Abstract

Hereditary pancreatitis is an autosomal dominant condition, which results in recurrent attacks of acute pancreatitis, progressing to chronic pancreatitis often at a young age. The majority of patients with hereditary pancreatitis express one of two mutations (R122H or N29I) in the cationic trypsinogen gene (PRSS1 gene). It has been hypothesised that one of these mutations, the R122H mutation causes pancreatitis by altering a trypsin recognition site so preventing deactivation of trypsin within the pancreas and prolonging its action, resulting in autodigestion. Families with these two mutations have been identified in many countries and there are also other rarer mutations, which have also been linked to hereditary pancreatitis.

Patients with hereditary pancreatitis present in the same way as those with sporadic pancreatitis but at an earlier age. It is common for patients to remain undiagnosed for many years, particularly if they present with non-specific symptoms. Hereditary pancreatitis should always be considered in patients who present with recurrent pancreatitis with a family history of pancreatic disease. If patients with the 2 common mutations are compared, those with the R122H mutation are more likely to present at a younger age and are more likely to require surgical intervention than those with N29I. Hereditary pancreatitis carries a 40 % lifetime risk of pancreatic cancer with those patients aged between 50 to 70 being most at risk in whom screening tests may become important.

INTRODUCTION

Hereditary pancreatitis (HP) is an autosomal dominant condition characterised by recurrent attacks of acute pancreatitis and progressing to the development of chronic pancreatitis over a variable period of time. Symptoms usually begin in childhood or adolescence and with time, exocrine and/or endocrine insufficiency may develop. The clinical spectrum of hereditary pancreatitis was first reported in 1952^[1]. Mutations causing HP have been identified in the PRSS1 gene which encodes cationic trypsinogen^[2-4]. This article discusses the genetics of HP, its pathophysiology and clinical spectrum.

THE GENETICS OF HEREDITARY PANCREATITIS

HP is an autosomal dominant condition with 80 % penetrance. The specific mutations responsible for HP were identified in 1996 when it was confirmed that the hereditary pancreatitis

gene could be mapped to chromosome 7q35^[5,6]. Whitcomb *et al* demonstrated that a mutation in these patients existed in the third exon of the cationic trypsinogen gene (PRSS1)^[7]. This mutation, a guanine (G) to adenine (A) transition, alters arganine (CGC) to histidine (CAC) at codon 117 (using the chymotrypsin numbering system) and was originally known as R117H. This first mutation is easily identified because it creates a novel recognition site for the restriction endonuclease *Af*/III. More recently, it has been shown that a neutral polymorphism within this enzyme recognition site may produce a false negative result^[8]. A second mutation in the cationic trypsinogen gene was subsequently discovered, which was found to be a single A to thiamine (T) transversion mutation in exon 2 resulting in an asparagine (ACC) to isoleucine (ATC) substitution at amino acid 21^[3]. These two mutations (R117H and N21I) have now been identified in families with hereditary pancreatitis from many countries including France^[4], Germany^[9], United Kingdom^[10], Japan^[11] and the USA^[3,7]. A further mutation, which appears to be much less common, is the A16V mutation, which was originally identified in three patients with idiopathic pancreatitis and in one patient with HP^[12]. There is also evidence that mutations in genes other than the cationic trypsinogen gene might be associated with HP^[13]. Since the discovery of the cationic trypsinogen gene mutations, a new nomenclature system for human gene mutations has been devised and accepted. This has changed the names of the common mutations from R117H to R122H and N21I to N29I^[14].

PATHOPHYSIOLOGY

The mechanism by which mutations of the cationic trypsinogen gene cause hereditary pancreatitis is important for several reasons. Firstly, the cellular mechanisms of acute pancreatitis and progression to chronic pancreatitis are poorly understood. Secondly it is not known why the pancreas of one individual is susceptible to alcohol whilst the pancreas of another is not. Thirdly, focusing on the link between genetics and pancreatitis might provide a clue to the etiology of pancreatic cancer which can occur as a complication in sporadic and hereditary pancreatitis.

Trypsinogen is secreted by the pancreatic acinar cell^[15]. It is activated to trypsin within the duodenum by enterokinase, which cleaves an 8-aminoacid N-terminal peptide. Trypsin then activates a cascade of digestive enzyme precursors. A number of mechanisms exist to prevent inappropriate activation of trypsin within the pancreas before its secretion into the duodenum. It is hypothesised that the R122H mutation alters a trypsin recognition site, which would prevent deactivation of trypsin within the pancreas, thus prolonging its action^[2]. The mechanism whereby the N29I mutation causes pancreatitis is unclear. It has been speculated, however, that the N29I mutation would enhance autoactivation of trypsinogen, altering the binding of pancreatic secretory trypsin inhibitor (PSTI)^[3] or impairing trypsin inactivation by altering the accessibility of the initial hydrolysis site to trypsin. Predicted molecular conformational changes in the structure of trypsin support this^[16]. The pathogenic mechanism whereby the A16V mutation causes pancreatitis is speculative but it is thought to alter the cleavage site of the signal peptide^[12]. Because the two common mutations, R122H and N29I produce such a similar

clinical picture, it has been speculated that these mutations, rather than being the cause of hereditary pancreatitis, simply represent markers for a number of linked pancreatic defects. There appears no doubt, however, that inappropriate prevention of the deactivation of trypsin within the pancreas is responsible for HP in the majority of cases.

The penetrance of cationic trypsinogen gene mutations remains at approximately 80 % in the majority of studies. To investigate factors contributing to this, a study of monozygotic twins with HP was carried out^[17]. Of 11 sets of twins, seven were suitable for this study. Whereas four of these seven sets were concordant for pancreatitis, three of the seven sets of twins (43 %) were discordant for phenotypic expression of pancreatitis. The overall penetrance in the seven pairs of twins was 78 %. The conclusion from this study was that genetic and/or environmental factors contribute to the expression and age of onset of HP. As yet the mechanism of non-penetrance remains unclear.

CLINICAL PRESENTATION IN HEREDITARY PANCREATITIS

The initial presentation of a patient with HP is usually indistinguishable from a case of sporadic pancreatitis. The clinical presentation is variable but typical patients present with recurrent attacks of acute pancreatitis in childhood, progressing to chronic pancreatitis with time^[1,18]. The presentation during an acute attack is identical to an attack of gallstone-induced, alcoholic or idiopathic, acute pancreatitis. The presentation of chronic pancreatitis in these patients is likewise indistinguishable from alcoholic, idiopathic or other forms of chronic pancreatitis^[18-20]. Pediatric patients with HP have a similar presentation to idiopathic juvenile chronic pancreatitis^[21]. It is however very common for these patients to remain undiagnosed for many years having often suffered from chronic symptoms since childhood. We have found that recognition of the disease within a family often results in several relatives being newly diagnosed with pancreatitis whereas previously they had been labelled as "peptic ulcer" or "chronic abdominal pain". In Newcastle upon Tyne, UK, the pancreatic clinic now has individuals belonging to thirteen families with hereditary pancreatitis. Data on nine of these families has been previously published^[10]. The R122H (R117H) mutation was identified in three families and the N29I (N21I) mutation was demonstrated in a further five families. In a remaining family, no mutations were demonstrated in any of the five exons of the PRSS1 gene. The families and patients belonging to the R122H group were compared with those belonging to the N29I group. Comparison of clinical details including complications of pancreatitis was carried out. The mean age at onset of symptoms of pancreatitis was lower in the R122H group at 8.4 vs 6.5 years, ($P=0.007$) and more patients with the R122H mutation had developed symptoms by the age of 20 years (89 vs 64 %). More patients with the R122H mutation required surgical intervention (8 of 12 vs 4 of 17, $P=0.029$) and this occurred at an earlier age. There was also a tendency for more patients with the R122H mutation to develop exocrine failure but the incidence and age of onset of endocrine failure (as measured by the development of insulin dependent diabetes mellitus) was similar in both groups. Patients in both groups identified alcohol as a provoking factor for the symptoms. These observations were also noted in the original description of the N21I mutation in 1997^[3] and have also been noted by the European Registry of Hereditary Pancreatitis and Pancreatic Cancer (EUROPAC)^[22]. It is also clear that as well as hereditary pancreatitis being identical to other forms of pancreatitis in terms of the mode of clinical presentation, radiological and histopathological features are also identical^[23]. Apart from earlier onset and delay in diagnosis, hereditary pancreatitis has been found to have a

natural history similar to that of chronic alcoholic pancreatitis in terms of a similar prevalence of pancreatic calcification, a similar amount of pancreatic insufficiency both endocrine and exocrine but a higher prevalence of pseudocysts^[24].

CATIONIC TRYPSINOGEN GENE MUTATIONS IN NON-HEREDITARY PANCREATITIS

Taking a family history is very important in all patients with pancreatitis because the majority of patients with cationic trypsinogen gene mutations have a clear cut family history of pancreatitis. It is, however, common for patients to be referred to a pancreatic specialist with so-called idiopathic pancreatitis without a reliable family history having been obtained^[25]. It has also been considered whether idiopathic chronic pancreatitis might be due to PRSS1 gene mutations. An investigation of patients with chronic alcoholic pancreatitis showed no evidence of the R122H or N29I mutation in 21 patients^[26] but a much larger and important study investigated 221 patients with idiopathic chronic pancreatitis and no family history. The entire PRSS1 gene was sequenced in these patients. Only three patients had mutations, one with R122H and two patients with A16V^[27]. A genetic background has also been investigated in patients with idiopathic juvenile chronic pancreatitis, a disease which closely mimics the clinical pattern of hereditary pancreatitis^[28]. The R122H mutation was detected in one patient with idiopathic juvenile chronic pancreatitis and the A16V mutation was also found in one patient. It is clear from these studies that new mutations do occur and that screening of individuals with idiopathic pancreatitis for cationic trypsinogen gene mutations is worthwhile. It is, therefore, our policy in patients with idiopathic pancreatitis, after exclusion of other causes, to perform genetic counselling and genetic testing. We have found that patients are keen to know their genetic status in relation to this disease.

RISK OF CANCER IN HEREDITARY PANCREATITIS

Sporadic chronic pancreatitis carries a significantly increased risk of pancreatic cancer. This has been clearly demonstrated by a multi-centre historical cohort study of over 2000 patients^[29]. The standardized incidence ratio, i.e. the ratio of observed to expected pancreatic cancers was 16.5. This study may have been subject to detection bias in that increased surveillance of chronic pancreatitis patients may have increased the number of cancers diagnosed compared with the general population. A study of Swedish patients, however, confirmed an increased risk of pancreatic cancer in sporadic chronic pancreatitis but with a standardised incidence ratio of 3.8^[30]. Patients with HP have not been included in either of these studies but have since been examined for the risk of developing pancreatic cancer by the International Hereditary Pancreatitis Study Group. A cohort of 246 patients with hereditary pancreatitis was identified from ten countries with a mean follow-up period of over 14 years^[31]. Eight patients with pancreatic adenocarcinoma were identified yielding a standardized incidence ratio of 53.3. The estimated cumulative risk of pancreatic cancer developing in these patients was nearly 40 % and was greater for patients with a paternal inheritance pattern. These figures have been confirmed by the Midwest Multicentre Pancreatic Study Group^[32]. The conclusions from these cancer studies are that, firstly chronic pancreatitis is a risk factor for pancreatic cancer and secondly hereditary pancreatitis puts patients at an even higher risk of developing cancer than the sporadic disease. Although it is not absolutely clear whether the risk of cancer is due to prolonged inflammatory change or whether it is related to the presence of a cationic trypsinogen mutation per se, the evidence available at present indicates that those patients with HP who

develop cancer, are those with a prolonged history of chronic pancreatitis^[32]. The number of cancers, which have developed in HP patients have so far not allowed an investigation into which mutation (s) might predispose to cancer more than another. This data, however, will be available with time. A study of pancreatic tissue from 34 patients with sporadic ductal adenocarcinoma has shown no specific relationship between the R122H mutation and pancreatic cancer^[33]. Further such studies are expected as tissue from patients with hereditary pancreatitis becomes available for analysis.

MANAGEMENT DILEMMAS IN HEREDITARY PANCREATITIS

When faced with a patient or a family with a possible diagnosis of HP, three questions are commonly asked. Firstly, what can be done about the patient with pancreatitis? Secondly, are other relatives likely to be affected? Thirdly, what can be done to reduce the risk of cancer?

Management of the pancreatitis

There are no specific medical therapies recommended in patients with HP. The management of acute attacks of pancreatitis are the same as for the sporadic disease that is, rehydration, analgesia and careful monitoring. Severe necrotising pancreatitis is rare in HP but pseudocysts seem to be relatively common. It has been suggested that antioxidant therapy may be helpful to prevent acute attacks but there is no evidence to support this and it is not recommended. Chronic pancreatitis should be treated as for any other patients. Enzyme supplements are likely to be required and analgesics as necessary. If diabetes mellitus occurs it is likely to require insulin therapy. Surgical treatment is for complications such as pseudocyst, biliary obstruction or duodenal obstruction. In older patients requiring surgery, a total pancreatectomy should be considered in order to abolish the cancer risk (see below).

Genetic counselling of relatives

Relatives should be told that although the majority of HP cases are revealed by the age of 18, the disease may not manifest itself until the age of 30 or older. In these unaffected individuals, genetic testing confers no advantage and should be discouraged. Since unaffected (non-carrier) individuals and unaffected carriers do not have pancreatitis, they carry no increased risk of developing cancer.

Screening of hereditary pancreatitis patients for cancer

Since patients with this disease exhibit a 53-fold increased risk of pancreatic cancer with a cumulative risk of 40 % by the age of 70, an attempt at screening would appear to be essential. Unfortunately, no adequate screening test exists. The measurement of tumor markers, endoscopic techniques and radiological imaging lack the sensitivity and specificity for early diagnosis. Tumors are particularly difficult to detect on a background of chronic pancreatitis. It is thought therefore that molecular based strategies are likely to offer the best opportunities for the screening of these high risk patients for pancreatic ductal adenocarcinoma^[34]. It has been suggested that the banking of blood and pancreatic juice samples should be mandatory in any screening protocol and that imaging of the pancreas should be carried out by endoscopic ultrasound^[35]. One such protocol for the secondary screening of patients with HP has been established by EUROPAC (European Registry of Hereditary Pancreatitis and Pancreatic Cancer). As part of a research programme only, affected individuals over the age of 30 are offered imaging by CT and endoscopic ultrasound (EUS), followed after genetic counselling, by genetic analysis of pancreatic juice obtained at ERCP for K-ras mutations. Patients negative for K-ras continue with repeat screening at

3 yearly intervals by CT, EUS and K-ras analysis of pancreatic juice. Patients who are K-ras positive undergo further genetic analysis in the form of p53, p16 and aberrant methylation. If positive, these patients may be at risk of pancreatic ductal carcinoma and an attempt should be made to obtain cells for cytology by ERCP brushing of the pancreatic duct. The ultimate preventative measure in these patients would be a total pancreatectomy but this is a relatively high morbidity operation with the certainty of becoming diabetic. Certainly any patient with HP aged 30 or over, who requires surgery for relief of symptoms should undergo a total pancreatectomy in order to abolish the cancer risk rather than a lesser procedure. This is not, however, appropriate in patients who are well unless there is clear evidence that they possess cellular atypia or a focal abnormality suspicious of cancer.

CONCLUSIONS

Hereditary pancreatitis is a fascinating condition which has provided new insights into the pathophysiology of pancreatitis. There are however many unanswered questions particularly in relation to the ways in which these mutations relate to pancreatitis and cancer. Management of these patients should be carried out by a team of experienced pancreatic specialists who are also able to provide genetic counselling. Registration of patients with one of the large Hereditary Pancreatitis Registries is essential if management strategies are to be improved and genetic research to be continued.

Abstract

AIM: To design a hammerhead ribozyme targeting human telomerase reverse transcriptase (hTERT) and clone it's gene for future use in the study of tumor gene therapy.

METHODS: Using the software RNAstructure, the secondary structure of hTERT mRNA was predicted and the cleavage site of ribozyme was selected. A hammerhead ribozyme targeting this site was designed and bimolecular fold between the ribozyme and hTERT was predicted. The DNA encoding the ribozyme was synthesized and cloned into pGEMEX-1 and the sequence of the ribozyme gene was confirmed by DNA sequencing.

RESULTS: Triplet GUC at 1742 of hTERT mRNA was chosen as the cleavage site of the ribozyme. The designed ribozyme was comprised of 22nt catalytic core and 17nt flanking sequence. Computer-aided prediction suggested that the ribozyme and hTERT mRNA could cofold into a proper conformation. Endonuclease restriction and DNA sequencing confirmed the correct insertion of the ribozyme gene into the vector pGEMEX-1.

CONCLUSION: This fundamental work of successful designing and cloning of an anti-hTERT hammerhead ribozyme has paved the way for further study of inhibiting tumor cell growth by cleaving hTERT mRNA with ribozyme.

INTRODUCTION

Telomeres form the ends of eukaryotic chromosomes consisting of an array of tandem repeats of the hexanucleotide 5'-TTAGGG-3'. Their functions are protecting the ends of chromosomes against exonucleases and ligase, preventing the activation of DNA-damage checkpoints, and countering the loss of terminal DNA segments that occur during linear DNA is replicated^[1,2]. Telomerase, a ribonucleoprotein enzyme, add

the hexanucleotides to the ends of replicating chromosomes^[3]. It is believed that telomerase plays a crucial role in cellular senescence and immortalization^[3-5]. Telomerase is strongly repressed in most human somatic cells, and telomeres shorten progressively with each cell division^[6]. Most cancer cells express telomerase activity^[3,6-9]. The restoration of telomerase activity is considered to immortalize cells and to be an important step in carcinogenesis. Inhibition of telomerase can lead to telomere shorting and tumor cell death. Thus, specific inhibition of human telomerase is suggested to be an efficient means of tumor therapy. Nowadays, a limited number of means can be used experimentally to inhibit the activity of human telomerase including chemical agents^[10], antisense oligonucleotide^[11,12], peptide nucleic acid^[13], and ribozyme^[14-16]. Telomerase is composed of at least three subunits^[17]. The RNA subunit and the catalytic subunit are the essential components for telomerase activity^[18]. The RNA subunit of telomerase serves as the template for addition of short sequence repeats to the chromosome 3' ends^[19]. And the catalytic subunit, telomerase reverse transcriptase (TERT), is the most important component in telomerase complex which is responsible of catalytic activity of telomerase. The expression of TERT correlates with the presence of telomerase activity^[20]. These studies suggest that hTERT is a good target for cancer gene therapy.

Ribozymes are *sis*- or *trans*-acting, sequence-specific catalytic RNA molecules. Based on the studies about natural ribozymes, we can design site-specific *trans*-acting ribozymes to suppress the expression of genes by recognize and splice the mRNA. Hammerhead ribozyme and hairpin ribozyme are intensively studied because of their simple structures and dual activity of splicing as well as blocking^[21]. Ribozymes may surpass the efficiency of the antisense oligonucleotide and are considered a promising means of gene therapy^[22,23]. In this study, we designed a hammerhead ribozyme targeting hTERT and cloned the gene encoding the ribozyme for future study of this ribozyme in the treatment of malignancies.

MATERIALS AND METHODS

Materials

Plasmid vector pGEMEX-1, X-gal and IPTG were Promega products. T4 DNA ligase, Klenow fragment and restriction endonucleases used in this study were purchased from Sino-America Biotechnology Co.

Design of the hammerhead ribozyme

Using the software RNAstructure 3.6 (mFOLD for windows version), the full-length telomerase mRNA (GenBank NM003219) was analyzed and the second structure of telomerase mRNA was predicted. Since *trans*-acting hammerhead ribozymes preferentially recognize and cleave the GUC sequence, all the fragments containing GUC were candidate target sequences for ribozyme binding and cleavage. Considering the predicted local conformation near the GUC triplets and the nucleotide sequences flanking the GUCs, triplet GUC located at 1 742 of the hTERT mRNA was chosen as the target site of ribozyme. According to the rules of hammerhead ribozyme design suggested by Haseloff *et al*^[24], the ribozyme

was primarily designed. Then, bimolecular fold between the ribozyme and substrate RNA was predicted and modification of the ribozyme sequence was made according to the prediction to improve the binding between the ribozyme and the substrate. The hammerhead ribozyme designed was comprised of 39 nucleotides, including 22nt catalytic core and 17nt (5' 7nt and 3' 10nt) flanking antisense sequence. The sequence is 5' - TCTCCGTCTGATGAGTCCGTGAGGACGAAACATAAAAGA - 3' (The underlined are nucleotides complementary to the substrate).

Synthesis of the ribozyme gene

DNA synthesis was carried out by Shanghai Sangon Biotechnology Co. LTD. with 3 900 DNA autosynthesis instrument. The primers used for the ribozyme were as follows: 5' - CCCAAGCTTCTCCGTCTGATGAGTC - CGTGAGGACGAAAC - 3' (strand A) and 5' - GGAATTCATCGATAGATCTTTTATGTTTCGTCTCA - 3' (strand B). Twelve nucleotides from the 3' ends of the two strands were complementary to each other. A *Hind*III restriction site was introduced into the 5' end of strand A. And restriction sites of *Bgl*II, *Cla*I and *Eco*RI were introduced into the 5' end of strand B. Equal molecule of the two strands were mixed and annealed to form a hemiduplex. The hemiduplex was extended with Klenow fragment to form full duplexes. The reaction mixture contained 50 mM Tris-HCl (pH 7.2), 10 mM MgSO₄, 0.1 mM DTT, 0.4 mM dNTP mixture, 4 µg each of the two single strand oligonucleotides, 20 U Klenow fragment in a final volume of 50 µl. The reaction was carried out at 37 °C for an hour. The reaction mixture was extracted with phenol-chloroform and precipitated with sodium acetate ethanol (The methods referred to Sambrook *et al*^[25]).

Cloning of ribozyme gene

The double strand DNA was digested with *Hind*III and *Eco*RI. The product was electrophoresed in 2 % agarose for purification followed by electroelution in a dialysis bag for DNA recovery. The recovered fragment was inserted into the *Hind*III/*Eco*RI site of plasmid vector pGEMEX-1 with T4 DNA ligase. *E. coli* JM109 was transformed with the recombinant plasmid and cultured on a solid medium containing ampicillin, X-gal and IPTG. Six white colonies were picked and plasmid was extracted by alkaline lysis. The plasmid was digested by *Hind*III, *Not*I, *Eco*RI, *Bgl*II, respectively. Endonuclease digests of plasmid DNA were analyzed on 1 % agarose. DNA sequencing was carried out to further confirm the inserted sequence of ribozyme gene (The methods referred to Sambrook *et al*^[25]).

RESULTS

Selection of cleavage site and design of the ribozyme

Aided by computer prediction of RNA secondary structure, we selected the triplex GUC situated at 1 742 of the hTERT mRNA as the cleavage site (Figure 1). The ribozyme could co-fold with the substrate RNA to form a desired conformation in computer-aided prediction (Figure 2).

Analysis of the transformants

Six white colonies were picked. All the plasmids were cleaved into two fragments (1.0kb+3.0kb) by *Bgl*II. The plasmid from colony number 6 was digested with *Hind*III, *Not*I and *Eco*RI respectively. The plasmid DNA was linearized by *Hind*III or *Eco*RI but not by *Not*I. This result suggested plasmid from colony number 6 was a correct recombinant (Figure 3,4).

DNA sequencing

The DNA sequencing of the plasmid DNA from colony number

6 confirmed that the ribozyme gene was correctly inserted into the vector pGEMEX-1. This recombinant was named pGEMEX-1-RZ. The diagram of DNA sequencing is shown in Figure 5.

DISCUSSION

A hammerhead ribozyme is composed of a 22nt or 23nt catalytic core and the flanking complementary sequences. The catalytic core determines the cleavage activity of the ribozyme. And the nucleotide sequence of the catalytic core is conserved. Whereas the flanking sequences determine the recognition specificity of the ribozyme^[24]. The catalytic mechanisms of hammerhead ribozyme and related factors have been intensively studied^[26]. Hammerhead ribozyme can cleave the triplet sequence NUH (N is anyone of A, U, C or G, and H could be C, U or A), but the triplet GUC is most efficiently cleaved^[27]. The length of complementary sequence also influences the catalytic activity. Short complementary sequence will decrease the recognition specificity of the ribozyme and the annealing between ribozyme and substrate. In contrary, long complementary sequence will influence the dissociation of ribozyme from the substrate and hence the turnover of the ribozyme. Commonly, the proper length of each of the flanking sequence is 6-8nt^[28,29] although some studies suggested that longer antisense flanking arms have higher intracellular cleavage efficacy^[30,31]. This opinion is also supported by the estimation that stretches of 11-15 nucleotides define unique sequences for cellular RNA^[32]. It was reported that asymmetric ribozymes (longer helixIII, shorter helixI) have higher cleavage activity than symmetric ribozyme^[33]. In this study, we designed a asymmetric hammerhead ribozyme which had 7nt helixI and 10nt helixIII.

The premise of ribozyme cleavage is the base pairing between flanking sequence of the ribozyme and the substrate mRNA^[34]. This step is akin to the antisense oligodeoxyribonucleotides used for the same purpose. And the base pairing is determined by the secondary structure of the target site, Triplet NUH situated in a loop, protruding or linker of the substrate is advantageous to the annealing between

ribozyme and substrate and then the cleavage of the substrate RNA by the ribozyme^[35]. The selection of the cleavage sites is most important in the design of ribozymes. Nowadays, two approaches are available in the selection of the cleavage sites of ribozymes. One approach is to use *in vitro* accessibility assays. The other is to use theoretical prediction, that is, computer-aided prediction. A number studies aimed to compare the two approaches in their consistency have suggested that theoretical prediction is positively correlate with the intracellular accessibility of the target sites in mRNA^[35-37]. So we performed computer-aided analysis of the secondary structure of the substrate RNA. mFOLD is a commonly used software for RNA secondary structure^[38], so we used mFOLD to predict the secondary structure of hTERT mRNA previous to designing the ribozyme. We choose 1742 GUC as the cleavage site of ribozyme in total 57 triplet GUC in hTERT mRNA. The reasons included: (1) 1 744 triplet RNA is located in coding region of an essential motif of telomerase activity-T motif, and T motif is unique to telomerase in all kinds of reverse transcriptase^[39]. (2) 1 742 triplet GUC is situated in a rather large loop of the predicted secondary structure of telomerase RNA where comparatively more unpaired bases are present near the cleavage triplet. It was reported this kind of structure was correlated with the hybridization accessibility for hammerhead ribozymes^[35]. (3) The sequence surrounding 1742 triplet GUC is rich of adenosine and uridine. It is reported that for efficient catalytic turnover, the free energy of the ribozyme-substrate duplex should be less than -16 kal/mol, that is, higher ratio of A+U will be advantageous to the annealing between ribozyme and substrate^[28]. Next, we performed a computer-aided bimolecular fold prediction between the ribozyme and the substrate and modified the complementary sequences until the ribozyme and the substrate can co-fold into a correct conformation in computer-aided prediction.

Commonly, cloning of short double-strand DNA is carried out by synthesizing the full-length sense strand and antisense strand, annealing and then inserting into a cloning vector. In this study, both the sense strand and antisense strand synthesized were partial of the ribozyme gene which were 12 nucleotides complementary to each other on the 3' ends. After annealing to form a hemiduplex, the hemiduplex was extended with Klenow fragment to obtain full-length double-strand DNA. The reliability of this method is proven by the present study. The advantages of this method including comparative simplicity, higher precision and lower cost to synthesize shorter single-strand DNA.

Since the hammerhead ribozyme gene is only about 50 bps in length, primary analysis of the recombinant relies on PAGE conventionally. Because PAGE is comparatively complex, in this study, we introduced *Bgl*II and *Cl*aI restriction sites to the 3' end of the ribozyme gene for the convenience of restriction analysis. As shown in figure, correct recombinants can be linearized by *Cl*aI as well as cleaved into two fragments (1.0kb+3.0kb) by *Bgl*II. Also, because *Not*I restriction site in pGEMEX-1 had been removed, correct recombinant could not be cleaved by *Not*I. Then agarose electrophoresis can be used to analyze the recombinants. One of the six recombinants selected by this strategy was sequenced, and the sequence of the inserted ribozyme gene was confirmed. The result suggests that this strategy is applicable. The recombinant plasmid pGEMEX-1-RZ also would be used as an *in vitro* transcription vector to test the *in vitro* cleavage activity of the ribozyme. The recovered 2.0 kb fragment after *Bgl*II restriction would be used as the transcription template. The transcribed product would have two additional nucleotides on the 3' end of the ribozyme, but these two additional nucleotides have no influence on the secondary structure of the ribozyme predicted by computer.

Design and cloning of a ribozymes are the essential work of

studies about ribozymes. In this study, we designed and cloned the anti-hTERT ribozyme successfully. Next, we will test the *in vitro* cleavage activity of the ribozyme and will investigate the growth inhibition effect of this ribozyme on colonic tumor cell lines.

Abstract

AIM: To seek for an effective method to improve the immune responses induced by DNA vaccine expressing HBV surface antigen (pCR3.1-S) in Balb/c mice (H-2^d).

METHODS: The pCR3.1-S plasmid and the eukaryotic expression vectors expressing murine IL-2 (pDOR-IL-2) or IL-12 (pWRG3169) were injected into mice subcutaneously. The immune responses to pCR3.1-S and the adjuvant effect of the cytokines plasmid were studied. Meanwhile the effect of pCR3.1-S on anti-translated subcutaneous tumor of P815 mastocytoma cells stably expressing HBsAg (P815-HBV-S) was also studied. Anti-HBs in serum was detected by enzyme-linked immunosorbent assay (ELISA) and HBsAg specific cytotoxic T lymphocytes (CTLs) activity was measured by ⁵¹Cr release assay. After three weeks of DNA immunization, the cells of P815-HBV-S were inoculated into mice subcutaneously and the tumor growth was measured every five days. The survival rate and living periods of mice were also calculated.

RESULTS: After 8 wk DNA immunization, the A 450 nm values of sera in mice immunized with pCR3.1, pCR3.1-S and pCR3.1-S codelivered with IL-2 or IL-12 plasmids were 0.03±0.01, 1.24±0.10, 1.98±0.17 and 1.67±0.12 respectively. Data in mice codelivered pCR3.1-S with IL-2 or IL-12 plasmids were significantly higher than that of mice injected pCR3.1 or pCR3.1-S only. The HBsAg specific CTL activities in mice coinjected with pCR3.1-S and IL-2 or IL-12 eukaryotic expression vectors were (61.9±7.1) % and (73.3±8.8) %, which were significantly higher than that of mice injected with pCR3.1 (10.1±2.1) % or pCR3.1-S (50.5±6.4) %. The HBsAg specific CTL activities in mice injected with pCR3.1, pCR3.1-S, pCR3.1-S combined with IL-2 or IL-12 eukaryotic expression vectors decreased significantly to (3.2±0.8) %, (10.6±1.4) %, (13.6±1.3) % and (16.9±2.3) % respectively after the spleen cells were treated by anti-CD8⁺ monoclonal antibody, but presented no significant change to anti-CD4⁺ monoclonal antibody or unrelated to monoclonal antibody. The HBV-S DNA vaccine (pCR3.1-S) could evidently inhibit the tumor growth, prolong the survival period of mice and improve the survival rate of mice and these effects could be improved by IL-12 gene codelivered.

CONCLUSION: HBV DNA vaccine has a strong antigenicity in humoral and cellular immunities, which can be promoted by plasmid expressing IL-2 or IL-12. CD8⁺ cells executed

the CTL activities. DNA vaccine may be useful for both prophylaxis and treatment of HBV infection.

INTRODUCTION

Many animal models of infectious diseases have been reported^[1-3] which shows DNA vaccine induced broad range of protective immunities, including antibodies, CD8⁺CTL, CD4⁺Th cells against challenge with the pathogens, such as plasmodium^[4], influenza virus^[5] simplex virus^[6] and HIV-1^[7]. Application of this genetic vaccination approach has been extended to the treatment of cancers^[8,9] as well as allergic diseases^[10,11] and autoimmune disease^[12]. Because DNA vaccines can induce weak and short-lived immune responses in large out-bred animal^[13], seeking for an effective way to promote the immune responses of DNA immunization is an urgent case. Relying on the knowledge above, we constructed a recombination vector expressing HBV S protein, pCR3.1-S, to study the possibility of DNA vaccine in controlling and preventing the HBV infection. In addition, the eukaryotic expression vectors expressing murine IL-2 or IL-12 were coimmunized to mice with pCR3.1-S and their effects as adjuvants for immune responses were also studied. Meanwhile, we established the HBV-infectious animal model through the inoculating of the P815-HBV-S and observed the treatment and preventive effect of pCR3.1-S to HBV infection *in vivo*.

MATERIALS AND METHODS

Plasmids, cell lines and mice

Plasmid expressing hepatitis B virus surface antigen (pCR3.1-S)^[14] was constructed by Prof. Yao ZHQ (in this Department). Plasmids expressing murine IL-2 (pDOR-IL-2) and IL-12 (pRW1369)^[15] were generous gift from Dr. Feng ZHH (in this Department). P815 mastocytoma cells were generous gift from Dr. Zhao (Department of Pathology, the Fourth Military Medical University). Female Balb/c (H-2^d) mice were obtained from the Center for Experimental Animals of the Fourth Military Medical University and used at the age of 5-8 weeks.

Transfection and expression of pCR3.1-S in P815

P815 cells were maintained in RPMI 1640 (Sigma) with 10 mL·L⁻¹ fetal bovine serum in a six-well tissue culture plate at 37 °C in 5 % CO₂ humidified atmosphere and then transfected with the pCR3.1-S or the pCR3.1 alone by using lipofectamine (GIBCO). For each transfection 20 µg of plasmid and 15 µL of lipofectamine in 0.2 mL of serum free medium were mixed in tube for 30 minutes. After 0.8 mL of serum-free medium were added to the tube, the DNA-lipofectamine complexes were overlaid onto the cells. After incubated 12 hours, the cells were washed two times with the complete culture medium and

the medium was replaced with 2 mL of the complete culture medium. After another 24–48-hour incubation, the cells were transferred from the culture medium, which was then replaced by medium contained $300 \text{ mg} \cdot \text{L}^{-1}$ G_{418} (Promega). Two weeks later, the G_{418} -resistant clones were selected and the expression of HBsAg was detected by using of indirect immunofluorescence (IIF). The HBsAg-expressed cells were designated as P815-HBV-S and used as the target cells for CTL assay.

DNA immunization in mice

Four groups of mice were used, each consisting of 5 mice which were immunized with one of the following regimens in 100 μL of sterile saline: (1) 100 μg of pCR3.1-S; (2) mixture of 100 μg of pCR3.1-S and 100 μg of pDOR-IL-2 (IL-2); (3) mixture of 100 μg of pCR3.1-S and 100 μg of pRW1369 (IL-12); (4) 100 μg of pCR3.1 vector. The mice in the last group served as negative control. All injections were done intramuscularly into the left thigh quadriceps muscle of mice at 0, 2, 4, 6 and 8 weeks.

HBsAg-specific antibody assay

Sera samples were collected by tail bleeding at different times, beginning at 1 wk after immunization, and the presence of HBsAg-specific antibody was analyzed by ELISA. The ELISA kits for the HBsAg-specific antibody detection were purchased from Huamei Co. and performed according to the manufacturer's instructions.

CTL assay

Spleen cells of mice were segregated 8 weeks after immunization and the CTL activities were measured by ^{51}Cr releases assay. $\text{Na}^{51}\text{CrO}_4$ was purchased from Dubang Co. Target cells (1×10^6) were labeled with 3.7 MBq radiolabeled sodium chromate. The assays were performed in triplicate with 1×10^5 targets/well at various effector cell/target cell (E:T) ratios of 100:1. Results were expressed according to the formula: % specific lysis = (experimental release - spontaneous release) / (maximum release - spontaneous release). Experimental release represents the mean count per-minute released by target cells in the presence of effector cells. Maximum release represents the radioactivity released after lysis of target cells with 50 $\text{g} \cdot \text{L}^{-1}$ Triton X-100. Spontaneous release represents the radioactivity present in medium derived from target cells alone.

Blocking of CTL response by monoclonal antibodies

At the effector cell/target cell ratio of 100:1, CTL assays were performed in the presence of 10 $\text{mg} \cdot \text{L}^{-1}$ of anti- CD_4^+ or anti- CD_8^+ monoclonal antibody added to the spleen cells in 96-well plates. As a control an unrelated antibody was added to the spleen cells. The monoclonal antibodies to mouse CD_4^+ or CD_8^+ cell were purchased from Sigma Chemical Co.

DNA vaccine against subcutaneous translated tumor

Four groups of mice were used, each consisting of 5 mice immunized with one of the following regimens in 100 μL of sterile saline: (1) 100 μg of pCR3.1-S; (2) mixture of 100 μg of pCR3.1-S and 100 μg of pRW1369 (IL-12). (3) 100 μg of pCR3.1; one group of mice without immunization. Three weeks after DNA immunization, cells of P815-HBV-S were inoculated into mice by subcutaneous injection in abdomen. The growing tumors were measured every five days with a calipers using average diameter. The survival period of mice was observed and the survival rate of mice was calculated.

Statistical analysis

Data were reported as $\bar{x} \pm s$ and were analyzed by professional statistical computer software SPSS. Significance was set at $P < 0.05$.

RESULTS

Codelivery of cytokines gene augmented the titer of antibody induced by pCR3.1-S

The pCR3.1-S showed a strong antigenicity in humoral immunity and the anti-HBsAg could be detected in sera of mice after pCR3.1-S vaccination. The serum titres of anti-HBsAg in mice increased with the times of immunization in a period of time. The titres of anti-HBsAg in sera of mice were significantly promoted by genes expressed murine IL-2 or IL-12, especially by IL-2 gene (Figure 1).

Figure 1 Serum anti-HBsAg level of Balb/c mice. ^b $P < 0.01$ vs pCR3.1; ^a $P < 0.05$ vs pCR3.1-S

Cytokines gene effected on the CTL activity induced by pCR3.1-S

The HBsAg specific CTL activities were developed in the mice after pCR3.1-S immunization. The CTL activities were augmented by coimmunized with IL-2 or IL-12 gene. The mice immunized with pCR3.1 alone did not elicited detectable HBsAg specific CTL activities. IL-12 was more effective than IL-2 in promoting the HBsAg specific CTL activities. The CTL activity was blocked by anti- CD_8^+ monoclonal antibody but not by anti- CD_4^+ monoclonal antibody or unrelated antibody (Table 1). Taken together, these results indicated that the CTL activity induced by pCR3.1-S *in vivo* was executed by cells expressing $\text{CD}_8^+/\text{CD}_4^-$ surface phenotype and the CTL activity could be enhanced or suppressed depending on the cytokines gene expressed.

Table 1 The effect of cytokines gene on CTL activity induced by pCR3.1-S ($n=5$; $\bar{x} \pm s$ %)

Group	Untreated	mAb		
		Unrelated	Anti- CD_4^+	Anti- CD_8^+ ^b
pCR3.1	10.1 \pm 2.1	10.7 \pm 1.9	9.7 \pm 1.2	3.2 \pm 0.8
pCR3.1-S	50.5 \pm 6.4	49.7 \pm 6.1	48.3 \pm 5.9	10.6 \pm 1.4
pCR3.1-S+IL-2	61.9 \pm 7.1	62.0 \pm 6.8	56.2 \pm 7.5	13.5 \pm 1.9
pCR3.1-S+IL-12	73.3 \pm 8.8	69.9 \pm 7.6	75.6 \pm 9.1	16.9 \pm 2.3

DNA vaccine inhibits the formation of subcutaneous translating tumor derived from P815-HBV-S

After inoculated with P815-HBV-S, all five mice with or without pCR3.1 (100 %) formed the tumor. The rate of tumor formation was 20 % (1/5) in mice immunized with pCR3.1-S and there was no tumor formed in mice coimmunized with pCR3.1-S and IL-12. The survival rate of mice immunized with pCR3.1-S alone or coimmunized with IL-12 increased significantly (Figure 2) and the tumor growth was evidently slower than that of mice immunized with or without pCR3.1 (Figure 3).

Figure 2 Survival rate in different group. ^a $P < 0.05$ vs pCR3.1

Figure 3 Growth curve of subcutaneous translating tumor in different group of mice. ^b $P < 0.01$ vs pCR3.1; ^a $P < 0.05$ vs pCR3.1-S

DISCUSSION

HBV infection is very common in China^[16-23]. It is estimated that approximately 130 million people in the world is infected by hepatitis B virus (HBV). These people are at risk of developing chronic hepatitis leading to liver cirrhosis and hepatocellular carcinoma. Up to now, vaccination is a main way in prevention^[24-31].

It has been suggested that the MHC class II and I restricted T cell responses to the virus are relatively weak during chronic HBV infection^[28] and there are no specific therapies to cope with it. DNA vaccine contains the gene for an antigenic portion of a pathogen, such as the core or the envelope protein, usually under the transcriptional control of a viral promoter^[29,30]. In DNA-based vaccination, immunogenic proteins are expressed in transfected cells of the vaccine recipients in their native conformation with correct post-translational modifications from antigen-encoding expression plasmid DNA *in vivo*. This ensures the integrity of antibody-defined epitopes and supports the generation of protective antibody. DNA vaccination is furthermore an exceptionally potent strategy to stimulate CD8+ cytotoxic T lymphocyte (CTL) responses because antigenic peptides are efficiently generated by endogenous processing of intracellular protein antigen^[31].

The results of our experiment indicate that the plasmids expressing either IL-2 or IL-12 can enhance the specific humoral and cellular immune responses against HBV infection elicited by pCR3.1-S in mice. The former mainly enhances the level of the HBsAg specific antibody and the latter mainly enhances the HBsAg specific CTL activity.

IL-2 can enhance the immune responses through promoting proliferation and differentiation of B cells and the antibody development. The proliferation and activation of many kinds of T-cells and the production of various cytokins can also be promoted and stimulated by IL-2. The effect of IL-2 enhancing the level of antibody may be related to its ability to induce the

increase of the Th1 cells but not Th2 cells. This can increase IgG2a type of antibody and lead to the increase of the total level of the antibody subsequently^[32-34]. IL-12 is so far the most potent cytokine with the widest scope of modulation of immune responses. The immune responses can be modulated by IL-12 promoting the production of Th1 type T cells and secretion of other cytokines, stimulating the polarization and proliferation of T cells and through promoting the maturity of CTL cells and LAK cells. All of these can enhance the ability of the host to kill and eliminate pathogens. The adjuvant activities of cytokines were also observed by others^[25,32-36].

The situations *in vivo* are different from that *in vitro* after all. In order to search the preventive and therapeutic effects of HBV DNA vaccine to the HBV infection *in vivo*, we serve the mouse injected with P815-HBV-S cells subcutaneously for an animal model of HBV infection. The preventive and therapeutic effects of pCR3.1-S on HBV infectious animal model were investigated by observing the inhibiting effects of pCR3.1-S on the neoplasia of P815-HBV-S cells inoculated by subcutaneous injection. The result indicates that the pCR3.1-S can reduce the formative rate of the subcutaneous translating tumor significantly, inhibit the growth of tumor, prolong the living periods and promote the survival rate of mice injected with the P815-HBV-S cells. Maybe all of these relate to the specific killing effect of CTLs to P815-HBV-S cells induced by DNA vaccine. Furthermore, these effects of pCR3.1-S can be enhanced obviously by IL-12 gene as shown in the experiment. The therapeutic potential of DNA-based immunization for the chronic HBV carrier states has also been demonstrated in a transgenic mouse model^[37]. This mode of immunization has been shown to successfully eliminate HBsAg in circulation.

These features of DNA-based immunization make it an attractive strategy for prophylactic and therapeutic vaccination against extra- and intracellular pathogens. Recently, DNA vaccines induced the specific humoral^[38] and cellular^[39-41] immune responses were observed in human experiments. The results of these experiments suggest that DNA vaccine might be a potential therapy for chronic HBV infection.

Abstract

AIM: To establish a mice model harboring hepatitis B virus *x* gene (adr subtype) for studying the function of hepatitis B virus X protein, a transactivator of viral and cellular promoter/enhancer elements.

METHODS: Expression vector pcDNA3-*HBx*, containing CMV promoter and hepatitis B virus *x* gene open reading fragment, was constructed by recombination DNA technique. Hela cells were cultured in DMEM and transfected with pcDNA3-*HBx* or control pcDNA3 plasmids using FuGENE6 Transfection Reagent. Expression of pcDNA3-*HBx* vectors in the transfected Hela cells was confirmed by Western blotting. After restriction endonuclease digestion, the coding elements were microinjected into male pronuclei of mice zygotes. The pups were evaluated by multiplex polymerase chain reaction (PCR) at genomic DNA level. The *x* gene transgenic mice founders were confirmed at protein level by Western blotting, immunohistochemistry and immunogold transmission electron microscopy.

RESULTS: Expression vector pcDNA3-*HBx* was constructed by recombination DNA technique and identified right by restriction endonuclease digestion and DNA direct sequencing. With Western blotting, hepatitis X protein was detected in Hela cells transfected with pcDNA3-*HBx* plasmids, suggesting pcDNA3-*HBx* plasmids could express in eukaryotic cells. Following microinjection of coding sequence of pcDNA3-*HBx*, the embryos were transferred to oviducts of pseudopregnant females. Four pups were born and survived. Two of them were verified to have the *HBx* gene integrated in their genomic DNA by multiplex PCR assay, and named C57-TgN(*HBx*)SMMU1 and C57-TgN(*HBx*)SMMU3 respectively. They expressed 17KD X protein in liver tissue by Western blotting assay. With the immunohistochemistry, X protein was detected mainly in hepatocytes cytoplasm of transgenic mice, which was furthermore confirmed by immunogold transmission electron microscopy.

CONCLUSION: We have constructed the expression vector pcDNA3-*HBx* that can be used to study the function of *HBx* gene in eukaryotic cells *in vitro*. We also established *HBx*

gene (adr subtype) transgenic mice named C57-TgN (*HBx*)SMMU harboring *HBx* gene in their genome and express X protein in hepatocytes, Which might be a valuable animal system for studying the roles of *HBx* gene in hepatitis B virus life cycle and development of hepatocellular carcinoma *in vivo*.

INTRODUCTION

Human hepatitis B virus (HBV) is the prototype for a family of viruses, referred to as *Hepadnaviridae*^[1,2]. It has at least 4 subtypes, ayw, adr, ayr, and adw, among which adr is the most prevailing subtype in China. The complete genomic DNA of subtype adr has been cloned and demonstrated only 3.2kbp in length, and which is different from the other 3 subtypes in DNA and protein sequence^[3]. HBV genome has 4 open reading frames (ORFs), including envelope genes coding region (*pre-s1*, *pre-s2* and *s* gene coding region), precore (*pc*) gene and core(*c*) gene coding region, polymerase (*p*) gene coding region, *x* gene coding region^[4-6].

Chronic HBV infection is associated with a high incidence of liver disease, including hepatocellular carcinoma (HCC)^[7-9]. Based on epidemiologic studies involving chronic HBV infection, it is estimated that the relative risk of developing HCC for HBV carriers may be 100- to 200-fold higher than that for non-carriers. It is proposed that the role of HBV played in HCC predisposition is modifying host gene regulation. Integration of viral DNA into the host genome can mediate host gene deregulation by a variety of mechanisms^[10-15]. X protein may alter host gene expression leading to the development of HCC^[16]. It has been demonstrated that X protein is a transactivator of a variety of viral and cellular promoter/enhancer elements and can mediate the activation of signal transduction pathways. Besides, it may affect DNA repair, cell cycle control, and apoptosis^[17-22]. It is now clear that X-defective virus is unable to initiate infection *in vivo*. However, the physiological role of X protein during the course of an infection remains a major issue unresolved in hepadnavirus biology^[23-27].

To explore the function of *HBx* gene *in vivo*, we generated transgenic mice harboring *HBx* gene from subtype adr by microinjection method, in which *HBx* gene could be expressed. This model might be valuable for the study of *HBx* biology and its associated biomedical issues *in vivo*.

MATERIALS AND METHODS

Reagents, antibodies, cells and animals

Restriction Endonucleases and T₄ DNA ligase were obtained from Promega Co. (USA). The mouse monoclonal antibody against X protein was purchased from DAKO (USA). Sheep anti mouse IgG-HRP was obtained from CALBIOCHEM (Germany). Gel extraction kit was purchased from QIAGEN. Hela cells were preserved in our laboratory. C57BL/6 mice were maintained in our Transgenic Animal Laboratory (SPF level).

Plasmid constructions

Plasmids pBR322-HBV (containing two tandem copies of the HBV genome of adr subtype) and pcDNA3 (containing CMV promoter) were preserved in our laboratory. Expression plasmid pcDNA3.1 (containing CMV promoter) was generously provided by Dr. Yu Hong-Yu. An 0.894-Kilobase pair DNA fragment containing *HBx* gene was isolated by gel extraction from plasmid pBR322-HBV after *Hind*III and *Bgl*II restriction digest. The fragment was then subcloned into plasmid pcDNA3.1 that has been digested by *Hind*III and *Bam*HI to yield intermediate plasmid pcDNA3.1-*HBx*, which was employed as a template for polymerase chain reaction (PCR) amplification of the *HBx* coding fragments. The primers (A: 5'-ACACA AGCTT CATAT GGCTG CTCGG G-3', B: 5'-CATGA ATTCT AGATG ATTAG GCAGA GGTG-3') were synthesized by Sangon Co. (Shanghai). Thirty five cycles of amplification were done in a total volume of 50 µl with an annealing temperature of 58 °C. PCR product and pcDNA3 were isolated after *Hind*III and *Xba*I digestion. After ligation, the plasmid of pcDNA3-*HBx* was confirmed by restriction endonucleases digestion and direct DNA sequencing.

Cell culture and DNA transfection

Hela cells were cultured in DMEM (Gibco) supplemented with 10 % FCS (Gibco) to confluence. Cells at 50 % confluency were transfected with pcDNA3-*HBx* or control pcDNA3 plasmids using FuGENE6 Transfection Reagent (Roche) with a total of 1 µg of DNA per 3.5-cm plate of cells. Selection in medium containing geneticin (G418; Gibco) at a concentration of 500 µg/ml was started 48 hours later. After 2 weeks selection, positive clones that were named Hela-*HBx* were isolated and further expanded.

Assay pcDNA3-*HBx* expression in hela cells

Hela-*HBx* cells cultured in 10-cm dishes were rinsed with phosphate-buffered saline (pH7.4) three times and collected in a microcentrifuge tube by trypsinization. Cells were lysed with lysis buffer^[18]. Supernatants were then diluted 5 times with phosphate-buffered saline (pH7.4) to assay the expression of the transfected pcDNA3-*HBx* vectors in Hela cells by Western blotting.

Microinjection and production of *HBx* transgenic mice

The pcDNA3-*HBx* plasmid was digested by *Sal*I and purified by gel extraction (Qiagen gel extraction kit). Purified coding fragment containing CMV promoter and *HBx* ORF were dissolved in TE buffer (10 mM Tris-HCl, 0.2 mM EDTA, pH7.5) at a final concentration of 2 µg/L (-4 000 copies/µl) and microinjected into zygotes. Microinjection and embryo manipulation were performed according to standard protocols.

Analysis of *HBx* gene integration

Genomic DNA was extracted from tail tissue of pups mice or normal mouse and dissolved in TE buffer. It was used for PCR assays to identify founders of transgenic mice with *HBx* gene. In order to set an internal control of the efficiency of PCR amplification, we developed a multiplex PCR, using two sets of primers to amplify the *HBx* gene and the autosomal *IL3* gene in the same reaction tube^[28,29]. PCR reaction was performed using 1 µl of dissolved DNA, 0.2 µM *HBx* gene specific primers (C: 5'-GGACG TCCTT TGTCT ACGTC CCGTC-3', D: 5'-CCTAA TCTCC TCCCC CAACT CCTCC-3', synthesized by Sangon Co. /Shanghai), and 0.1 µM *IL3* gene specific primers (E: 5'-GGGAC TCCAA GCTTC AATCA-3', F: 5'-TGGAG GAGGA AGAAA AGCAA-3', synthesized by Sangon Co. /Shanghai) in a total volume of 50 µl according to the cycling program: 94 °C, 40 s; 61 °C, 40 s; 72 °C, 60 s; 35 cycles.

Analysis of *HBx* gene expression in transgenic mice

Western blotting Liver samples were obtained from the transgenic mice with *HBx* gene and normal C57BL/6 mice. Specimens (approximately 100 mg) were homogenized in a screw-capped 1.5 ml microcentrifuge tube and lysed in lysis buffer (0.5 % Nonidet P-40, 10 mM Tris (pH7.4), 150 mM NaCl, 1 mM EDTA and 1 mM phenylmethanesulfonyl fluorid). 100 mg lysate was separated via 15 % SDS-polyacrylamide gel electrophoresis with Tris-Glycine buffer (pH8.3). One electrophoresis gel was stained with commassie brilliant blue R-250, and another was blotted to nitrocellulose filter. After blocked with 50 g/L defatted milk, the filter was incubated with X protein mouse monoclonal antibody for 40 min at 37 °C, then washed with TBS (three times, 15 min each time) and incubated with HRP-conjugated sheep anti-mouse IgG for 30 min at 37 °C. Finally, the filter was incubated with peroxidase substrate solution Diaminobenzidine (DAB) for 5 min to visualize the positive bands.

Immunohistochemistry analysis Hepatic tissue samples were fixed in 10 % neutral buffered formalin, paraffin-embedded and sectioned. Briefly paraffin-embedded sections were blocked with 3 % hydrogen peroxide (H₂O₂) for 10 min at 37 °C and washed with PBS. Subsequently, the sections were incubated in the X protein mouse monoclonal antibody (diluted 1:100) for 2hr at 37 °C. After washing with PBS, the sections were incubated in horseradish peroxidase-labeled sheep anti mouse IgG (diluted 1:50) for 40 min at 37 °C. Washed with PBS three times, the sections were subjected to color reaction with 0.02 % 3, 3-diaminobenzidine tetrahydrochloride containing 0.005 % H₂O₂ in PBS and counterstained with hematoxylin lightly.

Immunogold transmission electron microscopy The immunohistochemical X protein-positive mouse liver tissue was selected to be cut into small pieces (0.1 cm in diameter) and fixed first in 2 % paraformaldehyde and 0.5 % glutaraldehyde mixture buffer for 2hr at 4 °C, washed three times with PBS, acted upon by 0.25 % Triton X-100 for 10 min. After being blocked with blocking buffer, the pieces were incubated with X protein mouse monoclonal antibody over night at 4 °C, washed with TBS and incubated with avidin-gold (15 nm) for 2hr at room temperature; then postfixed in 1 % osmium tetroxide for 1hr at room temperature, dehydrated in gradient ethanol and embedded in epoxy resin. The sections were cut on an LKB Ultralome III, mounted on copper grids, stained with uranyl acetate and lead citrate, and examined by transmission electron microscopy.

RESULTS

pcDNA3-*HBx* vector construction and expression in Hela cells

A 0.465kb *HBx* gene was amplified from HBV genomic DNA and subcloned into the expression vector pcDNA3, with which the pcDNA3-*HBx* was constructed. The sequence of *HBx* gene in the plasmid was coincident with that reported before^[3], as identified by restriction endonucleases digestion and confirmed by DNA direct sequencing. After purification by gel extraction, pcDNA3-*HBx* plasmids were transfected into Hela cells. Positive clones, Hela-*HBx* cells were isolated by G418 selection. With Western blotting, hepatitis X protein was detected in Hela cells, suggesting pcDNA3-*HBx* plasmids expressed in eukaryotic cells (Figure 1).

Production of transgenic mice

The pcDNA3-*HBx* plasmid was digested by *Sal*I and target fragments containing CMV promoter and *HBx* ORF were purified by gel extraction. Target fragments then were microinjected into male pronuclei of zygotes from C57BL/6

mice. 45 zygotes were microoperated. 41 microinjected eggs were implanted into oviducts of 3 pseudopregnant recipient mice, and 4 pups were born and survived. The born rate was 11 %. By multiplex PCR screening, two of the pups were identified to harbour *HBx* gene in their genomic DNA, named C57-TgN *HMU1* and C57-TgN(*HBx*)SMMU3 (Figure 2).

Expression of *HBx* gene in transgenic mouse

To detect the expression of hepatitis X protein in transgenic mice, liver samples were obtained from C57-TgN(*HBx*) SMMU1 mice and normal C57BL/6 mice. Specimens were homogenized and lysed in lysis buffer. 100 mg lysate was used to assay HBX protein. A component of relative molecular mass 17 000 befitting the X protein was specifically detected with anti X protein monoclonal antibody by Western blotting (Figure 3A), suggesting the transgenic mice with *HBx* gene could express X protein in the liver tissue. The distribution of X protein in hepatocytes was determined by immunohistochemistry and immunogold electron microscopy, which revealed that X protein was mainly distributed in hepatocytic cytoplasm, little on plasm membrane and in nucleus (Figure 3B-3D).

