (breast cancer) and H (colon cancer) presented the positive reactions with antibody PD4.

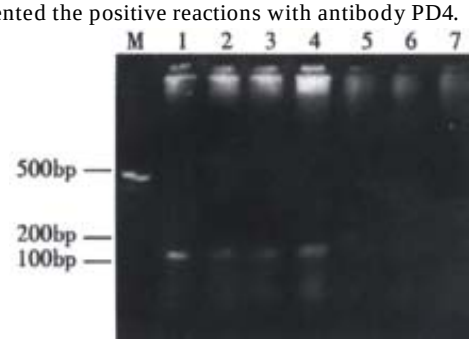

Figure 2 Amplification of mycoplasma 16srDNA from paraffin -N- embedded specimens. M: 100bp DNA Marker; Lane 1: Positive control; Lane 2-4: positive specimen; Lane 5-7: negative specimen. The arrow indicates the amplified mycoplasma DNA.

DISCUSSION

Mycoplasma exists widely in nature. Mycoplasma contamination in cultured cells is common and a major problem in bio-laboratory work. McAb, prepared with cultured tumor cells as immunogen and using these cells as selection targets, has been identified to be antibody against mycoplasma. Unfortunately, the molecules recognized by these antibodies are difficult to characterize and are usually researched as tumor-associated antigen. Meanwhile, these antibodies are regarded as tumor-specific[23,25]. McAb PD4 has been used as a tumor-specific antibody until its antigen was identified by protein sequencing. Because the characterization of tumor antigen is usually difficult, and mycoplasma contamination is common in cultured cells, researchers should be very careful in preparing antibody against tumor and take necessary steps to exclude the possibility of antibody binding to mycoplasma.

We observed that mycoplasma was present in 55% cases of gastrointestinal carcinomas ($P<0.05$) and 45.5% in otherdetected carcinomas. These results are similar to those presented by Philip[26] and Sasaki[27], where the rate of mycoplasma infection was 59.3% in ovarian cancer cases and 48% in gastric cancer, respectively. In gastrointestinal carcinomas, we found that cancer tissues with high differentiation had a higher mycoplasma infection ratio than that of low N differentiation cancers. The reason for this is unknown.

It may be logical to consider the correlation between the cancer and mycoplasma because of the high infection in the tumor tissues, but the role of mycoplasma as a causative or facilitative agent during tumor development has yet to be determined. Although the AIDS related *Mycoplasma fermentans* and *Mycoplasma penetrates* have been reported to induce cell transformation[15], and *Mycoplasma hyorhinis* was observed to increase invasiveness and inhibit cell contact inhibition *in vitro*[24], but direct evidence for a cause-and-effect relationship has not been discovered. In our recent work, we found that gastric cancer cell line MGC803 contaminated with *Mycoplasma hyorhinis* has a much higher capacity to form colonies on soft agar than that of MGC803 without mycoplasma contamination. Interestingly, we have observed McAb PD4 to inhibit colony formation of MGC803 with mycoplasma contamination, but no effect was observed on mycoplasma free MGC803 (unpublished). This result indicates that the protein recognized by McAb PD4 may play a critical role in colony formation increased by mycoplasma. Elucidating the mechanism by which PD4 inhibits colony formation will provide important information for understanding the relationship between mycoplasma infection and oncogenesis.

Abstract

AIM To determine whether diabetic care can be improved by combination of voglibose and gymnemic acid (GA), we compared the combinative and individual effects of voglibose and GA on maltose absorption in small intestine.

METHODS The small intestine 30 cm long from 2 cm caudal ward Treitz's ligament of Wistar rat was used as an in situ loop, which was randomly perfused in recircular mode with maltose (10 mmol/L) with or without different dosages of voglibose and/or GA for an hour. To compare the time course, perfusion of 10 mmol/L maltose was repeated four times. Each time continued for 1 hour and separated by 30 minutes rinse. In the first time, lower dosages of GA (0.5g/L) and/or voglibose (2 μmol/L) were contained except control.

RESULTS Absorptive rate of maltose was the lowest in combinative group ($P<0.05$, ANOVA), for example, the inhibition rate was about 37% during the first hour when0.5 g/L-GA and 2 μmol/L voglibose with 10 mmol/L maltose were perfused in the loop. The onset time was shortened to 30 minutes and the effective duration was prolonged to 4 hours with the combination; therefore the total amount of maltose absorption during the effective duration was inhibited more significantly than that in the individual administration ($P<0.05$, U test of Mann Whitney). The effect of GA on absorptive barriers of the intestine played an important role in the combinative effects.

CONCLUSION There are augmented effects of voglibose and GA. The management of diabetes mellitus can be improved by employing the combination.

INTRODUCTION

It has been well known that there is an association between hyperglycemia and diabetic complication. Patients who develop non-insulin-dependent diabetes mellitus (NIDDM) even at age 65 years may live long enough to develop micro-vascular and neuropathic complication[1]. A cluster of risk factors including hyperglycemia, hyper-insulinaemia, hypertension, dyslipidemia and obesity is called metabolic *X*-syndrome due to the correlationship of them[2]. Similar to cardiac syndrome X, metabolic syndrome X often induces vascular dysfunction[3-5]. Diet regimen and the control of nutrient entry, with the aim of avoiding glucose and anabolic hormone peaks and reducing the rise of developing long-term complications, are broadly accepted as the basic treatment for diabetes mellitus[6,7].

In the ordinary diet, carbohydrates, which contain far more starch than the other carbohydrates, normally represent the quantitatively greatest part of human diet and the main energies supply even though in diabetes. Glucose represents more than 80 per cent of the final products of carbohydrate digestion. Maltose is a rather important product during starch hydrolysis. Therefore, the digestive process in which various glycohydrolases work successively to hydrolyze starch to the final product glucose and the absorption of glucose in the small intestine could be a target for the control of the nutrient entry. Voglibose, an N-substituted derivative of valiolamine isolated from the fermentation broth of Streptomyces hygroscopicus subsp. limoneus, is a potent and structurally novel inhibitor of the intestinal disaccharidases, which not only can be used for treatment of NIDDM but also for insulin-dependent diabetes mellitus (IDDM)[8-11]. It has a potently inhibitory effect on maltase but with a short inhibitory duration[12,13]. On the other hand, GA[14], a mixture of triterpene glucuronides, which

was found in the leaves of the Indian plant, Gymnema sylvestre[15], inhibits glucose absorption of small intestine[16], but it needs a longer time and higher dosage to achieve its maximum effect.

In this experiment, the combinative effect of Voglibose with GA was examined on hydrolysis and absorption of maltose in rat small intestine.

MATERIALS AND METHODS

Animals

Male 8-9-week-old Wistar rats weighing 300 g ± 25 g (Shimizu, Kyoto), were housed in an air-conditioned room at 22℃ ± 2℃ with a nature lighting schedule for 1 to 3 weeks before experiment. They were fed with a standard pellet diet (Oriental Yeast Co., Kyoto) and tap water. Care and treatment of the animals conformed to Tottori University guidelines for the ethical treatment of laboratory animals.

Perfusion of small intestine in vivo

A modified technique of Barry *et al* was used[17]. Animals fasted overnight with free access to water, were anesthetized by intraperitoneal injection of sodium pentobarbital (50 mg/kg bw, Dainabot). The abdominal cavity was opened by a mild line incision. The small intestine 30 cm long from 2 cm caudal ward Treitz's ligament was used as an *in situ* loop, which was emptied of its contents with Ringer's solution. L-shape cannulae were inserted into each end of the selected intestine and connected with a peristaltic pump (SJ-1211H, Atto, Tokyo). The abdominal cavity was closed and the loop was rinsed with Ringer's solution (145.4 mmol/L NaCl, 5.4 mmol/L KCl, 1.8 mmol/L $CaCl_2$ and 2.4 mmol/L $NaHCO_3$) by uncirculated perfusion for 1 hour. Then the intestine was perfused in the recircular mode with 10mmol/L maltose (Sigma) or maltose plus different dosages of voglibose (Takeda Chemical Industries Ltd., Osaka) and/or GA for one hour to determine IC_{50} (concentration of the drug achieving 50% inhibition of maltose absorption or hydrolysis) for each drug. To compare the combinative and individual effects, the animals were randomly separated into four groups in which each loop was perfused for four times (T, R1, R2 and R3). In the first time (T), 10 mmol/L maltose with or without GA (0.5 g/L) and voglibose (2 μmol/L) was perfused. After rinsing for 30 minutes with Ringer's solution, perfusion of maltose (10mmol/L) only was repeated 3 times (R1, R2 and R3) to examine the time course of recovery. The perfusates of 4 groups in the first perfusion (T) were as follows: ① control group: 10 mmol/L maltose, ② voglibose group: 2 μmol/L voglibose +10 mmol/L maltose, ③ GA group: 0.5 g/L GA +10 mmol/L maltose and ④ Combined group: 0.5 g/L GA + 2 μmol/L voglibose +10 mmol/L maltose. All perfusates were dissolved in Ringer's solution. All solutions were kept at 37℃ and pH was regulated at 7.5-7.8.

Measurement of maltose absorption and hydrolysis

Two samples each containing twenty microlitter of perfusion fluid were taken at an interval of 15 minutes during the perfusion period to measure the amount of glucose and maltose remained and kept at 0℃ to prevent further hydrolysis in the collected samples. One was used to measure the amount of glucose remaining at time t (Gt) after the beginning of perfusion. Maltose in the other sample was completely hydrolyzed by incubating it with enough alpha-glucosidase (Funakoshi) to determine total glucose remaining at time t (TGt). The amount of glucose was determined by glucose determining kit (Glucose Test B, Wako, Osaka). Thus, the extents of absorption and hydrolysis of maltose at time t were obtained as follows:

$$\text{Absorption (\%)} = (TGo-TGt)/TGo \times 100$$

$$\text{Hydrolysis (\%)} = (TGo-TGt+Gt)/TGo \times 100$$

where subscript 0 and t represent the perfused time when the sample was taken, and the Go almost equals 0.

GA extraction

Dry-Gymnema sylvestre leaves were obtained from Okinawa, from which GA was extracted with water, ethanol and diethyl carbonate according to slightly modulated Kurihara's method and freeze-dried to obtain GA powder[16].

Statistical analyses

Statistical analyses were performed with the U test of Mann-Whitney or ANOVA, which was indicated in the result when ANOVA was used. $P<0.05$ was considered as significant difference.

RESULTS

Under the present conditions of experiment, about 63% of maltose in the perfusion fluid disappeared during 60 min perfusion as a result of being hydrolyzed to glucose and successive absorption by the intestinal loop. For simplicity we express hereafter this phenomenon as 'absorption of maltose', as was defined in Methods.

When voglibose was present in the perfusion fluid, the absorption of maltose was inhibited dose dependently with apparent IC_{50} of about 6.06×10^{-6} mol/L. On the other hand, GA inhibited the maltose absorption with IC_{50} of 0.85 g/L, whereas the IC_{50} of voglibose on the hydrolysis of maltose in the loop was 1.8×10^{-6} mol/L. In order to

investigate the combined effect of the two inhibitors, we chose rather low doses of the drugs such as concentrations lower than IC_{50}'s. In Figure 1, time courses of the absorption of maltose are shown during 60 min perfusion with or without voglibose (2 μmol/L) and/or GA (0.5 g/L). At such a low dose as 2 μmol/L, voglibose showed slight inhibitory effect on the absorption of maltose and the significant inhibition was observed at 60 min after the beginning of the perfusion. GA (0.5 g/L) exhibited a significant inhibitory effect at 45 min after the beginning of the perfusion. When the two inhibitors co-existed in the perfusion fluid, inhibitory effect was more pronounced. The significant effect was attained at 30 min after the beginning of the perfusion. The inhibition rate of about 37% was achieved at the end of the perfusion and the percentage of maltose absorption was lowest when GA and voglibose were presented in the perfusate ($P<0.05$ *vs* control; ANOVA).

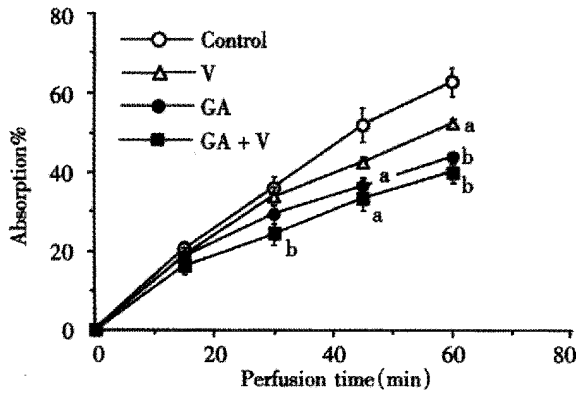

Figure 1 The inhibitory effects of GA (0.5 g/L), voglibose (V, 2 μmol/L) and the combination (GA+V) on 10 mmol/L maltose absorption. The maltose contained in the fluid at perfusion starting point was taken as 100%. Each bar is expressed as the Mean ± SE. ($^aP<0.05$, $^bP<0.01$)

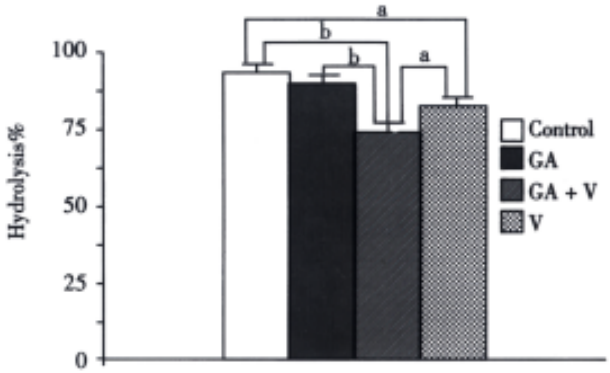

Figure 2 Alteration of maltose absorption following application with GA and voglibose. Each point is shown as the maltose absorption during 60 minutes perfusion of 10 mmol/L maltose following treatment with GA and/or voglibose, except the points of "CON" or "GA/V" which are shown as the absorption during first 1 hour perfusion with or without GA and voglibose. Others are the same as in Figure 1.

Time courses of the recovery from the inhibited states were compared with each other, where perfusion for 60 min with 10 mmol/L maltose only was repeated three times (R1, R2 and R3) inserting rinsing for 30 min between each perfusion, and the extent of recovery was assessed by the absorption of maltose at the end of each perfusion (Figure 2). As shown in the figure, the effect of voglibose was completely recovered during the first perfusion (R1). The effect of GA was still significant after R1 but completely recovered during R2. On the contrary, the suppressed absorption was still remained significant even after R2 and the complete recovery was attained during R3 in the combination group. The total inhibitory rates of maltose absorption in the 3 times perfusion (T, R1 and R2) were 5.39%, 22.21% and 35.55% in the 2 μmol/L voglibose, 0.5 g/L GA and combination groups respectively.

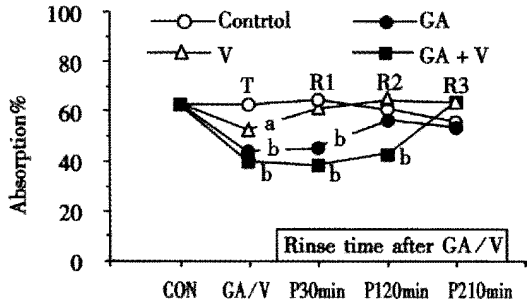

Figure 3 Hydrolytic rates of maltose in each group during R2 in Figure 2. The conditions are the same as in Figure 2.

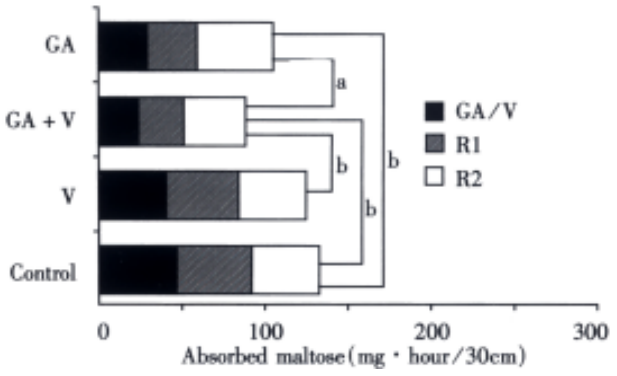

Figure 4 Total maltose absorption in 3 times perfusion during 4 hours. The absolute amounts of maltose absorbed during three perfusions (T, R1 and R2) are compared with each other.

To find the reason of the longer effective duration for the combined group of GA and voglibose, the hydrolytic rate of maltose during R2 in each group was measured (Figure 3). The hydrolysis in the combined group was the lowest among the four groups, although there was no significant difference between the GA and control

group.

Figure 4 shows the total amount of maltose absorbed during three perfusions (T, R1, and R2) in the rather low doses of voglibose (2 μmol/L) and GA (0.5 g/L). It was easily expected from the result shown in Figure 4, that the smallest amount of maltose was absorbed in case of mixing both inhibitors, reflecting the sustained inhibitory effect on the maltose absorption.

DISCUSSION

In the present study, the combinative effect of voglibose and gymnemic acid (GA) was investigated on the digestion and absorption in rat small intestine using maltose as a substrate. Voglibose is an inhibitor of the alpha-dissaccaridases and expected to suppress the absorption of maltose in small intestine as a result of inhibiting the hydrolysis of maltose. Apparent IC_{50} determined in the present experiment of perfusion was 6.6×10^{-6} mol/L for the absorption of maltose, which was about three times larger than that for the hydrolysis of maltose (1.8×10^{-6} mol/L). This difference of IC_{50} could be understood if the rate of hydrolysis of maltose in the intestinal loops was large enough compared to that of absorption of glucose. In fact, when 10mmol/L maltose only was perfused, free glucose appeared progressively in the perfusion fluid. Matsuo *et al*[18] reported the IC_{50} of voglibose on maltase originated from rat small intestine to be 6.4×10^{-9}mol/L *in vitro*. The difference could come from the methods employed in the two experiments.

It has been believed that the anti-diabetic effect of voglibose is due to the inhibition of the hydrolysis of disaccharidases. Recently Hirsh *et al*[19] reported that voglibose showed the inhibitory activity on the free glucose absorption *in vivo* with an IC_{50} near 3 mg/L (1.1×10^{-5} mol/L). The concentration of voglibose used in the present combinative treatment with GA and voglibose was 0.2×10^{-5} mol/L that was less than 1/5 concentration used in Hirshs' experiment. Therefore, the direct inhibitory effect of voglibose on the glucose absorption, if any, would be negligible in the present experiment.

The depressing effect of GA on the sweet taste sensation in human has been known for a long time [20-26]. The inhibitory effects of GA, a mixture of triterpene glucuronides, from the plant -Gymnema sylvestre, on the glucose absorption in the small intestine and the improvement of glucose tolerance have been noticed since the 1980s[15,16,27,28]. Recently we found that GA could inhibit the absorption of oleic acid and gluocose simultaneously[29]. Although the mechanism of the action of GA has not been fully understood, GA is thought to suppress the active transport of glucose suggesting the involvement of the interaction with Na^+ glucose cotransporter and/or ATPase[30-32] on the epithelial cells. The other mechanisms for GA's actions have been considered as participating in the glucose receptor[33] and insulin release[34].

By combining two inhibitors, faster, more effective and long-lasting inhibition of maltose absorption was achieved than those expected as the additive effect. Namely, under the present conditions, significant suppression of maltose absorption was attained at 30 min after the beginning of the perfusion and interestingly, the inhibitory effect was still significant even at 4 hr after the application, whereas almost complete recovery was attained at same time in the case of applying GA or voglibose alone. Therefore, the more effective reduction of postprandial hyperglycemia and hyperinsulinaemia could be expected with the combination.

In the present stage of our knowledge, the mechanism underlying this synergistic effect is not clear. However, as shown in Figure 3, GA enhanced significantly the inhibitory action of voglibose on maltose hydrolysis even at 4 hr after application, although no effect of GA alone on the hydrolysis of maltose can be observed simultaneously. It is well known that most of the disaccharidases produced by the enterocytes are binding with the membrane (under the unstirred layer) and a small amount of saliva and pancreatic amylase is in the glycocalyx[35,36]. The maltose is hydrolyzed during it passes through the glycocalyx and enterocytes[37]. Recently we have found that GA increased the function of unstirred layer by suppression of intestinal motility[38]. Is it possible that voglibose was kept longer time in/under the unstirred layer by GA.

The most common adverse effect of voglibose is hepatotoxicity and gastrointestinal disturbance[39-43] induced by fermentation of unabsorbed carbohydrate in the bowel and increments of gastrointestinal motility[44]. Unfortunately, the disturbance of digestive system also exists in diabetics[45,46]. Voglibose has only rarely been associated with systemic adverse effects, but in some cases acute ileus, pneumatosis cystoides intestinalis and acute dizziness have been reported[47-49]. These adverse effects tend to increase with higher doses of voglibose. GA may diminish the adverse effects not only by decreasing dosage of voglibose, but also suppressing the intestinal motility[38] and inhibiting the growth of anaerobia[50], because bacterial overgrowth plays a role in the development of gastrointestinal symptoms[51].

In summary, the combined effect of voglibose and GA is first reported here. With the combination, the onset time is shortened and the effective duration was prolonged each other, as a result the total amount of maltose absorption is inhibited significantly. Improvement in postprandial hyperglycemia, hyperinsulinaemia and insulin resistance, treatment of an overweight condition (syndrome[52]) and diminishing of the adverse effects of voglibose in diabetic control can be achieved by this combination.

Abstract

AIM To study the role of cholecystokinin octapeptide (CCK-8), β-endorphin (β-EP), and gastrin in an anorexic infantile rat model and no subsequent regulation of nose peptides by the Yunpi complex prescription ErBao Granule.

METHODS We fed infantile rats with special prepared forage. A liquid extract of ErBao Granule was administered to the rats daily for 3 weeks, CCK-8, β-EP, and gastrin concentrations in hypothalamus, gastric antrum, and plasma of the rats were measured by radioimmunoassay, and were compared with controls.

RESULTS Treatment of rats with ErBao Granule inhibited CCK-8 secretion and increased β-EP and gastrin secretion. CCK-8 concentration in hypothalamus and plasma of model control group increased significantly and correlated negatively with food intake of models, respectively. β-EP concentration in gastric antrum and plasma of model control group decreased significantly and showed a positive correlation with food intake of models, respectively. Hypothalamus concentration of β-EP was similar in models and controls. Gastrin concentration in gastric antrum of models was lower than in the blank control group, and correlated positively to food intake of models. Finally, CCK-8 concentrations in plasma of rats showed a positive correlation with plasma β-EP ($r = -0.68$, $P<0.05$).

CONCLUSION The increased plasma and hypothalamus concentration of CCK-8, decreased gastric antrum and plasma level of β-EP, and decreased gastric antrum concentration of gastrin are associated significantly with the anorexia of infantile anorexic rat models produced by special forage. ErBao Granule can reverse these changes, which may be the major mechanisms of ErBao Granule simulating feeding.

INTRODUCTION

In pediatrics it is well recognized that children may refuse to eat for long periods of time without any demonstrable organic disease, and that the origins of this anorexia are to a large extent unknown[1-3]. We investigated 300 cases of children with anorexia [4]. Among these cases (whose causes were clarified), 50.7% was caused by improper diet and feeding. The rest of them were correlated to improper diet and feeding too. Result of several studies supports this point[5-7]. In the view of traditional Chinese medicine, the principal pathogenesis of children anorexia is PiShiJianYun (dysfunction of spleen in transportation). Thus, the YunPi method (activating the spleen) is an important part of traditional Chinese medical treatment of anorexia in children and has been studied extensively by Chinese scholars[8-10]. Since 1989, ErBao Granule, a complex prescription constituted according to Yun Pi method, has been used to treat this disease and has been observed to be effective[11]. Many children who suffered from anorexia exhibited a normal appetite 2 weeks after ErBao Granule was administered. Further study for the mechanism of ErBao Granule stimulating feeding suggested that it may increase digestive enzyme secretion, and improve both intestinal peristalsis and intestinal absorption[11]. Other similar studies have reported the same result[12,13]. However, we did not think that the action of ErBao Granule on digestive function was the major mechanism of stimulating appetite, because children with anorexia showed no significant digestive

disturbances and malnutrition as compared with healthy children.

The regulation of appetite is a complex process that consists of both central and peripheral mechanisms and involves the integration of neurotransmitters, neuropeptides, hormones and metabolic signals[14-17]. Recently, a group of peptides, distributed in the brain and gut, have been discovered to be involved in appetite control mechanism[18]. Some brain-gut peptides stimulate eating, whereas others inhibit it. Inhibitors include cholecystokinin (CCK) and somatostatin, while enhancers include β-endorphin (β-EP) and neuropeptide Y. The secretion and release of some peptides are affected by food composition, and these peptides modulate appetite as a positive feedback or negative feedback factor at the same time[19]. We suggested the loss of appetite in children with anorexia might be related to an imbalance between the brain-gut peptides[20], because the main reason of anorexia for children is inadequate diet:more protein and fat, less mineral substance and vitamins[21,22].

To study the role of CCK, β-EP and gastrin, and their potential relationship with ErBao Granule, we used an anosexic infantile rat model[23]. ErBao Granule was used to treat the rats, and CCK-8, β-EP and gastrin concentration in hypothalamus and periphery of model rats and controls were measured.

MATERIALS AND METHODS

Animals

Forty-eight Sprague-Dawley rats (24 males, 24 females, aged 35 d-40 d,60 g ± 10 g, derived from Laboratory Animal Center of our university) were randomly divided into four groups of 12: a blank control group, a model control group, an ErBao low dose groups and an ErBao high dose group. Each rat was housed individually in a regulated environment (22℃ ± 2℃, 55% ± 10% humidity and 12 h light-dark cycle).

To establish the rat model with anorexia and treat models using ErBao Granule

The anorexic rat model was established by feeding infantile rats with forage we prepared ourselves. The model forage was a compound of ingredients including milk powder, dried minced fish , sugar corn powder, and soy bean powder. We mixed the ingredients together in 1: 1: 1: 1: 2: 2: 1.6, they were shaped into cakes, each weighing about 20 g. Dried by airing, the cakes were stored at 4℃. The major composition of model forage were measured and compared with common forage. Rats in blank control group were fed with common forage and in other three groups were fed with the model forage. All rats were allowed to drink and eat at will. Fresh food was provided each day at 09:00 and each rat's food intake was measured at the same time. ErBao Granule liquid extract (offered by Vegetable Drug Research Center of Nanjing University of Traditional Chinese Medicine) was administered (ig) for twenty days, beginning on the eighth day of the experiment. ErBao liquid extract 18.8 g/kg was given to the low dose group, and 37.6 g/kg to the high dose group. Equal amounts of saline was administered in blank control group and model control group. On the 29th day of the experiment, all animals were killed after an overnight fast.

Preparation of samples and RIA of three brain-gut peptides

Blood was obtained from the orbital artery and collected into chilled plastic tubes containing 1% heparin (10 μL/mL blood sample), miscing bene immediately and then placed on ice. Samples were centrifuged at 4℃ for 3 h. Supernatant fluid was obtained and frozen at -70℃ untilanalysis. The rats were decapitated. The brain and stomach were boiled in saline for 5 min. The hypothalamus was then separated from brain, and the gastric antrum mucosa was scraped. The hypothalamus was homogenized with glacial acetic acid (1 mol/L, 1 mL). The homogenate was incubated at room temperature for 100 min. We added NaOH (1 mol/L, 1 mL) and the suspensions were centrifuged at 4℃. Supernatant fluid was obtained and frozen at -70℃ until analysis. Levels of CCK-8, β-EP and gastrin in plasma and supernatant of animals were measured using commercial radioimmunoassay. The radioimmunoassay kits for CCK-8 and β-EP were provided by the Department of Neurobiology of the 2nd Military Medical University, and the gastrin immunoassay kits, were provided by the Institute of Atomic Energy Science of China. The standard curve for CCK-8 was r = 0.998, for β-EP, r = 0.999, for gastrin, r = 0.999, all fitted the quality control criteria.

Statistics

Data are presented as the means ± SE from 12 rats per group. Statistical analysis was performed using a two-tailed Student's t test, and correlations were examined using linear correlation. $P<0.05$ was considered significant.

RESULTS

Average daily food intake of rats in four groups

On day one, we observed no significant difference in daily food intake between rats in each group. On day seven, the daily food intake of animals in model control group, low dose group and higher dose group was significantly lower than that of the blank control group. The lower food intake of rats was maintained until the end of week 4 in model control group, whereas in low dose group and higher dose group, the daily food intake of rats increased significantly at the end of week 3 (Figure 1). The results indicate that the anorexia model was established successfully and ErBao Granule was effective to the model rats[23].

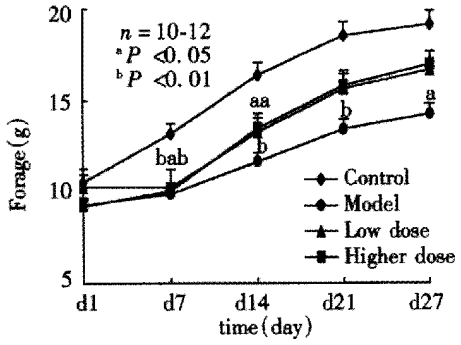

Figure 1 Daily food intake of rats in four groups. Rats of blank control group were fed with common forage. Rats of other three groups were fed with model forage. ErBao and saline were administered (ig) from the d 8 to d 28. Data are presented as the meanÀSE form 12 rats.
[a]Statistically significant difference from control, $P<0.05$, [b]$P<0.01$. At d 7, food intake of model control group, low dose group, and high dose group all was significantly lower than blank control group ($t = 3.76$, $P<0.01$; $t = 2.58$,$P<0.05$; $t = 2.83$, $P<0.01$, respectively). At d 14 food intake of the model control group, low dose group, and high dose group was still lower than blank control group ($t = 4.76$, $P<0.01$; $t = 2.53$, $P<0.05$; $t = 2.38$, $P<0.05$, respectively). At d 21, only model control group was lower than blank control group ($t = 4.71$, $P<0.01$). At d 27, still only model control group was lower than blank control group ($t = 2.33$, $P<0.05$).

Comparison of major composition between common forage and model forage

Each composition of forages was determined from parallel samples. The data were presented as the mean value. As compared with common forage, model forage showed higher concentration of coarse protein and fat (Table 1), lower concentrations of mineral elements (Table 2), and lower concentrations of vitamins (Table 3). Levels of Ca, Fe and Vitamin D were only 1/8, 1/10 and 1/7 of common forage, respectively. The results were similar to dietary survey from children with anorexia[22].

Table 1 Essential component of nutrient in two kinds of forage

Forage	Coarse protein (%)	Coarse fat (%)	Total carbohydrate (g/kg)
Model forage	18.03	39.74	389.43
Normal forage	16.12	14.99	501.05

Table 2 Content of mineral elements in two kinds of forage

Forage	Ca (%)	P (%)	Zn (mg/kg)	Cu (mg/kg)	Fe (mg/kg)
Model forage	0.17	0.08	22.7	7.24	42.39
Normal forage	1.36	0.21	40.46	9.64	428.20

Table 3 Content of vitamin in two kinds of forage (IU/g)

Forage	CaVit A	Vit D_3	Vit B_1	Vit B_2	Vit B_6
Model forage	11.1	2.3	5.3	3.3	4.7
Normal forage	21.5	17	7.3	14.3	19.9

CCK-8 level in four groups

CCK-8 concentration was significantly increased in hypothalamus (122.57 pmol/g ± 31.79 pmol/g) and in plasma (506.88 ng/L ± 113.32 ng/L) of model group compared with that of blank control group (89.15 pmol/g ± 17.94 pmol/g and 253.75 ng/L ± 95.09 ng/L). In high dose group, CCK-8 level dropped both in hypothalamus (95.55 pmol/g ± 20.68 pmol/g) and in plasma (322.14 ng/L ± 66.36 ng/L). In low dose group, it dropped to 100.00 pmol/g ± 18.83 pmol/g and 282.80 ng/L ± 75.63 ng/L, respectively. No significantly difference was observed between high or low dose group and blank control group (Figure 2). We found a negative correlation between food intake and CCK-8 concentrations of model control group in hypothalamus ($r = -0.67$, $P<0.05$) and in plasma ($r = -0.62$, $P<0.05$), and the hypothalamus level of CCK-8 was correlated positively to plasma level of CCK-8 in models ($r = 0.68$, $P<0.05$) (Figure 3).

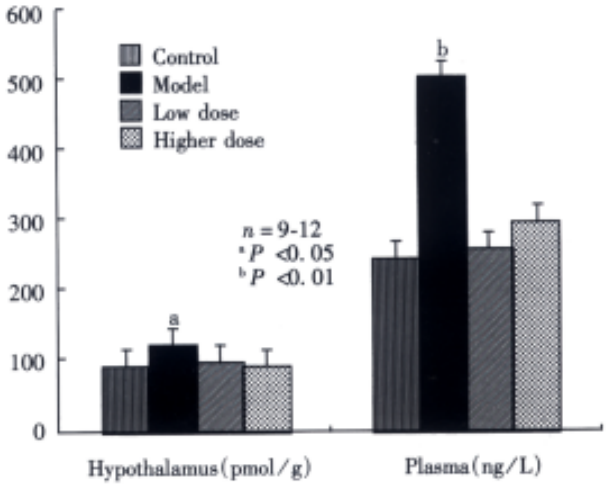

Figure 2 CCK-8 level in the four groups. Data are presented as the mean ± SE from 12 rats. [a]Statistically significant difference from control, $t = 2.55$, $P<0.05$; [b]$t = 5.81$, $P<0.01$.

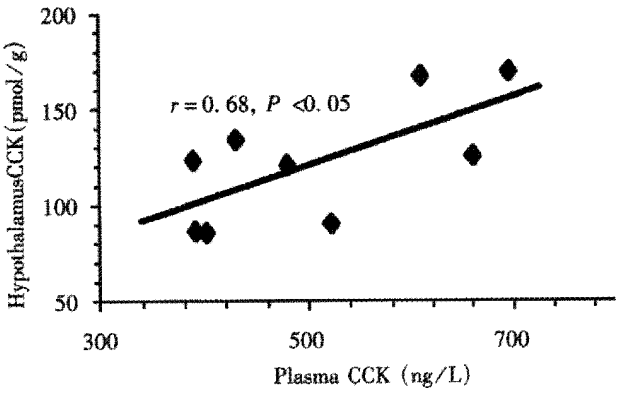

Figure 3 Correlation between hypothalamus CCK-8 and plasma CCK-8 level in model control group.

β-EP level in four groups

β-EP level in gastric antrum (1.45 μg/g ± 0.60 μg/g) and plasma (6.26 ng/L ± 1.73 ng/L) of models were significantly lower than those in the blank control group (6.28 μg/g ± 1.43 μg/g and 10.25 ng/L ± 4.86 ng/L), but hypothalamus concentration of β-EP showed no difference in rats of model control group (23.01 ng/g ± 8.01 ng/g) as compared to blank control group (24.83 ng/g ± 6.67 ng/g). In low dose group, β-EP levels in hypothalamus (28.05 ng/g ± 7.85 ng/g) and in gastric antrum (1.38 μg/g ± 0.32 μg/g) showed no obvious changes compared with model control group. Plasma level of β-EP (8.82 ng/L ± 2.86 ng/L) rose to common level. However, in high dose group, β-EP levels in hypothalamus (41.56 ng/g ± 8.74 ng/g) and gastric antrum (16.49 μg/g ± 4.07 μg/g) showed significant increases compared with those in other three groups, and plasma concentration of β-EP (8.43 ng/L ± 1.59 ng/L) raised to normal level (Figure 4). Food intake in model group correlated positively with β-EP in gastric antrum (r = 0.73, P<0.01) and in plasma (r = 0.58, P<0.05), but not in hypothalamus. We also found a negative correlation between CCK-8 and β-EP in plasma of model control group (Figure 5).

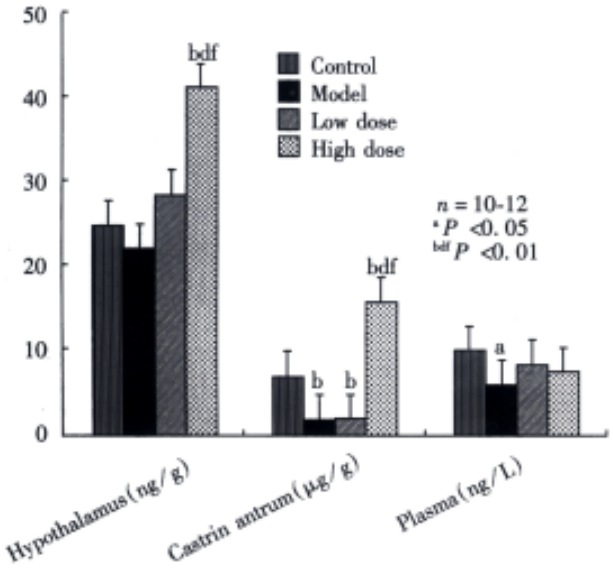

Figure 4 β-EP level between groups. Data are presented as the mean ± SE from 9-10 rats. [a]Statistically significant difference from blank control, [b]P<0.05, [d]P<0.01; from model control, [f]P<0.01; from low dose, P<0.01. In hypothalamus, β-EP level in the high dose group was higher than in the blank control group (t = 4.79, P<0.01), model control group (t = 4.82,P<0.01), and low dose group (t = 3.55, P<0.01). In gastric antrum, β-EP levels of model control group and low dose group were lower than in the blank control group (t = 9.05, P <0.01; t = 10.79, P<0.01), but β-EP level of high dose group increased more significantly than blank control group (t = 7.75, P<0.01), model control group (t = 11.34, P<0.01), and low dose group (t = 12.76, P<0.01). In plasma, β-EP level of model control group was lower than in the blank control group (t = 1.79, P<0.05).

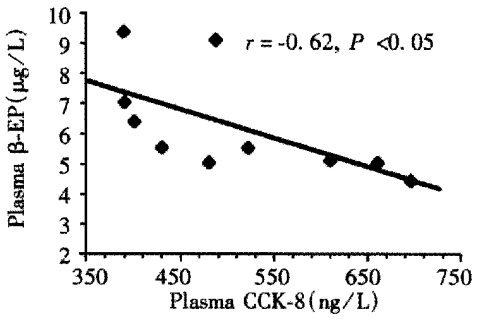

Figure 5 Correlation between plasma CCK-8 and plasma β-EP level in model control group.

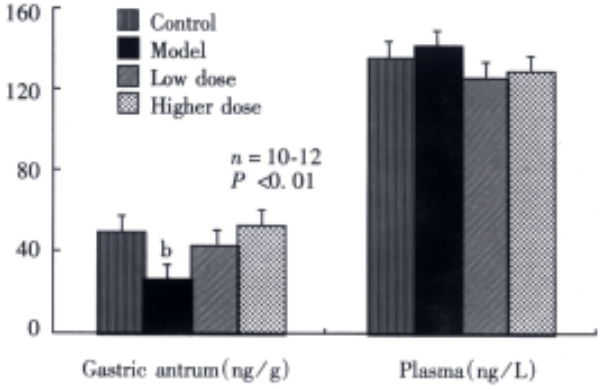

Figure 6 Gastrin level in four groups. Data are presented as the mean ± SE from 10-12 rats.[b]Statistically significant difference from blank control, t = 2.53, P<0.01.

Gastric level in four groups

Gastrin concentration in gastric antrum of model control group (27.04 ng/g ± 13.28 ng/g) was significantly lower than that of blank control group (42.78 ng/g ± 13.43 ng/g). In both the low and high dose groups, gastrin levels in gastric antrum increased to 42.78 ng/g ± 13.43 ng/g and 52.27 ng/g ± 12.37 ng/g, respectively. This increase was similar to that observed in the blank control group. Plasma concentration of gastrin remained constant in model control group, low dose group and higher dose group as compared to blank control group (Figure 6). Food intake of model control group showed a positive correlation with gastrin in gastric antrum of model group (r = 0.70, P<0.05), but not in gastrin level in plasma.

DISCUSSION

We observed an abnormal secretion status of CCK-8, β-EP and gastrin in hypothalamus and periphery of infantile rat model with anorexia produced by feeding our specially prepared forage. However, the secretion was regulated by ErBao Granule. CCK-8 is one of the most widely distributed peptides in the brain and gut. There is now strong evidence that endogenous CCK-8 is important in producing satiety in a variety of species[24,25], and it has been demonstrated to be a powerful suppressor of food

intake as compared with other peptides[26]. It has been reported that CCK-8 concentration increased in hypothalamus and gastric antrum of rat model with Spleen Deficiency[27]. No previous study has examined CCK-8 concentration in children with anorexia. However, some researchers have suggested that CCK-8 might play a role in the pathologic inhibition of food intake in idiopathic senile anorexia and anorexia nervosa [28,29]. In the present study, the model forage resulted in an increased endogenous CCK-8 secretion and release in brain and peripheral tissue of rats. Considering the negative correlation between food intake and elevated CCK-8 levels, we hypothesize that CCK-8 may be responsible, at least in part, for anorexia in children.

It remains unclear whether endogenous CCK is acting peripherally or centrally to produce satiety[30, 31]. Some studies have described that circulating CCK-8 suppressed food intake by inhibiting gastric emptying[32]. However, other investigations researches conclude that the satiety effect of endogenous CCK might not be mediated by circulating CCK[33,34]. Previous studies suggested that the satiety effect of CCK is primarily mediated by the type A receptor which is predominantly located in the periphery[35]. However, recent histochemical studies discovered that the A-type receptors are apparently present in the CNS to a greater extent than previously described[24], which indicated that CCK produces satiety by two modes:peripheral action and central action. Our study found food intake was correlated negatively with elevated CCK-8 concentration not only in plasma, but in hypothalamus of models as well, and that the hypothalamus concentration of CCK-8 was positively correlated with plasma CCK-8 level. These results agree with two modes by which CCK-8 act to inhibit food intake:one is peripheral endocrine effect, the other is a central neurocrine effect. ErBao Granule inhibited CCK-8 secretion and release both in the hypothalamus and intestines of models. We suggest that ErBao Granule might stimulate feeding by both of the two modes described above[36].

β-EP is an endogenous opiod peptide. Unlike CCK-8, β-EP can stimulate feeding significantly[37,38]. Although it has been reported that central opioids produce positive reinforcing effects, whereas peripheral opioids produce opposite effects acting as anorectic factors[39-41], a great deal of studies reported that β-EP levels in both CSF tissue and serum were reduced in anorexia of aging[42]. This suggests that β-EP concentrations in both of central and periphery play an important role in pathologic reduction of feeding. In our study, the food intake of models were positively correlated with decreased β-EP concentration in gastric antrum and plasma. We suggest that decreased peripheral concentration of β-EP might be one of the factors inhibiting feeding in models.

In the present study, ErBao Granule stimulated peripheral β-EP secretion and release. This inecreased stimulation was dose dependent, and inecreased from low dose group to the high dose group. This result indicates that the regulation of ErBao Granule on β-EP concentration in tissues was associated with dose. In addition, ErBao Granule significantly increased β-EP secretion in hypothalamus of high dose group, although there was no predominant change in hypothalamus of models, presumably because of a compensatory action in attempting to overcome anorexia. In addition, we also found a negative correlation between CCK-8 and β-EP in plasma of model group, which agree with the premise that there exists antagonism between CCK-8 and opioid system in the control of feeding behavior[43,44].

Gastrin is one of major hormones released by gastric mucosa after eating food. It has been demonstrated that gastrin is closely related to secretion and motility of the digestive tract[45,46]. Previous studies have reported abnormal high/low secretion of gastrin in patients with Spleen Deficiency syndrome and Liver-Qi Stagnation syndrome related to digestive functional disturbance[47-49]. Yet, the evidence for the role of gastrin in the control of food intake is lacking. The decreased gastrin level in serum of patients with anorexia nervosa suggested that the decrease of gastrin concentration might be one of the factors in pathologic inhibition of food intake[50]. In our study, gastrin concentration decreased in gastric antrum of models compared with controls, but not in plasma, and there was a positive correlation between higher/lower levels of gastrin and food intake in models. Therefore, we suggest that gastrin in gastric antrum might play a role in appetite control mechanisms. Furthmore, ErBao Granule may increase feeding of models by modulating gastrin secretion in gastric antrum,either directly or indirectly[51].

In summary, our results indicate that increased CCK-8 concentrations in plasma and hypothalamus, decreased β-EP level in gastric antrum and plasma, and decreased gastrin concentration in gastric antrum are associated significantly with the anorexia in rat models. The Yunpi complex prescription can regulate these changes which may be the major mechanisms of simulating feeding.

INTRODUCTION

Gastric cancer is one of the most common fatal malignancies in the world. The prognosis is generally poor in advanced gastric cancer. The low survival is related to delayed diagnosis, metastasis and recurrence after operation. The aim of this paper was to find correlation between clinical factors and biologic behavior of gastric cancer in a series of 1200 patients undergoing surgical resection.

PATIENTS AND METHODS

Between November 1992 and December 1999, 1200 patients with stomach cancer confirmed by pathology underwent radical operations. The mean patient age at operation was 54.2 (range 22-89) years, 836 patients were male and 364 were female, with a mean postoperative hospitalization of 16.2 (range 6-127) days.

We analyzed the following clinicopathologic and surgical factors: age, sex, hemoglobin, operation manners, operation time, amount of transfusion during operation, postoperative hospital stay, postoperative complications, positive proximal margin, location of tumor, tumor size, differentiation, depth of tumor invasion, lymph nodes and lymphatic metastasis rate. Frequency of positive lymph nodes = numbers of metastatic lymph nodes / all lymph nodes excised × 100%.

Statistics

All data were analyzed by SPSS statistics program. The comparisons were made by Chi-square test, one-way ANOVA, linear and multivariate regression analysis, $P<0.05$ was considered as significant.

RESULTS

Of these 1200 patients, 768 (64%) underwent distal gastrectomy, 72 (6%) proximal gastrectomy via abdomen and 264 (22%) via thorax, and 96 (8%) underwent total gastrectomy. Distal and total gastrectomy had more numbers of clearances of lymph nodes than the other operational approaches. The postoperative complications occurred in 96 patients (96/1200, 8%), including gastric retention in 22 (22/96, 23%), anastomotic leakage in 18 (18/96, 18.7%), infection of incision in 16 (16/96, 14.6%), disruption of wound in 8 (8/96, 8.3%), and thoracic cavity effusion in 8(8/96, 8.3%). The complication was most common in proximal gastrectomy via abdomen (16/96, 17% patients) (Table 1). The overall mortality was 0.4% (5/1200).

The diameter of the neoplasm was positively correlated with the depth of infiltration and lymphatic metastasis rate while hemoglobin was the opposite. One hundred and seventy-nine (14.9%) of 1200 were early gastric carcinoma (EGC) with metastasis of lymph nodes in 21 patients (21/179, 11.7%). The frequency of positive lymph nodes in these patients was 3%-4% less than in advanced gastric cancer (Table 2). In linear regression analysis, age and diameter of the tumor were negatively correlated with the preoperative hemoglobin ($P<0.001$). The diameter of the tumor was positively correlated with age and the frequency of positive lymph nodes ($P<0.01$).

The patients with tumor of bad differentiation were younger than the other groups, who had larger tumor diameter and higher frequency of positive lymph nodes. The degree of differentiation was not related with the depth of tumor invasion on the gastric wall (Table 3). The tumor diameter on the corpus and fundus was larger than the others, which had higher frequency of positive lymph nodes (Table 4). The proximal gastric cancer, bad differentiation and frequency >30% positive lymph nodes were more common in female than in male (Table 5).

Multiple analysis demonstrated that sex, location of tumor, tumor diameter, depth of tumor invasion and differentiation play an important role in the metastasis of lymph nodes (Table 6).

Table 1 Comparison of operation manner with numbers of lymph nodes, time for operation, amount of blood transfusion during operation, hospitalization days and complications ($\bar{x} \pm s_{\bar{x}}$)

Manners of operation	N (1200)	Numbers lymph nodes	Time for operation (hours)	Amount of blood transfusion (mL)	Hospitalization stays (days)	Complication (%)	Positive resection margin (%)
Distal gastrectomy	768	11.7 ± 0.3*	3.3 ± 0.04	426.5 ± 17.1*	16.9 ± 0.7	9.1	3.8

DISCUSSION

Gastric cancer remains one of most common causes of death. Although the etiology of gastric cancer is still unclear, but studies have shown that many factors are associated with the development, metastasis of gastric cancer, and recurrence after operation[1-9]. Recent studies suggest that infection with *Helicobacter pylori* may play an important role in the development of gastric cancer[10-15]. It has been proposed that *Helicobacter pylori* infection may produce acute and chronic gastritis, intestinal metaplasia, dysplasia, and eventually resulting in gastric cancer. Some abnormal expression[16-18] in gene is involved in carcinogenesis of gastric cancer such as matrix metalloproteinases gene, *p*53 gene and dinucleotide repeat sequence gene. Abnormal contents of some trace elements may also be one of the risk factors in gastric cancer[19,20].

Early gastric cancer (EGC) has been considered to be a form of gastric malignancy with a relatively good long-term prognosis compared to that of advanced gastric cancer because of rare metastasis in lymph nodes[21-26]. In Japan, EGC is diagnosed in 30%-50%, due to partly at least the extensive use of endoscopy and mass screening programs[27-29]. In this study, the proportion of EGC diagnosed in all patients is 14.9%, similar to the proportion in the United States and Europe[30,31]. In recent years, endoscopic treatment has become increasingly popular as an alternative to surgical treatment of patients with EGA in hope of offering superior quality of life (QOL)[32]. However, because of presence of metastasis in 10%-20% and skip metastasis of lymph nodes, whether the rationale for a standard resection with systematic lymphadenectomy is necessary is still a controversial issue[33-37].

Different operative approaches were carried out according to the different locations of the tumor. In our study, the number of lymph nodes excised were the largest in total gastrectomy, followed by distal gastrectomy which may be related to the resection of all or most parts of omentum. The number of lymph nodes excised in proximal gastrectomy via a transabdomen was similar to via transthorax. There was shorter time for operation and lower frequency of complication in proximal gastrectomy via transthorax while lower blood transfusion in proximal gastrectomy via transabdomen. The postoperative hospitalization stay and the positive resection margin was same between them. The complications varied among different operations: gastric retention was common in distal gastrectomy while thorax effusion and infection of lung were mainly found in total gastrectomy.

Although the overall incidence of gastric cancer has remained stable in the West, there is well-documented shift from distal to proximal lesion. The clinical relevance of this shift is that the overall prognosis for patients with proximal gastric cancer is worse than for those with distal tumor. This difference in survival may be attributed to a variety of factors, ranging from an increased biologic aggressiveness of proximal tumors to an advanced stage of presentation[38,39]. In study, a higher frequency of positive lymph nodes was found in gastric cancer located on corpus and the fundus which may be associated with the larger diameter of the tumor in corpus and the fundus. In tumors with larger diameters there were worse differentiation, deeper infiltration, and higher frequency of positive lymph nodes. Apparently, the prognosis will be worse in these patients. The present results also show that the more proximal lesions, bad differentiation, and the higher >30% frequency of positive lymph nodes can be found in female than in male.

The numbers of metastatic lymph nodes play an important role in the long-term outcome after curative resection[40-43]. Thus it is suggested that extended lymphadenectomy should be performed in advanced gastric cancer[44-47]. Our multivariate analysis indicated that among six clinicopathologic variables (age, sex, location of tumor, tumor diameter, depth of invasion and differentiation), the depth of invasion was the most important factor influencing metastasis of lymph node.

In conclusion, this retrospective study has shown that clinicopathological characters in gastric cancer varied with sex, location, and diameter of the tumor. The depth of invasion plays a very important role in metastasis of lymph node. The prognosis in female with gastric cancer may be worse than in man. Because metastasis of lymph nodes may occur even in patients with EGC, radical gastrectomy witi lymphadenectomy may be necessary in all stages of gastric cancer.

INTRODUCTION

Insulin-like growth factor II (IGF-II) is a mitogenic peptide of 74 kD and is mostly synthesized in fetal liver tissue. IGF-II is believed to play an important role in fetal growth and development and is involved in cellular proliferation and differentiation[1-5]. Recently, several researchers have reported increased expression of the IGF-II gene in human hepatocellular carcinoma(HCC) and adjacent non-cancerous liver tissues[6-10]. It is suggested that the aberrant overexpression of insulin-like growth factor II might be related to the deregulation of growth control in hepatocytes during malignant transformation via an autocrine or paracrine mechanism [11-14]. We have designed a study using an *in situ* hybridization technique to assess the effect of IGF-II and its receptor mRNAs on the carcinogenesis and development of HCC.

MATERIALS AND METHODS

Tissue samples

Thirty surgically resected HCC specimens were collected in the Tumor Hospital affiliated to Sun-Yet Medical University during the period of 1996-1997. All the HCC specmens were classified according to Edmondson-Steiner criteria[15]. Eighteen chronic hepatitis and 25 liver cirrhosis specimens were taken by liver biopsy. The tissues were fixed in 10% paraform and embedded in paraffin. Continuous sections were cut for *in situ* hybridization staining of IGF-II and IGF-IIR, respectively.

Hybridization probes

We designed the oligonucleotide probes of IGF-II and IGF-IIR. They were synthesized at the Shanghai Biochemistry Research Institute. The sequence of the oligonucleotides probes is: IGF-II, 5'-GTG-CTT-CTC-ACC-TTC-GCC-TTC-GCC-TCG-TGC-TGC-ATT-G-3'[16] IGF-IIR, 5'-ACA-ATG-CCT-GTC-TGT-GGG-ACC-ATC-CTG-GGA-AAA-CCT-GTC-T-3'[17].

In situ hybridization

The *in situ* hybridization protocols used are described by Tomita *et al*[18]. Briefly, the hybridization solution contained 50% formamide, 5 × SSC, 0.15 mol/L NaCl, 0.1% degraded herring sperm DNA, 0.1% bovine serum albumin, 0.1% SDS, 0.1% polyvinylpyrrolidone (PVP), and digoxin labeled the oligonucleotides probes of IGF-II or IGF-IIR and were kept at 40℃ overnight. The slides were digested prior to proteinase K (30 mg/L) treatment at 37℃ for 30 minutes. After the procedures, the slides were counter stained with nuclear fast red.

Controls

The fetal liver tissues with a high level of expression of insulin-like growth factor II served as positive controls. Negative control slides were treated with PBS and were subjected to all other steps of the staining procedure.

DNA extraction and Southern-blot hybridization

Genomic DNA was prepared using the proteinase K and Phenol-Chloroform extraction method. Southern-blot hybridization was used to detect HBV-DNA integration in various kinds of liver tissues[19].

Statistical analysis

Chi-square test was used for significance analysis. The difference was regarded as significant if P value was less than 0.05.

RESULTS

Expression of IGF-II and IGF-IIR mRNAs in chronic hepatitis, liver cirrhosis and HCC tissue

In normal adult human liver sections and negative control slides, IGF-II and IGF-IIR mRNAs were

not detected exclusively in the hepatocytes. However, in normal fetal liver tissue, very strong signals of IGF-II and IGF-IIR mRNAs were detected. The positive or ratios of IGF-II and IGF-IIR mRNAs increased stepwise starting with chronic hepatitis (33.3%), then HCC (66.7%) and finally liver cirrhosis (72.0%). There was a statistically significant difference in IGF-II and IGF-IIR mRNAs expression between chronic hepatitis and liver cirrhosis ($\chi^2 = 6.34$, $P<0.05$) or HCC ($\chi^2 = 5.04$, $P<0.05$). No significant difference of IGF-II and IGF-IIR mRNAs expression was observed between liver cirrhosis and HCC ($\chi^2 = 0.29$, $P>0.05$). The positive expression of IGF-II and IGF-IIR mRNAs was anchored locally in hepatocellular cytoplasm in a diffuse pattern. The signal intensity of IGF-II and IGF-IIR mRNAs was found to vary with cell type. The lower signal intensity was detected in chronic hepatitis sections, whereas the stronger signal intensity was detected in liver cirrhosis and HCC tissue. An intensive signal intensity was detected in liver regenerative nodules, liver cell dysplasia(LCD) and poorly differentiated HCC cells.

Expression of IGF-II and IGF-IIR mRNAs in differently differentiated HCC tissue

Expression of IGF-II and IGF-IIR mRNAs in HCC tissue of Edmondson grades I-IV were 0, 25.0%, 76.2% and 100.0% respectively. The poorly differentiated tissues (Edmondson grades III and IV) showed higher positive ratios than the well-differentiated tissues (Edmondson grades I and II). (comparison among all groups: $\chi^2 = 9.48$, $P<0.05$).

Relationship between expression of IGF-II/IGF-IIR mRNAs and HBV-DNA integration ratios

HBV-DNA integration ratios in chronic hepatitis, liver cirrhosis and HCC tissues were 61.1% (11/18), 84.0% (21/25) and 83.3% (25/30), respectively. The positive ratios of HBV-DNA integration in chronic hepatitis, liver cirrhosis and HCC tissues were 54.5% (6/11), 81.0% (17/21) and 76.0 (19/25), respectively. The negative ratios of HBV-DNA integration in chronic hepatitis, liver cirrhosis and HCC tissues were 0% (0/7), 25.0% (1/4) and 20.0 (1/5), respectively. These data showed that IGF-II and IGF-IIR mRNAs expression was closely related to HBV-DNA integration.

DISCUSSION

The occurrence of HCC is a process which involves multiple-steps[20,21]. Chronic hepatitis, liver cirrhosis and liver cell carcinogenesis are three important different steps in the occurrence of HCC. Our study demonstrated that IGF-II and IGF-IIR mRNAs were both abnormally expressed in chronic hepatitis, liver cirrhosis and HCC tissue. The expression ratio of IGF-II and IGF-IIR mRNAs in liver cirrhosis was the highest, while that in chronic hepatitis was the lowest. The expression of IGF-II and IGF-IIR mRNAs in liver cirrhosis and HCC was remarkably higher than that in chronic hepatitis. The results suggest that IGF-II and IGF-IIR participate in the process of HCC development at different stages[22,23].

IGF-II and IGF-IIR were expressed at low levels in chronic hepatitis. With the progression of chronic hepatitis to liver cirrhosis, the expression of IGF-II and IGF-IIR increased significantly (especially in regenerative nodules and of liver cell dysplasia). Not only the number of positive cells increased, but also the intensity of the positive signal, which suggests that their over-expression was related to the formation of liver cell dysplasia and liver cell regenerative nodules[24,25]. It is generally accepted that regenerative nodules and liver cell dysplasia are pre-cancerous pathological changes of HCC[26]. The over-expression of IGF-II and IGF-IIR in the pre-cancerous pathological changes of HCC suggests an early event in hepatocellular carcinogenesis. IGF-II and IGF-IIR possibly may play important roles at the early stage of hepatocellular carcinogenesis[27].

In the developmental process of chronic liver disease, repeated inflammation and necrosis of liver cells occurs, which leads to over-expression of IGF-II and IGF-IIR. All these stimulate the abnormal proliferation of liver cells, which creates conditions for the formation of regenerative nodules and liver cell dysplasia. The hepatocytes of liver cell dysplasia and regenerative nodules proliferate actively. IGF-II and IGF-IIR were highly expressed in the two kinds of pre-cancerous pathological changes of HCC, which further stimulates the abnormal proliferation of pre-cancerous liver cells and increases the mutation rate of pre-cancerous liver cells[28]. Their high expression could also induce the malignant transformation of pre-cancerous hepatocytes under certain conditions and eventually lead to hepatocellular carcinogenesis[29-31]. If the over-expressions of IGF-II and IGF-IIR are related to the abnormal proliferation of pre-cancerous hepatocytes, they could be regarded as markers for abnormal proliferation of pre-cancerous hepatocytes[32-34]. The pre-cancerous lesions with high expression of IGF-II and IGF-IIR may be high risk factors of carcinogenesis[35,36].

The expressions of IGF-II and IGF-IIR were related to the differentiation of HCC. Stronger positive signal were detected in poorly differentiated HCC cells. The expression of IGF-II and IGF-IIR in poorly differentiated HCC cells were significantly

higher than that in well differentiated HCC cells. All these magnify the signal transduction, stimulating cells to grow persistently what accelerates the growth of HCC cells and maintained the malignant phenotype of HCC cells[37-41]. If the expressions of IGF-II and IGF-IIR are related to the differentiation of HCC cells, it IGF-II and IGF-IIR may be regarded as a marker for HCC differentiation, which could contribute to better determination of prognosis for patients with HCC[42].

We observed that the expressions of IGF-II and IGF-IIR mRNA in liver cirrhosis were higher than that in HCC. This observation is similar to results reported by Yang Dong-Hua[43]. The over-expressions of IGF-II and IGF-IIR mRNAs were mainly detected in regenerative nodules and liver cell dysplasia. Their over-expressions provided necessary conditions for the malignant evolvement of pre-cancerous liver cells. Once the pre-cancerous liver cells became malignant, they got auto-growth ability and did not simply depend on the high expression of IGF-II and IGF-IIR to maintain their malignant proliferation. Although the expressions of IGF-II and IGF-IIR in HCC tissue were less than that in pre-cancerous liver cirrhosis tissue, when compared with normal more redundary hepatocytes and non-pre-cancerous liver tissue, the expressions of IGF-II and IGF-IIR in HCC tissue were higher. So the expressions of IGF-II and IGF-IIR in liver cirrhosis tissue were higher than that in HCC tissue.

Human HCC frequently occurs in patients with chronic hepatitis B virus (HBV) infection[44-46]. However, the exact molecular biological mechanism by which HBV leads to HCC is still unknown. HBV-DNA integration was reported in 80%-90% of HCC tissue derived from HBV infected patients, which would lead to the deletion, rearrangement, translocation or replication of cellular DNA at the integration site[47,48]. Therefore, the integration of HBV-DNA might play an important role in pathogenesis of some HCC cases. The 11th chromosome is the main site for HBV-DNA integration. The IGF-II gene is located on the short arm of 11th chromosome[49]. Hence, the integration of HBV-DNA on ^{11}P chromosome was probably related to the aberrance of IGF-II gene and therefore lead to abnormal over-expression of IGF-II[50]. Another possibility is that the instability of genome DNA caused by chronic liver disease interrupts the normal regulating sequence of IGF-II gene and therefore leads to the replacement, deletion and transition of IGF-II gene, leading to the persistent over-expression of IGF-II and eventually resulting in hepatocellular carcinogenesis. Our data indicates that the over-expressions of IGF-II and IGF-IIR were significantly higher with than without HBV-DNA integration in liver disease tissue. However, the accurate regulating mechanism and possible motivating or initiating relationship between over-expression of IGF-II/IGF-IIR and HBV-DNA integration remained obscure.

Zhang WZ, Han TQ, Tang YQ, Zhang SD. Rapid detection of sepsis complicating acute necrotizing pancreatitis using polymerase chain reaction. ***World J Gastroentero***, 2001;7(2):289-292

INTRODUCTION

Acute necrotizing pancreatitis usually takes a severe clinical course and is associated with multiple organ dysfunction. With the further understanding of pathophysiological events of acute pancreatitis and the therapeutic measuses taken by the clinicians, the patients can pass through the critical early stages, and then the septic complication caused by translocated bacteria, mostly gram-negative microbes from the intestines ensues[1]. During this stage, the clinical manifestation is not specific and is characterized by systemic inflammatory response, but bacterial cultures are often negative.

Identification of minute quantities of microbial-specific DNA has been made possible by using polymerase chain reaction techniques[2-19] and this method has been used to detect and identify specific pathogen in clinical specimens. It has been shown that PCR method is more sensitive than conventional blood cultures for detecting microbial products in blood[20-22].

The current study was performed to evaluate the technique of PCR with the universal primers targeting bacterial 16S rRNA genes in diagnosing the systemic infection secondary to acute necrotizing pancreatitis.

MATERIALS AND METHODS

Patients and sample collection

Between May 1998 and May 1999, 22 blood samples were obtained from 13 patients with CT or surgically confirmed acute necrotizing pancreatitis who were admitted consecutively to surgical ICU in Ruijin Hospital, Shanghai. There were 8 men and 5 women, the average age was 56.6 ± 8.9 years, and the average APACHE II scores were 10.5 ± 2.2 points.

The blood samples were drawn if the patients presented two or more of the following conditions: ① temperature more than 38℃ or less than 36℃, ② elevated heart rate more than 90 beats per minute, ③ respiratory rate more than 20 breaths per minute or $PaCO_2$ less than 32 mmHg, and ④ white blood cell count more than 12 000/cu mm, less than 4 000/cu mm, or more than 10% immature band forms. And the foci of infection were documented[23-26].

Twelve mL of blood was drawn from each patient, of which 2 milliliter was collected in sterile Na_2 EDTA anticoagulant Eppendorf tubes and stored at 4℃ until DNA extraction was performed, 10 milliliter was sent for conventional blood cultures.

At the same time, 10 blood samples were obtained from 10 healthy volunteers for controlled study.

Bacterial strains

The bacterial strains used were clinical isolates collected from Ruijin Hospital and identified by automated Vitek system. The strains were cultured at 37℃ on blood agar plates until DNA extraction was performed.

DNA extraction

Blood was transferred from Na_2EDTA tubes to sterile 1.5 mL Eppendorf tubes, red cells were lysed in 0.32M sugar-5 mmol $MgCl_2$-0.01M Tris-Cl -1% Triton-x for 10 minutes at room temperature. After centrifugation for 5 minutes at 5 000 rpm, the supernatant was discarded and sediment was preserved for DNA extraction.

The sediment was lysed in 10% Chelex-100 (Sigma) - 0.03% Sodium dodecyl sulfate - 1% Tween 20-1% Nonidetp-40 for 5 minutes at 95℃. After centrifugation (5 000 rpm) for 10 seconds, 5 μL of the supernatant was directly used for PCR amplification[2].

Oligonucleotide primers for PCR

One set of oligonucleotide primer pair was synthesized by the Promega Company, Shanghai Office. The target DNA sequence was the 16S rRNA gene. This set of primers was 5'-GGC GGA CGG GTG AGT AA-3' and 5'-ACT GCT GCC TCC CGT AG-3' to amplify a 255 bp region.

Positive and negative controls

DNA from clinical isolates of *E.coli* was extracted in the same manner as outlined previously. This DNA was used in PCR reactions to determine if the PCR reaction was successful. In addition to a positive control, each PCR experiment contained a reagent negative control that consisted of all PCR reagents but without DNA to determine whether the potential contamination was present.

Microbial DNA amplification

PCR assay was established according to the protocols described by Widjojoatmodjo *et al*[2]. The PCR mixture (50 μL) contained 50 mM Tris-HCl, 200 mM each deoxynucleoside triphosphate (dNTP), 0.4 μM each primer and 1.0 u of Super-Taq Polymerase (Promega Company, Shanghai Office) and 7 mM $MgCl_2$.

The PCR was performed in a DNA Thermal Controller (MJ, Research, INC, USA) as follows. The first step of 5 minutes at 94℃ was followed by 30 cycles of 30 seconds at 94℃, 10 seconds at 72℃ and 1 minutes at 55℃; and extension period of 2 minutes at 55℃ completed the cycling squence.

Identification of PCR products

After amplification, 5 μL of PCR products was run on a 1% agarose gel in 0.5 × TBE. DNA bands were detected by ethidium bromide staining and visualized by UV light photography.

Blood cultures

Blood obtained for culture was collected from patients in a sterile manner and inoculated directly into aerobic and anaerobic bottles. The procedure was performed in the department of clinical diagnosis, Ruijin Hospital.

Statistical analysis

Statistical analysis was done by using the Chi-square test. The difference was considered significant at $P<0.05$.

RESULTS

There was only 1 positive blood culture in the 22 blood samples of 13 patients (4.55%). The organism was *Escherichia coli* (Table 1). But PCR amplification was positive for 8 samples (36.36% $P<0.05$ *vs* culture) from patients and all clinical isolates, yielding the 255 bp band (Figure 1). No DNA amplification occurred in the blood samples from volunteers.

Table 1 Results of PCR and blood culture data for ANP patients

Sample No.	Age (yr)	Gender	Blood culture	PCR	T (℃)	HR (beats / min)	R (breaths / min)	WBC (10^9/L)

DISCUSSION

During the late course of acute necrotizing pancreatitis, starting from the second week, local and systemic complication caused by translocated bacteria from intestines are dominant. The infection occurs in 30% to 40% of patients with acute necrotizing pancreatitis. Around 80% of deaths in patients with acute necrotizing pancreatitis are caused by septic complication[1]. But during this stage, the clinical manifestation is not specific and

characterized by systemic inflammatory reaction and the blood culture is usually negative; this will levy a heavy toll on the clinician for the prompt management of the patients.

Recent studies showed that blood culture techniques, such as volume of inoculated blood, culture media could significantly influence the recovery of bacteria in clinically suspected septic patients and culture is more time-consuming[27-30].

Molecular biology techniques, such as PCR have been used in making a specific and sensitive diagnosis of bacterial infection[2,8,9,12,13,15,16]. The 16S rRNA sequence is highly conserved through the phylogenetic tree. The conserved sequences of the 16S rRNA have led to the development of conserved primers for PCR for the detection of eubacteria. Recently the PCR with universal primers targeting 16S rRNA genes has been used widely to define bacteria[2,15,16,31-41].

With the protocol described by Widjojoatmodjo *et al*[2,31], we developed PCR assay by using the 16S rRNA genes as the amplification targets. In this assay, we found no DNA amplification in healthy blood cells, suggestive of high specificity of these primer pairs. The disadvantage of PCR technique is the contamination of DNA templates, and therefore we employed negative controls at each PCR experiment to safeguard against the potential contamination of stock PCR reagants with microbial DNA products in the environment, and this study showed no false-positive results (Figure 1).

The gold standard of identifying sepsis is blood culture; however, the clinical sepsis is observed in the absence of documented infection in more than 50% of patients with MOF[21] and the prevalence of positive blood culture is around 12%. The positive rate of blood cultures in our study was 4.55% (propably due to small sample), whereas the PCR-positive rate was 36.36% ($P<0.05$), which signifies that this detection method has higher sensitivity than blood culture.

Another advantage of this PCR assay is its ability to perform serial measurements in the same patient for detection of bacterial DNA in the blood, as shown in patients 2, 3, 6, 8, 9 and 11 (Table 1), because PCR is time-saving (less than 8 hours) and blood cultures usually take much longer time (at least 2 days).

However, this detection method cannot identify whether it represents living invading organisms or dead ones engulfed by phagocytes, so this approach cannot differentiate between controlled and invasive infections. Until methods that quantitate bacterial DNA are developed[36], we should combined the results of PCR assays with relevant clinical information to determine whether the sepsis is present. Furthermore, if we apply multiple oligonucleotide primers in the PCR assay[21], there would be a higher PCR-positive rate.

In conclusion, the PCR assay with universal primers targeting 16S rRNA genes is more sensitive in detecting the sepsis secondary to acute necrotizing pancreatitis and this may prompt us to take more aggressive approach to the disease.

Luo Y, Yuan CX, Peng YL, Wei PL, Zhang ZD, Jiang JM, Dai L, Hu YK. Can ultrasound predict the severity of acute pancreatitis early by observing acute fluid collection. ***World J Gastroenterol***, 2001;7(2):293-295

INTRODUCTION

The spectrum of acute pancreatitis (AP) ranges from a mild spontaneously resolved disorder to severe disease with a mortality up to 20%-48.4%[1-3]. sAP is defined as the AP with organ failure and/or local complications which developed from acute fluid collection (AFC) including necrosis, abscess, pseudocyst formation into or around the pancreas[4]. sAP is only about 15%-25% but almost all of mortality and morbidity of AP is concentrated in it[5]. Early diagnosis and assessment of severity in AP are still far from ideal. The role of clinical assessment is reliable but for its subjectivity the value in the early detection of severity is limited[1, 6]. C-reactive protein (CRP) is a promising laboratory marker of severity, even though it is not specific for AP[1]. Single or multiple biochemical criteria and different scoring systems have been used as prognostic indicators, but none has been proven satisfactory in clinical practice[1,6].

The aim of this study is to investigate the prognostic significance of evaluating the severity of AP by observing AFC using ultrasonography.

SUBJECTS AND METHODS

General information

A total of 627 patients who underwent ultrasound examination for AP between 1996-01/1998-12 in the 1st Affiliated Hospital of West China University of Medical Sciences were analyzed retrospectively. Among them 293 were male and 334 female, aged from 4 to 82 years, with an average of 43.02 years; 502 had mild acute pancreatitis (mAP), and 125 severe acute pancrititis (sAP). All examinations were performed by attending doctors in the ultrasound department using AI Performa or Diasonics 2D Gateway ultrasound machines with 3. 5-5MHz probes.

The primary or first ultrasound examination

Usually on the d1 or d 2 after patient admission to our hospital, routine upper abdominal scanning was performed, with particular observation of the size and the echogenicity of pancreas, the pancreatic and bile ducts. Additional attention was made to peripancreatic AFC, including the lesser sac, anterior pararenal spaces, posterior pararenal spaces, peritoneal cavity, and even thoracic cavity.

Follow-up ultrasound examinations

Continued observation of the pancreas with further attention of those spaces mentioned above, as well as the presence or absence of AFC, the quality and the nature of the fluid (i.e., necrosis, abscess or psydeocyst). If necessary, an ultrasound-guided needle aspiration was performed in order to determine the nature of the fluid and to relieve any pressure build-up. Typically repeated scans were performed 3-7 days following the initial scan. However, this interval was dependent upon the severity of AP. For analysis, the patients were classified into four groups according to the fluid collection: no AFC, 1 site AFC, 2 sites AFC, more than 2 sites AFC.

Treatment

All patients were treated by the methods, including traditional Chinese therapy, aggressive intravenous fluid resuscitation, intensive monitoring of vital functions, supportive therapy. Operative intervention was used only when local complication occurred despite maximal conservative therapy.

Clinical parameter

Age, sex, etiology, hospital stay, local

complication, number of operation, mortality. sAP and mAP were diagnosed according to the clinical features, symptoms, physical examination, laboratory tests and image findings.

Data collection

The size of the pancreas, the number of spaces where there were AFC, as well as any regression or resolution in AFC were recorded. If fluid had resolved, the amount of time necessary for complete resolution and any complications associated with AP as well as the amount of time necessary to develop such complications were monitored. Meanwhile, the response to therapy (either medical or surgical), mortality, and length of hospital stay were noted.

Statistical analysis

Continuous variables were analyzed by *t* test. Discrete variables were analyzed by the χ^2 test and rank sum test using SPSS. $P<0.05$ was considered significant.

RESULTS

The number and distribution of AFC and the clinical outcome are summarized in Table 1.

Table 1 AFC and clinical outcome

	0 site	1 site	2 site	>2 sites	Total
Mild AP	256(51)	91(18.1)	75(14.1)	80(15.9)	502(100)[a]*P*
Severe AP	10 (8)	13(10.4)	18(14.4)	84(67.2)	125(100)[a]*P*
n	263	101	91	144	599
Mean hospital stay	12.2±6.14 [b]P [c]P [d]P	15.8±9.89 [b]P [e]P [f]P	19.4±10.13 [c]P [e]P [g]P	28.4±19.68 [d]P [f]P [g]P	17.8 ±14.37 [h]P
Local complication	0	22	16	40	78
Operation	0	2	5	33	40
Death	2	2	1	15	20

n: the number of mean hospital stay, exclude dead patients and the patients who discharged themselves without complete cure. Value in parentheses are percentage.

[a]$P<0.00001$, $\chi^2 = 147.78$, DF = 3.

To analyze the mean hospital stay using Kruskal-wallis test, [h]$P<0.00001$, $\chi^2 = 161.47$, DF = 3; furthermore using Wilcoxon test (l test) to analyze the mean hospital stay between every two group: [b]$P<0.00001$, l = 4.09; [c]$P<0.00001$, l = 6.69; [d]$P<0.00001$; [e]$P = 0.0206$, l = 2.32; [f]$P<0.00001$, l = 8.02; [g]$P<0.00001$, l = 5.07

In the local complication, all 22 local complications in one site were necrosis or pseudocyst formation in sac with or without infection; 56 local complication in two and more than two sites were sac necrosis formation with another space necrosis.

The operation meant all kind drainage for local complication during AP, did not include cholecytectomy after AP.

In dead cases, 4 cases with 0 and 1 site AFC died within 48 h of admission for multisystem organ failure with an average of 28 h; 16 cases with two and more than two sites AFC died within 2-35 days with an average of 18.6 d. Three patients died in wk 1, 4 died in wk 2, and 9 died in wk 3.

The prognostic significance of the severity of AP using AFC number are shown in Tables 2 and 3.

Table 2 To prognosticate the severity of AP using 2 and more than 2 sites AFC

DISCUSSION

Acute pancreatitis is an acute inflammatory process of pancreas, with varible involvement of other regional tissue or remote organ system, some inflammatory cytokine related to it and any high pressure of the pancreatic duct can lead to accumulation of pancreatic juice into pancreas or spill into the peripancreatic area[7-20]. As pancreas is situated in the anterior portion of the retroperitonium and behind the lesser sac, the fluid can accumulate in the lesser sac and the vast retroperitoneal space (especially in anterior pararenal space). The retroperitoneal space is bounded by the posterior parietal peritoneum in front and the transverse fascia behind , extending from the diaphragm to the upper brim of the pelvis. As soon as the pancreatic fluid and exudate enter the retroperitoneal space, they spread freely under tension, extending downward through the lateral part of the retroperitoneal space toward the iliac fossa and upward to the undersurface of the diaphragm and mensenteries involved[21-24].

AFC is quite common in acute pancreatitis[25], while more than 50% can resolve spontaneously, only part of them will develop into local complications, which include necrosis, abscess and pseudocyst formation into or around the pancreas[7]. Once local complications ensue, the onset of severe acute pancreatitis is established[4].

sAP is only about 15%-25% but almost all of mortality and morbidity of AP is concentrated in it[26-35]. The principle benefit of early correct assessment of severity in AP is that patients who require intensive monitoring and therapy are detected at once. The role of clinical assessment is reliable but for its subjectivity the value in the early detection of severity is limited[1,6]. C-reactive

protein (CRP) is a promising laboratory marker of severity, even though it is not specific for AP[1]. Multiple-factor biochemical criteria and different scoring system, such as Ranson's early prognostic signs and Acute Physiology and Chronic Health Evaluation (APACHE) have been used as prognostic indicators, but none has been proven ideal in clinical practice[1,6].

Contrast-enhanced CT is proven to be able to predict the severity of AP by scoring the degree of pancreatic tissue necrosis[36-39], yet the main and widely accepted indication for dynamic CT in AP is clinical suspicion of life threatening local complication and to plan invasive intervention 2-3 weeks after admission for its costliness and X-ray exposure. Therefore, the candidate with AP for contrast-enhanced CT was about 14%[1], and 11.5% patients receiving contrast-enhanced CT in our study was considered to be adequate. Preliminary experiences with magnetic resonance imaging have not identified advantages compared with contrast-enhanced CT[40].

Our data showed that the distribution of AFC is different in mAP and sAP, 96.4% (256/266) patients without AFC had mAP while 51.2% (84/164) patients in more than 2 sites AFC group had sAP. The number of AFC was related to the severity of AP, the hospital stay of patients, the emergence of local complication, and the operation possibility and mortality which is similar to other trials[37]. In other words, 69.1% patients in mAP had no AFC or 1 site AFC while 67. 2% patients in sAP had more than 2 sites AFC, and 2 sites AFC in both mAP & sAP were 14.1%, this seemed to imply that 2 sites AFC is the watershed for mAP and sAP in ultrasonography, when there are 2 sites AFC in AP patients, further examinations should be made and more close attention should be paid. The sensitivity, specificity and accuracy were 81.6%, 69.2% and 70.2% respectively if using 2 and more than 2 sites AFC to distinguish mAP and sAP. The sensitivity, specificity and accuracy were 67.2%, 84.2% and 80.1%, respectively if using more than 2 sites AFC.

In conclusion, the number of AFC is related to the severity of AP, the hospital stay of patients, the emergence of local complication, the operation possibility and mortality. Our preliminary experiences showed that ultrasound can be used as an early and elementary prognostic indicator for severity of AP by observing AFC.

Gordon H. Detection of alcoholic liver disease. ***World J Gastroenterol***, 2001;7(3):297-302

INTRODUCTION

Alcohol has been used in society over centuries and all over the world for its mood lifting properties and taste. It is probably, however, the commonest drug of abuse world wide and unfortunately causes considerable morbidity, mortality and social disruption. In 1990 the cost to the USA was more than $100 billion and 100 000 lives[1].

The relationship between alcohol and mankind is well documented from the earliest times. Wine-making equipment was found in the remains of an early neolithic village in Northern Iran dated about 5 000 BC[2]. In the Bible Noah 'planted a vineyard: and he drank of the wine, and was drunken'[3].

Beer was first produced in Ancient Mesopotamia, Egypt and Greece. There is evidence that alcohol was used for religious purposes and recreationally in Egypt around 3 000. The Ancient Greeks worshipped the God of wine, Dionysius, and seem to have been the first to develop large-scale wine fermentation and production, with export to other countries. The Romans in turn worshipped Bacchus, their God of wine, and were significant wine producers, planting vineyards across Europe. It is not just wine production that has survived through the ages. Barley provided both bread and beer from the first agricultural communities, but mead, made from fermented honey, was the preferred choice for most of Western Europe until Tudor times. Beer, brewed with hops, was introduced later from Germany.

Alcohol has long been an accepted part of human daily life, and throughout the centuries there has been evidence that, for both men and women, consumption gradually increased. This is due, at least in part, to the boiling of the water in the brewing process. An alcoholic beverage was wellknown as an adjunct in the treatment of cholera. For example, in the seventeenth century the water supply for Nottingham, Great Britain, came from the sewage laden river Leen, but there was a plentiful supply of ale houses (about one for every eighty people) thus ensuring some relatively clean fluid to drink[4].

However, there are long-term side effects and problems with excessive drinking. In 1726 the Royal College of Physicians in England issued a statement to the House of Commons asking for an increase in taxes on spirits to act as a disincentive to this 'great and growing evil'[5]. Concern for the effects of alcohol misuse continued and at the start of the twentieth century the British Prime Minister, Lloyd George, addressed factory workers during the first World War with 'we are fighting Germany, Austria, and drink; and, as far as I can see, the greatest of these three deadly foes is drink'[6]. As a result licensing laws were introduced in Britain limiting the hours during which alcohol could be served, and these are currently still in place[7].

Immoderate alcohol consumption may result in a broad spectrum of medical, psychiatric and social problems. These in turn are an expensive burden on any health service and society at large. However alcohol is also widely available and enjoyable so there have been attempts to identify levels of drinking at which alcohol related damage occurs.

LEVELS OF ALCOHOL RELATED DAMAGE

Harmful drinking is alcohol consumption that is causing actual physical or psychological harm[8]. Alcohol dependency refers to those individuals who 'have a compulsion to drink...the same amount each day...and suffer withdrawal symptoms on stopping' (Diagnostic and Statistical Manual of Mental Disorders, DSM III)[9]. This is the most obvious immediately attributable disorder directly related to alcohol misuse.

Regular excessive alcohol consumption is known to cause a wide range of diseases and disorders. Alcohol permeates every system in the body as it is water soluble. Every system in the body is therefore liable to alcohol induced damage, and the spectrum of deaths attributed to alcohol misuse reflects this. The commonest causes of death in the general population in the UK are cardiovascular causes (44.5%), cancer (28.6%) and then accidents (12.6%). These remain the three commonest causes for alcohol misusers, but accidents constitute a much larger proportion (44.1%) in this group[10]. The overall mortality in

Received 2001-03-20 **Accepted** 2001-04-15

individuals misusing alcohol is three and a half times that for the general population.

Alcoholic liver disease forms the largest component of gastrointestinal causes of alcohol related mortality. The first histologically identifiable change seen in alcoholic liver disease is fatty liver. It is usually asymptomatic and can develop within days of heavy drinking[1]. Histologically, droplets of triglyceride can be seen within the hepatocytes. This can progress to alcoholic hepatitis, severe fibrosis and finally cirrhosis.

The level of drinking that constitutes misuse and results in alcohol-related damage was first studied in France. The risk of developing significant liver injury increases with increasing alcohol intake above the threshold levels[11]. It has been suggested that the threshold level for developing liver injury, with or without cirrhosis, may be as low as 30 g per day of alcohol and that with increasing alcohol intake there is increasing risk[12]. Alternatively a study looking at a series of 400 male autopsies showed no significant features of alcoholic liver disease in those who it was estimated had drunk less than 40 g per day. Those drinking 40 g-80 g per day had an increased incidence of fatty liver and alcoholic hepatitis, while those drinking more than 80 g per day had an increased incidence of liver cirrhosis. The threshold for liver damage was seen to be 60 g per day, or 49 units per week in this study[13]. Cirrhosis may develop after only a minimal alcohol intake over a short period of time, or, despite drinking considerable amounts over a life time, never develop. Only 20% of chronic alcohol misusers progress to cirrhosis and the reasons for this have been postulated to be a combination of genetic and environmental factors, and are the subject of continued research.

One of the difficulties in establishing the level of alcohol intake required for liver damage to occur is that despite the common usage of alcohol, exact quantification of the amount drunk on an individual or population basis is difficult to estimate. In the UK, information on alcohol consumption comes from two main sources: Customs and Excise data and population surveys. Customs and Excise data have some confounding factors: they do not include 'home brew.

Population surveys consistently produce lower figures than the Excise data. The Office of Population Censuses and Surveys (OPCS) survey in 1987 estimated alcohol consumption to be 4.2 litres absolute alcohol per head per year, while Excise data estimated this at 7.4 litres per head per year[14]. Population surveys are difficult because, by their nature, they are based on several elements of subjectivity. There is a significant non-response rate which could be amongst the higher or problem drinkers. In general, individuals tend to underestimate their consumption to within, or close to, 'sensible limits'.

The UK Department of Health has suggested that 'sensible limits' for drinking are 21 units per week for men and 14 units per week for women. A unit contains 8g absolute alcohol and is approximately half a pint of beer, a glass of wine or a single measure of spirits. In December 1995 they changed this to 3-4 per day for men and 2-3 for women, in an attempt to reduce binge drinking.

The Royal Colleges of Physicians and Psychiatrists have collaborated to give indications of harmful levels of alcohol intake, and to demonstrate the relationship between alcohol intake and physical harm (Table 1). It was agreed that the threshold for definitely harmful drinking is 50 units per week for men and 35 units per week for women, while that for heavy or hazardous drinking is >35 units per week for men and >25 units per week for women[5].

Table 1 The royal college of physicians (UK) advice on 'safe' and at risk drinking[5]

	Men(units per week)	Women(units per week)
Low risk	21	14
Hazardous	22-49	15-35
Harmful	50^{+}	36^{+}

The problems related to alcohol misuse are preventable. There is a need for an effective screening method for the early detection of alcohol misuse so as to provide support services and then the monitoring of progress. To do this effectively there is a need for objective markers of alcohol misuse.

DETECTION OF ALCOHOL MISUSE

The early detection of alcohol misuse is vital, so that the physical and psychological damage can be limited and reversed where possible. Once those drinking at misuse levels have been identified they need to be monitored through treatment. The Royal College of Physicians (UK) recommend that 'Every person seen in general practice or in hospital should be asked about his or her alcohol intake as a matter of routine, along with questions about smoking and medication, and the answers recorded'[5].

HISTORY AND QUESTIONNAIRES

The history is the most important means for detecting alcohol misuse[15]. The history should cover current and past alcohol intake, and identify quantity and frequency of intake. Unfortunately, although self-report has been shown to be reliable and reproducible, it is subjective, and often is, intentionally or unintentionally, an underestimate.

Questionnaires have been used to try to improve

the identification of alcohol misuse. The CAGE questionnaire[16] consists of four questions; two or more positive answers warrant further investigation:

1. Have you ever felt that you should Cut down your drinking
2. Have people Annoyed you by criticising your drinking
3. Have you ever felt Guilty about your drinking
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (an Eye opener).