DISCUSSION

Transgenic mice are the valuable animal models to study the functions of genes^[30]. Although transgenic mice containing different HBV genes, including the entire viral genome, have been established and analysed before, there is little evidence to suggest that the virus plays a direct role in inducing hepatocellular carcinoma^[31-41]. Hepatitis X protein is essential for HBV genes expression and replication^[42,43]. *In vitro*, X protein exhibits a plethora of activities. From cell culture studies, it is believed that X protein can activate the transcription of host genes, including the major histocompatibility complex and c-myc, as well as viral genes. Aside from the transactivation of many promoters, the other activities linked to X protein include

(C, D) *HBx* gene Expression in hepatocyte cytoplasm of C57-TgN (*HBx*) SMMU1 transgenic mice detected by immunogold electron microscopy (arrows) 3C: ×20 000; 3D: ×40 000.

stimulation of signal transduction and binding, to various degrees, to well-known protein targets such as p53, proteasome subunit, and UV-damaged DNA binding protein^[44-58].

However, the role of *HBx* gene in the course of HBV infection and in inducing HCC is unknown. In the present study, we constructed an *HBx* gene (adr subtype) expression vector pcDNA3-*HBx* containing CMV promoter and *HBx* gene ORF. By Western blotting, we found that it could express X protein in eukaryotic cells. pcDNA3-*HBx* may be a useful vector to study the role of X protein and explore the mechanism of transactivation *in vitro*. We also generated two founders of transgenic mice with *HBx* gene (adr subtype) by microinjections,

named C57-TgN(*HBx*)SMMU1 and C57-TgN(*HBx*)SMMU3, which harboured *HBx* gene in their genomic DNA. The birth rate of the pups was lower than that of other transgenic mice, including entire hepatitis viral genome transgenic mice. This indicated that X protein was probably involved in some phases of development. The hepatitis X protein was expressed in the liver tissue of transgenic mice and distributed mainly in hepacytes cytoplasm by Western blotting, immunohistochemistry and immunogold electron microscopy, which suggested that the transgenic mice could be an important tool in studying the function of *HBx* gene *in vivo*. Besides, we also developed a multiplex PCR to rapidly and accurately screen the transgenic mice with *HBx* gene. This method, using an optimized ratio of primer pairs, allows for the detection of *HBx* gene in transgenic mice, which can not only amplify target genes, but also show its amplification efficiency.

In conclusion, we have established *HBx* (adr subtype) transgenic mice as a model system for defining the function of *HBx* gene (adr subtype) and the role of X protein in the virus life cycle and HCC. And the multiplex PCR is a rapidly and accurately method to detect the transgenic mice with *HBx* gene.

Abstract

AIM: Chronic hepatitis B is a serious health problem. Interferon has long been used to treat Chronic hepatitis B. To evaluate the effects of interferon on chronic hepatitis B better, we designed the study to investigate the changes in sera and liver histology of patients with chronic hepatitis B after interferon alpha-2b treatment.

METHODS: Twenty-four patients with chronic hepatitis B were enrolled in this study. They all received interferon alpha-2b treatment as following: 3 million units, i.m., t.i.w., for 18 weeks. Sera of all patients were obtained respectively for evaluation of ALT, HBsAg, HBcAg, HBeAg, HBV DNA and TIMP-1 before and after interferon treatment, also a liver biopsy pre- and post-treatment was performed for comparison of HAI, HBsAg, HBcAg, HBeAg, TIMP-1 and activated HSC in the liver tissue.

RESULTS: Patients who had normalization of serum ALT and seroconversion of HBeAg and/or HBV DNA (blot hybridization) after treatment were defined as responders. The response rate in this study group was 37.5 % (7/24). Compared to pretreatment, the serum HBV DNA and TIMP-1 decreased significantly ($P < 0.05$), so did the HAI, HBcAg, HBeAg, TIMP-1 and activated HSC ($P < 0.05$).

CONCLUSION: The significant decrease in HBV DNA in sera, the seroconversion of HBeAg, and the decrease of viral expression in liver indicated that interferon alpha-2b treatment can inhibit viral replication. The normalization of ALT in sera and the improvement of HAI in liver showed that interferon alpha-2b can improve the liver histology of patients with chronic hepatitis B. At the same time, interferon alpha-2b treatment can reduce the TIMP-1 in serum and liver and decrease the number of activated HSC, which may alleviate or inhibit hepatic fibrosis. Although the response rate was unsatisfactory, interferon play a beneficial role on patients with chronic hepatitis B in other respects. We still need further studies to improve the therapy effects.

Han HL, Lang ZW. Changes in serum and histology of patients with chronic hepatitis B after interferon alpha-2b treatment. *World J Gastroenterol* 2003; 9(1): 117-121

INTRODUCTION

Chronic hepatitis B is a serious problem threatening public health, especially in our country. Interferon has been used to treat it for a long time. It has been proved that after interferon

treatment, the response rate in patients with chronic hepatitis B is about 30-50 %, with normalization of ALT, seroconversion of HBeAg and HBV DNA and improvement of liver HAI^[1-11]. However, the effects on hepatic fibrosis and viral antigen in liver tissue have been seldom reported. In this study, we evaluated mainly the effects of interferon treatment on some indexes of sera and liver histology.

MATERIALS AND METHODS

Materials

Patients Twenty-four patients were enrolled in this study. Of these, 21 were male, 3 were female. The mean age was 38.4. All patients had moderately elevated serum ALT. All patients were negative for hepatitis C and D. None had alcoholic liver disease, autoimmune or drug-induced liver disease, no patients had received antiviral or immunomodulatory therapy. Informed consent was obtained from each patient before the study. All patients were treated with recombinant IFN- α -2b 3MU thrice a week for 18 weeks (The IFN- α -2b was a product of Anke Company of biological technic of Anhui Province). Liver biopsy was performed in each patient before and after IFN treatment and serum specimens were obtained at the same time.
Response to IFN- α -2b treatment Patients who had normalization of serum ALT and seroconversion of HBeAg and/or HBV DNA (blot hybridization) after treatment were defined as responders, while those with negative result were taken as non-responders.

Methods

Assay for serum HBV, HCV, CMV and EBV markers All markers were measured by using the enzyme linked immunosorbent assay (ELISA). Antibodies to HBsAg, anti-HBs, HBeAg, anti-HBe, anti-HBc-IgM, anti-HBc-IgG, anti-HCV-IgG and anti-HCV-IgM were products of American Abbott Company. Anti-CMV-IgG and anti-EBV-IgG were purchased from Italian Deyi Company. The reagents for HBV DNA blot hybridization were products of Yuanli Reagent Company of Shanghai Medical University.

Quantitative PCR of serum HBV DNA Blood samples were obtained under fasting conditions before and after the IFN treatment. All sera were stored at -40 °C until assay. Quantitative polymerized chain reaction (PCR) of HBV DNA was performed as the method introduced by American Biotronics Company^[12]. The logarithms of the HBV DNA levels were statistically analyzed.

Assay for serum TIMP-1 Serum TIMP-1 was evaluated by using sandwich method of ELISA. Multiclonal antibody to TIMP-1 was bought from Beijing Zhongshan Biological Company, while monoclonal antibody to TIMP-1 was from Fujian Maxim Biological Company. Other reagents for ELISA were purchased from Beijing Zhongshan Biological Company.

Histological analysis Liver specimens were graded by 2 pathologists blinded to the response to treatment, using the histological activity index (HAI) described by Knodell^[13].

Assay for viral antigen in liver Expression of HBsAg, HBcAg and HBeAg in liver were evaluated using immunohistochemical S-P method. S-P kit was produced by Fujian Maxim Biological

Company. The procedures were performed according to the kit instruction. Expression of viral antigen in the liver was evaluated by semi-quantitative scoring system referring to the method introduced by Lindh^[14]. Based on the ratio of positive cells, the score was 0-3 respectively, corresponding to the positivity in 0 %, 1-20 %, 20-50 %, and more than 50 % of hepatocytes examined.

Liver fibrosis (1) Using α -smooth muscle actin (α -SMA) as a marker of activated hepatic stellate cell (HSC), the changes of activated HSC in the liver were analysed. (2) The expression of TIMP-1 in the liver was also investigated by using immunohistochemical method. The reagents for both HSC and TIMP-1 were bought from Fujian Maxim Biological Company. Scoring systems were the same as that for viral antigens.

Statistical analysis

All statistics were performed by using statistical procedure of social science (SPSS), including chi-square test and Wilcoxon's rank sum test. The probability values less than 5 % were considered significant.

RESULTS

Responders and non-responders

After interferon treatment, 7/24 (37.5 %) of patients were responders who had normalization of ALT and seroconversion of HBeAg and/or HBV DNA. The other 15 (62.5%) patients were non-responders.

Changes in serum level of HBV DNA

The average logarithm of serum HBV DNA before interferon treatment was 8.20 ± 0.60 m, which changed to 7.21 ± 1.14 after treatment (Table 1 and Figure 1). Compared to pretreatment, the serum level of HBV DNA decreased significantly ($P < 0.05$). Moreover, the decrease of serum HBV DNA level of responders was significant ($P < 0.05$).

Table 1 Changes of serum HBV DNA of patients with chronic hepatitis B (Logarithm of the value expressed by copy/ml) ($\bar{x} \pm s$)

	responders (n=9)	non-responders (n=15)	all patients (n=24)
pretreatment	8.52 ± 0.39	8.00 ± 0.64	8.20 ± 0.60
post-treatment	7.24 ± 0.83	7.16 ± 0.14	7.21 ± 1.14
P value	$P = 0.028$	$P = 0.051$	$P = 0.002$

Figure 1 Changes of the logarithm value of serum HBV DNA of patients with chronic hepatitis B (B: before IFN treatment; A: after IFN treatment)

Changes in serum TIMP-1

Because of limited samples, only the serum TIMP-1 of 13

patients (4 responders and 9 non-responders) were evaluated. After the IFN treatment was completed, the optical density (OD) values of serum TIMP-1 of 10/13 (76.9 %) of patients decreased. Compared to pretreatment, the decrease was significant (pretreatment 0.481 ± 0.199 , post-treatment 0.367 ± 0.210 , $P < 0.05$) (Figure 2), regardless of the responders or non-responders.

Figure 2 Changes of OD value of serum TIMP-1 of patients with chronic hepatitis B

Changes in HAI

Before IFN treatment, there was no significant difference of the HAI between the responders and non-responders ($P > 0.05$). After treatment, the HAI of patients decreased markedly ($P < 0.05$), especially the necrosis and intralobular inflammation ($P < 0.05$), but not the portal inflammation and fibrosis ($P > 0.05$). The changes of HAI of responders was significant ($P < 0.05$), while that of non-responders was insignificant ($P > 0.05$). (Table 2).

Table 2 Changes of HAI of patients with chronic hepatitis B ($\bar{x} \pm s$)

	responders (n=9)		nonresponders (n=15)		all patients (n=24)

Viral antigens in liver

In the liver, HBsAg was expressed in the following pattern: membranous, submembranous, cytoplasmic or inclusion body. In this study, before IFN treatment, HBsAg was mainly located in the cytoplasm of hepatocytes, and was positive in 22/24 (91.7 %). The positivity of HBsAg in the liver of responders was not considerably different from that of non-responders ($P > 0.05$). After IFN treatment, 17 patients were found to have HBsAg expression in the liver, which was not significantly different from that of pretreatment (pretreatment 1.50 ± 1.79 , post-treatment 1.11 ± 0.83 , $P > 0.05$), regardless of responders or non-responders (Responders: pretreatment 1.33 ± 0.52 , post-treatment 1.17 ± 0.75 , $P > 0.05$; Non-responders: pretreatment 1.50 ± 0.80 , post-treatment 1.08 ± 0.90 , $P > 0.05$). The location of HBsAg switched from a diffuse cytoplasmic pattern to a membranous and/or sub membranous pattern.

HBcAg can be mainly detected in hepatocyte nucleus and cytoplasm (Figure 3). HBcAg expression was positive in 20/

24 (83.3 %). There was no significant difference between HBcAg expression in the liver of the responders and non-responders ($P>0.05$). However 12/20 (60 %) of patients were found to have a decrease in HBcAg expression in liver after IFN treatment, and the location of HBcAg changed to nucleic pattern mostly. Statistics showed that HBcAg expression in the liver declined significantly, Compared to pretreatment (1.28 ± 0.75 , post-treatment 0.61 ± 0.85 , $P<0.05$). The decrease in the responders was marked, but not that in the non-responders (Responders: pretreatment 1.67 ± 0.52 , post-treatment 0.17 ± 0.47 , $P<0.05$; Non-responders: pretreatment 1.08 ± 0.79 , post-treatment 0.83 ± 0.94 , $P>0.05$).

Positive HBeAg expression in liver was mainly located in cytoplasm and nucleus of hepatocytes (Figure 4). HBeAg was detected in the liver of 12/24 (50 %) of patients before IFN treatment and 4/24 (16.7 %) after treatment. Statistics proved that HBeAg expression decreased remarkably (pre-treatment 0.78 ± 0.94 , post-treatment 0.22 ± 0.43 , $P<0.05$). But the decrease in the responders was not significantly different from that in the non-responders ($P>0.05$).

Figure 4 HBeAg expression in liver of patients with chronic hepatitis B before IFN treatment

Liver fibrosis

HSC in liver Normally, there are only several activated HSCs which contain α -SMA. But in the liver of patients with chronic hepatitis B, there were large number of α -SMA-positive HSC, diffusely located in the sinusoids (Figure 5). This showed that the number of α -SMA-positive HSC in the liver decreased significantly after treatment (pre-treatment 1.39 ± 0.35 , post-treatment 0.61 ± 0.70 , $P<0.05$). The marked change of HSC was related to the change of HAI ($P<0.05$), but not to the fibrosis score in accordance with HAI.

TIMP-1 in liver TIMP-1 in the liver was located in cytoplasm of hepatocyte (Figure 6). Before IFN- α treatment, 21/24 (87.5 %) of patients were detected positive TIMP-1 in their livers. In addition, there was no significant difference in TIMP-1 expression between responders and non-responders ($P>0.05$). After treatment, the TIMP-1 in liver of 18/21 (85.6 %) patients decreased. Compared to pretreatment, TIMP-1 in liver decreased significantly (pre-treatment 1.765 ± 1.033 , post-treatment 0.588 ± 0.441 , $P<0.01$), regardless of the responders or non-responders.

DISCUSSION

Interferon- α treatment is effective in decreasing serum alanine transferase (ALT), converting serum HBeAg and HBVDNA to negative, and improving necroinflammation in the liver of patients with chronic hepatitis B. In this study, we evaluated the effect of interferon- α on both liver histology and serum parameters.

Viral markers in sera

Among the patients, 9/24 (37.5 %) showed response reaction after interferon treatment, which agreed with other studies^[14]. The serum ALT of responders became normal, and the serum HBeAg and/or HBVDNA became negative after treatment. Compared to pre-treatment, the serum HBVDNA of the patients decreased significantly ($P<0.05$), especially that of the responders ($P<0.05$). The results suggested that interferon- α could inhibit the viral replication.

Viral antigen in liver

It was reported that interferon- α can inhibit all hepatitis B virus antigens expression in primary hepatocyte culture^[15]. Moreover, interferon can change the location of HBsAg in hepatocyte from cytoplasm to the cell membrane or submembrane region^[15], which may enhance immune recognition and clearance of infected hepatocytes. Our study evaluated the effect of interferon- α on viral antigen in liver of chronic hepatitis B. In this group, the decline of HBsAg expression in liver was not significant, but the HBsAg expression switched from cytoplasmic to membranous/submembranous, which supported some previous studies^[5,6]. However, the HBcAg and HBeAg in the liver decreased significantly after interferon treatment, especially in the responders, but not in the non-responders. This might be related to the fact that HBcAg and HBeAg of hepatocytes were target antigens of immune reaction mediated by HBV. IFN could enhance the recognition of immune system on the infected hepatocytes.

HAI

Shiratori *et al* proved that interferon therapy can improve liver histology of hepatitis C by alleviating hepatic inflammation and fibrosis^[16]. Our study showed that after interferon treatment, HAI of liver of all the patients decreased significantly ($P<0.05$), mainly in the aspects of necrosis and intralobular inflammation. The change in responders was significant, but not that in the non-responders. This indicated interferon treatment can improve the hepatic lesions of patients with chronic hepatitis B.

Liver fibrosis

Many patients with chronic hepatitis B progress slowly to liver fibrosis even cirrhosis. During this course, HSC plays a key role in the process of fibrosis. Proliferation and transformation of HSC is basic characteristic of liver fibrosis. On the one hand, liver injury and cytokines released stimulate HSC to proliferate, differentiate and acquire myofibroblast phenotype, with increase of collagen synthesis, expression of α -SMA, secretion and desposition of extracellular matrix (ECM)^[17,18]. On the other hand, HSC can secrete matrix metalloproteinase (MMP) which can degrade ECM. It is worth noting that HSC also secretes tissue inhibitor of metalloproteinase (TIMP)-the inhibitor of MMP. TIMP can noncovalently bind with MMP to inhibit the degradation of ECM, and promote liver fibrosis. Researches showed that in liver of patients with liver disease related to hepatitis B, the expression of TIMPs and MMP altered to make the liver tend to develop fibrosis^[19-22]. Certain medicine can improve liver cirrhosis^[23]. Several reports suggested that interferon treatment can alleviate hepatic fibrosis caused by viral hepatitis^[24-30]. The mechanism is not clear. Some evidence

supported that interferon reduced HSCs^[31], probably by inducing the apoptosis of HSCs^[32]. Others believed that interferon changed the amount of enzymes, such as MMP and TIMPs^[33,34].

HSC in liver

In our study, the number of HSC containing α -SMA decreased significantly after interferon treatment ($P<0.05$). The α -SMA expression by HSC decreased in 50 % of patients. This suggested that interferon treatment might inhibit the proliferation or transformation of HSC with the same conclusion by Guido's^[31]. The significant association of α -SMA to liver HAI ($P<0.05$) suggested that the effect of interferon on HSC maybe related to its anti-inflammatory function. But there was no significant relation between reduction of HSC and change of fibrosis according to Knodell's HAI, which might be due to the small size of our patients.

TIMP-1 in serum and liver

Mitsuda *et al* found that IFN- α could not only reduce the TIMP-1 in serum to enhance fibrinolysis, but also inhibit the fibrogenesis of patients with chronic hepatitis C^[33]. Whether IFN- α has similar effect on the patients with chronic hepatitis B remains to be seen.

In this study, TIMP-1 in both serum and liver of patients with chronic hepatitis B decreased markedly after IFN- α treatment. This phenomenon suggests that IFN- α can inhibit production or TIMP-1 expression to improve fibrinolysis and inhibit fibrosis.

In conclusion, our study suggests that IFN- α treatment can inhibit viral replication, alleviate liver injury, inhibit activation of HSC, decrease TIMP-1 in liver and serum and inhibit liver fibrosis. The detailed mechanism and the optimal dose and course of IFN- α still deserve more studies. Although the interval of two biopsy was not very long, evidence suggested that interferon has long-term beneficial effect in patients with chronic hepatitis B^[35]. The result was not very satisfactory. Maybe we should combine interferon and other medicines to treat chronic hepatitis B, as some study did^[36].

Abstract

AIM: The finding that some *Helicobacter pylori* strains express Lewis b (Le^b) blood group antigen casts a doubt on the role of Le^b of human gastric epithelium being a receptor for *H. pylori*. The aim of this study was to determine if expression of Le^b in *H. pylori* interferes with bacterial adhesion property.

METHODS: Bacterial adhesion to immobilized Le^b on microtitre plate was performed in 63 *H. pylori* strains obtained from Singapore using *in vitro* adherence assay. Expression of Lewis blood group antigens was determined by ELISA assay.

RESULTS: Among 63 *H. pylori* strains, 28 expressed Le^b antigen. *In vitro* adhesion assay showed that 78.6 % (22/28) of Le^b-positive and 74.3 % (26/35) of Le^b-negative *H. pylori* isolates were positive for adhesion to immobilized Le^b coated on microtitre plate ($P=0.772$). In addition, blocking of *H. pylori* Le^b by prior incubation with anti-Le^b monoclonal antibody did not alter the binding of the bacteria to solid-phase coated Le^b.

CONCLUSION: The present study suggests that expression of Le^b in *H. pylori* does not interfere with the bacterial adhesion property. This result supports the notion that Le^b present on human gastric epithelial cells is capable of being a receptor for *H. pylori*.

INTRODUCTION

Helicobacter pylori is the major etiologic agent of chronic active gastritis, and is generally accepted as a causative factor in the pathogenesis of gastritis, peptic ulcer (PU) disease and gastric adenocarcinoma^[1-3]. It is estimated that over 50 % of the world's population are infected with *H. pylori*.

The bacterium shows a strict tropism for gastric epithelium and is usually isolated from gastric epithelium and duodenal mucosa with gastric metaplasia. The presence of specific receptors for *H. pylori* on the gastric mucosa may explain its gastric tropism. The Lewis^b (Le^b) blood group antigen has been reported to be a receptor of *H. pylori*, and the blood-group antigen-binding adhesin, BabA, has been shown to mediate binding of *H. pylori* to human Le^b on gastric epithelium^[4]. Following the finding that Le^b was expressed in some strains of *H. pylori*^[5], the role of host Le^b as a receptor for *H. pylori* has been questioned considering the *H. pylori* lipopolysaccharide (LPS) Le^b may interfere with the interaction between the bacteria BabA and Le^b on gastric epithelium^[5, 6]. This may be more important for the Asian strains where there is a higher frequency of *H. pylori* strains expressing type 1 blood-group antigens (Le^a, Le^b) (43.5 % for Le^b)^[7, 8] comparing with Western strains (<10 % for Le^b). The high frequency of Le^b expression in *H. pylori* strains in our population offers a unique opportunity to investigate the potential influence of Le^b in *H. pylori* on the bacterial adhesion property.

MATERIALS AND METHODS

Patients and H. pylori isolates

H. pylori strains were isolated from the gastric biopsies of 108 patients undergoing upper gastrointestinal endoscopy for dyspepsia at the National University Hospital, Singapore. Informed consent was obtained from all the patients for gastroscopy and biopsies. A subset of 63 *H. pylori* strains from these 108 strains which were performed in our previous study^[8] was randomly chosen for the *in vitro* adherence assay. Of these, 36 were isolated from male patients and 27 were from female patients. The average age of the patients was 43 years (16-78 years). Based on endoscopic and histologic examination, the patients were classified into the following groups: peptic ulcer ($n=33$), and chronic gastritis ($n=30$). The bacteria were isolated and identified as described previously^[8]. Each strain was cultured on chocolate agar for 3-4 days at 37 °C in a humid incubator (Forma Scientific, Mountain View, USA) supplemented with 5 % CO₂.

In vitro adherence assay

The adherence assay was performed according to Gerhard *et al*^[9] with minor modifications. Briefly, for each of the 63 *H. pylori* strains, the 4-day-old culture was harvested and washed twice in 0.05 M carbonate buffer (pH 9.6) before resuspending in 1 ml of the same buffer. A 10 µl of 10 mg·ml⁻¹ of digoxigenin (Roche Diagnostics, Mannheim, Germany) solution was added to the bacterial suspension and incubated for 60 min at RT. Polysorb 96-well- microtiter plates (Nunc, Rochester, USA) were coated with 50 ng per well of Le^a, Le^b, Le^x and Le^y, (IsoSep, Tullinge, Sweden) in 50 µl of 0.05 M carbonate buffer (pH 9.6) while 50 µl of the same buffer was added as negative control. Following overnight incubation at RT, the solution was decanted without washing, and 100 µl of blocking buffer (0.5 % non-fat milk/0.2 % Tween-20) was added. After the plate was further incubated at RT for 1 hour, the solution was decanted without washing, and then 50 µl of digoxigenin

labeled bacteria diluted to an OD of 0.5 at 600 nm were added to each well of the plates and incubated for another 1 hour at RT with gentle agitation. After washing with PBS, 50 µl of 150 mU·ml⁻¹ of anti-digoxigenin-HRP antibody (Roche Diagnostics, Mannheim, Germany) was added and incubated for 1 hour at RT. The plates were washed 3 times with PBS before adding 50 µl of o-phenylenediamine dihydrochloride (Sigma, Louis, USA) (0.4 mg·ml⁻¹ in citric acid buffer with 0.025 % H₂O₂). The reaction was stopped with the addition of 2.5 M sulfuric acid. The OD value was read at 490 nm in an ELISA reader (Bio-Tek, Houston, USA). The strains were considered positive for adhesion to the antigen if the ratio of OD_{Ag}/OD_{control} was >2.0^[9]. The assay was carried out in duplicate for all the strains tested.

Lewis antigen expression

The expression of Lewis blood group antigens (Le^a, Le^b, Le^x and Le^y) was determined by enzyme-linked immunosorbent assay (ELISA) as described previously^[8, 10]. The following murine monoclonal antibodies (mAb) were used: mAb 54-1F6A, specific for Lewis^x (Le^x); mAb 1E52, specific for Le^y; mAb 7Le, specific for Le^a and mAb 225Le, specific for Le^b. Bacterial whole cells from 3-day cultures (7.5×10⁶ ml⁻¹) were suspended in 1 ml phosphate buffered saline (PBS) at pH 7.4. One hundred ml of suspension was added to each well of 96-well microtitre plate (Nunc, Rochester, USA) and incubated overnight at room temperature (RT). Plates were then washed three times with PBS containing 0.05 % Tween-20 (PBST). Subsequently, an aliquot of 100 ml of mAbs (100 ng·ml⁻¹) was added and incubated overnight at RT. After washing three times with PBST, a 100 ml solution of 1:1 000 horseradish peroxidase-labelled goat anti-mouse immunoglobulin (DAKO, Glostrup, Denmark) diluted in PBST with 0.5 % goat serum was added. Color development occurred with the addition of H₂O₂ and o-phenylenediamine dihydrochloride (Sigma, St. Louis, USA) in phosphate citrate buffer (pH 5.4) in the dark for 30 min at RT. A 50 ml of 2.5 M H₂SO₄ solution was added to each well to stop the reaction. The optical density (OD) was read at 490 nm. OD of 0.2 was chosen as the cut-off value because the sum of non-specific background binding value for mAbs never exceeded an OD of 0.1. Synthetic protein-linked Lewis antigens, i.e., Le^a, Le^b, Le^x and Le^y (IsoSep, Tullinge, Sweden) were used as positive controls for the mAbs.

Adherence blocking assay by anti-Le^b mAb

To test if blocking LPS Le^b would alter the binding of the bacteria to Le^b on ELISA plate, two chemically characterized strains with Le^b (H428 and H507)^[7] were subjected to adherence blocking assay by incubation with mAb 225Le, specific for Le^b^[8, 11]. The bacteria were incubated with 225Le mAb (1.0, 10.0, and 100.0 µg·ml⁻¹) for 1 hour at RT, and then washed twice with PBST (PBS + 0.05 % Tween-20). The adherence assay was performed as described earlier.

Statistical analysis

Frequencies were compared using 2-tailed Fisher's exact test (SPSS 9.0, Chicago, USA). The ratios of OD values were expressed as means ± standard deviations, and the distributions of the ratios were compared by using Student's *t* test for comparison of means of independent samples. A *P* value <0.05 was considered statistically significant.

RESULTS

In vitro adherence assay

Of the 63 *H. pylori* strains tested, 48 (76.2 %) were positive for adhesion to immobilized Le^b antigen on microtitre plate. The positive *H. pylori* strains showed ratios of OD_{Ag}/OD_{control}

between 2.0-4.1 while the negative strains exhibited values between 0.89-1.67. None of the *H. pylori* strains bound to Le^a, Le^x or Le^y.

Effect of Le^b expression in *H. pylori* on bacterial adhesion property

In the test for expression of Lewis antigen in *H. pylori*, 28 out of the 63 *H. pylori* strains expressed Le^b while 35 did not express Le^b based on ELISA. Among these 28 Le^b-positive strains, 22 (78.6 %) were positive for adhesion to immobilized Le^b antigen coated on plate as compared to 26 (74.3 %) of 35 Le^b-negative strains (*P*=0.772). Furthermore, the ratio of OD_{Ag}/OD_{control} was not significant difference between LPS Le^b-positive strains and Le^b-negative strains (2.3±0.7 vs 2.3±0.7, *P*=0.988).

Adherence blocking assay by anti-Le^b mAb

Two chemically characterized Le^b positive *H. pylori* strains H428 and H507^[7] were subjected to adherence blocking assay by prior incubation with the bacteria with specific mAb 225Le (100.0 µg·ml⁻¹). The ratio of OD_{Ag}/OD_{control} for strain H428 was changed from 2.7 to 2.6 after incubation with mAb 225Le. The value of adhesion assay for strain H507 was showed minimal change from 1.1 to 1.0. No difference of the ratio of OD_{Ag}/OD_{control} was observed when the bacteria were incubated with different concentrations (1.0, 10.0, and 100.0 µg·ml⁻¹) of mAb 225Le, which suggested that Le^b expression in *H. pylori* did not interfere with the bacterial adhesion to Le^b.

Effect of mixed Lewis expression on bacterial adhesion property

Of the 63 *H. pylori* strains tested, 55 expressed 2 or more Lewis antigens (Le^a, Le^b, Le^x or Le^y), and the remaining 8 strains expressed 1 Lewis antigen. Among the 55 strains with expression of 2 or more Lewis antigens, 42 (76.4 %) were positive for adhesion to immobilized Le^b compared with 6 (75 %) of 8 strains with 1 Lewis antigen expression (*P*=1.000). Furthermore, the ratio of OD_{Ag}/OD_{control} was not significant difference between the strains with expression of 2 or more Lewis antigen and strains with 1 Lewis antigen (2.3±0.7 vs 2.2±0.8, *P*=0.836).

DISCUSSION

Attachment of *H. pylori* to gastric epithelium is important for its colonization and survival. This adhesion property protects the bacteria from the displacement from the stomach by gastric emptying and peristalsis^[12]. A recent study has demonstrated that the *H. pylori* blood-group antigen-binding adhesin, BabA, facilitates bacterial colonization and augments a nonspecific immune response^[13]. The fucosylated blood group antigens of Le^b and H type 1 have been proposed as receptors of *H. pylori*^[14]. In addition, a study using transgenic mice expressing the human Le^b epitope in gastric epithelial cells indicated that Le^b antigen functioned as a receptor for *H. pylori* adhesin and mediated its attachment to gastric pit and surface mucous cells. However, following the observation^[5] that some *H. pylori* strains also express Le^b, the question on the possible role of host Le^b as a receptor for *H. pylori* has been raised by Wirth *et al*^[5] as well as Clyne and Drumm^[6]. Furthermore, if host Le^b is the principle receptor for *H. pylori*, one might then expect a decreased prevalence of *H. pylori* in the secretor subjects because Le^b present in saliva or gastric mucus in secretor individuals would competitively inhibit the binding of *H. pylori*. However, numerous studies have shown that there is no association between prevalence of *H. pylori* and host secretor status^[14], which indicates that competitive inhibition by Le^b in gastric mucus in secretor individuals may not be able to effectively prevent the colonization of *H. pylori*.

In this study, it was shown that there was no significant difference between Le^b-positive and Le^b-negative *H. pylori* strains with respect to their ability to adhere to immobilized Le^b, mimicking the epithelial cell Le^b antigen. This suggests that expression of Le^b in *H. pylori* strains in our study population does not interfere with the bacterial adhesion to immobilized Le^b *in vitro*. Furthermore, the blocking experiment using anti-Le^b mAb on two Le^b expressing strains (H428 and H507) showed that the expression of Le^b in *H. pylori* had no effect on the adhesion property of *H. pylori*. Additionally, our study population are mainly of Chinese origin which are predominantly Le (b+) phenotype^[8], and *H. pylori* strains isolated from Asian population have a tendency to express type 1 Lewis antigen (Le^a and Le^b)^[7,8]. However, a high prevalence of *H. pylori* infection has been found in this population. These data further support our observation that expression of Le^b in *H. pylori* does not affect the bacterial adhesion.

Our previous study found that increased expression of Lewis antigens in *H. pylori* was associated with peptic ulceration in our population^[8]. We, therefore, attempted to determine whether strains with Lewis antigen expression have advantage for binding to immobilized Le^b, but only observed that the increased expression of a combination of Le antigens in *H. pylori* had no influence on bacterial adhesion.

The chemical structures of Le^a, Le^b, Le^x, Le^y, i antigen, H type 1 and blood group A antigens expressed by *H. pylori* have been elucidated^[7,15,16]. These antigens are also expressed on gastric mucosa^[14]. The possible interaction between Lewis antigens expressed by *H. pylori* and gastric epithelium is intriguing. Le^x-Le^x homotypic interaction has been found to be important in eukaryotic cell interaction, and Le^x structure has recently been proven to be involved in the formation of adhesion pedestal between *H. pylori* and gastric epithelium^[14]. More recently, Le^x structure in *H. pylori* has been demonstrated to promote the bacterial adhesion to gastric epithelium^[17]. However, Le^b-Le^b homotypic interaction has not been proven, and our *in vitro* study does not support such an interaction of *H. pylori* LPS Le^b with epithelial Le^b. The next question is how a *H. pylori* population can manage to exist as single bacterium *in vivo* but not autoaggregative, when bacterium expresses both BabA adhesin and Le^b? *H. pylori* lectins such as BabA may evolve an ability to distinguish between host and bacterial ligands based on differences in their core structure, and thus avoid bacterial autoaggregation^[18,19].

In conclusion, expression of Le^b blood group antigen in *H. pylori* strains in our Asian population does not interfere with the bacterial adhesion to immobilized Le^b on microtitre plate. This result supports the notion that host Le^b present on the gastric epithelium is capable of being a receptor for *H. pylori*.

ACKNOWLEDGEMENTS

The authors are grateful to Dr. Ben J. Appelmelk (Amsterdam Free University, The Netherlands) for generously providing all the monoclonal antibodies. We thank Dr. Mario A. Monteiro (Institute for Biological Sciences, National Research Council, Ottawa, Canada) for analyzing the chemical structures of the *H. pylori* strains. Abstract

AIM: There is increasing evidence that alcohol-induced liver damage may be associated with increased oxidative stress. We aimed to investigate free-radical scavenger effect of n-acetylcysteine in rats intragastrically fed with ethanol.

METHODS: Twenty-four rats divided into three groups were fed with ethanol (6 g/kg/day, Group 1), ethanol and n-acetylcysteine (1 g/kg, Group 2), or isocaloric dextrose (control group, Group 3) for 4 weeks. Then animals were sacrificed under ether anesthesia, intracardiac blood and liver tissues were obtained. Measurements were performed both in serum and in homogenized liver tissues. Malondialdehyde (MDA) level was measured by TBARS method. Glutathione peroxidase (GSH-Px) and superoxide dismutase (SOD) levels were studied by commercial kits. Kruskal-Wallis test was used for statistical analysis.

RESULTS: ALT and AST in Group 1 (154 U/L and 302 U/L, respectively) were higher than those in Group 2 (94 U/L and 155 U/L) and Group 3 (99 U/L and 168 U/L) ($P=0.001$ for both). Serum and tissue levels of MDA in Group 1 (1.84 nmol/mL and 96 nmol/100 mg-protein) were higher than Group 2 (0.91 nmol/mL and 64 nmol/100 mg-protein) and Group 3 (0.94 nmol/mL and 49 nmol/100 mg-protein) ($P<0.001$ for both). On the other hand, serum GSH-Px level in Group 1 (8.21 U/g-Hb) was lower than Group 2 (16 U/g-Hb) and Group 3 (16 U/g-Hb) ($P<0.001$). Serum and liver tissue levels of SOD in Group 1 (11 U/mL and 26 U/100 mg-protein) were lower than Group 2 (18 U/mL and 60 U/100 mg-protein) and Group 3 (20 U/mL and 60 U/100 mg-protein) ($P<0.001$ for both).

CONCLUSION: This study demonstrated that ethanol-induced liver damage is associated with oxidative stress, and co-administration of n-acetylcysteine attenuates this damage effectively in rat model.

INTRODUCTION

Reactive oxygen intermediates contributes to the pathogenesis of various hepatic disorders such as paracetamol intoxication, hemochromatosis, toxic hepatitis, and alcoholic liver injury^[1-4]. Increased oxygen radical production leads to lipid peroxidation by induced cytochrome P4502E1^[5,6]. Enhanced generation of acetaldehyde was shown to cause lipid peroxidation in isolated perfused livers^[7]. Oxidative damage correlates with the amount of ethanol consumed^[8].

Antioxidants such as vitamin E have been suggested as therapeutic options in acute and chronic liver diseases^[9,10]. N-acetylcysteine (NAC) exerts a strong antioxidant activity, and is the treatment of choice in acetaminophen intoxication. NAC provides protection from toxic liver damage by elevating intracellular glutathione concentrations^[11,12]. It has also been used in the treatment of CCl₄ poisoning^[12].

In this study, we tested whether NAC attenuates alcohol-induced free radical damage in the liver in a rat model.

MATERIALS AND METHODS

Male Wistar-Albino rats weighing 220-250 g obtained from University of Istanbul Animal Research Laboratory were kept in the same unit and fed chow (Eris Chow Industry, Istanbul, Turkey) *ad libitum*. All rats had free access to tap water. All animals received humane care in compliance with the National Institutes of Health criteria for care of laboratory animals.

Twenty-four rats divided into three groups and were given ethanol (Group 1) or both ethanol and NAC (Group 2) or isocaloric dextrose (Group 3). NAC and alcohol were administered respectively 4 hours apart. Ethanol and NAC were given intragastrically at doses of 6 g/kg/day and 1 mg/kg/day respectively.

All rats were sacrificed at 1 month under ether anesthesia. After exploration of the thorax, intracardiac blood and liver samples were quickly obtained. Serum alcohol levels were measured on the day the rats were sacrificed.

Glutathione peroxidase levels in erythrocytes, serum alcohol level and biochemistry were studied immediately. For the remaining studies, serum and liver tissue samples were stored at -70 °C.

Tissue Homogenization: Liver samples were weighed and homogenized in 0.15 M NaCl for lipid peroxidation parameters and for the other studies, and homogenates of 20 % were obtained. Tissue homogenates were sonicated two times at 30 sec. intervals. Homogenization and sonication were performed at 4 °C. After sonication, homogenates for lipid peroxidation and biochemical studies were centrifuged at 3 000 rpm for 10 minutes and at 15 000 rpm for 15 minutes respectively. Aliquots of the supernatants were used for both studies^[13]. The assayed parameters were expressed per mg protein and protein content of the aliquots was determined by the method of Lowry *et al*^[14].

Lipid peroxidation

Lipid peroxidation was measured by thiobarbituric acid method, a modified form of the procedure described by Beuge and Aust^[15]. This method measures several aldehydes derived

from lipid hydroperoxides and also known as TBARS (thiobarbituric acid reactive substances) method.

Superoxide dismutase (SOD) level

Serum and homogenized liver tissue SOD levels were measured by using commercial kits. (Randox-Ransod, Cat No:SD 125).

Glutathione level

Glutathione concentration was determined according to the method of Beutler *et al*^[16], using metaphosphoric acid for protein precipitation and 5' 5-dithiobis-2-nitrobenzoic acid for colour development. Erythrocyte and tissue glutathione concentrations were expressed as mg/grHb, mg/gr wet weight respectively.

Glutathione peroxidase level

Serum and homogenized liver tissue glutathione peroxidase levels were also measured by using commercial kits. (Randox-Ransel, Cat No: RS 505).

Biochemical studies were performed by using autoanalyser (Hitachi 717). Hemoglobin level was measured manually by cyanmethemoglobin method.

Alcohol level

Serum alcohol level was measured by fluorescent polarizing immunoassay using commercial kits (Abbot TDx, Cat No: 378190100).

Statistical analysis

All results are expressed as mean \pm standard deviation. Comparisons between the groups were performed by Kruskal-Wallis variance analysis and a *P* value <0.05 was accepted as statistically significant.

RESULTS

Blood alcohol levels of Group 1 and 2 were comparable (207 ± 33 mg/dL vs 182 ± 27 mg/dL).

AST level in Group 1 (302.00 ± 70.68 U/L), was higher than those in Group 2 (155.25 ± 24.07 U/L), and in Group 3 (168.25 ± 32.08 U/L) ($P=0.001$). ALT level also in Group 1 (154.13 ± 33.59 U/L), was higher than those in Group 2 (94.25 ± 16.02 U/L), and in Group 3 (99.00 ± 19.86 U/L) ($P=0.001$) (Figure 1).

Figure 1 Serum AST and ALT levels (U/L). Alc: alcohol, NAC: N-acetylcysteine, ^b $P=0.001$ vs control and Alc+NAC group.

Although serum GGT level in Group 1 (8.50 ± 3.16 U/L) tend to be higher than those in Group 2 (8.25 ± 3.92 U/L) and Group 3 (6.88 ± 3.76 U/L), the difference was not significant. However tissue GGT level in Group 1 (18.75 ± 5.90 U/g-protein) was significantly higher than those in Group 2 (7.23 ± 6.09 U/g-protein) and Group 3 (6.25 ± 3.33 U/g-protein) ($P<0.001$) (Figure 2).

Figure 2 Serum (U/L) and tissue (U/g-protein) GGT levels. Alc: alcohol, NAC: N-acetylcysteine, ^b $P<0.001$ vs control and Alc+NAC group.

Although serum ALP level in Group 1 (131.38 ± 33.84 U/L) tend to be higher than those in Group 2 (109.50 ± 49.75 U/L) and Group 3 (93.13 ± 32.42 U/L), the difference was not significant either. But tissue ALP level in Group 1 (26.88 ± 3.31 U/g-protein) was significantly higher than those in Group 2 (12.63 ± 2.67 U/g-protein) and Group 3 (11.25 ± 2.49 U/g-protein) ($P<0.001$) (Figure 3).

Figure 3 Serum (U/L) and Tissue (U/g-protein) ALP levels. Alc: alcohol, NAC: N-acetylcysteine, ^b $P<0.001$ vs control and Alc+NAC group.

Erythrocyte glutathione level was lower in Group 1 (356.2 ± 18.3 mg/g-Hb) when compared to Group 2 (387.8 ± 13.1 mg/g-Hb) and Group 3 (398.0 ± 18.0 mg/g-Hb) ($P<0.01$) (Figure 4).

Figure 4 Erythrocyte glutathione levels (U/g-Hb). Alc: alcohol, NAC: N-acetylcysteine, ^b $P<0.01$ vs control and Alc+NAC group.

Blood glutathione peroxidase level was lower in Group 1 (8.21 ± 1.15 U/g-Hb) when compared to Group 2 (16.04 ± 2.38 U/g-Hb) and Group 3 (16.84 ± 2.68 U/g-Hb) ($P<0.001$) (Figure 5). Also serum SOD level was lower in Group 1 (11.08 ± 1.13 U/mL) when compared to Group 2 (17.92 ± 0.81 U/mL) and Group 3 (19.68 ± 1.76 U/mL) ($P<0.001$). The same was true for the tissue SOD levels: it was lower in Group 1 (26.04 ± 8.49 U/100 mg-protein) when compared to Group 2 (59.96 ± 10.23 U/100 mg-protein) and Group 3 (60.34 ± 8.24 U/100 mg-protein) ($P<0.001$) (Figure 6).

Serum MDA level was significantly higher in Group 1 (1.84 ± 0.14 nmol/mL) than those in Group 2 (0.91 ± 0.14 nmol/mL) and Group 3 (0.94 ± 0.11 nmol/mL) ($P < 0.001$) (Figure 7). For the tissue levels, it was higher also in Group 1 (96.00 ± 18.20 nmol/100 mg-protein) than those in Group 2 (64.00 ± 11.63 nmol/100 mg-protein) and Group 3 (49.63 ± 12.11 nmol/100 mg-protein) ($P < 0.001$) (Figure 8).

Figure 5 Blood glutathione peroxidase levels (U/g-Hb). Alc: alcohol, NAC: N-acetylcysteine, ^a $P < 0.001$ vs control and Alc+NAC group.

Figure 6 Serum (U/mL) and tissue (U/100 mg-protein) superoxide dismutase (SOD) levels. Alc: alcohol, NAC: N-acetylcysteine, ^b $P < 0.001$ vs control and Alc+NAC group.

Figure 7 Serum MDA level (nmol/mL). Alc: alcohol, NAC: N-acetylcysteine, ^b $P < 0.001$ vs control and Alc+NAC group.

Figure 8 Tissue MDA level (nmol/100 mg-protein). Alc: alcohol, NAC: N-acetylcysteine, ^b $P < 0.001$ vs control and Alc+NAC group.

DISCUSSION

Ethanol is capable of generating oxygen radicals, inhibiting glutathione synthesis, producing glutathione loss from the tissue, increasing malonyldialdehyde levels and impairing antioxidant defense systems in humans and experimental animals. Lipid peroxidation results from the increased oxygen radical production by the induced 2E1^[6]. Enhanced generation of acetaldehyde was also shown to be capable of causing lipid peroxidation in isolated perfused livers^[7]. Lipid peroxidation is not only a reflection of tissue damage, it may also play a pathogenic role, for instance by promoting collagen production^[17]. The removal of the toxic metabolites is believed to be the vital initial step in providing cell survival during ethanol intoxication^[18].

Genc *et al*^[19], used melatonin in preventing lipid peroxidation due to acute alcohol intoxication. They found that melatonin administration prior to alcohol did not alter MDA and GSH levels of the tissue but an antioxidant enzyme (CuZn-SOD) was higher in animals receiving alcohol+melatonin. However since absorption and kinetics of this hormone are not widely known, and its antioxidant effect depend on both the tissue studied and the dose applied, the results of a melatonin study may not reflect the effects of other antioxidants.

Nanji *et al*^[20], used thromboxane inhibitors in alcoholic liver disease in rats. They found that treatment with thromboxane inhibitors prevented necrosis and inflammation, and suggested a role for the use of thromboxane inhibitors in the treatment of alcoholic liver disease. Flora *et al*^[21] tested NAC and a chelator agent meso 2,3-dimercaptosuccinic acid combination in the treatment of arsenic-induced oxidative stress, and found that these agents had a capability of reversing the toxic effects.

Bruck *et al*^[11], have used NAC in the treatment of thioacetamide-induced fulminant hepatic failure in the rat model. They found no protective effect of NAC. In this model, total hepatic glutathione content is not affected. Instead, other free radical scavengers, dimethylsulfoxide and dimethylthiourea having additional modes of action such as inhibition of nitric oxide formation prevented liver injury.

The results of our study show that co-administration of NAC diminishes oxidative stress, by increasing antioxidant enzymes. This restoration of oxidant/antioxidant balance is reflected by lower levels of transaminases, ALP, and GGT. Although the decrease in serum level of the latter two enzymes was not significant, tissue levels were lower. NAC has been used in acetaminophen intoxication. It reduces the incidence of organ failure and enhances survival^[22]. It acts by reducing tissue hypoxia, mediated by the activity of the nitric oxide/soluble guanylate cyclase system^[1]. Cysteine derived from NAC also serves as a precursor of glutathione which forms conjugates with carbon tetrachloride metabolites^[23] and increases intracellular glutathione concentrations^[1]. In a recent study, NAC - in a lower dose than used in the current study - has been shown to prevent the fatty acid changes produced by ethanol and also reduce inflammatory response by reducing the level of prostaglandin^[24].

Antioxidant protective mechanisms are both enzymatic and nonenzymatic. Impairments in these defense systems have been shown in alcoholics: alterations in ascorbic acid levels, glutathione, selenium, and vitamin E have been observed^[25,26]. Reduced hepatic alpha-tocopherol content after long-term ethanol feeding in rats under adequate intake of vitamin E^[27] and also in alcoholics^[28] has been reported. Alpha-tocopherol level was found to be reduced in the blood of the alcoholics^[29]. In addition to acetaldehyde and free radical generation by the ethanol-induced microsomes, these deficient defense systems were suggested to contribute to liver damage via lipid peroxidation^[17]. Lipid peroxidation is a reflection of tissue

damage and plays a pathogenic role by promoting collagen production^[30].

A growing body of experimental and clinical experience shows the importance of free radicals in ethanol-induced liver damage. Free radical scavenging property may be beneficial as ascertained by previous studies of NAC in both acetaminophen and carbon tetrachloride intoxication. In this rat model, we have used NAC to attenuate ethanol-induced free radical damage. In both serum and tissue levels, we observed a favorable result. The results of this study suggest a role for NAC in the management of ethanol-induced liver damage as a safe, cheap, and effective option.

Abstract

AIM: To investigate the intragastric mechanisms for regulation of gastric neuroendocrine functions during gastric distention in isolated vascularly perfused rat stomach.

METHODS: Isolated vascularly perfused rat stomach was prepared, then the gastric lumen was distended with either 5, 10 or 15 ml pH7 isotonic saline during a period of 20 min. During the distention, the axonal blocker tetrodotoxin (TTX), the cholinergic antagonist atropine, or the putative somatostatin-antagonist cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)] were applied by vascular perfusion. The releases of gastrin and somatostatin were then examined by radioimmunoassay.

RESULTS: The graded gastric distention caused a significant volume-dependent decrease in gastrin secretion [-183 ± 75 (5 ml), -385 ± 86 (10 ml) and -440 ± 85 (15 ml) pg/20 min] and a significant increase of somatostatin secretion [260 ± 102 (5 ml), 608 ± 148 (10 ml) and 943 ± 316 (15 ml) pg/20 min]. In response to 10 ml distention, the infusion of either axonal blocker TTX (10^{-6} M) or cholinergic blocker atropine (10^{-7} M) had a similar affect. They both attenuated the decrease of gastrin release by approximately 50 %, and attenuated the increase of somatostatin release by approximately 40 %. The infusion of somatostatin-antagonist cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)] (10^{-6} M) attenuated the decrease of gastrin release by about 60 %. Furthermore, combined infusion of the somatostatin-antagonist and atropine completely abolished distention-induced inhibition of gastrin release.

CONCLUSION: The present data suggest that distention of isolated rat stomach stimulates somatostatin release via cholinergic and non-cholinergic TTX-insensitive pathways. Both somatostatin and intrinsic cholinergic pathways are responsible for distention-induced inhibition of gastrin release.

INTRODUCTION

Early in 1948, Grossman first proposed that intragastric neurones could regulate gastric neuroendocrine response to gastric distention independent of the extrinsic nervous system^[1], and later Schubert and Makhlof reported that

distention of the distal part of the isolated rat stomach activates the intrinsic VIP neurones and the intrinsic cholinergic mechanism, thereby regulating gastrin and somatostatin release^[2]. However, the intrinsic pathways, independent of extrinsic nerves, which are activated by gastric distention and which modify gastrin release, have remained largely obscure until now.

After finding that distention of isolated rat stomach results in an inhibition of gastrin release and that distention of the extrinsically innervated stomach stimulates gastrin release *in vivo*^[3], we performed this study to examine the intragastric mechanisms involved in regulation of gastrin and somatostatin response to gastric distention. For the study, gastric distention was performed *in vitro* in isolated vascularly perfused rat stomach, an extrinsically denervated preparation that retains the integrity of intramural neurones as well as intragastric paracrine pathways^[4-7]. In this model the effect of graded gastric distention on the release of gastrin and somatostatin was determined. The importance of the intrinsic nervous system and, in particular, its cholinergic part was investigated by performing distention in presence of the axonal blocker tetrodotoxin (TTX) and the cholinergic antagonist atropine. The putative somatostatin-antagonist cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)] was employed in order to evaluate the role of endogenous somatostatin on regulation of gastrin release during gastric distention.

MATERIALS AND METHODS

Materials

Male Wistar rats ($n=101$), body weight 250-300 g (Charles River Wiga GmbH, Sulzfelden, Germany); dextran T-70 (Pharmacia, Uppsala, Sweden); bovine serum albumine (Serva, Heidelberg, Germany); cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)] (Bachem, Hannover, Germany); commercial gastrin-kit (Becton and Dickinson, Heidelberg, Germany); tetrodotoxin (TTX), atropine, somatostatin-14 and porcine gastrin-releasing peptide (GRP) (Sigma Chemie, Munich, Germany).

Experimental design

We first prepared the rat stomach. The stomach was isolated from rats fasted overnight using a procedure described by McIntosh *et al*^[8,9]. The isolated stomach was perfused through the celiac artery in a single pass perfusion system at a rate of 1.5 ml/min with a modified Krebs-Ringer buffer solution. The perfusion medium contained 4 % dextran T-70, 0.2 % bovine serum albumin and 5.5 mM glucose and was gassed with 95 % O₂ and 5 % CO₂. The gastric venous effluent was collected via a catheter in the portal vein at two-minute intervals and frozen immediately for subsequent radioimmunoassay. A further catheter was placed in the stomach via the esophagus with the tip at the cardia. A distal catheter was placed in the stomach at the ligated pylorus to drain gastric contents.

After insertion of the gastric catheters, the lumen of the stomach was gently rinsed with isotonic pH7 saline until clear. Thereafter gastric lumen was continuously perfused with saline (1.5 ml/min) during an equilibration period of 25 min and a basal period of 10 min and the perfusate was allowed to flow off via a distal catheter. Subsequently, graded gastric distention

was initiated by instillation of 5, 10 or 15 ml saline through the esophageal catheter at a rate of 2 ml per 10 sec while the distal catheter was blocked. After a distention period of 20 min the distal catheter was reopened and the gastric lumen was again perfused for a period of 20 min with saline. After instillation of the saline load, a fluid filled pressure transducer was connected to the esophageal catheter for recording of the intragastric pressure. During distention, intragastric pressure increased to 5.0 ± 0.4 cm water at 5 ml saline load, to 10.4 ± 0.9 cm water at 10 ml saline load and to 15.0 ± 1.1 cm water at 15 ml saline load. The increase in intragastric pressure induced by the tested distention volumes caused no visible mucosal damage and no impairment of vascular perfusion.

For neural blockade, either the neurotoxin TTX (10^{-6} M) or the cholinergic blocker atropine (10^{-7} M) was added to the vascular perfusate. In further experiments the putative somatostatin-antagonist cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)] (10^{-6} M) was added to the perfusate alone or in combination with atropine (10^{-7} M). Since the somatostatin-antagonist did not completely abolish distention-induced inhibition of gastrin release, its effectiveness was tested against the inhibitory action of somatostatin-14 (10^{-8} M) on gastrin release prestimulated by mammalia bombsin peptide GRP (10^{-8} M), which is well known in stimulating gastrin secretion^[10-12]. In each stomach only one experiment was performed.

Radioimmunoassay

Gastrin levels in the venous effluent were measured by radioimmunoassay as described elsewhere^[13] employing a commercial gastrin-kit. Somatostatin was determined as described in detail previously^[14], by employing antibody 80C which was generously provided by Dr. R.H. Unger (Dallas, TX, USA).

Data analysis

All data are expressed as mean \pm SE. Integrated peptide secretion was calculated as the sum of the differences between the value of each time point during gastric distention and the mean value of the preceding baseline period. For statistical evaluation of the point-to-point variations, the Friedman two-way analysis of variance was used, followed by the Wilcoxon matched-pairs signed rank test if the former allowed rejection of the null hypothesis. The difference in the values between the treatment groups was statistically evaluated by analysis of variance for multiple determinations. Differences resulting in *P*-values of 0.05 or less were considered significant.

RESULTS

Effect of graded gastric distention on release of gastrin and somatostatin

Graded distention of isolated rat stomach elicited a significant and volume dependent decrease in gastrin release from a mean baseline of 63 ± 4 to a minimum of 50 ± 3 pg/min ($P < 0.05$; $n = 8$), during distention with 5 ml, from 69 ± 6 to 41 ± 3 pg/min ($P < 0.01$; $n = 15$), with 10 ml and from 60 ± 7 to 25 ± 5 pg/min, and with 15 ml saline ($P < 0.01$; $n = 8$) (Figure 1). Gastrin secretion decreased throughout the distention period and returned promptly to baseline values after removal of the intragastric saline load. Integrated gastrin release decreased during distention by -183 ± 75 pg/20 min ($P < 0.05$) at 5 ml, by -385 ± 86 pg/20 min ($P < 0.01$) at 10 ml, and by -440 ± 85 pg/20 min ($P < 0.01$) at 15 ml saline distention (Figure 2).

Somatostatin levels rose volume-dependently during gastric distention from a mean baseline of 41 ± 5 to a maximum level of 61 ± 6 pg/min ($P < 0.05$) at 5 ml, from 40 ± 5 to 92 ± 12 pg/min ($P < 0.01$) at 10 ml and from 39 ± 6 to 116 ± 22 pg/min ($P < 0.01$) at 15 ml saline load (Figure 1). After distention,

somatostatin secretion decreased to its baseline level. The integrated incremental somatostatin release was 260 ± 102 pg/20 min ($P < 0.05$) during distention with 5 ml, 608 ± 148 pg/20 min ($P < 0.01$) during distention with 10 ml and 943 ± 316 pg/20 min ($P < 0.05$) during distention with 15 ml saline (Figure 2).