This tends to be too sensitive, having a high false positive rate but, if combined with self-report, can detect 90% of alcohol misusers[17]. The MAST (Michigan Alcohol Screening Test) is best at detecting alcohol misusers who have had complications and has been modified to the MmMAST (Malmo modified Michigan Alcoholism Screening Test)[18]. The AUDIT (Alcohol Use Disorders Identification Test) was developed by the WHO collaborative group and was designed to detect early heavy drinking. It consists of ten questions to be used in primary care[19] and has been shown to have a sensitivity of 92% and specificity of 94% in detecting harmful or hazardous drinking[20]. The CAGE, MmMAST and AUDIT were compared in Occupational Health and detoxification clinic settings and compared with self-report for alcohol intake[21]. Over all the sensitivities for the CAGE and MmMAST were 100% and for the AUDIT was 91% amongst the alcohol-misusers, but the AUDIT had the best performance in the Occupational Health setting.

CLINICAL SIGNS

There are a number of cutaneous signs of chronic alcohol misuse but these may be found in those with no significant liver disease. They include spider naevi, telangiectasiae, palmar erythema, gynaecomastia and Dupuytren's contracture. The mechanisms by which these develop are unknown, and with the exception of Dupuytren's contractures, they may all regress with abstinence. There may be truncal obesity mimicking Cushing's Syndrome and parotid enlargement.

In the withdrawal phase of alcohol misuse there may well be sweating, tremor and tachycardia, all of which are difficult to distinguish from thyrotoxicosis.

BIOLOGICAL MARKERS OF ALCOHOL MISUSE

These are particularly valuable to screen or confirm a suspicion of alcohol misuse as they are objective, are useful serially for monitoring, and may be helpful in motivating the patient. These markers can be divided into those indicating recent alcohol drinking, and those of chronic alcohol misuse.

Markers of recent alcohol consumption

Ethanol is the most obvious confirmation of recent drinking and can be detected in breath, serum or urine. It is useful to validate self-report, if positive. Alcohol is eliminated at the rate of $1g \cdot kg^{-1} \cdot hr^{-1}$, usually in 4-6 hours from breath and blood, and within 8 hours from urine, although the elimination rate is affected by the chronicity of alcohol misuse. Most patients know this and adapt their habits so that their clinical value is limited.

Methanol is present in the body and in small amounts in alcoholic beverages as a congener. Both ethanol and methanol are metabolised via alcohol dehydrogenase. However alcohol dehydrogenase has a much higher affinity for ethanol, so this is preferentially metabolised. The level of methanol therefore accumulates during ethanol metabolism and does not start to fall until ethanol has been removed. In practice this is at least 2-6 hours after ethanol has ceased to be detectable[22]. It can be detected in blood or urine.

Serotonin metabolites The urinary metabolites of serotonin (5-hydroxytryptamine) are 5-hydroxytryptaphol (5-HTOL) and 5 hydroxy indole acetic acid (5-HIAA). These are natural substrates. Normally 5-hydroxytryptamine (5-HT) is metabolised predominantly to 5-HIAA by aldehyde dehydrogenase, but a small amount is metabolised to 5-HTOL by alcohol dehydrogenase. However after alcohol ingestion, alcohol is metabolised to acetaldehyde, which than inhibits aldehyde dehydrogenase. Therefore there is a shift towards 5-HTOL and an increase in the 5-HTOL:5-HIAA ratio. The increase is dose-dependent and can be detected 5-15 hours after the ethanol has been eliminated. In urine, methanol and serotonin metabolites can be detected up to 18 hours after drinking, long after the ethanol is cleared[22]. The sensitivity and specificity of the 5HTOL:5HIAA ratio is proportional to the alcohol intake above 200 $\mu mol \cdot L^{-1}$. This is however affected by serotonin containing foods, for example bananas, and disulfiram which both increase the 5HTOL level but not the 5HIAA level. This can be resolved by using the 5HTOL/creatinine ratio in addition to the 5HTOL/5HIAA ratio.

In summary, both methanol and an increase in the 5-HTOL:5HIAA ratio can be detected after ethanol has been metabolised but neither test is routinely available. Ethanol remains the most frequently used test, whether in breath, urine or

serum.

Markers of chronic misuse

The markers most commonly evaluated are those readily available as part of routine screening: erythrocyte mean corpuscular volume (MCV), serum aspartate aminotransferase and alanine aminotransferase (AST, ALT), and gamma glutamyl transferase (GGT).

Erythrocyte mean cell volume (MCV) is thought to be elevated as a result of direct toxicity by ethanol[24]. It becomes elevated after six weeks of alcohol misuse but, in view of the half life of the erythrocyte it remains elevated for up to three months and so has a limited use in monitoring alcohol intake. The sensitivity is higher in women (86.3%) than in men (63.0%)[24]. False positives are found in hypothyroidism, vitamin B_{12} and folate deficiency, non-alcoholic liver disease and in some patients who smoke[25].

Serum aspartate amino transaminase (AST) and serum alanine transaminase (ALT) are markers of liver damage as opposed to alcohol misuse. Both transaminases are found in hepatocytes but AST is also found in skeletal and myocardial cells. In alcohol related liver damage, the AST is elevated more than the ALT, at least in part as a reflection of alcohol related skeletal damage. This is the reverse of the normal pattern in acute hepatocellular disease (for example acute viral hepatitis) where the ALT exceeds the AST.

False positive results are found in non alcoholic liver disease, muscle damage and myocardial damage. Despite these, the specificity is reasonably high at >90% (Table 2).

Table 2 Sensitivity and specificity of markers for detection of hazardous and dependent alcohol use

		Sensitivity(%)	Specificity(%)
MCV	Hazardous consumption	20-30	64-100
	Dependence/alcoholism	40-50	64-100
AST	Hazardous consumption	10-30	>90
	Dependence/alcoholism	35-50	>90
ALT	Hazardous consumption	10-20	>80
	Dependence/alcoholism	20-50	>80
GGT	Hazardous consumption	20-50	55-100
	Dependence/alcoholism	60-90	55-100

Adapted from Conigrave *et al*[23]

AST itself has a mitochondrial (mAST) and cytosolic component. It appears that alcohol selectively affects the mitochondrial component following damage to this organelle so that the serum increase in alcohol misusers is mAST. This has been proposed as a more sensitive marker of alcohol misuse. There is also a small increase in non alcoholic liver disease and it has therefore been suggested it should be used as a ratio of mAST to total AST[26].

Serum gamma glutamyl transferase (GGT) increases in alcohol misuse in a dose-dependent manner, and is often the first marker to be elevated[23]. It is less sensitive in women than men[27,28]. The exact mechanism of elevation of GGT in alcohol misuse is unclear. The enzyme may be released by hepatic cell injury or by induction following exposure to alcohol. In alcoholic liver disease a component of the increase is also from hepatocyte cholestasis and hepatocyte damage. It increases after five weeks of drinking more than 50 g per day. It usually increases to three times the upper reference limit, but will normalise within five weeks of abstinence, with a half-life of 26 days, although this is lengthened in chronic liver disease[29].

Some individuals misusing alcohol never have an elevated GGT; in some chronic alcohol misusers initially high levels fall despite continued drinking. False positives are seen in non-alcoholic liver disease, including fatty liver, biliary tract disease, obesity, diabetes, pancreatitis, hyperlipidaemia, trauma and heart failure, and with microsomal inducing drugs such as anti-epileptics[25].

The varying sensitivity and specificity makes it an unsuitable marker to be used alone for screening, but it is useful to confirm a clinical suspicion of alcohol misuse. Several isoforms of GGT exist and can be separated by electrophoresis. The pattern in alcohol abuse is distinctly different from not only that of healthy volunteers, but also from non alcoholic liver disease. It is, however, the same as that in those taking anti-epileptic drugs since both result in enzyme induction. It has been suggested that the analysis of GGT isoforms may improve the specificity of GGT for alcohol misuse[30].

Combinations of markers

As can be seen from Table 2 none of the routinely available markers has sufficient sensitivity or specificity to be used alone, and in practice a combination is usually used. AST and GGT both have higher sensitivity in men than women while MCV is higher in women. Each of MCV, AST and GGT are raised by a different mechanism and so used in combination will pick up varying parts of the alcohol misusing population. If two or more markers are positive then the number of false positives fall and the specificity is seen to increase[29,31].

The clinical case mix affects the test performance of any given marker. The sensitivity of the test is highest where there are a high number of

severe alcohol misusers, in for example the alcohol treatment centre. The sensitivity is lowest in the general community[23]. Chick *et al* found a sensitivity of 40% for in patient alcohol misusers and 23% for those in the setting of employment screening[31]. Sillanukee *et al* found a sensitivity of 4. 7% for MCV for detecting alcoholics in the context of a detoxification centre, but only 22% for detecting heavy drinkers voluntarily attending for health screening. Similarly using GGT there was a sensitivity of 65% in the detoxifica tion centre, but only 35% within the community[32].

Other markers

Serum urate is routinely available and may be elevated in 40% of male and 25% of female alcohol misusers. False positives results are seen in gout, renal disease and with some drugs.

Serum triglycerides are often measured for other reasons but increase after one - week of drinking in 40% of alcohol misusers, and normalise within one week of abstinence. False positives are seen in hyperlipidaemia, diabetes, obesity and with some drugs.

It can be seen that the currently available routine markers do not have sufficient sensitivity or specificity to be used alone to detect alcohol misuse. Considerable research has been undertaken to try to find any other potentially more useful markers. One such marker is carbohydrate deficient transferrin (CDT).

Transferrin is a large glycosylated protein which binds and transports iron in the plasma. It has terminal carbohydrate units containing sialic acid. Alcohol intake of greater than 60 g per day for two weeks results in loss of some or all of the sialic acid component of transferrin and hence the term - carbohyd rate deficient transferrin. Initial research gave promising results with sensitivities of 100% and specificities of 97%[33], confirmed by other workers[34-37] and prompted the development of commercial assays: CDTect (Pharmacia and Upjohn, Sweden) and AXIS %CDT (AXIS Biochemicals, Norway). There has been a considerable amount of research using these commercial assays and variation in the reported results[38,39]. It seems that in development of the assays there has been some loss of sensitivity and specificity, particularly in women and those with liver disease. This marker is increa singly being used in Europe, and often in combination with other markers.

SUMMARY AND CONCLUSIONS

Alcohol has been used in society over centuries and all the evidence we have ind icates that, to society as a whole, the risks are heavily outweighed by the benefits and it is particularly expensive in health terms. A means to identify those at risk is required so that these individuals can be targeted for help. This in turn requires a means for monitoring. Ideally detection should screen for alcohol misuse at a level at which damage occurs.

Histories and questionnaires are still the commonest initial means of detection of alcohol misuse. They are cheap, easily administered but are subjective. They still provide the 'gold-standard'. If the history remains uncertain and there is a suspicion of alcohol misuse biological markers provide objectivity, and a combination of markers remains essential in detection. The three commonest markers in current practice were GGT, AST and MCV. However these show problems with detection, particularly in the context of liver disease. Serum carbohydrate deficient transferrin initially showed promise as having a high sensitivity and specificity and could be ideally suited for both screening and monitoring. However following development of commercial assays, the sensitivity and specificity is not as promising as early work had suggested. Research continues in both investigating and refining markers of misuse.

Harris A.Treatment of *Helicobacter pylori*.***World J Gastroenterol***, 2001; 7(3):303-307

INTRODUCTION

Using an evidence-based approach this review discusses the current treatment of *Helicobacter pylori* infection in patients with peptic ulcer disease, functional (non ulcer) dyspepsia or gastro oesophageal reflux disease (GORD). It also briefly addresses the potential role of eradication of *H. pylori* in preventing gastric cancer.

PATIENTS WITH DUODENAL ULCER DISEASE (DU)

In a patient with a well documented DU, who is not taking non steroidal anti-inflammatory drugs (NSAIDs), *H. pylori* may either be assumed to be present (more than 90% prevalence) or may be confirmed at endoscopy by tissue biopsy (for rapid urease test, histology or microbiological culture). *H. pylori* eradication therapy (see below) may then be prescribed. *H. pylori* eradication therapy, if successful, will be effective in healing the ulcer regardless of whether the patient is seen at the initial presentation of the disease, or at a recurrence[1]. Patients on long-term treatment with histamine-2 receptor antagonists (H_2RAs) or proton pump inhibitors (PPIs) for DU should also be offered *H. pylori* eradication treatment, regardless of whether they are symptom-free, or still experiencing symptoms, because eradication of the bacterium will cure the disease[1].

DUs heal quickly and completely after eradication of *H. pylori*, so that a separate healing course of anti-secretory therapy is unnecessary in an uncomplicated ulcer[2,3]. After a course of eradication therapy it may be acceptable to await the clinical outcome, i.e. an improvement in symptoms, rather than to formally test for the presence or absence of *H. pylori*. Recurrence of symptoms signifies either failure of *H. pylori* eradication, or the "unmasking" of some other disease, for example, GORD[4]. In such cases, further management will not be clear unless the outcome of eradication therapy is known. The best way to determine this is either through the ^{13}C-urea breath test (^{13}C-UBT) or possibly, a faecal antigen test, performed no sooner than four weeks after eradication therapy[5].

COMPLICATED DU

Complications of DU such as bleeding or perforation are associated with appreciable morbidity and mortality, especially in the elderly. There is good evidence that eradication of *H. pylori* decreases the risk of re-bleeding and reperforation from DU[6]. In such patients *H. pylori* eradication therapy should be followed by treatment with an H_2RA (such as ranitidine 300 mg at night) for a further four weeks until either repeat upper g.i. endoscopy with biopsies to confirm re epithelialisation of the ulcer crater and to assess *H. pylori* status, or a ^{13}C-UBT. If *H. pylori* has been successfully eradicated (and the patient is not taking NSAIDs) anti-secretory therapy is no longer needed. The prevalence of *H. pylori* in patients with complicated DU may be lower than that in patients with simple DU and it is therefore important to confirm that the patient is colonised with the bacterium before prescribing eradication therapy and stopping anti-secretory medication[7].

GASTRIC ULCER

The main point of difference in the management of a patient with *H. pylori* associated GU is the need to exclude malignancy in an apparently benign GU. Patients with GU should therefore be re-endoscoped about 8 weeks after *H. pylori* eradication therapy to confirm healing, obtain further biopsies if re-epitheliasation is incomplete and to ascertain *H. pylori* status.

Eradication of *H. pylori* leads to healing of GU and markedly decreases the incidence of relapse[1,8]. The effect of eradication of *H. pylori* on GU complications is unknown at present. Anti secretory maintenance treatment should therefore be started after successful eradication of *H. pylori* in those patients with GU who have a history or haemorrhage or perforation, until complete healing of the ulcer is confirmed at follow up endoscopy.

H. PYLORI AND NSAID-ASSOCIATED ULCER

Despite several studies, no clearly defined guidelines about the relationship between NSAIDs, gastro-duodenal ulceration and *H. pylori* have emerged[9,10]. NSAIDs and *H. pylori* appear to be independent risk factors for gastro-duodenal ulceration and ulcer bleeding. There is some evidence that *H. pylori* eradication may prevent the development of ulcers in patients starting

NSAIDs[10]. However there is other evidence that *H. pylori* associated gastritis may even be beneficial, because of prostaglandin release protecting against mucosal injury by NSAIDs[9]. Indeed it appears that NSAID associated ulcers heal more rapidly after treatment with PPI in the presence of *H. pylori*[9]. In a *H. pylori* positive patient with a history of peptic ulcer disease, *H. pylori* should be eradicated before starting treatment with NSAIDs because the NSAIDs may increase the likelihood of ulcer relapse[9]. There is no evidence that eradication of *H. pylori* is of benefit in decreasing the dyspepsia associated with treatment with NSAIDs[9].

H. PYLORI AND GASTRIC CANCER

Infection with *H. pylori* is associated with a three to six fold increase in the risk of developing non-cardiac (body and antrum) stomach cancer[11]. Although prevention of gastric cancer through eradication of *H. pylori* is potentially extremely important in global terms (750 000 deaths attributable annually to the neoplasm), it must be emphasised that, at present, there is no evidence that eradication of *H. pylori* decreases that risk. Nor is it known at what stage *H. pylori* has to be eradicated to prevent the progression of chronic gastritis to atrophy, intestinal metaplasia, dysplasia and eventually to invasive cancer. Although infection with *H. pylori* is very common, the life-time risk of developing non-cardiac stomach cancer in infected individuals in the developed world is estimated to be less than 1%[11]. In subjects with other risk factors for stomach cancer, such as one or more first degree relatives with this condition, or the presence of gastric mucosal dysplasia or intestinal metaplasia found at gastroscopy, it seems reasonable to offer *H. pylori* eradication therapy. It is important however to discuss with the patient the possible side effects of the treatment, the lack of evidence to support this practice and the possibility of treatment failure.

PATIENTS WITH FUNCTIONAL DYSPEPSIA AND H. PYLORI INFECTION

Functional dyspepsia is defined as pain or discomfort in the central upper abdomen which originates in the upper gastrointestinal tract, which has been present for at least three months and in the absence of organic disease, such as peptic ulcer or GORD[12]. This diagnosis accounts for up to 60% of patients with non-NSAID associated dyspepsia[13]. The evidence for an association between *H. pylori* and functional dyspepsia is uncertain. Several well designed, randomised and controlled trials assessing the efficacy of *H. pylori* eradication treatment in patients with functional dyspepsia have been published in the past three years but have produced discordant results[13-16]. A recent systematic review has found that eradication of *H. pylori* was significantly superior to placebo in treating functional dyspepsia (relative risk reduction 9%, 95% confidence interval 4%-14%) suggesting that one case of dyspepsia would be cured for every 15 patients treated[17]. The mechanism by which eradication of *H. pylori* decreases dyspepsia in these patients is unclear. It is possible that the patients that benefited may have had an ulcer diathesis which was not active at the time of endoscopy.

PATIENTS WITH GORD

There is unequivocal evidence that infection with *H. pylori* is the principal cause of peptic ulcer disease and there appears to be a small, but definite association between the bacterium and functional dyspepsia[1,17]. The relationship between *H. pylori* and GORD is however still unclear[18,19].

The prevalence of *H. pylori* is not increased and may actually be decreased in patients with GORD[20]. Recent studies have reported that significantly fewer patients with GORD are infected with *H. pylori* than healthy, age and sex matched individuals[20,21]. More importantly, there appears to be a negative correlation between the prevalence of *H. pylori* infection and the severity of oesophagitis; patients with erosive (grade III) oesophagitis or Barrett's columnar lined oesophagus are significantly less likely to be infected with *H. pylori* than patients with either a normal oesophagus or milder degrees of oesophagitis[22,23]. This inverse relationship has been further assessed according to the subtypes or strains of *H. pylori*; patients with cagA positive strains appear to be significantly less likely to develop erosive oesophagitis or Barrett's oesophagus[24-27]. Furthermore the prevalence of cagA positive strains appear to be significantly less frequent in patients with oesophageal adenocarcinoma or dysplasia, conditions which may result from longstanding and severe GORD[25].

ERADICATION OF *H. PYLORI* AND GORD

There is no convincing evidence that GORD improves after eradication of *H. pylori*[18,19]. There is conflicting data regarding the development of GORD following eradication of *H. pylori*. Some studies have found that patients develop endoscopic oesophagitis after eradication of *H. pylori* either for duodenal ulcer disease or functional dyspepsia[28-30] but these findings were not confirmed in another study[31]. The prevalence of heartburn does not appear to increase between 6 months and 3 years after eradication of *H. pylori* in patients with either functional dyspepsia, GORD or DU disease[32-36].

Another reason to carefully evaluate the role of *H. pylori* eradication therapy in patients with GORD is the recent finding that the treatment of GORD may be more effective in the presence of the

bacterium: pantoprazole was significantly more effective at healing the oesophagus in the presence of *H. pylori*[37]. It was found that healing of oesophagitis (grades II and III) was significantly greater after 4 and 8 weeks treatment with pantoprazole in *H. pylori* positive patients compared with *H. pylori* negative patients. On that point, anti-secretory therapy also appears to more effective in the presence of *H. pylori* in patients with functional dyspepsia[38]. The exact mechanism for these most interesting findings is unclear at present.

Patients with GORD and *H. pylori* infection who need prolonged treatment with standard or high doses of PPIs, according to one uncontrolled study, may be at increased risk of developing atrophic gastritis[39]. During profound acid suppression with PPIs *H. pylori* may migrate from the antrum to the more proximal parts of the stomach leading to chronic active corpus gastritis which may progress to atrophic gastritis, which is associated with increased risk of carcinoma[40]. The latter changes do not occur with profound acid suppression in patients without *H. pylori* infection. It has therefore been recommended that patients with GORD who need prolonged treatment with a PPI should have their *H. pylori* status determined and if positive, eradication therapy should be given. This recommendation is based on hypothesis, rather than on scientific evidence, and it has to be borne in mind that *H. pylori* eradication may render PPIs to be less effective[37,38]. Further studies are needed before these contradictory considerations can be resolved[41].

H. PYLORI ERADICATION TREATMENT

The aim of treatment of *H. pylori* in any therapeutic context is eradication of the organism from the foregut. Eradication is defined as negative tests for the bacterium four weeks, or longer, after the end of anti-microbial therapy[42]. Failure to detect *H. pylori* on tests done less than four weeks after the end of therapy may give false negative results because clearance, or uppression of *H. pylori* may occur during treatment, followed by rapid recrudescence of the original infection.

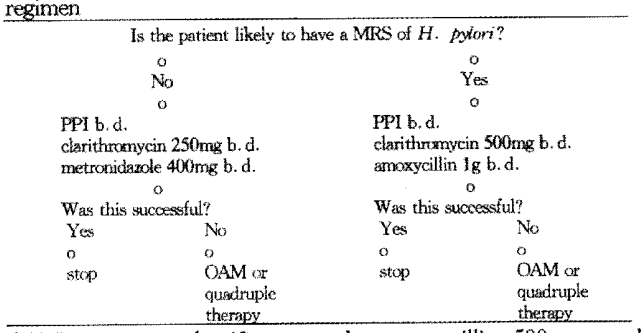
Antibacterial treatment of *H. pylori* is difficult because of the very rapid development of resistance to anti microbial agents, especially to nitroimidazoles, such as metronidazole and tinidazole, and clarithromycin[41]. The prevalence of resistance to these anti-microbial agents varies with gender, ethnic group and country of origin (Table 1)[41]. It was recently reported from Hong Kong that almost 50% of pre-treatment strains of *H. pylori* were resistant to metronidazole and over 10% to clarithromycin[42]. The efficacy of treatment for *H. pylori* is significantly decreased in the presence of pre-treatment anti-microbial resistance and the likelihood of this should influence the chosen regimen (Table 1, Figure 1)[5,41].

Monotherapy or dual therapy (PPI or ranitidine bismuth citrate (RBC) with an antibiotic) cannot be recommended and should not be used because of inconsistent and highly variable results[5,41].

Table 1 Risk factors for nitroimidazole resistance in *H. pylori*

- ☐ Previous use of nitroimidazoles, e.g. gynaecological infections, infective diarrhoeas
- ☐ Failed *H. pylori* eradication regimen containing a nitroimidazole
- ☐ Urban or inner city areas
- ☐ Patients born in emergent countries

Figure 1 How to choose a one week *H. pylori* eradication regimen



OAM – omeprazole 40 mg o. d., amoxycillin 500 mg and metronidazole 400 mg t. d. s.
MRS – metronidazole-resistant strain of *H. pylori*

LOW-DOSE TRIPLE THERAPY

The most overall effective *H. pylori* eradication regimens reported to date combine either a PPI (esomeprazole, lansoprazole, omeprazole, pantoprazole, rabeprazole) or RBC with two of the following: amoxycillin, clarithromycin, or a nitroimidazole (metronidazole or tinidazole)[5,42,43-49] (Table 2). These regimens are commonly prescribed for one week and the tablets are taken twice daily. There are few side effects (the most common are nausea, diarrhoea and taste disturbance). Results from large, randomised and controlled trials have consistently shown *H. pylori* eradication in about 90% of treated patients[44,46-49].

Table 2 Low dose triple therapy

Therapy	PPI or RBC Amoxycillin Clarithromycin	PPI or RBC Clarithromycin Metronidazole
Dosing	b.d.	b.d.
	1 g b.d.	250 mg b.d.
	500 mg b.d.	400 mg b.d.
Duration		One week
Side effects	Nausea, diarrhoea,	taste disturbances
H. pylori eradication	90%	90% in MSS
		75% in MRS

PPI- proton pump inhibitor; RBC- ranitidine bismuth citrate; b.d.- twice daily;
MSS- metronidazole-sensitive strain of *H. pylori*;
MRS- metronidazole-resistant strain of *H. pylori*

A one week course of omeprazole 40 mg once daily in combination with amoxycillin 500 mg and metronidazole 400 mg three times daily has been shown to be effective even in the presence of pre-treatment metronidazole resistant strains (MRS) of *H. pylori*, with 75% eradication[50]. Side effects are more common and compliance more complex than with the twice daily regimens, so that this regimen is best reserved for first line treatment failures (Figure 1).

CIASSICAL TRIPLE THERAPY

Bismuth based triple therapy was the first multi drug treatment to be widely investigated and used in clinical practice. Originally, it consisted of 14 days treatment with colloidal bismuth subcitrate 120 mg qds, together with metronidazole 400 mg tds and either amoxycillin, or tetracycline 500 mg qds. Unfortunately side effects are frequent and the regimen is complicated to follow with more than 11 tablets to be taken daily. Furthermore, the efficacy of the triple therapy is dependent on the susceptibility of *H. pylori* to metronidazole, with eradication in only 50% of those patients who are colonised by a metronidazole-resistant strain of *H. pylori*[5,41].

QUADRUPLE THERAPY

Classical bismuth-based triple therapy has been reported to be more effective when co-prescribed with a PPI. More than 90% *H. pylori* eradication is possible with a combination of omeprazole, colloidal bismuth subcitrate, tetracycline and metronidazole given for 7 days[5,41,51,52] (Table 3). Efficacy is highly dependent on patient's compliance with the complicated prescription. Furthermore, these quadruple regimens have been shown to work in 75%-80% of patients who failed first line eradication therapy with metronidazole and/or clarithromycin containing regimens[51,52].

Table 3 Quadruple therapy

Therapy	Omeprazole Colloidal bismuth subcitrate Tetracycline Metronidazole
Dosing	o.d. 120 mg q.d.s. 500 mg q.d.s. 400 mg q.d.s.
Duration	One week
Side effects	Common: nausea, diarrhoea, taste disturbances
H. pylori eradication	>75% in MRS >90% in MSS

o.d.- once daily; q.d.s.- four times daily;
MRS- metronidazole-resistant strains of *H. pylori*;
MSS- metronidazole-sensitive strains of *H. pylori*

FIRST-LINE TREATMENT (FIGURE 1, TABLE 2)

In areas with low (<30%) prevalence of pre treatment metronidazole-esistant strains of *H. pylori*, a one week triple therapy regimen consisting of a PPI, metronidazole and clarithromycin is recommended at present. Patients' compliance is likely to be good because of twice daily dosing and few side effects. If metronidazole resistance is likely (Table 1), a PPI in combination with amoxycillin and clarithromycin given for one week is preferable (Table 2).

SECOND-LINE TREATMENT (FIGURE 1, TABLES 2,3)

After a proven failure with a regimen containing metronidazole, the patient is likely to be colonised by a metronidazole-resistant strain of *H. pylori*. In this case, a PPI in combination with amoxycillin and clarithromycin given for one week should be used, with around 90% success. If *H. pylori* eradication is unsuccessful after a clarithromycin- and metronidazole-containing regimen or the patient is likely to harbour a pre-treatment metronidazole resistant strain of *H. pylori*, then either omeprazole in combination with amoxycillin and metronidazole[50] or quadruple therapy are the only logical options (Table 4), with approximately 75% success[51,52].

Table 4 Current indications for *H. pylori* eradication therapy

Diagnosis	Established evidence-based indications
Non-NSAID DU	+
Non-NSAID GU	+
NSAID DU or GU	-

Endoscopic difficulties in the diagnosis of upper gastrointestinal bleeding

M. N. Appleyard, C.P. Swain

Subject headings gastrointestinal hemorrhage/diagnosis; angiodysplasia/diagnosis; endoscopy, gastrointestinal/methods

Appleyard MN, Swain CP. Endoscopic difficulties in the diagnosis of upper gastrointestinal bleeding. ***World J Gastroenterol***, 2001;7(3): 308-312

INTRODUCTION

Bleeding from the upper gastrointestinal (GI) tract remains common, with a reported annual incidence of up to 172 per 100 000[1], which has if anything increased from earlier series. Case fatality was recently reported as 14%[2], which has probably not changed over several decades. These figures may reflect a rising proportion of elderly patients and increasing non-steroidal anti-inflammatory use, but occur despite apparently better treatments and understanding of the underlying pathophysiology of peptic ulcer disease. Of patients in whom a diagnosis is confirmed, more than 90% suffer from Peptic Ulcers, oesophageal or gastric malignancy, varices, Mallory Weiss syndrome, erosive disease and oesophagitis[1,2]. This report will focus on the some of the less common aetiologies of upper GI bleeding which are sometimes difficult to identify at endoscopy.

Angiodysplasia

Gastrointestinal angiodysplasia are the most common cause of obscure chronic blood loss from the digestive tract with small bowel angiodysplasia accounting for up to 40% of obscure GI bleeding[3]. The pathophysiology is unknown, but has been suggested to result from low grade venous obstruction of submucosal veins as they cross muscle layers[4]. It is said to be more prevalent in chronic renal failure patients[5]and in patients with aortic stenosis, although, recent reports have failed to confirm this link[6]. Isolated gastric angiodysplasia commonly occurs on the greater curve of the body (Figure 1), whereas small bowel angiodysplasia are often multiple and widespread but may cluster in the proximal jejunum.

Osler-Weber-Rendu Syndrome is an autosomal dominant condition characterized by angiodysplastic lesions involving the skin, mucosal membranes and organs other than the GI tract (Figure 2). Patients present as children or adults with epistaxis and up to 40% develop chronic iron deficiency secondary to GI bleeding usually after the age of 50. Their endoscopic appearance is indistinguishable from other angiodysplastic lesions, but they tend to be more widespread.

Acquired angiodysplastic like lesions such as those due to radiation damage can also lead to upper GI bleeding.

Various thermal coagulation devices, including heater probes, bipolar probes, the Nd:YAG laser and the argon plasma coagulator appear to be successful in treating these lesions. Coagulation should begin at the central feeding arteriole and work peripherally. Bleeding is common during treatment and usually self limiting. The depth of injury should be minimized, especially in the small bowel and right colon,in order to avoid either frank perforation, or the post-coagulation syndrome, in which patients develop rebound tenderness without detectable intraperitoneal gas. Laser treatment can cause deep injury relatively easily and must be used carefully. Our primary treatment modality is the bipolar probe because it causes more superficial injury than other thermal methods. Complication rates are low for gastric lesions and although no data exists, are also thought to be low in the small bowel. Colonic complications after laser therapy have been reported in up to 10% cases and include partially treated lesions and perforation. Treatment is not required for incidental lesions. Treatment of isolated gastric lesions will often terminate bleeding, whereas treatment of small bowel lesions can more often only hope to reduce transfusion requirements since many lesions are not reached and treated and new lesions will develop with time. The frequency of further endoscopic treatment sessions depends on clinical assessment, rate of recurrence of anaemia and transfusion requirements. Some patients will maintain a stable haemoglobin on iron therapy alone. A placebo-controlled trial mainly in patients with Osler Weber Rendu disease demonstrated decreased transfusion requirements in patients taking 0.05 mg ethinyl oestradiol and

1.0 mg of norethindrone daily[7].

Dieulafoy's lesion

Dieulafoy's lesion is a cause of diagnostic difficulty in patients with repeated haematemesis; the exposed, eroded vessel in a very small ulcer is difficult to spot at endoscopy (Figure 3) and accounts for perhaps 2% of upper GI bleeds[8]. It was described in detail by Dieulafoy in 1896[9], who described "Exulceratio Simplex": bleeding from a simple acute submucosal ulcer of small size. Histology demonstrates an artery with a diameter of 1 mm-3 mm usually surrounded by a small ulcer, less than 5 mm in diameter. Often no inflammation, sclerosis or aneurysmal dilatation is seen. The aetiology is uncertain with most cases occurring in the elderly. NSAIDS and *Helicobacter pylori* have not been implicated. Patients usually present with significant upper GI haemorrhage. The lesions endoscopically are commonly located high on the posterior aspect of the lesser curve within 3 cm of the gastro-oesophageal junction, but similar lesions have been identified throughout the GI tract. They are often difficult to see when not actively bleeding. Adequate inflation to distend the folds in the upper stomach, a retroflexed endoscope and close examination of the mucosa posteriorly on the lesser curve may help to identify this entity. Multiple examinations are commonly required and the abnormality is sometimes diagnosed when pulsatile arterial bleeding is seen coming from apparently normal mucosa. Endoscopic therapy is successful in more than 90% of cases. Adrenaline is frequently injected into the base prior to definitive treatment with electrocoagulation or, more recently, band ligation.

Gastric antral vascular ectasia (Watermelon Stomach)

This syndrome is a rare cause of GI bleeding, although increasingly recognized. It was first described in 1952 by Rider *et al* and used to be called gastric antral vascular ectasia. Jabbari *et al* [10] coined the phrase "watermelon stomach" to describe the endoscopic features: visible columns of vessels traversing the antrum in longitudinal folds converging on the pylorus and resembling the stripes of a watermelon (Figure 4). There is often marked mucosal and submucosal thickening which has been demonstrated with endoscopic ultrasound. It is said to occur more commonly in women, 71% in the largest series[11], with the mean age of presentation being 73 in women and 68 in men. Approximately 90% of patients present for evaluation of occult bleeding and persistent iron deficiency anemia, which characteristically fails to respond to iron therapy. Up to 62% of patients have associated autoimmune or connective tissue diseases, the most common being the CREST syndrome and pernicious anemia, which can confusingly normalize the mean corpuscular volume. Atrophic gastritis seems almost invariable with the majority having achlorhydria and hypergastrinaemia. Cirrhosis and portal hypertension occurs in up to 60% in some series, but is not a feature in more recent series. This lesion can be confused with portal hypertensive gastropathy. The diagnosis is usually made endoscopically if the characteristic lesion is seen. However, histology can help demonstrate the vascular nature of the disorder, with dilated and thrombosed laminar propria capillaries with reactive fibromuscular hyperplasia. It has been suggested that watermelon stomach arises from traumatic gastric peristalsis in a similar fashion to that seen in other prolapse syndromes such as stoma sites, solitary rectal ulcer and haemorrhoids. Excellent long term results have been reported with the use of endoscopic therapy. Nd:Yag laser has been the most studied with an average of 3-4 sessions being required to ablate visible disease and terminate transfusion requirements in over 90% of cases in follow up of up to 6 years. Other treatments such as bipolar or heater probes and the argon plasma coagulator, have also been shown to be successful. However, Nd:Yag laser, which can be used to "paint" the stripes of the watermelon, may require fewer treatments due to its increased depth of injury. Surgical antrectomy has also been reported to be successful, but is rarely necessary since endoscopic therapy is highly effective. Pharmacological agents such as steroids and 5-hydroxytryptamine antagonists have been used in small numbers of patients in uncontrolled trials with perhaps some success. Recognition of this characteristic lesion is important since it is commonly dismissed by less experienced endoscopists as antral gastritis.

Cameron erosions

Erosive disease is an uncommon cause of severe upper GI bleeding; however, some lesions warrant mentioning as they are often overlooked or missed at endoscopy. Cameron erosions were described by Cameron and Higgins as chronic linear erosions positioned on the crests of folds at the diaphragmatic impression in one-third of 109 patients with a large hiatus hernia[12]. They suggested that the erosions were caused by the mechanical trauma of the folds rubbing together during diaphragmatic movement with breathing (Figure 5) and the erosions were more common in patients with anaemia, perhaps due to blood loss from these erosions.

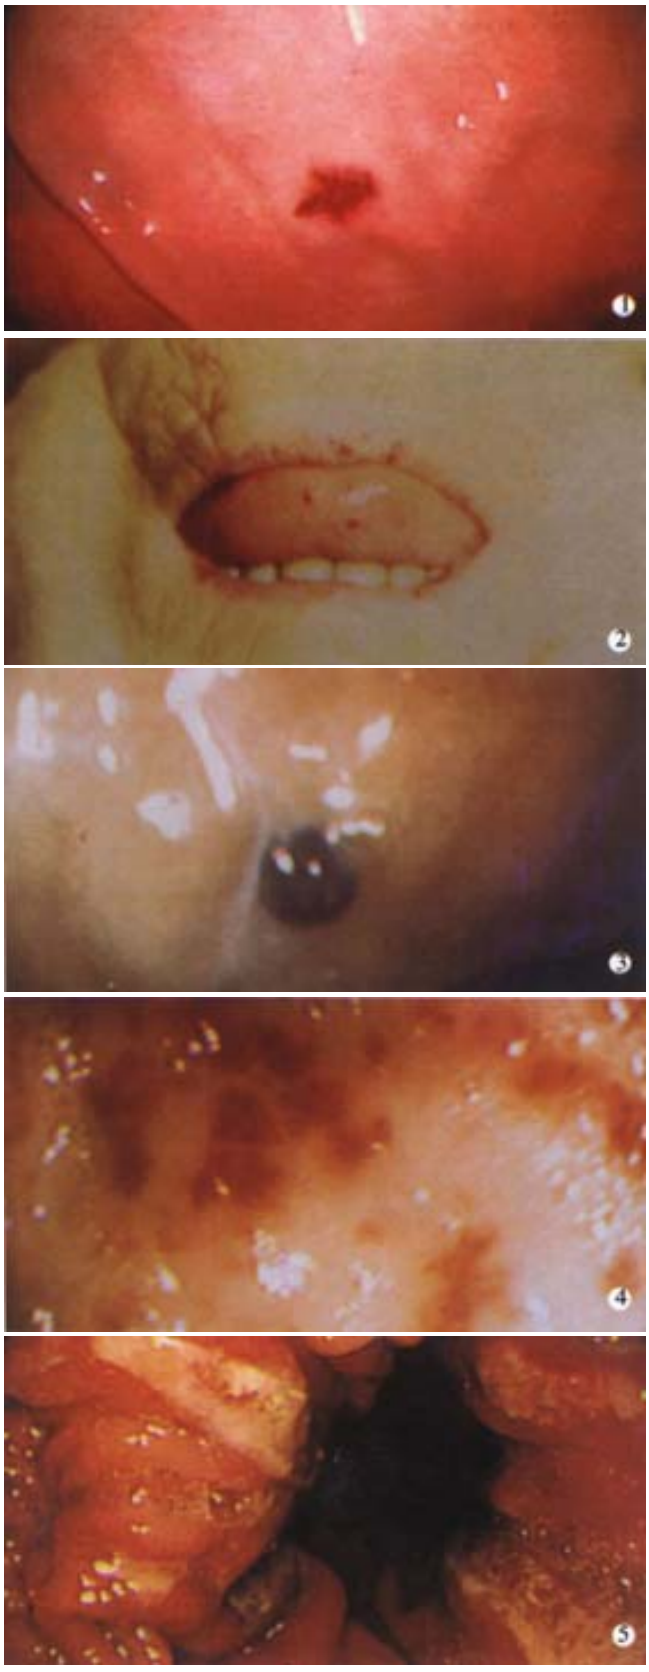

Figure 1 Cutaneous angiodysplasia in Osler-Weber-Rendu Syndrome.
Figure 2 Large gastric angiodyslasia.
Figure 3 Gastric Dieulafoy.
Figure 4 Watermelon stomach.
Figure 5 Cameron erosions.

Prolapse erosions

Prolapsing gastropathy is a syndrome characterized endoscopically by a focal area with subepithelial haemorrhage and, occasionally, erosions within a few centimeters of the cardioesophageal junction. This mucosal area may be seen to be the apex of a knuckle of gastric mucosa, most commonly coming from the 10 o'clock position which prolapses into the distal oesophagus during retching, often prior to haematemesis. Shepherd *et al* described the histological features at endoscopic biopsy of 21 cases of prolapsing gastropathy, describing inflammation in 85%, submucosal haemorrhage in 38% and superficial ulceration in 10%[13].

Unusual upper GI malignancies

Adenocarcinoma accounts for 90% of gastric tumours with lymphoma accounting for 5%, stromal tumours 2% and the rest including carcinoids, metastases and others. GI involvement occurs in 50% of non Hodgkin's lymphoma, with the stomach being the most common extranodal site. 95% of gastric lymphomas are non-Hodgkin's lymphoma. Lymphomas are often clinically silent early on, but progress to signs and symptoms of advanced gastric cancer including upper GI bleeding. Endoscopically lymphomas have a wide range of different appearances and may present as enlarged gastric folds, mucosal nodularities, multiple polypoid masses with or without ulceration, or with a diffuse infiltrative process (Figure 6). One unusual feature is that peristalsis is often preserved. Diagnosis can be difficult, sometimes requiring full thickness biopsy, but when combined with endoscopic ultrasound (EUS) diagnostic accuracy approaches 100%. Treatment is according to histology and includes helicobacter eradication for MALT lymphomas.

Stromal tumours such as leiomyomas tend to be indolent and slow growing, but can be aggressive. They most commonly present with GI blood loss, and are occasionally ulcerated but often appear entirely submucosal at endoscopy (Figure 7) and conventional biopsy usually fails to make the diagnosis. EUS and deep biopsy can assist in making the diagnosis. Surgical management should be considered for large gastric lesions of this type: small oesophageal stromal cell tumours seem to have a low incidence of malignant change. Carcinoid tumours only rarely cause GI bleeding. Like stromal cell tumours they are often submucosal requiring deep biopsies to make the diagnosis. Kaposi's sarcomas do not tend to bleed as much as their vascular appearance would suggest, but may bleed especially if the patient has a low platelet count. Multiple tumours metastasize to the stomach causing bleeding: these include secondary melanoma, and

cancer of the breast, lung, ovary, colon, liver and testes. Melanoma lesions can have a characteristic bullseye appearance or more rarely be amelanotic. Primary renal cancer on the right side can erode and bleed into the duodenum. A common problem with bleeding tumours is the diffuse, often friable area that needs to be treated. Endoscopic treatment of these lesions is often unrewarding, but includes the use of laser, argon plasma coagulator and injection of alcohol. Definitive treatment with resection is sometimes helpful in selected patients and some tumours are radiosensitive.

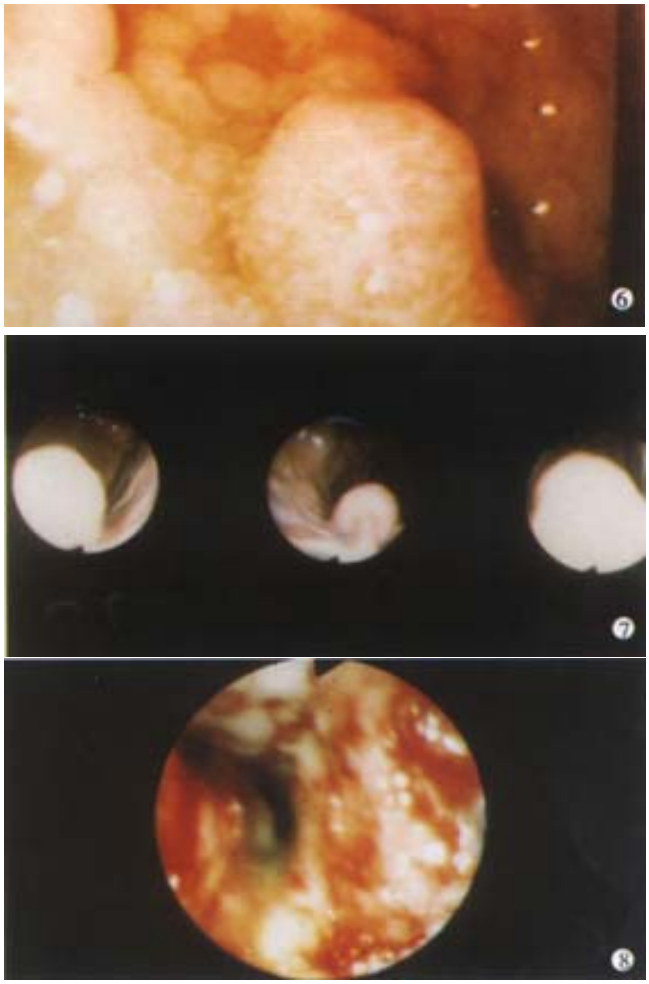

Figure 6 Nodular gastric lymphoma.
Figure 7 Gastric stromal tumour showing Schindler's sign: tenting and loss of gastric folds as mucosa is stretched over the submucosal tumour.
Figure 8 Intestinal amyloid.

Other vascular disorders

There are some other rare vascular lesions that can cause GI bleeding. The Blue Rubber Bleb Naevus Syndrome is an example of intestinal haemangioma which is an autosomal dominant condition causing GI bleeding in infants and children. These lesions are raised blue vascular lesions that can be multiple in the bowel associated with similar cutaneous lesions. The endoscopic lesions are usually redder in colour than the dark blue lesions seen on the skin. Endoscopic therapy has been successfully used, but care needs to be taken since the lesions can be transmural: some authors suggest that endoscopic therapy should be used only intraoperatively. Rarely, conditions involving the blood vessel itself can lead to bleeding. Connective tissue diseases such as pseudoxanthoma elasticum, vasculitis and infiltrating conditions such as amyloid all affect the integrity of the blood vessels resulting in bleeding (Figure 8).

Haemobilia

Bleeding from either the biliary tree (haemobilia) or from the pancreatic duct (Wirsungorrhagia) into the duodenum can be difficult to identify and may require the use of a side viewing endoscope to make the diagnosis. In earlier series, the most common cause of haemobilia was accidental trauma, accounting for 40%, with operative trauma, systemic infection, gallstone disease and aneurysms roughly contributing 15% each. Recent series indicate iatrogenic trauma accounting for 40% and accidental trauma 20%[14]. Classically, patients present with the triad of pain, jaundice and melaena, although only 40% of patients present in this way. A history of chronic pancreatitis or pseudocyst may be a pointer to a bleed from the pancreatic duct. Asymptomatic melaena and haematemesis with a normal endoscopic appearance are other recognized presentations. Endoscopically, blood is seen coming from the ampulla in less than 40% of patients and clot in the bile duct or pancreatic duct may be demonstrated during ERCP. It has been suggested that the endoscopic appearance at the ampulla of a filiform clot suggests biliary bleeding and of fresh bleeding a pancreatic origin. Angiographic or CT findings of an aneurysm, pseudoaneurysm or arterio portal venous fistula may be needed to make diagnosis. Management is often difficult. Some patients can be managed conservatively. However, if surgery is required 75% of patients can expect haemostasis. Embolization of aneurysms is occasionally effective.

Oesophageal apoplexy is a rare condition presenting with pain and haematemesis after swallowing and a large submucosal haematoma is seen, which can occlude the lumen and may be associated with a mucosal tear.

Conditions such as portal hypertensive gastropathy and aorto-enteric fistulae are only mentioned briefly here. A history of abdominal aortic graft surgery should prompt a careful

endoscopic examination of the second and third parts of the duodenum. If aorto-oesophageal fistula is suspected, usually in a patient with a massive bleed and a history of surgery, sepsis or trauma to the thoracic aorta, CT investigation should be undertaken prior to endoscopy in theatre since endoscopy can precipitate torrential bleeding.

Leahy A, Epstein O. Non-pharmacological treatments in the irritable bowel syndrome. ***World J Gastroenterol***, 2001;7(3):313-316

INTRODUCTION

The irritable bowel syndrome (IBS) is a gastrointestinal disorder characterised by chronic lower abdominal pain and disordered defaecation associated with bloating, tenesmus and extra intestinal symptoms including urinary frequency, dyspareunia, fibromyalgia and functional upper gastrointestinal symptoms. Currently there is no unifying hypothesis which adequately explains the pathogenesis of the disorder although a number of physiological and psychological abnormalities have been described. These include altered visceral sensitivity, abnormal intestinal motility and abnormalities of cortical processing of afferent stimuli from the gut. These observations are set against a background of abnormal psychological profiles and an over representation of negative early life experiences. Failure to identify the cause of IBS has led to the development of a range of therapies, some designed to influence the physical effects of the disorder and others to influence the psychological features of the syndrome.

Most IBS patients managed in primary care respond to dietary modification, conventional pharmacological interventions and reassurance. However, when considering any therapeutic efficacy in IBS, it is necessary to weigh the therapeutic effect against the placebo response rate which has been reported to range from 40%-70%.[1] Approximately 15% of IBS patients are resistant to medical therapy. Psychological treatments are usually reserved for these refractory patients and those who relapse despite an initial response to medical treatment. Tricyclic antidepressants have been widely used in IBS and are probably effective through anticholinergic and analgesic effects rather than antidepressant activity. Placebo-controlled trials of tricyclics indicate that even at low doses, they are helpful in the management of abdominal pain and diarrhoea in IBS[2].

Over the past two decades, there have been various attempts to treat IBS using non-pharmacological approaches. As evidence has accumulated to support a role for these interventions, both patients and gastroenterologists have shown increasing interest in exploring this approach to IBS treatment. In this review we consider the evidence for psychopathology in IBS and the efficacy of non-pharmacological interventions.

PSYCHOLOGICAL MORBIDITY IN IBS

From the very first reports of IBS in the medical literature, psychological factors have been recognised as an important component of the syndrome. In 1859, the cause for IBS was attributed to overeating, over-drinking and excess of "sexual or other emotional excitement, sedentary life, damp or hot atmosphere, and the abuse of purgatives, but above all aloes". A "highly excitable condition of nervous centres" was postulated as the cause of IBS, and in 1892, IBS patients were described as manifesting "hysterical, hyperchondriacal and neurasthenic personalities"[3].

With the development of scientific method in medical research, attempts have been made to provide both qualitative and quantitative measures of psychological morbidity in IBS. At least ten studies have assessed the prevalence of psychological disorders in IBS patients[4]. Between 42%-64% of IBS patients meet criteria for a psychiatric diagnosis compared to a median incidence of 19% in patients with organic gastrointestinal disease, and 16% in healthy controls. The most common diagnoses are a generalised anxiety disorder and depression. There is no unique psychological profile which characterises IBS. This higher prevalence of psychological dysfunction in IBS appears to relate only to those sufferers who seek medical advice. Indeed, the majority of individuals fulfilling the criteria for IBS never seek medical attention and these non-consulters have a similar psychological profile to asymptomatic controls[5-7]. This, in turn has provided evidence that psychological factors rather than severity of symptoms influences the decision to seek medical attention. Most IBS consulters have been shown to have experienced negative early life experiences and heightened anxiety about health status. These observations suggest that management in primary and secondary

care should focus not only on symptoms, but also on those psychological factors which have caused the patient to seek medical advice.

There is strong evidence that stress is an important factor in the pathogenesis of IBS[8]. Stress of major "life events", rather than the stress of everyday living, has been implicated as a trigger factor in many patients. In addition, patients often recognise that periods of excessive stress exacerbate their symptoms. In patients with IBS there is good evidence that stressful life events are more frequent, and the effects on GI function more profound, than controls[9,10]. It is against this background of anxiety, depression, stress and consulting behaviour patterns that psychodynamic strategies have been developed to manage IBS.

PSYCHOTHERAPY IN IBS

Psychotherapy is a treatment that primarily seeks to relieve symptoms by exploring the patient's underlying psychological conflicts and emotional disturbances. The first reported study of psychotherapy in IBS included 101 patients who were randomized to medical therapy with or without psychotherapy[11]. The psychotherapy was delivered over ten sessions and focused on mechanisms for coping with stress and resolving emotional problems. Psychotherapy was found to produce a greater improvement in abdominal pain and bowel dysfunction than medical therapy alone. Although symptoms were positively influenced, this short term therapy did not significantly influence the underlying psychopathology. The authors suggested that this might be explained by the relatively mild psychological morbidity in their patients, as the presence of a serious psychological disorder was an exclusion criteria for the study. This study, although of interest, and often quoted, has methodological flaws including the decision to exclude patients with more severe psychological disturbance in whom this therapy might have been of greater value. In addition, the study did not include a placebo arm or select placebo non-responders. The study left it unclear whether the improvement of physical symptom was a result of the psychotherapy or the considerable attention invested in the psychotherapy group.

These pitfalls were addressed by a later study of psychotherapy in IBS performed by Guthrie *et al*[12]. One hundred and two patients refractory to previous medical treatment were randomized to receive psychotherapy or supportive listening. The psychotherapy concentrated on developing a healthy patient-therapist relationship, recognizing other inter-personal relationships and their possible role in the patient's presenting problems. Psychotherapy was found to be superior to supportive listening in terms of improving both physical and psychological symptoms and the improvement in gastrointestinal function correlated significantly with improved psychological well-being. Excellent study design and attention to detail has made this study a benchmark for both pharmacological and non-pharmacological studies in IBS.

BEHAVIORAL THERAPY IN IBS

Behavioral treatment seeks to address and deal with current issues, anxieties and behavioral patterns rather than indulging in deep analysis of past experiences. An uncontrolled trial of behavioral therapy has been reported with a 4 year follow up[13]. In this study the authors used a combination of progressive muscle relaxation, thermal biofeedback, cognitive therapy and IBS education. All but two of the nineteen patients who were available for long-term follow-up rated themselves as at least 50% improved. Symptom diaries were used to demonstrate that the therapy resulted in significant reductions in abdominal pain, diarrhoea, nausea and flatulence. However, like many studies in IBS, the study was inadequately controlled. A more carefully controlled trial of behavioral therapy has been reported in IBS[14]. Forty-two patients were randomly allocated to receive either conventional medical treatment or behavioural therapy with a nurse therapist. The therapy concentrated on behaviour modification, bowel retraining and pain management techniques. It was noted that there were improvements in a number of physical and psychological symptoms, but no significant differences was found when the treatment group was compared with controls. The authors concluded that their approach to behaviour modification was no more effective than conventional medical therapy and reassurance.

HYPNOTHERAPY IN IBS

Hypnotherapy is a state of unusual concentration on the suggestions of the therapist and a willingness to follow their instructions[15] Whorwell *et al* have reported well constructed controlled trials of hypnotherapy in IBS. The technique is focused around a specific "gut directed" hypnosis protocol where the patient is taught to assert control over gut function and imagery whilst in an hypnotic state[16]. Patients are given a simple account of intestinal smooth muscle physiology and hypnotised in a standard manner. The patient is then requested to place their hand on the abdomen and to sense both a positive feeling of abdominal warmth and increased control over gut function. During hypnosis, visualisation is also employed, using the analogy of a gently flowing river and a gently flowing bowel to reinforce a positive bowel image.

Whorwell's initial study randomised thirty refractory IBS patients to seven sessions of either hypnotherapy or psychotherapy. When compared to psychotherapy, hypnotherapy was found to have a greater impact on abdominal pain, bowel habit, abdominal distension and general well-being. It

should be noted, however, that the response rate in the psychotherapy group was much lower than those reported from other centres[11,12]. Further experience of gut directed hypnotherapy has been reported in 250 IBS patients indicating an overall response rate of approximately 80%. Factors predicting a less satisfactory response to hypnosis includes atypical symptoms, older age and more profound psychological disturbance[17].

Two other independent groups have obtained similar results using gut directed hypnotherapy[18,19]. Both these studies were uncontrolled but do appear to support the value of hypnotherapy in IBS. In addition, it has been reported that hypnotherapy in groups of up to eight patients is as effective as individual therapy[18]. Further support for the effectiveness of hypnotherapy in IBS derives from studies on the effect of hypnotherapy on gut function. In two separate studies, hypnotherapy has been reported to reduce rectal sensitivity and colonic motility[20,21].

RELAXATION THERAPY IN IBS

Recognition that stress is a major factor in IBS has provided a basis to explore stress management as a therapy in these patients. Stress management has been compared to conventional therapy in a trial of 35 patients[22]. A physiotherapist delivered a median of six sessions aimed at recognizing the relationship between symptoms and stress, and teaching relaxation exercises. IBS symptoms were relieved in two thirds of patients receiving stress therapy, and only a small number of patients receiving conventional therapy. A small pilot study also found that teaching progressive muscle relaxation was effective in improving gastrointestinal symptoms[23]. Whilst these studies are encouraging, larger controlled studies are required to make a firmer statement on the potential of relaxation therapy in IBS.

BIOFEEDBACK THERAPY IN IBS

Biofeedback is a behavioural technique that uses visual or auditory cues to teach patients to alter physiological responses. With biofeedback, physiological events which are not normally appreciated by the patient are sensed by a technological interface and amplified to give the subject visual or auditory feedback. Patients soon learn to influence the loop and manipulate these physiological events thereby modifying organ function. A new form of biofeedback therapy has been developed and tested in IBS patients[24]. The biofeedback loop is based on the polygraph ("lie detector") which monitors tiny changes in electodermal conductivity occurring in response to stress and relaxation. Changes in cutaneous electrical activity are electronically transformed into a computerised animation of the gut shown on the computer screen. This animation can be controlled by the patient who learns to manipulate the computerised representation of bowel movement using a combination of mental and physical relaxation. In a study of computer aided gut directed biofeeback, 40 IBS patients who were refractory to conventional treatment underwent 4 half hour biofeedback sessions. Eighty percent of the patients learned to achieve progressively deeper levels of relaxation, and in 50%, the technique was reported helpful in controlling bowel symptoms on almost every occasion they became troublesome. The relaxation technique also resulted in significant reductions in global and bowel symptom scores. A control group was not included as it is not possible to administer placebo biofeedback but the study was restricted to treatment refractory patients (ie presumed placebo non responders). An independent group has also recently reported that biofeedback approach is beneficial in managing IBS[25]. In this uncontrolled study, all comers were entered and there was no attempt to select patients. Sixty patients received biofeedback with improvements in abdominal pain, urgency of defaecation and global well-being.

COMPLEMENTARY THERAPY IN IBS

A small open pilot study of acupuncture produced a significant improvement in general well-being and abdominal bloating[26]. There has not been any large controlled trial assessing any form of complementary treatment in IBS.

SUMMARY

Over the last two decades evidence has mounted to suggest that non-pharmacological therapies may be helpful in IBS. Like IBS trials of pharmacological therapies, the studies are often small and poorly controlled. The trials designed to account for a high placebo response rate have either compared non-pharmacological strategies with conventional treatment, or selected only patients who were placebo non-responders. There is broad agreement from the few adequately controlled trials that psychotherapy offers a clear additional therapeutic benefit over and above medical treatments[12]. Hypnotherapy appears to be particularly potent, and, in expert hands, produces consistently impressive therapeutic results even in patients refractory to conventional IBS treatment[17].

Most IBS patients respond to standard medical treatments. Psychological strategies are time consuming, labour intensive and generally unavailable to the relatively large numbers of patients who might benefit. Consequently, these therapies are best reserved for selected patients who fail to respond to reassurance and education, dietary manipulation, antispasmodics and low dose amitriptyline. Increasingly, patients are expressing a preference for non-pharmacological treatment

strategies. Where resources allow, it is not unreasonable to offer these patients a psychodynamic approach as first-line therapy. Ideally, the gastroenterologist should have access to a range of treatment strategies including diet, drugs, psychotherapy, hypnotherapy, relaxation therapy and biofeedback. New approaches such as gut directed, computer-aided biofeedback are particularly attractive as, unlike the interpersonal therapies, this mode of biofeedback does not require highly trained therapists and can be self-administered[24]. Whatever the choice of non-pharmacological therapy, there is evidence that both the doctor and patient can expect symptom improvement, especially when conventional medical measures have failed.

Subject headings lasers/therapy use; lasers/diagnosis use; gastroenterology

Lovat LB, Bown SG. Lasers in gastroenterology. ***World J Gastroenterol***, 2001;7(3):317-323

INTRODUCTION

Endoscopy has revolutionised our management of many gastrointestinal disorders over the past 30 years. We are increasingly able to diagnose gastrointestinal (GI) tumors at an early stage, and endoscopic therapy has made a difference to the outcome of GI haemorrhage. We still rely on surgery for cure of cancer but as diagnostic techniques improve the goal of minimally invasive diagnosis and therapy appears ever more attainable. As populations get older, it is also increasingly desirable. Laser light can be used for both diagnosis and therapy in the gut. This article reviews the value of lasers in these areas.

HOW LASERS WORK

Biological effects

Lasers are sophisticated sources of monochromatic light in the visible and near infrared part of the optical spectrum. The ones of most interest to gastroenterologists are those where the beam penetrates living tissue well and which can be transmitted via thin, flexible fibers, so they can be used with flexible endoscopes. These can be used to deliver light as heat to cause thermal contraction of soft tissue. The most important laser in this group has been the Neodymium yttrium aluminium garnet (NdYAG) laser with a near infrared beam at 1064nm. Short, sharp shots from this laser cause thermal contraction in soft tissues, which provides good haemostasis. Longer shots at high power can vaporise tissue and coagulate the underlying layers, which is effective for debulking advanced cancers. At much lower powers, it is possible to coagulate a larger volume of tissue without vaporisation.

The other main group of effects is *photodynamic* where there is no increase in tissue temperature, but laser light is used to activate a previously administered photosensitising drug. This causes the release of highly reactive singlet oxygen which causes cell death by necrosis and apoptosis over a prolonged period. This can be used to completely eradicate small tumours.

A minor application is to use pulsed lasers endoscopically to fragment gall stones. These effects are summarised in Table 1.

Table 1 Laser effects used in gastroenterology

Laser effect	Clinical use
High power thermal:	Haemostasis Cutting or debulking of tissue by vaporisation and coagulation
Low power thermal: (Interstitial laser photocoagulation,ILP)	Gentle coagulation of lesions within solid organs
Photochemical: (Photodynamic therapy, PDT)	Non-thermal destruction of tissue by activation of a previously administered photosensitising drug
Pulsed shock wave	Fragmentation of gall stones

Non-biological effects

All living tissue display a number of interactions with light, which are altered in areas of dysplasia. Intrinsic fluorescence may be detected at endoscopy by exciting the tissue with blue laser light and using special detector cameras on the endoscope. Elastic scattering depends on the different way light is scattered depending on the density of cellular and nuclear packing. These approaches may allow us to detect premalignant lesions of the GI tract that would otherwise beinvisible at conventional endoscopy.

THERAPEUTIC USES FOR LASER

Palliation of advanced cancers

The main role of high power, thermal lasers like the NdYAG in current practice is for palliation of advanced, inoperable cancers of the upper and lower gastrointestinal tract. Under direct vision, nodules of exophytic tumour can be vaporised and underlying tumour coagulated either to relieve obstruction or to reduce blood loss (Figure 1). The incidence of complications is low, although it often takes several treatments to achieve optimum recanalisation. These laser beams are dangerous if viewed directly, so safety filters must be fitted to fibreoptic scopes. There is no risk to operators with video scopes, although filters are required to protect the chips in the camera.

Most patients with cancers of the oesophagus or gastric cardia present when the disease is too

advanced for there to be any prospect of cure and the main aim of treatment is to relieve dysphagia as simply and rapidly as possible[1]. The main endoscopic options are stent insertion and laser therapy. Tumor dilatation and insertion of a silicone rubber stent was standard practice in Europe until 5 years ago, although these stents were never popular in North America. Using this approach most patients were unable to eat any more than pureed food. Since their introduction in the early 1990s, expanding metal stents have become popular as they require less dilatation (hence less risk of perforation) and are easier to insert. It is becoming clear with experience that they are far from ideal, particularly as the relief of dysphagia has never been shown to be better than silicone stents. New designs are appearing at regular intervals and the current generation of metal stent are covered to prevent tumour ingrowth and conical in shape to prevent stent slippage. Nevertheless, intractable pain occurs in 10% of patients after stent insertion and up to 40% will need further endoscopic interventions[2,3].

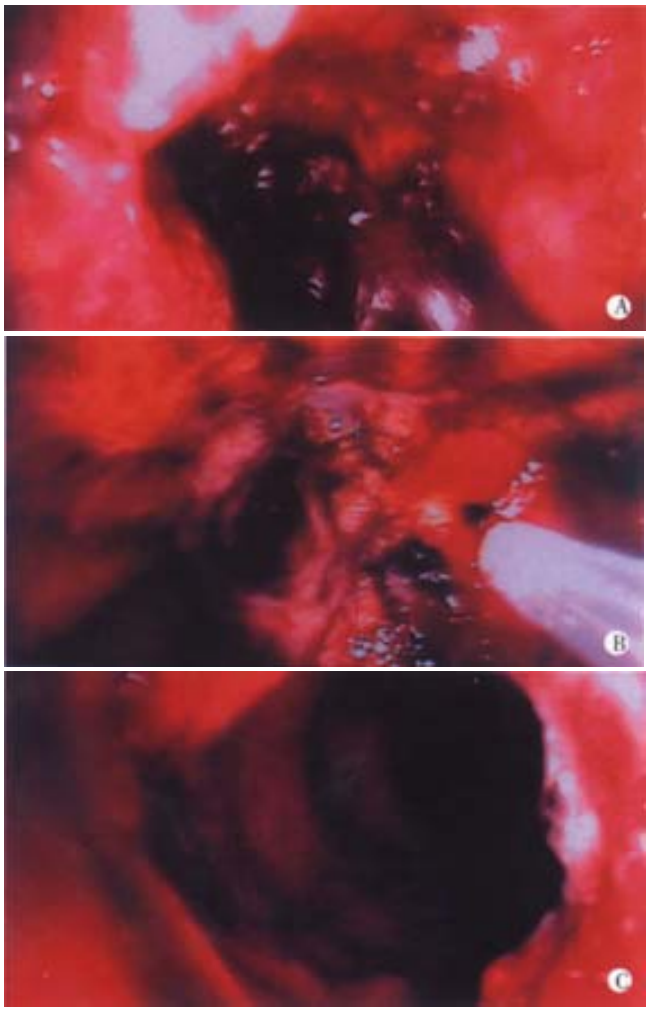

Figure 1 Advanced, obstructing carcinoma of the oesophagus: (a) at presentation; (b) during laser therapy; (c) after two endoscopic laser treatments. The oesophageal lumen has been re opened and the patient's dysphagia has been relieved.

Laser therapy has been shown to improve dysphagia to a similar degree as stents, and does not cause pain. The disadvantage is that laser therapy alone has to be repeated on average every 5-6 weeks. The addition of a palliative dose of external beam radiotherapy can increase this to 9 weeks and a single fraction of brachytherapy (intraluminal radiotherapy) will bring relief of dysphagia for a median of 5 months. Since the median survival time for advanced disease is less than this, a single course of laser and brachytherapy is an attractive option. The relative merits of lasers and stents are summarised in Table 2. Common sense dictates that the two are complimentary rather than competitive. An eccentric, exophytic tumour is best debulked with the laser whereas a circumferential tumour with little exophytic component is best stented. A fistula must be stented, whereas high cervical tumours can seldom be stented. What little data there is on comparative costs suggests that the lifetime treatment costs are similar for each of these approaches[4].

Table 2 Comparison of modalities for palliation of malignant dysphagia

	Laser	Conventional stent	Self expanding metal stent
Technique	Basically safe (risk of perforation if dilatation also needed)	10% risk of perforation on insertion	Usually safe & easy to insert
Cost	High setup cost Low patient costs	Low cost	High cost
Contra indications	Fistula No endoscopic target	High lesion Tracheal compression	High lesion Tracheal compression Care with lesions crossing cardia
Dysphagia post therapy Repeat Therapy	Variable, can be close to normal Possible. Usually required after 6-8 weeks	Semi-solids some solids Stent can be adjusted	Variable, can be close to normal Difficult to adjust once inserted. Second stent or laser debulking for tumour overgrowth
Enhancement of dysphagia relief with radiotherapy	Yes	No	No

A future direction may be the combination of laser palliation of dysphagia with radical chemoradiotherapy in inoperable patients. This approach is attractive as many patients with advanced disease present with severe malnutrition caused by their dysphagia. Radical treatment is not possible in a cachectic patient, but if dysphagia is overcome, patients regain weight and are able to tolerate intensive therapy. Long term data are lacking but early results suggest that this approach can lead to prolonged survival in at least some patients who have previously been thought to be terminally ill.

The situation with the small percentage of

rectal and recto-sigmoid cancers that are not suitable for surgery is very similar[5]. Endoscopic laser therapy can simply and effectively relieve symptoms due to exophytic tumour, usually as a day case procedure with minimal sedation. Bleeding, obstruction, mucus discharge and tenesmus can be helped, and the effect can be prolonged by the addition of palliative, external beam radiotherapy, although laser treatment cannot help pelvic pain or obstruction due to extraluminal tumour. Expanding metal stents are now available to relieve some distal colonic strictures, but they are unlikely to find an important role in palliating low rectal cancers.

Haemostasis for benign lesions

Lasers were first used with flexible endoscopes in the mid 1970s for the control of haemorrhage. Endoscopic treatment with the NdYAG laser significantly reduced the rebleeding rate after haemorrhage from peptic ulcers in a number of studies. Later trials showed that injection sclerotherapy worked just as well, and was simpler and cheaper. The only benign lesions for which endoscopic laser therapy retains an important role for control of blood loss are vascular lesions like hereditary telangiectasia, angiodysplasia and watermelon stomach. These can be managed by sclerotherapy and various thermocoagulatory modalities such as argon plasma coagulation, but laser treatment is effective, simpler to apply and needs less treatment sessions, especially when multiple lesions are present.

Interstitial laser photocoagulation

High power NdYAG laser is used during endoscopy, with short shots of a second or two, typically at 50-80W. The laser fibre is held away from the surface of the target to vaporize and coagulate tumour tissue under direct vision. An alternative approach is to insert the tip of the laser fibre directly into the target area and to use a much lower power (3-5W) to gently "cook" diseased tissue over a period of several minutes. This is known as interstitial laser photocoagulation (ILP). There is no selectivity of effect. Both normal and malignant tissue will be necrosed if heated to a high enough temperature for long enough. ILP can be used for the percutaneous treatment of small hepatic metastases (particularly from previously resected, primary colorectal cancers) in patients who are unsuitable or unfit for partial hepatectomy[6]. The key to using this technique succesfully is the imaging. Fibers can be inserted through needles positioned percutaneously under ultrasound, CT (computerised tomography) or MR (magnetic resonance) imaging. The best way to assess the effect is on contrast enhanced CT scans taken 24 hours after treatment, which show laser necrosed areas as new zones of non-enhancement. The size of the zone of necrosis depends on the number of laser fibres used, but it is possible to necrose lesions up to about 4 cm-5 cm in diameter. Treated areas heal mainly with regeneration of normal liver. ILP is only appropriate for hepatic metastases in patients with a small number of clearly identifiable lesions and no evidence of extrahepatic disease, but for these individuals, it may slow down the progression of their disease, and is likely to be complimentary to chemotherapy. Radiofrequency heating can achieve a similar thermal effect without the need for lasers.

Photodynamic therapy

Photodynamic therapy (PDT) is a technique for producing localised necrosis of tissue with light after prior administration of a photosensitising agent[7]. Drugs that are activated by red light are usually chosen as red light penetrates deeply into tissue, but mucosal disease (e.g. dysplasia in Barrett's oesophagus or squamous oesophagus) might be conveniently treated with green light, which penetrates only 1 mm-2 mm. On their own, neither the light nor the photosensitising drug produces any effect. The biological effect is photochemical with no increase in tissue temperature, so is quite different from the thermal techniques discussed above. ILP and PDT are compared in Table 3. In particular, PDT produces remarkably little effect on connective tissue like collagen, so it is possible to get full thickness necrosis in the wall of the gastrointestinal tract with minimal risk of perforation[8]. The effects produced vary with the photosensitiser used and may prove of value in a surprisingly wide range of conditions. Potential applications are summarised in Table 4.

Table 3 Comparison of interstitial laser photocaogulation (ILP) and photodynamic therapy (PDT)

	ILP	PDT
Nature of biological effect	Thermal	Photochemical
Wavelength of light used	Infrared (805-1064nm)	Green (510-530nm) Red (630-675nm)
Typical laser power per fibre	3-5 W	0.1-0.3 W (higher for illuminating hollow organs)
Effect on connective tissue	Destroyed	Largely unaffected
Healing	Resorption & scarring, some regeneration	Regeneration, sometimes with scarring
Selectivity of necrosis between tissue of origin of tumour and other adjacent tissues	None	Possible between mucosa and underlying muscle in hollow organs
Selectivity of necrosis between tumour and tissue of origin of tumour	None	Minimal
Cumulative toxicity	None	None

Table 4 Potential targets for photodynamic therapy in gastroenterology

Small, inoperable tumours in endoscopically accessible sites
Areas of dysplasia, especially in Barrett's oesophagus
Localised pancreatic cancer
Bile duct cancer
As an adjunct to surgery
Palliation of advanced cancers controversial
Eradication of *Helicobacter pylori* speculative

Tumors of the gastrointestinal tract

PDT is an attractive option for treating small tumours of the gastrointestinal tract in patients who are unsuitable for surgery. In a series of 123 patients with early oesophageal cancers treated with PDT using the photosensitiser porfimer sodium (Photofrin), a complete response (no evidence of tumour on endoscopy or biopsy) was seen in 87% at 6 months[9]. The disease specific survival was 75% although the overall 5 year survival was only 25%, This means that in the majority of the patients, the cancer was not the main cause of death. These patients were inoperable due to comorbidity and this minimally invasive therapy was well tolerated. Care must be taken not to treat too extensive a lesion as circumferential scarring in the muscle layer can cause a stricture. Strictures occured in 35% of the patients in this series, although they did all respond to dilatation. PDT can be applied at any endoscopically accessible site in the upper or lower gastrointestinal tract, but it cannot treat any lesion that has spread beyond the site of origin as, for example, to local lymph nodes.

Although the light for PDT is applied locally, the drug is given systemically, which means that the whole body is photosensitised, including the skin. This can be a problem, as there is a risk of skin damage due to drug activation by ambient light. With the photosensitiser porfimer sodium, patients must avoid bright sunlight for up to 3 months, although with the sensitiser mTHPC (meso-tetrahydroxyphenyl chlorin) it is 2-3 weeks and with ALA (5-amino laevulinic acid), it is only 1-2 days.

PDT has been proposed for the palliation of advanced malignant dysphagia. This was the first application for which PDT was licensed in the USA (using porfimer sodium). PDT does provide some relief in this situation, but there are very few cases that can be helped by PDT if NdYAG laser therapy or stent insertion fail, and it is certainly not desirable to make patients photosensitive for much of their remaining life[10]. PDT may be of value to treat tumour that has grown over or through a stent that cannot be adjusted and which cannot tolerate the heat from a NdYAG laser. In general terms, it seems more logical to licence PDT for treating early oesophageal cancers, as has been done by the Japanese authorities, although the UK seems more likely to follow the American pattern, at least initially.

Premalignant lesions of the gastrointestinal tract

ALA is a naturally occurring substance which is converted *in vivo* through a series of derivatives to haem via protoporphyrin IX (PPIX). PPIX is a photosensitiser, and after exogenous administration of ALA, enough PPIX accumulates to produce a PDT effect on activation with red or green light[7] (Figure 2). However, in contrast to porfimer sodium and mTHPC, PPIX accumulates primarily in the mucosa of hollow organs. This makes it possible to destroy mucosa (normal or abnormal) without damaging the underlying muscle layer. This is exactly what is required in the treatment of Barrett's oesophagus with dysplasia. In a recent report, using ALA PDT, high grade dysplasia was cleared in 10 of 10 and carcinoma in situ was cleared in 17 out of 22 patients with Barrett's oesophagus[11] and in a randomised placebo controlled trial, this modality had a significant impact on patient outcome[12]. There were no oesophageal strictures, in contrast to 35% of 100 patients with high grade dysplasia or intramucosal carcinoma arising in Barrett's oesophagus who were treated with PDT using porfimer sodium[13]. However, ALA PDT brings its own problems, as the depth of necrosis does not exceed 2 mm and this is not always sufficient. It is reassuring that the necrosed, neoplastic Barrett's mucosa healed with regeneration of normal squamous mucosa, but follow up biopsies showed that in some cases, there was still untreated columnar mucosa under the new squamous mucosa.

Figure 2 Photodynamic therapy for dysplasia in Barrett's oesophagus: (a) prior to therapy, columnar lined mucosa is seen at endoscopy. Dysplasia is not visible, but has been confirmed histologically; (b) one day after treatment, there is widespread sloughing of the oesophageal mucosa; (c) one month later, the oesophagus has completely healed with some regeneration of squamous mucosa.

Endoscopic management of Barrett's oesophagus is still a difficult problem. Thermal ablation with an argon plasma coagulation or KTP or NdYAG laser involves moving a small therapeutic beam across the area to be treated under direct endoscopic vision. It is easy to undertreat, and leave abnormal mucosa, or overtreat, with the risk of muscle scarring or even perforation. With PDT, balloon light delivery systems are available which illuminate all the relevant mucosa evenly, and there is very little risk of perforation, but using porfimer sodium, there is a high risk of a stricture as there is no selectivity of effect between the mucosa and underlying layers. PDT with ALA is the only technique at present that seems able to produce a selective effect, necrosing mucosa but not the underlying muscle, but to date, the results are no better than using other ablative techniques. More research is needed to find reliable ways of ensuring that the full thickness of the abnormal mucosa is ablated. In the present situation, surgery is still the treatment of choice for patients with high grade dysplasia or early carcinoma in Barrett's oesophagus. PDT should be reserved for those who are unfit for surgery. Endoscopic treatment of Barrett's oesophagus without evidence of dysplasia should be limited to the context of clinical trials. Since dysplasia and even cancer has been reported to occur in areas treated by PDT which have reverted to 'normal' squamous epithelium after treatment, long term surveillance endoscopy is still needed in patients treated this way.

TUMOURS OF THE PANCREAS AND BILE DUCT

Pancreatic cancer

Most of the applications of PDT in gastroenterology have been for lesions of the luminal gut. Interest is now growing in using this modality to treat localised tumours of the pancreas and bile ducts. Animal studies have shown that the pancreas and adjacent normal tissues can tolerate PDT and that necrosis can be produced in cancers transplanted into the hamster pancreas. These results justified a pilot clinical study[14]. The technique is shown in Figure 3. Sixteen patients with small, localised, pancreatic cancers, not involving major blood vessels, were sensitised intravenously with mTHPC. Three days later, up to 4 needles were inserted into the tumour percutaneously under computerised tomography (CT) guidance and laser fibres passed through the needles to activate the drug in the tumour. Contrast enhanced CT scans a few days later showed new areas of devascularisation in the pancreas consistent with PDT induced necrosis (Figure 4). There were no serious complications, and most patients were out of hospital within a week. The median survival from diagnosis was 12.5 months with the longest surviving subject living for 34 months. These preliminary data are encouraging but randomised trials are needed to establish just how successful this aproach will be. At present, it is far too early to judge what role PDT may develop in the management of this unpleasant cancer.

Cholangiocarcinoma

The median survival in patients with unresectable hilar cholangiocarcinoma is 4-6 months due to refractory cholestasis or sepsis. PDT may have a role in the treatment of bile duct cancers, particularly for relief of obstructive jaundice when biliary stents are ineffective or become occluded. Two small uncontrolled studies have shown prolongation of survival in this group of patients to more than one year and interstingly, areas of tumour not directly illuminated have also undergone regression, presumably due to conduction of light through the biliary tree[15,16]. Larger, controlled studies are needed in this area.

Figure 3 Photodynamic therapy for treatment of a small pancreatic cancer. Three days after photosensitisation with mTHPC, light is delivered to the tumour via fibres passed through needles positioned percutaneously under CT guidance. (Reproduced with permission from Bown SG, Br Med J, 1998;316:754-757)

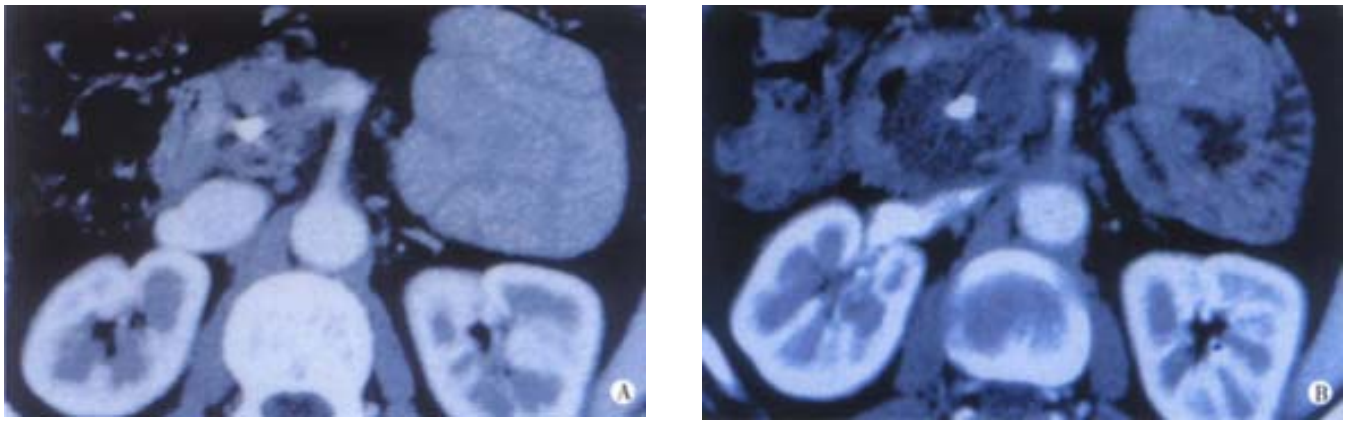

Figure 4 CT scans (a) before and (b) one week after PDT for pancreatic cancer. The tumour surrounding the biliary stent seen in the first scan has been replaced by a low density area of necrosis.

FUTURE APPLICATIONS OF PDT

A logical application of PDT is as an adjunct to surgery, to destroy small tumour deposits that are not visible to the naked eye or which involve areas that can not be resected. One randomised trial has been reported looking at PDT as an adjunct to resection of rectal cancers, but there was no difference between the two groups in the incidence of local recurrence[17].

A more speculative application of PDT is for the treatment of *Helicobacter pylori*. With the increasing incidence of antibiotic resistance, it would be attractive to have an alternative therapy and all sites colonised by *H. pylori* are easily accessible endoscopically for light delivery. The organism is certainly sensitive to PDT in culture, using methylene blue as the photosensitiser, and preliminary *ex vivo* experiments have also given encouraging results[18], but it would take considerable technical ingenuity to get adequate drug and light to all relevant sites to make this worth trying clinically.

TISSUE SPECTROSCOPY

Tissue spectroscopy is a way of interrogating tissue to obtain a characteristic 'tissue signature' that reveals its underlying histology. A number of spectroscopic techniques exist but all exploit the interaction between specific properties of light and the tissues under interrogation.

FLUORESCENCE ENDOSCOPY

All tissues exhibit a natural fluorescence. In luminal organs, dysplastic mucosa has a different fluorescence spectrum to normal tissue and this can be detected using specially modified endoscopes to emit blue light (either laser or a broader band source) and very sensitive cameras that detect green or red light. The technique is already proving useful for detecting early lesions in the bronchial tree. The accuracy of this technique is also under investigation for dysplasia in Barrett's oesophagus or in chronic ulcerative colitis but in both cases, the findings are confounded by the weak signals generated and the small differences between the fluorescence signal of normal, inflamed and dysplastic tissues. Studies are also underway to enhance the differences between normal and dysplasia by giving a drug exogenously that is selectively concentrated in the areas of dysplasia but this does not as yet appear to be beneficial. Although the idea is promising, real clinical application still seems a long way away.

ELASTIC SCATTERING: 'OPTICAL BIOPSY'

This technique exploits the difference in scattering of light of various wavelengths by different sized particles- the same principle that explains why the sky is blue and sunsets are red. It uses white light passed down a probe placed through the biopsy channel of an endoscope. This is a point measurement, like a biopsy but has the advantage of almost instantaneous diagnosis. Again, this is in early stages of development, but it is cheap, does not require complex equipment and initial reports suggest a high degree of accuracy[19,20].

CONCLUSIONS

Thermal laser is an established tool for endoscopic palliation of advanced gastrointestinal tract cancers. Interstitial laser photocoagulation may help in the management of patients with a small number of isolated hepatic metastases. However, the most important new applications of lasers being developed in gastroenterology are in photodynamic therapy, particularly for the endoscopic treatment of dysplasia in Barrett's oesophagus; for the treatment of small inoperable tumours in the gastrointestinal tract and in the pancreatobiliary

system. Finally, light based 'optical' methods are under investigation for instantaneous diagnosis in the gut and these may enable more accurate and faster diagnosis than have been available hitherto. The latter techniques are only at an early stage of clinical trials, but if these studies are successful, PDT and optical diagnosis could find an important role in gastroenterology practice.

Abstract

AIM To determine whether normal genetically immunocompetent rodent hosts could be manipulated to accept human hepatocyte transplants with long term survival without immunosuppression.

METHODS Tolerance towards human hepatocytes was established by injection of primary human hepatocytes or Huh7 human hepatoma cells into the peritoneal cavities of fetal rats. Corresponding cells were subsequently transplanted into newborn rats via intrasplenic injection within 24h after birth.

RESULTS Mixed lymphocyte assays showed that spleen cells from non-tolerized rats were stimulated to proliferate when exposed to human hepatocytes, while cells from tolerized rats were not. Injections made between 15d and 17d of gestation produced optimal tolerizaton. Transplanted human hepatocytes in rat livers were visualized by immunohistochemical staining of human albumin. By dot blotting of genomic DNA in livers of tolerized rats 16 weeks after hepatocyte transplantation, it was found that approximately 2.5×10^5 human hepatocytes survived per rat liver. Human albumin mRNA was detected in rat livers by RT-PCR for 15wk, and human albumin protein was also detectable in rat serum.

CONCLUSION Tolerization of an immunocompetent rat can permit transplantation, and survival of functional human hepatocytes.

INTRODUCTION

Transplantation of allogeneic hepatocytes into immunocompetent rodents has been shown to result in rejection of donor cells by host immune system, with T cell activation, and a delayed type hypersensitivity reaction[1-3]. This can been overcome by generalized immunosuppression or through the use of genetically immunodeficient animals[4-8]. Another strategy to avoid rejection is by inducing immunological tolerance specifically to the transplanted cells. In this regard, it has been demonstrated that the ability of the immune system to distinguish between endogenous and exogenous antigens develops shortly before birth. Studies have shown that if foreign antigens are introduced during this formative period, when the animals mature, they will be tolerant to those antigens[9], permitting the survival of allogeneic (cardiac) transplants in rats[10,11]. We hypothesized that, if human liver cell antigens could be introduced into normal rodents at the appropriate time during fetal development, those animals could be rendered tolerant and serve as suitable hosts for human hepatocyte transplants after birth without either genetic or pharmacological generalized immunosuppression. If successful, these animals could serve as convenient animal models for studying mechanisms of human hepatitis viral infections, serve as models for testing new antiviral agents, and as means for testing hepatotoxicity of drugs.

MATERIALS AND METHODS

Animals

Pregnant Sprague Dawley rats, 250 g to 300 g of body mass (Charles River Co., Inc., Wilmington, MA) were maintained on 12 h lightdark cycles, and fed *ad lib* with standard rat chow in the Center for Laboratory Animal Care at the University of Connecticut Health Center. All animal procedures were approved by Institutional Animal Care and Use Committee and conformed to USDA and NIH animal usage guidelines.

Cells

Cryopreserved human primary hepatocytes were obtained from Clonetics Corp. (Walkersville, MD) and kept in liquid nitrogen until use. Frozen cells were thawed, washed with human hepatocyte medium (Clonetics Corp.) plus 5 $g\cdot L^{-1}$ insulin and 0.39 $mg\cdot L^{-1}$ dexamethasone, and then spun at 50 × g for 10 min at 4℃. Cell viability was measured by trypan blue exclusion staining (approximately 65% of the cells were viable, and 90% were parenchymal

hepatocytes). Human hepatoblastoma cell lines Huh7 and HepG2, human fibroblast IMR-90 and human kidney 293 cells were grown in Dulbecco Modified Eagle's medium (DMEM) with 100 mL·L^{-1} fetal bovine serum (FBS) and antibiotics.

Intrafetal intraperitoneal injections of human hepatocytes

At 15 d to 17 d of gestation, groups of pregnant rats were anesthetized by intramuscular injections of ketamine (40 mg·kg^{1} body mass) and xylazine (5 mg·kg^{1} body mass). Laparatomies were performed under sterile conditions; gravid uteri were exposed, and transilluminated by a high intensity lamp (Fiberlite MI150, DolanJenner Industries, Lawrence, MA). Human hepatocytes or Huh7 cells, 1×10^5 cells in 10 μL PBS, were injected through the uterine wall into the peritoneal cavities of rat fetuses using a sterile 200 μLHamilton syringe with a 28 gauge beveled point needle (Hamilton Inc., Reno, NV).