Figure 1 Release of gastrin and somatostatin from perfused rat stomachs in control ($n = 8$) and during gastric distention with 5 ml ($n = 8$), 10 ml ($n = 15$) and 15 ml ($n = 8$) saline (mean \pm SE)

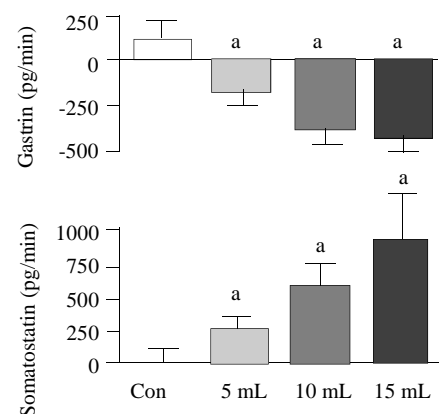

Figure 2 Integrated release of gastrin, somatostatin from perfused rat stomachs in control ($n = 8$) and during gastric distention with 5 ml ($n = 8$), 10 ml ($n = 15$) and 15 ml ($n = 8$) saline. (mean \pm SE) ^a $P < 0.05$ vs 10 ml distention in control

Effect of TTX and atropine on release of gastrin and somatostatin during gastric distention

The axonal blocker TTX (10^{-6} M) and the cholinergic antagonist atropine (10^{-7} M) elicited similar effects on distention-induced inhibition of gastrin. The decrease of gastrin release in response to distention with 10 ml saline was attenuated by approximately 50 % [from -385 ± 86 pg/20 min to -189 ± 89 pg/20 min ($P < 0.05$ vs control)] during infusion of TTX ($n = 10$), and to -224 ± 95 pg/20 min ($P < 0.05$ vs control) during infusion of atropine ($n = 10$) (Figure 3). The effects of TTX and atropine on distention-stimulated somatostatin release were also nearly identical, and the incremental somatostatin response to a 10 ml intragastric saline load was reduced about

40 % [from 608 ± 148 pg/20 min to 370 ± 100 pg/20 min ($P < 0.05$ vs control) in presence of TTX, and to 404 ± 77 pg/20 min ($P < 0.05$ vs control) during infusion of atropine] (Figure 3).

Effect of the somatostatin-antagonist on release of gastrin during gastric distention

In presence of the somatostatin-antagonist (10^{-6} M), the decrease in gastrin release induced by gastric distention with 10 ml saline was significantly attenuated (-167 ± 73 pg/20 min with somatostatin-antagonist vs -385 ± 86 pg/20 min without somatostatin-antagonist; $P < 0.05$, $n = 15$). Combined administration of the somatostatin-antagonist and atropine ($n = 15$) nearly completely abolished distention-induced inhibition of gastrin release (Figure 3).

Figure 3 Integrated release of gastrin and somatostatin from perfused rat stomachs during gastric distention with 10 ml in control ($n = 15$) and in presence of tetrodotoxin (TTX, 10^{-6} M; $n = 10$), atropine (Atro, 10^{-7} M; $n = 10$), somatostatin-antagonist (SA, 10^{-6} M; $n = 15$) and a combination of somatostatin-antagonist and atropine ($n = 15$), (mean \pm SE). * $P < 0.05$ vs 10 ml distention in control.

Effect of the somatostatin-antagonist on the inhibitory action of exogenous somatostatin-14 on GRP-prestimulated gastrin release

Infusion of GRP (10^{-8} M) produced a significant increase in gastrin release, from a baseline value of 58 ± 6 to a maximum of 136 ± 11 pg/min. GRP-prestimulated gastrin release was reduced significantly from 136 ± 11 pg/min to 84 ± 4 pg/min by exogenous somatostatin-14 (10^{-8} M; $n = 11$) ($P < 0.05$). When somatostatin-14 was removed from the perfusate, gastrin release promptly returned to prestimulated levels. At a dose of 10^{-6} M the somatostatin-antagonist did not change the baseline gastrin release, but completely blocked the inhibitory action of exogenous somatostatin-14 on GRP-prestimulated gastrin release ($n = 9$). (Figure 4).

Figure 4 Effect of somatostatin-14 (10^{-6} M) on gastrin release from perfused rat stomachs prestimulated by GRP (10^{-8} M) in control ($n = 11$) and during perfusion with somatostatin-antagonist (10^{-6} M; $n = 9$). (mean \pm SE.)

DISCUSSION

It is well established that gastric distention *in vivo* activates vagal mechanoreceptors within the gastric wall. The afferent vagal nerve fibers activate brainstem neurones which regulate vagal efferent fibers and thereby exocrine and endocrine functions of the stomach^[15-19]. Apart from this extrinsic nervous system, the stomach itself contains regulatory systems within the gastric wall such as intrinsic neurons and intrinsic paracrine pathways^[20-22]. The importance of these intragastric mechanisms on regulation of gastrin in response to gastric distention is largely unknown. Isolated perfused stomach allows examination of the remaining intragastric regulatory mechanisms since this model is separated from the extrinsic innervation and the systemic humoral signals, whereas the integrity of intrinsic neurocrine and paracrine pathways is maintained.

As previously reported, distention of the isolated stomach causes a decrease of gastrin release in proportion to the applied intragastric volume and intragastric pressure^[3]. To examine the functional role of the intragastric nervous system we employed the neurotoxin tetrodotoxin (TTX) which blocks all neural elements that are activated by an influx of Na^+ . This comprises all the adrenergic and cholinergic neurons and, presumably, the majority of peptidergic neurons as well. The effect was observed while using a very low concentration of TTX (10^{-6} - 10^{-8} M) which had no noticeable effect on other membrane parameters^[23]. The present data suggest that the inhibition of gastrin release during gastric distention is mediated in part by neural, particularly cholinergic, mechanisms.

However, the classical cholinergic neurotransmitter acetylcholine and its stable analogue carbachol stimulate gastrin release *in vivo* in the isolated stomach preparation and in cultured antral G-cells^[24-27]. Therefore the inhibitory effect of the cholinergic system on gastrin release in our experiment seems to be indirect, perhaps via peptidergic neurotransmitters. Furthermore, the present data suggest that gastric distention activates endogenous somatostatin through cholinergic and non-cholinergic TTX insensitive pathways, and endogenously released somatostatin can cause distention-induced inhibition of gastrin release. Several studies have shown a reciprocal relationship between stimulation of somatostatin and inhibition of gastrin, suggesting a functional linkage between somatostatin and gastrin release^[28-32]. Accordingly, the importance of endogenous somatostatin for regulation of gastrin release is supported by studies with antisomatostatin serum, demonstrating an augmented gastrin release after neutralization of endogenously released somatostatin in isolated rat stomach^[33]. These findings imply that endogenous somatostatin exerts its inhibitory effect on gastrin release via intragastric mechanisms. The secretion and expression of gastrin are under the paracrine control of somatostatin, produced by D cells situated in close contact with gastrin-producing G cells, and gastric D-cells extend the long cytoplasmatic processes that terminate close to gastrin-secreting G-cells in antral mucosa of both humans and rats^[34,35]. This morphological evidence for a paracrine mode of action is consistent with the functional study results.

The putative somatostatin-antagonist cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr (Bzl)] has been described as an antagonist of somatostatin in some peripheral tissues such as endocrine rat pancreas, the papillary muscle of the guinea pig heart and the ferret trachea, as well as in neural tissues such as avian choroid, rat cortex, rat hippocampus and rat pituitary^[36]. In the present study the somatostatin antagonist completely blocked the inhibitory effect of a high infusion rate of somatostatin-14 on gastrin release. During infusion of somatostatin-14 (10^{-8} M), somatostatin measured in the portal venous effluent of the isolated rat stomach rose to levels

between 1 000 and 1 600 pg/min, whereas somatostatin secretion during gastric distention was only between 60 and 120 pg/min. Since the inhibitory effect of exogenous somatostatin was sufficiently antagonized by the dose of the somatostatin-antagonist employed, it seems most likely that a sufficient amount of antagonist was administered to block all the effects of endogenously released somatostatin during gastric distention. Therefore the residual inhibition of gastrin during gastric distention in presence of the somatostatin-antagonist seems to be independent of endogenous somatostatin and may be mediated by inhibitory cholinergic pathways.

Schubert and Makhlof have previously shown that low distention of the antral part of the isolated rat stomach stimulated somatostatin and inhibited gastrin release probably via VIP-dependent mechanisms, whereas high distention caused an increase in gastrin and a decrease in somatostatin secretion via cholinergic pathways^[2]. Distention of the whole stomach seems to activate other regulatory mechanisms than selective distention of the distal part of the stomach, since Debas *et al.* have shown that distention of the oxyntic gland area of the stomach can modulate antral gastrin release^[37]. Furthermore the mechanoreceptors in the antrum have been reported to respond mainly to gastric contractions, while those located in the corpus and fundus respond primarily to distention^[38].

In conclusion, the present data suggest that distention of the isolated rat stomach inhibits gastrin release via intrinsic neurocrine and paracrine pathways. Both somatostatin and intrinsic cholinergic pathways are responsible for distention-induced inhibition of gastrin release. Somatostatin release is activated by gastric distention through cholinergic and non-cholinergic TTX-insensitive pathways.

ACKNOWLEDGEMENT

The author sincerely thanks Dr. N. Weigert and Professor V. Schusdziaarra in the Department of Internal Medicine II, Technical University of Munich, Germany, for their expert guidance in this experimental research.

Abstract

AIM: To study the effects of tetrandrine (Tet) on calcium release-activated calcium current (I_{CRAC}), delayed rectifier potassium current (I_K), and inward rectifier potassium currents (I_{K1}) in isolated rat hepatocytes.

METHODS: Hepatocytes of rat were isolated by using perfusion method. Whole cell patch-clamp techniques were used in our experiment.

RESULTS: The peak amplitude of I_{CRAC} was -508 ± 115 pA ($n=15$), its reversal potential of I_{CRAC} was about 0 mV. At the potential of -100 mV, Tet inhibited the peak amplitude of I_{CRAC} from -521 ± 95 pA to -338 ± 85 pA ($P < 0.01$ vs control, $n=5$), with the inhibitory rate of 35 % at 10 μ mol/L and from -504 ± 87 pA to -247 ± 82 pA ($P < 0.01$ vs control, $n=5$), with the inhibitory rate of 49 % at 100 μ mol/L, without affecting its reversal potential. The amplitude of I_{CRAC} was dependent on extracellular Ca^{2+} concentration. The peak amplitude of I_{CRAC} was -205 ± 105 pA ($n=3$) in tyrode's solution with Ca^{2+} 1.8 mmol/L ($P < 0.01$ vs the peak amplitude of I_{CRAC} in external solution with Ca^{2+} 10 mmol/L). Tet at the concentration of 10 and 100 μ mol/L did not markedly change the peak amplitude of delayed rectifier potassium current and inward rectifier potassium current ($P > 0.05$ vs control).

CONCLUSION: Tet protects hepatocytes by inhibiting I_{CRAC} , which is not related to I_K and I_{K1} .

INTRODUCTION

Tetrandrine (Tet) is a bisbenzylisoquinoline alkaloid from a Chinese medicinal herb (*Stephania tetrandra* S. Moore). In the past decade, lots of studies demonstrated that Tet possessed multiple bioactivities, such as potential immunomodulating, anticarcinoma^[1] and protective effect on CCl₄-injured hepatocytes^[2]. It has also been used in the treatment of ischemic heart diseases^[3] and hypertension^[3,4]. Recently, the antifibrotic effects of Tet have been received considerable attention^[1,5-10]. The former researches of Tet on the liver have probed into cellular and molecular levels^[9,10]. In the present paper, we used

whole-cell patch-clamp technique to observe the effects of Tet on I_{CRAC} , I_K , I_{K1} in normal isolated rat hepatocytes, in order to have a better understanding its hepatoprotective and antifibrotic effects.

MATERIALS AND METHODS

Solutions and drugs

Tet was from Jinhua Pharmaceutical Co. The stock solution (10 mmol/L) was dissolved in distilled water after acidification with 0.1 mol/L HCl and neutralized with 0.1 mol/L NaOH. Ca^{2+} -free Hank's solution was prepared without Ca^{2+} and Mg^{2+} . KB solution contained (mmol/L): glutamic acid 70, taurine 15, KCl 130, KH_2PO_4 10, HEPES 10, glucose 11, egtazic acid 0.5, pH was adjusted to 7.4 with KOH. The external solution used to record I_{crac} contained (mmol/L): NaCl 140, KCl 2.8, $CaCl_2$ 10, $MgCl_2$ 0.5, glucose 11, HEPES 10, pH was adjusted to 7.4 with NaOH. The internal solution used to record I_{CRAC} contained (mmol/L): potassium-glutamate 145, NaCl 8, $MgCl_2$ 1, Mg-ATP 0.5, egtazic acid 10, HEPES 10, pH was adjusted to 7.2 with KOH. The external solution used to record I_K contained (mmol/L): NaCl 144, KCl 4, $CaCl_2$ 1.8, $MgCl_2$ 0.53, NaH_2PO_4 0.33, glucose 5.5, HEPES 5, pH was adjusted to 7.4 with NaOH. The internal solution used to record I_K contained (mmol/L): KCl 130, K_2ATP 5, creatine phosphate 5, HEPES 5, pH was adjusted to 7.2 with KOH. The same external and internal solutions used to record I_{K1} contained (mmol/L): KCl 7, $MgCl_2$ 2, egtazic acid 1, potassium-glutamate 130, HEPES 10, pH was adjusted to 7.4 with KOH.

Isolation of single hepatocytes

Hepatocytes were isolated with the modified method reported by Seglen^[11]. Briefly, adult wistar rats of either sex (175 ± 25 g) were anesthetized by intraperitoneal injection of pentobarbital sodium (50 mg/kg). The portal vein was cannulated and perfused with oxygenated Ca^{2+} -free Hank's solution 30 ml/min at 37 °C for 4-5 min followed by perfusion with Ca^{2+} -free Hank's solution containing collagenase (Type 1, Sigma) (0.3g/L) for 10 min. The liver was chopped in 10 ml Ca^{2+} -free Hank's solution. The cell suspension was filtered through 200 mesh gauze and then centrifuged three times (50 g, 2 min) to separate liver cells. Cells were plated onto the coverslips and incubated in KB medium for 2 hour and preserved in DMEM at 4 °C.

Electrophysiologic recording

Whole-cell recordings were performed using a PC-II patch clamp amplifier (Huazhong university of science and technology). The recording chamber (1.5 ml) was perfused with the corresponding external solution. The pipettes were pulled in two stages from hard glass capillaries using a vertical microelectrode puller (Narishige, Japan). Electrode has a resistance of 2-5 M Ω for whole-cell recording when filled with electrode internal solution. All experiments were conducted at 22 ± 2 °C.

Statistic analysis

The data were expressed as $\bar{x} \pm s$. Statistical significances were analyzed by a unpaired *t*-test. A value of $P < 0.05$ was considered significant.

RESULTS

Effect of Tet on calcium release-activated calcium current (I_{CRAC})

I_{CRAC} was elicited for 200 ms from the holding potential of 0 mV to various potentials ranging from -10 mV to +80 mV with the step of 20 mV every 5 s^[12]. The peak amplitude of I_{CRAC} was -508 ± 115 pA ($n=15$) and the reversal potential of I_{CRAC} was about 0 mV, the current was steady and without run-down in 5 mins. Tet inhibited the peak amplitude of I_{CRAC} from -521 ± 95 pA to -338 ± 85 pA ($P < 0.01$ vs control, $n=5$), with the inhibitory rate of 35 % at 10 $\mu\text{mol/L}$ and from -504 ± 87 pA to -247 ± 82 pA ($P < 0.01$ vs control, $n=5$), with the inhibitory rate of 49 % at 100 $\mu\text{mol/L}$. Tet did not affect the shape of its current voltage curve (Figure 1,2).

Figure 1 Effect of Tet on I_{CRAC} in isolated rat hepatocytes. I_{CRAC} traces before and after Tet 10 $\mu\text{mol/L}$ and 100 $\mu\text{mol/L}$. I_{CRAC} was elicited for 200 ms from the holding potential of 0 mV to various potentials ranging from -100 mV to +80 mV with step of 20 mV.

Figure 2 Effect of Tet on I-V relationship of I_{CRAC} in isolated rat hepatocytes. Especially at the potential of -100 mV, Tet inhibited the peak amplitude of I_{CRAC} with the inhibitory rate of 35 % at 10 $\mu\text{mol/L}$ and with the inhibitory rate of 49 % at 100 $\mu\text{mol/L}$. ● control; ○ 10 $\mu\text{mol/L}$; □ 100 $\mu\text{mol/L}$.

The amplitude of I_{CRAC} was dependent on extracellular Ca^{2+} concentration. The peak amplitude of I_{CRAC} was -205 ± 105 pA ($n=3$) in tyrode's solution with Ca^{2+} 1.8 mmol/L ($P < 0.01$ vs the peak amplitude of I_{CRAC} in external solution with Ca^{2+} 10 mmol/L). Tet at 10 $\mu\text{mol/L}$ decreased I_{CRAC} from -205 ± 105 pA to -148 ± 96 pA ($n=3$).

Effect of Tet on delayed rectifier potassium current (I_K)

I_K was elicited by 900 ms depolarization steps from +30 mV to +140 mV with step of 10 mV at holding potential of -50 mV^[13]. Tet at 10 and 100 $\mu\text{mol/L}$ did not change the peak amplitude of I_K [from 2014 ± 686 pA to 2030 ± 692 pA and 2047 ± 710 pA respectively, $n=5$, cells from 3 rats, $P > 0.05$]. Tet did not affect the shape of its current voltage curve.

Effect of Tet on inward rectifier potassium current (I_{K1})

I_{K1} was elicited by a number of step pulses (40 ms) from the holding potential (E_h) of 0 mV to test potentials from -200 mV to +175 mV with the step of 10 mV^[14]. Tet at 10 and 100 $\mu\text{mol/L}$ did not change the peak amplitude of I_{K1} [from 2254 ± 718 pA to 2239 ± 700 pA and 2224 ± 658 pA respectively, $n=5$, cells from 3 rats, $P > 0.05$]. Tet did not affect the shape of its current voltage curve.

DISCUSSION

Hepatic fibrosis is a common consequence of chronic liver injury from many causes^[15-19], and the sustained hepatic injury is a primary factor for hepatic fibrogenesis^[20-28]. Preventing hepatocyte from injury is a matter of primary importance in blocking the fibrogenic pathway. Tet has been considered as an effective antifibrotic and hepatoprotective agent^[1,2,5-10], but its protection against toxic cell death has never been well illustrated.

The Ca^{2+} influx is mainly mediated by voltage-operated Ca^{2+} channels and receptor-activated Ca^{2+} channels. Voltage-operated Ca^{2+} channels are not present in hepatocytes^[29]. Calcium influx in isolated hepatocytes mainly depend on receptor-mediated Ca^{2+} entry which has been identified by indirect methods^[30]. Previous studies have shown that one type of receptor-activated Ca^{2+} channels, most likely a store-operated Ca^{2+} channel, in freshly isolated rat hepatocytes is inhibited by high concentrations of L-type voltage-operated Ca^{2+} channels antagonists^[30,31]. Besides, the mRNA encoding isoforms of L-type voltage-operated Ca^{2+} channels has been detected in rat hepatocytes, these observation suggested that receptor-activated Ca^{2+} channels in rat hepatocytes exhibit some characteristics of voltage-operated Ca^{2+} channels^[32]. Cui *et al* reported that I_{CRAC} (an important sub-type of store-operated Ca^{2+} channels) existed in isolated rat hepatocytes and 50 $\mu\text{mol/L}$ of verapamil, diltiazem and nifedipine could decrease the amplitude of I_{CRAC} effectively^[12]. The results in our experiment showed that Tet at the concentration of 10 and 100 $\mu\text{mol/L}$ could decrease the peak amplitude of I_{CRAC} . The concentration that Tet made a half-maximal inhibition of I_{CRAC} was approximately 100 $\mu\text{mol/L}$, which was substantially higher than that needed for the half-maximal inhibition of L-type voltage-operated Ca^{2+} channels by Tet. It suggested that Tet could protect hepatocytes by inhibiting I_{CRAC} and decreasing intracellular Ca^{2+} concentration, in which a higher concentration of Tet was needed.

Nietsch's study demonstrated that the activation of potassium and chloride channels by TNF- α induced apoptosis and death of the HTC rat hepatoma cells, which could be significantly delayed by K^+ channel blockers (Ba^{2+} and quinine)^[33]. Our result showed that Tet had no effect on I_K and I_{K1} , which suggested that the hepatoprotection of Tet might not relate to potassium channels. However, whether calcium activated potassium channels exist in rat hepatocytes or not remains controversial^[34,35]. The effect of Tet on potassium channels requires further investigation.

In conclusion, Tet protects hepatocytes by inhibiting I_{CRAC} , which is not related to I_K and I_{K1} .

Abstract

AIM: To investigate the influence of immune tolerance induced by intrauterine exposure to fetal hepatocytes on liver transplantation in the adult rat.

METHODS: LOU/CN rat fetal hepatocytes were injected into the fetuses of pregnant CHN rats (14-16 days of gestation). At 7-9 weeks of age, the surviving male rats received orthotopic liver transplantation (OLT) from male LOU/CN donors and the survival period was observed and monitored by mixed lymphocyte reaction assay and cytotoxicity test.

RESULTS: (1) A total of 31 pregnant CHN rats with 172 fetuses received fetal hepatocytes from LOU/CN rats via intrauterine injection. Among them, thirteen pregnant rats showed normal parturition, with 74 neonatal rats growing up normally. (2) The mean survival period after OLT in rats with fetal exposure to fetal hepatocytes was 32.1 ± 3.7 days, which was significantly different from the control (11.8 ± 2.3 days, $P < 0.01$) in rats without fetal induction of immune tolerance. (3) Mixed lymphocyte proliferation assays yielded remarkable discrepancies between the groups of rats with- or without fetal exposure to fetal hepatocytes, with values of 8411 ± 1361 and 22473 ± 1856 (CPM \pm SD, $P < 0.01$) respectively. (4) Cytotoxicity assays showed values of $21.2 \pm 6.5\%$ and $64.5 \pm 7.2\%$ ($P < 0.01$) in adult rats with or without fetal induction of immune tolerance.

CONCLUSION: Intrauterine injection of fetal hepatocytes into rat fetuses can prolong the survival period of liver transplant adult male rats recipients, inducing immune tolerance in OLT.

INTRODUCTION

In both experimental study and clinical practice, rejection responses induced by organ transplants necessitate the use of potent immunosuppressive drugs^[1-7]. It should be noted, however, that excessive dosage of immunosuppressive agents may result in severe side effects such as hypertension and

hepatic and/or renal toxicity. Moreover, prolonged usage of immunosuppressants often leads to severe infection and increased susceptibility to malignancy, thus critically affecting the health of recipients. Particularly in juvenile patients, immunosuppressive drugs can lead to stunted growth. It is therefore imperative to assess, as an alternative to immunosuppressants, the protective effect of induced immune tolerance on organ transplantation. The ideal strategy is to induce a low responsiveness or irresponsiveness in the recipients toward donors' grafts, while preserving normal immunological functions for the recognition of tumor antigens and prevention of infection. Thus immunosuppressive agents can be avoided or be used at dramatically reduced dosage. The key steps toward successful transplantation therefore include either attenuated immune reactions or induced immune tolerance to grafts^[8-15].

In utero, the stem cell transplantation represents a new therapeutic approach of experimental nature toward the treatment of hematopoietic diseases, immunodeficiency diseases, metabolic disorders and genetic diseases^[16-19]. Some reports support the possibility of using this method to induce immunologic tolerance in both human subjects and animals receiving organ transplantation^[20-22]. But the effect of *in utero* fetal exposure to fetal hepatocytes on liver transplantation in adulthood is unclear. In the present study, we injected fetal hepatocytes intraperitoneally into rat fetuses and then performed orthotopic liver transplantation (OLT) in surviving adult male rats. Some parameters were tested in order to confirm the anti-rejection effect of *in utero* injection of fetal hepatocytes.

MATERIALS AND METHODS

Animals

Male and female LOU/CN and CHN rats weighing 200-250 g were obtained from the Laboratory Animal Center of The Fourth Military Medical University, and fed with standard rat chow.

Timed pregnancy of CHN rats

Male CHN rats, or male LOU/CN rats, were housed individually in standard cages with a metal divider with 0.25-inch holes. One female CHN or LOU/CN rat was placed in the corresponding empty side. The cage divider was then removed 48 hrs later. Pairs of CHN or LOU/CN rats were allowed to mate overnight separately. The pairs were then separated with the females placed singly in cages. The presence of vaginal plug marked day 0 of gestation. Normal gestation is about 21 days.

Preparation of LOU/CN fetal rat hepatocytes

Pregnant LOU/CN females were killed by cervical dislocation at 15 to 16 days of gestation. All subsequent handling was done under sterile conditions. The uterine horns were removed and dissected in phosphate-buffered saline (PBS). Fetuses were separated from decidua and extraembryonic membranes and transferred to 35 mm petri dishes filled with PBS. Fetal livers were removed, with 5 to 10 livers placed in 1 to 2 ml RPMI 1640 medium (GIBCO BRL, Grand Island, CA) with 15 % fetal calf serum (FCS, GIBCO BRL, Grand Island, CA). Cell suspensions were prepared by repeated pipetting of the livers

through a 23-gauge needle attached to a 1ml pipette. The mononuclear cells were separated by centrifugation at 500 g for 20 minutes and filtered through a Nitex filter with a 41 μ m pore size (Huamei chemical company, Henan province, China). Cell viability counting (usually greater than 90 %) was done using trypan blue exclusion test, and the final cell suspension was prepared in PBS/15 % FCS at a concentration of 5×10^7 /ml. The cell suspension was used for intrauterine injection within 4 hours of preparation.

In utero intraperitoneal injection into CHN rat fetuses with LOU/CN fetal rat hepatocytes

Micropipettes were prepared from capillaries using a Brown and Flaming micropipette puller. The end of the needle was cut under a microscope with ophthalmological forceps, and the tip was sharpened on a micro-grinding wheel. Pregnant (11 to 13 days of gestation) CHN rats were anesthetized i.p. with sodium pentobarbital, and the uterine horns were exteriorized with ophthalmological forceps. Fetal hepatocytes from LOU/CN rats were injected into CHN fetuses through a hand-drawn glass micropipette with a beveled edge. The placenta was penetrated at an oblique angle. The number of cells injected per fetus was 10^6 (about 5×10^{10} cells/kg of recipient weight), except in experiments in which the effects of different cell concentrations and volumes of cell suspension used were examined. Muscle layers were closed with 4-0 silk suture, and 1-0 silk thread was used for skin suture.

Orthotopic liver transplantation (OLT)

Orthotopic whole-liver transplantation was performed^[23-26] using the simplified cuff technique for portal and intrahepatic vena cava anastomosis, whereas the hepatic artery was not reconstructed. The twenty male CHN rats, aged 7 to 9 weeks that survived intraperitoneal injection with fetal liver cells from LOU/CN rats, were taken as graft recipients, with normal male LOU/CN rats as liver donors. Both donors and recipients were anesthetized with methoxyflurane. After explantation, livers were stored at 0-4 °C for 1 hr in UW solution. Grafts were connected to suprahepatic vena cava with a running 7-0 prolene suture. We insert cuffs into the corresponding vessels, and anastomose the bile duct and hepatic artery over an intraluminal polyethylene splint. Transplantation required less than 40 min, while the portal vein was clamped for 12-15 min during this period. After transplantation, the recipients had free access to standard laboratory chow and tap water. Animals that died within 3 days were considered technical failures and were excluded from data collection. The rate of success of liver transplantation was more than 90 % in this study. Five rats were sacrificed at 5 days after OLT. Immediately before sacrifice, the livers were removed for histological investigation. Liver samples from 10 normal male CHN rats were taken as controls.

Mixed lymphocyte reaction assay

Mixed spleen cells were used for setting up lymphocyte cultures. Briefly, the spleens were aseptically removed from experimental CHN rats that survived *in utero* intraperitoneal injection of fetal LOU/CN rat liver cell, and from control CHN rats. Then they were separately disrupted mechanically using a pair of sterile forceps. LOU/CN spleen cells were treated with 25 μ g/ml mitocin-C (Kyowa Hakko Kogyo, Tokyo, Japan) at 37 °C for 45 min. Then the two groups of cells were washed by PBS, followed by lysis of erythrocytes in Tris-NH₄Cl solution (pH 7.2). After further washes, the cells were finally resuspended in RPMI 1640 with 10 % FCS. The numbers of two groups of spleen cells were adjusted, and 5×10^5 spleen cells from each of the two sources were mixed together (final

volume 0.2 ml) and added to triplicate wells of 96-well round-bottomed microtiter plates. Cells were cultured for 120 hr, and 1 μ Ci [3H]-thymidine was added into wells 18hr before cell harvesting. Radioactive thymidine incorporation rate was measured by a liquid scintillation counter (1205 Betaplate), with data expressed as CPM \pm SD^[27,28].

Complement-dependent cytotoxicity test

Recipient CHN rats were tested one week after OLT for complement-dependent cytotoxicity test against lymphocytes suspensions from LOU/CN donor rats. Sera from recipients were prepared and added into the wells of 96-well round-bottomed microtiter plates (1 μ l per well). Then 1 μ l lymphocytes (about 2 000 cells per 1 μ l volume) were added into the same wells. They were gently mixed and incubated for 30 min at 22 °C \pm 2 °C, then 5 μ l rabbit complement (Huamei chemical company, Henan province, China) was added, and the mixture incubated for 60 min at 22 °C \pm 2 °C. Afterwards, the mixtures were stained with eosin (50 g/L) for 5 min. The cells were fixed in 36 % formalin for 2 hr and observed with an inverted phase-contrast microscope (Olympus, Tokyo, Japan). Cytotoxicity was determined by eosin exclusion and percentage enumeration of cells killed by sera from OLT^[29,30].

Histology

Livers from CHN rats that underwent OLT were fixed in 10 % neutral formalin for five days and then embedded in paraffin. Five micron sections were cut and stained with hematoxylin and eosin for histological examination. Sections from normal rat livers served as controls.

Diagnostic criterion of graft rejection

Several diagnostic criteria were used to determine the existence of rejection response following hepatic transplantation. The first is survival of recipients over 7 days post-transplantation. The second entails the occurrence of acute hepatic dysfunction as typified by inappetence, weight loss, auricle or nail jaundice, depressed mood, with incidental diarrhea or ascites in some cases. The third criterion involves typical histological changes, such as enlarged liver bulk, yellowish white appearance of the liver, and the presence of liver conglutination to muscles or abdominal walls, and viscera. Also frequently encountered are apparent degeneration or necrosis of hepatic cells, and infiltration of numerous lymphocytes, especially at liver sinusoidal area. The fourth denotes the presence in good condition of the recipients plus good appetite, accompanied with normal weight 3 days after successful transplantation. The recipients that died from post-surgical complications such as necrosis of bile duct, intra-abdominal hemorrhage and infection were excluded from data collection.

Statistics

All the data were analyzed by Student's *t* test and expressed as mean \pm S. The statistical difference *P*<0.05 was considered significant and *P*<0.01 as very significant.

RESULTS

Influence of intraperitoneal injection into fetus in utero on survival of neonatal CHN rats

Thirty-one pregnant CHN recipients who later delivered 172 fetal CHN rats were injected into their fetuses with isolated fetal hepatocytes from LOU/CN rats. Among them, eleven pregnant females died from various surgical complications, and seven females aborted or consumed their litters. There were 17 pregnant rats with normal parturition, and 74 neonatal rats grew up normally.

Suppression of rejection response to rat liver transplantation after intrauterine injection

The mean survival period of rats with fetal intraperitoneal injection of fetal hepatocytes prior to OLT was 32.1 ± 3.7 day, in comparison to control values of 11.8 ± 2.3 day ($P < 0.01$) obtained from rats without this procedure.

Inhibitory effect of intraperitoneal injection in utero on mixed lymphocytes reaction assay

Mixed lymphocytes reaction assay showed significant differences in [^3H]-thymidine incorporation rates in groups of CHN rats that were either fetally exposed (8411 ± 1361 , CPM \pm SD) or not (22473 ± 1856 , CPM \pm SD) to intraperitoneal injection of fetal hepatocytes in utero ($P < 0.01$).

Suppressive effect of fetal intraperitoneal injection in utero on cytotoxicity test after rat liver transplantation in adulthood

Cytotoxicity test revealed percentage values of dead cells to be $21.2 \pm 6.5\%$ vs $64.5 \pm 7.2\%$ ($P < 0.01$) respectively from the two groups of CHN rats with or without fetal intraperitoneal injection in utero prior to OLT in the adult rats, the difference being statistically significant.

DISCUSSION

With rapid advances in antenatal diagnostic technology, many prenatal diseases (congenital metabolic liver disorders, congenital heart disease and hemophilia, e.g.) can be diagnosed. Therefore organ transplantation becomes a very useful choice for treating these diseases in afflicted children. However, routine regime of immunosuppression in use today suffered from many serious side effects, including stunted growth seen in children using most immunosuppressive drugs^[31-34]. If we can induce low responsiveness or even irresponsiveness in the recipients to the donors' grafts, immunosuppressive drugs can then be used at much reduced dosage. Until now, low responsiveness or irresponsiveness to the graft has not been achieved in clinical practice. Therefore, induction of immunologic tolerance becomes imperative in clinical transplantation^[35-42].

Clonal deletion theory maintains that burst of cell proliferation during embryonic period is very frequent, with resultant formation of multiple specific clones of lymphocytes capable of responding to respective antigens^[43,44]. During embryonic period, the lymphocyte clones encounter internal antigens or artificially introduced antigens, with consequent damage to, or suppression of these clones, the so-called abstinence clones. In postnatal life, the abstinence clone remains inactive to an internal antigen or an artificially introduced foreign antigen that has been present in utero, a status of immunologic tolerance in the adult to an antigen following prior exposure during the embryonic period. On the contrary, if a lymphocyte clone meets an antigen that has never been introduced during the embryonic period, the specific immunological response would ensue. According to the theory, intrauterine injection is considered a useful tool for the induction of immunologic tolerance, especially for clinical transplantation. Some advantages of intrauterine injection for evoking immunologic tolerance should be noted. Firstly, because the host at fetal stage can't recognize a foreign substance and thus display immunologic tolerance to a xenogen (the earlier the fetal stage of the host, the stronger the tolerance effect to the antigen), no immunologic reaction is seen between the host and ecdemic grafts. Therefore intrauterine injection spares tissue-matching work needed in routine transplantation and makes easier graft transplantation. Meanwhile, immunologic tolerance induced by intrauterine injection makes unnecessary pretreatment with immunosuppressive drugs, thus

avoiding possible side effects of immunosuppressive agents on the body. Secondly, fewer fetal liver cells are needed for transplanting into the recipients during embryonic period because of their small body size and weight. The latter assures little influence and gentle torture for the recipients. Thirdly, in addition to exempt from infection due to microorganism, the maternal body offers adequate nutrition and energy to the fetuses, thus the uterus can be seen as an ideal 'isolation room'^[45-51].

We also compared the effect of using rat spleen or bone marrow cells, with that of fetal liver cells, for intraperitoneal injection in utero into fetuses in pregnant rats. It was observed that the survival birth rate using fetal liver cells was much greater than that with spleen or bone marrow cells. Several factors may help to explain the discrepancy. The most important one may be that the response against the host is induced by active lymphocytes located in the spleen or bone marrow cells. In contrast, the main components of fetal liver cells are hematopoietic stem cells possessing two effects, with the first reducing graft versus host reaction, and the other for the maintenance of chimerism because hematopoietic stem cells are characterized by self-renewal and multipotential for differentiation^[52,53].

As evidenced by both *in vivo* and *in vitro* data in the present study, the method of fetal hepatocytes in utero injection can prolong the survival period of rat liver transplants. Although complete immune tolerance can not be induced, partial immune tolerance observed in our study is sufficient for liver transplantation. Further work will be needed to reveal if chimerism is induced by transplantation itself, as well as its possible influence on the immune system in the grafted recipients.

Abstract

AIM: To investigate functional change of dendritic cells (DCs) derived from allogeneic partial liver graft undergoing acute rejection in rats.

METHODS: Allogeneic (SD rat to LEW rat) whole and 50 % partial liver transplantation were performed. DCs from liver grafts 0 hr and 4 days after transplantation were isolated and propagated in the presence of GM-CSF *in vitro*. Morphological characteristics of DCs propagated for 4 days and 10 days were observed by electron microscopy. Phenotypical features of DCs propagated for 10 days were analyzed by flow cytometry. Expression of IL-12 protein and IL-12 receptor mRNA in DCs propagated for 10 days was also measured by Western blotting and semiquantitative RT-PCR, respectively. Histological grading of rejection were determined.

RESULTS: Allogeneic whole liver grafts showed no features of rejection at day 4 after transplantation. In contrast, allogeneic partial liver grafts demonstrated moderate to severe rejection at day 4 after transplantation. DCs derived from allogeneic partial liver graft 4 days after transplantation exhibited typical morphological characteristics of DC after 4 days' culture in the presence of GM-CSF. DCs from allogeneic whole liver graft 0 hr and 4 days after transplantation did not exhibit typical morphological characteristics of DC until after 10 days' culture in the presence of GM-CSF. After 10 days' propagation *in vitro*, DCs derived from allogeneic whole liver graft exhibited features of immature DC, with absence of CD40, CD80 and CD86 surface expression, and low levels of IL-12 proteins (IL-12 p35 and IL-12 p40) and IL-12 receptor (IL-12R β_1 and IL-12R β_2) mRNA, whereas DCs from allogeneic partial liver graft 4 days after transplantation displayed features of mature DC, with high levels of CD40, CD80 and CD86 surface expression, and as a consequence, higher expression of IL-12 proteins (IL-12 p35 and IL-12 p40) and IL-12 receptors (IL-12R β_1 and IL-12R β_2) mRNA than those of DCs both from partial liver graft 0 hr and whole liver graft 4 days after transplantation ($P < 0.001$) was observed.

CONCLUSION: DCs derived from allogeneic partial liver graft undergoing acute rejection display features of mature DC.

INTRODUCTION

The shortage of donor organs remains a major obstacle to the widespread application of liver transplantation in patients with end-stage liver disease. Although split grafting was used to increase the number of donor livers, the accelerated rejection induced by liver regeneration^[1,2] can interfere with the outcome of these liver grafts. Therefore, It is important to investigate the mechanism responsible for the accelerated rejection of split liver grafting.

After organ transplantation, interstitial donor dendritic cells (DCs) migrate to recipient lymphoid tissue. In the case of experimental skin, heart, or kidney allografts, these cells have been implicated as the principal instigators of rejection. Despite similar patterns of donor DCs migration, liver grafts are accepted without immunosuppressive therapy between MHC-mismatched mouse, and certain rat strains, and induce donor-specific tolerance. These phenomena and the persistence of donor hematopoietic cells, including DCs, in successful, long-term graft recipients, have raised important questions about the possible role of donor DCs in liver transplant tolerance. The capacity of DCs to initiate immune responses is determined by their surface expression of MHC gene products and costimulatory molecules (CD40, CD80 and CD86), and the secretion of the immune regulator, interleukin (IL)-12^[3-12]. Immature DCs resident in nonlymphoid tissues such as normal liver are deficient at antigen capture and progressing^[3,13], whereas mature DCs, resident in secondary lymphoid tissues, are potent antigen-presenting cells, which can induce naive T-cell activation and proliferation^[3-7]. Immature DCs that express surface MHC class II, but that are deficient in surface costimulatory molecules, can induce T-cell hyporesponsiveness^[13-15] and inhibit immune reactivity^[16,17]. It has been observed that liver-derived^[13,18] or bone marrow-derived immature DCs^[17], propagated *in vitro* and lacking surface costimulatory molecules, can prolong heart or pancreatic islet allograft survival. Whereas, marked augmentation of DCs numbers and maturation of DCs in liver allografts by donor treatment with the hematopoietic growth factor fms-like tyrosine kinase 3 (Flt3) ligand (FL) results in acute liver graft rejection^[19,20].

Recent findings have revealed increased immune responses to regenerating allogeneic partial liver graft in rats^[1,2], but little is known about the mechanism responsible for the accelerated rejection. The purpose of this study was to investigate the property of DCs isolated from allogeneic partial liver graft in comparison with DCs isolated from allogeneic whole liver graft, in an attempt to elucidate the possible mechanism responsible for the accelerated rejection of allogeneic partial liver graft. Given mature DC can induce naive T-cell activation and proliferation^[3-7], and consequently induce acute rejection^[19,20], we suspected that maturation of DCs derived from liver graft would be a key inducer of the accelerated rejection of allogeneic partial liver graft. In the present study, we first demonstrated that DCs derived from partial liver graft undergoing acute rejection displayed features of mature DC, including positive expression of costimulatory molecules, higher level expression of IL-12 protein and IL-12 receptor mRNA in these mature DCs.

MATERIALS AND METHODS

Animals

One hundred male LEW rats and one hundred male SD rats weighing 220-300 g were used in all the experiments. Allogeneic whole and 50 % partial liver transplantation were performed using a combination of SD rats to LEW rats. The animals were purchased from Chinese Academy of Science and Sichuan University. They were maintained with a 12-hr light/dark cycle in a conventional animal facility with water and commercial chow provided ad libitum, with no fasting before the transplantation.

Liver transplantation

All operation were performed under ether anesthesia in clean but not sterile conditions. All surgical procedures were performed from 8 a.m. to 5 p.m. Donors and recipients of similar weight (± 10 g) were chosen. Liver reduction was achieved by removing the left lateral lobe and the two caudate lobes, which resulted in a 50 % reduction of the liver mass. Whole liver transplantation (WLT) and partial liver transplantation (PLT) were performed with the two-cuff method described by Kammada and Calne^[21], Knoop *et al*^[22] and Uchiyama *et al*^[23]. Briefly, the whole and partial liver were perfused with 20 ml of chilled lactated Ringer's solution containing 200 U of heparin through the aorta. The liver was removed and immersed in chilled University of Wisconsin solution. Immediately after cuffs were placed on the portal vein and the infrahepatic vena cava, the liver graft was perfused with 8 ml of chilled University of Wisconsin solution through the portal vein and 2 ml of the same solution through the hepatic artery, and then the hepatic artery was ligated. Cold preservation time was approximately 1 hr in all experiments. After a total hepatectomy was performed in the recipient, the suprahepatic vena cava was anastomosed in a continuous fashion with 8-0 sutures. The portal vein and infrahepatic vena cava were then connected by a 6-FG and 8-FG polyethylene tube cuff, respectively. The bile duct was internally stented with a 22-gauge i.v. catheter. The portal vein was clamped for <18 min in all animals. In each group, the survival rate after grafting was >89 % at 24 hr after surgery. Deaths that occurred within this period were defined as resulting from technical failure. Penicillin was given perioperatively.

Histology

Part of liver graft tissues 4 days after transplantation were sectioned and preserved in 10 % Formalin, embedded in paraffin, cut with microtome, and stained with hematoxylin and eosin.

Propagation and purification of liver graft-derived DC populations

DCs from liver graft 0 hr and 4 days after transplantation were propagated in GM-CSF from nonparenchymal cells (NPC) isolated from collagenase-digested liver graft tissue, as described by Lu^[18]. Nonadherent cells, released spontaneously from proliferating cell clusters, were collected after 4 days' and 10 days' culture, and purified by centrifugation 500 \times g, 10 min at room temperature on a 16 % w/v metrizamide gradient (DC purity 80-85 %).

Morphological and Phenotypical features of DCs

Morphological characteristics of DCs derived from liver graft were observed by electron microscopy. Expression of cell surface molecules was quantitated by flow cytometry as described by Mehling *et al*^[4]. Aliquots of 2×10^5 DCs propagated for 10 days *in vitro* were incubated with the following primary mouse anti-rat mAbs against OX62, CD40, CD80, CD86

(Serotec, USA), or rat IgG as an isotype control for 60 min on ice (1 μ g/ml diluted in PBS/1.0 % FCS). The cells were washed with PBS/1.0 % FCS and labeled with FITC-conjugated goat anti-mouse IgG, diluted 1/50 in PBS/1.0 % FCS for 30 min on ice. At the end of this incubation cells were washed, PBS were added, and the cells were subsequently analyzed in an FACS-4200 flow cytometer (Becton-Dickinson, USA).

Semiquantitative RT-PCR for expression of IL-12R mRNA in DCs

Analysis of expression of IL-12R β_1 and IL-12R β_2 mRNA was determined by reverse transcription-PCR (RT-PCR) amplification in contrast with house-keeping gene GAPDH. Total RNA from 1×10^7 DCs propagated for 10 days *in vitro* was isolated using TripureTM reagent (Promega, USA). First-strand cDNA was transcribed from 1 μ g RNA using AMV and an Oligo (dT)₁₅ primer. PCR was performed in a 25 μ l reaction system containing 10 μ l cDNA, 2 μ l 10 mM dNTP, 2.5 μ l 10 \times buffer, 2.5 μ l 25 mmol \cdot L⁻¹ MgCl₂, 2 μ l specific primer, 5 μ l water and 1 μ l Taq. IL-12R β_1 and IL-12R β_2 were amplified using specific primer for IL-12R β_1 ^[24] and IL-12R β_2 ^[25]. Specific primers for GAPDH^[26] were also used for control. Thermal cycling of IL-12R β_1 and IL-12R β_2 and GAPDH primers were performed as follows^[25]: denaturation at 94 $^{\circ}$ C for 1 min, annealing at 55 $^{\circ}$ C for 1 min, and extension at 72 $^{\circ}$ C for 1 min, all cycling were performed for 35 cycles. The predicted PCR product size were 331 bp for IL-12R β_1 , 1 200 bp for IL-12R β_2 and 576 bp for GAPDH. PCR products of each sample were subjected to electrophoresis in a 15g \cdot L⁻¹ agarose gel containing 0.5 mg \cdot L⁻¹ ethidium bromide. Densitometrical analysis using NIH image software was performed for semiquantification of PCR products, and the expression level of each sample were expressed by IL-12R mRNA/GAPDH mRNA (%).

Western blotting for IL-12 protein expression in DCs

DCs cultured for 10 days *in vitro* were starved in serum-free medium for 4hr at 37 $^{\circ}$ C. These cells were washed twice in cold PBS, resuspended in 100 μ l lysis buffer (1 % Nonidet P-40, 20mM Tris-HCl, pH8.0, 137mM NaCl, 10 % glycerol, 2mM EDTA, 10 μ g/ml leupeptin, 10 μ g/ml aprotinin, 1mM PMSF, and 1 mM sodium orthovanadate), and total cell lysates were obtained. The homogenates were centrifuged at 10 000 \times g for 10 min at 4 $^{\circ}$ C. Cell lysates (20 μ g) were electrophoresed on SDS-PAGE gels, and transferred to PVDC membranes for Western blot analysis. Briefly, PVDC membranes were incubated in a blocking buffer for 1 hr at room temperature, then incubated for 2 hr with Abs raised against IL-12 p35 (M-19, goat anti-rat, Santa Cruz, CA), IL-12p40 (H-306, rabbit anti-rat, Santa Cruz, CA). The membranes were washed and incubated for 1 hr with HRP-labeled horse anti-goat or HRP-labeled goat anti-rabbit IgG. Immunoreactive bands were visualized by ECL detection reagent.

Statistics

Statistic analysis of data was performed using the Student's *t*-test; *P*<0.05 was considered statistically significant.

RESULTS

Histological rejection

Histology features of allografted livers were compared between the whole and partial groups on Day 4 after transplantation, allogeneic whole liver grafts demonstrated no rejection. In contrast, partial liver grafts demonstrated moderate to severe rejection, including inflammatory cellular infiltration in the portal tract, and endothelialitis and bile duct damage.

Figure 1 Morphological characteristics of liver graft-derived DCs propagated for 4 days in the presence of GM-CSF. **A:** DC from whole liver graft 4 days after transplantation ($\times 200$ b). **B:** DC from partial liver graft 4 days after transplantation ($\times 600$ b).

Lanes 2-4: extracts derived from DCs from liver graft 0 h after transplantation, whole liver graft (WLT) and partial liver graft (PLT) 4 days after transplantation, respectively. Compared with 4 d WLT group, $^bP < 0.001$; Compared with 0 h PLT group, $^dP < 0.001$.

Figure 4 Detection of IL-12 R mRNA in liver graft-derived DCs by RT-PCR. Lanes 1: marker; Lanes 2- 4: extracts derived from DCs from liver graft 0 h after transplantation, whole liver graft (WLT) and partial liver graft (PLT) 4 days after transplantation, respectively. Compared with 4 d WLT group, ^b $P < 0.001$; Compared with 0 h PLT group, ^d $P < 0.001$.

Phenotypic characteristics of liver graft-derived DCs propagated in vitro

After 4 days' culture in the presence of GM-CSF, liver graft-derived DCs were observed with electron microscopy, DCs from whole liver grafts 0 hr and 4 days after transplantation exhibited round shape, smaller body, bigger nucleus, and a few shorter dendrites, whereas DCs derived from partial liver graft 4 days after transplantation displayed typical morphological features of DC including anomalous shape, bigger body, and numerous longer dendrites (as shown in Figure 1). Flow cytometry showed 80-85 % of DCs both from whole and partial liver grafts strongly expressed rat DC-specific OX62 antigen molecule (as shown in Table 1), which was suggested high purity DCs were obtained. After 10 day' culture in the presence of GM-CSF, although DCs both from whole and partial liver grafts exhibited typical morphological features of DC by electron microscopy, flow cytometric analysis showed (as shown in Figure 2 and Table 1) whole liver graft-derived DCs displayed low amounts of costimulatory molecules (CD40, CD80 and CD86), whereas DCs from partial liver graft 4 days after transplantation expressed moderate to high levels of these markers. These results suggested allogeneic partial liver transplant could promote maturation of DCs derived from partial liver graft.

Table 1 Comparison of expression of DC surface markers from whole liver graft and partial liver graft ($\bar{x} \pm s$, $n=13$)

Groups	OX62	CD40	CD80	CD86
Whole liver graft-DC	85.63±3.81	7.24±1.87	6.58±2.39	7.01±2.54
Partial liver graft-DC	88.42±5.75	50.18±3.26 ^b	45.31±3.67 ^b	43.29±2.03 ^b

^b $P < 0.001$ vs whole liver graft-DC

IL-12 protein expression in liver graft-derived DCs

To investigate the functional change of DCs derived from liver grafts, we evaluated IL-12 protein expression in these DCs. As shown in Figure 3, DCs derived from both whole and liver grafts 0 hr after transplantation expressed detectable but low levels of IL-12 p35 and IL-12 p40, and expression levels of

IL-12 p35 and IL-12 p40 in DCs from whole liver graft 4 days after transplantation were similar to those of DCs from whole liver graft 0 hr after transplantation ($P > 0.05$). However, expression of IL-12 p35 and IL-12 p40 in DCs from partial liver graft 4 days after transplantation was markedly increased, and their expression levels were significantly higher than those of DCs both from partial liver graft 0 hr and whole liver graft 4 days after transplantation ($P < 0.001$).

IL-12R mRNA expression in liver graft-derived DCs

As shown in Figure 4, semiquantitative RT-PCR analysis revealed detectable but low levels of IL-12R β_1 and IL-12R β_2 mRNA expression in DCs both from whole and partial liver grafts 0 hr after transplantation, expression levels of IL-12R β_1 and IL-12R β_2 mRNA in DCs from whole liver graft 4 days after transplantation were not markedly changed compared with those of DCs from whole liver graft 0 hr after transplantation ($P > 0.05$). Whereas DCs from partial liver graft 4 days after transplantation expressed higher levels of IL-12R β_1 mRNA and IL-12R β_2 mRNA, and their expression levels were markedly higher than those of DCs both derived from partial liver graft 0 hr and whole liver graft 4 days after transplantation ($P < 0.001$).

DISCUSSION

DCs play critical roles in the initiation and modulation of immune responses^[27-34]. After vascularized organ transplantation, donor passenger leukocytes (mainly interstitial DCs) are mobilized out of the graft via peripheral blood to the recipient lymphoid and nonlymphoid tissues^[35-39]. Maturation of donor DC from thyroid, pancreatic islet, skin, or kidney allografts in recipient lymphoid organs lead to the activation of naive, alloreactive Th0 lymphocytes, and thus provides the primary stimulus for acute allograft rejection. However, in mouse and certain rat strain combinations, fully MHC-mismatched liver allografts accepted without any of immune suppression, and fail to elicit an effective rejection response^[38,39]. Moreover, in humans, the liver is considered the least immunogenic of transplanted whole organs. In a tolerant rat strain combination, depletion of interstitial leukocytes from liver by pretransplant donor radiation prevents the tolerogenic effect, and results in acute rejection^[40]. On the other hand, it has been reported that

immature, costimulatory molecule-deficient DCs (such as normal liver or bone marrow-derived DCs) propagated *in vitro* can promote graft survival in allogeneic recipients^[14,41,42], and posttransplant administration of donor leukocytes induces long-term acceptance of liver transplants^[43].

Therefore, passenger leukocytes (most likely DCs) may have a dualistic role with potential to elicit T cell activation and graft rejection, or induce T cell tolerance and graft acceptance. The sustained release from the transplanted liver of immature DCs, may contribute to allogeneic liver graft tolerance induction. These liver-derived DCs migrate *in vivo* to T cells areas of secondary lymphoid tissue, where they persisted for weeks in allogeneic recipients^[18, 44]. It is accepted that alloantigen-specific Th1 cells initiate allograft rejection, and that Th2 cells exert an inhibitory influence on the development of Th1 clones. It has been proposed that preferential induction of alloantigen-specific Th2 lymphocytes could suppress the development of Ag-specific Th1 cells, and as a consequence, inhibit allograft rejection. Liver-derived DCs might induce the proliferation of Th2 clones with capacity to inhibit Th1 responses^[18]. Liver-derived DCs display an immature phenotype with absence of costimulatory molecules (CD40, CD80 and CD86) surface expression, low levels of MHC class I and II, and as a consequence, low stimulatory capacity for naive allogeneic T cells. Unlike mature DC, these liver-derived DCs do not induce detectable levels of intracytoplasmic IFN- γ in allogeneic CD4⁺ cells in 72-h MLR, and elicited very low levels of CTLs *in vitro*^[3,13,18]. In contrast, acute liver graft rejection would be induced by maturation of liver grafts derived-DCs^[20]. These findings point to a pivotal role for donor immature or mature DCs in determining the outcome of liver transplantation. Mature DCs express high levels of costimulatory molecules such as CD40, CD80 and CD86. Activation of T cells by mature DCs has been shown to require direct contact between T cells and DCs through CD40-CD40L interaction^[45], upon ligation of CD40L on T cells with CD40 on DCs, DCs are triggered to produce even high quantities of IL-12, thus consigning T cells to Th1 responses^[46].

IL-12 is an important immune regulator produced primarily by DCs and macrophages that drives the preferential induction of Th1 immune responses. IL-12 appears to be a central mediator of acute graft-vs-host disease in mice^[47], whereas neutralization of bioactive IL-12 enhances allogeneic myoblast survival^[48]. Moreover, exogenous IL-12 mediates liver allograft rejection^[49], and IL-12 antagonism could promote liver graft tolerance^[19]. IL-12 binds to a unique, high affinity receptor on activated Th cells and NK cells, enhances the expression of antiapoptotic factors (bcl₂ and bcl_{xl}), and facilitates activated T cell and NK-lymphokine activated killer cell expansion. IL-12 indirectly promotes Th1 and inhibits Th2 development by inducing the secretion of IFN- γ by Th1 and NK cells^[19, 50-54]. Recent investigation showed IL-12 also induce autologous IL-12 production of DC by interaction with IL-12 receptor^[25]. Previous studies have shown that IL-12R is detected in T cells and NK cells, and IL-12R plays a crucial role for IL-12 mediated activation of these cell types^[25, 55-60]. IL-12R β_1 is the subunit primarily responsible for binding IL-12, and IL-12R β_2 plays an essential role in mediating the biological functions of IL-12. IL-12-induced phosphorylation of STAT4 and IFN- γ production are absent in Con A and anti-CD3-activated splenocytes from IL-12R β_2 ^{-/-} mice^[56]. Recent investigations suggested that DCs exhibited expression of IL-12R β_1 and IL-12R β_2 ^[25,61-66], and mature DCs express high level of IL-12R β_1 and IL-12R β_2 ^[25, 64].

Although Omura T *et al*^[1] and Shiraishi M *et al*^[2] reported that allogeneic partial liver grafts exhibited increased immune response compared with allogeneic whole liver grafts as early as 3 days after transplantation, little is known about the exact

mechanism responsible for the accelerated rejection. In the present study, accelerated rejection was demonstrated in allogeneic partial liver graft 4 days after transplantation. Our results first demonstrated that DCs derived from allogeneic whole liver graft without acute rejection 4 days after transplantation exhibited an immature phenotype with absence of CD40, CD80 and CD86 surface expression, and low expression of IL-12 proteins (IL-12 p35 and IL-12 p40) and IL-12 receptor (IL-12R β_1 and IL-12R β_2) mRNA. In contrast with immature DCs derived from whole liver graft, DCs derived from partial liver graft undergoing acute rejection 4 days after transplantation displayed a mature phenotype with high level of CD40, CD80 and CD86 surface expression, and as a consequence, high level expression of IL-12 proteins (IL-12 p35 and IL-12 p40) and IL-12 receptors (IL-12R β_1 and IL-12R β_2) mRNA. Given immature DCs can induce T-cell hyporesponsiveness^[13-15] and immune reactivity inhibition^[16,17], whereas mature DCs can stimulate Th1 response and the development of alloantigen-specific CTLs^[3-7, 27-34], together with IL-12 is an important inducer of liver graft rejection, we suggest that maturation of liver graft-derived DCs may be an important mechanism of the accelerated rejection of allogeneic partial liver graft, and inhibition of maturation of liver graft-derived DCs may suppress rejection of allogeneic partial liver graft.

Abstract

AIM: Cloning and analyzing the up-regulated expression of transthyretin-related gene following short interval successive partial hepatectomy (SISPH) to elucidate the mechanism of differentiation, division, dedifferentiation and redifferentiation in rat liver regeneration (LR).