Cell transplantation

Within 24 h of birth, newborn rats were placed on ice for 2-5 min. Under sterile conditions, left paracostal incisions were made, and primary human hepatocytes or Huh7 cells, 1×10^{10} cells·L^{-1} in200 μL PBS were injected over 30 into the spleen by sterile Hamilton syringe.

Sample collection

Peripheral blood samples were drawn from tail veins, spun, and serum stored at -20℃. Liver samples were collected either by sacrificing animals or by performing partial hepatectomies. Samples were fresh frozen in liquid nitrogen, and stored at -80℃.

Mixed lymphocyte assays

The tolerance of host animals towards human hepatocytes was assessed by mixed lymphocyte assays in which the proliferation of host spleen cells was measured after exposure to exogenous antigens[12]. Briefly, spleens were removed from tolerized or control animals, 1 wk after cell transplantation or for non-transplanted controls one week after birth, and dispersed into RPMI1640 medium (Gibco-BRL) with 50 mL·L^{-1} FBS. Stimulator cells (primary human hepatocytes, Huh7, IMR-90 and 293 cells) were gamma irradiated with 20Gy to inhibit proliferation. Irradiated stimulator cells, 0.5 mL of 3×10^8·L^{-1}, were mixed with 0.5 mL of 1×10^9·L^{-1} rat spleen cells, pulselabeled with 37kBq of ^{3}H-thymidine (2960TBq·mol^{-1}, Amersham Life Science), and then incubated at 37℃ with 50 mL·L^{-1} CO_2 for 72 h. After trichloroacetic acid (TCA) precipitation, cells were harvested onto Whatman glass fiber filter papers (Whatman), washed successively with phosphate buffered saline (PBS), TCA and ethanol. Filter papers were counted in a scintillation counter (Tri-CARB 4530, Parkard). Spleen cells from untreated rats as well as stimulator cells incubated alone served as controls. All experiments were performed with triplicate animals, and the results expressed as $\bar{x} \pm S\bar{x}$ in units of nBq·cell^{1}.

Detection of human albumin gene sequences in rat liver

To detect human hepatocytes that survived transplantation in rat livers, human albumin gene sequences were sought as specific markers using a 5' primer (5'-CTGGTCTCACCAATCGGG-3') and a 3' primer (5'-CTGGTCTCACCAATCGGGGG-3'). Genomic DNA extracted from Huh7 cells served as a positive control. Genomic DNA from untreated rats, and rats tolerized without transplantation were used as negative controls.

Quantitation of human albumin DNA in rat liver

To quantify the number of human hepatocytes present in rat livers, dot blots using probes specific for the human albumin gene were performed by modifying the method of Kafatos[13] with a ^{32}P-labeled 1750bp *Bam*H I /*Bst*e II human albumin DNA fragment excised from palb-3, a plasmid containing the complete human albumin gene[14]. All assays were performed in triplicate, and the results were expressed as $\bar{x} \pm s_{\bar{x}}$. Genomic DNA from known numbers of Huh7 cells was measured in an identical fashion.

Detection of human albumin mRNA in rat livers

To determine whether transplanted human hepatocytes retained liver-specific transcription, the presence of human albumin mRNA was sought by RT-PCR after extraction according to the method of Chomczynski[15] using primers for human albumin (sense 5'-CCTTGGTGTTGATTGCCTTGCTC-3', antisense 5'-CATCACATCAACCTCTGGTCTCACC-3') and rat albumin (sense 5'-CGGTTTAGGGACTT-AGGAGAACAGC-3', antisense 5'-ATAGTGTCCCA-GAAAGCTGGTAGGG-3'). The expected size of PCR products for human and rat albumin mRNA were 315 bp and 388 bp, respectively.

Detection of human albumin in rat liver

Sixteen weeks posttransplantation, groups of rats were sacrificed, and livers sectioned into 5 μm slices in tissue freezing medium (Triangle biomedical Sciences, Durham, NC). Immunofluorescence staining was performed using a modification of the method of Osborn[16] using monoclonal mouse antihuman albumin antibody (Sigma, St. Louis, MO) and goat anti-mouse IgG second antibody conjugated with Texas Red (Amersham Pharmacia Biotech). Immunohistochemical staining for human albumin was done according to the method of Kieran[17]. Tissue samples were examined using confocal laser scanning microscopy (LSM-410, Zeiss, Germany).

Assays for human albumin in rat serum

To measure human albumin in rat serum, Western blotting was performed in a manner similar to the

method of Gershoni[18] using monoclonal mouse anti-human albumin antibody (Sigma, St. Louis, MO) and rabbit anti-mouse IgG second antibody conjugated with horseradish perioxidase (HRP) (Sigma, St. Louis, MO). The signal was detected by an enhanced chemiluminescence method (ECL kit, Amersham) and exposed to film.

RESULTS

Mixed lymphocyte assays were used to detect changes in immune response as a result of intrafetal injections. In these assays, spleen (responder) cells taken at wk 1 after birth were mixed with irradiated stimulator cells (primary human hepatocytes, or controls consisting of Huh7 human hepatoblastoma cells, IMR-90 human fibroblasts, or 293 human kidney cells). Figure 1, lane 1 shows that spleen cells from animals that were not injected with hepatocytes intrafetally, incubated alone (without any stimulator cells) had baseline uptake of (1446 ± 111) nBq·cell^{-1}. Irradiated hepatocytes incubated alone only took up (222 ± 100) nBq·cell^{-1}. Lane 2, in contrast, the spleen cells from lane 1, from rats with no intrafetal injection, but subsequently exposed to irradiated human hepatocytes, lane 3, were stimulated to take up (10842 ± 1585) nBq·cell^{-1}, a 7.5-fold increase. But, when spleen cells from rats that had intrafetal injection of primary human hepatocytes, were subsequently exposed to irradiated primary human hepatocytes, lane 4, they were not stimulated as uptake was only (1390 ± 139) nBq·cell^{-1}. To determine whether the lack of stimulatory effect was hepatocytespecific, spleen cells from animals injected intrafetally with primary hepatocytes were exposed to human IMR-90 fibroblasts. In contrast to hepatocyte stimulator cells, the spleen cells were stimulated by the fibroblasts, taking up (14373 ± 1473) nBq·cell^{-1}, lane 5, which was similar to the uptake of cells from rats not intrafetally injected with hepatocytes, (13956 ± 2085) nBq·cell^{-1}, lane 7. In another control, uptake by 293 human kidney cells was also stimulated in spleen cells from rats either intrafetally injected with hepatocytes, lane 6, or not, lane 8. Irradiated IMR-90, lane 9, and 293 cells, lane 10, incubated alone had negligible uptake, indicating that the contribution of these cells could not account for the observed increases in uptake results found in lanes 5 and 7.

To determine whether transformed human hepatocytes could be also used to induce immunological tolerance, Huh7, and HepG2 human hepatoblastoma cell lines, were compared to primary human hepatocytes in terms of induction of tolerance. Figure 2 shows that spleen cells from rats not injected intrafetally with hepatocytes, and subsequently exposed to primary hepatocytes, lane 1; Huh7 cells, lane 2; or HepG2 cells, lane 3 all had uptake ratios significantly and substantially greater than cells from rats intrafetally injected and subsequently exposed to the corresponding cells, lanes 4, 5 and 6, respectively.

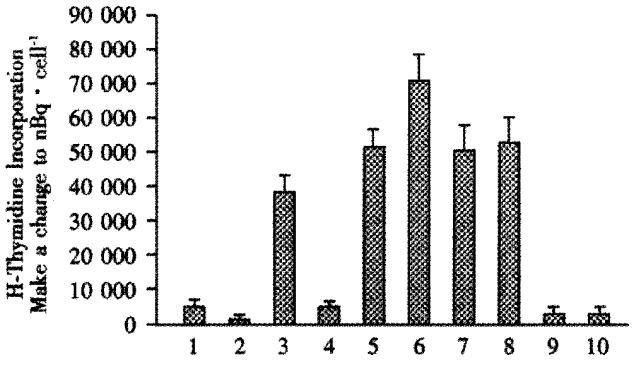

Figure 1 Mixed lymphocyte assays. Rat spleen (responder) cells, from 3 rats per group, were incubated either alone, or with (stimulator) irradiated primary human hepatocytes, IMR-90 human fibroblasts, or 293 human kidney cells in the presence of ^{3}H-thymidine. The incorporation of radioactivity was used as a measure of proliferation of rat spleen cells induced by exposure to foreign cells. When performed, rats were intrafetally injected with primary human hepatocytes on d16 of gestation. Mixed lymphocyte assays were performed at wk1 after birth. Spleen cells from rats neither injected intrafetally with hepatocytes, nor transplanted, lane 1; irradiated primary human hepatocytes incubated alone, lane 2; spleen cells from rats neither intrafetally injected nor transplanted, but which were incubated with irradiated hepatocytes, lane 3; spleen cells from rats intrafetally injected and transplanted and subsequently exposed to irradiated hepatocytes, lane 4; responder spleen cells from intrafetally injected and transplanted, exposed to irradiated IMR-90 fibroblasts, lane 5, and 293 kidney cells, lane 6; spleen cells from animals neither intrafetally injected nor transplanted, but exposed to irradiated IMR-90 cells, lane 7, or 293 cells, lane 8; irradiated IMR-90 and 293 cells incubated alone, lanes 9 and 10, respectively. Results were expressed as means ± S. E. *indicates statistical significance, P<0.05.

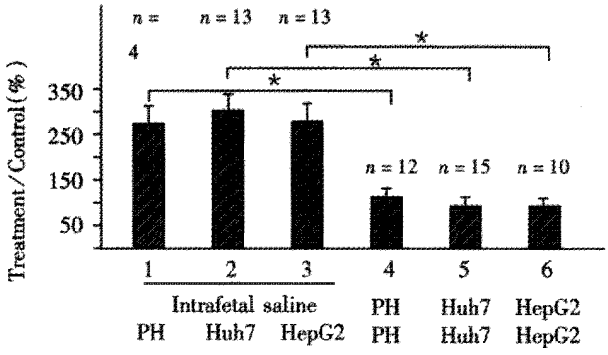

Figure 2 Mixed lymphocyte assays for measuring tolerance induced by different types of human hepatocytes. Rats were intrafetally tolerized with either primary human hepatocytes (PH), or Huh7 cell, or HepG2 cells. All assays were performed at wk1 after birth and show radioactive incorporation by spleen cells from rats that were injected intrafetally with only saline, and subsequently incubated with primary hepatocytes, hepatoblastoma cell lines Huh7, or HepG2, lanes 1, 2 and 3, respectively. Radioactive uptake of spleen cells from rats intrafetally injected with primary hepatocytes, Huh7 or HepG2 cells and incubated with their corresponding irradiated cells is shown in lanes 4, 5, and 6, respectively. The number of rats in each group is indicated on the top of each column. Results are expressed as percentage of controls (spleen cells from untreated rats incubated alone) as $\bar{x} \pm s_{\bar{x}}$. Duncan's test was used to analyze the significance between different treatment groups. *indicates significant differences between groups 1 and 4, between 2 and 5; and 3 and 6, P < 0.05.

Because of the difficulty in obtaining primary human hepatocytes, immunohistochemical methods for detection of transplanted cells were established using Huh7 hepatoblastoma cells. To visualize these cells in livers of rats that were previously tolerized intrafetally and transplanted with Huh7 cells, staining with monoclonal mouse antibody against human albumin was performed. Figure 3 shows that staining was detectable in rat livers on day 1 after transplantation mostly as single cells, but with occasional pairs, fairly evenly distributed throughout the parenchyma, panel A and with high magnification, panel B. Seven days after birth, clusters of 2 and 3 cells each were visible, and single cells less common, panel E and with higher magnification, panel F. No human albumin was detected in rats that were tolerized with Huh7, but were not transplanted, panel C and at higher magnification, panel D, confirming that the antibody was specific for human albumin and lacked cross reactivity with endogenous rat albumin.

Laser scanning confocal microscopy was used to visualize transplanted hepatocytes by staining with monoclonal antibody against human albumin. Figure 4 shows that in tolerized rats transplanted with human hepatocytes, human albumin was detected at week 16 post-transplantation, panel B. In tolerized rats without transplantation, no staining was detected, panel C. Rat liver sections stained with secondary antibody alone, panel D demonstrated that the staining was not an artifact due to nonspecific interaction with second antibody. As expected samples stained with monoclonal goat anti-rat albumin antibody, panel A, resulted in positive signals for rat albumin in virtually every parenchymal cell in the liver.

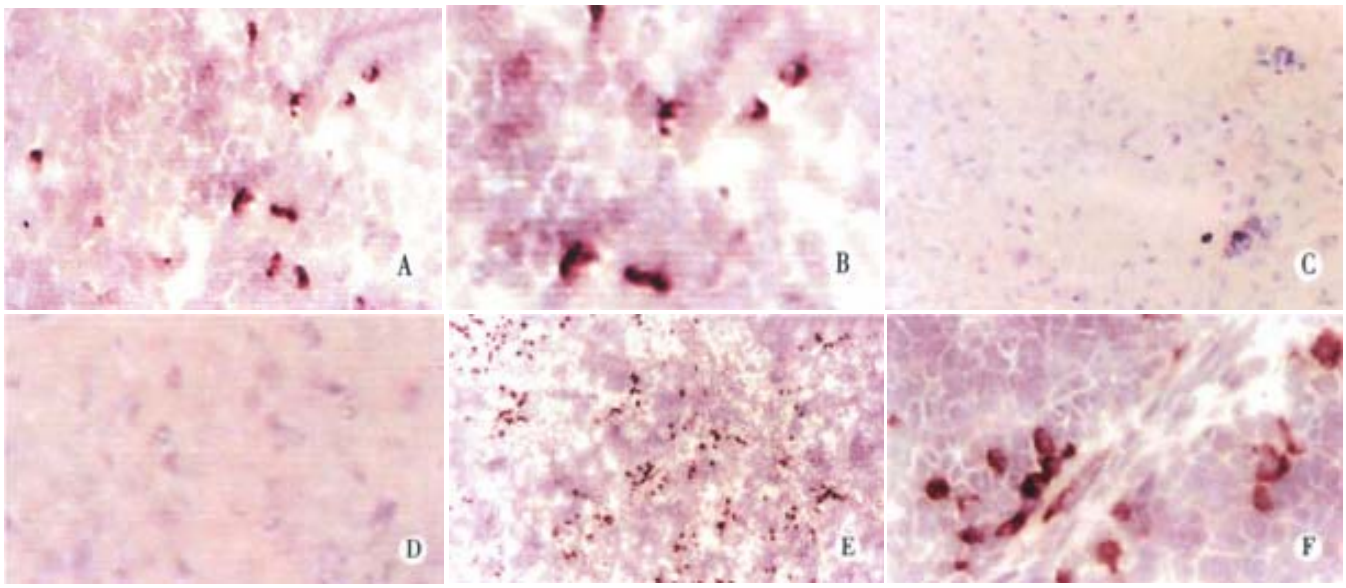

Figure 3 Immunohistochemistry for detecting human albumin in rat livers. Antibody against human albumin was visualized using a DAB method as described in Materials and Methods. Fifteen SD fetal rats were tolerized with Huh7 cells. Ten newborn rats were subsequently transplanted with Huh7 cells on d1 after birth, and the rest were not transplanted. Panel A, a representative rat that was tolerized and transplanted with Huh7 cells, sacrificed on d1 post-transplantation, magnification ×125; panel B, same as panel A, ×250; panel C, a representative rat that was tolerized with Huh7 cells, but without transplantation, ×125; panel D, same as panel C, ×250; panel E, a representative rat that was tolerized and transplanted with Huh7 cells, sacrificed on d7 after birth, ×125; panel F, same as panel B, ×250.

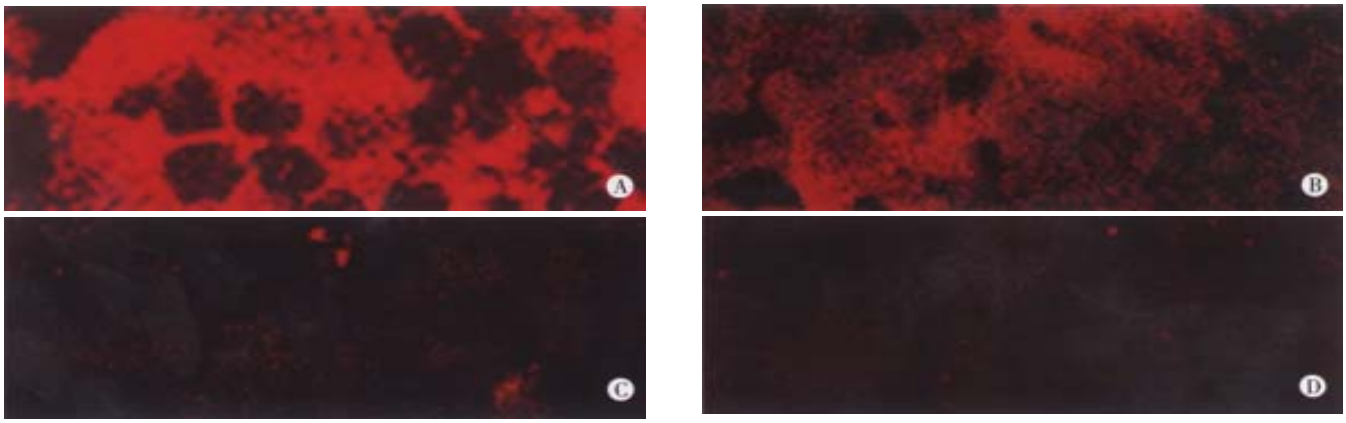

Figure 4 Confocal immunofluorescence microscopy for detection of human albumin in rat livers at wk16 post-transplantation. Panel A, a representative rat intrafetally injected with primary hepatocytes and subsequently transplanted with those same cells, stained with monoclonal goat anti-rat albumin. Panel B, a section from the same sample stained with monoclonal mouse anti-human albumin antibody. Panel C, a representative rat intrafetally injected with primary human hepatocytes, but not transplanted with hepatocytes, stained with anti-human albumin antibody. Panel D, the same sample as in Panel A stained with only second antibody. Magnification, ×250.

To estimate of the number of human hepatocytes present in rat liver transplanted with human hepatocytes, human albumin DNA sequences were detected by amplification of rat liver genomic DNA by PCR. Figure 5, lanes 3-5 show human albumin DNA extracted from 10^4, 10^3 and 10^2 Huh 7 cells, respectively. PCR produced expected 307 bp products with decreasing intensities of signals. DNA from a rat intrafetally injected with primary human hepatocytes and transplanted with those cells, lane 6 produced a band at the expected position. In contrast, a littermate intrafetally injected with human hepatocytes, but without hepatocyte transplantation, lane 7, produced no detectable human albumin DNA signal. Bands at the bottom of the gels are due to excess primers. Neonatal rats sustained intrasplenic transplantation of human hepatocytes well, with a mortality rate of about 5%.

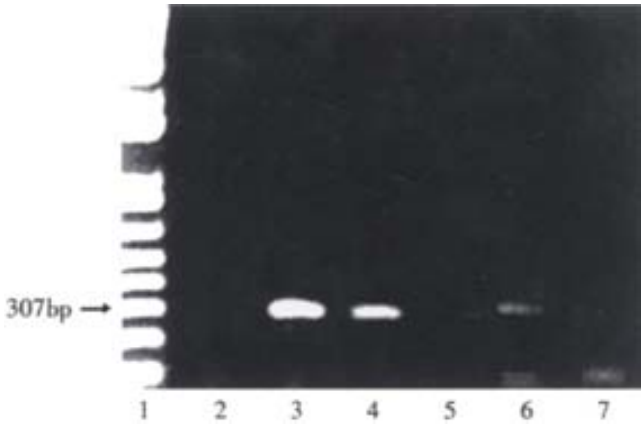

Figure 5 Detection of human albumin DNA in rat liver genomic DNA 16wk post-transplantation. From livers of animals treated as described in Figure 4, DNA was extracted, and assayed for the presence of human albumin sequences by PCR as described in Materials and Methods. Lane 1, molecular markers; lane 2, liver from untreated rats; lanes 3 to 5, 10^4, 10^3 and 10^2 Huh7 cells, respectively; lane 6, a representative rat intrafetally injected with primary human hepatocytes, and transplanted with those cells; lane 7, a rat intrafetally injected with primary hepatocytes, but not transplanted. The expected position of the amplified human albumin sequence is indicated by the arrow corresponding to 307 bp based on the DNA molecular markers in lane 1.

To quantitate the amount of human albumin gene present, dot blotting for human albumin DNA was performed. In Figure 6, the upper row of panel A, shows that liver samples from a representative rat intrafetally injected and transplanted with primary human hepatocytes had positive signals for human albumin DNA at 6 wk and 16 wk post-transplantation, with little obvious change in signal between the time points. In contrast, a littermate tolerized with human hepatocytes, but not transplanted, lower row, had no signals at the same time points indicating that the human albumin signal detected in the upper panel were not due to residual DNA from the tolerization procedure or cross reactivity with rat sequences. In panel B, the plasmid palb3, was loaded in serial dilutions as standards for human albumin DNA. Based on the amount of human albumin DNA in 10 (g rat liver DNA, the number of surviving human hepatocytes was calculated to be 2.5×10^5 cells per whole adult liver 16 wk posttransplantation. The ratio of human to rat hepatocytes that were present, 16 weeks posttransplantation, was calculated to be approximately 1 human cell per 6×10^3 rat hepatocytes.

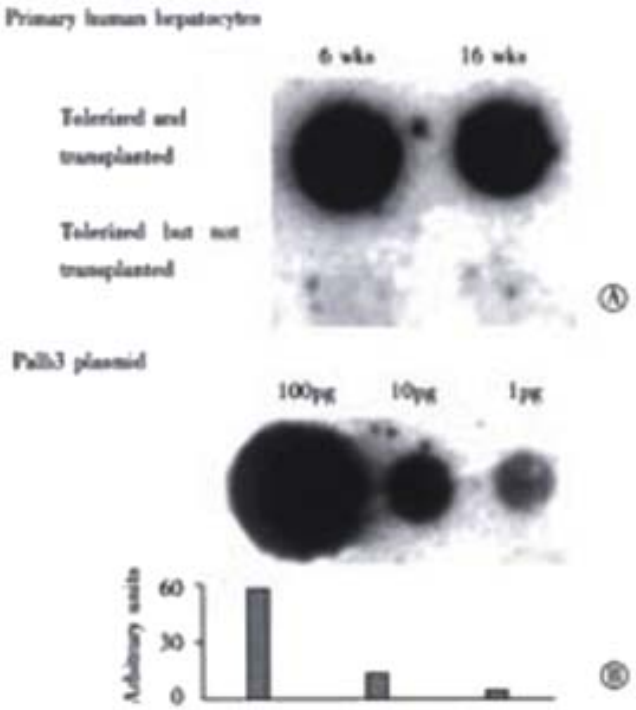

Figure 6 Quantitation of human albumin DNA in rat livers by dot blotting. Panel A, upper row, shows DNA extracted from liver samples from a intrafetally injected, and transplanted rat at wk 6 and 16 post-transplantation, respectively. Lower row shows results from a rat tolerized but without transplantation at the same time points. All dots were hybridized with a ^{32}P-labeled probe for human albumin DNA. Panel B shows a plasmid, palb-3, containing the complete human albumin gene, applied in decreasing amounts, 100 pg, 10 pg and 1 pg as standards.

To assess albumin gene transcription in rat livers, RTPCR of albumin mRNA was performed. In Figure 7, panel A, lane 3 shows that human albumin mRNA extracted from Huh7 cells was detected by RT-PCR by the presence of a product with the expected size of 315 bp. As expected, the same sample failed to generate a signal when rat albumin primers were used indicating that the human primers were specific for the detection human albumin mRNA, lane 7. In tolerized rats 16 wk after human hepatocyte transplantation, human albumin mRNA was also detected as a 315 bp band, lane 4. However, no human albumin mRNA was detected in a littermate intrafetally injected,

but without transplantation, lane 5, or from a nonfetally injected, and nontransplanted rat, lane 2. However, a band corresponding to the rat albumin amplification product of 388 bp was demonstrated in a representative rat neither intrafetally injected, nor transplanted, lane 6; a rat intrafetally injected, and transplanted, and sampled 16 weeks after transplantation, lane 8; and a rat intrafetally injected, but without transplantation, lane 9. As standards, RNA extracts from Huh7 cells were amplified with primers for human albumin, and as expected produced decreasing signals of 315 bp products, lanes 10-12.

The transcriptional activity of transplanted human hepatocytes as a function of time was measured over the entire experimental period of 16 wk. Figure 7, panel B, lane 3 shows that human albumin mRNA extracted from Huh7 cells in culture and detected by RTPCR produced a product with the expected size of 315 bp. Human albumin mRNA levels from rats were not obviously different at wk2, 6, and 16 after transplantation, lanes 4, 5 and 6, respectively, suggesting that, within the limits of the assay, the function of transplanted human hepatocytes, at least with regard to albumin production, remained unchanged for at least 16 weeks.

Figure 8 shows Western blots of serum from a representative rat tolerized and transplanted with primary human hepatocytes. A band with migration corresponding to 56 ku, the expected size of human serum albumin, as shown by standard human albumin in lane 1 was found in serum from a rat intrafetally injected and transplanted with primary human hepatocytes 1 wk posttransplantation, lane 3, and remained detectable at 2 and 3 wk posttransplantation, lanes 4 and 5, respectively. There was no cross reactivity of antibody with rat liver not transplanted with human cells as shown in lane 2. These data support the conclusion that human hepatocytes can be transplanted, and survive in the livers of intrafetally tolerized rats, and remain sufficiently active to secrete detectable amounts of human serum albumin into the circulation.

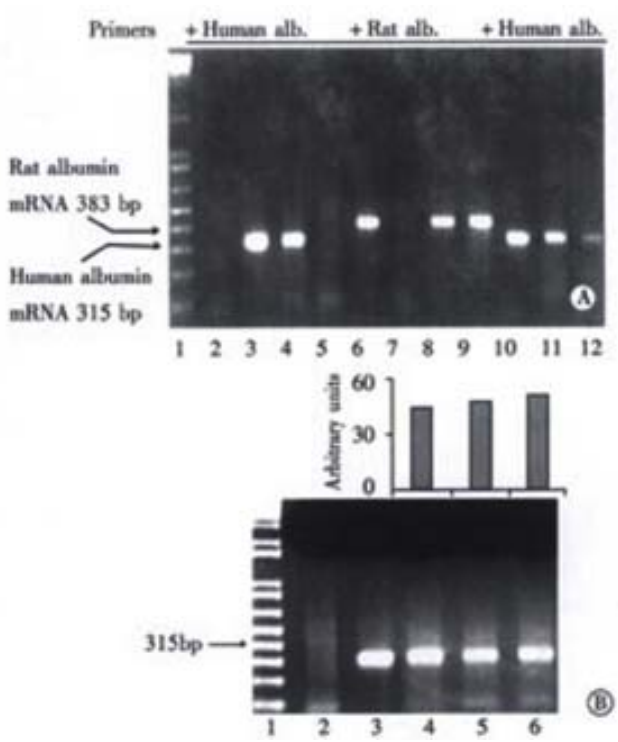

Figure 7 Detection of human albumin mRNA in rat livers by RT-PCR. Panel A, RT-PCR of RNA extracts from liver samples collected at wk16 post-transplantation. Lane 1, 1 kb plus molecular markers; lanes 2 and 6, non-intrafetally injected, non-transplanted rats; lanes 3 and 7, Huh7 cells as positive control; lanes 4 and 8, rats intrafetally injected, and transplanted with primary human hepatocytes; lanes 5 and 9, rats intrafetally injected, but not transplanted with human hepatocytes. For lanes 2 to 5, samples were amplified with primers for human albumin DNA, and for lanes 6 to 9, samples were amplified with primers for rat albumin DNA. In lanes 10 to 12, DNA from 10^4, 10^3 and 10^2 cultured Huh7 cells were amplified with primers for human albumin. The expected positions of human and rat albumin mRNA products at 315 bp and 388 bp, respectively, are indicated by arrows. Panel B, Time course of human albumin mRNA expression in the rat livers. Lane 1, 1 kb plus molecular markers; lane 2, samples from a nontolerized and non-transplanted rat; lane 3, Huh 7 cells as a positive control; lanes 4 to 6, samples from a representative rat tolerized and transplanted with primary human hepatocytes collected at wk2, 6 and 16 post-transplantation, respectively.

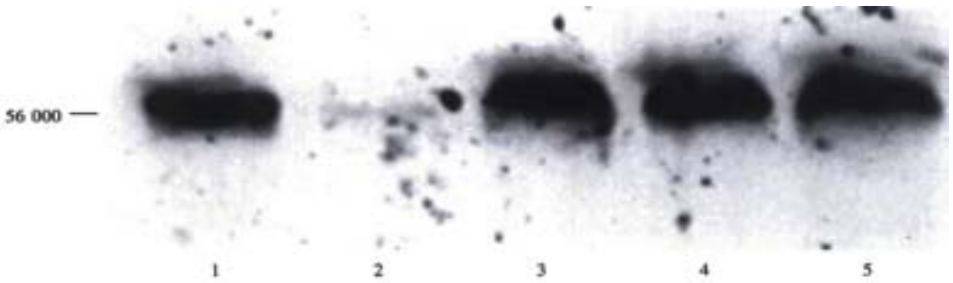

Figure 8 Detection of human albumin protein in rat serum by Western blots. Western blots of serum samples from a representative rat intrafetally injected and transplanted with primary human hepatocytes at post-transplantation wk1, lane 3; wk 2, lane 4; and wk 3, lane 5. Lane 1: standard human albumin and lane 2: standard rat albumin.

DISCUSSION

The developing immune system in the fetus allows a unique opportunity for the induction of tolerance to specific cells without generalized suppression of the immune system. *In utero* injection of donor cells directly into the peritoneal cavities of fetuses during gestation has been shown previously to result in a donor-specific tolerance[10,11,19]. With regard to the timing of cell injections for induction of tolerance, previous studies in normal mice demonstrated that *in utero* injections of splenocytes on days 14 to 16[20] were satisfactory for induction of donor-specific tolerance and prolongation of the survival of allogeneic skin grafts. In our experiments, intrafetal injections performed on any of three days, from day 15 to 17 of gestation, resulted in equal effectiveness in establishing tolerance to human hepatocytes.

Livers of tolerized rats transplanted with human hepatocytes was found to contain the human albumin gene up to 16 weeks post-transplantation, the duration of the experiment, Figures 5 and 6. The transplanted cells were functional as indicated by the presence of human albumin mRNA, Figure 7, and human albumin gene product, Figures 4 and 8. The presence of antibodies to human albumin was not detected (data not shown).

Chimeric liver models have been described previously, but in immunocompromised hosts. For example, normal adult woodchuck hepatocytes were transplanted into uPA/RAG2 knock out mice via intrasplenic injection. These cells eventually reconstituted 90% of those mouse livers[6]. Similarly, immortalized primary human hepatocytes have been transplanted into RAG-2 knock out mice[7]. Recently, primary human hepatocytes were transplanted under the kidney capsule of SCID/NOD mice[8]. The results demonstrate that when transplanted into immunocompromised hosts, human hepatocytes can not only survive, but also maintain differentiated cellular function in foreign hosts and even in unnatural locations. Our current data further indicate that general immune deficiency or suppression is not required, and intrafetal tolerization is sufficient to prevent rejection. Furthermore, the technique could be used to generate tolerance to other cell types, that might result in development of other useful animal models.

The mechanism of tolerance induction via intrauterine exposure to foreign antigen has been ascribed to T- cell clonal deletion[20]. Recently, Knolle and colleagues[21,22] described another method of inducing tolerance in the liver to foreign antigens: direct injection of foreign antigens into portal circulation resulted in the presentation of foreign antigens by liver endothelial cells to $CD8^+$ T cells. Such a model for tolerance has not been tested specifically for induction of tolerance to xenografted human hepatocyte transplantation.

Abstract

AIM To study the effects of aminoguanidine (AG) and two L-arginine analogues N$^{\omega}$-nitro-L-arginine methyl ester (L-NAME) and N$^{\omega}$-nitro-L-arginine (L-NNA) on nitric oxide (NO) production induced by cytokines (TNF-α, IL-1β, and IFN-γ) and bacterial lipopolysaccharide (LPS) mixture (CM) in the cultured rat hepatocytes, and examine their mechanisms action.

METHODS Rat hepatocytes were incubated with AG, L-NAME, L-NNA, Actinomycin D (ActD) and dexamethasone in a medium containing CM (LPS plus TNF-α, IL-1β, and IFN-γ) for 24 h. NO production in the cultured supernatant was measured with the Griess reaction. Intracellular cGMP level was detected with radioimmunoassy.

RESULTS NO production was markedly blocked by AG and L-NAME in a dose-dependent manner under inflammatory stimuli condition triggered by CM *in vitro*. The rate of the maximum inhibitory effects of L-NAME (38.9%) was less potent than that obtained with AG (53.7%, $P<0.05$). There was no significant difference between the inhibitory effects of AG and two L-arginine analogues on intracellular cGMP accumulation in rat cultured hepatocytes. Non-specific NOS expression inhibitor dexamethasone (DEX) and iNOS mRNA transcriptional inhibitor ActD also significantly inhibited CM-induced NO production. AG (0.1 mmol·L^{-1}) and ActD (0.2 ng·L^{-1}) were equipotent in decreasing NO production induced by inflammatory stimuli *in vitro*, and both effects were more potent than that induced by non-selectivity NOS activity inhibitor L-NAME (0.1 mmol·L^{-1}) under similar stimuli conditions ($P<0.01$).

CONCLUSION AG is a potent selective inhibitor of inducible isoform of NOS, and the mechanism of action may be not only competitive inhibition in the substrate level, but also the gene expression level in rat hepatocytes.

INTRODUCTION

The pathogenesis of inflammatory sepsis and multiple autoimmune diseases (such as insulin-dependent diabetes mellitus, arthritis and viral hepatitis) is linked to the overproduction of nitric oxide (NO), a potentially toxic molecule, which is likely to be responsible in part for the cytotoxicity and mutagenicity of the inflammatory process. NO has been reported to cause DNA damage and mutations, and to induce apoptosis in several cell types for example macrophages, hepatocytes and pancreatic β-cells[1-7]. The analogues of L-arginine, N$^{\omega}$-nitro-L-arginine (L-NNA) or N$^{\omega}$-nitro-L-arginine methyl ester (L-NAME) may be useful in treating patients with the above diseases. However, the known inhibitors of the inducible enzyme can also exert their actions on the constitutive isoform NO synthase (cNOS), which resulted in an inappropriate vasodilatation or hypertension[8-10]. Thus, to inhibit selectively the inducible NOS (iNOS) may yield less side effects.

Aminoguanidine (AG) has effects on several enzyme systems, it interferes with non-enzymic glycosylation, leading to its potential use as a treatment for the complications of diabetes. Furthermore, recent work has showed that AG can also be used as a novel selective iNOS inhibitor in rat isolated vassels[11-13], although the mechanism

underlying this is unclear. The aim of this study was to determine the effects of AG and two nonselective NOS inhibitors L-NNA and L-NAME, on the NO production and cGMP release induced by cytokines and LPS in rat cultured hepatocytes.

MATERIALS AND METHODS

Reagents

Collagenase (Type IV, 340kU·g^{-1}), bovine insulin, lipopolysaccharide (LPS, *E. coli* 0111:B4), N$^{\omega}$-nitro-L-arginine methyl ester (L-NAME), N$^{\omega}$-nitro-L-arginine (L-NNA), aminoguanidine (AG), dexamethasone were purchased from Sigma Chemical Co.; human recombinant (rh) tumor necrosis factor-alpha (TNF-α), interleukin-1 beta (IL-1β), interferon-gamma (IFN-γ) were from Academy of Military Medical Sciences (Beijing), and Dulbecco's modified Eagle's medium (DMEM) from Gibco BRL; Bacille Calmétte-Guérin vaccine (BCG) was obtained from the National Vaccine and Serum Institute (Beijing), [^{3}H]-radioimmunoassay kit for cyclic guanylate monophosphate (cGMP) was bought from Beijing Institute of Nuclear Research. All the reagents were diluted in medium and prepared freshly before use.

Isolation and culture of hepatocytes

Hepatocytes were harvested from male adult Wistar rats (weighing 180 g-220 g) using an *in situ* collagenase perfusion technique[14]. After inhalation anesthesia, the abdomens of the animals were opened and shaved, the portal vein was exposed and cannulated. Then the liver was perfused at 37 ℃ *in situ* first with a calcium-free phosphate-buffered saline solution (PBS). This perfusion was continued for 5 min, then it was switched to 0.5 g·L^{-1} collagenase and 10 g·L^{-1} bovine albumin in PBS buffer for 15 min. The liver was removed and the cells were combed gently in tissue culture medium. Hepatocytes were pelleted, washed, and separated from nonparenchymal cells by differential centrifugations at 50 × g. Viability of cells exceeded 90% as determined by trypan blue exclusion. Hapatocytes were plated onto 6-well plastic tissue-culture plates (1 × 10^9 cells·L^{-1} in each well). Medium in the control consisted of DMEM with L-arginine (0.5 mmol·L^{-1}), insulin(1 μmol·L^{-1}), Hepes (15 mmol·L^{-1}), L-glutamine, penicillin, streptomycin, and 100 mL·L^{-1} low-endotoxin newborn calf serum. After overnight incubation, the medium was changed with a cytokines mixture (CM) containing LPS (10 mg·L^{-1}), IL-1β (10KU·L^{-1}), TNF-α (500KU·L^{-1}) and IFN-γ (100KU·L^{-1}). Other experimental conditions included addition of NOS inhibitors (L-NAME, L-NNA or AG), actinomycin D (ActD) or dexamethasone (DEX) to the CM. After primary cultures were maintained for 24 h at 37℃ in 50 mL·L^{-1} CO_2, hepatocytes or cultured supernatants were collected for nitrite and cGMP assays[15].

Determination of NO production and cGMP levels

To determine the amount of NO produced by hepatocytes, the culture supernatants were assayed for the stable oxidative product, nitrite, by an automated procedure based on the Griess reaction, as previously described[7]. The intracellular levels of cGMP were determined using a [^{3}H]-labeled radioimmunoassay (RIA) kit, as described[14,15].

Statistical analysis

Data were expressed as $\bar{x} \pm s$. The significance of differences was determined with the Student's *t* test. Statistical significance was established at a *P* value <0.05.

RESULTS

Effect of aminoguanidine and N$^{\omega}$-nitro-L-arginine methyl ester on nitrite production

Being consistent with our previous results, the inflamatory factors induced a large amount of NO in a time- and dose-dependent manner in the primary culture of rat hepatocytes. Both L-NAME and AG inhibited LPS and cytokines-induced NO production (Table 1) in a dose-dependent fashion. On the other hand, AG completely blocked NO production stimulated by inflamatory factors in rat hepatocytes, however,the rate of the maximum inhibitory effects of L-NAME (38.9%) was less potent than that obtained with AG (53.7%, $P<0.05$).

CM (Cytokines mixture): IL-1β 10KU·L^{-1}, TNFα 500KU·L^{-1}, and IFNγ 100KU·L^{-1} plus LPS 10 mg·L^{-1}; Cultured hepatocytes were stimulated *in vitro* with CM in the absence or presence of inhibitors (aminoguanidine or L-NAME) at various concentrations for 24 h. Amounts of nitrite in the supernatant were assayed 24h after start of stimulation *in vitro*. $\bar{x} \pm s$, *n* = 6-16 rats (3 well for each treatment in each experiment); ^bP <0.01, compared with control, ^aP<0.05, ^dP<0.01 compared with corresponding CM.

Effect of aminoguanidine, L-NNA and L-NAME on intracellular cGMP accumulation

To confirm that AG and two L-arginine analogues NOS inhibitor L-NAME and L-NNA, inhibit NO production induced by inflamatory stimuli, the effects of the three compounds on CM-induced accumulation of intracellular cGMP (a sensitive but non-specifical index of NO production) were investigated. Two L-arginine analogues L-NAME and L-NNA almost completely inhibited cytokines-stimulated intracellular cGMP accumulation from 3.0±1.5 (pmol·L^{-1}) to 1.4±0.4 (pmol·L^{-1}) with L-NAME, and to 1.3±1.1 (pmol·L^{-1}) with L-NNA (Table 2). AG on intracellular cGMP accumulation was also parallel with NO production, although the inhibitory effect of AG seemed weaker as compared with that of the two L-arginine analogues to 1.48±0.8 (pmol·L^{-1}).

Table 2 Effect of aminoguanidine, L-NAME and L-NNA on intracellular cGMP accumulation induced by CM *in vitro*

Groups	*n*	c (cGMP) (pmol·L^{-1})	Inhibition rate (%)

CM (Cytokines mixture): IL-1β 10KU·L^{-1}, TNFα 500KU·L^{-1}, and IFNγ 100KU·L^{-1} plus LPS 10 mg·L^{-1}; Cultured hepatocytes were stimulated *in vitro* with CM in the absence or presence of inhibitors (aminoguanidine, L-NAME, or L-NNA, respectively) for 24 h; Levels of intracellular cGMP were assayed 24 h after start of stimulation *in vitro* (CM or CM were co-incubated with inhibitors,respectively); $\bar{x} \pm s$, n = 7 rat or 12 rat (4 replicates for each treatment in each experiment); [a]P<0.05 compared with control, [c]P<0.05 compared with CM.

Comparison of inhibitory effects of aminoguanidine, L-NAME, DEX and ActD on nitrite production stimulated by CM in vitro

NO production was blocked by AG and L-NAME under inflammatory condition triggered by CM *in vitro*, AG (inhibition 52.2%) is a more potent inhibitor than L-NAME (35.5%, P<0.01, Table 3), the former completely blocked NO formation induced by CM *in vitro*. Similarly, both dexamethasone (DEX, 33.9%) and actinomycin D (ActD, 53.8%), inhibitors of non-specific NOS expression and iNOS mRNA transcription, also inhibited CM-induced NO production in rat hepatocytes. Furthermore, AG and ActD were equipotent in decreasing NO production triggered by inflammtory stimuli *in vitro*, and both effects more potent than that induced by L-NAME under similar stimuli condition (P<0.01).

Table 3 Effect of AG, L-NAME, DEX or ActD on rat hepatocytes NO production stimulated by CM only *in vitro*

Groups	*n*	c (NO^{2-}) (μmol·L^{-1})	Inhibition rate (%)
Control	12	6.0±2.4

CM (Cytokines mixture): IL-1β 10KU·L^{-1}, TNFα 500KU·L^{-1}, and IFNγ 100KU·L^{-1} plus LPS -10 mg·L^{-1}; cultured hepatocytes were harvested from rats that control group stimulated *in vitro* with CM in the absence or presence of inhibitors (AG, L-NAME, ActD or DEX, respectively) for 24 h; the amount of nitrite in the supernatant was assayed 24 h after start of stimulation *in vitro*. $\bar{x} \pm s$, n = 12 or 15 rats (3 wells for each treatment in each expriment); [b]P<0.01, compared with control. [c]P<0.05, [d]P<0.01, compared with CM.

DISCUSSION

Recent work showed that AG, a nucleophilic hydrazine compound, is structurally similar to L-arginine in that these compounds contain two chemically equivalent guanidino nitrogen groups and to L-arginine analogues that competitively inhibit NO synthase. The present study showed that AG completely prevents inflammatory stimuli induced formation of NO and confirmed that it is a potent inhibitor of the cytokine-inducible isoform NOS. On the other hand, administration of L-NAME failed to completely suppress the NO production induced by inflamatory stimuli in rat hepatocytes. This result was not associated with the previous observation[16,17] that AG and two L-arginine analogues, L-NNA and L-NAME, were equipotent in inhibiting the NO production induced by endotoxin only in rat aortic rings, suggesting that the role of AG may be due to incomplete inhibition of NOS, or that the development of immunological hepatic damage[18-21] may involve both NO-sensitive and NO-insensitive phases.

It has been recognized that the cNOS is Ca^{2+} dependent and produces small amounts of NO that activate soluble guanylate cyclase, resulting in the formation of cGMP, which mediates endothelium-dependent relaxation and neural transmission. NO is produced in much larger amounts by the iNOS, which is Ca^{2+} independent and appears to mediate the cytotoxic actions of macrophages on target cells, and which may implicate in the existence of other cGMP-independent mechanisms[22-25]. The present results showed that AG failed to inhibit completely the formation of cGMP by inflammatory stimuli, in contrast to NO production. Therefore, the effects of AG and two L-arginine analogs on the cGMP level were different, supporting the hypothesis that AG is a selective inhibitor for inducible isoform of NOS.

The specificity and possible mechanisms of

various L-arginine analogs as NOS inhibitors have been investigated. Recent work suggested that L-NAME and L-NNA may affect NOS activity by modifying electron transfer through iron centers, and then limits arginine transport or utilization[26,27]. However, it is unlikely that a difference in the transport of AG into the cells can explain the lack of effects of this inhibitor on cNOS since it effectively inhibits iNOS[28]. Furthermore, the difference between in affinity or in arginine binding sites for the constitutive and inducible isoforms of NOS may not be used to explain the differences between the effects of L-arginine analogs and AG, since iNOS is not only regulated in the enzyme activity but also in the gene expression level[29,30]. Moreover, in the present study the results showed that AG and transcriptional inhibitor ActD were equipotent in decreasing NO production triggered by inflammtory stimuli *in vitro*, and both effects more potent than that induced by dexamethasone, the latter have non-specifical and post-transcriptional inhibitory effect on NOS enzyme activity [31-33], suggesting that there is possibility of other mechanism in the AG inhibition, which in addition to competitive inhibition in the substrate level, also in gene transcription level. Further experiments will be required to determine whether AG directly affected the transcription of the iNOS gene or via the modulation of an intermediary protein(s) activity which indirectly influence on mRNA stability.

Abstract

AIM To demonstrate the relationship between H-ras oncogene and hepatocellular carcinoma (HCC) metastasis.

METHODS Activated H-ras oncogene was transfected into SMMC 7721, a cell line derived from human HCC, by calcium phosphate transfection method. Some metastasis related parameters were detected in vitro, including adhesion assay, migration assay, expression of collagenase IV (c IV ase) and epidermal growth factor receptor (EGFR).

RESULTS The abilities of H-ras-transfected cell clones in adhesion to laminin (LN) or fibronectin (FN), migration, c IV ase secretion increased markedly, and the expression of EGFR elevated moderately. More importantly, these alterations were consistent positively with the expression of p21, the protein product of H-ras oncogene.

CONCLUSION H-ras oncogene could induce the metastatic phenotype of HCC cell in vitro to raise its metastatic potential.

INTRODUCTION

Hepatocellular carcinoma (HCC) is common in China[1-6], and metastasis occurs early with poor prognosis[7-13]. Numerous studies on various human solid tumors have shown that H-ras oncogene is associated with tumor metastasis[14-21]. However, therelationship between H-ras and HCC metastasis remains an open question[22-25]. In the present study, we transferred activated H-ras genes into SMMC 7721, a cell line derived from human HCC, by the method of calcium phosphate transfection. The metastatic properties of ras-transfected clones were detected *in vitro*. This research was conducted to investigate the influence of H-ras oncogene on the metastatic characteristics of this liver cancer cell line from each link in the chain of tumor metastasis: adhesion-degration-migration, in order to reveal the relationship between H-ras oncogene and metastatic behavior of HCC cell.

METERIALS AND METHODS

Materials

Carrier plasmid pSV_2-neo and recombinant plasmid pSV_2-neo-*ras* (with activated H-*ras* DNA inserted at BamH I site) were gifts from Professor Luo, Director of Department of Biophysics, Fudan University. Human HCC cell line SMMC 7721 was provided by the Liver Cancer Institute, Zhongshan Hospital. Calcium phosphate transfection kit was purchased from Promega Company. DACO $p21^{ras}$ antibody, purchased from Sigma Company, could recognize specifically the 126-140 amino-acids of C-terminal. Antibodies of c IV ase and EFGR were products of Oncogene Company.

Methods

Transfer of recombinant plasmid into SMMC 7721 The method of calcium transfection, was used according to the protocol in the kit. Transfected clones were selected by G418.

Southern blotting The presence of the transfected ras oncogene in the DNA of the clones was assessed by Southern blot. Briefly, total DNA was digested with *Bam* H I, separated by electrophoresis in a 8 $g \cdot L^{-1}$ agarose gel, and transferred to nitrocellulose. The filter was then probed with H-*ras*-T_{24} DNA (6.6kb *Bam* H I fragment of plasmid pT_{24}) which had been radiolabeled with [^{32}P]dCTP.

Following hybridization, the filter was washed and X-rayed.

Immunochemistry The avidin-biotin-peroxidase complex (ABC) method was employed to detect the expression of c IV ase, EFGR and p21. The results were graded according to the percentage of positively stained cells: - less than 5%; + 5%-25%; ++ 25%-50%; +++ 50%-75%; and ++++ above 75%.

Cell adhesion assay The cell adhesion assay was performed as previously described by Busk *et al*. In brief, some wells of polystyrene 96-well flat-bottom microtiter plates were coated with increasing concentrations of laminin (LN) or fibronectin (FN), and additional wells with poly-lysine (positive control) or 10 g·L^{-1} bovin-serum albumin (BSA) (negative control) respectively. Cells were added after all the plates were blocked with 10 g·L^{-1} BSA. The plates were then incubated for 2 h at 37 ℃ in humidified CO_2. Non-adherent cells were removed and the attached cells were fixed and stained. The relative number of cells in each well was evaluated by measuring the absorbance (A) at 595 nm with a Microplate Reader. The percentage of cells attached to the experimental wells was calculated according to the formula as follows:

$$\frac{A\text{ (experimental well) - A(mean of BSA-coated wells)}}{A\text{ (mean of poly-lysine well) -A (mean of BSA-coated wells)}} \times 100\%$$

The data were expressed as $x \pm s_x$ of triplicate wells.

Cell migration assay The wound assay described by Birch *et al* was used to determine the random migration capacity of various clones. Cells were plated into the wells of 24-well plates and incubated until the cultures were subconfluent. A wound track (approximately 4 mm in size) was scored in each well. Replicate wells were terminated at 8, 16 and 24 h after wounding by fixing and staining the cell cultures with 10 g·L^{-1} crystal violet in methanol. The stained cells were then examined under an inverted microscope.

RESULTS

Identification of transfected cell clones

The four clones transfected with recombinant plasmid pSV_2-neo ras (named RC_1, RC_2, RC_3 and RC_4) and the two clones transfected with carrier plasmid pSV_2-neo (named NC_1 and NC_2), along with SMMC 7721, were tested for both Southern blot analysis and p21 expression. The presence of the transfected ras oncogene in RC_1-RC_4 was confirmed by Southern blotting, while it was absent in NC_1, NC_2 and SMMC 7721. The immunochemistry staining showed that the percentage of positive stained cells of RC_1-RC_4 was 71%, 76%, 55% and 49%, respectively. However, it was less than 5% in SMMC 7721, NC_1 and NC_2. The staining grade of these cell clones is presented in Table 1. The results showed that H-*ras* DNA had been transferred into SMMC 7721 successfully and it could express its protein product normally.

Table 1 Expression of p21, c IV ase and EGFR in different cell clones

	Staining grade						
	SMMC 7721	NC_1	NC_2	RC_1	RC_2	RC_3	RC_4
p21	-	-	-	+++	++++	+++	++
c IV ase	+	+	+	+++	++++	+++	+++
EGFR	+	+	+	+++	+++	++	++

Detection of metastasis-related parameters

Adhesive ability When ras transfected clones were assessed for their ability to bind LN or FN, it was found that there was a substantial difference in the adhesive capabilities of these variants (Figure 1). The attachment percentage of RC_1-RC_4 to LN increased by different degree as compared with SMMC 7721, the maximal was up to 69.7%, 74.4%, 38.5% and 55% respectively. Similar results were observed in adhesion assay to FN. The adhesive capabilities of NC_1 and NC_2 had no significant difference from that of SMMC 7721, suggesting that the carrier plasmid itself had no effect on cell metastatic properties.

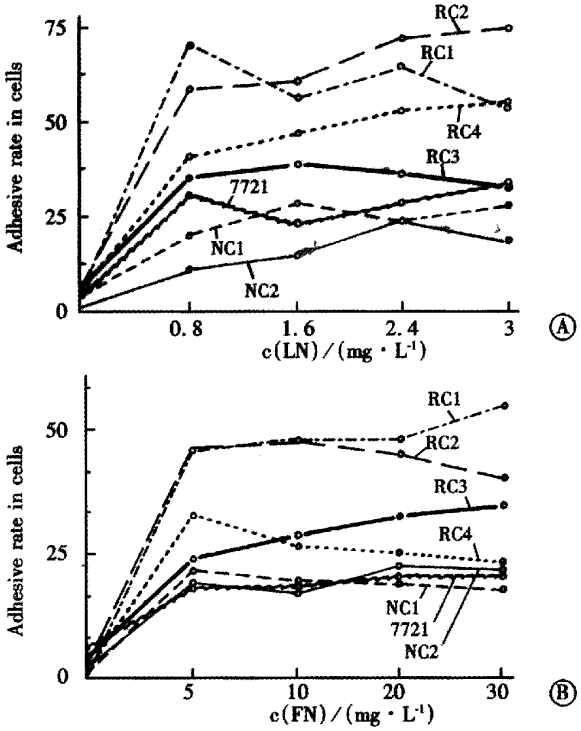

Figure 1 Attachment of different cell clones to LN or FN ($x \pm s_x$).
A: To increasing concentrations (0, 0.8, 1.6, 2.4 and 3mg·L^{-1}) of LN
B: To increasing concentrations (0, 5, 10, 20 and 30 mg·L^{-1}) of FN

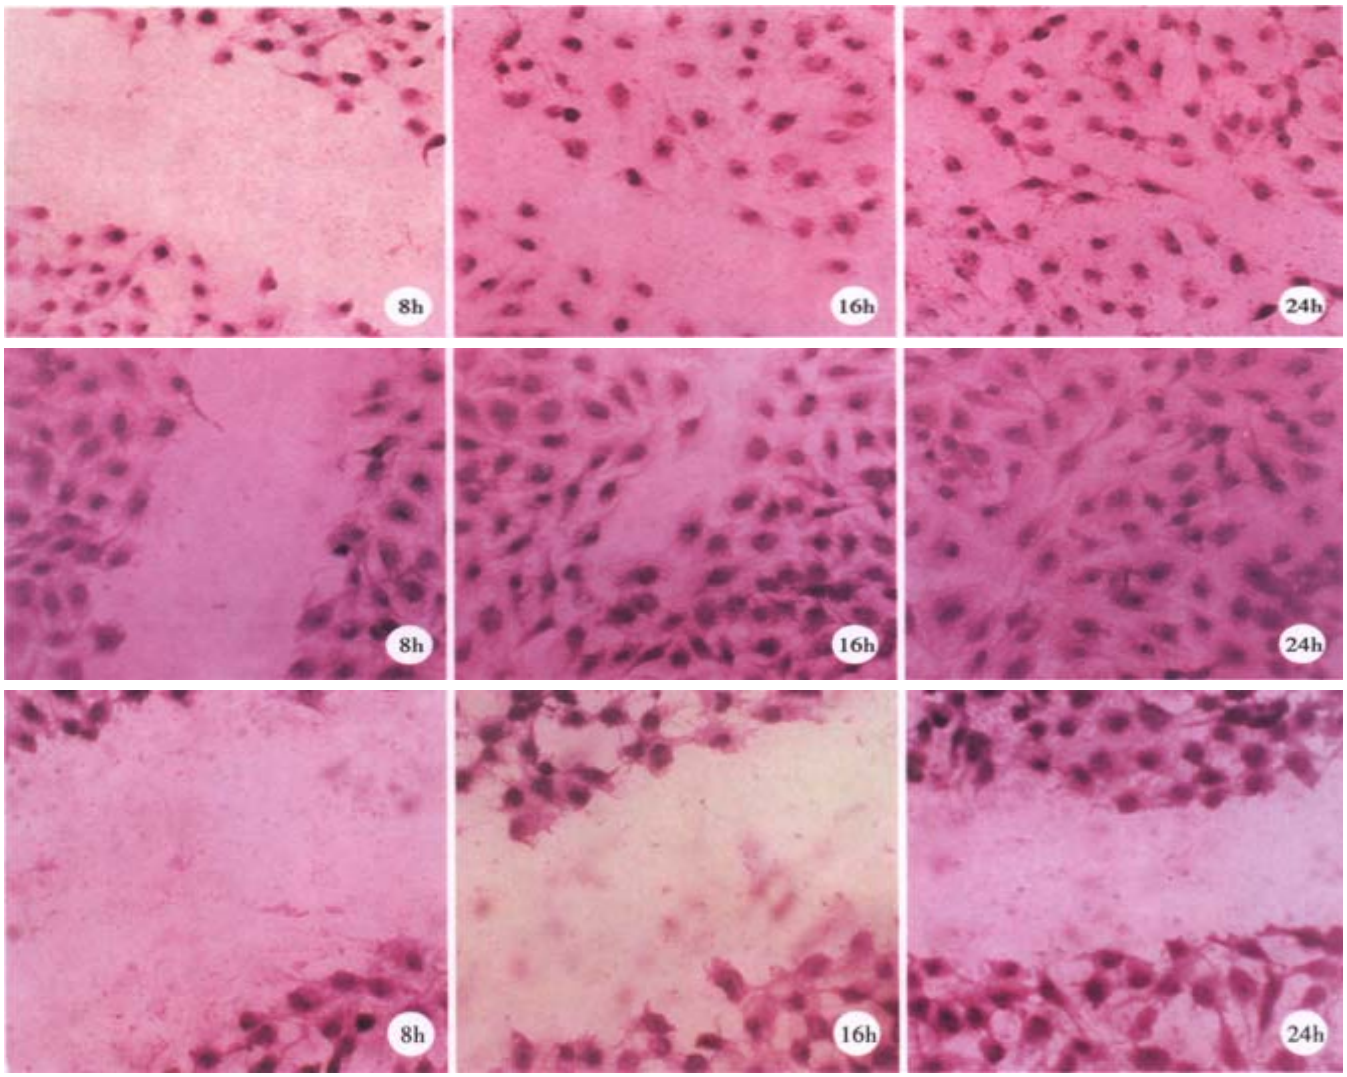

Figure 2 Migration ability of representative clones. Subconfluent monolayers of the clones were "wounded" at time 0. The cells were allowed to migration into the cell-free area for 24 h then fixed and stained with crystal violet.
A: RC_1; B: RC_2; C: SMMC 7721

Migration assay The migration of the different clonal lines was analyzed by using the "wound" system *in vitro*. Wounds of approximately4mm were made in subconfluent monolayers of the different clones and cells were allowed to migrate into the cell-free area over a 24 h period. Representative experiments using three clones are illustrated in Figure 2. The cell-free areas were filled up with cells within 24 h in the tests of RC_1-RC_4, but they still remained empty even after 24 h in the tests of SMMC 7721, NC_1 and NC_2.

Expression of c IV aes and EGFR The expressions of c IV aes and EGFR were significantly different before and after ras transfection (Table 1) and these alterations were consistent positively with the expression of p21.

DISCUSSION

The process of tumor invasion and metastasis can be divided into three steps at molecular level: adhesion, degration and migration. This consecutively complex process involves many kinds of cytokines, enzymes and cell surface receptors [26-29]. Ras gene has been implicated in these processes through the signal transduction pathway [30-42]. In malignant tumors, cell-matrix interactions are very important for tumor invasion and metastasis. LN and FN, major components of the basement membrane, are involved in several biologic activities. We investigated the adhesive abilities of H-*ras* transfected SMMC 7721 cells to LN and FN. The results showed that the adhesive abilities of different cell clones raised in different

degree. The reason that the adhesive ability of RC_3 to LN had no significant increase as against SMMC 7721, may be contributed to the heterogeneity of transfected clones. Some data have shown that the property of transfected clones is not expressed stably and that heterogeneity may develope during the growth of the clones. Experimental studies with several different tumors have suggested that the instability causing the heterogeneity of metastatic properties is due to a variety of genetic and epigenetic processes.

c IV ase is also associated with tumor metastasis[43]. It is considered that activated or overexpressed H-*ras* gene can induce the secretion and synthesis of c IV ase directly. Ura *et al* revealed that the transcription level of c IV ase gene was obviously higher in BEAS-2B cells transformed by H-*ras* gene than in their parent cells. The c IV ase secretion ability of these cells increased, and metastatic behavior *in vitro* was positively related to c IV ase secretion *in vivo*. Our results showed that the c IV ase expression level increased markedly following *ras*-transfection, the percentage of positively stained cells increased 2 to 5 times after transfection. It was indicated that oncogenic p21 ras may upregulate translational efficiency by activating the eukaryotic translation initiation factor 4E (eIF-4E), thereby enhancing the protein expression of ras-induciable genes.

EGFR is known to be interrelated with and interact on ras gene in cell signal transduction pathway[44-47]. It has some effects on tumor cell attachment, secretion of proteolytic enzymes, cytoskeleton structure and cell migration[48-52]. We found that the expression of EGFR in ras-transfected clones increased moderately, and the expressions of EGFR and c IV ase had definite relevance to p21 expression.

In summary, we have demonstrated that H-*ras* oncogene can induce the metastatic phenotype of human HCC cell *in vitro*, to raise its metastatic potential. The detections of some metastasis-related parameters, such as cell adhesion ability, migration ability, expressions of c IV ase and EGFR may have predictive value in the metastatic potential of HCC clinically.

Abstract

AIM In this study we investigated the relationship of the X protein of HBV and nuclear factor-κB (NF-κB) and the expression of NF-κB in human hepatocellular carcinoma tissues.

METHODS Immunohistochemistry SP method was used to detect the expression of NF-κB and the X protein of HBV in human hepatocellular carcinoma tissues of 52 cases. Gene transfection mediated by lipofectamine was used to transfect the eukaryotic expression vector pCDNA3-1-HBX of HBV x gene into human hepatocellular carcinoma cell line HCC-9204 and NF-κB was detected.

RESULTS NF-κB was widely expressed in human hepatocellular carcinoma tissues in a total of 52 cases and its expression was related to the X protein of HBV. NF-κB was localized both in the cytoplasm and the nuclei of hepatocellular carcinoma cells in 11 cases which were positive for the X protein of HBV while in 41 cases negative for the X protein of HBV, NF-κB was only localized in the cytoplasm of hepatocellular carcinoma cells but translocated to the nuclei of hepatocellular carcinoma cells after the eukaryotic expression vector pCDNA3-1-HBX was transfected into HCC-9204 cells.

CONCLUSION This study strongly suggests that the nuclear factor NF-κB is widely expressed in hepatocellular carcinoma tissues in different styles according to the expression of the X protein of HBV. NF-κB is abnormally activated in hepatocellular carcinoma, which is probably related to the X protein of HBV. The X protein of HBV can activate NF-κB to translocate into nuclei of hepatocellular carcinoma cells.

INTRODUCTION

Hepatitis B virus is closely related to human hepatocellular carcinoma, but the mechanism of HBV in tumorigenesis of hepatocellular carcinoma is still unclear. HBV-associated hepatocellular carcinoma is a dominant type in China. It is reported that the X protein of HBV plays a key role in the tumorigenesis of HBV-associated hepatocellular carcinoma and it participates in many signal tranduction pathway of hepatocellular carcinoma cells[1,2].

NF-κB was extensively studied since it was first found in 1986. It plays an important role in physiologic and pathologic conditions as an inducible nuclear factor. More than 60 proinflammatory genes involved in controling. The differentiation, immuno stimulation, apoptosis, chemoattraction, cell adhension, extracellular matrix degradation have been shown to be regulated by NF-κB[3].However, concerning the relatetionship of the X protein of HBV to the activation of NF-κB and the role of NF-κB in the tumorigenesis of hepatocellular carcinoma is unclean. In this study we investigated the expression of NF-κB in hepatocellular carcinoma tissues and its relationship with the X protein of HBV.

MATERIALS AND METHODS

Material

Human hepatocellular carcinoma cell line HCC-9204 was established by the Department of Pathology, the Fourth Military Medical University. 52 cases of hepatocellular carcinoma tissues were collected from on Department. The main reagents such as rabbit NF-κB p65 antibody was purchased from Sant Cruz Company. DNA random primer labelled reagent kit and ALLN inhibitor were purchased from Bornglinman Company. The primer of HBV x gene was synthesized by Shengon Biology Company in Shanghai. G418 were purchased from Promega Company. Lipofectamin was purchased from GIBCORL Company. Other reagents were bought from Zhongshan Company, Beijing.

Method

Detection of NF-κB in hepatocellular carcinoma

Immunohistochemistry SP method was used to detect the expression of NF-κB in 52 cases of human hepatocellular carcinoma tissues. The main steps

were as follows: ① Tissues were treated with 3% H_2O_2 methanol at room temperature for 30 minutes and then incubated in 5% goat antiserum for 30 minutes at 37℃. ② Rabbit anti p65 and HBX antibody were added to adjacent tissue sections respectively and incubated overnight at 4℃. The dilution of p65 and HBX were 1: 80 and 1:50. ③ Biotin labelled goat anti-rabbit IgG was added to the sections and incubuated at 37℃ for 30 minutes. ④ SP complex was added and then DAB-H_2O_2 was used for the colour reaction. The tissues sections were washed with PBS (0.01M, pH 7.4)between each step.

Gene transfection and selection The eukaryotic expression vector pCDNA3.1-HBX of HBV x gene and the empty vector pCDNA3.1 were transfected into human hepatocellular carcinoma cell line HCC-9204 respectively by gene transfection mediated by lipofectamine. The main steps were as follows. ① HCC-9204 cells were seeded in culture plate. A liquid (100 μL 1640 serum free medium containing 2 μg plasmid) and B liquid (100 μL 1640 medium free of serum containg 10 μL lipofectamine) were mixed at room temperature for 30 minues to form DNA-lipofectamine complex. ② HCC-9204 cells were washed with 2 mL 1640 serum free medium twice. The DNA-lipofectamine complex were diluted with 0.8 mL 1640 medium and added to cells. The cells were cultured at 37℃ 5% CO_2 condition for 5 hours. ③ These the cells were cultured in 10% vitulary serum for 72 hours. (4) Cells were cultured in the selective medium containing G418 700g·L^{-1} for 1 week, and then cultured in the selective medium containing G418 500g·L^{-1}. Untransfected HCC-9204 cells were cultured in the same selective medium as control test.

Detection of HBV x mRNA in HCC-9204 cell *In situ* hybridization was used to detect HBV x mRNA in the fourth passage of HCC-9204 cells which were transfected with the eukaryotic expression vector pCDNA3.1-HBX of HBV x gene. DNA probe was labelled by using DNA random primer method. Control experiment: HCC-9204 cells which were not transfected served as negative control. Empty controls were those without adding any probes. The main steps were as follows: ① The cells were fixed in 4% paraformaldehyde for 30 minutes and were digested in 25 g·L^{-1} protease for 5 minutes at 37℃. ② The forehibridization liquids were added to the cells for 2 hours at 42℃, and then the hybridization liquids were added to the cells at 42℃ overnight (the constitutions of the hybridization liquid was 50% mathane amide, 1 x Denharts liquids, 10% sulfuric acid dextran,0.5 g·L^{-1} herring DNA, probes labled with digoxin). ③ The cells were washed with 2 × SSC, 1 × SSC, and buffer 1 sequencesly. ④ Anti-digoxin alkaline phosphatase complex (1:500) diluted with 1% goat serum -0.3% Triton X-100 was added to the cells for 2 hours at room temperature and then washed with buffer 1 and buffer 3 respectivily. ⑤ Chromogenic liquids (100 μL buffer III,4.5 μL NBT, 3.5 μL BCIP) was added to the cells in the darkness and observed under microscope. Buffer IV was used to terminate the chromogenic reaction.

Detection of the X protein of HBV in HCC-9204 cell Immunofluorimetry was used to detect the X protein of HBV in the fourth passage of HCC-9204 cells which were transfected with pCDNA3.1-HBX or the empty vector pCDNA3.1. HCC-9204 cells untransfected served as the negative control. The main steps were as conventional. The dilution of HBx antibody was 1:50.

Detection of NF-κB in HCC-9204 cells Immunohistochemistry SP method was used to detect NF-κB in cells which were transfected or not transfected by HBV x gene. The dilution of rabbit p65 NF-κB is 1:80. The detailed steps were as the above.

RESULTS

Expression of NF-κB in hepatocellular carcinoma tissues

Immunohistochemistry SP method was used to detect the expression of NF-κB in 52 cases of hepatocellular carcinoma tissues. It was found that NF-κB was widely expressed in hepatocellular carcinoma tissues. The cells which were positive for NF-κB distributed diffusely. The cells used were hepatocellular carcinoma cells and the expression of NF-κB was closely related to the expression of the X protein of HBV. In 11 cases of hepatocellular carcinoma tissues which were positive for X protein of HBV, NF-κB was localized both in the cytoplasm and the nuclei of hepatocellular carcinoma cells, while in 41 cases of hepatocellular carcinoma tissues which were negative for X protein of HBV, NF-κB was localized only in the cytoplasm of hepatocellular carcinoma cells (Figures 1,2).

Expression of NF-κB in HCC-9204 cells which were transfected with the eukaryotic expression vector pCDNA3.1-HBX of HBV x gene

Gene transfection and selection Gene transfection which was mediated by lipofectamine was used to transfect the eukaryotic expression vector pCDNA3. 1-HBX of HBV x gene and the blank vector pCDNA3.1 respectively into HCC-9204 cells. The cells were cultured in the selective medium containing G418. Most of the cells died after 2 weeks, only a few anchorage-dependent cells grew clonely. All of the control cells untransfected died 2 weeks after they were cultured in the same condition. It was suggested that gene transfection were successful primarily.

Figure 2 Expression of NF-κB in hepatocellular carcinoma which is negative of the X protein.

Detection of HBV x mRNA in HCC-9204 cells *In situ* hybridization was used to detect HBV x mRNA in cells which were transfected with the eukaryotic expression vector pCDNA3.1-HBX of HBV x gene. It was shown that positive siganls were loacted in the cytoplasm of HCC-9204 cells, while the nuclei were negative. There was no positive signal in both cytoplasm and nuclei of HCC-9204 cells untransfected served as the negative control (Figure 3).

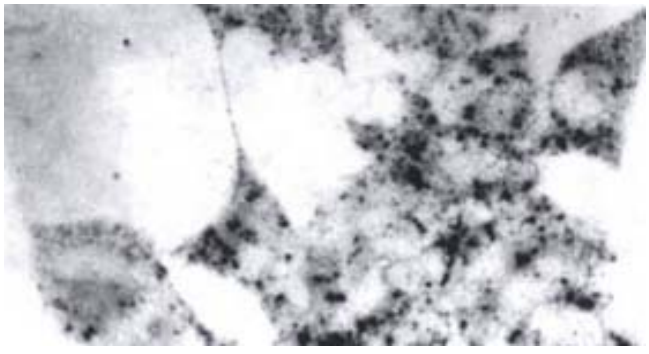

Figure 3 HBV x mRNA in HCC-9204 cells which were transfected with pCDNA3.1-HBX. (×400)

Detection of the X protein of HBV gene in HCC-9204 cells Expression of the X protein of HBV gene in the fourth passage of HCC-9204 cells which were transfected with pCDNA3.1-HBX or the blank vector pCDNA3.1 were detected by using immunofluorimetry. It was observed under fluorescent micrscope that the yellow-green fluorescence was localized in both cytoplasm and nuclei of hepatocellular carcinoma cells which were transfected with pCDNA3.1-HBX, but none in the cell not transfected (Figure 4).

Figure 4 X protein in HCC-9204 cells which were transfected with pCDNA3.1-HBX. (×400)

Expression of NF-κB in HCC-9204 cells which was transfected with eukaryotic expression vector of HBV x gene It was found NF-κB was localized in both cytoplasm and nuclei of hepatocellular carcinoma cells. NF-κB was localized only in cytoplasm of hepatocellular cells which were not transfected by the eukaryotic expression vector pCDNA3.1-HBX (Figures 5,6).

DISCUSSION

An estimated 300 million hepatitis B virus (HBV) carriers in the world are at an increased risk for the development of chronic active hepatitis (CAH), cirrhosis, and hepatocellular carcinoma[4]. HBV associated HCC is among the 10 most frequent cancers worldwide. At least 250 000 cases of HCC are diagnosed annually, less than 3% survive 5 years. The relative risk of HBV carrier developing HCC approaches 200:1, which is one of the highest relative risks known for human cancers[5,6]. Among the four proteins translated from the hepatitis B virus geneome, the x gene produt (the X protein) has drawn much attention for its role as a transacting factor for exploitation of the host cell machinery. Up to now, several significant discoveries had been made regarding the functions of the X protien, and from these studies, the X protein was established as essential in viral replication, HCC, and activation of certain signal transduction pathyway[7-11]. Although there is a cotroversy about the role of the X protein in viral replication, the x-gene product was shown to be required for the replicatiion of woodchuck hepatitis virus in animal studies, which were considered to reflect the *in vivo* phenomenon more precisely. Generally, it is believed that the X protein contributes to the generation of hepatocellular carcinoma. The X protein was reported to induce transformation of NIH3T3 cells. Forthermores, the development of HCC was observed in HBx transgenenic liver. The possible mechanism is based on the ability of the X protein to activate cellular signal transduction pathways. The X protein stimulates the ras /raf/mitogen-activated protein kinase cascade, leading to the activation of AP-1-dependent transcriptional activation[1,2]. In addition, c-Jun, N-terminal kinase were shown to be activated by the X protein[4,12-15]. Probably, through the combined actions of the above mechanisms, the X protein contributes to tumorigenesis[16-20]. In fact, the X protein has been shown to deregulate the cell cycle check point cotrols through the activation of ras.

Originally defined as the nuclear factor bound to the B site of the immunoglobin κ light chain gene enhancer in B lymphocytes[3], NF-κB is now known to be a family of dimeric transcription factors. NF-κB is ubiquitously expressed in non-B cells inactive form sequestered in the cytoplasm with specific inhibitory proteins termed IêBs[21-25]. NF-κB/Rel have been implicated in the inflammatory response and synthesis of adhesion molecule. When cells are stimulated by TNF-α and interleukin-1 (IL-1), I-κB proteins associated with NF-κB in the cytoplasm become phosphorylated, ubiquitinated, and degraded. Degradation of I-κB proteins frees NF-κB proteins, which then translocate into the nucleus, where they activate transcription[26-28]. Recently, it was demonstrated a role for the NF-κB/Rel family in survival of B lymphocytes. Downregulation of NF-κB/Rel activity induces apoptosis of normal and transformed murine B cells, whereas ectopic expression of c-Rel leads to survival of B lymphoma cells. Interestingly, mice lacking the p65 subunit of NF-κB displayed embryonic lethality, accompanied by massive liver apoptosis on the 15th and 16th days of gestation[29]. These findings suggest that expression of NF-κB/Rel activity in murine hepatocytes acts directly to promote survival of these cells and suggest that apoptosis observed in the hepatocytes of mice lacking relA is a direct effect of p65 deficiency[30,31]. In addition, many cells are resistant to stimuli that can induce apoptosis. The activation of the transcription factor nuclear NF-κB by tumour necrosis factor (TNF), ionizing radiation was found to protect from cell killing. Inhibition of NF-κB nuclear translocation enhanced apoptotic killing by these reagents but not by apoptotic stimuli that do not activate NF-κB[32-34]. Furthermore, NF-κB is also related to cell proliferation, transformation[35]. The abnorma activation of NF-κB was ralated to the tumorigensis of maglinant cancer, for example, in Hodgkin's lymphtoma, breast carcinoma and other cancers[36-50].

The X protein of HBV has been shown to be closely related to human hepatocellular carcinoma, but the relationship of the X protein of HBV and NF-κB and its role in the tumorigenesis of hepatocellular carcinoma, has not been elucidation. We firstly detected the expression of NF-κB in hepatocellular carcinoma tissues using immunohistochemistry SP method. It was shown that NF-κB was expressed diffusely in hepatocellular carcinoma tissues and its localization in cells was related to the expression of the X protein of HBV. In hepatocellular carcinoma tissues which was positive for X protein of HBV, the NF-κB was expressed in both cytoplasm and nuclei of hepatocellular carcinoma cells, whereas in hepatocellular carcinoma tissues which were negative for X protein of HBV, the NF-κB was expressed only in the cytoplasm of hepatocellular carcinoma cells. Gene transfection further indicated that the X protein of HBV could activate NF-κB translocate it to the nucleus.

This finding strongly indicated that there was abnormal activation of NF-κB in human hepatocellular carcinoma tissues which was probably related to the X protein of HBV. The X protein can activate NF-κB and translocate it to the nuclei from the cytoplasm of hepatocellular carcinoma cells. Gene transfection further demonstrated that the X protein of HBV can activate NF-κB. Activated NF-κB probably regulate the target gene transcription in the nuclei of hepatocellular carcinoma cells. The role of NF-κB in tumorigenesis of hepatocellular carcinoma was probably related to the cell cycle. Recently, it was reported that cyclinD1 is a target gene of NF-κB and activated NF-κB can initate the transcription of cyclinD1 and regulation of G_0/G_1 to-S phase transition. This led to loss of the normal regulation of cell cyccle and cell proliferation and

transformation.

In conclusion, NF-κB is abnormally activated in huamnn hepatocellular carcinoma, which is related to the role of the X protein of HBV, but the detailed mechanism of NF-κB in the tumorigensis of HBV-associated hepatocellular carcinoma worths further study. This study has important significance, because it sheds new light in revealing the role of the key nuclear factor NF-κB in the tumorigenesis of HBV-associated hepatocellular carcinoma from a new primt of view.

Abstract

AIM To evaluate antihepatoma effect of antisense phosphorothioate oligodeoxyribonucleotides (S-ODNs) targeted to alpha-fetoprotein (AFP) genes in vitro and in nude mice.

METHODS AFP gene expression was examined by immunocytochemical method or enzyme-linked immunosorbent assay. Effect of S-ODNs on SMMC-7721 human hepatoma cell growth in vitro was determined using microculture tetrazolium assay. *In vivo* antitumor activities of S-ODNs were monitored by measuring tumor weight differences in treated and control mice bearing SMMC-7721 xenografts. Induction of cell apoptosis was evaluated by fluorescence-activated cell sorter (FACS) analysis.

RESULTS Antisense S-ODN treatment led to reduced AFP gene expression. Specific antisense S-ODNs, but not control S-ODNs, inhibited the growth of heaptoma cells *in vitro*. *In vivo*, only antisense S-ODNs exhibited obvious antitumor activities. FACS analysis revealed that the growth inhibition by antisense S-ODNs was associated with their cell apoptosis induction.

CONCLUSION Antisense S-ODNs targeted to AFP genes inhibit the growth of human hepatoma cells and solid hepatoma, which is related to their cell apoptosis induction.

INTRODUCTION

Primary hepatocellular carcinoma (PHCC), one of the most common malignancies in the world, is an aggressive cancer. The mean survival time from establishment of the diagnosis is only about 4 months (2 months if the diagnosis is made late). It causes approximately 250 000 deaths annually. Although much less common in western Europe, the Americas, and Australia than elsewhere, PHCC is responsible for approximately 10 000 deaths per year in the United States. A number of strategies such as surgery, radiation, chemotherapy, and biological response modifiers have been applied for the treatment of PHCC, there is still no satisfactory method that can obviously improve the overall survival rate. Most of the treatment protocols are related to significant side effects and, at best, result in an overall median survival of 7-8 months[1]. Therefore, PHCC with a high fatality rate and short disease period has been one of the major health problems in the world.

Alpha-fetoprotein (AFP) is a major serum protein produced by the liver or yolk sac in fetal life in mammals and other vertebrates, and it is hardly detectable in normal adult life. However, AFP is often elevated to a significant level in association with development of PHCC, and has been defined as an oncofetal antigen[2]. Currently, AFP has become one of the most important markers in the diagnosis of PHCC[3]. The biological roles of AFP have been widely investigated. Two functions of AFP have withstood the test of time, i.e., the carrier-transport of various ligands and the regulation of certain aspects of the immune responses. AFP binds to a large variety of ligands such as fatty acids, estrogens and phytosteroids. The nature of AFP ligand(s) can orient cells toward multiplication or differentiation. The immunoregulatory activity of AFP is another important character. AFP has been found to inhibit T- cell-dependent mitogen responses and allogenic one-way mixed lymphocyte reaction[4,5]. AFP also suppresses the natural killer cell activity and induces suppressor T cells. AFP causes selective and rapid down regulation of monocyte major histocompatibility complex class II molecules. The immunological activities of tumor necrosis factor, interleukin-1, transforming growth factor, and interferon are also decreased by the treatment with AFP[6,7]. The concept of AFP as an immuno-

regulatory agent provides an attractive explanation for the immunologic tolerance during pregnancy, since the fetus may be considered an allograft in the mother's body. Furthermore, it is also conceivable that AFP may some day be employed to treat certain autoimmune disorders such as rheumatoid arthritis[8]. The third function of AFP, only recently described, is the regulatory control of cell growth. AFP synergizes growth factors such as epidermal growth factor and insulin like growth factor-I to cause a marked increase in the proliferation of porcine granulosa cells. Placental cells undergo increased proliferation *in vitro* in response to AFP. AFP has also been found to regulate the proliferation of human mammary tumor cells[9]. AFP can inhibit apoptosis in HL-60 human leukemia cells and AFP receptors may play a role in anti-cellular senescence.

However, the relationship between AFP and PHC is still far from clear. Our recent investigations indicate that human AFP can enhance the proliferation of mouse hepatoma H-22 and human hepatoma SMMC-7721, BEL-7404 or QGY-7703 cells *in vitro*[10-12]. Similar growth stimulatory effect of low concentrations of AFP has also been obtained in human hepatoma Hep G_2 cells. These results have an important implication that AFP may function as a hepatoma growth stimulator, thus suppression of AFP gene expression and its biological activities may become a new strategy for the treatment of AFP-associated tumors such as PHCC[13]. Antisense oligodeoxynucleotides can inhibit gene expression by forming RNA-DNA duplexes, thereby preventing mRNA translation and are now commonly used to investigate their role in the treatment of human malignancies, both *ex vivo* and *in vivo*[14]. In this study, we investigated the antiproliferative action of AFP antisense phosphorothioate oligodeoxyribonucleotides (S-ODNs) on an established SMMC-7721 human hepatoma cell line *in vitro*. We also evaluated the efficacy of AFP antisense S-ODNs in the treatment of human hepatoma xenografts growing in nude mice.

MATERIALS AND METHODS

Tumor cells and tumor implants

A previously characterized human hepatoma cell line SMMC-7721 derived from a male patient with liver cancer was used for the present studies. The cell line as monolayer cultures was maintained in RPMI-1640 medium supplemented with 10% heat inactivated new born calf serum, 100 units/mL of penicillin and 100 mg/L of streptomycin, at 37℃ in a 5% carbon dioxide atmosphere in a humidified incubator[15]. The culture medium was replaced with fresh medium every two to three days. The SMMC-7721 hepatoma cells were also employed for *in vivo* studies. The solid tumor was obtained by subcutaneous injection of 2.5×10^6 viable cells into the right flank of male Balb-c nude (nu/nu) mice. Subcutaneous implantation resulted in 100% tumor obtained by days 6-7 after tumor cell injection.

Synthesis of S-ODNs

S-ODNs complementary to the translational initiation region of AFP mRNA (antisense: 5'-ACTTCATGGTTGCTA-3', 15 mer; sense: 5'-TAGCAACCATGAAGT-3', 15 mer) were used in the present study[16]. They were with phosphorothioate residues in the last two linkages at each end of the oligomers. Oligo-dT15 having the same modifications as the sense or antisense S-ODNs was used for controls. These oligomers were synthesized by β-cyanoethyl-phospho-ramidite chemistry using a model 381 A automated DNA synthesizer, as suggested by the manufacturer. Deprotection and purification were carried out according to the protocol on the user's manual (Applied Biosystems).

Analysis of AFP gene expression

AFP gene expression in cells was determined by avidin-biotin-peroxidase complex immunocyto-chemical method. Briefly, adhesive cells were fixed in 4% paraformaldehyde. Rabbit anti-human antibody (Dako) was used as the first antibody, while normal rabbit serum served as negative control. The second antibody was biotinylated sheep anti-rabbit immunoglobulins. Final incubation was in rabbit avidin-biotin-peroxidase complex. All incubations were made at 37℃. The positive intensities of AFP in cells were analyzed with a Leitz MPV-3 microspectrophotometer and expressed as absorbance at 460 nm.

AFP content in the serum of nude mice bearing SMMC-7721 xenografts was evaluated by two-site sandwich enzyme-linked immunosorbent assay. Briefly, the mice were killed by cervical dislocation the second day after the final injection of S-ODNs and the serum samples from the animals in each group were collected. AFP-containing serum was pipetted into the relevant wells of antiserum-precoated microtiter plate. The plate was incubated at 37℃ in a humid chamber for 1 h after which it was washed three times. Antibodies to AFP, labeled with horseradish peroxidase, were added to each well at a concentration of 1 mg antibody/L. After a 45-min incubation at 37℃ with the antibody conjugate and subsequent washing, 0.001% hydrogen peroxide and O-phenylenediamine 0.4 g/L were added. The color development was stopped 15 min later at 37℃ by the addition of sulfate 4 mol/L. The absorbance of each well was measured at 492 nm using an automatic microplate reader. Standards of defined concentrations were run in each assay allowing the construction of a calibration curve by plotting absorbance *versus*

concentration. The AFP concentration in the serum was then calculated from this calibration curve and expressed into μg/L.

In vitro cell growth assay of established cell line

SMMC-7721 cells were seeded in the wells of 96-well culture plates. After 24 h, AFP antisense S-ODNs were added. Equimolar amounts of AFP sense and Oligo-dT 15 were used in control experiments. In this procedure, the culture medium was removed and the S-ODNs added directly to the cells for 30-60 seconds to facilitate uptake, whereafter the culture medium was added. Cell growth was determined using the microculture tetrazolium assay. Briefly, after culture, the cells were incubated with 800 mg/L 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (Fluka, Switzerland), which is used to assay the activity of mitochondrial dehydrogenases. Four hours later, 10% sodium dodecyl sulphate-5% isobutanol-0.12% hydrochloric acid solution was added to solubilize the formazan product. The plate was then incubated at 37℃ for another 12 h. The absorbance at 570 nm was measured with a model EL × 800 enzyme-linked immunosorbent assay automated microplate reader (Bio-Tek).

In vivo administration of S-ODNs

Blab/c male nude (nu/nu) mice, 6-8 weeks in age and 22 g-24 g in body weight, were purchased from the Tumor Biology Laboratories, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China. Mice were housed under pathogen-free conditions and given acidified, autoclaved water and a γ-irradiated commercial diet ad libitum. All manipulations were performed under sterile conditions in a laminar air flow hood. All procedures involving animals and their care were in accord with institutional ethical guidelines in compliance with national and international laws and policies. Each experimental group of mice included six animals. S-ODNs were dissolved in 50 μL sterile distilled water and administered 8 days after tumor cell implantation by injecting them directly into the tumor every 24 h for 8 consecutive days. Tumor weights were calculated from caliper measurements according to the previous method with the formula: tumor weight (mg) = length (mm) × width 2 (mm)/2. Antitumor activity of S-ODNs was assessed by using percent tumor weight inhibition, calculated by dividing the mean tumor weight of the treated group by the mean tumor weight of the control group, subtracting the resulting value from 1, and multiplying that value by 100. Toxicity was evaluated based on the apparent drug-related deaths and net body weight loss. Death in a treated mouse was presumed to be treatment-related if the mouse died within 7 days after the last treatment. Net body weight loss was calculated as a percentage of the mean net body weight of untreated mice.