METHODS: Lobus external sinister and lobus centralis sinister, lobus centralis, lobus dexter, lobus candatus were removed one by one from rat liver at four different time points 4, 36, 36 and 36 hr (total time: 4 hr, 40 hr, 76 hr, 112 hr) respectively. Suppression subtractive hybridization (SSH) was carried out by using normal rat liver tissue as driver and the tissue following short interval successive partial hepatectomy (SISPH) as tester to construct a highly efficient forward-subtractive cDNA library. After screening, an interested EST fragment was selected by SSH and primers were designed according to the sequence of the EST to clone the full-length cDNA fragment using RACE (rapid amplification of cDNA end). Homologous detection was performed between the full-length cDNA and Genbank.

RESULTS: Forward suppression subtractive hybridization (FSSH) library between 0 h and 112 h following SISPH was constructed and an up-regulated full-length cDNA (named LR_1), which was related with the transthyretin gene, was cloned by rapid amplification of cDNA end. It was suggested that the gene is involved in the cellular dedifferentiation in LR following SISPH.

CONCLUSION: Some genes were up-regulated in 112 h following SISPH in rat. LR_1 is one of these up-regulated expression genes which may play an important role in rat LR.

INTRODUCTION

In mammals, liver is the only organ that possesses the strong capability of regeneration^[1-7]. Since Higgins and Anderson^[8] established the model of partial hepatectomy (PH), it has been widely used to study the reconstruction and regeneration of tissue and organs, cellular multiplication, dedifferentiation, stress response and the regulation of physiology and biochemistry^[8-16]. But due to the complexity of liver regeneration, the molecular mechanism of LR remains to be elucidated. In order to better understand the mechanism of PH, researchers have established a series of successive partial hepatectomy (SPH) models. These included the long interval successive partial hepatectomy (LISPH) that involved an interval of more than three weeks and short interval successive partial hepatectomy (SISPH) which had an interval of 4 and/or 36 hr^[17]. Because the hepatocytic initiation, dedifferentiation, division and redifferentiation mainly occurred within 144 hr following PH^[18-22]. It is doubtless that the study on the change of liver tissue, cellular morphology, structure, physiology and biochemistry in every crucial point following SISPH can offer more data about LR. In this paper, we used the normal liver tissue as control and the liver tissue in 112 hr SISPH as experimental materials, and adopted the whole-mount research strategy of genome and resorted to SSH technique to construct a differential expressed forward-subtracted cDNA library. From the library, we picked some significant expressed sequence tags (ESTs) clones. Then the primers were designed according to these ESTs. By RACE PCR, some full-length cDNAs were obtained. After sequencing these full-length cDNAs, it showed that one of them belonged to the gene of related transthyretin, termed LR_1 gene, which was up-regulated expression in LR.

MATERIALS AND METHODS

Making SISPH model and preparation of samples

Adult Spargue-Dawley rats (weighing 200-250 g) were provided by the experimental animal house of Henan Normal University and 0-4-36-36-36 hr SISPH model was made according to the method of Xu *et al*^[17]. Lobus external sinister and lobus centralis sinister, lobus centralis, lobus dexter, lobus candatus were removed one by one at four different time points 4, 36, 36 and 36 hr (total time: 4 hr, 40 hr, 76 hr, 112 hr) respectively. The control and the four resected liver hepatic lobus were washed with precooled phosphate-buffered saline (PBS) thoroughly before these samples were frozen in liquid nitrogen and transferred to the -80 °C freezer for storage.

Preparation of control mRNA and the 112 hr SISPH mRNA

Isolation of total RNA and mRNA was carried out according to the protocol of RNAease kit and oligotex mRNA spin column purification kit (Qiagen). The quantity and integrity of mRNA were detected by ultraviolet spectrometer and by electrophoresing on a denaturing formaldehyde agarose

stained by EtBr. Chemicals and reagents used were at least of analytical grade.

Generating of a subtracted cDNA library

SSH was performed between the aforementioned tester and driver liver tissue mRNA preparations using a PCR select™ cDNA subtraction kit and 50×PCR enzyme kit (Clontech, Heidelberg, Germany) following the instructions of the manufacturer. Briefly, 2 µg aliquots each of poly (A⁺) mRNA from the tester and the pooled driver were subjected to cDNA synthesis. Thereafter, the tester and driver cDNAs were digested with Rsa I. The tester cDNA was subdivided into two portions, and each was ligated with a different cDNA adaptor. In the first hybridization reaction, an excess of driver was added to each sample of tester. The samples were heat denatured and allowed to anneal. Due to the second-order kinetics of hybridization, the concentration of high- and low-abundance sequence is equalized among the single-stranded tester molecules. At the same time, single-stranded tester molecules are significantly enriched for differentially expressed sequences. During the second hybridization, the two primary hybridization samples were mixed together without denaturation, only the remaining equalized and subtracted single-stranded tester cDNAs can reassociate to form double-stranded tester molecules with different ends. After filling in the ends with DNA polymerase, the entire population of molecules was subjected to nested PCR with two adaptor-specific primer pairs. The tester control was amplified with primer1 and nested primer 1 and 2 provided in the kit. The subtraction efficiency was evaluated by house-keeping gene *g3pdh*.

Cloning the subtracted library into a TA vector

Products from the secondary PCR reactions were ligated into a pGEM-T vector (Promega) and the resultant ligation products were then transformed into JM109 *E. coli* competent cells. The bacterial were subsequently grown in 800 µl of liquid Luria-Bertani medium and allowed to incubate for 45 min at 37 °C with shaking at 150 rpm. Thereafter, the cells were plated onto agar plates containing ampicillin (50 µg/ml), 5-bromo-4-chloro-3-indolyl-β-D-galactoside (x-gal; 20 µg/cm²) and isopropyl-β-D-thiogalactoside (IPTG; 12.1 µg/cm²) and incubated overnight at 37 °C. Individual recombinant white clones were picked and grown in single line pattern onto Luria-Bertani agar solid medium containing ampicillin and allowed to incubate at 37 °C for 6-7 hr before single clone was picked from single-line pattern agar medium and allowed to grow in Luria-Bertani liquid medium containing ampicillin overnight at 37 °C with shaking of 150 rpm.

Identifying the subtracted clones

Plasmids were isolated from bacterial clones harboring differentially expressed cDNA sequences as described by Sambrook *et al.* Plasmids containing cDNA inserts were amplified by PCR with nested primer 1 and primer 2 and the amplified product of every plasmid was detected by agarose gel electrophoresis. After that, the inserts that appeared as distinct bands were sequenced by T7/SP6 chain termination reaction in TaKaRa (DaLian, China). Nucleic acid homology searches were subsequently performed at the National Center of Biotechnology Information (National Institutes of Health, Bethesda, Md., NCBI).

RACE

An interested EST fragment was chosen from the established cDNA library for primer design according to the instructions of the 5' /3' RACE kit (Roche) manufacturer. RACE, a procedure to amplify nucleic acid sequences from a mRNA template between a defined internal site and unknown

sequences at 5' -and 3' -end of mRNA, was then performed by using 5' /3' RACE kit and following the supplier's protocol. The primer used for 3' RACE was SP5: 5' -AGCTGGGAG CCGTTTGC-3' and the primer used for 5' RACE was SP1: 5' -TGCTGTAGGAGTACGGGCT-C3' , SP2: 5' -A C C A G A G T C A T T G G C T G T -3' , SP3: 5' -G C C C G T G C A G C T C T -3' respectively. Proofreading *pfu* DNA polymerase was purchased from MBI and the 3' RACE PCR parameters were: predenaturation at 94 °C for 2 min before amplification was done for 40 cycles at 94 °C for 45 sec, annealing at 65 °C for 1 min and extension at 72 °C for 1 min and 30 sec followed by an additional extension period at 72 °C for 5 min. The 5' RACE used touchdown PCR and amplification was carried out with the following conditions: 94 °C for 2 min, 25 cycles including a denaturation step at 94 °C for 15 sec, an annealing step from 68 °C to 55 °C for 30 sec, and extension at 72 °C for 1 min and 30 sec; 15 cycles as above except that the annealing step at 55 °C; a final extension step at 72 °C for 7 min ended the PCR reaction. The products were subjected to electrophoresis in a 1 % agarose gel, purified according to qiaquick PCR purification kit protocol and added dATP-tailing to blunt-ended fragments at 70 °C for 30 min in the presence of Taq DNA polymerase before ligated into the pGEM-T vector. Transformation, screening, and sequencing were then performed as described above.

Splicing the full-length nucleotide sequence

Alignment of the sequences was spliced, in light of contig of 5' /3' sequencing result, to get a full-length nucleotide sequence. Homology search was performed using the BLAST program at NCBI.

RESULTS

Construction of the subtracted cDNA library and screening of the differential fragments

By means of suppression subtractive hybridization (SSH) technique, we prepared driver cDNAs and tester cDNAs of liver tissue from control and liver tissue 112 hr following SISPH. After two rounds hybridization and two PCR reactions, we obtained the forward-subtractive cDNA library (Figure 1). The subtracted cDNA was evaluated by the house-keeping gene *g3pdh* (Figure 2). Our results showed that the constructed forward-subtracted cDNA library was highly efficient after cDNA library was subcloned into pGEM-T vector and transformed into JM109, we obtained 120 white clones and 40 clones randomly selected were then subjected to sequencing (Figure 3). The sequencing results were sent to NCBI for BLAST searches.

Determination of the full-length nucleotide sequence of *LR₁* cDNA by RACE

The original cDNA isolated from the cDNA subtraction screening was about 311bp long. This cDNA fragment was used to design primers according to 5' /3' RACE kit. After amplification, ligation, screening and sequencing, we obtained the sequence of the 3' end and 5' end (Figure 4). Alignment of contig sequences enabled us to delineate the entire cDNA sequence (Figure 5). We found a single long ORF starting with a methionine codon ATG at nucleotide 47 and ending with a TAA stop codon at 625 and a putative polyadenylation signal AATAAA upstream from the poly (A⁺). Homology search using *LR₁* cDNA sequence revealed that it is 88.8 % homologous to rat transthyretin gene and 88.4 % homologous to albumin gene. Protein homology (Swissport database) search of the peptide encoded by the *LR₁* ORF revealed that it is 91% homologous to rat transthyretin, submitting this full-length cDNA to NCBI and obtain GenBank Accession No. AF479660.

DISCUSSION

SSH technique was developed based primarily on a recently described technique called cDNA suppression PCR which combines normalization and subtraction in a single procedure

to generate subtracted cDNA library^[23-25]. Compared to the methods of mRNA differential display^[26], representational difference analysis of DNA^[27], it has two distinct advantages: (1) it has a high subtraction efficiency; (2) it harbors an equalized representation of differentially expressed sequences which can separate effectively both high and low copy expressed genes mainly because of normalization. The normalization step equalizes the abundance of cDNAs within the target population and the subtraction step excludes the common sequences between the target and the driver populations^[23,28,29]. The experimental results showed the SSH technique can enrich for rare sequences over 1 000-5 000 fold in one round of subtractive hybridization^[23,24,30]. By resorting to SSH and high-density array scanning technique, using non-metastatic counterpart Bsp73-1AS as driver, metastatic adenocarcinoma cell line Bsp73-ASML as tester, Von Stein^[31] found up to 252 over-expressed clones among 625 clones with no homologous sequences in GenBank. By using a EST fragment derived from the forward-subtracted cDNA library as probe, we have cloned a novel gene from the liver tissue 112 hr cDNA library following SISPH. These results suggest that SSH technique is applicable to many molecular genetic and positional cloning studies for the identification of disease, developmental, tissue-specific or other differentially expressed genes.

With the aim to shed light on the molecular mechanism of PH, Xu *et al*^[17] established the SISPH model which selected the intervals at the crucial periods, e.g. the peak of cell activation (4 hr after PH), the peak of cell division (36 hr after PH) and the peak of re-differentiation (48 hr after PH). We have examined some biological activated factors, heat shock proteins (HSPs), proteases, proteins related to cell proliferation and dephosphorylation^[13,14,17,18,32]. These data have provided useful information to reveal the molecular mechanism of LR. The results suggested that SISPH model may offer more abundant data than that of PH. In present study, We took 0 h and 112 hr as driver and tester respectively in 0-4-36-36-36hr SISPH model when resorting to SSH strategy, then we constructed a forward-subtractive cDNA library in short time by using RACE, subsequently we cloned a full-length cDNA and blast search showed that the cDNA is 88.8 % and 88.4 % homologous to the transthyretin and albumin in rat respectively. This suggested that the gene may exert partial function identical to transthyretin. It is well known that thyroxine and its metabolic products integrated thyroxine-binding prealbumin and albumin is derived from liver to operate. In the physiological conditions, 99.9 % 3,3', 5,5' -tetraiodothyronine (T_4) and 99.7 % 3,3' 5-triiodothyronine (T_3) are complexed with proteins which contain over 60 % transthyretin and 15-30 % thyroxine-binding prealbumin and 10 % albumin. Our present study showed that the injured liver released abundant analogs of transthyretin. As we know, the changes of transthyretin concentration is regarded as one of the important reasons that metabolic or biochemical abnormality in thyroid gland responsible for hepatopathy^[33,34]. The up-regulations of transthyretin in liver tissue is speculated to have following functions: (1) breaking the balance of HSS (hepatocyte stimulate substrate) and inhibitor and thus enhancing the dedifferentiation. We have cloned two up-regulated genes, one of which is 78.6 % homologous to rat transferring gene and the other is 72 % homologous to mouse embryonic stem cell gene from 112 hr cDNA library following SISPH (remains to be published). It is also known that over-expression of transferring gene and embryonic stem cell gene have close relations with the cellular dedifferentiation; (2) influencing the induction of enzyme and consumption of oxygen. Compensatory respiration was promoted in mitochondrion responsible for partial hypoxia following PH, but the energy produced from tricarboxylic acid cycle couldn't meet the

structural recovery of damaged liver due to successive partial hepatectomy and thus triggered the related genes to express in hypoxia metabolism. The over-expressed gene of alcohol dehydrogenase have cloned from 112 hr cDNA library following SISPH (remains to be published) seems to explain this hypothesis which is consistent with the result of Cheng Lingzhong.

In conclusion, complicated physiological and biochemical reaction changed in the liver tissue following SISPH, we postulated that this kind of up-regulated gene *LR₁* expression involve in liver regeneration may (1) relate with compensated increase of stress molecules following SISPH; (2) lead to the initiation of other metabolism; (3) maintain the homeostasis in the body. As to, whether severe dedifferentiation happened following SISPH and what are the key dedifferential factors and how they influence the dedifferentiation, remain to be further investigated.

Abstract

AIM: To study the effects of pentoxifylline (PTX) on the content of hepatic TGF- β 1, type I and type III collagen in schistosomiasis japonica mice with liver fibrosis and its mechanism of anti-fibrosis.

METHODS: Forty mice with schistosomiasis were divided into four groups: one group as control without any treatment, other three were treated with Praziquantel 500 mg/(kg·d) for 2 d, high dose PTX 360 mg/(kg·d) for 8 wk, and low dose PTX 180 mg/(kg·d) for 8 wk respectively. Immunohistochemical technique and multimedia color pathographic analysis system were applied to observe the content change of hepatic TGF- β 1, type I and type III collagen in schistosomiasis japonica mice with liver fibrosis before and after PTX treatment.

RESULTS: Effects of PTX on the content change of hepatic TGF- β 1, type I and type III collagen in schistosomiasis japonica mice with liver fibrosis were related to the dosage of PTX, high dose PTX treated group could significantly reduce the content of TGF- β 1 (0.709 ± 0.111), type I (0.644 ± 0.108) and type III (0.654 ± 0.152) collagen compared with those of control group (0.883 ± 0.140 , 0.771 ± 0.156 , 0.822 ± 0.129) with statistical significance ($P < 0.05$). Low dose PTX could also reduce the hepatic content of TGF- β 1 (0.752 ± 0.152), type I (0.733 ± 0.117) and type III (0.788 ± 0.147) collagen, but without statistical significance ($P > 0.05$). Both high dose and low dose PTX groups have significant differences on the content of TGF- β 1, type I and type III collagen ($P < 0.05$, $P < 0.05$, $P < 0.01$, respectively).

CONCLUSION: High dose of PTX treatment could reduce the content of hepatic TGF- β 1, type I and type III collagen significantly in schistosomiasis japonica mice with liver fibrosis, and thus plays its role of antifibrosis.

INTRODUCTION

Liver fibrosis is the main reason for portal hypertension and hemorrhagic of upper digestive tract in schistosomiasis and there fore the main reason for the mortality of schistosomiasis. The basic pathological changes of liver fibrosis are the disturbance and degradation of extracellular matrix (ECM), which causes accumulation of ECM in the liver^[1,2]. Within the major components of ECM, type I and type III collagen constitute more than 95 % of the total content of increased collagen in liver fibrosis^[3-5]. It is well known that fibrosis is reversible whereas cirrhosis is irreversible, so it is important to prevent fibrosis progressing to cirrhosis^[6,7]. However, there is no ideal antifibrosis drug to date. Recent researches found that PTX has antifibrosis function^[8,9], while its effects on hepatic fibrosis of schistosomiasis japonica are still unknown. Since the main pathological characteristic of schistosomiasis japonica is the deposition of type I and III collagen and TGF β 1 has very important influence on the fibrosis development, it is considered the key cytokine to accelerate cirrhotic procession^[10-15], we studied the effects of PTX on the expression of collagen I and III and TGF β 1 in mice with schistosomiasis japonica and intended to evaluate the roles of PTX in hepatic fibrosis.

MATERIALS AND METHODS

Materials

Forty female Kunming mice, weighted 16-20 g and aged 4-6 w, provided by Experimental Animal Center of Tongji Medical College, were infected with 25 cercaria of schistosoma japonica (provided by Wuhan Institute of Schistosomiasis Prophylactic and Therapy) and fed for 2 weeks and then divided randomly and equally into 4 groups: one group as control without any treatment, other three were treated with Praziquantel 500 mg/(kg·d) for 2 d, high dose PTX (provided as SHUANLIN tablet by Shijiazhuang Pharmaceutics CO.) 360 mg/(kg·d) for 8 wk, and low dose PTX 180 mg/(kg·d) for 8 wk respectively. The mice were then deceased and hepatic tissue sections were prepared for examination. Immunohistochemical technique and multimedia color pathographic analysis system were applied to observe the content of hepatic TGF- β 1, type I and type III collagen before and after treatment.

Assay of TGF β 1, collagen I and collagen III

Rabbit anti-mouse TGF β 1 was purchased from Santa Cruz. Rabbit anti-mouse collagen I and III, and SABC kit were provided by Boster Biological Technology Co., Ltd. The immunohistochemical studies were performed by the avidin-biotin-peroxidase method, briefly described as following. The tissue sections were blocked in 3 % hydrogen peroxide, washed in buffer solution, and then incubated in mixed digestive solution for 5 min in room temperature. The sections were washed in PBS and then incubated in goat serum blocking solution for 10 min. The sections were then incubated with the primary antibodies at 37 °C for 30 min, washed and then incubated with biotin conjugated secondary antibodies at 37 °C for 20 min, washed with PBS, and then labeled with peroxidase-conjugated streptavidin for 20 min at 37 °C. The washed

sections were then incubated with Diaminobenzidine (DAB), counterstained and prepared for microscopic examination.

Results analysis

The sections were analyzed with MPZAS-500 multimedia color pathological graph analyzing system. The average integral light density (ILD) of positive staining in each section was obtained and presented as $\bar{x} \pm s$. Results were then analyzed with student *t* test.

RESULTS

Effects of PTX on TGF- β 1 expression

The contents of TGF β 1 in praziquantel group, high dose PTX group and low dose PTX group decrease by 44.62 %, 19.71 %, 14.84 % respectively compared with control group. The difference between praziquantel group and control group is very significant ($P < 0.01$). The effect of PTX on TGF β 1 content is dose related and there is significant difference on TGF β 1 contents between high and low dose groups. The TGF β 1 content in high dose PTX group is significantly ($P < 0.05$) different from that of control group while no significant difference between low dose PTX group and control group. Both high dose and low dose PTX groups have significant difference on TGF β 1 contents between praziquantel group and themselves. The results are shown in Table 1.

Table 1 Content of TGF- β 1, collagen I and III in liver of each treated group and control group ($\bar{x} \pm s$, ILD, $n=10$)

Group	TGF- β 1	Collagen I	Collagen III
Control	0.883 \pm 0.140	0.771 \pm 0.156	0.822 \pm 0.129
Praziquantel	0.489 \pm 0.105 ^a	0.596 \pm 0.103 ^a	0.613 \pm 0.116 ^a
High dose PTX	0.709 \pm 0.111 ^{bd}	0.644 \pm 0.108 ^{bd}	0.654 \pm 0.152 ^{be}
Low dose PTX	0.752 \pm 0.152 ^{cd}	0.733 \pm 0.117 ^{cd}	0.788 \pm 0.147 ^{cdg}

^a $P < 0.01$, vs control group; ^b $P < 0.05$, vs control group; ^c $P > 0.05$, vs control group; ^d $P < 0.01$, vs praziquantel group; ^e $P > 0.05$, vs praziquantel group; ^f $P < 0.05$, vs high dose PTX group; ^g $P < 0.01$, vs high dose PTX group.

Effects of PTX on collagen I expression

The contents of collagen I in praziquantel group, high dose PTX group and low dose PTX group decrease by 22.70 %, 16.47 %, 4.93 % respectively compared with control group. The difference between praziquantel group and control group is very significant ($P < 0.01$). The effect of PTX on collagen I content is dose related and there is significant difference on collagen I contents between high and low dose groups. The collagen I content in high dose PTX group is significantly ($P < 0.05$) different from that of control group while no significant difference between low dose PTX group and control group. Both high and low dose PTX groups have significant difference on collagen I contents between praziquantel group and themselves. The results are shown in Table 1.

Effects of PTX on collagen III expression

The contents of collagen III in praziquantel group, high dose PTX group and low dose PTX group decrease by 25.43 %, 20.44 %, 4.14 % respectively compared with control group. The difference between praziquantel group and control group is very significant ($P < 0.01$). The effect of PTX on collagen III content is dose related and there is significant difference on collagen III contents between high and low dose groups ($P < 0.01$). The collagen III content in high dose PTX group is significantly ($P < 0.05$) different from that of control group while no

significant difference between low dose PTX group and control group ($P > 0.05$). Compared with praziquantel group, high dose PTX group has no difference on collagen III contents ($P > 0.05$), whereas low dose PTX group has significant difference ($P < 0.01$). The results are shown in Table 1.

DISCUSSION

PTX is a trimethylated xanthine derivative product. As an inhibitor of phosphodiesterase, it can induce the increase of intracellular cAMP, dilation of the blood vessels and smooth muscles, ameliorating the microcirculation. It has been used to improve the peripheral blood vessel disease for many years^[16,17]. Recently, PTX has been found to have antifibrosis effect. *In vitro* studies show that PTX can inhibit the proliferation of myofibroblast from hepatitis patients and depress the synthesis of collagen. Treatment with PTX in early stage can alleviate the hepatic lesion and inflammatory reaction^[18]. In animal hepatic fibrosis models, PTX also has anti-fibrosis effect. It has been reported that treated with PTX prior to the inducing of hepatic fibrosis with CCL₄-acetone can alleviate the proliferation of hepatic stellate cell (HSC), and previous treatment with PTX decelerate the differentiation of HSC in mouse with hepatic fibrosis induce by bile duct ligation^[19]. It was reported that previous treatment with PTX could improve the regeneration and function of liver after partial hepatectomy in mice with hepatic fibrosis and alleviate the hepatic fibrosis. But there is no report on the effects of PTX on schistosomal hepatic fibrosis^[20]. The fibrosis in schistosomal has its special characteristics against those caused by hepatic cell lesion or bile duct obstruction. Therefore, the effects of PTX in the schistosomal hepatic fibrosis should be explored.

Hepatic stellate cell (HSC) plays a pivotal role in the fiber synthesis and degradation. The activation of HSC is mediated by various cytokines and reactive oxygen species released from the damaged hepatocytes and activated Kupffer cells^[21-26]. HSC can release TGF β 1 by autocrine^[27,28] and TGF β 1 has been proved to be a strong mitogen to HSC. This autocrine effect is upgraded when HSC has been activated. TGF β 1 depresses the regeneration of hepatic cells, activates and promotes HSC to synthesize extracellular matrix such as collagen, fibronectin, proteinopolysaccharide, promotes the synthesis of TIMP and inhibits the synthesis of MMPs^[29-37].

We established a mouse hepatic fibrosis model induced by cercaria of schistosomiasis japonica infection and studied the effect of PTX on the fibrosis development in the early stage. We found that PTX could inhibit the development of fibrosis in this model significantly. The quantitative immunohistochemical evaluation of TGF β 1, type I and III collagens shows that, high dose of PTX can reduce the content of TGF β 1, type I and III collagens in hepatic tissue of mice with schistosomal hepatic fibrosis. Its capability to reduce the hepatic content of type III collagen is similar to praziquantel ($P > 0.05$) and its effects on TGF β 1 and type I collagen are weaker than praziquantel. Compared with the control group, low dose of PTX can also reduce the contents of TGF β 1, type I and III collagens but the effects have no statistical significance.

The results indicate that PTX treatment in the early stage inhibits the development of schistosomal hepatic fibrosis by reducing the content of TGF β 1, type I and III collagens.

Abstract

AIM: Available experimental evidence from both clinical and animal models shows that both Chinese medicines tetrandrine (Tet) and Qing Yi Tong (QYT) have positive treatment effects on acute pancreatitis (AP). This investigation was conducted to explore the treatment mechanisms of Tet and QYT on AP at the molecular level and thereby explain their therapeutic affects. It included an investigation of the effects of these drugs on gene expression of both intercellular adhesion molecule 1 (ICAM-1) and superoxide dismutase (Mn-SOD and Cu, Zn-SOD) in a rat model with AP.

METHODS: AP in the test rats was induced by subjecting them to laparotomy followed by a retrograde injection of 4 % sodium taurocholate into the bilio-pancreatic duct. The test rats with AP were divided into three groups. One was treated with Tet, one with QYT, and one with normal saline solution. The sham-operated control group (SO) rats were only subjected to laparotomy. They were given no further treatment. For the Tet group, Tet was injected intraperitoneally, and for the QYT group, QYT was given with a nose-gastric catheter. These procedures were done at both 10 min and 5 h after AP induction. The levels of ICAM-1 mRNA expression and of SOD (Mn-SOD and Cu, Zn-SOD) mRNA expression in the pancreas and liver tissues were measured by RT-PCR at 1, 5, and 10 h after AP induction.

RESULTS: When compared with the SO group during the observation time, rats with AP showed a higher expression of ICAM and a lower expression of Mn-SOD in both pancreas and liver tissues, and a lower expression of Cu, Zn-SOD in the pancreas. Tet treatment attenuated changes in the expression of both ICAM-1, and SOD (Mn-SOD and Cu, Zn-SOD) to a significant degree. A similar effect on the expression of SOD (Mn-SOD and Cu, Zn-SOD) was also found in the QYT group, but no obvious suppressive effect on ICAM-1 expression was observed.

CONCLUSION: The results of this study suggest that one of the main mechanisms of Tet and QYT in treating AP is to enhance anti-oxidation of the body. The results also suggest that the anti-inflammatory effect of Tet is involved in the reduction of ICAM-1 expression. This explains why Tet and QYT are beneficial in treating AP.

<http://www.wjgnet.com/1007-9327/9/155.htm>

INTRODUCTION

Acute pancreatitis (AP) is a severe disease with both high morbidity and high mortality. Therefore, much research has been focused on the specific and effective therapies for AP^[1-6]. Tetrandrine (Tet) is a kind of dibenzyl quinoline alkaloid extracted from the root of *Stephania tetrandra* S., a Chinese herbal medicine. Qing Yi Tang (QYT) is a medicine composed of several Chinese herbs. Both Tet and QYT have shown positive treatment effects on AP clinical patients and on animal models. These include attenuation of clinical symptoms, improvement of morphology and biochemistry changes in the tissues and blood, prolongation of survival time, and decrease of mortality^[7-10]. In order to explore some of the molecular mechanisms combating AP, the effects of Tet and QYT on gene expression of both intercellular adhesion molecule 1 (ICAM-1) and superoxide dismutase (Mn-SOD and Cu,Zn-SOD) were investigated in a rat model with AP.

MATERIALS AND METHODS

Chemicals

Chemicals used in this experiment were purchased as follows: Sodium pentobarbital and sodium taurocholate (NaTc) from Shanghai Chemical Reagent Company; TRIzol reagent and SuperscriptTM II from GIBCO-BRL (Shanghai); Oligonucleotide primer pairs from Chinese Academy of Science, Institute of Cell and Biology (Shanghai); Taq DNA polymerase from Promega (Shanghai); Tet from the Department of Pharmacology of Second Military Medical University (Shanghai); QYT from Zunyi Medical College (Zunyi); other reagents from Sigma Chemical (Shanghai).

Animals and AP model

The subjects for the experiment were adult male and female Sprague-Dawley rats weighing 170-230 g ($n=36$; the Animal Center, Fudan University Medical College, Shanghai). After fasting with free access to water overnight, the rats were anesthetized by an intraperitoneal (ip) injection of 40 mg/kg sodium pentobarbital. AP was induced by a retrograde injection of 4 % NaTc into the bilio-pancreatic duct (BPD) according to the method of Aho *et al*^[11]. Briefly, a small median laparotomy was performed first, and then the pancreas was exteriorized and the BPD was temporarily closed at the liver hilum with a soft microvascular clamp to prevent reflux of the infused material into the liver. A retrograde injection of 4 % NaTc into the distal BPD was then given (100 μ l/100body wt, pressure 50cmH₂O). The clamp was removed 5 min after the injection. In the sham-operated control group (SO) rats only underwent laparotomy. Finally, the abdomen was closed with a silk suture and the rats were placed back into their cages with free access to water and food.

Animal group

The test rats with AP were divided into three groups: Tet, QYT and normal saline (NS). The Tet group ($n=9$) received an injection (ip) of 4 % Tet at a dosage of 80 mg/kg body wt. The QYT group ($n=9$) received an infusion of QYT (1 ml/100 g body wt), and the NS group ($n=9$) received an infusion of NS (1 ml/100 g body wt), by use of a nose-gastric catheter. Rats in the SO group received the same infusion as the NS group. All groups were treated two times (at 10 min and 5 h after the AP operation).

Preparation of RNA and RT-PCR assay

At selected times (1,5,10 h) after the AP induction or sham operation, the rats ($n=3$ at each time point) underwent relaparotomy under pentobarbital anesthesia, and samples of the pancreas and liver were rapidly collected. Total RNA was extracted from pancreatic and liver tissues using the TRIzol reagent. RNA quality was verified by ethidium bromide staining of ribosomal RNA bands on agarose gel. Total RNA was precipitated and re-suspended in diethylpyrocarbonate-treated sterile H_2O , quantified by spectrophotometry (A_{260}/A_{280} ratio >1.80) and diluted to a concentration of 1.0 $\mu\text{g}/\mu\text{l}$. Then the extracted RNA was used for a semi-quantitative reverse transcription-polymerase chain reaction (RT-PCR). Total RNA (5 $\mu\text{g}/\text{sample}$) was reverse-transcribed using oligo (dT) as a primer. The oligonucleotide primer pairs were designed from published sequences for each gene studied. The sequences used as G3PDH, SOD and ICAM-1 specific primers are shown in Table 1.

Table 1 Sequence of primers and length of fragments

Gene	Primer (5' → 3')	Length
G3PDH	ACCACAGTCCATGCCATCAC	452 bp
	TCCACCACCCTGTTGCTGTA	
Mn-SOD	ATTAACGCGCAGATCATGCAG	483 bp
	TTTCAGATAGTCAGGTCTGACGTT	
CuZn-SOD	TTCGAGCAGAAGGCAAGCGGTGAA	396 bp
	AATCCCAATCACACCACAAGCCAA	
ICAM-1	CCTTAGGAAGGTGTGATATCCGG	415 bp
	AGGTGGTCACCCATGCTGGTGCT	

Two-microliter aliquots of cDNA were used as a target for separate PCR reactions in the presence of 0.5 units of Taq DNA polymerase, 50 $\mu\text{mol/L}$ of a primer pair specific for G3PDH, SOD or ICAM-1, and amounts of the corresponding constructs. The total volume of the reaction fluid was 25 μl .

The amplification cycles were carried out in a DNA Thermalcycler (Perkin Elmer) under the following conditions: initial denaturation at 94 for 2 min, followed by amplification cycles of 1min at 94 $^{\circ}\text{C}$, 1min at 58 $^{\circ}\text{C}$ and 1 min at 72 $^{\circ}\text{C}$. This procedure was repeated for 30 cycles. PCR products were separated by polyacrylamide gel electrophoresis and then visualized by ethidium bromide staining. The intensities of gene-specific bands were photographed and quantified by measuring the optical density (OD) of the bands in a UVP (white/UV transilluminator, GDS 7500). In the same sample, mRNA levels were normalized to the density of an internal control housekeeping gene RT-PCR product, glyceraldehyde-3-phosphate dehydrogenase (G3PDH), which is commonly used as an internal standard control in mRNA expression studies. RT-PCR was performed independently at least twice starting from the same RNA.

Statistical analysis

Data were expressed as mean \pm SE. Statistical differences between values from two groups were determined by the unpaired Student's *t*-test and statistical significance was set at $P<0.05$.

RESULTS

G3PDH level

The level of G3PDH was approximately the same for all pancreas and liver samples tested (Figure 1), which indirectly showed that the cDNA concentration did not differ in the samples from each group.

Figure 1 GAPDH mRNA expression in the liver in the parts of different group.

ICAM-1 mRNA expression in the pancreas and liver

Semi-quantitative evaluation of ICAM-1 level was obtained by measuring its gene expression by RT-PCR. As shown in Figure 2 and Figure 2B, the pancreas showed an increased ICAM-1 mRNA expression in the NS group at 5 h and 10 h after AP induction when compared to the SO group. Tet attenuated the increase at the same time-points. But QYT showed an increase effect for ICAM-1 mRNA expression at 10 h after AP. In the liver, compared with the SO group, the level of ICAM-1 mRNA expression in the NS group was elevated at 1 h and sustained up to 10 h, with a maximum increase (2-fold) at 5 h after AP induction. A similar change but at a lower level was observed in the Tet group. And in the QYT group a modest increase of ICAM mRNA expression occurred only at 5 h and 10 h after AP induction. (Figure 3 and Figure 3B).

Figure 2A ICAM-1 mRNA expression in the pancreas in the different groups.

Figure 2B ICAM-1 mRNA expression in the pancreas in the different groups.

Figure 3A ICAM-1 mRNA expression in the liver in the different groups.

Figure 3B ICAM-1 mRNA expression in the liver in the parts of different groups.

Mn-SOD mRNA expression in the pancreas and liver

As shown in Figure 4 and Figure 4B, in the pancreas, compared to the SO group, Mn-SOD mRNA expression in the NS group was lower from 1 h to 5 h after AP induction. The Tet-treated group had a higher expression at the same time-points, and the QYT-treated group had a much higher expression at 10 h, nearly a 2-fold increase compared to that of the NS group. As shown in Figure 5 and Figure 5B, the NS group showed a similar decrease of Mn-SOD mRNA expression in the liver to that in the pancreas at 1 h and 5 h. When compared to the NS group, the Tet-treated group had a higher Mn-SOD mRNA expression from 1 h to 10 h, and the QYT group had a higher Mn-SOD mRNA expression from 5 h to 10 h, after AP induction.

Figure 4B Mn-SOD mRNA expression in the pancreas in the parts of different groups.

Figure 5A Mn-SOD mRNA expression in the liver in the different groups.

Figure 5B Mn-SOD mRNA expression in the liver in the parts of different groups.

Cu,Zn-SOD mRNA expression in the pancreas and the liver

As shown in Figure 6 and Figure 6B, in the pancreas, the NS group decreased significantly in Cu, Zn-SOD mRNA expression after AP induction to 1/3 of that in SO group. The Tet and QYT-treated groups had much higher levels of Cu, Zn-SOD mRNA expression at 1 h and 10 h respectively. These high levels were a 2-fold increase when compared with the SO group, and a 4-fold increase when compared with the NS group at the same time points. In the liver, no obvious changes of SOD expression were observed (Figure 7).

DISCUSSION

Research on AP can be traced back at least one hundred years, yet the treatment of AP continues to be a difficult aspect of clinical practice, especially for severe acute pancreatitis (SAP). SAP is recognized to be a multiple-stage disease where the pathological events at the pancreatic acinar cell level are paralleled by an exaggerated local and systemic inflammatory response (SIRS), and even by multiple-organ damage (MODS) or failure (MOF), with a high mortality^[12-15]. Considerable progress in understanding of pathophysiologic events during the early stage of AP has been made over the years, but the underlying pathogenic processes responsible for the inflammatory cascade and MOF are still unknown to a large extent. Most recent studies have revealed that the excessive releases of oxygen-derived free radicals (OFRs), destructive inflammatory mediators and cytokines, such as TNF- α , IL-1 β , IL-6, IL-8, IL-10, PAF, ICAM-1, play key roles in the AP process^[16-19]. Recent evidence suggests that, besides their directly detrimental effects on AP, OFRs may activate certain gene transcription factors, notably the nuclear transcription factor-kappa B (NF- κ B) and activator protein-1 (AP-1), which then mediate the induction of certain adhesion molecules (ICAM, VCAM, etc.) and other cytokines^[15,20-23]. These factors prompt neutrophil aggregation, adherence and activation, then tremendous amounts of inflammatory mediators and cytokines are released. The pancreas and remote organs are then severely injured and MOF occurs. Meanwhile, activation of leukocyte may release more OFRs, and the vicious circle continues^[24-27].

The manganese superoxide dismutase (Mn-SOD) and copper/zinc superoxide dismutase (Cu, Zn-SOD) existing in the mitochondria or cytoplasm of cells are the major OFR scavengers of the body. Previous experiments have demonstrated that the pathological changes in AP could be reduced by SOD^[28,29]. By immunohistochemistry, Su *et al* have proved the localization of SOD in acinar cells and have found Mn-SOD mRNA expression peaked at 2 hours after the addition of arginine to the cell culture medium^[30]. These data suggest that increased SOD expression reflects a defensive mechanism of acinar cells against oxidative stress. G. Teleck *et al* discovered that the increase of OFRs and ICAM expression could be measured within one hour and lasted for the 24 hour observation period^[31]. These findings, along with others from different laboratories, suggest that OFRs and ICAM induce morphologic change, aggregation, adherence, and activation of polymorphonuclears (PMNs), which then shift out of blood vessels and consequently cause microcirculation dysfunction^[32,33]. Our experimental results showed that during the process of AP, the expression of ICAM-1 in both the pancreas and the liver (especially in liver) was significantly increased, while the expressions of Mn-SOD and Cu-Zn-SOD were decreased in the pancreas by 1/3 as compared to the SO control group. This was similar to the finding of the experiment by L. Czako *et al*^[28]. These results provide further evidence that the increased ICAM-1 and decreased OFRs scavengers take part in the

pathophysiologic processes of AP.

Tet is a kind of dibenzyl quinoline alkaloid extracted from the root of *Stephania tetrandra* S., a Chinese herbal medicine with the effect of a non-selective calcium channel blocker (CCB). It has recently been found that Tet also has a widely anti-inflammatory effect by reducing the activity of PLA2 from inflammatory leukocytes, inhibiting the release of inflammatory mediators, eliminating OFRs and dilating blood vessels, and then improving microcirculation function of the body^[7,8,34,35]. QYT is a combined medication of Chinese herbs containing *Rheum officinale* Baillon, *ructus gardeniae*, etc., and also has the effects of anti-inflammation, cleaning OFRs, eliminating hazardous metabolite, dilating blood vessels and improving microcirculation^[9,10]. We found in this experiment that Tet reduced ICAM expression in the pancreatic and hepatic tissues during AP, while increasing the expression of Mn-SOD, and Cu, Zn-SOD. QYT had no significant effect on the expression of ICAM-1, but significantly enhanced the expression of Mn-SOD, and Cu, Zn-SOD. These findings suggest that Tet and QYT demonstrate the potentially useful effects of eliminating OFRs and reducing their damage, and also demonstrate the ability of Tet inhibiting ICAM production. The experiment provided a molecular level explanation of why clinical treatment of AP using Tet and QYT has been successful.

It is generally recognized that the induction of AP follows a uniform mechanism independent of different etiologic causes such as gallstones, alcohol, ischemia, hyperlipidemia, hypercalcemia, heredity and others. Firstly, each cause seems to affect primarily the acinar cell, resulting in intracellular activation of trypsinogen and other digestive enzymes and over-production of OFRs, which injure the acinar cells and pancreatic tissue. Then tremendous amounts of inflammatory mediators and cytokines, mentioned above, are released into the tissue and result in microcirculation disturbance. This not only worsens the local damage, but also influences the remote organs and causes systemic inflammatory response syndrome (SIRS). In the final stage of the pathophysiological process, multi-organ damage develops and multi-organ failure (MOF) may happen due to the combined effects of all the factors. Klar *et al* pointed out^[36] that since the initial enzyme activation and cytokine release were irreversible by the time of clinical presentation, specific therapy must be directed towards microperfusion failure as a secondary pathogenic stage. The beneficial therapeutic principles of this included the inhibition of leukocyte-endothelium interaction with ICAM-1 antibodies and the control of local vasoconstriction to stop the progression of the disease. Therefore, based on previously observed clinical effects and on the experimental results with Tet and QYT in this study, we conclude that Tet and QYT which inhibit ICAM-1 and enhance SOD expression are beneficial in treating AP.

Abstract

AIM: To characterize the alteration and significance of p53 and PCNA in cancer and adjacent tissues of concurrent cancers from the esophagus and gastric cardia in the same patient.

METHODS: P53 and PCNA protein accumulation in 25 patients with concurrent cancers from the esophagus and gastric cardia (CC, concurrent carcinomas of esophageal squamous cell carcinoma and gastric cardia adenocarcinoma) were detected by immunohistochemical method (ABC).

RESULTS: In CC patients, both esophageal squamous cell carcinoma (SCC) and gastric cardia adenocarcinoma (GCA) tissues showed different positive immunostaining extent of p53 and PCNA protein ($P > 0.05$). The positive immunostaining rates for p53 and PCNA were 60 % (15/25) and 92 % (23/25), respectively in SCC; and 40 % (10/25) and 88 % (22/25), respectively in GCA. "Diffuse" immunostaining pattern was frequently observed in both p53 and PCNA. High coincidence rates for p53 and PCNA positive staining were observed in SCC and GCA from the same patients, and accounted for 56 % and 96 %. In SCC patients, with the lesions progressed from normal esophageal epithelium (NOR) to basal cell hyperplasia (BCH) to dysplasia (DYS) to carcinoma *in situ* (CIS) to SCC, the positive rates for p53 were 27 %, 50 %, 50 %, 29 % and 72 %, and 55 %, 70 %, 75 %, 71 % and 93 % for PCNA, respectively. In GCA, with the lesions progressed from normal gastric cardia epithelium to DHS to CIS to GCA, the positive rates of p53 expression were 44 %, 27 %, 22 % and 36 % respectively, the difference was not significant; the positive rates of PCNA protein expression were 67 %, 64 %, 67 % and 86 %, respectively. The χ^2 test, Fisher's Exact Test, Mantel-Haenszel χ^2 Test and Kappa Test were used for the statistics.

CONCLUSION: The high coincident alterations for P53 and PCNA in SCC and GCA from the same patient indicate the possibility of similar molecular basis, which provides important molecular basis and etiological clue for similar geographic distribution and risk factors in SCC and GCA.

Chen H, Wang LD, Guo M, Gao SG, Guo HQ, Fan ZM, Li JL. Alterations of p53 and PCNA in cancer and adjacent tissues from concurrent carcinomas of the esophagus and gastric cardia in the same patient in Linzhou, a high incidence area for esophageal cancer in northern China. *World J Gastroenterol* 2003; 9(1): 16-21

INTRODUCTION

Esophageal squamous cell carcinoma (SCC) and gastric cardia adenocarcinoma (GCA) are the two most frequent malignant diseases in the world^[1-3]. SCC is characterized by its remarkable geographic distribution; the ratio between the incident rates of high- and low-risk areas can be as high as 500:1. Consistent geographic distribution with SCC in the same high-incidence area (HIA) is the remarkable epidemiological characteristic of GCA^[3], and in America and Europe the incidence of GCA increased dramatically in recent decades^[4-8]. Linzhou and the nearby counties in Henan province, have the highest incidence and mortality for SCC and GCA in the world, SCC and GCA remain the leading cause of cancer-related death in these areas^[9].

It is noteworthy that the concurrent cancers from esophagus and gastric cardia in the same patient (CC) is not uncommon in this area, with an incidence of 0.4-2.5 %^[10-13]. This special pattern indicates that there may be same or similar risk factors and mechanism involved in the carcinogenesis. The molecular mechanism of SCC/GCA is still not clear, and the information from the concurrent cancers of SCC & GCA in the same patient in the HIA is very limited. It is apparent to further characterize the molecular changes of CC patients may provide not only more information on the molecular mechanism but also the etiological clues for SCC and GCA.

Recent studies indicate that esophageal and gastric cardia carcinogenesis is a multistep progressive process involving multiple genetic changes (accumulation or overlap). The accumulation of p53 protein and p53 gene mutation were observed in the very early stage of esophageal carcinogenesis, even in the microscopically normal esophageal epithelium, with positive immunostaining and mutation rates increasing with the progression of lesions^[14-24]. In addition, recent study showed that PCNA protein overexpression was also observed in the carcinogenesis of GCA^[25].

To elucidate the molecular mechanisms of SCC/GCA carcinogenesis and to expand the knowledge for early detection of SCC/GCA and screening high-risk population, the present study was undertaken to analyze the alternations of p53 and PCNA in cancer tissues and adjacent cancerous tissues with different degrees of precancerous lesions in CC patients.

MATERIALS AND METHODS

Tissue collection and processing

25 cases with concurrent cancers of SCC & GCA enrolled in this study were from Linzhou City Hospital, Yaocun

Esophageal Cancer Hospital and Anyang City Tumor Hospital, the high-incidence area for EC, including 16 males and 9 females, with a mean age of 59 (59±9.88) in male and 60.6 (60.6±11.44) in female. None of these patients received any treatment of chemotherapy or radiotherapy before operation. All the resected tissues and biopsied tissues were fixed with 85 % alcohol, embedded with paraffin and serially sectioned at 5 µm. The sections were mounted onto the histostick-coated slides. Four or five adjacent ribbons were collected for histopathological diagnosis (hematoxylin and eosin stain) and immunohistochemical staining.

Histopathology analysis

Histopathological diagnosis for esophageal and gastric cardia epithelia was based on the changes in cellular morphology and tissue architecture using previously established criteria^[26-32]. The normal esophageal epithelium (NOR) contained 1 to 3 basal-cell layers; the papillae were confined to the lower half of the epithelium. In basal cell hyperplasia (BCH), the number of proliferating basal cells was increased to more than 3-cell layers. Dysplasia (DYS) was characterized by the partial loss of cell polarity and nuclear atypia. SCC was characterized by confluent and invasive sheets of cohesive, polymorphous cells with hyperchromatic nuclei. The following histopathological classification was used for the gastric-cardia epithelia: dysplasia (DYS), neoplastic features including nuclear atypia and/or architectural abnormalities confined to the gastric epithelium, without invasion; GCA: invasion of neoplastic gastric cells through the basement membrane. The diagnosis of CC was based on the following criteria: (1) the tumors must be clearly separated on histological phenotype; (2) the tumors must be malignant; (3) Metastasis must be excluded.

Immunohistochemical staining (IHC)

Anti-p53 antibody is a monoclonal mouse anti-serum against p53 of human origin, and recognizes both wild and mutant type p53 (Ab-6, Oncogen Science, Manhasset, NY). Anti-PCNA antibody is a monoclonal mouse anti-serum against PCNA of human origin (Mab, DAKO, Carpinteria, CA). The avidin-biotin-peroxidase complex method was used for the immunostaining of p53, PCNA. In brief, after dewaxing, inactivating endogenous peroxidase activity and blocking cross-reactivity with normal serum (Vectastain Elite Kit; Vector, Burlingame, CA), the sections were incubated overnight at 4 °C with a diluted solution of the primary antibodies (1:500 for p53 and 1:200 for PCNA). Location of the primary antibodies was achieved by subsequent application of a biotinylated anti-primary antibody, an avidin-biotin complex conjugated to horseradish peroxidase, and diaminobenzidine (Vectastain Elite Kit, Vector, Burlingame, CA). The slides were counter-stained by hematoxylin. Negative controls were established by replacing the primary antibody with PBS and normal mouse serum. Known immunostaining-positive slides were used as positive controls.

Specific staining for each protein was categorized as either positive or negative based on the presence of brown coloration staining. More than 10 % positively stained cells were graded as positive^[33,34]. Clear staining for nuclei was the criterion for a positive reaction. Immunostaining patterns^[26] were graded into the “focus”, “scattered”, “diffuse”, according to cell distribution in one microscopic eyeshot (×40). All the immunostaining slides were observed by two pathologists independently. The slides with different diagnosis by two pathologists were reviewed again (less than 5 %) until the agreed diagnosis was made.

Statistics analysis

The χ^2 test, Fisher's Exact Test, Mantel-Haenszel χ^2 Test and

Kappa Test were used for the statistics ($P < 0.05$ was considered significant).

RESULTS

Histopathological results

Histopathologically, primary SCC and GCA in the same patient were verified in all 25 cases by two pathologists using an Olympus microscope independently. Of the 14 CC patients (both with cancer and adjacent tissues) examined, in esophagus 11 samples were diagnosed as normal, 10 as BCH, 8 as DYS, 7 as CIS and 14 as SCC; in gastric cardia 9 as normal, 11 as DYS, 9 as CIS and 14 as GCA.

Expression of p53 protein in CC patients (Table 1)

P53 positive immunostaining was observed in the epithelial and tumor cells of esophagus and gastric cardia. In CC patients, both SCC and GCA tissues showed a different extent positive immunostaining of p53 protein (Figure 1,2). In 25 CC patients, the immunostaining rate of p53 protein in SCC was 60 % (15/25) and in GCA was 40 % (10/25), and statistical analysis showed that the difference was not significant ($P > 0.05$). “Diffuse” was the most frequent immunostaining pattern observed in both SCC (60 %, 9/15) and GCA (70 %, 7/10). High coincidence alteration for positive staining of p53 was observed in SCC and GCA from the same patients, and accounted for 56 %.

Expression of p53 and PCNA in adjacent cancerous tissues

In SCC patients, with the lesions progressed from normal esophageal epithelium to BCH to DYS to CIS to SCC, an increasing tendency of p53 protein accumulation and PCNA expression were observed, the positive rates for p53 were 27 %, 50 %, 50 %, 29 % and 72 %, and 55 %, 70 %, 75 %, 71 % and 93 % for PCNA, respectively. In GCA, with the lesions progressed from normal gastric cardia epithelium to DYS to

CIS to GCA, the positive rates of p53 expression were 44 %, 27 %, 22 % and 36 % respectively, the difference was not significant; the positive staining of PCNA protein expression were 67 %, 64 %, 67 % and 86 %, respectively, positive rates of PCNA expression in GCA was generally higher than those in precancerous lesions (Table 3) (Figure 5-8).

Table 3 Expression of P53 & PCNA in precancerous lesions of adjacent cancerous tissues

Number of samples		P53		PCNA	
		+	%	-	%
Esophagus

DYS	11	3	27	7	64
CIS	9	2	22	6	67
CGA	14	5	36	12	86

DISCUSSION

In this study, indistinguishable overexpressions of p53 and PCNA protein and the same main immunostaining pattern (Diffuse) of immunoreaction were observed in primary SCC and GCA from the same patient. We also found that in CC patient p53 and PCNA had high coincident alteration in both SCC and GCA. These results indicated that SCC and GCA in the same patient might have the similar molecular basis and mechanism of carcinogenesis. These results might be a molecular explanation of the consistent geographic distribution of SCC and GCA. That further characterized the molecular alterations in different stages of SCC and GCA and their relations with morphological changes would provide more information to elucidate the carcinogenesis of SCC and GCA. In this study, high PCNA positive staining rates were observed in CC patient, both in esophageal and gastric cardia epithelia. It inferred that in this high-incidence area, the alimentary canal of patients exposed to similar risk factor might lead the esophageal and gastric cardia epithelial cells to become the hotspot of hyperproliferation, which might be a molecular evidence of hypothesis of field cancerization^[35,36]. The hypothesis of field cancerization is an explanation of multiple primary malignant neoplasms, which consider the tissues of similar architecture exposed to similar pathogen might occur independently as precancerous lesions in multiple sites of the organ.

It is very important for the diagnosis of CC and multiple primary SCC/GCA to exclude local metastasis. In this study, microscopic observation showed that mixed of SCC and GCA tissue was observed occasionally in some patients, and the tissues adjacent to SCC and GCA had different patterns of precancerous lesions, which were characterized by either isolated or in succession. These unique information provided important clues to study the molecular basis of SCC/GCA carcinogenesis and sensibility.

Through the contrast study of adjacent cancerous tissues of SCC and GCA, we found that different extent of overexpressions of p53 and PCNA were already observed in the apparently normal epithelia and very early precancerous

lesions of esophagus and gastric cardia. Especially, from normal epithelia (NOR) to different precancerous lesions to SCC, of both p53 and PCNA protein positive staining rate increased accordingly in the esophagus, and PCNA increased in gastric cardia, but did not show the tendency of increase. Other researchers' results showed that from NOR to precancerous lesions to SCC/GCA, positive staining of p53 and PCNA showed a continuous increasing tendency^[14,25,37-44]. So the explanation of our result might be that IHC qualitative analysis cannot reflect the number of immunostaining cells, and only show the alteration of immunostaining rates. The use of quantitative analysis may solve this problem. In this study we also found that in the stage of CIS, both esophagus and gastric cardia tissues showed a decrease of positive staining rate of p53. It might due to that precancerous lesions have an instable characteristic of bidirectional development, that is, in the multistage progression course of carcinogenesis precancerous lesions might progress to cancer, or reverse to low-grade lesion or even normal^[14]. These results inferred that the molecular changes of SCC and GCA not only were similar in the ultimate stages but also in the early stages, so the CC patient might have similar carcinogenetic course in primary SCC and GCA, but their precise mechanism and biological significance need further study.

Abstract

AIM: To study the expression of neurokinin-1 receptor (NK-1R) and neurokinin-2 receptor (NK-2R) in distal ileum of acute necrotizing pancreatitis (ANP) and to evaluate the relationship between expression of these two receptors and intestinal mucosal damage.

METHODS: A total of 130 adult Sprague-Dawley rats were randomly divided into two groups: the rats in ANP group ($n=80$) were induced by the retrograde intraductal infusion of $30\text{ g} \cdot \text{L}^{-1}$ sodium taurocholate. And the rats in normal control group ($n=50$) received laparotomy only. Sacrifices were made 6 h, 12 h, 24 h and 48 h later in ANP and normal control group after induction respectively. Intestinal mucosal permeability was studied by intrajejunal injection of 1.5mCi radioactive isotope $^{99\text{m}}\text{Tc}$ -diethylene triamine pentacetic acid (DTPA) and the radioactivity of $^{99\text{m}}\text{Tc}$ -DTPA content in urine was measured 6 h, 12 h, 24 h and 48 h after induction. Then the pancreas and intestine were prepared for pathology. Reverse transcription polymerase chain reaction (RT-PCR) was used to determine the mRNA expression of NK-1R and NK-2R, and Western blot was used to investigate the protein level of NK-1R and NK-2R.

RESULTS: In ANP rats, serious histologic damages in intestinal mucosa were observed, and the radioactivity of $^{99\text{m}}\text{Tc}$ -DTPA in urine increased significantly in the ANP group. RT-PCR revealed that NK-1R and NK-2R mRNA level was overexpressed in the distal ileum of ANP as compared with the normal control group. Western blot discovered stronger NK-1R (14-fold increase) and NK-2R (9-fold increase) immunoreactivity in the intestinal mucosa of ANP rats. Moreover, the overexpression of NK-1R was associated with mucosal pathological score ($r=0.77$, $P<0.01$) and intestinal permeability ($r=0.68$, $P<0.01$) in ANP rats.

CONCLUSION: NK-1R and NK-2R contribute to disrupted neuropeptides loop balance, deteriorate intestinal damage, and are involved in pathophysiological changes in ANP.

INTRODUCTION

Acute necrotizing pancreatitis (ANP) has a complicated and ill-defined pathophysiology. It is associated with a high complication rate and unpredictable outcome, with a mortality rate of 10-45 %^[1]. The hypothesis that ANP promotes bacterial translocation, leading to infection in the inflamed pancreas and peripancreatic tissue, has been studied in rats fed with fluorescent beads, sensitive inert markers of translocation^[2]. The results suggested a translocated bacteria route for pancreatic infection. Normal intestinal mucosal barrier can keep the bacteria from translocation, however, this barrier is damaged in ANP^[3,4]. The mechanism, which leads to the dysfunction of mucosal barrier, remains unclear^[5-9].

Recent studies have revealed the important role of Substance P (SP) and its receptors in ANP^[10-13]. However, the expression of SP's two receptors- neurokinin-1 receptor (NK-1R) and neurokinin-2 receptor (NK-2R) in intestinal mucosa of ANP, remains unclear. And their roles in mucosal damage has not been revealed.

Therefore, in the present study the mRNA of NK-1R and NK-2R in intestinal mucosa of ANP was analyzed using reverse transcription polymerase chain reaction (RT-PCR), the protein level of these two receptors was analyzed by Western blot. And the relationship between mRNA level and intestinal mucosal damage/intestinal permeability was also investigated.

MATERIALS AND METHODS

Animals

Adult Sprague-Dawley rats weighing 250-300 g were obtained from the Laboratory Animal Center of Southeast University, and fed with standard rat chow. Animals were fasted overnight and anesthetized with $20\text{ g} \cdot \text{L}^{-1}$ sodium pentobarbital (intraperitoneal injection). ANP models ($n=80$) were induced by the retrograde intraductal infusion of $30\text{ g} \cdot \text{L}^{-1}$ sodium taurocholate ($0.1\text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$). And the rats in normal control group ($n=50$) received laparotomy, the duodenum was taken out of the abdominal cavity and the pancreas was turned over for three times.

Sacrifices were made 6 h, 12 h, 24 h and 48 h later in ANP and normal control group after induction respectively. The distal ileum, pancreas and blood in portal vein were obtained for further studies. Freshly removed tissue samples were immediately fixed in paraformaldehyde solution for 12-24 hours and paraffin-embedded for routine histopathologic analysis. Concomitantly, tissue samples destined for RNA and protein extraction were immediately snap-frozen in liquid nitrogen and maintained at -80°C until use. Blood was obtained for serum amylase determinations.

Pathological examination for intestinal mucosa and pancreas

Paraffin-embedded tissue sections (2-3 mm thick) were subjected to hematoxylin & eosin staining. Intestinal mucosal damage was evaluated blindly under microscope by two pathologists^[14, 15].

Determinants of intestinal mucosal permeability

Intestinal mucosal permeability was investigated by intrajejunal

injection of 1.5mCi radioactive isotope ^{99m}Tc (Chinese Institute of Nuclear Power)-diethylene triamine pentacetic acid (DTPA, Chinese Institute of Nuclear Power) and the radioactivity of ^{99m}Tc -DTPA content in urinary were measured 6 h, 12 h, 24 h and 48 h after induction. Urinary volume was measured and radioactive impulse was determined using radio-immunity γ counter. Intestinal mucosal permeability was calculated using the following formula: Intestinal mucosal permeability (%) = $\frac{^{99m}\text{Tc}\text{-DTPA excretory rate (\%)} - [(\text{urine-background}) \times \text{volume}]}{(\text{standard-background})} \times 100\%$ [16, 17].

RNA extraction and RT-PCR

Total RNA was extracted using the single-step guanidinium isothiocyanate method, as previously reported [18,19]. Following DNase treatment, total RNA was reversely transcribed into cDNA using random hexamers according to the manufacturer's instructions (Roche Diagnostics, Rotkreuz, Switzerland). The primers were designed using Primer Express software (Germany) and synthesized by Amplimmun (Amplimmun AG, Madulain, Switzerland). The sequence is shown in Table 1.

Table 1 The sequence of primers used for RT-PCR

PCR amplification was carried out using either NK-1R or NK-2R or GAPDH in a final volume of 25 μl with a Perkin-Elmer GeneAmp System 9 700 and 0.625 U of Taq DNA polymerase (Roche Diagnostics GmbH, Mannheim, Germany). Cycling conditions were as follows: 35 cycles of denaturation at 94 °C for 1 min, annealing at 62 °C for 1 min and elongation at 72 °C for 2.5 min. The first PCR cycle was preceded by denaturation at 94 °C for 3 min, and last PCR cycle was followed by incubation at 72 °C for 10 min.

For each PCR reaction, an identical tube containing the same amount of reagent, and same amount of water was substituted for cDNA in these tubes. These tubes served as negative control of PCR.

RNA concentrations and PCR were titrated to establish standard curves to document linearity and to permit semiquantitative analysis of signal strength [20-22]. Amplified PCR products were separated by electrophoresis through a 1 % agarose gel at 45 V for 120 min. The cDNA bands were visualized by ultraviolet illumination after the gels were stained with 0.5 $\text{g} \cdot \text{L}^{-1}$ ethidium bromide dissolved in Tris-borate-EDTA buffer (89 mM Tris, 89 mM boric acid, 2.5 mM EDTA, pH 8.2). The gels were photographed, and the films were scanned and analyzed with a computerized densitometer (Image-Pro Plus, Version 3.0.01).

Western blot

Western blot for NK-1R and NK-2R was performed as previously reported with certain modifications [18,19]. Briefly, 200 mg of tissue samples were powered in liquid nitrogen and

then homogenized in lysis buffer (50 mM Tris-HCl, pH 7.5, 150 mM NaCl, 2 mM EDTA, 1 % SDS) supplemented with a protease inhibitor cocktail (Roche Diagnostics, Rotkreuz, Switzerland). The lysate was collected and centrifuged at 4 °C for 10 min with 14 000 rpm to remove the insoluble material. The protein concentration was measured by spectrophotometry using the BCA protein assay (Pierce, Rockford, IL, USA). For each sample, 40 mg of protein was separated on 12 % SDS-polyacrylamide gels and electroblotted onto nitrocellulose membranes.

The blots were incubated in blocking solution (50 $\text{g} \cdot \text{L}^{-1}$ non-fat milk in 20 mM Tris-HCl, 150 mM NaCl, 1 $\text{g} \cdot \text{L}^{-1}$ Tween-20 [TBS-T]), followed by incubation with 1:1 000 dilution of goat anti-rat NK-1R antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) or 1:1 000 dilution of goat anti-rat NK-2R antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) at 4 °C overnight. The membranes were then washed with TBS-T and incubated with donkey anti-goat IgG (1:3 000 dilution) for 60 min at room temperature. Antibody detection was performed with an enhanced chemiluminescence reaction (ECL Western blotting detection, Amersham Life Science, Amersham, UK).

Statistical analysis

Results were expressed as mean \pm SD. Statistical analysis was made using the Prism software (Prism, GraphPad Software Inc., San Diego, CA, USA). The comparative statistical evaluations among groups were done using the Mann-Whitney U test or Chi-square test. Spearman correlation analysis was used for correlation analysis of the parameters. Significance was defined as $P < 0.05$.

RESULTS

Serum amylase and pathological examination

Serum amylase increased significantly in ANP group as compared with normal controls ($P < 0.01$). The diagnoses of ANP were confirmed by gross appearance and microscopy. In ANP group, mucosal edema, epithelia degeneration, necrosis or even abscission were observed after 6 h. Hemangiectasia, hemorrhage and inflammatory cell infiltration were revealed in mucosa or submucosa (Table 2).

Table 2 The pathological score of intestinal mucosa

Groups	0 h	6 h	12 h	24 h	48 h
Control	0.92 \pm 0.47	0.90 \pm 0.35	0.93 \pm 0.38	0.93 \pm 0.29	1.07 \pm 0.36
ANP		2.11 \pm 0.47 ^a	2.65 \pm 0.49 ^b	3.91 \pm 0.82 ^b	4.89 \pm 1.21 ^b

^a $P < 0.05$ vs each time point of control group, respectively; ^b $P < 0.01$ vs each time point of control group, respectively

Intestinal mucosal permeability change in ANP rats

The intestinal mucosal permeability was determined using isotope. The results revealed that permeability increased significantly after 6 h (Table 3).

Table 3 Changes of intestinal mucosal permeability

Groups	0 h	6 h	12 h	24 h	48 h
Control	0.0411 \pm 0.0156	0.0455 \pm 0.0174	0.0532 \pm 0.0188	0.0693 \pm 0.0153	0.0698 \pm 0.0223
ANP		0.2367 \pm 0.1132 ^a	0.3457 \pm 0.0473 ^a	0.6651 \pm 0.1411 ^a	0.7021 \pm 0.1523 ^a

^a $P < 0.01$ vs each time point of control group, respectively

mRNA expression of NK-1R and NK-2R in distal ileum

The rats were sacrificed 6 h, 12 h, 24 h or 48 h after model inducing, distal ileum was obtained for determination of NK-1R and NK-2R mRNA. Figure 1 shows the amplification plot at the time point of 6 h. The gene above had been amplified effectively, and amplification of GAPDH was comparable in each sample, which suggested comparable mRNA in each sample (Figure 1B, 1D), whereas amplification of NK-1R in normal controls was so weak that some of the samples could only be observed in the gel. In contrast, the amplification of NK-1R in ANP group was relatively stronger (Figure 1A). The expression of NK-2R was similar to NK-1R (Figure 1C). After 12 h, 24 h or 48 h, the expression of above genes maintained the same pattern as before.

Figure 1 Amplification results of NK-1R, NK-2R and GAPDH from RT-PCR in control and ANP intestinal tissue. A: amplification results of NK-1R; C: amplification results of NK-2R; B, D: amplification results of GAPDH. N: PCR negative control; M: PCR Marker (upper to lower: 1 000, 800, 600, 400, 200 and 100bp); 1-5: group of normal control; 6-11: group of ANP

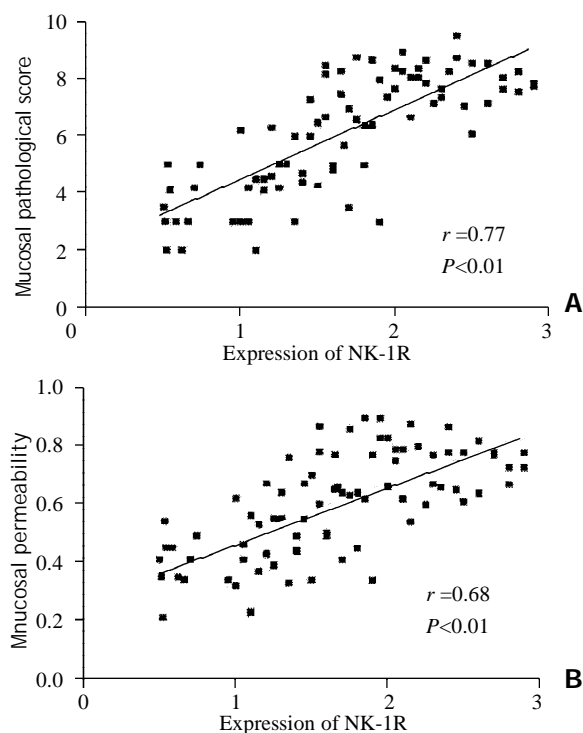

Figure 2 The expression level of NK-AR mRNA was correlated with intestinal mucosal pathological score (A) and mucosal permeability (B) in ANP rats

Correlation of expression of NK-1R and NK-2R with intestinal mucosal damage

We then evaluated whether there was a relationship between the expression levels of these two genes and intestinal mucosal pathological score and permeability. A significant relationship between NK-1R mRNA and mucosal pathological score ($r=0.77$, $P<0.01$) was found (Figure 2A). Furthermore, statistical analysis revealed a significant relationship between NK-1R mRNA and mucosal permeability ($r=0.68$, $P<0.01$, Figure 2B). Although NK-2R mRNA was overexpressed in ANP, there was no significant relationship between this gene expression and intestinal mucosal pathological score ($r=0.32$, $P=0.31$) and permeability ($r=0.28$, $P=0.21$).

NK-1R and NK-2R protein expression in distal ileum

We then performed the Western blot analysis in controls and ANP group. All the normal controls exhibited approximately 46 kDa band of NK-1R protein of weak intensity. In contrast, the ANP samples showed a more intense signal (Figure 3A). The densitometric analysis demonstrated a 14-fold increase of NK-1R protein level in ANP ileum compared with the normal ileum ($P<0.01$).

When Western blot analysis for NK-2R was performed, similar pattern was observed, protein signal was weak in normal control, but much stronger in ANP group (Figure 3B). Densitometry revealed a 9-fold increase of NK-2R in ANP ileum ($P<0.01$).

Figure 3 Western blot revealed the protein level of NK-1R (A) and NK-2R (B) in normal control and ANP intestinal tissue

DISCUSSION

Intestinal bacterial translocation is the main source leading to infection of pancreas, whereas this translocation is dependent, to some degree, on the function of intestinal mucosal barrier. Intestinal mucosal barrier is made up of mechanical, biological, immunologic and chemical barrier, while the mechanical barrier is the fundamental one, which can prevent large molecule and bacteria from passing through^[23,24]. More and more evidence showed that gut barrier dysfunction is related to multiorgan system failure in sepsis and immune dysregulation^[25-35]. Pancreatitis-induced hypovolaemia due to endothelial barrier leakage and gut arteriovenous shunting causes intestinal ischaemia and reperfusion injury with concomitant gut barrier dysfunction. Gut endothelial barrier dysfunction probably plays a central role. Potential molecular mechanisms could be associated with alterations in intracellular signal transduction, intercellular signal and expression of adhesion molecules on endothelial cells. Bacterial infections are often seen during the progression of ANP, concomitant with the potential development of multiple organ dysfunction^[36,37]. The mechanisms underlying gut barrier dysfunction in acute pancreatitis are thus complex and still not fully elucidated.

SP is synthesized by small-diameter C sensory 'pain' fibers, and release of this peptide into the dorsal horn of the spinal cord following intense peripheral stimulation was thought to promote central hyperexcitability (central sensitization)^[38,39]. In addition, it could result in plasma extravasation, neutrophil infiltration, and vasodilatation. In rats, both SP and NK-1R selective agonist stimulated pancreatic plasma extravasation, and this response was blocked by the NK-1R antagonist. Selective agonist of NK-2R showed no effect^[12]. Continuous infusion of SP stimulated plasma extravasation in rat pancreas via activation of NK-1R^[40-42].

In the present study, expression of NK-1R and NK-2R mRNA was investigated by RT-PCR and the protein levels of NK-1R and NK-2R were determined using Western blot analysis in normal control and ANP intestines. The results revealed that both NK-1R and NK-2R were overexpressed in ANP intestines, and the overexpression of NK-1R was correlated with mucosal damage in ANP rats. Increased level of SP^[43] in ANP, together with overexpression of its receptors-NK-1R and NK-2R, results in excessive biological effect, such as aggregation of neutrophilic granulocyte, cascade release of inflammatory transmitter, tissue fluid and plasma extravasation, thus resulting in deterioration of intestinal pathological changes and gut barrier dysfunction, and facilitating gut bacterial translocation.

Better understanding of the molecular biological changes in ANP will provide novel therapies to this disease. Once specific receptors were identified, selective antagonists which blocked these receptors would have therapeutic effects. Antagonists against NK-1R have showed some effects in acute pancreatitis on animal models^[12,42]. Knowledge about the regulating events will probably make future pharmacological therapy available for prevention and treatment of the severe complications of ANP, including gut barrier dysfunction.

Abstract

AIM: To investigate the effects of oxytocin (OT) on isolated rabbit proximal colon and its mechanism.

METHODS: Both longitudinal muscle (LM) and circular muscle (CM) were suspended in a tissue chamber containing 5 mL Krebs solution (37 °C), bubbled continuously with 950 mL·L⁻¹ O₂ and 50 mL·L⁻¹ CO₂. Isometric spontaneous contractile responses to oxytocin or other drugs were recorded in circular and longitudinal muscle strips.

RESULTS: OT (0.1 U·L⁻¹) failed to elicit significant effects on the contractile activity of proximal colonic smooth muscle strips ($P>0.05$). OT (1 to 10 U·L⁻¹) decreased the mean contractile amplitude and the contractile frequency of CM and LM. Hexamethonium (10 μmol·L⁻¹) partly blocked the inhibition of oxytocin (1 U·L⁻¹) on the contractile frequency of CM. N^ω-nitro-L-arginine-methylester (L-NAME, 1 μmol·L⁻¹), progesterone (32 μmol·L⁻¹) and estrogen (2.6 μmol·L⁻¹) had no effects on OT-induced responses.

CONCLUSION: OT inhibits the motility of proximal colon in rabbits. The action is partly relevant with N receptor, but irrelevant with that of NO, progesterone or estrogen.

INTRODUCTION

Oxytocin (OT) is a very abundant neuropeptide. The structure of the OT gene was elucidated in 1984^[1], and the sequence of the OT receptor was reported in 1992^[2]. OT exerted a wide spectrum of central and peripheral effects^[3-5]. It was reported that hypothalamic paraventricular nucleus is a site of controlling gastric function^[6], oxytocin facilitated the manifestation of inhibitory effects of hypothalamus on the motor function of gastrointestinal tract^[7]. The experiments on rats had shown that gastric motility was inhibited by microinjection of oxytocin into the dorsal motor nucleus of the vagus (DMN), and that the inhibition of gastric motility after electrical stimulation of the hypothalamic paraventricular nucleus was blocked by microinjection of an oxytocin receptor antagonist directly into the DMN. These results suggested that oxytocin acted on the gastric motility via DMN^[8]. The reports on peripheral action of oxytocin to influence gastrointestinal

(GI) motility were controversial: OT decreases the contractions of the guinea pig stomach *in vitro*, and inhibits the tone and peristaltic contractions of stomach and small intestines in fasting dogs *in vivo*^[9]; but increases the gastric emptying of semisolid food in normal human and the contractions of gastric smooth muscle strips in rats^[10]. The effect of oxytocin on colonic motility is still unknown.

OTR is functionally coupled to GTP binding proteins, stimulates the activity of phospholipase C-β isoforms. Finally, a variety of cellular events are initiated. For example, the forming Ca²⁺-calmodulin complexes triggers the activation of neuronal and endothelial isoforms of nitric oxide (NO) synthase^[11]. Steroid hormones were reported to control oxytocin receptor (OTR) activity via both genomic and nongenomic pathways^[12]. Estrogen induces the OTR mRNA expression, and then increases the OTR density on the membrane of the uterus smooth muscle and central nervous system^[13,14]; on the other hand, progesterone inhibits the nuclear OTR mRNA expression, and decreases the sensitivity of the target cell on OT stimulation^[15,16]; progesterone was also reported to bind to OTR with high affinity and inhibit the receptor function^[17]. In this study, we investigated the effect of OT on proximal colonic motility of rabbits; We also investigated if the OT-induced responses were relevant with NO, steroid hormones or N receptor.

MATERIALS AND METHODS

Animal preparation

Rabbits of both sexes, weighing 1.5-2 kg, were fasted for 24-hour and sacrificed. The proximal colon (1 cm from the cecocolonic junction) was removed. The segment of the colon was opened along the mesentery. Muscle strips (8×2 mm) were cut, parallel to either the circular or the longitudinal fibers, and named circular muscle (CM) and longitudinal muscle (LM). The mucosa on each strip was carefully removed.

Experiments

The muscle strip was suspended in a tissue chamber containing 5 mL Krebs solution (37 °C) and bubbled continuously with 950 mL·L⁻¹ O₂ and 50 mL·L⁻¹ CO₂^[18]. One end of the strip was fixed to a hook on the bottom of the chamber. The other end was connected to an external isometric force transducer (JZ-BK, BK). Motility of colonic strips (under an initial tension of 1 g) in 2 tissue chambers were simultaneously recorded on ink-writing recorders (LMS-ZB, Cheng-Du). After 1 h equilibration, OT (0.1, 1, 10 U·L⁻¹) was added in the tissue chamber to observe their effects on proximal colon; N^ω-nitro-L-arginine-methylester (L-NAME, 1 μmol·L⁻¹), hexamethonium (10 μmol·L⁻¹), progesterone (32 μmol·L⁻¹) or estrogen (2.6 μmol·L⁻¹), given 3 min before the administration of OT (1 U·L⁻¹), was added separately to investigate whether the actions of OT were relevant with NO, N receptor or steroids. The resting tension, the contractile frequency, and the mean contractile amplitude of LM and CM were measured.

Drugs preparation

The following agents were used: oxytocin (Biochemical Pharmaceutical Company, Shanghai, China), N^ω-nitro-L-arginine-methylester (L-NAME) and hexamethonium (Sigma Chemical Company), progesterone and estrogen (The Ninth Pharmaceutical Factory in Shanghai).

Data analysis

The results were presented as $\bar{x} \pm s$, and statistically analyzed by paired *t* test, $P < 0.05$ was considered to be significant.

RESULTS

Effect of OT on the spontaneous contraction of colonic smooth muscle strips

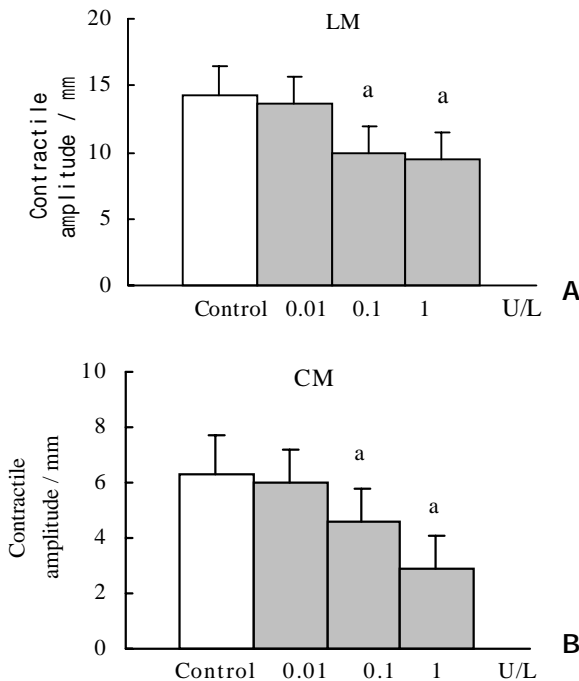

Figure 1 A: Effect of oxytocin on the mean contractile amplitude of longitudinal muscle (LM) of proximal colon in rabbits. B: Effect of oxytocin on the mean contractile amplitude of circular muscle (CM) of proximal colon in rabbits. ^a $P < 0.05$ vs control, $n = 10$.

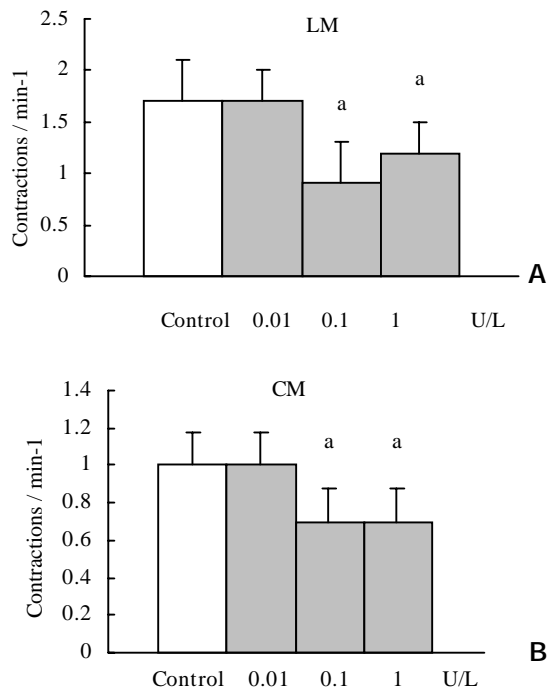

Figure 2 A: Effect of oxytocin on the contractile frequency of longitudinal muscle (LM) of proximal colon in rabbits. B: Effect of oxytocin on the contractile frequency of circular muscle (CM) of proximal colon in rabbits. ^a $P < 0.05$ vs control, $n = 10$.

OT ($0.1 \text{ U} \cdot \text{L}^{-1}$) failed to elicit significant effects on the contractile activity of proximal colonic smooth muscle strips ($P > 0.05$). OT (1 to $10 \text{ U} \cdot \text{L}^{-1}$) decreased the mean contractile amplitude and the contractile frequency of CM and LM (Figure 1, Figure 2). It had no significant effects on the resting tension of CM and LM.

Effect of hexamethonium on the OT-induced responses

Hexamethonium ($10 \text{ } \mu\text{mol} \cdot \text{L}^{-1}$) had no significant effect on the contractile activity of each colonic smooth muscle strip. Hexamethonium given 3 minute before administration of OT ($1 \text{ U} \cdot \text{L}^{-1}$) decreased OT-induced inhibition on the contractile frequency of CM (Figure 3). It had no significant effects on the other action of OT.

Figure 3 Effect of oxytocin on the contractile frequency of circular muscle (CM) of proximal colon after hexamethonium pretreatment in rabbits. OT, oxytocin; Hex, hexamethonium. ^a $P < 0.05$ vs control, ^b $P < 0.05$ vs oxytocin, $n = 6$.

Effect of L-NAME on the OT-induced responses

L-NAME ($1 \text{ } \mu\text{mol} \cdot \text{L}^{-1}$) itself had no significant effects on proximal colon in rabbits. When given 3 min before the administration of OT ($1 \text{ U} \cdot \text{L}^{-1}$), It had no significant effects on OT-induced responses.

Effect of progesterone and estrogen on the OT-induced responses

Progesterone ($32 \text{ } \mu\text{mol} \cdot \text{L}^{-1}$) and estrogen ($2.6 \text{ } \mu\text{mol} \cdot \text{L}^{-1}$) had no significant effects on proximal colonic motility. When given 3 min before the administration of OT ($1 \text{ U} \cdot \text{L}^{-1}$), neither progesterone nor estrogen had significant effects on OT-induced responses.

DISCUSSION

The present study revealed that oxytocin $1 \text{ U} \cdot \text{L}^{-1}$ to $10 \text{ U} \cdot \text{L}^{-1}$ inhibited the spontaneous contractile motility of proximal colonic smooth muscle in rabbits. Petring *et al* reported that vein injection of oxytocin could increase the gastric emptying of semisolid food in normal human^[10]. Oxytocin 10 – $100 \text{ U} \cdot \text{L}^{-1}$ stimulated the spontaneous contractile motility of gastric body and gastric antrum in rats *in vitro*. But oxytocin ($10 \text{ pmol} \cdot \text{L}^{-1}$ – $10 \text{ nmol} \cdot \text{L}^{-1}$) suppressed the spontaneous contractions of circular smooth muscle from guinea-pig gastric antrum and gastric emptying in male rats^[19,20]. Therefore, it seems that there are species, region and OT concentration differences in OT-induced contractions in gastrointestinal tract.

Our results showed that hexamethonium partly blocked the decreasing action of oxytocin on the contractile frequency of colonic strips, but not that of the contractile amplitude of the strips. These results suggested that oxytocin partly inhibited the contractile frequency of colonic strips via ganglion N receptor.

NO is found to be an inhibitory neurotransmitter of enteric neurons. NOS neurons has been identified in the myenteric plexus^[21–23]. The action of OT has been reported to relevant

with NO^[24] We observed the effect of L-NAME (inhibitor of NOS activity) on the inhibitory action of oxytocin to decide whether oxytocin inhibits the colonic contraction via NO synthetic pathway. The results showed that L-NAME had no effect on the inhibitory action of oxytocin, which suggested that the inhibitory action of oxytocin on colonic motility was irrelevant with NO.

OT has been identified to exert the actions via OT receptors in many tissues, including the hypothalamus, uterus, kidney, pancreas, heart, vasculature, and thymus^[25-30]. Oxytocin receptor are suggested to be present on the members of guinea-pig antral smooth muscle cells^[19]. OT might act on the proximal colonic smooth muscle via selective oxytocin receptor, which still need to be further studied.

The function and physiological regulation of the OT system has been reported to be strongly steroid dependent^[31,32]. But our results showed that both progesterone and estrogen had no significant effects on OT-induced responses.

Effects on the gastrointestinal tract muscle during pregnancy are caused primarily by hormonal changes, such as progesterone, estrogen, and other hormones^[33]. Motility changes occur throughout the gastrointestinal tract during pregnancy, including colonic transit manifested primarily as abdominal bloating and constipation^[34]. Both progesterone and estrogen have been shown to inhibit colonic motility and transit in rats^[35]. But Hinds and associates^[36] reported that no significant differences in colon transit were found between phase of the menstrual cycle or between women and men. Our results also showed that neither progesterone nor estrogen affected the proximal colonic motility in rabbits. OT was another hormone relate to pregnancy, and its plasma concentration was higher in late pregnancy^[37,38]. Our results showed that OT inhibited the colonic motility. Results from these studies provided new insight into the mechanisms controlling colonic motility during pregnancy and may form the basis for drug treatments of colonic motility disorders.

In conclusion, oxytocin inhibit the contractile activity of proximal colonic smooth muscle of rabbits *in vitro*. The action is partly relevant with N receptor, but irrelevant with that of NO, progesterone or estrogen.

Abstract

AIM: To investigate experimentally the effects of methionine enkephalin on signal transduction of mouse myeloma NS-1 cells.

METHODS: The antigen determinate of delta opioid receptor was designed in this lab and the polypeptide fragment of antigen determinate with 12 amino acids residues was synthesized. Monoclonal antibody against this peptide fragment was prepared. Proliferation of Mouse NS-1 cells treated with methionine enkephalin of 1×10^{-6} mol·L⁻¹ was observed. The activities of protein kinase A (PKA) and protein kinase C (PKC) were measured and thereby the mechanism of effect of methionine enkephalin was postulated.

RESULTS: The results demonstrated that methionine enkephalin could enhance the proliferation of NS-1 cells and the effect of methionine enkephalin could be particularly blocked by monoclonal antibody. The activity of PKA was increased in both cytosol and cell membrane. With reference to PKC, the intracellular activity of PKC in NS-1 cells was elevated at 1×10^{-7} mol·L⁻¹ and then declined gradually as the concentration of methionine enkephalin was raised. The effects of methionine enkephalin might be reversed by both naloxone and monoclonal antibody.

CONCLUSION: Coupled with the findings, it indicates that the signal transduction systems via PKA and PKC are involved in the effects of methionine enkephalin by binding with the traditional opioid receptors, and therefore resulting in different biological effects.

INTRODUCTION

A number of studies have documented the involvement of endogenous opioid peptide on the cellular functions. It has been known that opioid receptors exist on the surface of cells pertinent to immune function, and that the activation or inhibition of these receptors may enhance or down regulate

some cell activities. Methionine enkephalin, the native opioid peptide, has been identified and defined as a cytokine because of its non-neurotransmitter function and sharing all of the major properties of cytokines^[1-4]. Although numerous studies have shown that opioid-induced alteration of cellular function can be mediated indirectly via the central nervous system (CNS) or through direct interaction with cells, the precise cellular mechanisms underlying the immunomodulatory effects of opioids are largely unknown.

It is especially true that the opioid receptors contain consensus sites for phosphorylation by numerous protein kinases. Protein kinase C (PKC) has been shown to catalyze the *in vitro* phosphorylation of delta-opioid receptors and to potentiate agonist-induced receptor desensitization^[5,6]. On the other hand, studies suggest that acute and chronic opioid can regulate the cAMP-dependent protein kinase (PKA) signaling pathway and the changes in this pathway may be involved in opioid tolerance^[7-9]. It has been documented that increased PKA activity can maintain cellular tolerance to opioid receptor agonist by chronic opioid treatment^[10].

Although there is mounting evidence supporting the concept that opioids are members of the cytokine-like family, the relative contribution of the opioids to immunoregulation remains unclear. Furthermore, little has been studied how methionine enkephalin acts as binding with the receptor of cell surface and trigger the intracellular biological events via some kinases. In this series of experiments, we analyzed the effect of methionine enkephalin, the endogenous opioid, on the activities of PKA and PKC at various dosages. The effects of monoclonal antibody and naloxone were also determined so that the mechanism of effect of methionine enkephalin on the signal transduction will be further clarified.

MATERIALS AND METHODS

Materials

Methionine enkephalin, naloxone, dithiothreitol (DTT), leupeptin, histone, phosphatidyl serine (PS), diacylglycerol (DG) and ATP were purchased from SIGMA; DMEM medium, bovine serum albumin (BSA) and 1-eth-3-3-dimethylaminopropyl carbodimide-HCl (EDC) were purchased from GIBCO; phenylmethyl sulfonyl fluoride (PMSF) and egtazic acid (EGTA) were from SERVAL.

Methods

Design of polypeptide fragment of delta opioid receptor
Delta opioid receptor is composed of 372 amino acids residues. Hydrophilic analysis and structure prediction were performed in our laboratory by typing the sequence of opioid receptor into a special computer program designed according to the principle of prediction of antigen determinants, and by which fragment of antigen determinant was selected^[11]. The amino acids residues sequence of antigen determinant was selected from the 3rd hydrophilic peak based on the feature of possibility of antigen determinant and listed as follows: NH₂-Gly-Ser-Leu-Arg-Arg-Pro-Arg-Gln-Ala-Thr-Thr-Arg-COOH.

Synthesis of polypeptide fragment and preparation of monoclonal antibody Polypeptide fragment with 12 amino

acids residues of delta opioid receptor was synthesized in North West University, USA. Monoclonal antibody against this polypeptide fragment was prepared according to the routine procedure. In short, BABL/C mice was immunized with synthesized polypeptide fragment conjugated with bovine serum albumin in complete Freund's adjuvant at 2- to 3-week intervals. The splenic cells separated from mice were fused with myeloma cells to form a stable antibody-producing hybridoma cell line. Positive clones were screened by the method of ELISA and inoculated into BALB/C mice. The antibody was harvested from ascitic fluid and purified with affinity chromatography. The titers of monoclonal antibodies were higher than 3 000. The specificity and effects of monoclonal antibody were verified in this experiment.

Effect of methionine enkephalin on proliferation of NS-1 cell lines NS-1, Mouse myeloma cell line, was cultured in DMEM medium containing 10 % fetal calf serum at 37 °C in a humidified atmosphere of 5 % CO₂. After the cell growth occupied full of the bottom of the flasks, the cells were washed once and resuspended in medium at a density of 5×10^4 cells per ml. 1 ml of the cells per well was liquated in a 24 wells plate. When the cells were grown about 70 % full of wells, the supernatant was taken out. Then the cells were resuspended in 1 ml of medium without serum and cultured for one more day. After 1 d, supernatants in all wells were removed and the cells were resuspended in 1 ml of medium (with 10 % fetal calf serum). The cells were administrated with 1×10^{-6} mol·L⁻¹ of methionine enkephalin. Different concentrations of monoclonal antibody (0.1 – 10×10^{-9} mol·L⁻¹) were used to block the effect of methionine enkephalin. The culture was continued for 2 d and then pulsed with 18.5×10^3 Bq of ³H-TdR in each well. 4 h later, the cells were harvested onto glass microfiber filter using a multiple sample harvester. The incorporation of ³H-TdR was measured by using LKB 1209 Rackbeta liquid scintillation counter.

Determination of protein kinase A activity NS-1 cells were adjusted to 5×10^4 cells per ml with DEME medium (containing 10 % fetal calf serum) and aliquot into 24 well plate at 1 ml cell suspension per well. When the cells were grown about 70 % full of the wells, the supernatant was taken out. Then the cells were resuspended in 1 ml of medium without serum, cultured for one more day and added 1×10^{-6} mol·L⁻¹ of methionine enkephalin. For the blocking assay, the different concentration of monoclonal antibody (0.1 – 10×10^{-6} mol·L⁻¹) and naloxone (0.1 – 10×10^{-6} mol·L⁻¹) were added at the same time. After 24 h, the cells were collected, resuspended in 500 µl of buffer A (containing 200 mmol·L⁻¹ Tris-HCl pH 7.5, 0.25 mol·L⁻¹ sucrose, 2 mmol·L⁻¹ edetic acid, 2 mmol·L⁻¹ dithiothreitol, 10 mg·L⁻¹ leupeptin and 0.5 mmol·L⁻¹ PMSF) and destroyed by supersonic instrument for 2 min in ice bath. The supernatants were collected following a spin at 10 000 g for 45 min and defined as the cytosol fraction. The pellet was resuspended in 400 µl of buffer A containing 0.5 % Triton X-100, supersonically destroyed for 2 min and defined as the membrane fraction. The measurement of PKA activity was carried out as described with modifications^[12]. In short, 40 µl of extracted enzyme fractions were mixed with 160 µl of the solution at the final concentration of 20 mmol·L⁻¹ Tris-HCl pH 7.5, 5 mmol·L⁻¹ MgCl₂, 0.25 g·L⁻¹ BSA, 0.5 g·L⁻¹ histone, 2×10^{-7} mol·L⁻¹ ATP (γ -³²P ATP, 3.7×10^4 Bq) and $8.0 \mu\text{mol} \cdot \text{L}^{-1}$ of cAMP at 37 °C for 10 min. After followed by incubation in ice bath for 5 min to terminate the reaction, 150 µl of the solution from each sample was collected onto Whatmen GF/C filter paper. After washing 2× with 10 % TCA-2 % phosphoric acid for 30 min at room temperature followed by 2× wash with 5 % TCA for 30 min, the activities of PKA were measured by using liquid scintillation counter and expressed as pmol value of ³²P in histone catalyzed by per mg protein per min.

Determination of protein kinase C activity The procedures of cell treatment and enzyme extraction were similar to that described in the determination of PKA instead of cells resuspended in 500 µl of buffer B (buffer A+10 mmol·L⁻¹ egtazic acid). The final volume was 200 µl with final concentration of 20 mmol·L⁻¹ Tris-HCl pH 7.5, 5 mmol·L⁻¹ MgCl₂, 0.25 g·L⁻¹ BSA, 0.5 g·L⁻¹ histone, 2×10^{-5} mol·L⁻¹ ATP (γ -³²P ATP, 3.7×10^4 Bq), and 40 µl of extracted enzyme fraction. The measurement of activity of PKC was performed as described by Choi *et al.* with modification^[13]. Briefly, 5 mmol·L⁻¹ CaCl₂, 80 mg·L⁻¹ PS and 3 mg·L⁻¹ DG were added into reaction system. The collection and assay of samples and the addition of methionine enkephalin, also monoclonal antibody and naloxone, were according to the measurement of PKA. The activities of PKC were expressed with pmol value of ³²P in histone catalyzed by per mg protein per min (pmol·mg⁻¹·min⁻¹).

Statistical analysis

The data were expressed as $\bar{x} \pm s$ obtained from at least 3 independent experiments and analyzed by *t* test.

RESULTS

Effects of methionine enkephalin on the proliferation of NS-1 cells

Methionine enkephalin could stimulate the proliferation of NS-1 cells. When 1×10^{-6} mol·L⁻¹ of methionine enkephalin was added into the cultured cells, the cells could proliferate up to 109 %. Monoclonal antibody at a lower concentration of 0.1×10^{-9} mol·L⁻¹ could not block the effect of methionine enkephalin. Whereas 1 and 10×10^{-9} mol·L⁻¹ of monoclonal antibody could reverse the enhancing effect of methionine enkephalin on the cell proliferation that showed significantly the differences as compared with treatment group of methionine enkephalin alone (Figure 1).

Figure 1 Blockage of monoclonal antibody to the effect of methionine enkephalin on the proliferation of NS-1 cells. Treatment groups; 1: control group; 2: 1×10^{-6} mol·L⁻¹ methionine enkephalin; 3: 1×10^{-6} mol·L⁻¹ methionine enkephalin plus 1×10^{-10} mol·L⁻¹ monoclonal antibody; 4: 1×10^{-6} mol·L⁻¹ methionine enkephalin plus 1×10^{-9} mol·L⁻¹ monoclonal antibody; 5: 1×10^{-6} mol·L⁻¹ methionine enkephalin plus 1×10^{-8} mol·L⁻¹ monoclonal antibody. *n*=3 from 3 independent experiments. ^b*P*<0.05 and ^c*P*<0.01 vs control group, ^e*P*<0.05 and ^f*P*<0.01 vs group 2

Effects of methionine enkephalin on the activity of PKA

Methionine enkephalin at various concentrations could enhance the level of activity of PKA in cytosol and cell membrane. The effects could be observed at the concentration of 0.1 – 10×10^{-6} mol·L⁻¹ in cytosol and 0.01 – 10×10^{-6} mol·L⁻¹ in cell membrane. The effects of methionine enkephalin on the activity of PKA were consistent in the cytosol and the cell membrane (Figure 2).

Antagonism of monoclonal antibody and naloxone on the activity of PKA

1×10^{-6} mol·L⁻¹ of methionine enkephalin was used for the blocking assay of monoclonal antibody on the activity of PKA. The reversed effects could be observed at the concentration of 1×10^{-10} and 1×10^{-9} mol·L⁻¹ of antibody (Table 1). After administration of different concentrations of naloxone in the case of cytosol, the reversed effects were also obvious (Figure 3).

Treatment groups: 1: control; 2: 1×10^{-6} mol·L⁻¹ methionine enkephalin; 3: 1×10^{-6} mol·L⁻¹ methionine enkephalin plus 1×10^{-7} mol·L⁻¹ naloxone; 4: 1×10^{-6} mol·L⁻¹ methionine enkephalin plus 1×10^{-6} mol·L⁻¹ naloxone; 5: 1×10^{-6} mol·L⁻¹ methionine enkephalin plus 1×10^{-5} mol·L⁻¹ naloxone. $n=3$ from 3 independent experiments. ^c $P<0.01$ vs control, ^f $P<0.01$ vs group 2

Effects of methionine enkephalin on the activity of PKC

In Figure 4, a narrow effective range of methionine enkephalin was displayed. At the concentration of 1×10^{-7} mol·L⁻¹,

methionine enkephalin could enhance the intracellular activity of PKC (Figure 4), but the higher concentration (10^{-6} – 10^{-5} mol·L⁻¹) of methionine enkephalin showed a suppressive effect compared with control (0 mol·L⁻¹).

Figure 4 The influences of different concentrations of methionine enkephalin on the intracellular activity of PKC in NS-1 cells. $n=3$ from 3 independent experiments. ^b $P<0.05$ and ^c $P<0.01$ vs control (0 mol·L⁻¹).

Antagonism of monoclonal antibody and naloxone on the activity of PKC

Based on the data in Figure 4, 1×10^{-6} mol·L⁻¹ of methionine enkephalin was used to inhibit the PKC. Like observed in the case of PKA, the effect of methionine enkephalin could be blocked by different concentrations of monoclonal antibody (Table 2). Naloxone at concentrations of 1×10^{-6} and 1×10^{-5} mol·L⁻¹ could also reverse the suppressed effect of methionine enkephalin in the cytosol (Figure 5).

Table 2 Antagonism of different of concentrations of monoclonal antibody (MAB) to methionine enkephalin (MENK) at 1×10^{-6} mol·L⁻¹ on the intracellular activity of PKC in NS-1 cells. $n=3$ from 3 independent experiments. ^b $P<0.05$ vs control, ^e $P<0.05$ and ^f $P<0.05$ vs group 2

DISCUSSION

The biological and clinical effects of opiate interaction with immune cells are well appreciated. In recent years, investigations from several laboratories have indicated that opioids can operate as cytokines, the principal communication signals of the immune system^[1,2]. Our previous studies have also proved the cellular modulation of methionine enkephalin^[3,4]. In this experiment, the results that methionine enkephalin could enhance the proliferation of NS-1 cells and perform the effect of growth factor-like, were consistent with the conclusion.

One possible component in the receptor signal cascade that can be responsible for these differences is the ligand-receptor interaction site. Receptor chimera studies followed by mutational analysis have revealed that functions of receptor domains were different for various opioid alkaloids and opioid peptides^[14-19]. Based on the principle of antigen determinant, we prepared the monoclonal antibody against delta opioid receptor. Our data showed that the effects of methionine enkephalin were reversible in the presence of different concentration of monoclonal antibody, which indicating the existence of a functional domain at the peptides segment.

Although some laboratories have provided evidences that supporting agonist-induced down-regulation of opioid receptors appear to require the phosphorylation of the receptor protein^[20-24], the identities of the specific protein kinases that perform this task remain uncertain. Moreover, it is unknown whether the change of protein kinase activation was dependent on the effect of methionine enkephalin. Our data showed that the activities of PKA were up-regulated in both cytosol and membrane of NS-1 cells in a variety of concentrations of methionine enkephalin. The elevation of PKA activity showed dose-independent and the most efficient concentration of methionine enkephalin was at 10^{-7} mol·L⁻¹. It had been shown that increased PKA activity related to the maintenance of cellular tolerance to opioid receptor agonists^[10, 25, 26].

However, in the case of PKC, the enzyme activity was elevated when methionine enkephalin at the concentration of 1×10^{-7} mol·L⁻¹ and declined gradually at 1×10^{-6} to 10^{-5} mol·L⁻¹. The coincident results have also been observed in other laboratory. It had been reported that a biphasic response of opioid on expression of some cytokines had been demonstrated that nanomolar concentration of opioid augmented the secretion of both IL-6 and TNF- α , whereas micromolar concentration inhibited their synthesis^[27]. It had also been reported that opioid-induced PKC translocation followed a time-dependent and biphasic pattern beginning 2 h after opioid addition, when a pronounced translocation of PKC to the plasma membrane occurred. When exposure to opioids was lengthened to >12 h, both cytosolic and particulate PKC levels dropped significantly below those of control-treated cells because of the decrease of membrane-bound PKC density^[15, 28].

From our data, the effect of methionine enkephalin could be reversed by a lower concentration of monoclonal antibody. Although little previous information was available to compare the usage of antibody, it was postulated that a complex ligand-receptor interaction was involved. The results that an antagonism of monoclonal antibody to the effect of methionine enkephalin on the activity of PKA or PKC indicated that the antigen determinant of the receptor fragment was also the functional domain of the receptor. The postulate was reinforced by studies involving μ/δ receptor chimeras that investigated the function of each domain^[14, 15]. Likewise, the same results could be observed in the assay of naloxone, the antagonist of opioid receptor. The effect of naloxone abolishing the effect of opioid on the activity of PKA had been reported^[29, 30]. Thus, a traditional opioid mechanism on signaling pathway of PKA and PKC was thereby involved.

Abstract

AIM: With successful surgical treatment of gastroesophageal reflux disease (GERD), there is interest in understanding the anti-reflux barrier and its mechanisms of failure. To date, the potential use of vector volumes to predict the DeMeester score has not been adequately explored.

METHODS: 627 patients in the referral database received esophageal manometry and ambulatory 24-hour pH monitoring. Study data included LES resting pressure (LESP), overall LES length (OL) and abdominal length (AL), total vector volume (TVV) and intrabdominal vector volume (IVV).

RESULTS: In cases where LESP, TVV or IVV were all below normal, there was an 81.4 % probability of a positive DeMeester score. In cases where all three were normal, there was an 86.9 % probability that the DeMeester score would be negative. Receiver-operating characteristics (ROC) for LESP, TVV and IVV were nearly identical and indicated no useful cut-off values. Logistic regression demonstrated that LESP and IVV had the strongest association with a positive DeMeester score; however, the regression formula was only 76.1 % accurate.

CONCLUSION: While the indices based on TVV, IVV and LESP are more sensitive and specific, respectively, than any single measurement, the measurement of vector volumes does not add significantly to the diagnosis of GERD.

INTRODUCTION

With the recognition of gastroesophageal reflux disease (GERD) as a surgical pathology, there is deep interest in understanding the anatomical and physiological anti-reflux barrier and its mechanisms of failure^[1-8]. The anatomical components of the barrier include the crural fibers of the diaphragmatic esophageal hiatus, the smooth muscle sling fibers of the gastric cardia, and the semicircular and clasp fibers of the distal esophagus^[1-5]. Augmented by positive intrabdominal pressure over the most

distal portion of the lower esophagus and proximal cardia, the sphincter approximates the mucosal epithelium covering the internal surface area of the esophagogastric junction. This distinct high-pressure zone is a critical factor in the barrier against reflux of gastric contents^[5-8]. The anatomical function of the lower esophageal sphincter (LES) is complemented by neutralization of refluxate by alkaline oral secretions and rapid clearance of esophageal contents by intermittent and reflex peristalsis^[8].

Various means have been devised to measure the mechanical integrity of the LES^[8-11]. Traditional pull-through manometry has been succeeded in some laboratories by sophisticated equipment and software that allows measurement of the closure pressure generated by the three-dimensional sphincter mechanism. Directional pressures can be summated over the length of the sphincter to produce a vector volume that describes the overall physical resistance of the barrier to continuous reflux^[11,12]. Other measures of the sphincter competence include resting pressure of the LES at various points along its length, the vector volume of the intrabdominal portion of the LES as well as overall and intrabdominal lengths of the LES. While many observers have noted the relationship between abnormal manometry and GERD^[4-14], we have sought to quantify this relationship in a way that describes the comparative ability of such measurements to predict positive ambulatory pH monitoring as described by DeMeester and colleagues^[15]. It was our goal to compare traditional manometric measurements, vector volume analysis and results of 24-hour pH monitoring. We postulated that one or more of the manometric measurements would yield a statistically significant relationship to a positive DeMeester score. Because of the complexity of the procedure, expense, and general discomfort to the patient, it was hoped that detection of a defective LES would obviate the need for subsequent pH monitoring in certain cases.

MATERIALS AND METHODS

Materials

Manometric studies were performed using a 9-lumen catheter (ESM38R, Arndorfer, Greendale, Wisconsin) coupled to a hydraulic capillary infusion system (Arndorfer). The catheter consisted of a central lumen of 1.8 mm internal diameter surrounded by 8 lumens of 0.8 mm internal diameter. Four channels extended to the distal end of the catheter with ports at the same level and oriented radially at 90° intervals. The remaining 4 ports were spaced contiguously at 5 cm intervals proximal to, and offset by 45° from, the radial ports, providing 20 cm of working length. The central lumen was not used. The catheter was pulled at a 3 mm/second using a mechanical puller. The transducer information was translated into digital information using a polygraph (Medtronic Synectics, Shoreview, Minnesota). External transducers were also used to detect swallow and respiratory waves. The information was saved for real-time and retrospective review using Polygram software (Medtronic Synectics).

Methods

The original audit population consisted of 1 900 patients referred to the Esophageal Function Laboratory in the

Department of Surgery at Creighton University. This population received either esophageal manometry, 24-hour pH monitoring or both. Patients were referred to the laboratory for typical or atypical symptoms thought to represent GERD. Of the 1 900 patients in the referral database, only 627 received both esophageal manometry with measurement of LES vector volumes and ambulatory 24-hour pH monitoring. Vector volume data were available for the total length of the lower esophageal sphincter (total vector volume, TVV) and for the intrabdominal length (intrabdominal vector volume, IVV). The vector volume is a calculated value representing the directional pressures within the LES over a specific portion of the sphincter. Additional data included age, weight, resting pressure of the LES (LESP), overall LES length (OL) and abdominal LES length (AL).

In preparation for station pull-through (SPT), the catheter assembly was introduced through either nare and advanced into the stomach. SPT was performed using a mechanized puller (Medtronic Synectics) at 3 mm/sec to avoid swallowing with pauses every centimeter to allow pressure measurement. Using the gastric baseline pressure as the reference point, a port entered the LES when a sustained positive deflection away from the baseline was observed. A wet swallow of 5 mL tap water was performed at this level to observe relaxation of the LES. The SPT proceeded through the entirety of the LES resulting in five measurements from separate channels which were averaged to produce the final value. The patient was instructed to breathe regularly and not to swallow. Swallowing (except for the wet swallow) required another attempt.

The resting pressure of the LES (LESP) was defined as the mean pressure at the respiratory inversion point (RIP). The RIP was the place on the pressure waveform where the positive deflections in the abdomen caused by inspiration changed to negative deflections in the chest. OL was the distance between the distal and proximal borders of the LES; AL was the distance between the distal border of the LES and the RIP. Both measurements were obtained during SPT.

Measurements for vector volume calculations were obtained from transducers attached to the 4 radial ports located at the same level on the catheter. Each channel yielded a separate pressure and direction (pressure vector) over the length of the LES. The distal border of the LES was defined as the position at which two or more of the four channels deflected positively from the gastric baseline. The crural component, often represented as the distal hump in the bimodal waveform, was intentionally included in the TVV. The proximal border was defined as that position in which two or more of the four channels returned and stayed below the gastric baseline. Computer software summated the pressure vector measurements into a single vector volume (mm Hg³). A three-dimensional image was also generated but not included in the database.

IVV was determined similarly. The proximal endpoint of the IVV was the RIP; the distal endpoint was the same as for TVV. As with TVV determination, when two or more of the four channels reached the RIP, all were considered to be at the RIP. Computer software similarly produced a value for the vector volume.

Upon completion of manometry, the pressure catheter was replaced with a pH probe catheter (Ingold Bipolar Glass pH Probe, Mui Scientific, Mississauga, Ontario). All patients had been off their medication (PPI's for 7 days, H2 blockers for 3 days) for the appropriate time. The catheter was passed through the nose and into the stomach to obtain a baseline reading from the ambulatory recording equipment to be carried by the patient (Digitrapper, Medtronic Synectics). The catheter was then withdrawn to a position 5 cm above the LES as determined by SPT. A baseline reading was again obtained. The catheter was secured to the nose and patients were given instructions to eat at

least three meals (limited to foods in which the pH was known), to stay upright at least 4 hours after eating, and to be recumbent for no more than 8 hours during sleep. Patients were instructed to note in a diary the time of each symptom occurrence, when and what they ate, and when they retired for bed.

At the completion of the 24-hour period, the catheter was removed and the information in the Digitrapper was downloaded and analyzed using pH-metry software (EsopHagram, Synectics). A DeMeester score was then tabulated by the computer and recorded for both acid and alkaline reflux. A score <14.8 was considered negative for GERD.

Except for the logistic regression, sensitivities and specificities for the receiver-operating characteristics (ROC) were calculated manually. The purpose of the ROC was to find an optimal cut-off point, if any, for measurements that would yield the greatest combination of sensitivity and specificity. The formulas for calculations involving LESP (for example) were:

$$\text{Sensitivity} = \frac{[\text{'n' patients with GERD and LESP} \leq \text{'x'}]}{[\text{'n' patients with GERD}]}$$

$$\text{Specificity} = \frac{[\text{'n' patient without GERD and LESP} > \text{'x'}]}{[\text{'n' patient without GERD}]}$$

In those calculations, 'x' refers to a progressively larger cut-off value for LESP (following the example above). Therefore, a particular sensitivity represented the probability that a patient with an $\text{LESP} \leq \text{'x'}$ would have GERD. Likewise, the specificity represents that probability that a patient with an $\text{LESP} > \text{'x'}$ would not have GERD. Cut-off values were chosen at increments that resulted in enough data points to provide adequate resolution to the curve but with enough cases within each range to reflect real trends. This was done for LESP, TVV, IVV, AL and OL.

All other calculations were performed by SAS statistical software (version 6.12). The logistic regression process was automated and resulted in a formula for predicting GERD-positive or GERD-negative. According to its program, the statistical software started with all predictors in a test formula, then through backward selection, removed predictors that failed to meet the appropriate confidence interval. The software rejected predictors when p-values were >0.05 %. There were no attempts at relating the manometry measurements directly to DeMeester score in a continuous fashion. Rescaling in order to account for outliers consisted of setting values above the 95th percentile for any measurement equal to the value of that measurement at the 95th percentile. Values for normal were derived from a prior study in this laboratory using 50 healthy (non-GERD) volunteers. No attempts were made to sort patients or data according to age, sex or weight.

RESULTS

Demographic data with respect to the diagnosis of GERD is presented in Table 1. There were no attempts at age or sex matching. Table 2 includes the means, standard deviations, p-values, sensitivities and specificities for the measured parameters. The sensitivity and specificity of LESP, TVV and IVV, respectively, were 67.3 % and 73.3 %; 72.5 % and 62.6 %; and 58.5 % and 77.3 % at the lower values for normal. The sensitivity and specificity for AL and OL reflect the fact that very few patients had abnormal values of either (4 and 2 patients, respectively); this was also reflected in the similarity relatively large standard deviations between the average AL and OL for GERD and non-GERD sufferers. Because AL and OL were so weakly sensitive for reflux disease, Any-low refers only to cases where LESP, TVV or IVV were below normal. The sensitivity of Any-low indicated an 81.4 % probability a patient with either abnormally low LESP, TVV or IVV will have GERD. Similarly, AL and OL were also excluded from calculations of the All-low values. There was an 86.9 %

probability that a patient with all three normal measurements will not have an abnormal esophageal acid exposure; this is the specificity for All-low.

Table 1 Demographic data for study cases

	Range	non-GERD mean \pm SD	GERD mean \pm SD
Age (years)	4 – 86	47.0 \pm 16.1 (n=308)	48.5 \pm 14.9 (n=319)
Weight (lbs)	87–397	173.6 \pm 42.2 (n=310)	190.2 \pm 38.0 (n=317)
Sex	F: 313M: 314	F: 101 M: 80	F: 108 M: 162

Table 2 Summary of manometric data

	Normal range	Range of measurements	non-GERD mean \pm SD	GERD mean \pm SD	P	Sens. %	Spec. %
LESP	6.1–25.6	0–59.3	10.9 \pm 8.4 (n=319)	5.7 \pm 4.8 (n=308)	<0.001	67.3	71.3
IVV	1855–10953	0–45830	4090 \pm 4709 (n=321)	1712 \pm 2080 (n=306)	<0.001	72.5	62.6

Any low	–	–	–	–	–	81.4	51.0
All ow	–	–	–	–	–	49.3	86.9

LESP=Lower esophageal sphincter resting pressure (mm-Hg), IVV=Intrabdominal vector volume (mm-Hg³), TVV=total vector volume (mm-Hg³), AL=abdominal length of the LES (mm), OL=overall length of the LES (mm). “Any-low” refers to cases where LESP, IVV or TVV are lower than normal. “All-low” refers to cases where LESP, IVV and TVV are all lower than normal. SD=Standard deviation, Sens.=Sensitivity, Spec.=Specificity. ‘P’ is the probability value from the chi-squared test for GERD vs. non-GERD; $P<0.05$ is significant. Sensitivities and specificities are calculated using the lowest normal value.