Detection of cell apoptosis

Cell suspensions from *in vitro* cultures and tumor xenografts were used for fluoroescence-activated cell sorter (FACS) analysis. Cell sample preparation and propidium iodide staining for FACS analysis were performed according to the method reported previously. Briefly, the cells were fixed with 80% ethanol at 4℃ for 60 min. The ethanol-treated cells were washed twice with phosphate-buffered saline, pelleted by centrifugation and resuspended in a solution containing 50 mg/L propidium iodide and 100 mg/L RNase A. The percentage of apoptotic cells was determined by the fluorescence of individual cells measured by FACS flow cytometry (Becton Dickinson, San Jose, CA).

Statistical analyses

The experimental results summarized in Table 1 and the apoptosis data in Table 3 were analyzed by Student's *t* test for statistical significance. The statistical significance of AFP protein expression differences in Table 3 was evaluated using one-way analysis of variance. The results in Table 4 were analyzed by Mann-Whitney U-test for statistical significance. Differences were considered significant at P value <0.05.

Table 1 Specific inhibition of SMMC-7721 human hepatoma cell growth by alpha-fetoprotein (AFP) antisense phosphorothioate oligodeoxyribonucleotides (S-ODNs) *in vitro*

Concentration (μmol/L)	Hepatoma cell growth (absorbance at 570 nm)

Mice were treated the eighth day after tumor cell implantation with S-ODNs following different schedules. Untreated mice received normal saline only. *Time after S-ODN administration (day). Values in parentheses: percent inhibition. Each value represents mean ± SD of 6 samples. [a]$P<0.05$ (Mann-Whitney *U* test) compared with untreated mice and mice treated with sense S-ODNs.

RESULTS

In vitro studies

As shown in Table 1, when SMMC-7721 cells were exposed to AFP antisense S-ODNs for 48 h, the growth of the cells was significantly suppressed as compared with untreated cells. Moreover, the antisense oligomers showed concentration-dependent effect although not following a linear relationship. However, the inhibitory effect of the sense S-ODNs was much weaker than that of the antisense S-ODNs. No obvious inhibitory influence of Oligo-dT15 on SMMC-7721 cell growth was observed. The growth of unhepatoma HL-60 leukemia cells was not affected by the three above-mentioned oligomers (data not shown). It was suggested that the antiproliferative effect of the antisense S-ODNs may be due to a hybridization-based mechanism. In order to confirm it, a 10-fold excess of complementary sense S-ODNs was added to the culture system for 48 h. The obvious reversal of the SMMC-7721 cell growth inhibition of 10 μmol/L antisense S-ODNs was obtained by the hybridization competition. The addition of equal amounts of antisense and sense S-ODNs produced intermediate degrees of growth suppression (Table 2). The unmodified phosphodiester oligomers were not testable *in vitro* because of their poor stability in culture medium.

We examined AFP gene expression in SMMC-7721 cells by immunocytochemical method. The positive grains were found to diffuse throughout the cytoplasm of SMMC-7721 cells. Reaction products were visible in almost all the cells although in various amounts. In contrast, we could not detect positive grains when rabbit anti-human AFP primary antibody was replaced by normal rabbit serum. It is indicated that SMMC-7721 cells could express AFP protein. Similar results were obtained by using BEL-7404 human hepatoma cell line [17,18]. Treatment of SMMC-7721 cells with AFP antisense S-ODNs for 48 h markedly downregulated AFP protein expression. Downregulation of AFP protein expression by the antisense oligomers was specific, since the sense S-ODNs and Oligo-dT15 having the

same modification did not downregulate AFP protein expression (Table 3). The results obtained from HuH-7 human hepatoma cell line were similar. These data argue strongly that the growth inhibition of AFP antisense oligomers is likely caused by the sequence-specific blocking of AFP protein expression in SMMC-7721 cells. To determine whether the decrease in AFP protein expression was due to a downregulation of AFP gene expression induced by antisense S-ODNs and not merely related to the apoptotic status of the cell population, AFP protein expression was analyzed 6 h after S-ODNs treatment The results indicated that treatment with 25 μmol/L antisense S-ODNs resulted in an obvious inhibition of AFP protein expression, whereas no evidence of an increase in apoptosis was observed at this time point. The same concentrations of sense S-ODNs and oligo dT-15 had no effect on the AFP protein expression and hepatoma cell apoptosis (data not shown).

After exposure of exponentially growing SMMC-7721 cells to AFP antisense S-ODNs for 48 h, cells showed a hypodiploid DNA content indicative of apoptosis as determined by FACS analysis (Table 3). The presense of apoptosis was also confirmed by morphologic observation. It is concluded that SMMC-7721 cells are rapidly induced to undergo apoptosis by AFP antisense S-ODNs.

In vivo studies

Nude mice bearing SMMC-7721 tumors were treated with 0.25 and 0.5 mgS-ODNs per day for 8 consecutive days. As shown in Table 4, a marked decrease in tumor weight was observed after antisense S-ODNs treatment. Moreover, treatment with 0.25 mg per day proved less effective than treatment with 0.5 mg per day. No obvious toxicity was observed in mice receiving either 0.25 or 0.5 mg per day of antisense S-ODNs for 8 days.

In order to verify whether the antitumor effect observed *in vivo* was due to a specific antisense effect, AFP protein content in the serum of untreated mice and mice treated with S-ODNs was measured by using avidin-biotin-peroxidase complex method. The results indicated that treatment with AFP antisense S-ODNs decreased the AFP protein in the serum (Table 4). FACS analysis of the DNA content histograms of hepatoma cells from tumors of untreated mice revealed an accumulation in the hypodiploid region representative of about 40% of the cell population, indicating apoptotic cell death This cell death was expected, since the FACS analysis was performed when the tumors were at a late stage of growth (day 16 of growth). Similar levels of apoptosis were found in tumor cells from sense S-ODN-treated mice. Treatment with AFP antisense S-ODNs produced a marked increase of the percentage of apoptotic tumor cells to about 80% (Figure 1).

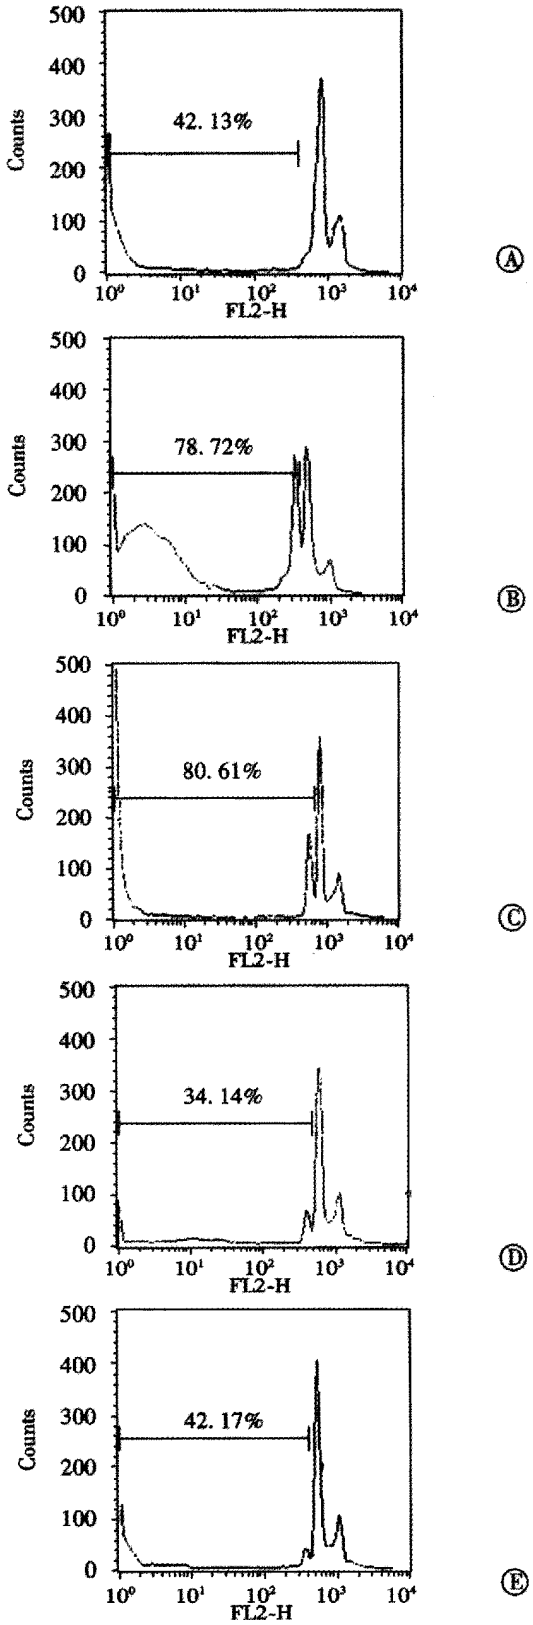

Figure 1 Effect of AFP antisense [S]ODNs on the *in vivo* induction of apoptosis. Representative fluorescence-activated cell sorter analysis of DNA content (propidium iodide fluorescence) in untreated (A), 2 mg antisense (B), 4 mg antisense (C), 2 mg sense (D) and 4 mg sense [S]ODN (E)-treated SMMC-7721 hepatoma cells. Apoptosis analysis of the cells was done by using tumor xenografts of nude mice treated with [S]ODNs for 8 days. Percentages indicate the proportion of cell population with a subdiploid DNA content.

DISCUSSION

Since AFP was found in the mid 1950s,this oncofetal protein has demonstrated clinical utility as a PHCC marker. But its biological activities in mammals have still remained an enigma. To date, only two functional roles of AFP (i.e., ligand / carrier transport and modulation of immune responses) have been ascertained. In the last decade, the growth regulatory properties of AFP have aroused interests as a result of studies involving ontogenetic and oncogenic growth in both cell cultures and animal models. Particularly, the effect of AFP administration on the development of experimental tumors in mammals has been investigated *in vivo* with the use of carcinogens. The influence of murine AFP on the threshold dose, mean tumor size, regression time, and number of progress or for moloney sarcoma virus-induced tumors in mice was studied. AFP-treated mice developed larger tumors, required a longer period for regression and had a significantly higher mortality. Furthermore, AFP, but not murine albumin or transferrin,allowed the growth of tumors when normally subthreshold doses of virus were injected. The effect of AFP could be abrogated by pretreatment with an anti-AFP antibody. AFP, but neither albumin nor transferrin, also accelerated the appearance of plasmacytomas. Chicken-AFP-treated quails developed tumors with shorter latent periods than those of the tumors that developed in untreated quails after inoculation with Rous sarcoma virus[19]. The *in vivo* tumor growth stimulation by AFP can be explained by its immunosuppression. Cell-mediated immunity is an important and central mechanism of host resistance to malignant neoplasms. Recently, we found that antihepatoma effects of AFP antisense S-ODNs were more significant in normal mice than in nude mice. Moreover, thymus weight of the normal mice was obviously increased after AFP antisense S-ODNs treatment (data not shown). It is suggested that there exists a relationship between AFP and the susceptibility of hepatoma cells to immunity-mediated cytotoxicity. If the effective immune system does not exist, however, can AFP still enhance the growth of tumor cells It was found that AFP stimulated, in a dose-dependent manner, human mammary tumor cell growth induced by platelet-derived growth factor *in vitro*; ablation of endogenous AFP by anti-AFP monoclonal antibody affinity chromatograph significantly reduced the proliferative activity of human mammary tumor cells. Recent studies indicated that AFP did directly stimulate the proliferation of hepatoma cells *in vitro*, independent of its immunosuppression. In the authors'view, AFP should be considered as a direct or indirect factor associated with tumor growth.

The precise relationship between AFP and PHC is not known. AFP was highly expressed in populations of hepatic oval cells during the early stages of carcinogenesis. These cells did not show the histological patterns that were diagnostic of trabecular hepatocellular carcinoma[20,21]. AFP-expressing hepatic oval cells in hepatocellular foci and nodules proliferating after carcinogenic treatment seem to be precursor cells of the hepatic carcinoma. On the other hand, high levels of AFP in the fully developed PHCC, or in the serum of the host, are associated with more aggressive behavior, and increased anaplasia[22]. The present study also demonstrated that AFP antisense S-ODNs are effective inhibitors of hepatoma cell growth *in vitro* and *in vivo*. Based on all the data, it is strongly inferred that AFP may play a role in the generation and development of PHCC.

The present results indicated that AFP antisense S-ODNs exhibited significant antihepatoma activities *in vitro* and *in vivo* by the sequence-specific blocking of AFP gene expression. AFP sense oligomers and Oligo-dT15 as controls had no or at least much weaker effects. Likewise, AFP antisense S-ODNs could also inhibit BEL-7404 human hepatoma cell proliferation *in vitro*[23,24]. We thus propose the possibility of suppressing human hepatoma proliferation by specifically decreasing AFP gene expression with antisense oligomers. The recent use of antisense oligomers as a therapeutic tool represents a newly established strategy for treating diseases[25]. Therefore, the successful designing of antisense S-ODNs for blocking the AFP gene expression in human hepatoma cells may not only further confirm the growth stimulatory effect of AFP, but also become an important therapeutic approach for PHCC[26]. However, the antitumor effects of AFP antisense S-ODNs were obtained at relatively high concentrations that might be difficult to achieve clinically for a number of reasons, among which are high cost and difficulties in the large-scale production of S-ODNs. Hopefully, the development of new generation ODN analogues or a more efficient delivery of S-ODNs, perhaps using liposomes as vehicles, will lead to therapeutic applications in humans. Thus this antisense therapy awaits further investigations[27,28]. And, antihepatoma therapeutic strategies relying on the use of AFP antisense S-ODNs may be enhanced by using these compounds in combination with other antitumor agents[24].

It is well-known that activation of an endonuclease in apoptotic cells results in extraction of the low molecular weight DNA following cell permeabilization, which, in turn, leads to the decreased stainability with DNA-specific fluorochromes. Thus, measurements of DNA content by FACS make it possible to identify

apoptotic cells. Using the FACS method, we have observed that AFP antisense S-ODNs induced apoptosis of SMMC-7721 hepatoma cells. Moreover, the presence of apoptotic cells has also been confirmed by morphologic observation. Therefore, although the mechanisms of antihepatoma action of AFP antisense S-ODNs are not fully understood, the induction of hepatoma cell apoptosis may be responsible for their growth-inhibitory effect.

Abstract

AIM To study the genetic alteration in ACF and to define the possibility that ACF may be a very early morphological lesion with molecular changes, and to explore the relationship between ACF and colorectal adenoma even carcinoma.

METHODS DNA from 35 CRC, 15 adenomas, 34 ACF and 10 normal mucus was isolated by means of microdissection. Direct gene sequencing of K-ras gene including codon 12, 13 and 61 as well as the mutation cluster region (MCR) of APC gene was performed.

RESULTS K-ras gene mutation frequency in ACF, adenoma and carcinoma was 17.6% (6/34), 13.3% (2/15), and 14.3% (5/35) respectively, showing no difference ($P>0.05$) in K-ras gene mutation among three pathologic procedures. The K-ras gene mutation in adenoma, carcinoma and 4 ACF restricted in codon 12 (GGT→GAT), but the other 2 mutations from ACF located in codon 13 (GGC→GAC). K-ras gene mutation was found more frequently in older patients and patients with polypoid cancer. No mutation in codon 61 was found in the three tissue types. Mutation rate of APC gene in adenoma and carcinoma was 22.9% (8/35) and 26.7% (4/15), which was higher than ACF (2.9%) ($P<0.05$). APC gene mutation in carcinoma was not correlated with age of patients, location, size and differentiation of tumor.

CONCLUSION ACF might be a very early morphological lesion in the tumorogenesis of colorectal tumor. The morphological feature and gene mutation status was different in ACF and adenoma. ACF is possibly putative "microadenoma" that might be the precursor of adenoma. In addition, the development of a subgroup of colorectal carcinomas might undergo a way of "normal epithelium→ACF→carcinomas".

INTRODUCTION

Colorectal cancer (CRC) is a complex pathological procedure in which multiple genes are involved during multiple steps. It is widely accepted that the order of "normal epithelium→hyperplastic epithelium→adenoma→cancer→cancer with metastasis" exists in majority of coloretal carcinoma[1,2]. The corresponding molecular order is demonstrated as follows: APC→altered methylation[3]→K-ras→MCC/DCC→P53. The activation of K-ras gene and inactivation of APC gene are frequent early events in the carcinogenesis of colorectal carcinoma[4-8]. Recent studies showed that aberrant crypt foci (ACF) is the earliest morphological lesion detectable in colorectal epithelium[9,10]. We studied CRC, adenoma and ACF with the aim to understand the relationship between ACF and colorectal neoplasm.

MATERIALS AND METHODS

General data of patients

Thirty-five CRC were obtained from an unselected cohort in which the patients underwent initial curative resection in 1999 in the Cancer Hospital of Fudan University. Twenty CRC occurred in men and 15 in women. The age of the patients ranged from 28 to 85 years. The median age was 54.2. Fourteen of 35 patients had their tumor in proximal colon, and 21 in the distal part of large intestine (including rectum). Macroscopically, 22 were ulcerative type with more endophytic extension and 11 showed exophytic growth (including rape flower like polypoid and nodal). Histologically, 6 were highly, 22 were moderately and 7 were poorly differentiated. Fifteen adenomas during the same time period were collected from 9 men and 6 women. In histological type, 5 were tubular, 6 tubular villous, and 4 villous adenoma. The macroscopically normal epithelium 5 cm apart from

the tumor site served as ACF study and that 10 cm at least apart from the primary tumor as normal control.

Identification of ACF and histological microdissection

Cryostat frozen sections (5 μm, stained with 0.1% methylene blue for 5 min) of epithelium 5 cm apart from the primary tumor were used for identifying ACF according to Shpitz and Gregorio *et al*[11-15]. ACF was determined by two qualified pathologists when the following features appeared: large crypts, tight arranging, dark and overlapping nuclei, dysplastic morphology, "saw tooth like" and elongated luminal surface, follicular distribution and no inflammation cells or lymph follicle (Figure 1). Ten slides of 8 μm from 10 normal epithelia, 34 identified ACF and 35 CRC were stained with methylene blue and subsequently microdissected under the dissect microscope (40 folds). Individual crypts from CRC, adenoma, ACF and normal epithelium were isolated with scalpels and transferred to the centrifuge tube for DNA extraction. One crypt or about 100 cells from each case were used for the study[16] (Figure 1).

DNA extraction of minimal amount tissue

Microdissected tissue samples were digested in 50 μL cell lysis buffer (0.5 M Tris-Cl, pH 8.9, 20mM EDTA, 10mM NaCl, 1% SDS), digested with proteinase K (500 mg/L) overnight at 37℃. Genomic DNA was purified using DNA extract kit (DX Biotech Co. Ltd., Shanghai). The precipitation was suspended in TE for using[17,18].

Primer design and PCR amplification

Computer PC gene analysis software was used and according to the study by Losi[19-23]. The primers for K-ras gene encompassing exon 1, 2, the primers for APC gene encompassing the mutation cluster region in exon 15 (codon 1263-1596) were designed. PCR products were checked in agarose gel for size confirmation. All primers and PCR protocols are listed in Table 1.

Table 1 Primers for K-ras and APC gene sequencing

Genes	Region	Codon	Size of PCR	AT	Sequence
K-ras	exon1	1-54	163	56℃	5-GACTGAATATAAACTTGTGG
					5-CTGTATCAAAGAAGTGTCCT
K-ras	exon2	31-84	161BP	54℃	5-GACTGTGTTTCTCCCTTCT
					5-GGCAAATACACAAAGAAAG
APC	15-A	1263-1393	390BP	54℃	5-GTGTAGAAGATACTCCAATA

					5-GGCTGGCTTTTTTGCTTTAC

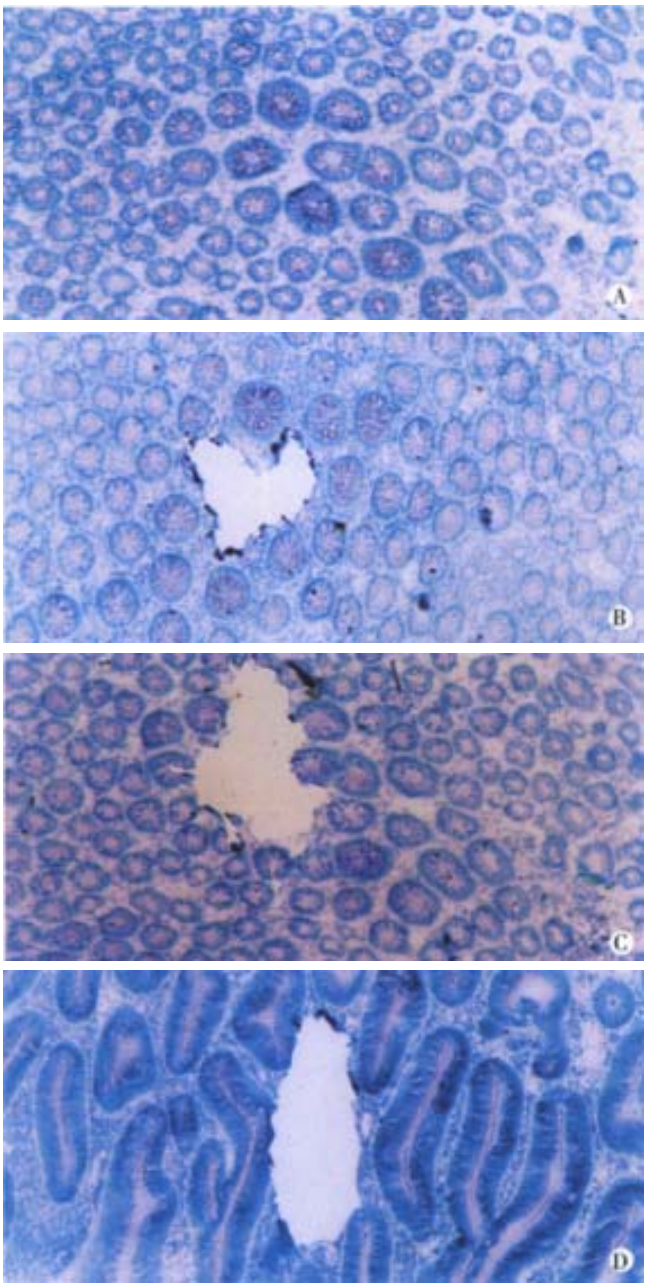

Figure 1 A. morphology of ACF; B-C. microdissection of ACF; D. microdissection of adenoma.

PCR products purification and sequencing

PCR products were purified with QIAquick PCR kit as described. Sequencing reaction was performed with Ready Reaction Kit from PE Company (96℃ 10"→55℃5"→60℃4', 25 cycles). The reaction product was precipitated in 100% ethanol (2.5 volume) and 3M NaAc (0.1 volume), and washed with 75% ethanol. The precipitation was resuspended in TSR (template suppression reagent), denatured at 94 ℃ and snap cooled at 4℃ before the automatic electrophoresis.

Statistical analysis

Chi-square study was used for the comparison between two groups.

RESULTS

K-ras gene mutation and its feature-Five of 35 (14.3%) carcinomas, 2 of 15 (13.3%) adenomas and 6 of 34 (17. 6%) ACF showed K-ras gene mutation. The mutation frequency was comparable among three types of tissues (P>0.05). No mutation was detected in normal epithelium. The mutation in carcinoma, adenoma and 4 ACF located at the second nucleotide of codon 12 (GGT →GAT). Two mutation in ACF located at the second nucleotide of codon 13, (GGC→GAC). The carcinoma and ACF patient No.30 shared the same mutation at codon 12. No mutation of codon 61 was found. K-ras mutation in carcinoma was related to the age and macroscopic type. The patients with mutation (median age of 70.8 years) were older than the patients without mutation (median age of 52.3 years) (P<0.01). Four out 5 carcinomas with mutation were polypoid carcinoma (P<0.05). All of 6 ACF with mutation were obtained from distal colon, most of their primary carcinomas showing polypoid (5 cases). The patients with mutation (median age of 68.4 years) in their ACF were older than that without mutation (median age of 43) in their ACF. This is coincident with the mutation in carcinomas. One of 2 adenomas with mutation was villous adenoma and another one was tubular adenoma (Figure 1).

APC gene mutation and its feature

Eight out of 35 carcinomas (22.9%) and 4 of 15 adenomas (26.7%) showed mutation in APC gene. The mutation frequency was close in two tissue types (P>0.05). Only 1 of 34 ACF showed mutation. APC gene mutation in carcinoma was not related to the age, gender, tumor site, macroscopic type and histological differentiation. All 8 mutations were scattered in region A (2 cases), region B (4 cases), and in region C and D (1 case), respectively. Among the 4 cases of adenomas with APC mutation, 2 were villous adenomas and other two were villous tubular adenomas; 2 mutations in region A, 1 in region C and 1 in region D. A mutation in region A was demonstrated in both ACF and primary carcinoma (Figure 2). APC gene mutations were displayed in Table 2. Altogether 13 mutations were detected in regions A →D of APC gene, 5 were stop codon, 1 was nonsense mutation, the other were point mutation.

Table 2 APC gene mutation

DNA	Region	Codon	Mutation	Amino acid exchange
N 3 CRC	A	1354	TTT→TTA	Phe→Leu
N17 CRC	A	1309	GAA→TAA	Stop cocon
N14 CRC	B	1389	TCT→TTT	Ser→Phe
N 5 CRC	B	1357	GGA→AGA	Gly→Arg
N21 CRC	B	1365	GGT→GGC	nonsense
N26 CRC	B	1398	AGT→ACT	Ser→Thr
N28 CRC	C	1465	GTG→GCG	Val→Ala
N33 CRC	D	1547	GAA→TAA	Stop codon
Tubular villous adenoma	A	1301	ins1 A	Stop codon
Villous adenoma	A	1309	GAA→TAA	Stop codon
Villous adenoma	C	1490	ins8 TTATTACA	Frame shift
Tubular villous adenoma	B	1367	CAG→CAC	Gln→His
ACF	A	1309	GAA→TAA	Stop codon

DISCUSSION

In 1987, Bird[24] established a mouse model of colorectal carcinoma by injecting F334 mouse with carcinogen AOM. He observed the changes of methylene blue stained large intestine mucus in different stages and found for the first time the earliest morphological change in normal colorectal mucus. Several or dozen aberrant crypts, scattering in the crypt level, were termed as aberrant crypt foci. It is recently reported that similar lesions exist in the human colorectal epithelium apart from the carcinoma[25-27]. The order "normal epithelium→ metaplasia→adenoma→carcinoma→carcinoma with metastasis" is widely accepted by most authors. APC and K-ras gene mutation is the early event in the carcinogenesis[28-30]. Our results revealed that normal epithelium showed no mutation, but K-ras gene mutation appeared in ACF, adenoma and carcinoma with a close rate (P>0.05), suggesting that K-ras mutation initiates in ACF stage and maintains during the process of the carcinogenesis. This demonstrates the possible relationship of ACF to carcinoma and ACF as a preneoplastic lesion in the carcinogenesis of colorectal carcinoma[31, 32]. K-ras gene point mutation at codon 12 and 13 endows the epithelium with transformation ability. All mutations in carcinoma and adenoma located at codon 12 (4/6), while 1/3 mutation (2/6) of ACF was found at codon 13 (GGC→ GAC). In the previous reports by American and European scientists, the K-ras gene mutation located both at codon 12 and 13, more frequently at codon

12[16,33-37]. Japanese and Chinese scientists reported the similar results as ours[22,38,39], the mutation in carcinoma limited in codon 12. The reason might be the difference in the genetic predisposition, the food, the environment and the pathogeny. The cell clone with mutation at codon 13 might have weaker clone selection and such cells have, therefore, weaker ability to expand themselves to grow out. ACF is reported to be located more frequently in rectum than in colon, more in distal than in proximal colon[40]. All 6 ACF with K-ras gene mutation in the current study located in distal colon, implying the same site of predisposition of colorectal carcinoma. ACF might be the earliest morphological lesion with detectable molecular genetic alteration in it.

APC gene was cloned, isolated and defined as a tumor suppressor gene in 1990. Germline mutation of the gene is responsible for the pathogenesis of familial adenomatous polyposis (FAP). Thirty-five sporadic CRC and 15 adenomas had similar frequent APC gene mutation in the MCR (P>0.05). It is coincident with previous report[41-45]. APC gene mutation was not correlated with age, tumor site, macroscopic type and histologic differentiation. This is identical to the previous demonstration that APC gene is involved very early in the carcinogenesis of sporadic CRC. There have been many reports about the APC gene mutation in sporadic adenoma. APC gene mutation occurred even in the adenoma <0.3 cm. The mutation was more frequently found in villous and tubular villous adenoma than in tubular adenoma. Our results support this documentation. Two of 4 adenomas with APC gene mutation were villous adenoma and 2 were tubular villous adenoma. The same mutation in codon 1309 (GAA→TAA) was found simultaneously in ACF, adenoma and primary carcinoma. This mutation was also found in other 4 of 15 adenomas. The mutation at codon 1309 is also the hot spot in Chinese sporadic colon tumors. Exactly alike the other reports, the mutation at codon 1301, 1309 and 1547 lead to stop codon. It is reported that the mutations cause most commonly truncation of the protein. The truncated protein binds to the wild type protein, causing a negative effect and decreasing their function as a tumor suppressor[46-48]. Because APC gene is too large to be wholly sequenced and the mutations scatter throughout over the gene, it is difficult for us with so less cases to find more mutation characterization of this gene.

ACF differ with adenoma in morphological and molecular level on the following points: ① ACF is surrounded by normal crypts, ② cells in ACF are not so dysplastic as that in adenoma, ③ mitosis is rare, ④ ACF is much smaller than adenoma, ⑤ APC mutation is rare, ⑥ mutation in K-ras gene at codon 13 is detectable. The above fact suggests the hypothesis that ACF is a preneoplastic lesion. The concept "microadenoma" could be used to describe such morphological lesion[49]. Nucci and Kobayashi have suggested that ACF could be added to the order: "normal epithelium→ACF→adenoma→carcinoma"[50-52]. Many studies demonstrated that K-ras gene mutation is induced by the APC gene mutation. We found in our study in contrast that 6/34 ACF displayed K-ras gene mutation. Only 1 out of 6 showed APC gene mutation. The possible interpretations are: ① not all K-ras gene mutations are induced by APC gene mutation, ② adenoma formation could occur in the basis of APC and K-ras gene mutation, ③ ACF formation is related to K-ras gene mutation but not to APC gene, ④ there might be another path of CRC. In addition, 27 of 34 CRC in our study were not accompanied with adenoma, but the ACF is proved to possess the same molecular alteration as in the primary CRC. We speculate that except the classical path of CRC, there might be another path "normal epithelium→ACF→carcinoma", without the stage of adenoma. More detailed molecular approach to understanding the role of ACF in this path is necessary.

Wu GH, Zhang YW, Wu ZH. Modulation of postoperative immune and inflammatory response by immune-enhancing enteral diet in gastrointestinal cancer patients. ***World J Gastroenterol***,2001;7(3): 357-362

Abstract

AIM To evaluate if the administration of an enteral diet supplemented with glutamine, arginine and ω-3-fatty acids modulates inflammatory and immune responses after surgery.

METHODS A prospective randomized double-blind, clinical trial was performed. Forty-eight patients with gastrointestinal cancer were randomized into two groups, one group was given an isocaloric and isonitrogenous standard diet and the other was fed with the supplemented diet with glutamine, arginine and ω-3-fatty acids. Feedings were started within 48 hours after operation, and continued until day 8. All variables were measured before operation and on postoperative day 1 and 8. Immune responses were determined by phagocytosis ability, respiratory burst of polymorphonuclear cells, total lymphocytes lymphocyte subsets, nitric oxide, cytokines concentration, and inflammatory responses by plasma levels of C-reactive protein, prostaglandin E2 level.

RESULTS Tolerance of both formula diets was excellent. There were significant differences in the immunological and inflammatory responses between the two groups. In supplemented group, phagocytosis and respiratory burst after surgery was higher and C-reactive protein level was lower ($P<0.01$) than in the standard group. The supplemented group had higher levels of nitric oxide, total lymphocytes, T lymphocytes, T-helper cells, and NK cells. Postoperative levels of IL-6 and TNF-α were lower in the supplemented group ($P<0.05$).

CONCLUSION It was clearly established in this trial that early postoperative enteral feeding is safe in patients who have undergone major operations for gastrointestinal cancer. Supplementation of enteral nutrition with glutamine, arginine, and ω-3 fatty acids positively modulated postsurgical immunosuppressive and inflammatory responses.

INTRODUCTION

Patients with gastrointestinal cancer frequently suffer from protein calorie malnutrition. This is due, largely to a systemic anorexia in conjunction with varying degrees of local anorexia in response to obstructive symptoms. In addition, the metabolic response to injury that is seen in these patients postoperatively produces a redistribution of endogenous macronutrients, causing further depletion of body fat stores and lean body mass. If the injury response persists and nutritional support is not instituted, pre-existing malnutrition will be exacerbated and the risk of postoperative complications as well as morbidity and mortality will be increased. It is well known that major surgery and other types of trauma are associated with severe alterations of the host defense mechanisms, making the patients highly susceptible to septic and inflammatory complications. Nutritional support after injury may modulate the immune, inflammatory, and metabolic responses, and the clinical outcome of critically ill subjects. In different experimental and clinical settings, enteral *vs* parenteral route, early *vs* delayed enteral feeding, and immuneenhancing enteral *vs* standard diets are related to better results[1-3]. Supplementation of enteral diets with glutamine, arginine and ω-3 fatty acids has been reported to improve clinical outcome after major operations and to reduce the risk of septic complications above and beyond the role of standard enteral formula[4].

The purpose of this study is to compare the effect of early enteral nutrition with immune enhancing enteral diet with standard diets on postoperative immune, inflammatory and metabolic response in a group of cancer patients. The endpoints of the study were the evaluation of the

immune response by polymorphonucler (PMN) cell respiratory burst and phagocytosis ability, total lymphocytes, lymphocyte subsets, nitric oxide (NO), and cytokines concentrations, the inflammatory response by C-reactive protein (CRP), α_1-1antitrypsin, fibrinogen levels, and prostaglandin E_2 level.

MATERIALS AND METHODS

Study protocol

In this prospective, randomized, and blinded study, 48 adult patients, aged between 34 and 75 years, with gastrointestinal malignancies, who were scheduled for major abdominal surgery due to their cancer, were included in the study. Exclusion criteria were clinical relevant alterations of the pulmonary, cardiovascular, renal, intestinal or hepatic function; history of recent immunosuppressive therapy (including preoperative radiochemotherapy) or immunological disease; ongoing infection; intestinal obstruction; or emergency surgery. The comparability of the groups is shown in Table 1.

Table 1 Characteristics in 2 groups of GI cancer

Characteristics	Supplemented (n = 25)	Control (n = 23)
Age / y	55.2±12.1	52.6±9.8
M / F	16 / 9	15 / 8
Site of cancer		
Stomach	14	13
Colorectum	8	7
Pancreas	3	3
Type of operation		
Gastrectomy (subtotal or total)	14	13
Miles or Dixon procedure	8	7
Pancreatoduodenectomy	3	3
Time of surgery / min	220±45	245±60
Operative blood loss / mL	400±325	450±400
Transfused patients	22	20

Patients were randomized to receive either an immuneenhancing enteral diets, Stresson (Nutricia; n = 25) or a standard diets, Nutrison (Nutricia; n = 23) supplemented with protein power to make the diets isonitrogenous. Table 2 summarizes the nutrient content of these diets. Enteral feeding was started within 48 h of operation via a needle catheter jejunostomy, or a nasoenteric tube, and was delivered by continuous pump infusion. The diets were started at half strength 50 $mL \cdot h^{-1}$, and all patients reached their nutritional goals by 72 h after the initiation of enteral nutrition. The goals of nutritional delivery in the study included 146 $kJ \cdot kg^{-1} \cdot d^{-1}$ and protein 2.2 $g \cdot kg^{-1} \cdot d^{-1}$. Patients had to receive enteral nutrition for a minimum of 7 days to be included in the study. All patients received intravenous fluid (50 $g \cdot L^{-1}$ dextrose and normal saline solution) and other electrolytes as indicated.

Table 2 Composition of Diets

Variables	Composition of formula (per 100 mL)	
	Supplemented	Control
Calories (kcal)	100	125
Protein (g)	4.00	7.50
Glutamine	0.40	1.30
Arginine	0.16	0.89
Fat (g)	3.89	4.17
LCT	3.89	2.45
MCT	0.00	1.72
EPA	0.00	0.079
DHA	0.00	0.030
*n*6:*n*3	5:1	3.45:1
â carotene (mg)	—	0.40 (66.70 μg RE)
Vit. E (mg TE)	0.81	4.92
Vit.C (mg)	5.00	13.30
Osmolarity (mOsm / L)	250	380

During the postoperative period, patients were evaluated prospectively for a number of symptoms: nausea, vomiting, abdominal cramping, abdominal distention, and diarrhea. Advanced the tube feeds or adjust the rates as the patients tolerate.

On admission, the following baseline variables were determined in all patients: plasma levels of glutamine, arginine, CRP, α_1-1antitrypsin, and fibrinogen. polymorphyonuclear (PMN) cell function, nitric oxide (NO), lymphocyte subsets (CD3, CD4 and CD8), natural killer cells, circulating cytokine level (IL-1, IL-2, IL-6 and TNF-α) and prostaglandin E-2 (PGE-2) level were also determined. Baseline variables were reassessed 1 day and 8 days after surgery.

Immune response assays

PMNs were separated on a sodium metrizoate and methylecellulose column by the method of Boyum and suspended in pHadjusted (7.2-7.4) Eagle's medium at a density of 5×10^9 cells$\cdot L^{-1}$. The oxidative metabolism of PMNs was assayed by measuring the superoxide production with nitroblue tetrazolium (NBT) red uction test[5]. The PMNs ability to phagocytose zymosan particle was detected as described by Brain. The degree of phagocytosis was expressed as percentage of PMNs in which zymosan particles were detected over a hundred PMNs. The production of NO by macrophages was measured by the Greiss reaction. This is an indirect colorimetric assay of NO. Greiss reaction consists of measurement of stable end breakdown products of NO such as nitrite which are considered to be reliable markers for NO formation.

The cytokines (IL-1, IL-2, IL-6, TNF-α) concentration in the supernatant were measured using commercially available ELISA kits. Total lymphocyte and lymphocyte subset were assayed by flow cytometry.

Inflammatory response assays

Prostaglandin E_2 (PGE_2) level in the supernatants were measured using the PGE_2 ^{125}I-scintillation proximity assay system. Plasma levels of CRP, α_1-

antitrypsin, and fibrinogen were measured with standard techniques.

Statistical analysis

Data were presented as the $\bar{x} \pm s$ and analyzed by analysis of variance (ANOVA) using Sigmastat software (Jandel Scientific, San Rafael, CA, USA). Statistical significance was predetermined as $P<0.05$.

RESULTS

The preoperative diagnoses and operations were similar between the two groups. At the time of entry into the study, there were no significant differences in nutritional state or type of disease, the age ranges were similar in both groups. There were no significant differences between groups in mean age, usual body weight, mean duration of operation, or the number of patients who received transfusions during the procedure or postoperatively (Table 1). Tolerance of both formula diets was excellent and there were no differences between the groups. No patient was withdrawn because of intolerance. Three patients in immune enhancing enteral diet group and two patients in the standard diet group developed diarrhoea.

Plasma arginine and glutamine levels are shown in Table 3, at baseline, there were no significant differences between the groups, but decreased1d after operation in both groups. After 7d feeding, the study group had a higher plasma levels of arginine and glutamine, but, in the control group, no variation was observed. As expected, plasma levels of PGE_2, CRP, α_1-antitrypsin, and fibrinogen were increased after operation in both groups. In patients receiving immune enhancing enteral diet, the levels of CRP were significantly lower than in the standard diet group over the 7d feeding. However, the levels of PGE_2, α_1-antitrypsin and fibrinogen had no significant differences between the groups at the end of study (Table 3).

Total lymphocyte and lymphocyte subset analyses are depicted in Table 4. At baseline, the study and control groups did not have significant numbers of total lymphocytes, T lymphocytes (CD3), T helper (CD4), T suppressors (CD8) or natural killer cells. A significant postoperative decrease in total lymphocyte, CD3, CD4 and natural killer cells were observed in both groups, but they recovered after 7 days feeding in the supplemented group. No significant difference was noted in CD8 cell numbers.

Circulating cytokine levels of IL-1, IL-2, IL-6 and TNF-α are displayed in Table 5. At baseline, there were no significant differences between groups. There was a significant postoperative decrease in all cytokines . After 7d of feeding, the absolute levels of IL-1 and IL-2 as well as the changes from baseline were not different. However, IL-6 and TNF-α concentrations were significantly lower in the group given immune enhancing enteral diet on postoperative d8.

The ability of PMNs to phagocytose zymosan particles is shown in Figure 1. Both groups had a similar baseline phagocytosis ability. A significant

decrease in phagocytosis was observed after surgery in the control group. Conversely, phagocytosis ability remained similar to the preoperative values in the study group. The PMN oxidative metabolism is shown in Figure 2. At baseline, there are no significant differences between the groups. A sharp postoperative increase of the oxidative metabolism compared with preoperative values was observed in both groups, the levels still remained higher in the study group than the control group (P<0.05). Figure 3 gives the variations of NO. The circulating levels of NO increased after operation in both groups, but, the study group had significantly higher NO levels than control group postoper atively (P<0.05).

DISCUSSION

Malnutrition in patients with cancer has been shown to have increased risk of postoperative complications. Effects to reduce the impact of malnutrition initially focused on the use of parenteral and enteral nutrition for perioperative nutritional support. Enteral feeding has gained popularity for the nutritional support of surgical patients. Biologically, there have been several reasons reported including better substrate utilization, prevention of mucosal atrophy, preservation of normal gut flora, gut integrity, and immune competence. Early enteral vs parenteral feeding in traumatized and surgical patients is gaining wide consensus after the promising results showing good tolerance and notable reduction of septic morbidity[1,6-9]. Our data confirm that early postoprative enteral feeding may be carried out safely in patients who have undergone major operations for cancer. Gastrointestinal side effects were minimal and were similar in both groups. Though diarrhoea, bloating, and abdominal cramps occurred, there were no major gastrointestinal complications in either group.

Current investigations in enteral nutrition have focused on the ability to modulate the metabolic and immune response to injury via specially formulated enteral diets. Specific nutrients shown to have the potential to modulate immune function include glutamine, arginine, and ω-3 fatty acids as well as nucleotides. These specialized diets have generally been termed “immuneenhancing diets” (IEDs). A number of recent studies have compa red IEDs with standard enteral diet in the management of patients with trauma, critically illness and cancer[3,10,11]. Although evidence appears to be accumulating in support of some clinical benefits for IEDs, the specialized diets used in most of these studies generally delivered more nitrogen and often more calories than the control “standard” diet, thus making it difficult to conclude that the beneficial effects noted were due to the special nutrient supplements. The current study was intentionally designed such that both groups of patients received isocaloric and isonitrogenous diets, and differed only in their glutamine and arginine content, fatty acid compositi on, and the levels of the antioxidant micronutrients vitamin C, E and carotene. Our purpose is to examine the influence exerted by the dietary supplements on postoperative immune, inflammatory and metabolic response in a group of cancer patients.

Both cellular and humoral immune function are compromised in patients undergoing operations for cancer. The immune suppression is a common phenomenon and seems to be related to both postoperative outcome and to diseasefree survival. There are many reports about the use of enteral nutrition during the early posto perative period to ameliorate immune dysfunction induced by the

tumor and operation[12]. Certain nutrients such as glutamine, arginine, and ω-3 fatty acids as well as nucleotides, may act pharmacologically on the immune system. It has been suggested that these nutrients may improve host immune defences[13-16]. Our data show that plasma glutamine and arginine levels were decreased 1d after operation in both groups. It is likely that glutamine uptake in certain tissues increase, and glutamine utilization may exceed endogenous glutamine production after injury. It is indicated that glutamine supplementation upregulates human immune cell number and function. Glutamine is critical for human lymphocyte proliferation in *in vitro* system. Our study demonstrated that enteral glutamine supplement ation could increase plasma glutamine concentrations, and might improve immune function.