Figure 1 Receiver-operating characteristics for total vector volume (TVV), intrabdominal vector volume (IVV) and LES resting pressure (LESP). Included is a comparable ROC for the logistic regression. The points on the curves that correspond to the normal values in Table 1 are circled

Figure 1 shows the receiver-operating characteristics for LESP, TVV, and IVV. The curves for AL and OL fell below all of the other curves and (for clarity) have not been depicted. There are no obvious points at which both specificity and sensitivity are optimal for any of the measurements. Cut-off values equal to the lowest normal values are indicated by the circled data points. Also shown in Figure 1 is an ROC curve for the regression formula (below) indicating that it does not

have a better combination of sensitivity and specificity than the measurements themselves.

The logistic regression formula following backward selection was

$$Y = 1.24 + [\text{LESP}](-0.1056) + [\text{IVV}](-0.00019)$$

where Y is equal to a nominal value for GERD (1=the presence and 2=absence of GERD). P-values for the factor estimates were all <0.0001. Various attempts were made at rescaling the data (as described in Materials and Methods) and ranking without effect. The “native” logistic regression (unscaled and unranked) was superior or equal in every case with 76.1 % concordance, 23.6 % discordance and 0.3 % tied. Table 3 contains data from the logistic regression process. TVV, OL and AL were excluded by the software from the regression formula because of P-values >0.05 %. When ranked values were used for logistic regression, similar estimates were obtained for the y-intercept, LESP and IVV factors and the P-values were all <0.0001. The formulas for the ranked and rescaled data were equally good or worse at predicting GERD and have been excluded from further discussion.

Table 3 Logistic regression with the results of backward selection

Variable	Estimate	P
Intercept	+1.241	<0.0001
LESP	-0.106	<0.0001
IVV	-0.00019	<0.0001
TVV	(rejected)	0.43
AL	(rejected)	0.089
OL	(rejected)	0.79
Concordant = 76.1%		
Discordant = 23.6%		
Tied = 0.3%		

DISCUSSION

Intraabdominal vector volume is more sensitive than TVV or LESP, but only marginally, and no more than 72.5 % (Table 2). Measurements of TVV and LESP are more specific for GERD; that is, findings of normal TVV and LESP are 77.3 % and 71.3 % likely in a non-GERD patient, respectively. While the mean values for LESP, TVV and IVV are all significantly lower in GERD patients ($P<0.0001$), the standard deviations are nearly equal to the means themselves in every measurement (Table 2). Intrabdominal length (AL) and overall length (OL) of the LES are clearly unimportant in the assessment of gastroesophageal reflux disease. Only 4 and 2 patients, respectively, had abnormally low values for AL or OL.

When measurements are viewed as ROC curves (Figure 1), there are no points where a measurement has both a high sensitivity and high specificity. That is to say that there appears to be no optimal cut-off value for predicting GERD. Ideally, an ROC curve is a parabolic figure with the apex in the upper right corner (using the axes as in Figure 1) which drops sharply from a point where sensitivity and specificity are both high to a point where sensitivity is very low and specificity is very high. In fact, there are no values for which there is a high sensitivity and even a moderately useful specificity. At cut-off values representing 85 % sensitivity for GERD (≤ 1600 mm-Hg³ for TVV; ≤ 1000 mm-Hg³ for IVV; and ≤ 3 mm-Hg for LESP), the specificities of the measurements fall between 35 % and 45 %. Finding significantly lower-than-average TVV, IVV and LESP in GERD patients (Table 2.) reiterates our understanding of the pathological consequences of a weakened LES. It also confirms our present understanding that there is a more complex relationship between the

anatomical correlates of the LES and function than can be expressed by a single measurement.

Use of the "Any-low," "All-low," and logistic regression models were attempts to use the measurements in a combined fashioned, similar to the calculation of the DeMeester ambulatory pH score. While Any-low had a relatively better sensitivity (81.4 %) and All-low had relatively better specificity (86.9 %) for the DeMeester score than the original measurements, the logistic regression-presumably the more rigorous mathematical model-was little better than the ROC curves for LESP, IVV or TVV. The computer generated a series of sensitivities and specificities for predictions made by the regression formula. This data is represented in Figure 1 as a means of comparison. Interestingly, total vector volume of the LES (TVV) was rejected by the computer due to a failure to meet the 95 % correlation confidence interval. The logistic regression formula was only 76.1 % accurate in predicting the real data. Attempts at ranking the data and rescaling in order to account for a number of outlying measurements made no improvement in the accuracy of the formula. The regression formula was clearly unable to improve on the predictive power of the raw measurements. As such, the formula has no practical use in the laboratory.

We have been motivated to find a way to identify surgical candidates without directly measuring distal esophageal reflux because of the inherent difficulty with ambulatory pH monitoring (patient discomfort, cost, compliance). Recently, Fass and colleagues have suggested that the test itself may have the effect of reducing reflux-provoking activities, thereby reducing the sensitivity of the test^[16]. In studies of different patient populations where vector volumes were found to have greater use^[11-14] we are unaware of the degree to which they were able to control patient compliance with ambulatory pH monitoring protocols (either maintaining a normal daily diet and activities or maintaining a controlled regimen). Certainly, patient compliance would be expected to be higher when he or she is made to understand the importance of maintaining normal habits. This is also an uncontrolled factor in the present study. In a sense, this might be a form of "compliance bias" reflected in the sensitivity of the test, where poor compliance (relatively less daily activity, smaller meals, more conservative food choices) results in more falsely negative screening tests. Quigley has also referred to the multiple difficulties with pH-metry as the gold standard for diagnosing GERD, namely the issue of patient compliance with testing conditions^[17]. It remains to be seen if patient compliance, or any other factors, have any real effect on 24-hour pH monitoring and the treatment indications for GERD.

To improve surgical results, it is helpful but not mandatory to find evidence that a defective lower esophageal sphincter is the cause for GERD. This is based on the reports by numerous authors who have sought to describe the sphincter and its mechanisms of failure^[1-10]. Studies have demonstrated the effectiveness of anti-reflux surgery to improve symptom scores, esophagitis and LES resting pressure^[2,7,11,13]. Authors have asserted that measurement of vector volumes would be superior to standard lower esophageal manometry for detecting a defective LES^[11-15]. Wetscher and colleagues made the observation that IVV was more sensitive than LESP (i.e. standard manometry) and TVV at detecting a defective lower esophageal sphincter^[12]. They concluded that measurement of vector volumes would be a valuable adjunct to current esophagogastric studies. Our study suggests that measurement of vector volumes is not greatly more valuable than traditional manometry.

There is an 81.4 % chance that a patient with either a low LESP, TVV or IVV (when all three are measured) will have a positive DeMeester score. Whether or not this would suffice

as an indication for surgery would require inclusion of surgical outcome data into the analysis. Alternatively, a priority ranking system used by Martinez-Serna and colleagues might serve as an effective adjunct to manometry data^[18]. Those authors found a positive association between high symptom priority ranking for heartburn and regurgitation and abnormal pH and manometry results. Analysis of traditional manometry, vector volumes, symptom scores and surgical outcomes will be necessary to confidently define indications for surgery without ambulatory pH monitoring.

Transient relaxation of the lower esophageal sphincter may be an important etiology for pathologic reflux^[8-19]. Dodds and colleagues found that 65 % of reflux episodes in GERD patients were due to transient relaxation of the LES^[8]. This finding is difficult to interpret when 82 % of normal reflux in non-GERD patients can also be attributed to transient LES relaxation^[20]. Sloan and colleagues found that abrupt increases in intrabdominal pressure resulted in a higher occurrence of reflux in GERD patients who also had hiatal hernia and low LES resting tone^[21]. Kahrilas *et al.* found the degree of separation of the LES from the crura is associated with the transient relaxations^[22]. This separation can be detected by manometry and is described as the double hump.

Based on our findings, we draw the following conclusions: (1) a patient with a low TVV, IVV or LESP (when all three are measured) is 81.4 % likely to have a positive DeMeester score; and (2) when LESP, TVV and IVV are normal, a patient is 86.9 % likely to have a negative DeMeester score. This is a marginal improvement over the sensitivities and specificities of the native measurements, but the probabilities are not large enough to justify omission of the ambulatory pH study despite its inherent challenge to patient compliance and reliability. It appears that vectors volumes, particularly intrabdominal vector volume, are just as sensitive and specific for GERD as LES resting pressure, and thus cannot be considered superior in the evaluation of GERD.

Abstract

AIM: To elucidate the role of NF- κ B activation in the development of multiple organ dysfunction (MOD) during acute obstructive cholangitis (AOC) in rats.

METHODS: Forty-two Wistar rats were divided into three groups: the AOC group, the group of bile duct ligation (BDL group), and the sham operation group (SO group). All the animals in the three groups were killed in the 6th and 48th hour after operation. Morphological changes of vital organs were observed under light and electron microscopy. NF- κ B activation was determined with Electrophoretic Mobility Shift Assay (EMSA). Arterial blood gas analyses and the serum levels of lactate dehydrogenase (LDH), alanine aminotransferase (ALT), blood urea nitrogen (BUN) and creatinine were performed. The concentrations of TNF- α and IL-6 in plasma were also measured.

RESULTS: The significant changes of histology and ultrastructure of vital organs were observed in AOC group. By contrast, in BDL group, all the features of organs damage were greatly reduced. Expression of NF- κ B activation in various tissues increased in AOC group when compared to other two groups. At 6 h, the arterial pH in three groups was 7.52 ± 0.01 , 7.46 ± 0.02 , and 7.45 ± 0.02 , and the blood pCO₂ was 33.9 ± 0.95 mmHg, 38.1 ± 0.89 mmHg, 38.9 ± 0.94 mmHg, there was difference in three groups ($P < 0.05$). At 48 h, the blood pH values in three groups was 7.33 ± 0.07 , 7.67 ± 0.04 , and 7.46 ± 0.03 , and blood HCO₃⁻ was 20.1 ± 1.29 mmol·L⁻¹, 26.7 ± 1.45 mmol·L⁻¹ and 27.4 ± 0.35 mmol·L⁻¹, there was also difference in three groups ($P < 0.05$). In AOC group, Levels of LDH, ALT, BUN and creatinine were 16359.9 ± 2278.8 nkat·L⁻¹, 5796.2 ± 941.9 nkat·L⁻¹, 55.7 ± 15.3 mg/dl, and 0.72 ± 0.06 mg/dl, which were higher than in SO group (3739.1 ± 570.1 nkat·L⁻¹, 288.4 ± 71.7 nkat·L⁻¹, 12.5 ± 2.14 mg/dl, and 0.47 ± 0.03 mg/dl) ($P < 0.05$). Levels of plasma TNF- α and IL-6 in AOC at 48 h were 429 ± 56.62 ng·L⁻¹ and 562 ± 57 ng·L⁻¹, which increased greatly when compared to BDL group (139 ± 16 ng·L⁻¹, 227 ± 43 ng·L⁻¹) and SO group (74 ± 10 ng·L⁻¹, 113 ± 19 ng·L⁻¹) ($P < 0.05$).

CONCLUSION: The pathological damages and the NF- κ B activation of many vital organs existed during AOC. These

findings have an important implication for the role of NF- κ B activation in MOD during AOC.

INTRODUCTION

In humans with acute obstructive cholangitis (AOC) or other sepsis, the onset of multiple organ dysfunction (MOD), especially involving the liver, the heart, the lungs, and the kidneys, is a well known complication that is associated with a high mortality rate^[1-10]. MOD in either humans or animals appears to emerge as a consequence of progressive development of activation of mononuclear phagocytes system and an unregulated release into the blood of a variety of proinflammatory mediators (interleukins, cytokines, chemokines)^[11-14]. NF- κ B is highly activated at sites of inflammation in diverse diseases and can induce transcription of proinflammatory cytokines^[15-17]. For example, NF- κ B is overexpressed in neutrophil, peripheral blood mononuclear cells (PBMC), dendritic cells (DC), and Kupffer cell, and so on. Its activity may enhance recruitment of inflammatory cells and production of proinflammatory mediators like IL-1, IL-6, IL-8, and TNF- α ^[18-21]. These events may be associated with the development of MOD.

In our original study of patients with AOC, the changes of NF- κ B activation were documented^[1], but evidence of MOD and the effects of NF- κ B were not assessed. In the current studies, we observed the pathological changes of the damages of many vital organs and correlated the role of NF- κ B activation with MOD in animal model with AOC.

MATERIALS AND METHODS

Reagents

E. coli and type IV of collagenase were obtained from Sigma Chemical Company (St. Louis, Mo.). The kits of TNF- α and IL-6 were obtained from Beijing Bang Bing Co.. Other reagents were purchased from Ke Hua Co. or Zhong Sheng Co..

Animals and experimental groups

Forty-two male Wistar rats, weighing 250-300 g, were obtained from the Laboratory Animal Center of Chongqing University of Medical Science. The animals were fed with standard rat food and water *ad libitum* for 1 wk before use and kept in a climate-controlled environment with a 12 h light-dark cycle. The animals were handled in accordance with the guidelines set by the Experimental Animals Society of Chongqing University of Medical Science. These animals were randomized into three groups: the AOC group, the group of bile duct ligation (BDL), and sham operation (SO). All the animals in these groups were killed in the 6th and 48th hour after operation. Seven rats from each group at each time point were examined.

Preparation of animal models

All rats were starved overnight and underwent an upper midline laparotomy with an intraperitoneal injection of 30 mg·kg⁻¹ sodium pentobarbital for anesthesia. In AOC group, a median incision was made on the upper abdomen. The common bile duct was mobilized and doubly ligated. 0.2 ml of the *E. coli* suspension (5×10^{12} cfu·L⁻¹) was injected into the ligated common bile duct. In BDL group, the common bile duct was doubly ligated but no *E. coli* suspension was injected. In SO group, neither *E. coli* suspension injection nor common bile duct ligation was done, but only routine operative procedure was performed.

Histology

Morphological changes of liver, heart, lungs, and kidneys were observed by light microscope and transmission electron microscope (TEM). These samples from different organs were fixed with 10 % buffered formalin or 2.5 % glutaraldehyde immediately. For optical microscopy, the tissue blocks were embedded in paraffin, and the sections were stained with hematoxylin and eosin (H&E). For TEM, the tissue blocks were embedded in Epon 618 resin and ultrathin sections were stained with uranyl acetate and lead citrate. A transmission electron microscope (JEM-2000) was used.

Electrophoretic mobility shift assay for NF- κ B

Isolation of nuclear proteins Nuclear proteins were isolated as previously described^[1,22]. In brief, the liver, heart, lungs, and kidneys tissues were placed in 0.8 mL of ice-cold hypotonic buffer [10 mmol·L⁻¹ HEPES (pH7.9), 10 mL KCl, 0.1 mmol·L⁻¹ EDTA, 0.1 mmol·L⁻¹ ethylene glycol tetraacetic acid, 1 mmol·L⁻¹ DTT; Protease inhibitors (aprotinin, pepstatin, and leupeptin, 10 mg·L⁻¹ each)]. The homogenates were incubated on ice for 20 min, vortexed for 20 s after adding 50 μ L of 10 per cent Nonidet P-40, and then centrifuged for 1 minute at 4 °C in an Eppendorf centrifuge. Supernatants were decanted, the nuclear pellets after a single wash with hypotonic buffer without Nonidet P-40 were suspended in an ice-cold hypertonic buffer [20 mmol·L⁻¹ HEPES (pH7.9), 0.4 mol·L⁻¹ NaCl, 1 mmol·L⁻¹ EDTA, 1 mmol·L⁻¹ DTT; Protease inhibitors], incubated on ice for 30 min at 4 °C, mixed frequently, and centrifuged for 15 min at 4 °C. The supernatants were collected as nuclear extracts and stored at -70 °C. Concentrations of total proteins in the samples were determined according to the method of Bradford.

Electrophoretic mobility shift assay (EMSA) NF- κ B binding activity was performed in a 10- μ L binding reaction mixture containing 1 \times binding buffer [50 mg·L⁻¹ of double-stranded poly (dI-dC), 10 mmol·L⁻¹ Tris-HCl (pH 7.5), 50 mmol·L⁻¹ NaCl, 0.5 mmol·L⁻¹ EDTA, 0.5 mmol·L⁻¹ DTT, 1 mmol·L⁻¹ MgCl₂, and 100 mL·L⁻¹ glycerol], 5 μ g of nuclear protein, and 35 fmol of double-stranded NF- κ B consensus oligonucleotide (5' -AGT TGA GGG GAC TTT CCC AGG-3') that was endly labeled with γ -³²P(111TBq mmol⁻¹ at 370GBq L⁻¹) using T4 polynucleotide kinase. The binding reaction mixture was incubated at room temperature for 20 min and analyzed by electrophoresis on 7 per cent nondenaturing polyacrylamide gels. After electrophoresis the gels were dried by Gel-Drier (Bio-Rad Laboratories, Hercules, CA) and exposed to Kodak X-ray films at -70 °C. The binding bands were quantified by scanning densitometer of a Bio-Image Analysis System.

Arterial blood gas analyses

In some animals, a carotid artery catheter was placed through an anterior cervical area, and arterial blood samples were collected to measure blood lactate, pH, pO₂, pCO₂, and HCO₃⁻ using a blood gas analyzer.

Measurement of biochemical parameters

Blood was obtained from the inferior vena cava at the time of

sacrifice, heart, liver, kidney injury were assessed by measuring the serum lactate dehydrogenase (LDH), alanine aminotransferase (ALT), blood urea nitrogen (BUN) and creatinine, respectively, which were performed with an Automatic Biochemical Analyser.

Assay of TNF- α and IL-6 in plasma

The concentrations of TNF- α and IL-6 in plasma were measured by a commercially available enzyme-linked immunosorbent assay (ELISA) according to the manufacture instructions which has a low detection limit of 50 ng·L⁻¹. Briefly, microtitre plates were coated with anti TNF- α or IL-6 mAb overnight at room temperature on a plate shaker and then, after they had been blocked, samples were added. The detecting antibody was biotinylated anti TNF- α or IL-6. The results were determined at 492 nm with DG 3022 Enzyme Linkage Essay Instrument.

Statistical analysis

The results are presented as means \pm SEM. Data sets were analyzed with a one-way ANOVA. The differences were regarded significant when the *P* value was less than <0.05.

RESULTS

The changes of histology and ultrastructure of vital organs

In AOC group, in the liver, there was multifocal and patchy lytic necrosis. hepatocytes showed swelling and partly fatty degeneration, focal cytoplasmic degeneration and many myelin figures could be seen in the cytoplasm (Figure 1), Kupffer cells showed proliferation and many myelin figures in the cytoplasm (Figure 2). In the lungs, polymorphonuclears neutrophil (PMN) aggregated in alveolar capillary. In the heart, mitochondria were swollen or even vacuolated (Figure 3). In the kidneys, there was extensive fusion of foot processes of podocytes in glomeruli. The cells had lost their cell membranes and exhibited mitochondrial swelling together with intracellular edema in proximal convoluted tubules (Figure 4).

Changes of NF- κ B activation

In AOC group, The NF- κ B activity increased significantly in liver, nearly fivefold over other organs after 6 h. At 48 h, the NF- κ B activity increased also significantly in lung and heart besides liver (Figure 5). In BDL group and SO group, the active form of NF- κ B was minimal in hepatic tissue and other tissues.

Arterial blood gas analyses

In AOC group, arterial blood gases showed early respiratory alkalosis and late metabolic acidosis. At 6 h there was a mild respiratory alkalosis, with the arterial pH rising from 7.45 ± 0.02 to 7.52 ± 0.01 , the blood pCO₂ fell from a value of 37.9 ± 0.86 to 34.23 ± 0.89 . At 48 h, similar group showed evidence of metabolic acidosis, with the blood pH values falling from 7.46 ± 0.003 to 7.33 ± 0.007 , and blood HCO₃⁻ (mmol·L⁻¹) falling from 27.4 ± 0.35 to 20.1 ± 1.29 . In contrast, in BDL group, the blood pH and pCO₂ values were the same as those values obtained in SO group (Table 1).

Biochemical parameters

Biochemical parameters in three groups were showed in Table 2.

Cytokines contents in plasma

In AOC group, Levels of plasma TNF- α and IL-6 increased greatly in 6 h and 48 h. Levels of two cytokines were over 4-fold and 5-fold higher than that in other two groups. In BDL group, the levels of TNF- α and IL-6 in 48 h increased modestly when compared to that in SO group (*P*<0.05). Low levels of TNF- α and IL-6 was detectable in plasama in SO group (Table 3).

DISCUSSION

AOC in humans often leads to progressive MOD, which is still associated with a high mortality rate^[1-5]. Recent studies showed NF- κ B is rapidly in response to many pathologic signals that may be relevant during surgical trauma, including cytokines, adhesion molecules, endotoxin, hypoxia, and shear^[23-27]. Activation of NF- κ B results in the transcription of genes that can participate in the inflammatory reaction by inducing the production of cytokines, immunoreceptors, and cell adhesion molecules^[28-32]. These cytokines and proinflammatory mediators are therefore a potentially attractive target inducing MOD during sepsis and endotoxemia^[33-47]. Information on the role of NF- κ B in sepsis, AOC and MOD is limited but shows that NF- κ B is increased during inflammation and sepsis^[1,18].

The role of NF- κ B activation in sepsis and in complication such as MOD is a debatable issue. Pennington *et al*^[20] observed the degree of NF- κ B activation with severity of acute appendicitis and found that NF- κ B binding activity is elevated in these patients and correlates with symptoms longer than 24 hours. Arnalich *et al*^[18] determined NF- κ B activation in peripheral blood mononuclear cells of 34 patients with severe sepsis and serial concentrations of inflammatory cytokines and resulted the prognosis value of early measurement of NF- κ B activity in patients with severe sepsis. Gong and Paterson *et al*^[1,20] determined NF- κ B activation in mononuclear and neutrophils from critically ill patients and compared NF- κ B activation with circulating concentrations of IL-6, IL-8 and soluble intercellular adhesion molecule (sICAM)-1, and found NF- κ B activation in patients systemic inflammatory response syndrome, which increased markedly before death. However, Chen *et al*^[48] observed intrahepatic changes in TNF- α and NF- κ B activation in Sprague-Dawley rats with cecal ligation and puncture, and their results implied NF- κ B activation was not linked to the outcome in sepsis. In our original study of patients with AOC, the changes of NF- κ B activation were documented, but evidence of MOD and the effects of NF- κ B were not assessed. So it would be helpful to further analyze the expression with the inflamed tissues. There is, however, no published information about a key role of NF- κ B in

development of multiple organ dysfunction during biliary infection. In this study, we investigated the role NF- κ B in the development of MOD in rats with AOC.

The present study shows a correlation among the pathological damages of many vital organs, NF- κ B activation and release of proinflammatory cytokines. This is only one published investigation about the correlation of NF- κ B activation and MOD during AOC. The present study demonstrated that NF- κ B activation plays a key role during AOC. The finding that prompt surgical inflammatory condition of the inflammatory focus results in a rapid normalization of NF- κ B activation adds further validity to this assay.

Perhaps other important finding of this study was the marked difference in NF- κ B levels among various organs during AOC. During AOC, Expression of NF- κ B was observed first in liver at 6 h. At 48 h, NF- κ B also expressed in the lung, the heart, and the kidney besides the liver. The liver was the main organ which was injured by bacteria during AOC, liver and other organs influence each other in their function, the liver plays a key role in host defense. Matuschak *et al* reported that the liver failure affected on the incidence and resolution of the adult respiratory distress syndrome. Seki *et al*^[49] Hepatocytes produce acute phase protein and complement in bacterial infections. KCs are activated by various bacterial stimuli, including LPS and bacterial superantigens, and produce IL-12 and other monokines. So the liver plays a crucial role in the first line of defense against bacterial infections^[50-52]. However, if this defense system is inadequately activated, sepsis and shock associated with MOD takes place. It was found in our previous study that when liver was injured, especially KCs function failed, gram-negative bacteria normally restricted to the biliary tract invaded the bloodstream and were trapped in vital organs, and NF- κ B activation occurred, eventually MOD ensued. Further clinical trials are indicated to confirm that this “molecular biology” marker indeed will be a useful clinical tool in the management of the patients with AOC^[53-56].

In conclusion, we have shown the expression of NF- κ B and the pathological changes of the damages occurred in many vital organs, especially in liver during AOC. These findings have an important implication for the role of NF- κ B activation in MOD during AOC.

Abstract

AIM: To explore the potential carcinogenicity of bile from congenital choledochal cyst (CCC) patients and the mechanism of the carcinogenesis in congenital choledochal cyst patients.

METHODS: 20 bile samples from congenital choledochal cyst patients and 10 normal control bile samples were used for this study. The proliferative effect of bile was measured by using Methabenzthiazuron (MTT) assay; Cell cycle and apoptosis were analyzed by using flow cytometry (FCM), and the PGE₂ levels in the supernatant of cultured cholangiocarcinoma cells were quantitated by enzyme-linked immunoabsorbent assay (ELISA).

RESULTS: CCC bile could significantly promote the proliferation of human cholangiocarcinoma QBC939 cells compared with normal bile ($P=0.001$) and negative control group ($P=0.002$), and the proliferative effect of CCC bile could be abolished by addition of cyclooxygenase-2 specific inhibitor celecoxib (20 μ M). The QBC939 cells proliferative index was increased significantly after treated with 1 % bile from CCC patient ($P=0.008$) for 24 h, the percentage of S phase (29.48 ± 3.27 %) was increased remarkably ($P<0.001$) compared with normal bile (11.72 ± 2.70 %), and the percentage of G0/G1 phase (54.19 ± 9.46 %) was decreased remarkably ($P=0.042$) compared with normal bile (69.16 ± 10.88 %), however, bile from CCC patient had no significant influence on apoptosis of QBC939 cells ($P=0.719$).

CONCLUSION: Bile from congenital choledochal cyst patients can promote the proliferation of human cholangiocarcinoma QBC939 cells via COX-2 and PGE₂ pathway.

INTRODUCTION

Congenital choledochal cyst (CCC) is a rare disease in Western countries^[1-3]. Most of the reported cases come from Asia, particularly from Japan^[4-7]. In recent years, cases of CCC are reported increasingly in China^[8-17]. The incidence of carcinoma arising in the wall of a congenital bile duct cyst is high and this lesion is considered as a precancerous state of the biliary

tract, but its underlying precise mechanisms remain unclear. For the purpose of resolving these mechanisms we used the whole bile of CCC patients to act directly on the QBC939 cells to determine the effects of CCC bile on the growth of cholangiocarcinoma cells.

MATERIALS AND METHODS

Materials

Bile samples collection and treatment: Experiments were classified into CCC bile group, normal control bile group and negative control group. 20 CCC bile samples were obtained from the common bile duct of patients (5 male, 15 female, age range 5-49 years, mean 26.8 years) with CCC underwent operation at the Department of Surgery, Tongji hospital, Wuhan, China. 10 normal control bile samples were obtained from the common bile duct of patients (5 male, 5 female, age range 23-51 years, mean 42.3 years) with a normal hepatobiliary tract underwent surgery at the Department of Surgery, Tongji hospital, Wuhan, China. All patients didn't take any nonsteroid anti-inflammatory drugs, antibiotics or anti-tumor drugs before operation. Bile samples were filtered (0.22 μ m, Millipore) by sterile technique immediately twice and stored at -80 °C. PBS (pH7.2) instead of bile sample was used as negative control. Human extra-hepatic cholangiocarcinoma cell line QBC939 was established and given to us through the courtesy of professor Xu-Guang Wang (Third Military Medical University, China)^[18], cells were maintained as mono-layers in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10 % fetal bovine serum (FBS, Gibco, USA.), 100 units/ml penicillin and 100 mg/ml streptomycin in a humidified atmosphere of 95 % air and 5 % CO₂ at 37 °C. They were subcultivated every 3-5 days and given fresh medium every other day. 70-80 % subconfluent monolayers of human cholangiocarcinoma cells were employed in all experiments. PGE₂ ELISA detection kit was purchased from Jingmei Biotech Co., Wuhan, China. Celecoxib was synthesized and given as a gift by Dr Zhi-Nan Mei (Wuhan University, China)^[19]. Stock solution was prepared in dimethylsulfoxide (DMSO) and stored at -20 °C. In all experiments DMSO final concentration in the medium was ≤ 0.1 %.

Methods

Cytotoxicity pretesting Cytotoxicity pretesting was taken with each of the gradient diluted bile sample to determine the concentration of experimental bile samples. Our results showed that 1 % bile (10 μ L bile/mL medium) had no significant cytotoxic influence on QBC939 cells.

MTT assay The human cholangiocarcinoma cells QBC939 in proliferating status was determined by using MTT assay. Cholangiocarcinoma cells were seeded at a density of 1×10^4 cells per well in flat-bottomed 96-well microplates. 12 h after incubation, cells were treated with 1 % bile samples with or without 20 μ M celecoxib. After 24 h incubation, 20 μ L MTT (5 g/L) was added to each well, cultured for 4 h. After removed of supernatant, 150 μ L DMSO was added and shaken for 5 min until the crystal was dissolved. OD490nm value was

measured by using an enzyme-linked immunoabsorbent assay reader. The negative control well had no cells and was used as zero point of absorbance. Each assay was performed three times in triplicate.

ELISA The PGE₂ levels in the supernatant of cultured human cholangiocarcinoma cells QBC939 were quantitated by ELISA: Cells were seeded into 24-well microplates (4.0×10⁵/well) and allowed to adhere overnight. The cells were then incubated in the presence 1 % bile samples with or without 20 μM celecoxib for 24 h. The supernatants were aspirated and centrifuged to prepare for the detection of PGE₂. 0.5 mL supernatant was added into 0.1 mL 1N HCl and centrifuged for 10 min at room temperature; then 0.1 mL 1.2N NaOH was used to neutralize the acidified samples. Standard solution (200 μL per well) or activated samples were added into the microplates. Then the steps were proceeded as instructed. The value of OD of each well was determined at 450nm. The supernatants were harvested in triplicate and the experiment was performed three times.

Flow cytometric analysis Cholangiocarcinoma cells QBC939 were trypsinized and plated in 6-well culture dishes in the presence of 1 % CCC bile or 1 % normal bile. After 24 h, cells were harvested, centrifuged at low speed and fixed in 70 % ethanol. After overnight incubation at 4 °C, cells were stained with 50 μg/ml propidium iodide in the presence of Rnase A (10 μg/ml) and 0.1 % Triton X-100 and determined by using a flow cytometer.

Statistical analysis

Data were expressed as $\bar{x} \pm s$. Student's *t*-test was used for statistical analysis. *P*<0.05 indicates significant difference.

RESULTS

Assay of COX-2 activity

The COX-2 activity was determined by PGE₂ levels in the supernatant released by the cultured human cholangiocarcinoma cells QBC939. The concentrations of PGE₂ in culture medium of QBC939 cells treated with 1 % CCC bile, 1 % normal bile or 1 % PBS (pH7.2) with or without 20 μM celecoxib for 24 h were quantitated by ELISA (Table 1). CCC bile could induce the release of PGE₂ in QBC939 cells: the PGE₂ level was higher significantly (*P*<0.001) in CCC bile group (184.0±9.7 ng/well) compared with that in normal control bile group (131.0±7.3 ng/well) and negative control group (123.3±8.4). Celecoxib could suppress QBC939 cells PGE₂ production, the PGE₂ concentration was 80.3±7.1 ng/well, 74.1±9.7 ng/well and 72.4±10.8 ng/well in CCC bile group, normal control bile group and negative control bile group respectively, when pre-treated with 20 μM celecoxib, there was no statistical difference (*P*>0.05).

Table 1 PGE₂ level released by QBC939 in the existence of bile with or without celecoxib

Group	<i>n</i>	PGE ₂	<i>P</i>	+CE PGE ₂	<i>P</i>
A	20	184.0±9.7	^b <i>P</i> <0.001, ^d <i>P</i> <0.001	80.3±7.1	^b <i>P</i> =0.057, ^d <i>P</i> =0.055
B	10	131.0±7.3	^b <i>P</i> =0.087	74.1±9.7	^b <i>P</i> =0.771
C	5	123.3±8.4		72.4±10.8	

The concentrations of PGE₂ (ng/well) in culture medium of QBC939 cells treated with 1 % CCC bile (A), 1 % normal bile (B) or 1 % PBS (C) with or without 20 μM celecoxib (+CE) for 24 h were quantitated by ELISA. Data were expressed as $\bar{x} \pm s$, b vs C, d vs B.

Effects of bile on the growth of QBC939

QBC939 cells were incubated in 1 % bile samples with or without 20 μM celecoxib, and the cell density was measured by using MTT assay (Table 2). CCC bile could significantly promote the proliferation of human cholangiocarcinoma QBC939 cells compared with normal bile (*P*=0.001) and negative control group (*P*=0.002), and the proliferative effect of CCC bile could be abolished by addition of cyclooxygenase-2 specific inhibitor celecoxib.

Table 2 Effects of bile on the growth of QBC939 with or without celecoxib

Group	<i>n</i>	OD ₄₉₀	<i>P</i>	+CE OD ₄₉₀	<i>P</i>
A	20	0.59±0.17	^b <i>P</i> =0.002, ^d <i>P</i> =0.001	0.29±0.09	^b <i>P</i> =0.089, ^d <i>P</i> =0.190
B	10	0.47±0.14	^b <i>P</i> =0.398	0.26±0.07	^b <i>P</i> =0.052
C	5	0.43±0.10		0.24±0.09	

QBC939 cells were incubated in 1 % CCC bile (A), 1 % normal bile (B) or 1 % PBS (C) with or without 20 μM celecoxib (+CE), and the cells density (OD_{490nm}) was measured by using MTT assay. Data were expressed as $\bar{x} \pm s$, b vs C, d vs B.

Flow cytometric analysis of cell cycle and apoptosis

The QBC939 cells proliferative index (PI) increased significantly (*P*=0.008) after treated with 1 % CCC bile (41.53±5.68) compared with normal bile (25.46±4.41), PI=(S+G2/M) % × 100. The percentage of S phase cells was increased remarkably (*P*<0.001) in CCC bile group (29.48±3.27) % compared with that in normal bile group (11.72±2.70) %, and the percentage of G0/G1 phase cells was decreased remarkably (*P*=0.002) in CCC group (54.19±9.46) % compared with that in normal group (69.16±10.88) %, CCC bile had no significant influence on the apoptosis of QBC939 cells compared with normal bile (*P*=0.719). The percentage of apoptotic cells in CCC bile group and normal bile group were (2.38±0.41) % and (2.09±0.36) % respectively (Figure 1).

Figure 1 Representative data of cell cycle and apoptosis from QBC939 cells in the presence of 1 % CCC bile (B) or 1 % normal bile (A) for 24 h was analyzed by using flow cytometry.

DISCUSSION

As one of the high risk factors of cholangiocarcinoma, CCC is a common disease in eastern countries. Choledochal cysts are associated with a 10 % overall incidence of cholangiocarcinoma: there is a 1 % cumulative risk which plateaus after 15-20 years^[20]. In almost all cases congenital bile duct cysts are related to anomalous arrangements of the pancreaticobiliary duct system (APBDU) which seems to play a crucial role in the development of cystic bile ducts and biliary carcinogenesis. Bile stasis together with reflux of pancreatic juice causing longstanding inflammation and activation of bile acids might be the factors in carcinogenesis of the exposed bile duct epithelium in the cystic wall^[21]. Ohtsuka^[22] have reported that bile presented one possible explanation for the predisposition to carcinoma in choledochocoele as bile containing amylase may stagnate in the choledochocoele and then carcinoma may develop in the inner epithelium of the choledochocoele by the same mechanism as that leading to carcinogenesis in patients with APBDU.

Elevation of the secondary and free bile acid concentrations is considered as a risk factor for biliary carcinogenesis in CCC patients. Yuzuru *et al*^[23] have suggested that elevation of the lysolecithin (LL) in the bile is one of the factors for development of biliary tract carcinoma in patients with CCC: the LL in the phospholipid, which is produced from lecithin by activated phospholipase A₂ in refluxed pancreatic juice, was significantly elevated in the CCC group. Yoon *et al*^[24] have indicated that bile acids both induced EGFR phosphorylation and enhanced COX-2 protein expression. EGFR was activated by bile acids and functioned to induce COX-2 expression by a MAPK cascade. The induction of COX-2 might participate in the genesis and progression of cholangiocarcinomas.

In an effort to delineate the underlying mechanisms of the carcinogenesis in CCC patients, we used the whole bile from CCC patients for the first time to act directly on the human cholangiocarcinoma QBC939 cells *in vitro* to determine the effects of CCC bile on the growth of human cholangiocarcinoma cells. Our data showed that CCC bile could significantly promote the proliferation of human cholangiocarcinoma QBC939 cells compared with normal bile, and the proliferative effect of CCC bile could be abolished by addition of cyclooxygenase-2 specific inhibitor celecoxib. Our research indicated that CCC bile promoted the proliferation of human cholangiocarcinoma QBC939 cells via COX-2 and PGE₂ pathway.

Substantial evidences have shown that COX-2 is important in carcinogenesis^[25-33]. Celecoxib as a new COX-2 selective inhibitor has shown its safety and efficiency in human and animal. Several studies have demonstrated that celecoxib has significant efficacy in animal models: Celecoxib inhibited intestinal tumor multiplicity up to 71 % compared with controls in the Min mouse model, inhibited colorectal tumor burden in the rat azoxymethane (AOM) model^[34-36]. Recently celecoxib has been approved by FDA to reduce the number of adenomatous colorectal polyps in patients with familial adenomatous polyposis (FAP). Our data suggested that celecoxib as a chemopreventive and chemotherapeutic agent might be effective in cholangiocarcinomas and could be used as a chemopreventive strategy in the people of high-risk conditions for the development of cholangiocarcinoma such as CCC patients. Our research demonstrated that the QBC939 cells proliferative index increased significantly after treated with CCC bile for 24 h, the percentage of S phase was increased remarkably compared with normal bile, and the percentage of G0/G1 phase was decreased remarkably compared with normal bile, however, CCC bile had no significant influence on apoptosis of QBC939 cells. These data suggested that CCC bile could effect on the QBC939 cell proliferation cycle and

the proliferative activity of CCC bile was on cell cycle but not on apoptosis.

In conclusion, CCC bile can promote the proliferation of human cholangiocarcinoma QBC939 cells and these effects are via COX-2 and PGE₂ pathway.

Abstract

AIM: To investigate the utility of K-ras mutation analysis of ultrasound guided fine-needle aspirate biopsy of pancreatic masses.

METHODS: Sixty-six ultrasound guided fine-needle biopsies were evaluated by cytology, histology and k-ras mutation. The mutation at codon 12 of the k-ras oncogene was detected by artificial restriction fragment length polymorphisms using *Bst* NI approach.

RESULTS: The presence of malignant cells was reported in 40 of 54 pancreatic carcinomas and K-ras mutations were detected in 45 of the 54 FNABs of pancreatic carcinomas. The sensitivity of cytology and k-ras mutation were 74 % and 83 %, respectively. The speciality of cytology and k-ras mutation were both 100 %. The sensitivity and speciality of k-ras mutation combined with cytology were 83 % and 100 %, respectively.

CONCLUSION: High diagnostic accuracy with acceptable discomfort of FNAB make it useful in diagnosis of pancreatic carcinoma. Ultrasound guided fine-needle biopsy is a safe and feasible method for diagnosing pancreatic cancer. Pancreatic carcinoma has the highest K-ras mutation rate among all solid tumors. The mutation rate of k-ras is about 80-100 %. The usage of mutation of codon 12 of k-ras oncogene combined with cytology is a good alternative for evaluation of pancreatic masses.

INTRODUCTION

Pancreatic adenocarcinoma is a very aggressive carcinoma and has the worst prognosis in common abdominal cancer^[1-3]. Despite the poor prognosis, patients with localized disease may be cured with surgery^[4-6]. However, it is difficult to diagnose

pancreatic cancer in the earlier stages. This dismal prognosis is a result not only of biological aggressiveness but also of diagnosis late in the chronological progression of the tumor. If pancreatic cancer can be resected when it is small, the prognosis is much better, with a 5-year survival of approximately 40 %^[7-9]. When pancreatic cancer is clinically suspected and a pancreatic mass identified by ultrasonography or computed tomography scan, a guided percutaneous fine-needle biopsy (FNAB) can be obtained; this may be the only sample available for diagnosis in most patients^[10-12].

Even though alternative techniques for sampling cellular or tissue material have been developed, FNAB is still widely used for morphological verification of intra-abdominal malignancies, especially in pancreatic cancer. Although it has been questioned because of the risk of peritoneal seeding and seeding of tumor cells along the needle tract. It is still widely used for the diagnosis of pancreatic cancer combined with modern molecular biological techniques^[13].

The high incidence of mutations at codon 12 of the K-ras gene (65-100 %) leads to consider them as a potential tumor marker at the tissue level^[14-19]. The development of PCR-based techniques for detection of K-ras mutations has allowed its use in the clinical setting. The high incidence of mutation suggests that it may be used as a tumor marker at the tissue level. The role of k-ras detection in the clinical evaluation of pancreatic mass has to be established in a large series of patients. Data suggest that a combination of cytological examination and K-ras mutation detection in cellular material may improve diagnostic accuracy^[20-26]. In this study we evaluated the diagnostic utility of cytological and histological examination and k-ras mutation detection, alone and in combination under the ultrasound guided FNAB from 66 patients with pancreatic masses.

MATERIALS AND METHODS

Patients and samples

Between January 1997 and May 2001, 66 consecutive patients (38 men and 28 women, mean age of 54±9 years) with pancreatic masses were included. In all cases FNAB of the masses were percutaneously obtained under ultrasonographic guidance. A portion (50 %) of each FNAB was immediately examined by pathologist. The other 50 % of the same specimen was frozen and stored in liquid nitrogen.

Final diagnosis of pancreatic carcinoma was established if malignant cells were identified in the FNAB or in surgically resected specimens or when death occurred within six months after diagnosis, with clinical evolution compatible with disseminated cancer disease. Other types of neoplasm were diagnosed on the basis of pathological findings. The diagnosis of chronic pancreatitis was based on standard clinical criteria. In chronic pancreatitis, a minimum of 6-month (range, 6-27 months) follow-up period with no evidence of cancer was available. Pancreatic tuberculosis was confirmed by positive Lowenstein culture.

Detection of K-ras codon 12 mutations

DNA was extracted following standard procedures. We utilized

*Bst*NI (Promega, USA) restriction fragment length polymorphism/polymerase chain reaction (RFLP/PCR) method that enriches for the amplification of mutant codon 12 K-ras alleles by cleaving amplified wild-type allele through intermediate digestion between first- and second-round PCR^[27]. To create the restriction site for the enzyme *Bst*NI [CCTGG], which is lost when a K-ras codon 12 mutation exists, the first-round amplification was performed using the mutant primers K-ras 5' and DD5P (Table 1) in a volume of 50 µL containing PCR buffer (50 mmol/L KCl, 20 mmol/L Tris HCl, pH 8.4), 1.5 mmol/L MgCl₂, 0.2 mmol/L each dNTP (Promega, USA), 1U of Taq polymerase (Life Technologies, USA), and 150 ng of PCR primers^[28]. The reactions were 10 cycles of 92 °C(15s), 44 °C(15s) and 72 °C(15s). An aliquot of 5 µL of the amplified product was enzymatically digested with *Bst*NI following the manufacturer's directions. One microliter of the digested product was reamplified using a heminested reaction with mutant amplimers K-ras 5' and K-ras 3' ^[28]. The reaction conditions were 35 cycles of 92 °C(15s), 54 °C(15s) and 72 °C(15s). The latter primer artificially introduces an internal control to assure the completion of enzymatic digestion. After polyacrylamide gel electrophoresis (6 %) and ethidium bromide (0.5 g/L) staining, the 143-bp band depicted the mutant allele, and the 114-bp band the wild-type allele. RFLP/PCR method consistently detected a mutant allele in serial dilutions containing at least 1 mutant allele in 1 000 wild-type alleles. Positive bands were always clearly identifiable when DNA obtained from FNAB was examined. All samples were analyzed in duplicate. Results were available 48-72 h after the tissue sample was obtained.

Table 1 Primers for K-ras mutation detection

Round	Primer	Sequence
First	K-ras 5'	5'-ACTGAARARAACTTGTGGTAGTTGGACCT-3'
	DD5P	5'-TCATGAAAATGGTCAGAGAA-3'
Second	K-ras 5'	5'-ACTGAATATAACTTGTGGTAGTTGGAACCT-3'
	K-ras 3'	5'-TCAAAGAATGGTCCTGGACC-3'

RESULTS

Cytological examination

Final diagnoses were as follows: 54 pancreatic carcinomas, 3 other malignancies (1 lymphoma, and 2 cholangio-carcinomas), 6 benign diseases (5 chronic pancreatitis and 1 tuberculosis), and 3 endocrine tumors. The presence of malignant cells was reported in 40 of 54 pancreatic carcinomas with no false positives. However, in 14 of the 54 FNABs of pancreatic carcinomas, the cytological report was not conclusive: 12 because of insufficient material and 2 because of suspicion. The sensitivity of cytology was 74 % in the diagnosis of pancreatic cancer.

Molecular diagnosis

Molecular analysis was possible in 54 of 66 FNABs. K-ras mutations were detected in 45 of the 54 FNABs of pancreatic carcinomas, with no false positives. The combination of cytology and enriched RFLP/PCR analysis was always informative and showed a sensitivity of 83.3 %, with a specificity of 100 %. Only nine pancreatic carcinomas failed to be correctly classified after the combined cytological and molecular analysis.

In three cases, a K-ras positive analysis in combination with the presence of suspicious cells was considered confirmation of pancreatic cancer, and no further studies were performed. Two of these patients died 1 and 3 months later, respectively,

with a clinical course consistent with advanced pancreatic cancer. In the other, positive peritoneal disease was present at surgery. In one patient with insufficient material at cytology, molecular analysis was the endpoint of the diagnostic work-up, and laparotomy was not performed because of the poor clinical status of the patient. Finally, in the remaining one patient with insufficient material for cytological evaluation and K-ras positive analysis, surgical resection of a histologically confirmed pancreatic carcinoma was performed.

DISCUSSION

The influence of biopsy on the natural history of pancreatic carcinoma is still unclear, considering the increasing intention to treat and the development of new multimodality therapies^[29,30]. Our data indicate the FNAB of pancreatic malignancy can be easily performed without serious side effects and is still a safe and useful procedure for establishing the diagnosis of pancreatic carcinoma. High diagnostic accuracy with acceptable patient discomfort has also been reported when using an 18-gauge cutting needle with an automatic spring-loaded sample device. The large amount of tissue obtained could improve the microscopic evaluation, but it has not been verified that microhistology offers advantages over cytology in the diagnosis of pancreatic cancer. The complication rate, including needle tract seeding, in pancreatic carcinoma is lower than in other tumors^[31,32].

The main limitation of cytological analysis is the substantial proportion of cases in which a conclusive report is not possible, and where a second procedure to confirm diagnosis is required. FNAB can get a bigger tissues for microhistological examination. The molecular approach allows detection of K-ras mutants even when cells are present in a small proportion. Mutation detection would have complemented the cytological evaluation of FNAB when cellular material was insufficient, suspicious cells were present, or when healthy-appearing duct cells were reported^[33].

Pancreatic carcinoma is known to have the highest K-ras mutation rate among all tumors. The codon 12 of this gene is affected in 80-100 % of the cases^[34-36]. Only a minority of pancreatic cancers (9 cases) failed to be correctly classified by the combined histological and molecular approach in our studies. Although inaccurate sampling of the lesion may account for some of the false negatives observed, the molecular approach has some limitations^[26,37]. The discrepancies between the results of the various studies are based on the wide range of investigated cases, the selection of lesion types, and the sensitivity of the microdissection and PCR techniques employed. The clinical usefulness of ras mutations relies on the development of rapid, sensitive, and reproducible techniques for their detection. Moreover, a positive molecular diagnosis avoided iterative pancreatic fine-needle aspiration or further diagnostic procedures in these patients.

In Japanese studies, a comparison of the K-ras mutation pattern in ductal lesions with that of the adjacent carcinomas revealed nearly identical mutation patterns^[38,39], whereas in a study from North America a concordance rate of only 50 % was reported^[40]. The results of our analysis showed identical mutation patterns in the primary tumor confirming the results of the Japanese authors. There are large differences in the incidence of ras mutations between Japanese and Western populations, although the reason is still unclear and the number of subjects is limited. In Japan, the frequency of K-ras mutation ranged from 55-80 %^[41-44], whereas in West it was relatively low, ranging from 0-31 %^[45,46]. The current data suggest that most patients have ras gene mutations in the tumor itself, which is similar to previous Japanese reports.

In conclusion, the results of the present study indicate that

K-ras analysis is a highly specific and sensitive approach in pancreatic carcinoma patients and suggest that a k-ras assay may have a role in the diagnostic assessment of these patients. Further investigations are needed to confirm these results, to improve the technique's sensitivity, and to establish its usefulness in the early.

Abstract

AIM: To reduce the incidence of postoperative anastomotic leak, stenosis, gastroesophageal reflux (GER) for patients with esophageal carcinoma, and to evaluate the conventional method of esophagectomy and esophagogastric anastomosis modified by a new three-layer-funnel-shaped (TLF) esophagogastric anastomotic suturing technique.

METHODS: From January 1997 to October 1999, patients with clinical stage I and II (IIa and IIb) esophageal carcinoma, which met the enrollment criteria, were surgically treated by the new method (Group A) and by conventional operation (Group B). All the patients were followed at least for 6 months. Postoperative outcomes and complications were recorded and compared with the conventional method in the same hospitals and with that reported previously by McLarty *et al* in 1997 (Group C).

RESULTS: 58 cases with stage I and II (IIa and IIb) esophageal carcinoma, including 38 males and 20 females aged from 34 to 78 (mean age: 57), were surgically treated by the TLF anastomosis and 64 by conventional method in our hospitals from January 1997 to October 1999. The quality of swallowing was improved significantly (*Wilcoxon* $W=2\ 142$, $P=0.0\ 001$) 2 to 3 months after the new operation in Group A. Only one patient had a blind anastomotic fistula diagnosed by barium swallow test 2 months but healed up 3 weeks later. Postoperative complications occurred in 25 (43 %) patients, anastomotic stenosis in 8 (14 %), and GER in 13 (22 %). The incidences of postoperative anastomotic leak, stenosis and GER were significantly decreased by the TLF anastomosis method compared with that of conventional methods ($\chi^2=6.566$, $P=0.038$; $\chi^2=10.214$, $P=0.006$; $\chi^2=21.265$, $P=0.000$).

CONCLUSION: The new three-layer-funnel-shaped

esophagogastric anastomosis (TLFEA) has more advantages to reduce postoperative complications of anastomotic leak, stricture and GER.

<http://www.wjgnet.com/1007-9327/9/22.htm>

INTRODUCTION

Surgical therapy is considered the major method for treatment of operable esophageal cancer^[1-2]. Unfortunately, there are many operative complications after classical standard esophagectomy and esophageal reconstruction with stomach in patients with esophageal carcinoma. Anastomotic leak, with a rate of about 12-14 % as reported, is the most severe complication and the principal cause of death after operation^[3-7]. Anastomotic stenosis and gastroesophageal reflux (GER), with higher rates of about 36.4-40 % and 50-60 % respectively, result in dysphagia, heartburn, regurgitation and nausea^[3-7].

We modified the conventional method of esophagectomy and created a new three-layer-funnel-shaped (TLF) esophagogastric anastomotic suturing technique, which significantly reduced postoperative complications of anastomotic leak, stricture and GER.

MATERIALS AND METHODS

Patients and preoperative examination

From January 1997 to October 1999, the patients with clinical stage I and II (IIa and IIb) esophageal carcinoma, which met the enrollment criteria, were allocated into two groups and surgically treated by a new method (Group A) and the conventional operation (Group B) in our hospitals. All patients were diagnosed by esophagoscopy and biopsy. Barium swallow test confirmed that the cancer length was <5 cm, there was absence of sinus or fistula. No lung or liver metastases were detected by radiography and/or computed tomography (CT) scan of the chest and ultrasonography of the upper abdomen. Supraclavicular lymph nodes were not involved by physical examination in all patients. Karnofsky performance status was >70. All patients assessed by pulmonary functional test were fit for thoracotomy. Patients with stage III or IV esophageal carcinoma, inoperable conditions, receiving chemotherapy or radiotherapy before or after operation were precluded.

Methods of operation

Partial or sub-total resection of esophagus was routinely performed through left or right thoracic incision, some cases need cervical incision, with removal of paraesophageal, subcarinal, supradiaphragmatic, perihilar, as well as left gastric and coeliac lymph node group. Partial gastrectomy was performed with esophagogastric junction carcinoma. The stomach remained and was reconstructed as a tube-like pouch to replace the resected part of the esophagus. The anastomotic

techniques were improved as follows:

When the gastric tube was constructed, an adequate amount of greater omentum was reserved for protecting the right gastroepiploic vessels and the blood supply of the gastric tube. The gastric tube was kept long enough to avoid tension and pulled along the esophageal bed, anchored to the back of the chest wall beside the mediastinum (The cervical cancer need a cervical incision to perform the anastomotic suture in the neck). First, the esophageal muscular layer was cut 3.0-3.5 cm in length into the inclined cycle, and the esophageal mucosa was kept 1.0-1.5 cm longer. Between the short gastric vessel, the sero-muscular layer was incised 4.0-4.5 cm, and its posterior aspect was hand-sewn to the same aspect of esophageal muscular layer. Then, excised the inner circular muscle layer and mucosa of stomach for 2.5-3.0 cm long and anastomosed to the esophageal mucosa by interrupted suture. The anterior aspect of the esophageal muscular and the gastric sero-muscular layer was sewn finally with fundoplication by inversion suture. The fundoplication suture cycle is 1.0 -2.0 cm larger than the suture cycle of the esophageal muscular-to-sero-muscular layer of the stomach (Figure 1). The other procedures were performed as usual.

Figure 1 Technique of three-layer-funnel-shaped (TLF) esophagogastric anastomosis. A: mucosa-to-mucosa suture cycle; B: the esophagus muscular to gastric sero-muscular suture cycle; C: fundoplication suture cycle.

Postoperative management and follow-up

After the operation, all patients were treated routinely by thoracic drainage, nutrition support, and antibiotics. The swallowing ability and symptoms of anastomotic leak, stricture and GER were observed clinically as reported^[3-7]. All patients were evaluated clinically by their general condition, eating habits, swallowing ability and barium swallow test or esophagoscopy 2 to 3 months after the completion of all treatments and followed up at intervals of 2-3 months for at least 6 months.

Postoperative anastomotic leak was diagnosed clinically by leakage of gastrointestinal contents and radiographically extravasation of water-soluble contrast medium at the site of anastomosis. The anastomotic stricture was defined as any form of narrowing in the anastomosis region by contrast swallow study (≤ 2.0 cm in diameter in obverse and lateral posture)

and any symptom of dysphagia when swallowing solid food, semisolids or liquids, requiring endoscopic dilation. GER was present if the patient had intermittent or continuous heartburn, regurgitation and nausea, especially that required antacids for relief of heartburn, or barium regurgitation at horizontal posture or Trendelenburg's position on radiographic examination.

Statistical analysis

All patients' general characteristics, pathological pattern of carcinoma, clinical staging, swallowing ability, postoperative complications, and incidences of anastomotic leak, stricture, and GER were recorded and compared to that treated by conventional methods in the same hospitals and that reported previously by McLarty *et al*^[7]. Quantitative data were compared by using Independent-Samples *t* test and qualitative data by Chi-square, Fisher's exact test, and Wilcoxon rank test. Statistical significance was assumed at $P \leq 0.05$.

RESULTS

58 patients (Group A), including 38 males and 20 females aged from 34 to 78 (mean age: 57), 54 cases with dysphagia, 4 without any symptom by routine examination, were successfully treated by the new method and 64 (Group B) by the conventional operation. There were no severe intraoperative complications, no operative mortality, no abscesses or uncontrolled infections occurred in all patients. Treated by the new method, the quality of swallowing of the patients improved significantly ($P=0.001$) 2 to 3 months after the operation (Table 1). In Group A, only one patient had a minute blind anastomotic fistula into the immediate paraesophageal soft tissues without causing any symptoms which was diagnosed by barium swallowing test 2 months after the operation, but healed up automatically without any treatment 3 weeks afterwards. Postoperative complications occurred in 25 patients (43 %), including incision and/or thoracic cavity bleeding in 2, wound infection in 1, pneumonia in 1, anastomotic stenosis in 8 (14 %), and GER in 13 (22 %). There were 7 of 8 cases with symptom of dysphagia but dilated successfully by endoscopy, 1 case with moderate stricture could only eat semisolid or liquid food 1 year after the operation.

Table 1 Evaluation of swallowing quality after operation (Group A, $n=58$)

	No symptom of dysphagia	With symptom of dysphagia		
		Solid Food	Semisolids	Liquids
Preoperation	4 (6.9%)	23 (39.7%)	26 (44.8%)	5 (8.6%)
Postoperation	50 (86.2%)	5 (8.6%)	2 (3.4%)	1 (1.7%)

Analysed by wilcoxon rank test (*Wilcoxon W*=2 142, $P=0.001$), swallowing quality of patients after operation increased significantly compared with that before operation.

Except the difference of pathological type of carcinoma in the west from that in China, which was not the major factor that affected the operation modality and the early outcomes, the patients' general characteristics, tumor site and clinical staging in Group A were analogous to those in Group B and that reported previously by Allison *et al* (Table 2). Although the total incidence of postoperative complications were not different due to different method of calculation, the incidences of anastomotic leak, stricture, and GER in our new method therapy group were significantly reduced compared with that of conventional therapy groups (Table 3).

DISCUSSION

There are clear evidences that patients with earlier stage esophageal carcinoma have relatively good outcomes when treated with resection only, especially through thoracic incision which is easy to remove the regional lymph nodes and to carry out the whole operation^[1,2,8]. Multimodality treatment with neoadjuvant chemotherapy or chemoradiotherapy was recommended for esophageal carcinoma by some studies but the results are debatable recently by other studies due to poor outcomes at present^[9-12]. Yet there are still many postoperative complications such as leaks, stricture, and GER, which affect the esophageal function and quality of life, as well as long-term survival of the patients^[3-7].

Anastomotic leak is mainly caused by ischemia of the anastomosis and errors in surgical technique^[7]. Except few recurrence of carcinoma which occurs usually above 6 months after operation, small-bore anastomosis and fibrotic stenosis are the principal causes of anastomotic stricture that results in poor function of swallowing^[3,4,7]. Some studies show that there is a trend toward slightly higher leaking rate for one-layer

anastomosis and a higher stricture rate for two-layer anastomosis^[4,13,14]. As for GER, it is basically caused by loss or alteration of normal anatomical structure, location, and function of esophagus, cardia and stomach^[3,5,6].

The new three-layer-funnel-shaped esophagogastric anastomotic suturing technique, we report here, has more advantages than the classical ones. First, it not only maintains adequate arterial perfusion and venous drainage by reserving enough amount of greater omentum, protecting the right gastroepiploic vessels, and avoiding excessive tension of gastric tube and esophagus, but also maintains accurate mucosa-to-mucosa, muscular-to-muscular apposition and enhances the anastomosis by three-layer sutures, as well as omentum or pleura covering. This significantly avoids the occurrence of anastomotic leak according to our clinical data.

Second, it forms three inclined suture cycles in different diameters at different levels (Figure 1). The fundoplication suture cycle and the esophageal muscular-to-gastric sero-muscular suture cycle are ellipse like and big enough to form a large-bore anastomosis that reduces stricture formation. That

is why the incidence of anastomotic strictures being low and dilated easily and effectively in our study.

Third, with adequate mucosa-to-mucosa suture, the new method reconstructed a soft mucosa petal which forms the third suture cycle, smaller in diameter and easier to open or shrink automatically, and prevents GER effectively. Although postoperative GER still occurred in 22 % which need further study, it was significantly decreased compared to the conventional method^[15]. Twenty-four-hour esophageal pH monitor is a new method to diagnose GER and we plan to carry out a further randomized clinical trial to more scientifically evaluate the anti-GER effects of the mucosa petal created by the new anastomosis^[16].

Like all conventional anastomotic suture techniques, we also emphasize that it is important for the anastomotic healing to prevent infection, malnutrition, influence of chemotherapy and radiotherapy and other related factors in perioperative stage. To prevent the anastomotic tissue injury from strangulation, one should never suture too tightly, or place an excessive number of sutures. In addition, each suture 'bite' of esophageal muscular layer may be transversely sewn so as to overcome the problem because the longitudinally oriented esophageal muscle holds suture poorly.

Some studies recommend that the stapled esophagogastric anastomosis after resection for esophagogastric or cardia cancer is a simple and expeditious procedure, carrying an acceptable perioperative morbidity and cancer recurrence rate^[17-19]. But except the technical problems caused by the staples, the stricture rate of stapled anastomosis was higher^[17-21]. Beitler *et al* systemically reviewed the related randomized controlled trials and pointed out that both stapled and hand-sewn techniques are acceptable but both need further improvement^[22]. GER is recently demonstrated as a main risk factor for esophageal adenocarcinoma and is the main factor that decreases the quality of life of patients after operation^[7,23-30]. The new three-layer-funnel-shaped esophagogastric anastomotic suturing technique is a pilot study, its effect on anti-GER has not been very ideal, and we are making further efforts for improvement, especially that on the prevention of anastomotic leak, stricture and GER.

Abstract

AIM: To investigate CpG methylation and single nucleotide polymorphism (SNP) of a specific promoter region of *hMLH1* in primary gastric carcinoma.

METHODS: Primary gastric carcinomas ($n=80$), their corresponding normal mucosal samples, and gastric mucosal biopsies from normal/gastritis control patients ($n=54$) were used. Hypermethylation at -253 nt and -251 nt in relation with the translational start site and SNP of a silencing specific region (-339 nt-46 nt) in the *hMLH1* promoter were analyzed by *Bst* UI-combined bisulfite assay (COBRA), denaturing high performance liquid chromatogram (DHPLC), and sequencing.

RESULTS: (A) The specific methylation at -253 nt and -251 nt was observed in 2 of 60 primary gastric carcinomas, but neither in all of the corresponding mucosa nor in normal/gastritis samples, by *Bst* UI-COBA and DHPLC. (B) The *hMLH1* promoter was methylated homogeneously in the xenograft of the primary gastric carcinoma with the methylated and unmethylated *hMLH1*. (C) The pattern of SNP at -93 nt of the *hMLH1* promoter in 54 Chinese patients with gastric carcinoma was the same as that in the control patients: 51 % was A/G heteroalleles, 34 % and 15 % were A/A and G/G homoalleles, respectively.

CONCLUSION: Biallelic inactivation of *hMLH1* by epigenetic silencing existed in human primary gastric carcinoma homogeneously. Hypermethylation of *hMLH1* may play a role in the early stage of development of a few gastric carcinomas. The SNP at -93 nt is not related to the susceptibility of gastric carcinomas.

INTRODUCTION

Hypermethylation of CpG islands in upstream is an epigenetic

mechanism of lost of functions of tumor suppressor genes, DNA repair genes, *etc*^[1-3]. The methylated *hMLH1* was observed in most of primary gastric carcinomas with the microsatellite instability-H phenotype (MSI-H)^[4-12]. Silencing of *hMLH1* by CpG methylation may play an important role in the development of MSI-H tumors. However, the *hMLH1*-methylated proportions in MSI-L and MSI-stable sporadic gastric carcinoma varied greatly (0-75 %) in previous reports. Nakajima *et al.* reported that *hMLH1* methylation was detected in 8 of 100 primary gastric carcinoma cases, but not detected in their corresponding normal mucosa or in intestine metaplastic mucosa^[13]. Kang *et al.* reported a much higher rate of *hMLH1* methylation in gastric carcinoma (20.3 %), adenoma (9.8 %), and intestine metaplastic mucosa (6.3 %)^[14]. Different results might result from applications of both different markers used to classify MSI tumors, and different approaches or primers used to detect methylation of CpG island of *hMLH1*. It was reported recently that the methylation of CpGs in a small C-region (-270 nt ~ -199 nt) of the *hMLH1* promoter was invariably correlated with the absence of gene expression^[15-17]. Thus, it is of interest to further explore the silencing specific methylation of the *hMLH1* promoter in primary gastric carcinomas. In the present study, we analyzed the silencing specific *hMLH1* methylation at -253 nt and -251 nt in the C-region in primary gastric carcinoma and normal/gastritis control.

Deng *et al.* established a novel approach to detect CpG methylation by denaturing high performance liquid chromatography (DHPLC)^[18,19], which was further developed to quantify CpG methylation and SNP of CpG islands simultaneously^[20,21]. It was reported that there is a SNP at -93 nt of the *hMLH1* promoter^[22]. In order to evaluate the possible role of the SNP in the gastric carcinogenesis, the pattern of the SNP in patients with gastric carcinoma was also compared with that in control patients without malignant diseases using DHPLC.

MATERIALS AND METHODS

Gastric samples

60 primary gastric carcinomas and their corresponding normal gastric mucosa were collected: 34 from the Beijing Institute for Cancer Research (BICR) surgically (28 males and 6 females, 29-59 years old, average age: 47.7 years old), and 26 from the University of Virginia Health System (Uva) (18 males and 8 females, 41-84 years old, the average age: 63.8 years old). Three Uva xenografted human GC were obtained from nude mice as described^[23]. In addition, 56 biopsy samples of gastric epithelial tissues were collected from normal/gastritis patients at BICR (50 males and 4 female, 18-47 years old, the average age: 29.7 years old). All samples were used in the analysis of both methylation and SNP. Additional 18 corresponding normal gastric mucosal samples from BICR (Chinese patients, 13 males and 5 females, 26-78 years old, average age: 48.7 years old) with gastric carcinoma were used in SNP analysis in order to have the same number of cases as control. All clinical samples and histopathological information for each case were obtained according to approved institutional guidelines.

Figure 1 Detection of *hMLH1* methylation by *Bst*UI-COBRA assay. PCR products and methylated ssPCR products (294 bp) were digested into two small fragments (206 bp and 88 bp). Unmethylated ssPCR products were not digested by *Bst*UI. T1, T2: primary gastric carcinomas; N1, N2: corresponding normal gastric mucosal samples; X2: xenograft of primary gastric carcinomas (T2) with *hMLH1* methylation; NC1, NC2: negative control xenografts of primary gastric carcinomas without *hMLH1* methylation; PC: PCR products of the *hMLH1* templates not treated by bisulfite

DNA extraction and bisulfite modification

Genomic DNA of tissue samples was isolated with QIAGEN DNA Purification Kits. Two mg genomic DNA was treated with sodium bisulfite in order to convert the unmethylated C to U (T in PCR products) as described^[24].

Design of Primers and PCR Conditions

Primers were designed according to the specific region (-339 nt ~ -46 nt in relation to the translational start site) of CpG islands of the sense strand of *hMLH1* (GenBank accession number U83845, gi: 2511457) as described^[18, 20]. The strand-specific primers for the modified CpG islands included *hMLH1*-mF (5' -gtattttgtttttattgttgata-3') and *hMLH1*-mR (5' -aatacttcaaccaatcacctcaata-3'). Primers for the templates without bisulfite-treatment included *hMLH1*-wF (5' -gcattctctgctcctattggctggata-3') and *hMLH1*-wR (5' -agtgccttcagccaatcacctcagt-3'). Hot-started touchdown PCR (-1.0 °C per cycle, total 35 cycles) was used to amplify *hMLH1* without bisulfite-treatment (72 °C → 58 °C), and the sense strand templates with bisulfite-treatment (ssPCR, 65 °C → 50 °C for *hMLH1*)^[18, 20].

Detection of CpG methylation by combined bisulfite restriction analysis (COBRA) and DHPLC

The specific region of the methylated CpG island contain a *Bst*UI restriction site (CGCG) that is converted to UGUG in the unmethylated CpG island after bisulfite modification. Hence the methylation of the bisulfite-modified *hMLH1* could be analyzed directly by *Bst*UI-COBRA. In the confirmation study, methylation status was detected further by DHPLC. Basic mechanism to detect methylation by DHPLC is that the retention time of the methylated PCR products is longer than that of the unmethylated ones, because of higher denaturing temperature of the methylated sequence resulted from higher G+C content after bisulfite modification^[20].

Analysis for SNP by DHPLC and sequencing

The SNP at -93 nt in the corresponding normal mucosal samples and the gastric biopsies from the control patients was detected by DHPLC and confirmed by sequencing as described^[20]. Because all control normal/gastritis samples were collected from Chinese patients, therefore only corresponding normal samples from Chinese cases with gastric carcinomas hospitalized in BICR were used in the SNP analysis.

RESULTS AND DISCUSSION

Silencing-specific methylation of *hMLH1* promoter

One *Bst*UI restriction site (CGCG) exists in the silencing-specific C-region of the CpG island that was invariably correlated with the absence of gene expression^[15]. This site remains only in the methylated templates but not in the

unmethylated ones after bisulfite modification. Therefore, *Bst*UI-COBRA was used to detect the methylation of the specific region^[18]. If the template is methylated, its ssPCR product (294 bp) is digested into a 206 bp and an 88 bp fragments. If not methylated, not digested. The specific CpG methylation of the *hMLH1* promoter was observed in only 3.3 % (2 of 60) of primary gastric carcinoma cases by this assay (Figure 1-T1, T2). T1 sample was distal adenocarcinoma (mod-poor differentiation) from BICR, and T2 was gastro-esoph junction adenocarcinoma (poor differentiation) from UVa. Such methylation was neither observed in all 60 corresponding normal gastric mucosa (Figure 1-N1, N2) nor in 54 normal/gastritis samples from the BICR control patients. The unmethylated *hMLH1* was detectable in all tested human samples (Figure 1-T1, T2, N1, N2). The same result was observed by DHPLC analysis (Figure 2-A, B).

The positive rate (3.3 %) of the specific CpG hypermethylation of *hMLH1* in the present study was lower than those reported by others. Nakajima *et al.* reported that *hMLH1* methylation was observed in 8 of 100 primary gastric carcinomas (8 %) by *Rsa*I-COBRA (restriction site GTAC)^[13]. Although the specific C-region was also included in the ssPCR products in Nakajima's work, the *Rsa*I restriction site GTAC is at -76 nt in the D-region where the correlation between CpG methylation and gene expression is not as well as the C-region^[15]. Kang *et al.* reported that *hMLH1* methylation was detected in 20.3 % of gastric carcinoma cases^[14]. The possible reason for the higher positive rate might result from detection of CpG methylation in A-region of the *hMLH1* promoter that are methylated partially even in cells expressing *hMLH1*^[15]. Another reason was that they used a very sensitive assay, methylation-specific PCR (MSP)^[24], which would result in a positive result even if 0.1 % of testing cells were methylated. Detection of methylation by *Bst*UI-COBRA used in the present study reflects the exact status of the *hMLH1* methylation in the testing samples. Therefore, the low methylation rate in the present study most likely represents the true state of these gastric cancers.

Only the methylated *hMLH1* was detectable in the xenograft of primary gastric carcinoma

It was reported that bialleles of *hMLH1* were inactivated by CpG methylation in cell lines^[25]. Unlike in cell lines, both the methylated and unmethylated *hMLH1* were observed in primary gastric carcinomas (Figure 1-T1, T2). In order to confirm that *hMLH1* is methylated homogeneously in malignant cells, we detected the status of *hMLH1* methylation in UVa xenografts originated from *hMLH1*-methylated and -unmethylated primary gastric carcinomas by *Bst*UI-COBRA. No *hMLH1* methylation was detected in two xenografts from two *hMLH1*-unmethylated primary gastric carcinoma (Figure 1-NC1, NC2). Only methylated *hMLH1* was observed in the X2 xenograft from primary gastric carcinoma T2, in which both the methylated and unmethylated *hMLH1* were observed

(Figure 1-X2, T2). This result was also confirmed by results of DHPLC (Figure 2-B). These results suggested that bialleles of *hMLH1* was methylated homogeneously in all of the malignant cells. The unmethylated *hMLH1* in T2 should come from normal cells such as fibrocytes, fibroblasts, and lymphocytes comprising the primary carcinoma. To best of our knowledge, this is the first report to describe the distribution of methylation status of CpG islands in primary carcinoma.

Thus, all of the malignant cells in the primary gastric cancer T2 appear originate from a single initiated cell with biallelic aberrant methylation of the *hMLH1* promoter. It is useful to study whether certain extent of methylation in the specific C-region of *hMLH1* CpG island is detectable in precancerous gastric lesions by sensitive assays such as MSP^[24] and MethyLight^[26]. Taken together, the *hMLH1* methylation may play an important role in the initiation stage of a few gastric carcinomas. In addition to inactivation of *hMLH1* by germline defects^[27-32], silencing of *hMLH1* by CpG methylation is an alternative way to inactivate *hMLH1*.

Table 1 Pattern of the SNP at -93 nt of the *hMLH1* promoter in patients with and without gastric carcinoma

Patients	n	G/G	A/G	A/A
Without gastric carcinoma	56	9(16.1%)	29(51.8%)	18(32.1%)
With gastric carcinoma	54	8(14.9%)	27(50.0%)	19(35.2%)
Total	110	17(15.5%)	56(50.9%)	37(33.6%)

Figure 2 DHPLC Chromatograms of the specific methylation of the *hMLH1* promoter ssPCR products were analyzed at partial denaturing temperature 54 °C, point mutation mode. T1 and T2, primary gastric carcinomas; N1 and N2, the corresponding normal gastric mucosal samples; X2, the xenograft of T2 in nude mouse

SNP at -93 of the *hMLH1* promoter is not correlated with gastric carcinoma

There is a SNP at -93 of the *hMLH1* promoter^[22], which is located within the D-region tested in the present study. In order

to evaluate the correlation of the SNP with risk of gastric cancer, we compared the pattern of the SNP in 54 Chinese patients with gastric carcinoma with that in 56 Chinese control patients through DHPLC and sequencing. Similar percentages of homoalleles (G/G and A/A) and heteroalleles (A/G) were observed in samples from both groups (Table 1). The result suggested that this SNP was not correlated with the risk of gastric carcinoma. Similar result was observed in hereditary nonpolyposis colorectal cancer (HNPCC) and non-HNPCC populations^[22].

Abstract

AIM: To clone genes that may predispose us to human gastric cancer and to analyze its expression in gastric tissues.

METHODS: Specimens of paired tumor, paratumor and normal gastric mucosa tissues collected from fifteen patients who suffered from stomach antrum adenocarcinoma were used for analysis. Seven out of the fifteen cases were first studied by fluorescent differential display reverse transcription polymerase chain reaction (DDTR-PCR) analysis. The differentially expressed bands of interest were cloned, analyzed by Northern blot, sequencing and RT-PCR. Through BLAST, the sequencing results were compared with GenBank database for homology analysis. *In situ* hybridization with DIG-labeled cRNA probes was used to analyze the expression of interesting cDNA bands in paraffin embedded paired normal gastric mucosa and cancer tissues isolated from 30 gastric adenocarcinoma patients.

RESULTS: DDRT-PCR showed that one of the interesting cDNA bands, which was named W2, expressed much higher in all seven tested tumor and paratumor samples than in their normal counterparts, it was sub-cloned into a pGEM-T Easy vector. Two subclones were subsequently obtained. One of the subclone, GCRG224, was studied further. The sequencing result showed that GCRG224 consisted of 1 159 base pairs and had one open reading frame (ORF). It located at human chromosome 11q14. No homologue was found in GenBank database with GCRG224-ORF. This nucleotide sequence data were submitted to GenBank with accession No. AF438406. RT-PCR showed that GCRG224 expressed higher in 11/15 gastric cancer tissues than in non-tumor tissues. However, the result of Northern blot analysis showed a higher GCRG224 expression in the non-tumor tissue than in the tumor one. Human multiple tissue Northern blot analysis revealed that GCRG224 also expressed in human normal colon tissue, and peripheral blood leukocyte. *In situ* hybridization analysis showed that only 5/30 adenocarcinoma, 3/18 dysplasia and 6/18 intestinal metaplasia showed higher GCRG224 expression level than the normal gastric glands. However, GCRG224 was over-expressed predominantly in 26/30 cases of normal mucosal epithelium.

CONCLUSION: A novel gene named GCRG224 was identified from human gastric mucosal tissue. It

overexpressed in almost all gastric mucosal epithelium but only a small portion of cancer and precancerous lesions. The role of GCRG224 expression in gastric epithelium needs further study.

INTRODUCTION

Gastric cancer is one of the most commonly diagnosed malignancies and remains an important cause of mortality world wide^[1]. Considerable evidence supports the pivotal role of genetic factors in the pathogenesis of gastric cancer^[2-7]. However, the mechanism of the process of multistage carcinogenesis is still unknown for gastric cancer. Abundant clinical and histopathological data suggest that most, if not all, intestinal-type gastric cancer arise from precancerous lesions, which indicated intestinal-type gastric cancer to be an excellent model for studying the genetic alterations involved in the development of human neoplasms. It would be desirable, therefore, to screen directly from human intestinal-type gastric cancer and its precursor lesions the differentially expressed genes that are closely related to human gastric cancer.

In this study, differential display reverse transcription polymerase chain reaction (DDRT-PCR) analysis was used to identify and characterize differentially expressed genes in human gastric cancer tissues in comparison with their surrounding paratumor and nontumor counterparts. One novel cDNA with a complete cds was identified. We designated this gene as gastric cancer related gene 224 (GCRG224). Expression of GCRG224 in gastric tissues was analyzed using RT-PCR and *In situ* hybridization (ISH).

MATERIALS AND METHODS

Tissue acquisition

Fresh primary intestinal-type gastric adenocarcinoma, paratumor tissue which is 1.0 cm away from the tumor mass and their surrounding noncancerous stomach mucosal tissues obtained from 15 patients (11 male, 4 female, with average age 54±15 years) undergoing surgery were used for reverse transcription polymerase chain reaction (RT-PCR) analysis. 7 cases (4 male, 3 female, with average age 51±18 years) out of the 15 patients were used for differential display analyses. Paraffin embedded gastric adenocarcinoma and their corresponding normal gastric mucosal tissues obtained from 30 advanced gastric adenocarcinoma patients (21 male, 9 female, with average age 59±10 years) were used for ISH analysis. All tissues were histologically confirmed by pathologists.

RNA preparation and differential display

Total RNA was extracted from tissues using TRIzol reagent (Life Technologies, Inc., Rockville, Maryland). The fluorescent

DDRT-PCR procedure was performed essentially as described previously^[8]. The primers used in the assay included 4 T₁₂MN primers and 20 arbitrary oligonucleotide primers (ARP-1 to ARP-20) (Genomix Corporation, Foster City, CA).

Cloning and sequencing

The cDNA fragment of interest were subcloned into pGEM-T Easy vector (Promega Corporation, Madison, WI) and confirmed by EcoR I (Life Technologies, Bethesda, MD) digestion according to the manufacturer's instruction. Sequence analysis was performed with CEQTM 2000 DNA sequencer (Beckman Coulter, Fullerton, CA). The sequenced cDNA were analyzed via the BLAST program for homology matches in the GenBank database^[9].

Northern blot analysis

Samples containing 20 µg of total nontumor and tumor RNAs were fractionated on an 1.2 % agarose gel containing 5.5 % formaldehyde and 1×MOPS and transferred to a nylon membrane. Fix the RNA to the membrane by baking at 80 °C for 2 hours. Human multiple tissue Northern (MTN) blot II membrane (Clontech Laboratories, Inc., Palo Alto, CA) was used for analysis. Anti-sense cRNA probe labeled with digoxigenin was generated from a digested cDNA insert using Dig Northern Starter Kit (Roche Diagnostic Corporation, Indianapolis, IN) by means of *in vitro* transcription. The membrane was prehybridized and then hybridized according to the manufacturer's protocol. The results were detected using chemiluminescent detection.

RT-PCR

First-strand cDNAs were synthesized by SuperscriptII Rnase H⁻ reverse transcriptase (Life Technologies, Bethesda, MD) using oligo d(T) primers according to the protocol. PCR primers were designed using Primer Premier software (Premier biosoft international, Palo Alto, CA). The PCR primers used were: forward primer: 5' AAGGGTCACCTCTGTTCAAAGTG3', reverse primer: 5' GCAGGGTTTATGGGCTCAATAG3', Product length: 929 bp. G3PDH was used as internal control. Reactions were carried out in 10 µl solutions containing 100 ng cDNA, 0.2 µM of each primer, 50 µM of each dNTP, and 0.5 U of AmpliTaq DNA polymerase (Life Technologies, Bethesda, MD). The amplification conditions were (25 cycles): 1 min at 94 °C, 40 sec at 56 °C, 1 min at 72 °C.

In situ hybridization

Specimens were fixed in 10 % neutral buffered formalin and embedded in paraffin wax. A series of 5 µm sections were cut for analysis. The antisense cRNA probe was prepared according to procedure described in Northern blot analysis section. ISH was performed as described previously^[10,11]. Negative control (no probe applied) was performed. Slides were examined using an Olympus microscope. Images were captured using a cooled CCD camera (JVC, Japan). Cytoplasmic staining was noted.

Any appreciable blue staining was considered positive, and graded as ± if very light blue were barely detectable, 1+ if light blue staining were seen diffusely throughout the cytoplasm, 2+ if easily seen fine staining were present throughout the cytoplasm, and 3+ when dark blue were observed. Generally, more than 100 cells (nontumor or tumor) were quantified in each measurement and at least one measurement was taken per slide. H&E slides were then reviewed to determine diagnosis and to map the location of the various histological patterns and correlate with the staining patterns observed in the ISH preparations.

Informed consents

The study protocol was approved by the Institutional Review Board of the hospital under the guidelines of the 1975 Declaration of Helsinki. Written informed consents were obtained from patients.

RESULTS

Isolation of differentially expressed cDNA by DDRT-PCR in gastric cancer

In order to run the assay efficiently, among 80 combinations of primer pairs (4 T₁₂MN primers vs 20 ARP primers), 4 pairs able to amplify more bands in one set of paired tissues were chosen and used to amplify cDNA from 7 sets of paired tissues. One primer pair (T₁₂GG vs ARP-3: 5' GACCATTGCA3') was found to amplify genes expressed differentially in 7 of 7 sets of the paired tissues. As shown in Figure 1, in comparison with results in the normal tissues, a cDNA fragment (arrowed) was found to be more abundant in the tumor and paratumor samples in all tested patients. The results of mRNA differential display were reproducible. This differentially expressed cDNA band was named as W2.

Sub-clone and sequence analysis

Two subclones, GCRG213 and GCRG224, were identified from the subcloning procedure. GCRG213 consisted of 1 194 base pairs, while GCRG224 consisted of 1 159 base pairs and had one open reading frame (ORF). The GCRG224-ORF consists of 35 amino acids with an estimated molecular weight of 3.8 kDa. BLAST analysis revealed that GCRG224 nucleotide sequence had 98 % homologue with Homo sapiens clone RP11-718B12, but the deduced amino acid sequence of GCRG224-ORF had no homology with any known peptide in the GenBank database. GCRG224 nucleotide sequence data was submitted to GenBank with accession No.AF438406. Further bioinformatic study in the GenBank database showed that GCRG224 is located at human chromosome 11q14.

RT-PCR and northern blot analysis

To confirm the expression pattern of GCRG224 in human gastric cancer, we performed RT-PCR analyses in 15 cases of paired gastric adenocarcinoma, paratumor and non-tumor

Figure 1 Differential analysis of expressed genes among human gastric cancer, paratumor and normal stomach mucosal tissues by means of fluorescent differential display. The differentially expressed cDNA fragment W2 (arrowed) showed higher expression in tumor and paratumor tissues than that in normal ones. N: normal; P: paratumor; T: tumor; 1-7: patient number.

tissues. GCRG224 expressed higher in 11/15 gastric cancer tissues than non-tumor tissues. However, the result of Northern blot analysis was contrary to that of DDRT-PCR, the non-tumor tissue showed higher GCRG224 expression level than the tumor did (Figure 2a). MTN results showed that GCRG224 also expressed in human normal colon tissues and peripheral blood leukocyte (Figure 2b).

Figure 2 Northern blot analysis of GCRG224 expression in (a) human gastric cancer T/N pairs. T: tumor, N: non-tumor. (b) various adult human tissues. From left to right: spleen, thymus, prostate, testis, ovary, small intestine, colon, peripheral blood leukocyte.

In situ hybridization

GCRG224 expression was analyzed at mRNA level. The hybridization signal that appears as blue is restricted to the cytoplasmic portion. All normal gastric glands showed \pm 1+ staining. Only 5 out of 30 cases of adenocarcinoma had 2+ staining while the rest had \pm staining. Of the 18 cases of intestinal metaplasia (IM) and dysplasia found in the paratumor site, 6/18 IM and 3/18 dysplasia had 2+ staining, respectively. Interestingly, in 26/30 cases the gastric mucosal epithelial cells were stained 2++3+ (Table 1, Figure 3).

Figure 3 ISH analysis of GCRG224-ORF mRNA in formaldehyde-fixed, paraffin-embedded gastric tissues with a digoxigenin-labeled anti-sense probe, NBT/BCIP was used as

alkaline phosphatase substrates, the expression appeared as cytoplasmic staining (blue precipitates). (a): Mild expression in tumor (left) and intestinal metaplasia glands (right) (200 \times); (b): Strong expression in gastric mucosal epithelium cells, while the adjacent normal gastric glands showed little staining (200 \times).

Table 1 GCRG224 expression in different types of cells in gastric mucosa

	gastric mucosal epithelium	Gastric glands	IM	DYS	adenocarcinoma
\pm	0	19	8	13	25
1+	4	11	4	2	0
2+	15	0	6	3	4
3+	11	0	0	0	1
Total	30	30	18	18	30

DISCUSSION

Advances in molecular biology have revealed a consistent set of genetic alterations that may correspond to multi-step stomach cancer development. Aberrant expression and amplification of oncogenes such as c-met, c-myc, K-ras, c-erbB-2^[12-16], etc., inactivation of tumor suppressor genes such as p53, p16, Rb, DCC, APC, PTEN^[17-24], etc, DNA ploidy and microsatellite instability^[25-28], abnormal transcript of genes related to metastasis like nm23, CD44, E-cadherin^[29,30], etc., are reported common events in the steps of carcinogenesis. Newly found cancer related genes such as COX-2, survivin, metallothionein II and RUNX3, etc. were also expressed abnormally in gastric cancer^[31-38]. Recognition of genetic factors had also improved the the treatment of cancer^[39-41]. However, very little is currently known about genes that may predispose us to gastric cancer. The primary aim of this study was to identify genes that were closely related to human gastric cancer by means of DDRT-PCR.

DDRT-PCR has been widely applied to identify cancer-related genes^[42-47], some of these genes look like to be of clinical value. It might reflect the true patterns of genetic changes in human gastric cancer if we identify gastric cancer-related genes directly from human gastric tissues.

One of the defects when using tissues for DDRT-PCR analysis is that some cDNA fragments amplified in the tumor tissues may actually originate from normal cells present in the tumor tissues, which may affect the results of the analyses. In order to decrease the chance of error in this study, we used 7 sets of tumor, paratumor and non-tumor tissues for the assay, displayed the results simultaneously and chose interesting bands showing distinctive patterns in all sets of specimens. One cDNA fragment which is up-regulated in gastric cancer tissues was identified. However, two subclones were identified from the subsequent subcloning procedure. Sequencing results revealed that these two subclones contained nucleotides of nearly the same size but of totally different sequences. This should be the result of PCR amplification in which arbitrary primers were used.

Because the deduced amino acid sequence of GCRG224-ORF had no homology with any known peptide in the GenBank database, further study was focused on this gene. The result of RT-PCR analysis was consistent with that of DDRT-PCR, but Northern blot analysis revealed an opposite result. Furthermore, ISH analysis also failed to see a general higher expression of GCRG224 in tumor cells. On the other hand, ISH showed an extensively strong expression of GCRG224 in gastric mucosal epithelial cells in almost all tested cases. This indicated GCRG224 might come mainly from normal gastric epithelium

other than tumor cells. Although the tissues applied for DDRT-PCR, Northern blot and RT-PCR in this study were examined by pathologists before their usage, they were actually a mixture of different types of cells, the exact percentage of tumor and non-tumor cells in each tissue could not be identified, this resulted in the contradiction we faced. It would be better, therefore, to separate different types of cells using techniques such as microdissection in tissues like gastric mucosa prior to the analyses^[48-51].

Correlations between prognoses and the expression of genes such as p53, ras, myc, nm23, etc. were studied extensively in gastric cancer^[15-17,52-57]. However, the results turned out to be controversial. It is meaningful to find a biomarker that might predict the diagnosis or prognosis of gastric cancer. The consistent over-expression of GCRG224 in all tested tumor tissues in the DDRT-PCR and RT-PCR analyses prompted us to study further the expression pattern of GCRG224 in gastric mucosal tissues using ISH. However, GCRG224 did not show the expression pattern in gastric cancer and its precancerous lesions as RT-PCR revealed. Only around 20 percent tumor and precancerous lesions showed GCRG224 over-expression comparing with their normal gastric glands. Thus, GCRG224 may not serve as a potential marker for the diagnosis of gastric cancer.

A significant finding in this study is the extensive staining of GCRG224 in gastric epithelium. Up till now, the function of gastric mucosal cells is believed to be a barrier of the stomach as well as secretion of alkali and other ions such as Na⁺, K⁺ and Cl⁻. It will be of great interest to study the role of GCRG224 expression in gastric mucosal epithelium.

Abstract

AIM: To detect the expression of PTEN encoding product in normal mucosa, intestinal metaplasia (IM), dysplasia and carcinoma of the stomach, and to investigate its clinical implication in tumorigenesis and progression of gastric carcinoma.

METHODS: Formalin-fixed paraffin embedded specimens from 184 cases of gastric carcinoma, their adjacent normal mucosa, IM and dysplasia were evaluated for PTEN protein expression by SABC immunohistochemistry. PTEN expression was compared with tumor stage, lymph node metastasis, Lauren's and WHO's histological classification of gastric carcinoma. Expression of VEGF was also detected in 60 cases of gastric carcinoma and its correlation with PTEN was concerned.

RESULTS: The positive rates of PTEN protein were 100 % (102/102), 98.5 % (65/66), 66.7 % (4/6) and 47.8 % (88/184) in normal mucosa, IM, dysplasia and carcinoma of the stomach, respectively. The positive rates in dysplasia and carcinoma were lower than in normal mucosa and IM ($P < 0.01$). Advanced gastric cancers expressed less frequent PTEN than early gastric cancer (42.9 % vs 67.6 %, $P < 0.01$). The positive rate of PTEN protein was lower in gastric cancer with than without lymph node metastasis (40.3 % vs 63.3 %, $P < 0.01$). PTEN was less expressed in diffuse-type than in intestinal-type gastric cancer (41.5 % vs 57.8 %, $P < 0.05$). Signet ring cell carcinoma showed the expression of PTEN at the lowest level (25.0 %, 7/28); less than well and moderately differentiated ones ($P < 0.01$). Expression of PTEN was not correlated with expression of VEGF ($P > 0.05$).

CONCLUSION: Loss or reduced expression of PTEN protein occurs commonly in tumorigenesis and progression of gastric carcinoma. It is suggested that PTEN can be an objective marker for pathologically biological behaviors of gastric carcinoma.

INTRODUCTION

PTEN/MMAC1/TEP1 gene (phosphatase and tensin homology deleted from chromosome ten/mutated in multiple advanced cancer 1/TGF- β -regulated and epithelial cell enriched phosphatase 1) was the firstly defined tumor suppressor which product acted as phosphatase and shared extensive homology with cytoskeletal protein, mapping to human chromosome 10q23.3. PTEN encoding product could not only dephosphorylate the phosphatidylinositol-3, 4, 5-triphosphate (PIP₃), but also be involved in cytoskeletal reconstruction and cellular mobility^[1-6]. Recently, many studies showed there were several putative mechanisms relating to tumor suppression as follows: inhibiting cell invasion and metastasis by dephosphorylating focal adhesion kinase (FAK); inhibiting cell apoptosis and increasing cell growth by dephosphorylating PIP₃; restraining cell differentiation by inhibiting mitogen-activated protein kinase (MAPK) signal pathway^[7-9]. Mutation or abnormal expression of PTEN protein occurred commonly in multiple tumors and significantly correlates with tumorigenesis and progression of different malignancies^[10-20]. It was reportedly suggested that deletion or mutation of PTEN could enhance the expression of vascular epithelial growth factor (VEGF) and stimulate the proliferation of microvessels in tumor tissues, which in turn closely correlated with tumor invasion and metastasis^[21-28].

Gastric carcinoma was one of the commonest malignancies in the world, and even the most frequent in China^[29]. Although the achievement of early diagnosis and treatment have somewhat improved the patients' outcome, gastric cancer still remains the major killer among Chinese because the mechanisms of its tumorigenesis and progression were unclear^[30]. In this study, we detected the expression of PTEN proteins in gastric cancer and its adjacent noncancerous mucosa, compared PTEN protein expression with its pathologically biological behaviors, and discussed the relationship between the expression of PTEN and VEGF in order to explore the role of PTEN gene product in tumorigenesis and progression of gastric cancer, and to provide scientific foundation for evaluating prognosis of gastric carcinoma.

MATERIALS AND METHODS

Pathology

One hundred and eighty-four cases of surgically removed specimens of gastric carcinoma were collected from Cancer Institute, China Medical University. This study included 102 cases of adjacent normal mucosa, 63 cases of adjacent IM and 6 cases of adjacent dysplasia. According to clinical staging, 37 cases were early, and 147 cases advanced. According to metastasis, 124 cases were accompanied with lymph node metastasis, 6 with liver metastasis (4 of them with lymph node metastasis) and 2 with ovary metastasis. All gastric specimens were classified according to the Lauren's and WHO's histological classification criteria.

Immunohistochemistry

All specimens were fixed in 4 % formaldehyde solution,

embedded in paraffin and incised into 5 μm sections. The rabbit anti-human polyclonal antibody against PTEN (ready to use) and mouse anti-human monoclonal antibody against VEGF (ready to use) were purchased from Maixim Biotech. SABC complex kit was from Boster Biotech. For negative control, sections were incubated with PBS (0.01 mol/L, pH7.4) instead of the primary antibodies.

Evaluation of PTEN and VEGF expression

Clearly brown staining was restricted to cytoplasm, which was considered as positive for PTEN or VEGF. Slides were scored semi-quantitatively based on staining intensity and distribution. Two pathologists assessed the positive rate according to the percent of positive cells in all counted cells from 5 randomly selected representative fields. The degree of staining was graded in the light of proportion of positive cells as follows: negative (-), positive rate <5 %; weakly positive (+); 5-25 %; moderately positive (++) : 25-50 %; strongly positive (+++~++++): >50 %.

Statistical analysis

Statistical evaluation was performed by chi-square test to differentiate the rates between two groups. *P*-value less than 0.05 was considered as statistically significant. SPSS 10.0 software was employed to analyze all data.

RESULTS

PTEN was expressed in normal mucosa, intestinal metaplasia, dysplasia and carcinoma of the stomach at the rate of 100 % (102/102), 98.5 % (65/66), 66.7 % (4/6), 47.8 % (88/184), respectively. Dysplasia and carcinoma expressed less frequent than normal mucosa or intestinal metaplasia (*P*<0.01) (Table 1, Figure 1,2).

Figure 1 PTEN protein was restricted to cytoplasm. It was moderately expressed in normal mucosa (below), while decreased in IM (left top) and dysplasia (right), (20×)

Figure 2 Well differentiated papillary-tube adenocarcinoma showed weakly positive expression of PTEN protein (40×)

Table 1 PTEN expression in normal mucosa, intestinal metaplasia, dysplasia and carcinoma of the stomach

	<i>n</i>	PTEN expression		
		+~++++	-	%
“Normal” mucosa	102	102	0	100.0
Intestinal metaplasia	66	65	1	98.5
Dysplasia	6	4	2	66.7 ^a
Carcinoma	184	88	96	47.8 ^b

^aCompared with “normal” mucosa or intestinal metaplasia, *P*<0.01 (modified $\chi^2=18.729$, 7.115); ^bCompared with “normal” mucosa or intestinal metaplasia, *P*<0.01 ($\chi^2=80.106$, 52.499)

Positive rate of PTEN in advanced gastric carcinoma (AGC) was 42.9 % (63/147), lower than in early one (EGC)(67.6 %, 25/37) (*P*<0.01). In 124 cases with lymph node metastasis, 50 expressed PTEN protein (40.3 %), whose positive rate of PTEN was higher than those without lymph node metastasis (63.3 %, 38/60) (*P*<0.01). 41.5 percent of 118 diffuse-type gastric cancers expressed PTEN, less than that of intestinal-type ones (51.8 %, 37/64). Signet ring cell carcinoma expressed PTEN protein at the lowest level (25.0 %, 7/28), more than well and moderately differentiated adenocarcinoma (61.8 %, 21/34) (*P*<0.01).

None of the gastric normal mucosa showed expression of VEGF, while 75.0 percent of gastric carcinoma expressed it (45/60) (*P*<0.05) (Figure 3,4). The PTEN-positive cases expressed VEGF at the rate of 78.1 % (25/32), whereas PTEN-negative ones did it at the rate of 71.4 % (20/28). Both rates were not significantly different by statistical analysis (*P*>0.05).

Figure 3 Mucinous adenocarcinoma of the stomach moderately expressed VEGF (20×)

Figure 4 SRC showed strongly positive expression of VEGF protein (40×)

Table 2 Relationship between expression of PTEN and the biological behaviors of gastric carcinoma

	n	PTEN expression		%

^dCompared with well and moderately differentiated gastric carcinoma, $P<0.01(\chi^2=8.380)$

DISCUSSION

Deletion or down-regulation of tumor suppressing genes plays an important role in the multiple steps of tumorigenesis and progression of gastric carcinoma. Previous studies on the relationship between alteration of tumor suppressor genes and the development of gastric carcinoma focused on p53^[31, 32], p16^[33], p27^[34], p33 (ING1)^[35], RB^[36], DCC^[37] etc. However, few reports were involved in the newly discovered tumor suppressing gene- PTEN in tumorigenesis and progression of gastric carcinoma.

As a tumor-suppressing gene, PTEN makes great contribution to cellular differentiation, reproduction and apoptosis, as well as cellular adhesion and mobility. Some studies showed down-regulation of PTEN protein expression due to genetic changes like mutation, loss of heterozygosity, hypermethylation in gastric cancer, prostate cancer and breast cancer^[2,14,16,19,38]. Our results showed that decreased expression of PTEN during the courses of normal mucosa→intestinal metaplasia→dysplasia→carcinoma. Gastric dysplasia or carcinoma expressed less PTEN than normal mucosa or intestinal metaplasia ($P<0.01$), revealing that genetic changes of PTEN gene may play an important role in malignant transition of epithelial cells of gastric mucosa.

Low expression of PTEN gene product was involved in clinicopathological stage and metastasis of stomach neoplasms. We found that 42.9 percent of AGC expressed PTEN, less than EGC ($P<0.01$). Positive rate of PTEN was lower in gastric cancer with than without lymph node metastasis (40.3 % vs

63.3 %, $P<0.01$). One of the six liver metastases showed negative expression of PTEN in primary or liver metastasis, while the other five cases with liver metastasis showed reduced expression of PTEN protein. These results were similar to other kinds of tumors^[39-46]. It is suggested that deletion or reduced expression of PTEN protein probably facilitate the metastatic ability of gastric cancer cells. Hwang *et al.* found that PTEN could enhance mobility and metastasis of tumor cells by regulating matrix metalloproteinases (MMPs) and VEGF^[47]. There was another report that PTEN dephosphorated FAK so as to be involved in cellular adhesion^[7]. Deletion or reduced expression of PTEN could result in decreasing cellular adhesion, increasing synthesis of MMPs and VEGF, which subsequently contributed to invasion and angiogenesis of cancer cells. These biological effects possibly underlay prelude of invasion and metastasis of tumor. Our results revealed that reduced expression of PTEN was implicated in progression of gastric cancer probably by decreasing cellular adhesion, increasing cellular mobility and angiogenesis and could act as an objective marker to reflect the biological behaviors of gastric cancer.

In addition, signet ring cell carcinoma showed the lowest expression of PTEN among histological classifications, less than well and moderately differentiated adenocarcinoma ($P<0.01$), suggesting that decreased expression of PTEN was closely associated with carcinogenesis of signet ring cell carcinoma. Diffuse-type cancer showed less expression of PTEN at the rate of 41.5 % than intestinal-type one. ($P<0.05$). In this sense, it supported that there were different tumorigenic pathways between diffuse and intestinal -type gastric carcinoma. Diffuse-type gastric cancer, main part of which was signet ring cell carcinoma, showed diffusely invasive growth pattern. It is possible that down-regulation of PTEN could affect the function of cellular skeleton, mobility and adhesion of cancer cells.

Some reports suggested that decreased expression of PTEN encoding product could down-regulate PI₃K/AKT pathway, leading to increasing synthesis of VEGF induced by hypoxia inducing factor-1 (HIF-1)^[48-50]. Our study showed that 75.0 percent of gastric carcinomas expressed VEGF (45/60), significantly more than normal mucosa (0/5) ($P<0.05$), indicating that VEGF was up-regulated in gastric cancer. But PTEN was down-regulated in gastric cancer. Both PTEN and VEGF showed negative correlation, which was not statistically significant ($P>0.05$). The relationship between expression of both PTEN and VEGF in tumorigenesis and progression of gastric cancer need proving by amplifying the sample.

In all, loss or reduced expression of PTEN protein occurred commonly in gastric carcinogenesis. Altered expression of PTEN contributed to progression of gastric cancer by increasing cell adhesion, angiogenesis, cell mobility and so on. It was suggested that PTEN could be a useful marker for pathologically biological behaviors of gastric carcinoma. However, the role of PTEN gene and its encoding protein in tumorigenesis and progression of gastric cancer need further investigation.

Abstract

AIM: To elucidate the relationship between lymph node sinuses with blood and lymphatic metastasis of gastric cancer.

METHODS: Routine autopsy was carried out in the randomly selected 102 patients (among them 100 patients died of various diseases, and 2 patients died of non-diseased reasons), their superficial lymph nodes locating in bilateral necks (include supraclavicle), axilla, inguina, thorax, and abdomen were sampled. Haematoxylin-Eosin staining was performed on 10 % formalin-fixed and paraffin-embedded lymph node tissue sections (5um). The histological patterns of the lymph sinuses containing blood were observed under light microscope. The expression of CD31, a marker for endothelial cell, was detected both in blood and non-blood containing lymph node sinuses with the method of immunohistochemistry.

RESULTS: Among the 1322 lymph nodes sampled from the autopsies of 100 diseased cases, lymph node sinuses containing blood were found in 809 lymph nodes sampled from 91 cases, but couldn't be seen in the lymph nodes sampled from the non-diseased cases. According to histology, we divided the blood containing lymph node sinuses into five categories: vascular-opening sinus, blood-deficient sinus, erythrophago-sinus, blood-abundant sinus, vascular-formative sinus. Immunohistochemical findings showed that the expression of CD31 was strongly positive in vascular-formative sinuses and some vascular-opening sinuses while it was faint in blood-deficient sinuses, erythrophago-sinuses and some vascular-opening sinuses. It was almost negative in blood-abundant sinus and non-blood containing sinus.

CONCLUSION: In the state of disease, the phenomenon of blood present in the lymph sinus is not uncommon. Blood could possibly enter into the lymph sinuses through the lymphaticovenous communications between the veins and the sinuses in the node. Lymph circulation and the blood circulation could communicate with each other in the lymph node sinuses. The skipping and distal lymphatic metastasis of gastric cancer may have some connection with the blood containing lymph node sinuses.

INTRODUCTION

It is well known that one of the most common behaviours of lymphatic metastasis of gastric cancer is their great tendency to produce skipping metastasis with the tumor emboli traversing the proximal lymph nodes encountered on their route or even bypassing them to form distant nodal metastasis (mainly at left supraclavicle). Skipping metastasis is a peculiar kind of lymphatic metastasis. Until now, there have been few reports of this condition and its pathogenesis has not yet been clarified. Blood present in lymph node sinuses is a phenomenon that haven't been deeply researched too. In the routine lymph node biopsy, erythrocytes in the lymph node sinuses could occasionally be seen. In the early literature, vascular transformation of lymph node sinus (VTS) and haemal lymph node sinus (HLs) have been reported. Their common feature is blood presenting in the lymph node sinus. Since lymph node sinus is also the place where the metastatic malignant tumor is located, we speculated there might be some inner relationships between the two phenomena. The purpose of this study is to find out the relationship between lymph node sinuses with blood and lymphatic metastasis of gastric cancer.

MATERIALS AND METHODS

When routine autopsy was carried out in the randomly selected 102 patients died of different reasons, their superficial lymph nodes locating in the bilateral necks (include supraclavicle), axilla, inguina, thorax, and abdomen were sampled. Haematoxylin-Eosin staining was performed on 10 % formalin-fixed and paraffin-embedded 5 um lymph node tissue sections. The histological patterns of the lymph node sinuses containing blood were observed under light microscope. The expression of CD31, a marker for endothelial cell, was detected both in blood and non-blood containing lymph node sinuses by immunohistochemistry.

RESULTS

Clinical findings

The randomly selected 102 cases included 62 males and 38 females whose ages ranged from 2 months to 90 years (mean 45.08 years, median 57 years). Among the 102 cases, 100 patients died of various diseases, and 2 died of non-diseased reasons. The total number of the sampled lymph nodes was 1 362 (1 322 from the 100 patients died of various diseases and 40 from the 2 patients died of non-diseased reasons).

Light microscopic findings

Among the 1 322 lymph nodes sampled from the 100 autopsy diseased cases, blood containing lymph node sinuses were found in 809 lymph nodes sampled from 91 cases, whereas such sinuses couldn't be seen in the lymph nodes sampled from the non-diseased cases. According to the histology, we divided the blood containing lymph node sinuses into five categories: vascular-opening sinus (in 338 lymph nodes from 68 cases), blood-deficient sinus (in 291 lymph nodes from 69 cases), erythrophago-sinus (in 344 lymph nodes from 69 cases), blood-

abundant sinus (in 80 lymph nodes from 34 cases), and vascular-formative sinus (in 364 lymph nodes from 82 cases). In the vascular-opening sinus, venules and/or capillaries in the cortex and medulla extended or opened directly in the lymph node sinuses. Through the opening, blood could enter into the sinus (Figure 1). Blood-deficient sinus was defined as a small quantity of erythrocytes present in the lymph node sinuses (Figure 2). When erythrocytes in the sinuses were phagocytosed, erythrophago-sinus appeared. When the sinuses filled with blood, we called it blood-abundant sinus (Figure 3). Vascular-formative sinus was defined as vascular formation in the sinuses. We could see short to long sinuous vascular slits or vascular channels with round or oval contours lined by flat or plump endothelium. The channels were either empty or filled with an amorphous lymph-like materials and some red cells, occasionally they were markedly engorged with blood (Figure 4).

Figure 2 Blood-deficient lymph node sinus HE×400

Figure 3 Blood-abundant lymph node sinus HE×100

Figure 4 Vascular-formative lymph node sinus HE×200

Immunohistochemical findings

Immunohistochemical findings showed that the expression of CD31 was strongly positive in vascular-formative sinuses and some vascular-opening sinuses while it was faint in blood-deficient sinuses, erythrophago-sinuses and some vascular-opening sinuses. It was almost negative in blood-abundant sinuses and non-blood containing sinuses.

DISCUSSION

One of the most prominent features of the behaviour of carcinomas is their great tendency to produce secondary growths in regional lymph nodes. The early lymphatic metastasis of cancers almost invariably appear in the lymph nodes in the direction of normal lymph flow and the marginal sinus is the place where the metastatic growths are initially situated for the afferent lymphatics of lymph node enter the marginal sinus^[1-7]. As for the spread of the tumor to the lymph nodes in the direction contrary to the normal lymph flow or the lymph nodes far from the primary carcinomas, what is called skipping metastasis, it has always been convinced to be the consequence of the cancerous occlusion of the principal lymphatics; the lymph flow is diverted or sometimes reversed, into collateral channels passing to neighbouring unaffected nodes. Skipping metastasis is a peculiar kind of lymphatic metastasis. It was mostly recognised in the metastasis of gastric cancer to the supraclavicular lymph nodes which could be found as the earliest clinical symptom^[8-11]. There have been some reports of this condition, but most were concerning with how to detect the metastatic foci and the relationship with clinical nodal stage^[12,13]. Few mentioned the pathogenesis of skipping metastasis. The presence of previously unknown lymphatic tracts have been reported to explain the phenomenon^[14]. The skipping of intact lymph nodes can also be explained by anatomically demonstrable intra- and perinodal short circuit connections. Apart from this, preexisting lymph node changes (silicosis, fibrosis) also play an important part^[15].

Blood present in lymph node sinus is a phenomenon that haven't been deeply researched. How the blood entering the sinus remains to be elucidated^[16-29]. It's well recognized that there are two circulations in the lymph node, one is the lymphatic circulation, the other is the blood circulation. They could communicate via the high endothelial venules (HEV) in the paracortex, but it is not certain whether there is some other pathway for the communication in human lymph node. In 1961, Pressman and Simon^[24] devised experiments in dog to show that there were some other lymphatic-venous communications in lymph node. They inferred that the lymph node contained numerous lymphaticovenous communications between the lymph node sinuses and the veins. This claim has such far

reaching implications that the work should be repeated both in the dog and in other species. When it come to the human lymph node, the studies of blood containing lymph node sinus were concentrated on the vascular transformation of sinuses (VTS) and Hemolymph nodes (HLs). The term VTS was first coined by Haferkamp *et al*^[16] in 1971 for a distinctive benign vasoproliferative lesion of lymph node, which needed to be distinguished from Kaposi's sarcoma(KS); venous obstruction was thought to be the underlying mechanism, but it was still controversial^[30,31]. VTS is characterized by conversion of nodal sinuses into capillary-like channels, often accompanied by fibrosis^[21,32]. Hemolymph nodes (HLs) were another target for the study of the communication between lymph circulation and blood circulation in the lymph node sinuses. HLs are unique lymph nodes, because their lymphatic sinuses contain numerous erythrocytes. In 1969, Turner DR^[25] reported that blood entered the sinus through the communication between venule and sinuses, but it is still controversial^[26-29]. From the above-mentioned phenomenons and the researches, we hypothesized that the two circulations in the lymph node could communicate in the lymph node sinus.

In this study, blood in the lymph node sinuses could be found frequently in the lymph nodes sampled from the patients died of disease. The histologic patterns of the changes were not limited to HLs and VTS. According to the histologic patterns, the blood containing lymph node sinuses were divided into 5 categories. Vascular-opening sinus was characterized by venules or capillaries stretching into the sinus with blood in the vascular releasing into the lymph node sinuses (Figure 1). So that, it testified the existence of lymph-venule communication in human lymph node sinuses. Through the vascular-opening sinus, blood could enter the lymph node sinuses directly. This finding was in accordance with Pressman and Simon^[24]. Blood deficient sinus was possibly formed in the early period of the formation of sinuses containing blood, but the artifact factors should be excluded (Figure 2). The erythrophago-sinus was formed as a result of the phagocytosis of sinus-histocytes in the sinus. The red cells entered into the sinus were recognised as foreign bodies and engulfed by histocytes. When the pressure in venule increased for the stasis, plenty of red cells could rush into the sinus and the blood abundant sinus came into being due to the communication between lymph node sinus and venule (Figure 3). When the blood kept staying in the sinuses, an exceptional sinus containing blood -vascular formative sinus emerged. This kind of sinus was characterized by vascular formation in the lymph node sinus (Figure 4).

In order to clarify the features of endothelial cells of the lymph node sinus containing blood, monoclonal antibody CD31 was used to label the endothelial cells by immunohistochemistry^[33-36]. The expression of CD31 was different in the 5 blood contained sinuses. It was strongly positive in vascular-formative sinus and some vascular-opening sinus while it was weak in blood-deficient sinus, erythrophago-sinus and some vascular-opening sinus. It was almost negative in blood-abundant sinus and non-blood containing sinus. According to the expression of CD31 in different lymph node sinuses, we could speculated that the endothelial cells might experience the transformation from the lymph node sinus endothelial cells to the vascular endothelial cells. This course may have some connection with the blood in the sinuses^[37]. The Prompt recognition of the ultrastructure and the mechanism of the phenomenon was needed.

Since lymph node sinus is the place where the metastatic malignant tumor is located and we found in this study that in the state of disease, there was the communication between lymph and blood circulations in the sinus, we speculated there might be some inner relationships between lymphatic skipping metastasis of gastric cancer and blood containing lymph node sinuses.

Early clinical observations let to the impressions that

carcinomas frequently spread and grew in the lymphatic system, whereas tumors of mesenchymal origin spread more frequently by way of the blood stream^[38]. In fact, this division is arbitrary because these two routes are actually interlinked and inseparable. Cancer cells may invade the lymphatics directly or gain access to them via blood vessels. Tumor cells can readily pass from blood to lymphatic communication via the interstitial spaces of lymph nodes and other tissues exist. When tumor cells entered the local blood circulation and was brought to the distant area, through the communications between the lymph circulation and the blood circulation in lymph node sinuses, they could enter the lymph node and stay in the lymph node sinuses where the foci of skipping metastatic tumors are formed. When the lymph circulation was obstructed, through the communication, blood metastasis of tumor cell could also be accelerated.

Although, lymph node sinus containing blood was only found in the cases died of disease in our study, it was not certain if this kind of lymph node could also be found in non-diseased cases, because such cases were limited. An in-depth study in a larger cohort of gastric cancer patients is needed to confirm whether lymph node sinus containing blood is also very common in such alived human lymph nodes, and their physiological and pathological significance in the skipping metastasis.

Abstract

AIM: To explore the inhibition of conjugated linoleic acid isomers in different purity (75 % purity c9,t11-, 98 % purity c9,t11- and 98 % purity t10,c12-CLA) on the formation of forestomach neoplasm and chemopreventive mechanisms.

METHODS: Forestomach neoplasm model induced by B(a)P in KunMing mice was established. The numbers of tumor and diameter of each tumor in forestomach were counted; the mice plasma malondialdehyde (MDA) were measured by TBARS assay; TUNEL assay was used to analyze the apoptosis in forestomach neoplasia and the expression of MEK-1, ERK-1, MKP-1 protein in forestomach neoplasm were studied by Western Blotting assay.