Arginine is a semiessential amino acid which may become essential in catabolic states. Supplementation with arginine improved wound healing and enhanced immune function in animals by decreasing the T- cell dysfunction associated with injury. Additionally, arginine is a precursor for nitrates, nitrites, and nitric oxide . Nitric oxide is particularly important as a vasodilator but also participates in immunologic reactions, including the ability of macrophages to kill tumor cells and bacteria, and it may inhibit the development of precursor cytoloytic T- cells. In the present study, the increased NO levels observed 1 and 8 days after operation in the supplemented group may be a mechanism involved in the enhanced immune response early after surgery as shown by the improved phagocytosis ability and respiratory burst of PMNs.

Cytokines play a vital and integral role in both cellular and humoral immunity. The different mechanisms of action of the cytokines can be summarised as a coord inated immune response of the organism to exogenous or endogenous stimuli such as cancer, infection, injury, and operation. Measurement of cytokine concentrations may, therefore, give information about the immune response in patients after major operations. In this study, the mean IL-1 and IL-2 concentrations were only a slight but not significant difference between the two groups until the postoperative d8. The IL-6 and TNF-α concentrations were similar before operation and the first postoperative day in both groups, and they both showed a decline in IL-6 and TNF-α concentrations on the first postoperative day. Subsequently, IL-6 and TNF-α concentrations exceeded preoperative levels in the group that received the standard diet and kept rising as compared with the group given the supplemented diet, whose IL-6 and TNF-α concentrations remained below the preoperative values. As both IL-6 and TNF-α are important mediators of the acute phase reaction, it seems that systemic inflammatory responses were reduced in the group given the supplemented diet.

The acute phase reaction is a systemic inflammatory reaction to injury, including fever, tachycardia, leucocytosis, and changes in circulating protein concentrations. It has been proposed that injury promotes the switching of protein synthesis from constitutive to acute phase proteins through the release of proinflammatory cytokines such as IL-6 and TNF-α. In the present study, CRP levels significantly increased 1d after operation in both groups, but, this increase in patients receiving the supplemented diet was significantly lower than in the standard diet group after 7d feeding. A reduction in CRP concentrations may therefore be at least partly responsible for the lower postoperative levels of IL-6 and TNF-α in the group given the supplemented diet. ω-3 fatty acids, e.g., present in fish oils or canola oil, can replace arachidonic acid, which is derived from ω-6 fatty acids, in cell membranes and have modulating effects on immune function. Because the arachidonic acid metabol ite PGE_2 is known to inhibit the function of many immune cells, decreasing its generation by supplementing diets with ω-3 fatty acids would theoretically result in a relative enhancement of the immune response. Our data demonstrated that macrophage PGE_2 production increased after operation in both groups. However, there was no trend toward significance between the supplemented and standard diet groups on the d8 after operation, and it was an unexpected finding. Many of the immunosuppressive effects of the ω-6 fatty acids are found to be related to the immunosupp ressive prostaglandins, particularly PGE_2. It has been shown in previous studies that increasing the ratio ω-3 fatty acids in the diet effectively alters the monocyte/macrophage lipid membrane, decreasing the production of PGE_2. This decrease in immune inhibition thus should potentiate immune function. The normal to increased level of PGE_2 seen in the monocytes from supplemented diet group represents several alternatives. It is likely that the nutritional fat source used in the present study was not an effective source of ω-3 fatty acids. The duration of feeding might be insufficient to induce the changes in cell membrane fatty acids necessary to alter PGE_2 production. Alternatively, arginine or other contents of the supplemented diet may differentially affect PGE_2 production. Higher PGE_2 levels may be a counterregulatory phenomenon that results from an autocrine effect of the higher levels of cytokines produced by these monocytes.

The heterogeneity of T lymphocytes responsible for cell-mediated im munity is well known. There are two major types of T cells; CD4 cells recognize antigens associated with major histocompatibility complex (MHC) class II molecules, whereas CD8 suppressor cells recognize antigens associated with

MHC class I molecules. CD4 T cells play an important role in immunoregulation, and CD8 cells provide an inhibitory function, suppressing cellmediated immune responses. In the present study, supplemented diet improved immune response in surgical patients as demonstrated by increase in peripheral mature total lymphoc ytes, T lymphocytes, Thelper cells, and NK cells. Alterations in the number and ratio of the various Tcell subsets may subsequently influence the effectiveness of the overall immune response.

bstract

AIM To observe the inhibition of antisense oligonucleotides (asON) phosphorthioate to the tissue inhibitors metalloproteinase-1 (TIMP-1) gene and protein expression in the liver tissue of immunologically induced hepatic fibrosis rats. The possibility of reversing hepatic fibrosis through gene therapy was observed.

METHODS Human serum albumin (HSA) was used to attack rats, as hepatic fibrosis model, in which asONs were used to block the gene and protein expressing TIMP-1. According to the analysis of modulator, structure protein, coding series of TIMP-1 genome, we designed four different asONs. These asONs were injected into the hepatic fibrosis models through coccygeal vein. The results was observed by RT-PCR for measuring TIMP-1 mRNA expression, immunohistochemistry and in situ hybridization for collagen I, III, special staining of collagen fiber, and electron microscopic examination.

RESULTS Hepatic fibrosis could last within 363 days in our modified model. The expressing level of TIMP-1 was high during hepatic fibrosis process. It has been proved by the immunohistochemical and the electron microscopic examination that the asON phosphorthioate of TIMP-1 could exactly express *in vivo*. The effect of colchicine was demonstrated to inhibit the expressing level of mRNA and the content of collagen I, III in the liver of experimental hepatic fibrosis rats. However, the electron microscopy research and the pathologic grading of hepatic fibrosis showed that there was no significant difference between the treatment group and the model group ($P>0.05$).

CONCLUSION The experimental rat model of hepatic fibrosis is one of the preferable models to estimate the curative effect of anti-hepatic fibrosis drugs. The asON phosphorthioate of TIMP-1 could block the gene and protein expression of TIMP-1 in the liver of experimental hepatic fibrosis rats at the mRNA level. It is possible to reverse hepatic fibrosis, and it is expected to study a new drug of anti-hepatic fibrosis on the genetic level. Colchicine has very limited therapeutic effect on hepatic fibrosis, furthermore, its toxicity and side effects are obvious.

INTRODUCTION

In China, the incidence of liver cirrhosis is still high for quite a long period in the future[1-5]. The pathological basis of hepatic cirrhosis is fibrosis[6-14]. Many factors inducing liver injury and inflammation will lead to chronic liver disease, and hepatic fibrosis is inevitable[15-25]. Researchers have paid more attention to reversing the hepatic fibrosis[26,27].

Recently, studies on the role of tissue inhibitors of metalloproteinase-1 (TIMP-1) and tissue inhibitors of metalloproteinase-2 (TIMP-2) in the process of hepatic fibrosis have attracted more attentions[28-33]. The main aim of our study is to seek for an approach of reversing hepatic fibrosis, to investigate the role of TIMPs in the pathogenesis of hepatic fibrosis and to observe the fluctuation of TIMPs in patients with various liver diseases in order to set up a new laboratory diagnotic index of hepatic fibrosis. It had been considered as the target gene and the antisense oligonucleotides (asON) phosphorothioate was used to inhibit the gene and

protein expressing in experimental rat hepatic fibrosis.

In 1973, Miller *et al*[34] reported that non-ionic oligonucleotide and its derivant could specifically inhibit cellular DNA/RNA replication, transcription, translation. In 1978, Stepherson *et al*[35] obtained favorable anti-virus effect in infected fibroblast by Rous sarrcoma virus using 13-polyoligonucleotide. Since then attention has been made to the studies of the application of antisense oligonucleotide technology in antineoplastic and antiviral therapy[36,37]. This technology has been carried out under clinical trial stage[38-40]. In present study, we attacked the rats with HSA in order to establish experimental immune hepatic fibrosis model, and tried to block the gene and protein expression of TIMP-1 in rats with asON, so as to investigate the possible mechanism of reversing hepatic fibrosis.

MATERIALS AND METHODS

Design and synthesis of antisense oligonucleotide

According to the whole TIMP-1 cDNA sequence in rats[41], we analysed the sequences of modulator, structural protein and coding region and then designed four different antisence oligonucleotide as follows:

DNA Seq1 5'-GGCGCCATCGTGGTATCTGC-3'
Seq2 5'-GCTCTAGCGTGTCTCTAGGA-3'
Seq3 5'-GATAAACAGTGTTCAGGCTTC-3'
Seq4 5'-GTTCAGGCTTCAGCTTTTGC-3'

Twenty-polyligodeoxyribonucleotide phosphorthioate was automatically synthesized by the 391A PCRMATE EP DNA synthesis machine (ABI Company, USA). AsON was modified by phosphorthioate using TETD/acetonitrile method and purified by high-performance thin layer chromatography (purity>99%), which was accomplished by Wang SQ and Wang XH (Chinese Academy of Military Medical Sciences).

Animal experiment

Forty healthy adult female Wistar rats, weighing 120 g-150 g (provided by Experimental Animal Center of FMMU), were employed in the study. Immune hepatic fibrosis rat model was produced by immunological attacking with HSA, a method introduced by Wang *et al*[42]. Anti-mouse monoclonal antibody IgG was bought from Coulter Company (France).

The animals survived from the experimental attack were randomly allocated as follows. Model group: animals with hepatic fibrosis did not receive any interventional factors. Treatment group: animal models in this group received colchicine (0.28 $mg \cdot kg^{-1}$) treatment, six times a week, lasting 3 months. Experimental group: animals in this group received asON phosphorthioate through coccygeal vein injection (20 $\mu g \cdot g^{-1}$), every other day, 15 times in all. Control group (normal group): animals in this group were injected with same quantity of N.S. Three months after the beginning of injection, all animals were killed under narcosis, and their liver samples were kept in N_2, 100 $mL \cdot L^{-1}$ formalin or glutaraldehyde for designed investigations.

Detection parameters

Pathologic observation Some hepatic sections were stained with hematoxylin and eosin, while other sections for *Von Gieson* and *Masson* special staining.

Transmission electron microscope The liver samples were fixed with glutaraldehyde, and examined with electron microscope.

Immunohistochemical staining of TIMP-1 The liver samples were embedded with paraffin, and serial sections at 4 μm thickness were prepared. SP immunostaining was performed as described by streptomycin avidin-peroxidase immunochemistry kit (purchased from Maxim Biological Technology Company). Paraffin was removed from the sections with xylene and rehydrated with graded ethanol. After repairing the antigens, nonspecific binding sites were blocked by a 20 min preincubation with 100 $mL \cdot L^{-1}$ normal human serum. The sections were incubated with monoclonal antibody against TIMP-1 at 4℃ overnight, and then secondary antibody at 37℃ for 30-40 min, avidin-peroxidase at 37℃ for 20 min, finally added DAB to be colorated. After several washings, the sections were counterstained with hematoxylin, dehydrated with ethanol, rinsed in xylene, and the sections mounted with gum for microscopic examination and photography.

Immunohistochemical staining of collagen I, III Immunohistochemical kits of collagen I, III were purchased from Bo-Shi-De Biological Technology Limited Company (Wuhan, China). The numbers of antibodies of collagen I, III were BA0325, BA0326 respectively. The immunostaining was performed as described by the kit.

Procollagenase I, III *in situ* hybridization We used digoxin-labeled probes to detect the mRNA expression of procollagen I, III. The *in situ* hybridization kit was purchased from Bo-Shi-De Biological Technology Limited Company (Wuhan, China, No. MK1171). *In situ* hybidization was performed according to the manufacturer's directions. Briefly, the paraffin embedded serial sections(thickness 4 μm), were dried at 80℃, paraffin was then removed by xylene and

rehydrated in graded ethanol. The sections were acidified in HCl for 30 min, and blocked in 300 mL·L^{-1} 3 mL, H_2O_2, for 10 min before digestion in proteinase K for 30 min, and then dehydrated with graded ethanol. After prehybridization at 37℃-40℃ for 2 h, the labeled cDNA probes were denatured in hybridization buffer at 95℃ for 10min,then -20℃ for 10 min, added on tissues which had been prehybridized at 37℃ overnight. Sections were washed with 2 × SSC, 1 × SSC, 0.2 × SSC, added Buffer I, and blocking water at room temperature for 20 min, and then rabbit anti-digoxin at 37℃ for 60 min, biotinylated goat anti-rabbit at 37℃ for 30 min, SABC at 37℃ for 30 min, finally added DAB to be colorated. After several washings, the sections were counterstained with hematoxylin, dehydrated with ethanol, rinsed in xylene, and mounted the sections with gum for microscopic examination and photography.

Image pattern analysis and data processing After gray scale scanning and quantification the statistical analysis was performed. Comparison among groups was analyzed by *t* test, and the *P* value was used to judge the significant difference.

Detection of TIMP-1 by PCR method

The PCR primers of TIMP-1 are listed in Table 1.

Table1 TIMP-1, β-actin primer sections

	Primer	Nucleic acid sections	Position (bp)
TIMP-1	Positive strand	5'-TTCGTGGGGACACCAGAAGTC-3'	
	Antisence strand	5'-TATCTGGGACCGCAGGGACTG-3'	482
β-actin	Positive strand	5'-GGAGAAGATGACCCAGATCA-3'	
	Antisence strand	5'-GATCTTCATGAGGTAGTCAG-3'	234

RNA extraction The total RNA of liver was extracted with total RNA isolation system (produced by Promega Co.).

PCR amplification PCR was performed in 20 μL reactive volume containing 2 μL cDNA, 2 μL 10 × PCR buffer, 2 μL (2 mmol·L^{-1}) 4 × dNTP, 10 mmol·L^{-1} primer (2 μL TIMP-1, 2 μL β-actin), and 1U Taq DNA polymerase. The samples were subjected to 30 thermal cycles of 2min at 97℃ for predenaturation, 30s at 94℃ for denaturing, 30s at 56℃ for annealing, 50s at 72℃ for extension, and 7 min at 72℃ for final extension after the last cycle.

Quantitative analysis of PCR product Ten μL samples of PCR product was subjected to electrophoresis in 20 g·L^{-1} agarose gel with TAE buffer at 50V for 1h. After colorating with ethidium bromide and image forming, the quantitative analysis was performed. TIMP-1/ β-actin quotient is the indication of TIMP-1 expression level.

Pathologic grading of hepatic fibrosis

The pathologic grading of hepatic fibrosis used in our present paper was reported by Wang *et al*[43].

0: Normal liver without hyperplasia of collagenous fibers.

I: Slight extension of collagenous fibers from portal area or central veins.

II: Remarkable extension of collagenous fibers, without connecting each other and encysting the whole hepatic lobules.

III: Remarkable extension of collagenous fibers, connecting each other, and encysting the whole hepatic lobules.

IV: The hepatic lobules are encysted and separated by collagenous fibers. The normal structure of hepatic lobules is destroyed. The pseudolobules are formed, and it is dominant by big-square pseudolobuli.

V: The structure of hepatic lobules is fully destroyed, and the big square pseudolobules and small round ones occupy 50% respectively.

VI: The small round hepatic lobuli occupy almost the whole liver and the hyperplatic thick collagenous fibers are visible.

RESULTS

TIMP-1 immunohistochemical results

Image pattern analysis showed that the positive density value of the model group was the highest, and the colchicine treatment group was in the second place. There is no significant difference (P>0.05) between the above-mentioned two groups, and the density value of the experimental group is low (P<0.001, Table 2, Figures 1,2).

Table 2 Expression of TIMP-1 related antigen in the liver of rats

Group	*n*	TIMP-1
Normal group	10	59.8±20.3
Experimental group	6	98.7±25.7
Treatment group	6	396.1±58.4
Model group	6	481.1±61.0

The gene expression level of TIMP-1

The gene expression level of the model group was the highest, and the colchicine treatment group was the next. There was no significant difference (P>0.05) between the two above mentioned groups. The gene expression level of the experimental group was low (P<0.001, Table 3).

Table 3 Gene expression of TIMP-1 in the liver of rats

Group	*n*	TIMP-1
Normal group	10	0.3±0.1
Experimental group	6	0.6±0.1
Treatment group	6	1.7±0.4
Model group	6	1.9±0.5

Immunohistochemical study of collagen I, III

The hepatic content of collagen I, III of all the experimental animals was remarkably higher than that of the normal control group ($P<0.05$, $P<0.001$). Moreover, in all experimental animals, the hepatic content of collagen I, III of the model group was the highest, but that in the experimental group was the lowest (Table 4, Figure 3).

Table 4 Collagen I, III in the liver of rats

Group	*n*	Collagen I	Collagen III
Normal group	10	62±17	100±19
Experimental group	6	165±47	349±48
Treatment group	6	314±65	516±72
Model group	6	441±87	699±102

mRNA expression of procollagen I, III

There was distinct decrease of procollagen I, III expression in the liver of rats of the experimental group, it was significantly different compared with the model group ($P<0.05$). But there was no statistical difference (Table 5), between the experimental group and the treatment group.

Table 5 mRNA expression of procollagen I, III in the liver of rats

Group	*n*	Procollagen I	Procollagen III
Normal group	10	245.6±88.7	228.3±57.5
Experimental group	6	917.9±206.9	1050.9±271.4
Treatment group	6	896.8±198.1	977.8±221.4
Model group	6	1217.3±202.9	1484.5±249.1

Pathologic grading of hepatic fibrosis

From Table 6, we can see the significant difference of pathologic grading between the control and other groups ($P<0.05$, $P<0.001$). The pathologic grading status was better in the experimental group than that in the treatment group (Figures 4,5). There was no significant difference between the treatment group and the model group.

Electron microscopic observations

The activated hepatic stellate cell (HSC) and surrounding collagen fibers in the experimental group and the treatment group were observed. Neither deposition of collagen at the portal area in the experimental group, nor a lot of collagen deposition at the portal area were found in the treatment group. Compared with the model group, there was little change in the treatment group (Figure 6).

DISCUSSION

Nucleic acid complemented with DNA/RNA of genome is called antisense nucleic acid, including antisense DNA, antisense RNA, and ribozyme. According to the complementary principle, oligonucleotide can specifically bind to DNA/RNA of genome, therefore, the replication, transcription, translation of definite gene will be specifically inhibited and blocked. Such oligonucleotide is called antisense oligonucleotide (asON)[44]. AsON has the advantage of specificity, high potency and easy to be synthesized artificially. If asON is properly modified, it is possible to enhance the penetrating power, stability and bioavailability. Therefore, the purpose of this study mainly focused on exploring a possible way of reversing hepatic fibrosis and try to manufacture a new drug for anti-hepatic fibrosis through specifically inhibiting the gene and protein expression of TIMP-1 by asON phosphorthioate.

In our study, the expression level of TIMP-1 in the injured liver was found, and the expression appeared early with a major amplitude, especially in hepatic fibrosis and cirrhosis. The promoting effect of TIMP-1 in hepatic fibrosis and cirrhosis is stronger than TIMP-2[45-50], and 38% sequences of TIMP-2 are identical with TIMP-1, 12 cysteines of TIMP-2 are situated at the same sites, having similar spatial structure with TIMP-1, but they are non-glycosylated. There is no cross immunity reaction between TIMP-1 and TIMP-2[51-56]. TIMP-1 was chosen as the target gene. In our study, we found that the expression of TIMP-1 in the model group was four times higher than that in the normal control group. However, after asON phosphorthioate was injected through coccygeal vein, the gene and protein expression of TIMP-1 was remarkably lower than those in the other experimental groups ($P<0.001$). This result was demonstrated by the detection of TIMP-1 in liver by the immunohistochemical method and PCR. Our study clearly indicate that the asON phosphorthioate can be expressed *in vivo*, and is able to block the gene and protein expression of TIMP-1 in experimental hepatic fibrosis rats so as to enable the reversion of hepatic fibrosis.

In healthy human liver, the collagen type I, III accounts for about 80% of the total collagen of liver, while it rises up to more than 95% in fibrotic livers. The collagen type I covers about 60%-70% of the total collagen of fibrotic livers, and type III only 20%-30%[57-60]. MMP-1 is the main protease which can be inhibited by TIMP-1. Collagen I, III is the main target of MMP-1. MMP-1 has similar capacity of degrading collagen I, III. Therefore, collagen I, III are regarded as the important parameters to reflect the metabolism of collagen. Through the observation of the quantity of the collagen, we can judge the therapeutic effect of the anti-fibrotic drugs of the liver[61-63].

It was found that, in a same experimental animal treated with a same factor, the change of the hepatic content of collagen I, III showed a high uniformity ($r = 0.904$, $P<0.01$). The hepatic content of collagen I, III was lower in the experimental group (treated with as ON) and the treatment group with Colchicine than that in the model group. This suggests that the therapeutic factors have some effect in reversing the hepatic fibrosis. Immunohistological examination revealed that the content of collagen I, III was significantly lower in the experimental group than that in the treatment group with chlocoichne, while the mRNA levels of procollagen I, III were similar. In the liver of all experimental animals, both the hepatic content of collagen I, III and the mRNA level were significantly higher than the normal control group, which suggests the intervening factors do not reverse the hepatic fibrosis to normal within a period of time. This also shows the limitation of the therapeutic factor at present, which is demonstrated by the pathologic grading of hepatic fibrosis and the electron microscopic findings.

Histological examination revealed that asON therapy had better effect on hepatic fibrosis than colchicine. The asON is efficacious to reverse the hepatic fibrosis. However, colchicine had extremely limited effect on the therapy of hepatic fibrosis. The pathologic grading of hepatic fibrosis showed no remarkable difference as compared with the model group, although chlocoichne had some inhibitory effect on the rat hepatic content of collagen I, III and mRNA level.

Until now, the study on gene therapy for hepatic fibrosis and cirrhosis is limited to the animal models, and not yet applied to human beings[14,64]. The target gene is HGF[65] or TGF-β[66]. It has not yet been reported to make TIMP as the target gene. These developments are noteworthy, but there are many works to be done before it can be used in clinical practice[67].

To sum up, the animal experiment,

pathological examination and electronmicroscopic observation have proved that the asON phosphorthioate directed to TIMP-1 has some anti-hepatic fibrosis effect in the experimental immune hepatic fibrosis rat models. This result is quite heartening, but many studies should be done, especially the study of internalization of asON *in vivo*.

Abstract

AIM To study persistence and replication of hepatitis C virus (HCV) in patients' peripheral blood mononuclear cells (PBMC) cultured *in vitro*.

METHODS Epstein-Barr virus (EBV) was used to transform the hepatitis C virus from a HCV positive patient to permanent lymphoblastoid cell lines (LCL). Positive and negative HCV RNA strands of the cultured cells and growth media were detected by reverse transcriptase-polymerase chain reaction (RT-PCR) each month. Core and NS5 proteins of HCV were further tested using immunohistochemical SP method and in situ RT-PCR.

RESULTS HCV RNA positive strands were consistently detected the cultured cells for one year. The negative-strand RNA in LCL cells and the positive-strand RNA in supernatants were observed intermittently. Immunohistochemical results medicated expression of HCV NS3 and C proteins in LCL cytoplasm mostly. The positive signal of PCR product was dark blue and mainly localized to the LCL cytoplasm. The RT-PCR signal was eliminated by overnight RNase digestion but not DNase digestion.

CONCLUSION HCV may exist and remain functional in a cultured cell line for a long period.

INTRODUCTION

Hepatitis C virus has a positive-strand RNA genome of about 10kb in length, which is grouped in the family Flaviviridae[1,2]. The viral particles are spherical with spike-like projections, and have morphological features similar to those of the Flavivirus[3]. The liver is the main target for replication of HCV *in vivo*[4,5], which occurs via minus-strand RNA as a replicative intermediate[7,8]. Recently, positive and negative strands have been detected in peripheral blood mononuclear cells (PBMC) isolated from HCV infected patients by both RT-PCR[6,7] and *in situ* hybridization[9]. PBMC are therefore suspected as a possible site of extra-hepatic replication of HCV. It has been recognized for almost 31 years that Epstein-Barr virus (EBV) is capable of transforming lymphocytes into immortal cell lines[10]. We detected HCV RNA of the cultured cells and growth media by reverse transcriptase-polymerase chain reaction (RT-PCR) each month. Antigens of HCV were further tested using the immunohistochemical and the streptavidin/peroxidase (SP) staining methods and *in situ* RT-PCR. Our results offer strong evidence for the persistence of HCV RNA in mononuclear blood cells.

MATERIALS AND METHODS

Human peripheral blood mononuclear cells

PBMCs were obtained from a female patient. PBMCs were whose serum tested positive for both anti-HCV antibodies and HCV RNA isolated from heparinized peripheral blood by using a diatrizoate-Ficoll (Eurobic) density gradient and washed three times in PBS before being resuspended in RPMI-1640 medium containing 20% fetal calf serum (FCS) (Gibco BRL).

Ebstein-Barr virus preparation

Viral stocks were prepared from the growth medium of a B95-8 cell line EBV-transformed marmoset lymphocyte cells. The viral stocks were centrifuged at 400 × *g* to sediment cells, frozen and thawed three times, and then passed through a 0.45 μm Millipore filter. They were determined to be free of mycoplasma and bacteria by culture.

Cell culture[11,12]

Before exposure to EBV, isolated PBMC populations were maintained for 13-24 hours at 2×10^6 cells/mL in 96-well plates. This procedure removed many phagocytic cells. Medium was RPMI-1640 supplemented with 20% heat-inactivated (56℃, 30 min) fetal calf serum, penicillin (50U/mL), and streptomycin (50 μg/mL). The cells were cultured at 37℃ in an atmosphere of 5% CO_2. Phytohemagglutinin A-M (PHA-M) (Difco) was dissolved in RPMI-1640, sterilized by passage through a 0.45 μm Millipore filter, and added to the lypmphocytes 24 hours before addition of EBV. Twenty-four hours after EBV transformation, the cultures were treated with Cyclosporin A (0.5 g/mL and 1.0 g/mL).

Stock of B lymphocytes transformed by EBV and its growth medium. After about one month, B lymphocytes transformed by EBV and subcultured were observed to have achieved immortalization. The culture medium was exchanged semi-quantity every week. The exchanged LCL was centrifuged at 400 × *g* for 5 minutes to sediment the cells. The cell pellets were placed in RPMI medium containing 20% FCS and 10% DMSO. The cells and supernatants were separately stored in liquid nitrogen. Before PCR, the fresh or stored sedimentary cells were washed ten times in DEPC-treated PBS. The last wash was collected and saved. The cells were diluted at 5×10^7 cells/mL.

RNA purification

Total RNA was extracted from 100 uL of culture supernatant or from 5×10^7 cells resuspended in 100 μL of DEPC-treated water by a single-step method as described by Chomczinsky[13].

Reverse transcription and nested PCR[14-17]

The synthesis of cDNA and the two rounds of PCR were performed using oligonucleotide primers from the highly conserved, untranslated 5'- region of the genome: P1 (Sense strand: 5'-CTGTGAGGAACTACTGTCTT-3', nucleotides 28-47), P2 (Antisense strand: 5'-AACACTACTCGGCTAGCAGT-3', nucleotides 229-248) for the first PCR round and P3 (Sense strand: 5'-TTCACGCAGAAAGCGTCTAG-3', nucleotides 46-65), P4 (Antisense strand: 5'-GTTGATCCAAGAAAGGACCC-3', nucleotides 171-190) for the second PCR round. Detection of the HCV positive strand: ten L of the RNA solution was denatured at 70℃ for 10 min and incubated in 42℃ for 40 min with 1U AMV and 50pmol the outer antisense oligonucletide primer (P2). Synthesis of cDNA was stopped by heating the samples at 95℃ for 10 min. Amplification of the DNA was performed using 10 uL cDNA solution and 50pmol one of the outer primers (P1). Thirty cycles of DNA amplification were carried out, followed by an extension step for 10 min at 72℃. Each cycle of PCR consisted of 95℃ for 60s, 55℃ for 90s and 72℃ for 120s. The second PCR was carried out in the same way with 5 uL of the first PCR mixture and 50pmol of each inner primer (P3 and P4).The amplified DNA was detected by 6% polyacrylamide gel electrophoresis and ethidium bromide staining. The size of the second DNA fragment generated by the PCR was 145 bp. Detection of the HCV negative-strand: 10 μL RNA solution was denatured at 70 ℃ for 10 min and incubated in 42℃ for 40 min with 1U AMV and 50pmol of the outer sense oligonucleotide primer (P1). The following PCR was as same as the detection of the HCV positive-strand.

Immunocytochemistry

Immunocytochemistry was performed according to streptavidin/peroxidase (SP) staining method [18-21] using antibodies against HCV Core and NS5. The anti-HCV Core monoclonal antibody was kindly supplied by L Haoying (Academy of Military Medical Sciences, Beijing, China). The antibody was produced by immunizing a mouse with synthetic peptide based on the sequence of the HCV genome. Monoclonal antibodies to HCV NS3 proteins were produced against a recombinant HCV NS5 protein and were kindly supplied by Zhan Meiyun (Institute of Virology, Chinese Academy of Preventive Medicine) and Gao Jianen (Institute of Hepatology, People's Hospital, Beijing Medical University). Histostain TM-SP kit was a ZYMED product (U.S.A.).

In situ RT-PCR[22-30]

LCL cells were carefully washed in sterile saline, resuspended in ice-cold 10% buffered formaldehyde solution and kept for 2 hours at 4℃. For each set of experiments, 2×10^6 cells were aliquoted in 0.5 mL Eppendorf tubes and treated with a 1% sterile saline solution of Triton-X100 (Sigma,St Louis, MO)at 4℃ for 10min with gentle shaking. Permeabilized LCL cells were then resuspended in 20 uL RT buffer (50 mmol/L Tris-HCl, 75 mmol/L KCl, 3 mmol/L $MgCl_2$) containing 10 mmol/L dithiotreitol, 200U cloned Moloney's murine leukemia virus RT (Gibco-BRL, Gaithersburg, MD), 40U RNase inhibitor (RNA guard; Pharmacia), 1 mmol/L each dGTP, dATP, dTTP, dCTP, and 50pmol of the outer antisense oligonucletide primer (P2) of HCV. The tubes were incubated at 37℃ for 1 hour, 95℃ for 10 min to

inactivate residual RT activity, and immediately chilled on ice. After the RT step, LCL cells were washed again with ice-cold sterile saline, spun down, and resuspended in 25 uL of PCR buffer (50 mmol/ L KCl, 10 mmol/L Tris-Cl,2.5 mmol/L $MgCl_2$) containing 1 mmol/L each of dGTP, dATP, dTTP, dCTP, and 25pmol of both antisense (P2) and sense (P1) primers. After preheating the tubes for 7 min at 82℃, 1U Taq DNA polymerase (Promega) was added to each sample. Pre-melting at 95℃ for 5 min was followed by 20 cycles of 1min each at 94℃ (DNA denaturation), 55℃ (primer annealing), and 72℃ (primer extension). After the first PCR, LCL cells were washed again with ice-cold sterile saline, spun down, and resuspended in 25 uL PCR buffer (50 mmol/L KCl, 10 mmol/L Tris-Cl, 2.5 mmol/L $MgCl_2$) containing 1 mmol/L each dGTP, dATP, dTTP, dCTP, and 25pmol of both antisense (P3, its N-end labelled biotin) and sense (P4) primers. The second PCR processes were the same as the first. At the end of suspension PCR, LCL cells were carefully washed 3 times again with ice-cold sterile saline and 1 time in TE buffer (10 mmol/L Tris-HCl, 1 mmol/L EDTA, pH 7.4), with gentle agitation at 37℃. Cells (between 2×10^3 and 4×10^3) were spread on a glass slide coated with polytetrafluoroethylene. The slides were air dried and then washed in 2 × saline sodium citrate (SSC), buffer (0.3M sodium chloride and 0.03M sodium citrate). Amplification products were incubated with alkaline phosphatase-conjugated streptavidin (AP-SA) for one hour at 37℃. After incubation, slides were thoroughly washed with phosphate-buffered saline. The color was developed with nitroblue tetrazolium /5-bromo-4-chloro-l-3 indolyphosphate (NBT/BCIP) as the chromagen, which yields a dark blue color at the site of biotin binding avidin. The counterstain, nuclear fast red, stains nuclei pale pink and does not stain the cytoplasm.

RESULTS

Hepatitis C virus persistence in cell lines

We observed two distinct morphologies as early as 24 hours post-infection with EBV, indicating successful transformation of the virus into the B cells: ① blastogenesis became evident resulting in enlargement of the lymphocytes or ② there was increasing development of cell aggregates of proliferative lymphoblast cells (Figure 1). After one month, the EBV transformed lymphocytes exhibited huge, spherical cell bodies, a few projections on the body surface, and large, varying nuclei (Figure 2).

HCV of LCL and medium detected by nested RT-PCR

In order to observe the persistence of HCV in LCL, the appearance of viral plus-strands and minus-strands of the cell line were assayed in cell lysates and cultured media and the tenth wash of LCL each month during culturing continuously. The plus-strand HCV RNA in cell was successively detected during 12 months in the subcultured cells. The plus-strand HCV RNA in supernatants and the minus-strand HCV RNA in cells were intermittently positive RT-PCR(Table 1, Figures 3-5).

Table 1 Detection of HCV-RNA positive-strand and negative-strand by RT-PCR in EBVTB and their growth medium after incubation

	Incubation months											
	1	2	3	4	5	6	7	8	9	10	11	12
Cells (p/n)	+/+	+/-	+/-	+/+	+/-	+/-	+/+	+/-	+/-	+/-	+/-	+/+
Growth medium (p/n)	+/-	-/-	-/-	-/+	-/+	-/-	-/-	-/-	+/-	-/-	-/+	-/-

p = plus-strand, m = minus strand; +:PCR positive; -: PCR negative.

HCV core and NS3 antigens of immunocytochemistry positive in LCL

Expression of the virus-encoded proteins in the cells was tested by immunocytochemistry using a monoclonal antibody to synthetic HCV core peptide and recombinant HCV NS3. The immunocytochemical staining for both antigens was detected in the cytoplasm. The staining granular was seen as a brown lump in a side cytoplasm (Figures 6-8).

To verify the specificity of the immunocytochemical staining, the following controls were employed: ① negative control, the PBMC of the normal donors; ② staining with a mouse monoclonal antibody to surface antigen of hepatitis B virus as a negative control antibody; ③ PBS taking the place of specific antibody as a replacement test; ④ the normal human PBMC transformed by EB virus as a negative control; and ⑤ omission of incubation with horseradish-peroxidase-labeled streptavidin to test for endogenous peroxidase activity in LCL. The immunocytochemical staining reaction was absent in the negative controls and endogenous peroxidase activity was not detected in the cells under the current condition of immunocytochemistry.

HCV RNA signal of PCR product in situ RT-PCR

The positive signal of PCR product was dark blue and mainly localized to LCL cytoplasm (Figure 9). The specificity of the *in situ* cDNA product was checked in LCL cells. The RT-PCR signal was eliminated by overnight RNase digestion but not DNase digestion (Figure 10).

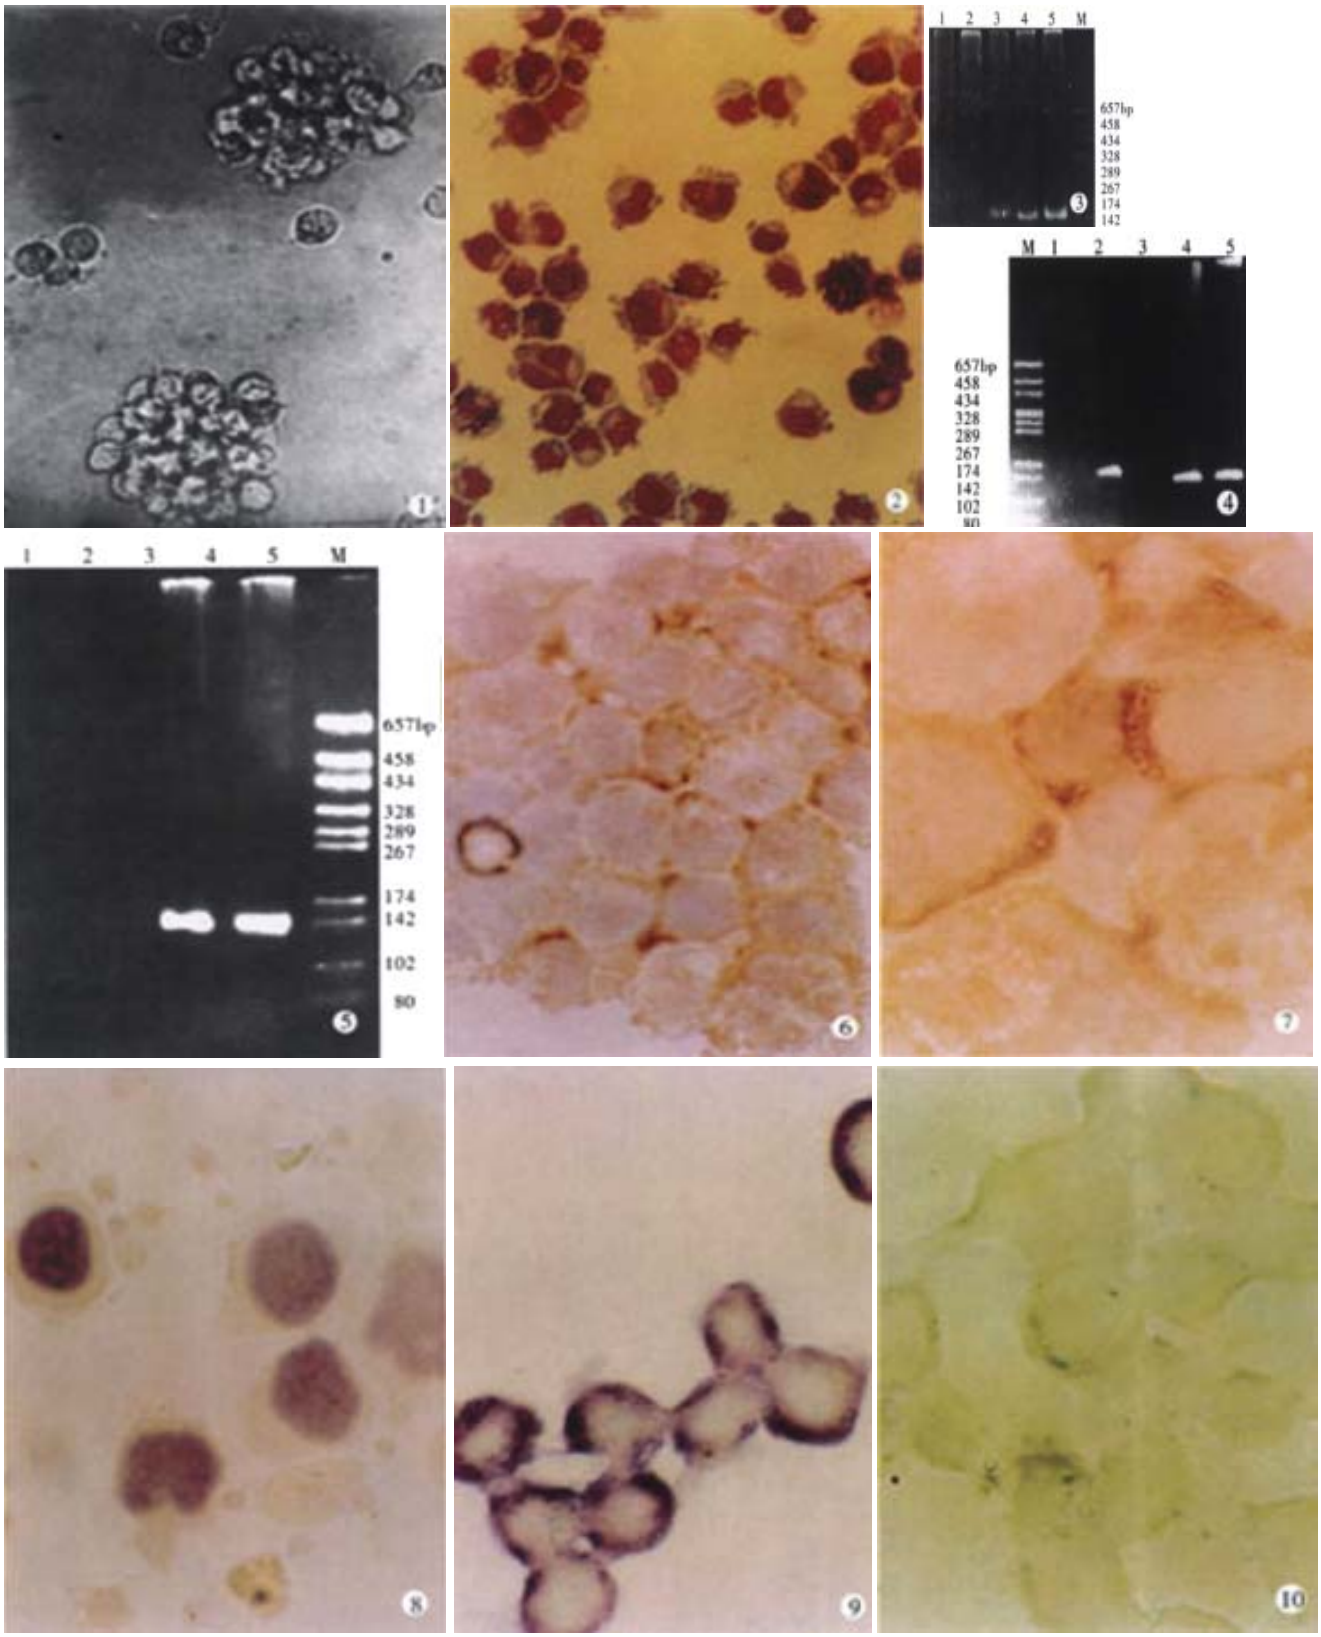

Figure 1 There was increasing development of cell aggregates of proliferative lymphoblast cells.
Figure 2 The immortal cell line of human peripheral blood mononuclear cells transformed by Epstein-Barr virus. The cell bodies are larger and sphereical. There are the false foot-like hairs or thorns on their surface. The cell nuclei are large and varied. The cells multiply and grow as cell regiments or clusters.

DISCUSSION

Our results indicate that PBMCs from hepatitis C patients may be easily transformed into immortal lymphocytes and subcultured over a long period of time. We did not observe any signs of humoral or cellular immunity against LCL cells in the culture media. The presence of HCV in cells was not achieved by incubation with HCV-positive sera. HCV plus-strand or minus-strand RNA was detected in the cells, and the plus-strand HCV was detected in the growth media. Our results offer strong evidence for *in vivo* HCV infection of PBMC, and indicate that HCV may persist in the cells transformed by EBV and cultured *in vitro*. The detection of viral particles and HCV gene expressing proteins in the cells by immunohistochemistry[18-21] and *in situ* PCR[23-29] confirmed further that such cells may support complete HCV multiplication. Investigation of the hepatitis C virus life cycle and the evaluation of novel anti-viral strategies are limited by the lack of an efficient cell culture systems. Although chimpanzees can be successfully infected with HCV sera from human patients, they do not serve as a good animal model due to their limited numbers and high cost. Many researchers have reported using the HCV positive sera incubated with Molf-4[31], HPB-MA[31] and H9 cells[32] (the human T cell lines), fetal hepatocytes[33], bone marrow-derived B cell line[34], PBMC from a healthy donor[35], and daudi cells (a human B cell line)[22] as a cell model of *in vitro* HCV replication. These experiments have provided abundant material fowards the establishment of new satisfactory models. PBMCs have been suspected as a possible site of extra-hepatic replication of HCV and a bank of latent infection of HCV. It relates closely to relapse of chronic hepatitis C[36-41].

Just for this reason, PBMCs from hepatitis C patients were transformed by EBV into immortal cell *in vitro* and subcultured. We hope to establish a new cell model which is more representable of the true state of *in vivo* HCV infection.

The development of human cytogenetics demonstrates scientific progress on new methodological approaches. Thus, the real beginning of clinical cytogenetics was marked by introduction of the lymphocyte culture technique as an easily accessible source of mitotic cell. However, due to the limited life-span of cells, new blood sampling is necessary in cases of re-examination. This might be difficult or even impossible if patients are not available for different reasons. Our procedure is available for routine use and allows efficient transformation of peripheral B lymphocytes by EBV and thus the establishment of lymphoblastoid cell lines[42]. Compared to other methods of long-term cultivation, these cell lines have a number of advantages: ① the original material can easily be obtained from any hepatitis C patient. ② LCL is the ideal source for HCV molecular biology studies in humans as repeated HCV RNA preparations can be obtained without effort.