RESULTS: The incidence of neoplasm in B(a)P group, 75 % purity c9, t11-CLA group, 98 % purity c9,t11-CLA group and 98 % purity t10, c12-CLA group was 100 %, 75.0 % ($P>0.05$), 69.2 % ($P<0.05$) and 53.8 % ($P<0.05$) respectively and the effect of two CLA isomers in 98 % purity on forestomach neoplasia was significant; CLA showed no influence on the average tumor numbers in tumor-bearing mouse, but significantly decreased the tumor size, the tumor average diameter of mice in 75 % purity c9,t11-CLA group, 98 % purity c9,t11-CLA group and 98 % purity t10, c12-CLA group was 0.157 ± 0.047 cm, 0.127 ± 0.038 cm and 0.128 ± 0.077 cm ($P<0.05$) and 0.216 ± 0.088 cm in B(a)P group; CLA could also significantly increase the apoptosis cell numbers by 144.00 ± 20.31 , 153.75 ± 23.25 , 157.25 ± 15.95 ($P<0.05$) in 75 % purity c9,t11-CLA group, 98 % purity c9, t11-CLA group and 98 % purity t10,c12-CLA group (30.88 ± 3.72 in BP group); but there were no significant differences between the effects of 75 % purity c9,t11-CLA and two isomers in 98 % purity on tumor size and apoptotic cell numbers; the plasma levels of MDA in were increased by 75 % purity c9,t11-CLA, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA. The 75 % purity c9,t11-CLA showed stronger inhibition; CLA could also inhibit the expression of ERK-1 protein and promote the expression of MKP-1 protein, however no influence of CLA on MEK-1 protein was observed.

CONCLUSION: Two isomers in 98 % purity show stronger inhibition on carcinogenesis. However, the inhibitory

mechanisms of CLA on carcinogenesis is complicated, which may be due to the increased mice plasma MDA, the inducing apoptosis in tumor tissues. And the effect of CLA on the expression of ERK-1 and MKP-1 may be one of the mechanisms of the inhibition of CLA on the tumor.

INTRODUCTION

Conjugated linoleic acid (CLA) refers to a group of dienoic derivatives of linoleic acid that can be found in natural foods, such as the milk fat and meat of ruminant animals^[1-4]. CLA can also be synthesized in the laboratory and is available commercially as a dietary supplement and has shown to be non-toxic^[5]. In several animal experiments, supplementation of feeding with CLA showed an anticarcinogenic effect against chemical-induced cancers of the skin, forestomach, colon and breast^[6-9]. Moreover, of the individual isomers of CLA, c9,t11 isomer has been implicated as most active biologically because it is the predominant isomer incorporated into the phospholipids of cell membrane, however recent evidence showed the t10, c12-CLA isomer might also exert biological activity^[10]. To date, the sample used for animal experiment or cell experiment is the isomer mixture of conjugated linoleic acid which mainly containing c9,t11-, t10,c12-, t9,t11-, t10,t12-CLA. Potent anticarcinogenic effects have been attributed to a synthetic mixture of CLA containing c9,t11- and t9,c11-CLA (43 %) and t10,c12-CLA (45.3 %)^[7,11-14]. For example, CLA used in Ha's report contained c9,t11-, t10,c12-, t9,t11-, t10,t12-CLA which accounted for about 90 % of the material^[7]; Hubbard applied a mixture of CLA isomers with 32.5 % c9,t11-CLA and 32.5 % t10,c12-CLA isomers making up 66 % to mammary tumor metastasis^[14], etc. In summary, there were few reports assessing the effects of CLA monomer on the carcinogenesis in animal model.

Now the effect of CLA on carcinogenesis had been confirmed and there were evidences to support CLA action on the every stage of cancer, including initiation^[15,16], post-initiation (promotion)^[17,18], progression^[19] and metastasis^[14,20-22]. However the mechanisms through which CLA inhibits tumorigenesis are moot. Ha *et al*^[7] suggested an antioxidant mechanism; Schonberg reported that the biochemical mechanisms by which CLA exerted its anticancer activity possibly including the formation of cytotoxic lipid peroxidation products, but this might not be sufficient to explain all the effects of these naturally occurring isomers of CLA^[23]; Ip's data showed an effect on growth and development of certain types of mammary cells^[24,25]; Reduced formation of carcinogen-DNA adducts had been implicated^[15,16]; Durgam's work showed CLA inhibit cancer by influences on the oestrogen response system^[26]; Others suggested inhibition mechanisms of CLA including its effects on eicosanoid metabolism^[27-31], apoptosis^[32,33], the gene

expression such as stearoyl-CoA desaturase^[34,35], PPRA^[36-38], cyclin A,B(1), D(1) cyclin-dependent kinases inhibitors and (CDKI)(P16 and P21)^[39] ect.

In our research group, we found that 75 % purity c9,t11-CLA inhibit cancer incidence by 40 %; at the same time that 98 % purity c9,t11 and t10,c12-CLA showed stronger inhibition on human gastric cancer (SGC-7901) and breast cancer cells(MCF-7)^[39-42]. Our study was designed to investigate the inhibition effects of synthetically-prepared individual isomer of CLA in different purity (75 % purity c9,t11-CLA, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA) on the forestomach neoplasia induced by B(a)P and the mechanism whereby CLA acted as an anticarcinogen, especially in terms of lipid peroxidation, apoptosis and MAPKs pathway.

MATERIALS AND METHODS

Material

BP was purchased from Fluka Chemie AG of Switzerland. Salad oil was purchased from a local grocery. 75 % purity c9, t11-CLA, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA were provided by Dr. Ruihai Liu at Cornell University.

Treatment of mice (43)

KunMing mice, 6 to 7 wk of age, were purchased from Cancer Research Institute of HarBin Medical University in China. Two weeks later the animals were randomized by body weight and divided into 7 groups (15 mice/group). They were then subjected to a forestomach tumorigenesis as follows: each animal except animals in salad control group was given 0.2 ml salad oil solution per 20 mg body weight (1 mg BP in 0.2 ml of salad oil solution) by gavage and animals in salad control group were given 0.2 ml salad oil only twice every week for over after 4 wk. And the following diets were given after 2 weeks of giving BP and continue for 7 wk (Table 1). Beginning with the first intubation and continuing thereafter, the body weight and food intake were recorded twice weekly. All surviving mice were sacrificed 26 wk after the first dose of BP.

Table 1 The diets given after 2 wk of giving BP

Group	diets
Salad oil Control(A)	Standard diet+salad oil: fat(salad oil) concentration was 20 %
BP Control(B)	Standard diet+salad oil: fat(salad oil) concentration was 20 %
BP+75 % c9,t11-CLA(C)	Standard diet+salad oil+75 %c9,t11-CLA: Fat (salad oil) concentration was 20 %, CLA 0.8 %
BP+98 % c9,t11-CLA(D)	Standard diet+salad oil+98 % c9,t11-CLA: Fat (salad oil) concentration was 20%, CLA 0.5 %
BP+98 %t10,c12-CLA(E)	Standard diet+salad oil+98 %t10,c12-CLA: Fat (salad oil) concentration was 20 %, CLA 0.5 %

Gross pathology and histopathology

At termination of the study, the forestomach was removed. Tumor numbers and size were recorded, and then fixed in 10 % formalin and paraffin-embedded; 4 μ m sections were cut and stained with hematoxylin and eosin (HE).

Lipid peroxidation analysis

The TBARS test was used to measure malonaldehyde (MDA). The mouse plasma MDA levels was determined by TBARs kits (Jiancheng Biotechnology Institute, NanJing, P.R. China).

Measurement of apoptosis cell numbers in forestomach neoplasia

In situ Cell Death Detection Kit, Fluorescein, were purchased from Boehringer Mannheim. Briefly, Fixed and permeabilized

apoptotic tissue sections, incubated the tissue section with the TUNEL reaction mixture containing TdT and fluorescein-dUTP, detected the incorporated fluorescein with an anti-fluorescein antibody POD conjugate and at last visualized the immunocomplex with a substrate reaction were in light microscope. The apoptosis cell number was counted in 10³ cells.

Protein extract and western blotting

Three mice forestomaches in each group were homogenated and lysed in RIPA buffer (150 mM NaCl, 0.1 % NP40, 0.5 % deoxycholic acid, 0.1 % SDS, 50 mM Tris, pH 7.4) with protease inhibitor, leupeptin and aprotinin. Equal amounts of protein (80 μ g/lane) were resolved by SDS-polyacrylamide gel electrophoresis, transferred onto nitrocellulose membranes, and immunoblotted with an mouse anti-MEK-1, rabbit anti-ERK-1 and rabbit anti-MKP-1 antibody, then incubated with horseradish peroxidase secondary antibodies. Immunoreactive bands were detected using DAB (diaminobenzidine tetrahydrochloride) substrate and analyzed with a ChemiImager™ 4 000 Low Light Imaging System (Alpha Innotech Corporation, at the same time used GAPDH as house-keeping protein.

RESULTS

Establishment of mouse forestomach model

Figure 1(A) showed the normal forestomach with smooth surface and without tumor. However, the white-yellow cauliflower-like neoplasia in different size appeared in the forestomach of mice induced B(a)P(Figure 1B,C). The structure of mouse forestomach in Figure 2(A) was normal and squamous epithelial cells and glandular epithelium cells were in order; The pathological analysis of B(a)P-induced forestomach neoplasia showed atypical hyperplasia in Figure 2(B) with stratified squamous epithelium excessively cornified, with focal proliferative basal cells and hypertrophic echinocyte; The basal cells, proliferating actively and out of order, grew through basement membrane and developed carcinoma *in situ* (Figure 2C).

Effect of CLA on forestomach neoplasia

The effect of CLA on BP-induced neoplasia of the forestomach in female KunMing mice was shown in Table 2. The incidence of the tumor and average diameter of tumor in 98 % purity c9, t11-CLA group and 98 % purity t10,c12-CLA group were significantly lower than that in B(a)P group ($P<0.05$). 75 % Purity c9,t11-CLA only decreased the tumor incidence which was no significant ($P>0.05$), but its influence on the average diameter being significant ($P<0.05$). The average tumor number of each tumor-bearing mouse showed no statistical significance ($P>0.05$).

Table 2 Inhibition of BP-induced forestomach neoplasia in female KunMing mice by CLA

Group	No. of mice (No. of tumor-bearing mice) /treatment	Total number of tumors	Tumor incidence (%)	Tumors/ tumor-bearing mouse ^d	Diameter/ tumor (CM)
A	14(0)	0	0	0	0
B	12(12)	31	100	2.58 \pm 0.90	0.216 \pm 0.088
C	12(9)	23	75.0 ^a	2.56 \pm 0.73	0.157 \pm 0.047 ^e
D	13(9)	22	69.2 ^{bc}	2.44 \pm 0.53	0.127 \pm 0.038 ^e
E	13(7)	21	53.8 ^{bc}	3.00 \pm 0.58	0.128 \pm 0.077 ^e

^a $P>0.05$ compared to the group B; ^b $P<0.05$ compared to the group B;

^c $P>0.05$ compared to the group C; ^d $P>0.05$, ^e $P<0.05$ compared to the group B

Figure 3 Apoptosis induced by CLA in mice forestomach. (A or B): there were few apoptotic cells in group A and B; (C): the apoptosis induced by CLA. Arrow showed apoptotic cells $\times 40$.

Analysis on lipid peroxidation

The plasma levels of MDA measured by the TBARS assay increased in mice treated by 75 % purity c9,t11-CLA, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA ($P < 0.05$). Moreover, 75 % purity c9,t11-CLA were more effective than purity 98 % c9,t11-CLA and 98 % purity t10,c12-CLA.

Table 3 The effects of CLA on mouse plasma lipid peroxidation

Group	MDA in plasma(nmol/L)
A	9.995 \pm 1.634
B	9.937 \pm 1.854
C	17.668 \pm 4.610 ^{ab}
D	14.005 \pm 4.116 ^a
E	13.303 \pm 3.593 ^a

^a $P < 0.05$ compared to the group A, B; ^b $P < 0.05$ compared to the group D, E.

The effect of CLA on apoptosis in forestomach neoplasia

Figure 3 showed the apoptosis in forestomach neoplasia. Table 4 showed that 75 % c9,t11-CLA, purity 98 % c9,t11-CLA and 98 % purity t10,c12-CLA can significantly induce apoptosis but with no statistical difference ($P < 0.05$).

Table 4 The effects of CLA on apoptosis in mice stomach(10^3 cells)

Group	Apoptotic cell numbers
A	42.63 \pm 6.02
B	30.88 \pm 3.72
C	144.00 \pm 20.31 ^a
D	153.75 \pm 23.25 ^a
E	157.25 \pm 15.95 ^a

^a $P < 0.01$ compared to the group A, B.

The effect of CLA on the MAPKs pathway

Figure 4, 5, 6 showed that 98 % purity t10,c12-CLA decreased

the expression of MEK-1 protein, but no influence was observed in mice treated by 75 % purity c9,t11-CLA and 98 % c9,t11-CLA. The expression of ERK-1 protein in 75 % purity c9,t11-CLA group, 98 % purity c9,t11-CLA group and 98 % purity t10,c12-CLA group was inhibited significantly, and 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA showed more effective than 75 % purity c9,t11-CLA. The expression of MKP-1 was increased in mice treated by 75 % purity c9,t11-CLA, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA.

Figure 4 The effect of CLA on the expression of MEK-1 protein.

DISCUSSION

To date, all of the *in vivo* work with CLA has been done with a commercial free fatty acid preparation containing a mixture of c9,t11-, t10,c12-, c11, t13-isomers, although food CLA is predominately the c9,t11-isomer present in triacylglycerols (80-90 %). Ha *et al* reported that dietary mixture of c9,t11-CLA, t10,c12-CLA, t9,t11-CLA and t10,t12-CLA significantly decreased the incidence of mouse neoplasm induced B(a)P (up to 20 %) [7]. In DMBA-induced mammary adenocarcinoma model, the incidence in mice treated with dietary 0.05 %, 0.1 %, 0.25 %, 0.5 % CLA isomer mixture was 58 %, 42 %, 34 %, 36 %, respectively (that of the control was 56 %) [9]. In this study, we found that the incidence in mice fed with diet containing 75 % purity c9,t11-CLA (75 %), 98 % purity c9,t11-CLA (69.2 %), 98 % purity t10,c12-CLA (53.8 %) had been decreased, moreover, 98 % purity isomers showed significant influences in the inhibition of carcinogenesis; although 75 % purity c9,t11-CLA decreased tumor incidence with no statistical significance, it still significantly decreased the tumor size; all of which suggested that the effect of CLA on carcinogenesis was possibly related to the CLA purity. In addition, the different isomers of CLA in different purities decreased the average diameter of the tumors, but no influence was observed in

average tumor numbers of each tumor-bearing mouse, which might be one of characteristics of the inhibition of food components on carcinogenesis.

Lu reported that arachidonic acid and linoleic acid may promote HSC proliferation, but increased concentration can be cytotoxic to HSC [44]. As one of the positional and structural isomer of linoleic acid, more interests in conjugated linoleic acid promoting oxidation in cancer cells were paid upon. The study results in Stanton's group showed that CLA could make breast cancer cell more susceptible to lipid peroxidation, moreover, the extent of lipid peroxidation of CLA treated cells was related to CLA-induced cytotoxicity against cancer cell lines. At the same time, they found that milk fat triglyceride-bound CLA, consisting primarily of the c9,t11 isomer, was also cytotoxic towards MCF-7 cells [45-47]. In our study, 75 % purity c9,t11-CLA, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA increased the levels of MDA in mouse plasma and 75 % purity c9,t11-CLA was most effective, but 75 % purity c9,t11-CLA did not show strongest inhibition of carcinogenesis, which suggested that the cytotoxic effect of lipid peroxidation to tumor cells might be one of mechanisms by which CLA exerted its biochemical activity. And Schönberg also reported that the formation of MDA induced by 40 $\mu\text{mol} \cdot \text{L}^{-1}$ CLA in lung adenocarcinoma cell lines was completely abolished by 30 microM vitamin E, but the growth rates were only partially restored, which indicated that cytotoxic lipid peroxidation products were only in part responsible for the growth inhibitory effects of CLA [24]. Furthermore, the lipid peroxidation product induced played important role in apoptosis [48]. We found that purity 75 % c9,t11-CLA, purity 98 % c9,t11-CLA and 98 % purity t10,c12-CLA induced significant apoptosis cells in forestomach neoplasia, but there were no differences between 75 % purity c9,t11-CLA group, 98 % purity c9,t11-CLA and 98 % purity t10,c12-CLA groups. The MAPK family consists of at least three different subgroups which include: ERKs, JNKs (SAPKs), and p38 MAPK kinase [49-53]. The Ras-Raf-MEK1/2-ERK1/2 pathway has been explained more clearly. Lavoie found that the transcription of cyclin D1 requires the long-term activation of ERK, which suggests that ERK can regulate cell cycle. In one report, there is a homeostasis between JNK/SAPKs and ERK systems: when ERK cascade is predominant in lymphocyte, cells will proliferate; by contraries, JNK/SAPK cascade will activate cell apoptosis [54]. It is found that the abnormalities of Ras/Raf/MAPK cascade reaction may contribute to malignant transformation of hepatocytes and activation of MAPK proteins may be an early event in hepatocellular carcinogenesis [55]. In summary, The activation of Ras-Raf-MEK-ERK can promote cell proliferation and inhibit cell apoptosis. In addition, The product of the immediate early gene MAP kinase phosphatase (MKP-1), is able to dephosphorylate phosphoserine/threonine as well as phosphotyrosine residues, and shows selectivity for ERKs 1 and 2 *in vitro*, with lower activity toward other MAP kinases such as JNK and P38 MAP kinase [56]. MKP-1 inactivates ERK following growth factor stimulation in intact cells and also suppresses signaling downstream of ERK at the level of gene transcription and proliferation [57], most likely through its inhibitory effects on MAP kinase. In our study, we found that CLA could inhibit the expression of ERK-1 protein, and at the same time inactivate the ERK-1 by increasing the expression of MKP-1, which might be one of mechanisms of CLA anticarcinogen.

In summary, it is confirmed that CLA shows inhibition on forestomach neoplasia induced by B(a)P, which is possibly related with CLA purity. Although the inhibition of different isomers (c9,t11- and t10,c12-CLA) on carcinogenesis is different, they show no significant difference. Moreover, the

inhibition mechanism of CLA is complicated and difficult to be explained by an mechanism.

ACKNOWLEDGEMENTS

We thank Dr. Rui-Hai Liu at Cornell University for helps and 75 % purity c9,t11-CLA, 98 % purity c9,t11-CLA, 98 % purity t10,c12-CLA.

Abstract

In the past few years, a variety of extradigestive disorders, including cardiovascular, skin, rheumatic and liver diseases, have been associated with *Helicobacter pylori* (*H. pylori*) infection. The activation of inflammatory mediators by *H. pylori* seems to be the pathogenetic mechanism underlying the observed associations. The present review summarizes the current literature, including our own studies, concerning the association between *H. pylori* infection and respiratory diseases.

A small number of epidemiological and serologic, case-control studies suggest that *H. pylori* infection may be associated with the development of chronic bronchitis. A frequent coexistence of pulmonary tuberculosis and *H. pylori* infection has also been found. Moreover, recent studies have shown an increased *H. pylori* seroprevalence in patients with bronchiectasis and in those with lung cancer. On the other hand, bronchial asthma seems not to be related with *H. pylori* infection.

All associations between *H. pylori* infection and respiratory diseases are primarily based on case-control studies, concerning relatively small numbers of patients. Moreover, there is a lack of studies focused on the pathogenetic link between respiratory diseases and *H. pylori* infection. Therefore, we believe that larger studies should be undertaken to confirm the observed results and to clarify the underlying pathogenetic mechanisms.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a slow-growing, microaerophilic, gram-negative bacterium, whose most striking biochemical characteristic is the abundant production of urease. This bacterium colonizes gastric mucosa and elicits both inflammatory and immune lifelong responses, with release of various bacterial and host-dependent cytotoxic substances^[1]. Pathological studies and extensive clinical trials, carried out in the past few years, have proved the causative role of *H. pylori* in the development of chronic gastritis^[2] and peptic ulcer disease^[3]. It seems that this bacterium is also causally related to low-grade B-cell lymphoma of gastric mucosa-associated-lymphoid-tissue (MALT-lymphoma)^[4]. Moreover, *H. pylori* infection has been established as a risk factor for the development of both diffuse and intestinal types of gastric cancer^[5].

Recent studies suggest an epidemiological association

between *H. pylori* infection and several extragastrointestinal pathologies, including cardiovascular, skin, rheumatic and liver diseases (Table 1)^[6,7]. Unfortunately, such epidemiological studies are influenced by a wide variety of confounding factors, i.e. socioeconomic status, time of acquisition of the infection, presence of different bacterial strains and previous antibiotic therapy. However, according to many authors, the observed associations might be true and explained by a role of *H. pylori* infection in the pathogenesis of certain extradigestive disorders. It is well known that *H. pylori* colonization of the gastric mucosa stimulates the release of various proinflammatory substances, such as cytokines, eicosanoids and proteins of the acute phase^[8]. Moreover, a cross mimicry between bacterial and host antigens exists in *H. pylori* infected patients^[9]. Therefore, a pathogenetic link between *H. pylori* infection and diseases characterized by activation of inflammatory mediators and/or induction of autoimmunity might exist.

Chronic inflammation and increased immune response have been observed in a variety of respiratory diseases, including chronic bronchitis^[10,11] and bronchiectasis^[12]. Moreover, both chronic obstructive pulmonary disease^[13,14] and pulmonary tuberculosis^[15] are more prevalent in peptic ulcer patients than in the general population. Based on these facts, many recent studies have focused on the potential association between *H. pylori* infection and various respiratory disorders. Table 2 summarizes those respiratory diseases whose relation with *H. pylori* infection has been studied in the literature.

The aim of the present report is to provide a critical review of the current literature, including our own studies, as regards the association between *H. pylori* infection and respiratory diseases.

Table 1^[6,7] Extradigestive diseases associated with *H. pylori* infection

Vascular diseases

Ischaemic heart disease
Primary Raynaud's phenomenon
Primary headache

Skin diseases

Idiopathic chronic urticaria
Rosacea
Alopecia areata

Autoimmune diseases

Sjogren's syndrome
Autoimmune thyroiditis
Autoimmune thrombocytopenia
Schoenlein-Henoch purpura

Other diseases

Liver cirrhosis
Growth retardation
Chronic idiopathic sideropenia
Sudden infant death
Diabetes mellitus

Table 2 Respiratory diseases studied for a relationship with *H. pylori* infection

Chronic bronchitis

Pulmonary tuberculosis
Bronchiectasis
Lung cancer
Bronchial asthma

HELICOBACTER PYLORI INFECTION AND CHRONIC BRONCHITIS

Chronic bronchitis is a pulmonary disease characterized by, primarily irreversible, airflow obstruction due to the chronic inflammation of the small airways. The presence of airflow obstruction that is not fully reversible is confirmed by spirometry (postbronchodilator FEV₁<80 % of the predicted value, in combination with an FEV₁/FVC<70 %). Although its true prevalence remains unknown, it is estimated that approximately 12.5 million persons in the United States suffer from chronic bronchitis^[16].

Chronic bronchitis had been associated with gastroduodenal ulcer many years before the identification of *H. pylori* infection as a cause of peptic ulcer disease. Three epidemiological studies, carried out between 1968 and 1986, showed that the prevalence of chronic bronchitis in peptic ulcer patients was increased two-to-three fold compared with that in ulcer-free controls^[13,14,17]. Moreover, a follow-up study demonstrated that chronic bronchitis was a major cause of death among patients with peptic ulcer disease^[18].

The reported association between these two diseases was originally attributed to the known role of cigarette smoking as an independent factor in both ulcerogenesis and development of chronic bronchitis. However, in 1998, Gaseli and colleagues carried out a prospective pilot study in a sample of 60 Italian patients with chronic bronchitis and found an increased seroprevalence of *H. pylori* infection compared to that detected in 69 healthy controls (81.6 % versus 57.9 % respectively, $P=0.008$). In this study, the odds ratio for chronic bronchitis in the presence of *H. pylori* infection, calculated after adjustment for age and social status, was 3.4^[19]. These results suggested, for the first time, that *H. pylori* infection per se might be related to an increased risk of developing chronic bronchitis. Two years later, a large epidemiological study in 3608 Danish adults showed that chronic bronchitis might be more prevalent in *H. pylori* IgG seropositive women than in uninfected ones (odds ratio 1.6, with a 95 % confidence interval of 1.1-2.5)^[20]. In order to further investigate the reported association between *H. pylori* infection and chronic bronchitis, we recently performed a case-control study in a cohort of 144 Greek patients with chronic bronchitis and 120 control subjects. Our results were in accordance with those of Gaselli and associates, as we also found that *H. pylori* seropositivity in patients was significantly higher than that in controls (83.3 % vs 60 %, $P=0.007$)^[21].

The mechanisms underlying the suggested association between *H. pylori* infection and chronic bronchitis remain unclear. This association might reflect either susceptibility induced by common factors or a kind of causal relationship between these two conditions. It is well known that age, sex and socioeconomic status are related with both *H. pylori* infection^[1] and risk of developing chronic bronchitis^[16]. However, in all mentioned studies above patients with chronic bronchitis were well matched with control subjects for these parameters. Tobacco use could be another confounding factor. Cigarette smoking is the major cause of chronic bronchitis^[16]. On the other hand, data on the relation between *H. pylori* infection and smoking habits are controversial. The prevalence of *H. pylori* infection in smokers has been variously reported as low^[22], normal^[23], and high^[24]. As the relation between smoking and *H. pylori* infection has not been clarified yet, the possible impact of cigarette smoking on both chronic bronchitis and *H. pylori* infection should be regarded as a potential limitation of the reviewed studies.

Unfortunately, there are no studies in the literature focused on the potential aetio-pathogenetic role of *H. pylori* infection in chronic bronchitis. Some authors hypothesized that the chronic

activation of inflammatory mediators induced by *H. pylori* infection might lead to the development of a non-specific inflammatory process, such as chronic bronchitis^[19,21]. It is well known that *H. pylori* and particularly those strains bearing the cytotoxin associated gene-A (cagA positive strains), stimulates the release of a variety of proinflammatory cytokines, including interleukin-1 (IL-1), IL-8 and tumour necrosis factor- α ^[25,26]. The eradication of *H. pylori* leads to normalization of serum cytokines levels^[27]. Recent studies showed that the same cytokines might be released during the course and exacerbations of chronic bronchitis^[10,11,28]. The underlying mechanisms, which induce and control this inflammatory process in chronic bronchitis, are still unclear. Therefore, we could hypothesize that *H. pylori* infection might play a proinflammatory role and co-trigger chronic bronchitis with other more specific environmental, genetic and unknown yet factors.

In conclusion, the primary evidence for an association between *H. pylori* infection and chronic bronchitis rests on serologic, case-control studies. Studies estimating the relative risk of developing chronic bronchitis for *H. pylori* infected patients and the effect of *H. pylori* eradication on the natural history of chronic bronchitis should be undertaken. The pathogenetic mechanisms underlying this association need also further evaluation. Future studies concerning this aspect should be focused on the prevalence of cagA positive *Helicobacter* strains and their induced proinflammatory markers, in patients with chronic bronchitis.

HELICOBACTER PYLORI INFECTION AND PULMONARY TUBERCULOSIS

Tuberculosis (TB) is a chronic bacterial infection caused by *Mycobacterium tuberculosis* and characterized by the formation of granulomas in infected tissues and by cell-mediated hypersensitivity. The lungs are primarily infected. However, any other organ may be involved. Although there is a lack of epidemiological evidence concerning the worldwide prevalence of TB, it has been estimated that one third of the world population is infected with *Mycobacterium tuberculosis* and there are ten million new cases of active TB each year. The vast majority of them occur in the developing countries, where TB remains a common health problem^[29].

In 1992, Mitchell *et al* carried out a large cross-sectional study concerning the *H. pylori* epidemiology in a southern China population. They found that a history of pulmonary TB might be associated with an increased prevalence of *H. pylori* infection^[30]. More recently, Woeltje *et al* assessed the prevalence of tuberculin skin test (TST) positivity in a cohort of 346 newly hospitalized patients. A history of peptic ulcer disease was one of the identified risk factors for a positive TST test (odds ratio: 4.53, $P=0.017$)^[31]. In order to further investigate the possible association between pulmonary TB and *H. pylori* infection, Sanaka *et al* performed, in 1998, a serologic case-control study in a hospitalized population. No difference in *H. pylori* seroprevalence among 40 inpatients on antituberculosis chemotherapy for less than three months, 43 TB patients on chemotherapy for more than three months and 60 control subjects was detected (73.3 %, 65 % and 69.8 % respectively, $P>0.5$ in all comparisons)^[32]. However, in this study the eradication of *H. pylori* by antituberculosis drugs could not be excluded. Rifampicin and Streptomycin, two drugs commonly used in antituberculosis regimens, are effective against *H. pylori* and decrease in *H. pylori* seroprevalence during antituberculosis therapy has been reported^[33,34]. Therefore, we recently carried out a case-control study focused on the seroprevalence of *H. pylori* in TB patients, before the initiation of antituberculosis treatment. A total of 80 TB patients and 70 control subjects, well matched for age, sex and social

status, were recruited into this study. We found that the *H. pylori* seropositivity in the TB group was significantly higher than that of controls (87.5 % vs 61.4 %, $P=0.02$). The mean serum concentration of IgG antibodies against *H. pylori* was also significantly higher in TB patients than in control subjects (39.0 ± 25.2 U/ml vs 26.1 ± 21.2 U/ml, $P=0.001$)^[35].

Taken together, data in the literature on the relationship between *H. pylori* infection and pulmonary TB are still insufficient. The observed frequent coexistence of both infections must be confirmed in a larger number of patients. This coexistence might reflect susceptibility to both *H. pylori* and *Mycobacterium tuberculosis* induced by common host genetic factors. It has been suggested that HLA-DQ serotype may contribute to enhanced mycobacterial survival and replication^[36]. Recent studies showed that the same serotype is also associated with increased susceptibility to *H. pylori* infection^[37,38]. Poor socioeconomic and sanitary conditions during childhood could be another factor responsible for the association between the two infections, as it is well known that in developing countries acquisition of both *H. pylori* and *Mycobacterium tuberculosis* occurs early in life^[39,40]. Therefore, we believe that studies focused on the common, either genetic or environmental, predisposition to both bacteria are needed.

HELICOBACTER PYLORI INFECTION AND BRONCHIECTASIS

Bronchiectasis is an abnormal and permanent dilation of bronchi, due to inflammation and destruction of the structural components of the bronchial wall. Persistent or recurrent cough, purulent sputum production and/or hemoptysis are symptoms presented during the clinical course of this disorder. A wide variety of respiratory infections, toxic substances and rare congenital syndromes are associated with the development of bronchiectasis. However, a great percentage of cases are of unknown cause^[41].

In 1998, Tsang *et al* found that the *H. pylori* seroprevalence in 100 patients with bronchiectasis (76 %) was higher than that in the controls (54.3 %, $P=0.001$). Further analysis in studied patients revealed an association between *H. pylori* seropositivity and 24-hours sputum volume ($P=0.03$)^[42].

As far as we know, the study of Tsang *et al* is the only report in the literature concerning the association between *H. pylori* infection and bronchiectasis. The authors hypothesized that the spilling or inhalation of *H. pylori* into the respiratory tract might lead to a chronic bronchial inflammatory disorder such as bronchiectasis. However, although *H. pylori* has been identified in the tracheobronchial aspirates in mechanically ventilated patients^[43], neither identification in human bronchial tissue nor isolation from bronchoalveolar lavage (BAL) fluid have been achieved yet^[1]. On the other hand, recent studies have shown that inflammation in bronchiectasis is primarily cytokine-mediated^[12,44]. Therefore, the activation of systemic inflammatory mediators by chronic *H. pylori* infection could represent a possible pathogenetic link between these two diseases.

In conclusion, the possible association between *H. pylori* and bronchiectasis seems intriguing and might have a pathogenetic basis. However, studies in larger series are needed to confirm this association and to clarify the underlying mechanisms. As pulmonary TB is a common cause of bronchiectasis, we believe that the increased prevalence of *H. pylori* infection in TB patients should be taken into account in the design of these future studies.

HELICOBACTER PYLORI INFECTION AND OTHER RESPIRATORY DISEASES

Lung cancer A recent study showed a higher *H. pylori* seroprevalence (89.5 %) among 50 patients with lung cancer than that in control subjects (64 %, $P<0.05$). The CagA strain

seropositivity was about thrice as high as in controls. (63 % vs 21.5 % respectively, $P<0.05$). Lung cancer patients were characterized by a significant increase of gastrin concentration in both serum and bronchoalveolar lavage (BAL). An enhanced m-RNA expression for gastrin and its receptor, as well as for cyclooxygenase (COX)-2, in the tumor tissue was also detected. Therefore, the authors hypothesized that *H. pylori* might contribute to lung carcinogenesis, via enhancement of gastrin synthesis. Gastrin might induce increased mucosal cell proliferation of bronchial epithelium and lead to atrophy and induction of COX-2, as it happens in gastric cancer. Finally, the authors proposed that *H. pylori* should be eradicated in lung cancer patients, in order to reduce the *H. pylori* provoked hypergastrinemia and COX-2 expression^[45].

Chronic bronchitis, which is associated with both lung cancer and *H. pylori* infection, might be a confounding factor in this study. Moreover, although some authors have also showed an increased gastrin concentration in serum and BAL fluid in lung cancer patients^[46,47], others did not confirm this finding^[48]. Therefore, we believe that before adapting the *H. pylori* eradication in lung cancer patients, further studies are needed to examine whether the reported epidemiological association between these two diseases has a pathogenetic basis. **Bronchial asthma** In 2000, Tsang *et al* estimated the prevalence of *H. pylori* infection in a cohort of 90 patients with bronchial asthma. *Helicobacter pylori* seroprevalence did not differ significantly between asthmatic and control subjects (47.3 % vs 38.1 %, $P>0.05$), while serum concentration of IgG antibodies against *H. pylori* did not correlate with spirometric values and duration of asthma. The authors concluded that bronchial asthma might not be associated with *H. pylori* infection^[49]. Moreover, as far as we know there is a lack of a theoretical hypothesis that might explain a possible association between these two diseases. Therefore, we believe that our knowledge on the association between *H. pylori* infection and respiratory diseases is unlikely to be advanced by more studies concerning the prevalence of *H. pylori* infection in patients with bronchial asthma.

CONCLUSIONS-FUTURE CHALLENGES

At present, the primary evidence for a link between *H. pylori* infection and respiratory diseases rests on case-control studies, concerning relatively small numbers of patients. Future studies should be large enough for moderate-sized effects to be assessed or registered reliably. The activation of inflammatory mediators by *H. pylori* infection might be the pathogenetic mechanism underlying the observed associations. Therefore, the role of genetic predisposition of the infected host, the presence of strain-specific virulence factors and the serum concentration of proinflammatory markers in *H. pylori* infected patients with respiratory diseases needs further evaluation. Finally, randomized control studies should be undertaken, in order to clarify the effect of the *H. pylori* eradication on the prevention, development and natural history of these disorders.

Abstract

AIM: To identify a molecular marker for gastric cancer, and to investigate the relationship between the polymorphism of pepsinogen C (PGC) gene and the genetic predisposition to gastric cancer.

METHODS: A total of 289 cases were involved in this study. 115 cases came from Shenyang area, a low risk area of gastric cancer, including 42 unrelated controls and 73 patients with gastric cancer. 174 cases came from Zhuanghe area, a high-risk area of gastric cancer, including 113 unrelated controls, and 61 cases from gastric cancer kindred families. The polymorphism of PGC gene was detected by polymerase chain reaction (PCR) and the relation between the genetic polymorphism of PGC and gastric cancer was examined.

RESULTS: Four alleles, 310bp (allele 1), 400bp (allele 2), 450bp (allele 3), and 480bp (allele 4) were detected by PCR. The frequency of allele 1 was higher in patients with gastric cancer than that in controls. Genotypes containing homogenous allele 1 were significantly more frequent in patients with gastric cancer than that in controls (0.33, 0.14, $\chi^2=3.86$, $P<0.05$). There was no significant difference between the control group of Zhuanghe and the group of gastric cancer kindred. But the frequency of allele 1 was higher in control group of Zhuanghe area than that in control group of Shenyang area and genotypes containing homogenous allele 1 were significantly more frequent in the control group of Zhuanghe area than those in control group of Shenyang area (0.33, 0.14, $\chi^2=4.32$, $P<0.05$). In the group of gastric cancer kindred the frequency of allele 1 was significantly higher than that in control group of Shenyang area (0.5164, 0.3571, $\chi^2=4.47$, $P<0.05$). Genotypes containing homogenous allele 1 were significantly more frequent in the group of gastric cancer kindred than those in control group of Shenyang area (0.36, 0.14, $\chi^2=4.91$, $P<0.05$).

CONCLUSION: These results suggest that there is some relation between pepsinogen C gene polymorphism and gastric cancer, and the person with homogenous allele 1 predisposes to gastric cancer than those with other genotypes. Pepsinogen C gene polymorphism may be used as a genetic marker for a genetic predisposition to gastric

cancer. The distribution of pepsinogen C gene polymorphism in Zhuanghe, a high-risk area of gastric cancer, is different from that in Shenyang, a low risk area of gastric cancer.

<http://www.wjgnet.com/1007-9327/9/50.htm>

INTRODUCTION

Gastric cancer is the second most common cancer in the world. Especially in China and other eastern Asian countries, the mortality of gastric cancer is still in the leading status of all cancers. The 5-year survival rate of gastric cancer is low, and identification and a better control of risk factors seem to be the most effective means of prevention. It was showed that many factors were ascribing to the cause of gastric cancer, including the living habit, nutrition^[1-3], microbe^[4-6], and genetic predisposition^[7-10]. Recently, following the primary completion of Human Genome Project, the association of genetic polymorphisms with diseases came to the study frontier^[11-14]. Genetic polymorphisms are defined as variations in DNA that are observed in 1 % or more of the population. The study of genetic polymorphisms promises to help define pathophysiologic mechanisms^[15,16], to identify individuals at risk for disease^[17-19] and to suggest novel targets for drug design and treatment^[20-24].

Pepsinogen C (PGC), also known as progastricsin, is the precursor of pepsin C or gastricsin. PGC can be detected throughout the stomach and proximal duodenum from the period of late infant stages to adult. Therefore it is also considered to be a mature marker of stomach cells^[25]. PGC consists of two electrophoretic isozymogens^[26]. No genetic variation was reported at the protein level. At the DNA level, however, an about 100bp insertion-deletion polymorphism was observed between exon 7 and exon 8 with several restriction enzymes. The polymorphism in PGC gene locus can be identified by both Southern blot and PCR methods.

In this study, we analyzed the PGC gene polymorphism of patients with gastric cancer and members with gastric cancer family history, and then examined the association between PGC gene polymorphism and gastric cancer.

MATERIALS AND METHODS

Patients

A total of 289 cases were involved in this study. 42 cases as health control came from the Blood Bank of the First Affiliated Hospital, China Medical University, whose health condition were checked up before blood was collected. 73 gastric cancer patients came from the Department of Oncology. 174 cases came from Zhuanghe, an area with high gastric cancer mortality, in the eastern Liaoning Province, China as described previously^[27], including 61 members from seven gastric cancer kindred families and 113 health controls whose family do not have gastric cancer history. In every gastric cancer kindred, at least two persons of the family are gastric cancer patients.

Analysis of PGC gene polymorphism

The genomic DNA from peripheral blood was amplified by PCR. The primers used were: upstream, 5'-AGCCCTAAGCCTGTTTTTGG-3'; and the downstream, 5'-GGCCAGATCTGCGTGTTTTA-3' [28]. The reaction mixture including 32.15pmol of each primer was subjected to 5 minutes at 95 °C; 35 cycles of one minute at 94 °C, one minute at 57 °C, one minute at 72 °C; with a final extension at 72 °C for 5 minutes. The amplification reaction proceeded in a thermocycler (PE-9 600). 12 µl of reaction mixture (50 µl in total volume) underwent electrophoresis in 2 % agarose gel, and the gel was stained with ethidium bromide.

Statistical analysis

The association between the polymorphism of PGC gene and gastric cancer was tested using χ^2 test, with significance assigned to values below $P<0.05$.

RESULTS

Detection of PGC gene polymorphism

After PCR, four alleles with different size were obtained: 310bp (allele 1), 400bp (allele 2), 450bp (allele 3), and 480bp (allele 4) (Figure 1). These results showed a little difference from the data showed by Southern blot, which demonstrated two different alleles (3.5kb and 3.6kb). According to the study of Ohtaki *et al.*, the 400bp, 450bp and 480bp of the PCR products correspond to the 3.6kb, and the 310bp correspond to 3.5bp of EcoRI fragments in Southern blot [28].

Figure 1 Analysis of PCR products. 1: The standard of molecule (174 HincII); 2-9: Genotype of samples--450bp/480bp; 310bp/310bp; 450bp/480bp; 310bp/310bp; 310bp/400bp; 400bp/480bp; 310bp/480bp; 310bp/310bp.

Distribution of PGC gene polymorphism

Ten different genotypes were obtained from the four alleles. Table 1 showed the distribution of these ten genotypes of PGC gene polymorphism in gastric cancer patients, members of gastric cancer kindred, health controls of Shenyang and Zhuanghe areas. Table 2 showed an estimated frequency of the four alleles in the four groups, and Table 3 showed the distribution of allele 1 homogenotype in above four groups. The frequency of allele 1 was higher in patients with gastric cancer than that in controls of Shenyang. Genotypes containing homogenous allele 1 were significantly more frequent in patients with gastric cancer than those in controls of Shenyang ($P<0.05$). In the group of gastric cancer kindred the frequency of allele 1 was significantly higher than that in control group of Shenyang area ($P<0.05$). Genotypes containing homogenous allele 1 were significantly more frequent in the group of gastric cancer kindred than those in control group of Shenyang area ($P<0.05$). The frequency of allele 1 was higher in control group

of Zhuanghe area than that in control group of Shenyang area and genotypes containing homogenous allele 1 were significantly more frequent in the control group of Zhuanghe area than those in control group of Shenyang area ($P<0.05$). There was no significant difference between the control group of Zhuanghe area and the group of gastric cancer kindred.

Table 1 The distribution of genotypes of PGC gene polymorphism in health control, gastric cancer patients, and gastric cancer kindred group

Genotypes	Controls (Shenyang)	Gastric cancer patients	Controls (Zhuanghe)	Gastric cancer kindred

DISCUSSION

Family members of gastric cancer patients have been found to have a 1.5-fold to 3-fold increase in the risk of developing this cancer [29]. This familial aggregation may be due to genetic or environmental factors shared by family members [30-32]. To understand the genetic predisposition to gastric cancer, we selected pepsinogen C gene as a marker gene, and focused first on the distribution of the PGC gene polymorphism in gastric cancer patient group and health control. After PCR,

four alleles of pepsinogen C gene with different size were obtained. The frequency of allele 1 was higher in patients with gastric cancer than that in controls. Genotypes containing homogenous allele 1 were significantly more frequent in patients with gastric cancer than those in controls. This result showed that there is relation between the pepsinogen C gene polymorphism and gastric cancer, and the person with homogenous allele 1 seems to predispose to gastric cancer than those with other genotypes.

To further study the relation of the PGC gene polymorphism to gastric cancer and the genetic background of Zhuanghe, the high-risk area of gastric cancer, we selected three groups as our next research objects: gastric cancer kindred group in Zhuanghe, the control group of Zhuanghe and the control group of Shenyang. There was no significant difference in the distribution of PGC gene polymorphism between the health control group of Zhuanghe and gastric cancer kindred group, though the frequency of allele 1 in gastric cancer kindred group was a little higher than that in the control group of Zhuanghe. Our understanding for this phenomenon was that the persons who lived in Zhuanghe did not move frequently because of the historical reason, and this consanguinity between the two groups was the main factor responsible for the above result. But the frequency of allele 1 was higher in control group of Zhuanghe area than that in control group of Shenyang area, and genotypes containing homogenous allele 1 were significantly more frequent in the control group of Zhuanghe area than those in control group of Shenyang area. The frequency of allele 1 in the group of gastric cancer kindred was significantly higher than that in control group of Shenyang area. Genotype containing homogenous allele 1 was significantly more frequent in the group of gastric cancer kindred than that in the control group of Shenyang area. The result showed the distribution of PGC gene polymorphism in Shenyang area was different from that in Zhuanghe area.

The mortality of gastric cancer in Zhuanghe area is more than 50 per five hundred thousand. In the low risk area of that cancer, such as Shenyang, however, the mortality is less than 10 per five hundred thousand. From gastric cancer kindred group, the control groups of Zhuanghe and Shenyang, the risk ratio of gastric cancer becomes lower in turn. The data in this study showed that the frequency of allele 1 and Genotype containing homogenous allele 1 in the gastric cancer kindred group, the control groups of Zhuanghe and Shenyang in turn decreases, which is consistent with the risk ratio of gastric cancer in the above three groups. Therefore, we could conclude that the polymorphism of PGC gene may be related to the predisposition of gastric cancer, and the allele 1 associated with the risk of gastric cancer.

The mechanism of the association between PGC gene polymorphism and gastric cancer is not clear, in this study however, several hypotheses can be proposed. One is that the PGC gene itself is one of the genes responsible for gastric cancer. PGC, distributed throughout the stomach and proximal duodenum, is an important enzyme in stomach. It was reported that PGC not only was a digestive enzyme, but also might be a growth factor during the healing of gastric lesions^[33] and the change of serum PGC was associated with many gastric diseases^[34-37]. The polymorphism of PGC gene is in the intron between exon 7 and exon 8. Whether this polymorphism could affect the expression of PGC gene or regulate the PGC gene expression when the stomach was attacked by some pathogenetic factors was not known. In the following study, we will concentrate on the association of the PGC gene polymorphism and the PGC gene expression. It is interesting to note that in this study the frequency of allele 1 of PGC in the group of gastric cancer kindred was also higher than that in the group of gastric cancer group. As we know, the members

of the gastric cancer kindred all come from Zhuanghe, a place in which the incidence of gastric cancer is higher, and so is that of some other gastric diseases. In the study of Ohtaki's group, their data showed the polymorphism of PGC gene was associated with gastric body ulcer^[28]. Comparing with our data, we can conclude the polymorphism of PGC is related to gastric lesions.

Another possible explanation of the association between the PGC gene polymorphism and gastric cancer was that the PGC gene was not itself responsible for the predisposition but one of the responsible genes was closely linked to it. It is interesting to note that the PGC gene was localized to human chromosome 6p21.1-pter by analysis of mouse x human somatic cell hybrids. The recent linkage analysis demonstrated that the PGC gene is 22cM proximal to HLA cluster which has been investigated to determine the associated with gastric disease^[38-41], between D6S5 and D6S4, at a distance of 4.5 and 13.1cM. Further molecular biological studies using polymorphism markers for this chromosome region will clarify whether PGC polymorphism is linked to disequilibria of the causative genetic variations for gastric cancer. Lastly, the presence of reduced penetrance, other modifier genes, or an interaction with the environment may explain the association.

Abstract

AIM: To investigate the relationship between *Helicobacter pylori* (*H.pylori*) infection and the expressions of the p53, Rb, c-myc, bcl-2 and hTERT mRNA in a series of diseases from chronic gastritis (CG), intestinal metaplasia type I or II (IMI-II), intestinal metaplasia type III (IMIII), mild or modest dysplasia (DysI-II), severe dysplasia (DysIII) to gastric cancer (GC) and to elucidate the mechanism of gastric carcinogenesis relating to *H.pylori* infection.

METHODS: 272 cases between 1998 and 2001 were available for the study including 42 cases of CG, 46 cases of IMI-II, 25 cases of IMIII, 48 cases of DysI-II, 27 cases of DysIII, 84 cases of GC. *H.pylori* infection and the expressions of p53, Rb, c-myc, bcl-2 were detected by means of streptavidin-peroxidase (SP) immunohistochemical method. hTERT mRNA was detected by *in situ* hybridization (ISH).

RESULTS: The expressions of p53, Rb, c-myc, hTERT mRNA and bcl-2 were higher in the GC than in CG, IM, Dys. The expression of c-myc was higher in IMIII with *H.pylori* infection (10/16) than that without infection (1/9) and the positive rate in DysI-II and DysIII with *H.pylori* infection was 18/30 and 13/17, respectively, higher than that without infection (4/18 and 3/10, respectively). In our experiment mutated p53 had no association with *H.pylori* infection, the expression of Rb was associated with *H.pylori* infection in GC, but the p53-Rb tumor-suppressor system abnormal in DysI-II cases, DysIII and GC cases with *H.pylori* infection was 21/30, 15/17 and 48/48 respectively, higher than non-infection groups (4/18, 3/10, 28/36). Furthermore the level of hTERT mRNA in GC with *H.pylori* infection (47/48) was higher than that without infection (30/36), however the relationship between bcl-2 and *H.pylori* was only in IMIII. C-myc had a close association with hTERT mRNA in DysIII and GC ($P=0.0253, 0.0305$ respectively).

CONCLUSION: In the gastric carcinogenesis, *H.pylori* might cause the severe imbalance of proliferation and apoptosis in the precancerous lesions (IMIII and GysIII) first, leading to p53-Rb tumor-suppressor system mutation and telomerase reactivation, and finally causes gastric cancer.

INTRODUCTION

Gastric cancer is one of the most fatal malignancies and in the world about 628 000 persons die of it every year. A close association between *Helicobacter pylori* (*H.pylori*) and gastric cancer has been found^[1-14], mainly on the basis of seroepidemiological data. Recently the animal models that developed gastric cancer owing to *H.pylori* infection provided powerful evidence^[15]. Although *H.pylori* has been classified as a type I carcinogen for gastric cancer by the International Agency for Research on Cancer (IARC)^[16], the exact nature and strength of the association with gastric cancer has remained indistinct.

A two-stage pattern has been introduced to explain the escape from senescence of the cultured human cells^[17,18]. The mortality stage 1 (M1) mechanism causes senescence, where normal human diploid cells become incapable of further division. However this cessation of cellular division can be overcome by the inactivation of human tumor suppressor genes p53 and Rb in fibroblasts^[18,19] that are mutated in a variety of human neoplasm. In non-neoplastic cells, wild type p53 modulates cell proliferation and differentiation by regulating the transcription of several gene products, inducing p21^{waf1} expression which acts as a regulator of the cell cycle at the G1 checkpoint^[20,21], and plays a crucial role in repairing damaged DNA through inducing GADD45 (growth arrest and DNA damage)^[22]. Moreover p53 induces the Bax gene, which is followed by apoptosis, in contrast to bcl-2^[23]. The cells which have overcome the M1 mechanism are able to divide until crisis occurs, which is caused by the mortality stage 2 (M2) mechanism. It is difficult for human cells to escape from this crisis, but in rare instances some populations can achieve immortality by overcoming this M2 mechanism through the reactivation of the enzyme telomerase^[24-29]. Telomerase is a unique ribonucleoprotein enzyme that is responsible for adding the telomeric repeats onto the 3' end of chromosomes and composed of a catalytic protein subunit (hTERT, for human telomerase reverse transcription) and a template RNA (TR), and hTERT is the rate-limiting enzyme in the telomerase complex^[30-34].

From all the above it is apparent that the understanding of the association of *H.pylori* infection with some genes (for example p53, Rb) as well as telomerase can contribute to the elucidation of the mechanisms that regulate the development of gastric cancer. The aim of the present study, therefore, was to examine this association by detecting the expressions of *H.pylori*, hTERT, p53, Rb, c-myc and bcl-2 in a series of gastric diseases.

MATERIALS AND METHODS

Patients

Two hundred seventy-two patients (174 men, 98 women, ranging in age from 21 to 80 years, mean 54.22 years) underwent endoscopy (noncancerous patients) or curative gastrectomy (gastric cancer patients) in our hospital between 1998 to 2001, including 42 cases of CG, 46 cases of IMI-II, 25 cases of IMIII, 48 cases of DysI-II, 27 cases of DysIII, 84 cases of GC diagnosed according to the updated Sydney System^[35] and the Japanese Research Society for Gastric Cancer^[36]. No patients had received chemotherapy or radiation therapy before surgery.

All specimens were fixed in 10 % buffered neutral formalin and embedded in paraffin and serial sections (4 µm thick).

Histochemical staining

Hematoxylin-eosin (HE) staining was used for the histopathological diagnosis, evaluation and grading of gastritis, atrophy, intestinal metaplasia, dysplasia and cancer. High iron diamine (HID)-alcian blue (AB) (PH 2.5)-periodic acid schiff (PAS) method was used to distinguish sulphates, neutral and acid mucus, which were stained brown-black, red and blue respectively. Using both morphological and histochemical criteria, the cases of intestinal metaplasia were classified into three types^[37].

Immunohistochemistry

Was performed using the streptavidin-peroxidase (sp) method. The following primary antibodies and the kit were used: monoclonal antibodies against p53, Rb, c-myc, bcl-2 and the kit (Maixin-Bio, Fujian), polyclonal antibodies against *H. pylori* (antibody, diagnostica Inc. USA). Dewaxed sections were heated in a microwave oven (700W) for 12 min to retrieve the antigens and cooled to room temperature. Endogenous peroxide was blocked by 3 % hydrogen peroxide (H₂O₂) for 15 min in methanol. After being washed with phosphate-buffered-saline (PBS, 0.01M), the sections were further blocked by 10 % rabbit serum for 15 min to reduce nonspecific antibody binding and then incubated with the primary antibodies of p53, Rb, c-myc, bcl-2 or *H. pylori* (1:60 dilution) at 4 °C overnight. After being washed with PBS for 2×5 min, the sections were incubated with the secondary anti-mouse immunoglobulin (Ig) conjugated with biotin at room temperature for 15 min, washed again with PBS, followed by incubation with streptavidin-peroxidase complex for 15 min. The reaction products of peroxidase were visualized by incubation with 0.05 M Tris-HCL buffer (PH7.6) containing 20 mg 3,3'-diaminobenzidine (Maixin-Bio, Fujian) and 100 µl 5 % hydrogen peroxide per 100 ml. Finally, the sections were counterstained for nuclei by hematoxylin solution. To examine the specificity of immunostaining, PBS was used to replace the primary antibodies as the control. The assessment of all the samples was conducted by an observer who did not know any details of this study by calculating the average ratio of positive cells (the nuclei or the plasma, staining brown-yellow) under ten 400× microscopes. If the ratio was more than 10 %, this

sample was considered positive. However the *H. pylori* immunostaining was assessed positive as long as the brown-black dotish, stake or bend material was stained on the surface of mucosa or in the gland's cave.

In situ hybridization

(ISH) was used to detect hTERT (human telomerase reverse transcriptase) mRNA. The probe (5' -CCCAG GCGCC GCACG AACGT GGCCA GCGGC-3') and the kit were bought from Boster Bio (Wuhan). Dewaxed sections were incubated with 3 % hydrogen peroxide for 30 min to reduce the non-specific binding and then with 1 µg/ml pepsin for 5-8 min to improve the penetration of the probe. The prehybridization was performed at 40 °C for 3 h to enhance hybridization efficiency, and the hybridization was conducted in a 42 °C water bath with each section covered with a coverslip, then the thorough washing procedure was followed: 2×SSC (sodium chloride and sodium citrate) at 37 °C for 15 min, 0.5 ×SSC for 15 min, 0.2×SSC for 15 min. Then the sections were visualized according to the kit manufacturer's instructions. We calculated the positive cells ratio to assess the positive sample by calculating the average ratio of positive cells (the plasma was stained brown-yellow) under ten 400× microscopes. If the ratio was more than 10 %, this sample was considered positive.

Statistics

The chi-square test and the Fisher's exact probability test were used to compute the frequencies by SPSS 10.0 for Windows. $P < 0.05$ was considered to be statistically significant.

RESULTS

With the development of the diseases from CG, IM, Dys to GC, the positive expressions of p53, Rb, c-myc, bcl-2 and hTERT mRNA were augmented significantly (Table 1). In particular, the frequencies of Rb, c-myc and hTERT mRNA in IMIII (8/25, 11/25, 4/25, respectively) were statistically higher than those in IMI-II (4/46, 8/46, 1/46, respectively) ($P < 0.05$). The expressions of all variables in GC were statistically higher than in DysIII and IMIII, higher in DysIII e than in IMIII ($P < 0.05$). In general the frequencies of them in *H. pylori* infection groups were higher than those in non-infection groups. The expression of c-myc was 10/10, 18/30,

Table 1 Expressions of c-myc, bcl-2, p53, Rb and hTERTmRNA in the different gastric diseases (%)

	GC	IMI-II	IMIII	DysI-II	DysIII	GC
c-myc	5(11.90)	8(17.39)	11(44.00)	22(45.83)	16(59.26)	74(88.09)

^a $P < 0.05$ vs the non-infected group.

13/17 in IMIII, DysI-II and DysIII with *H.pylori* infection respectively, higher than non-infection group (1/9, 4/18, 3/10, respectively). In our experiment mutated p53 had no association with *H.pylori* infection, the expression of Rb was associated with *H.pylori* infection in GC, but the p53-Rb tumor-suppressor system abnormal in DysI-II cases, DysIII and GC cases with *H.pylori* infection was 21/30, 15/17 and 48/48, respectively, higher than that in non-infection groups (4/18, 3/10, 28/36, respectively). The association between bcl-2 and *H.pylori* only existed in IMIII (9/16, 1/9). The expression of hTERT mRNA in GC with *H.pylori* infection was 47/48, higher than non-infection group (30/36) (Table 2). We also found the association between c-myc and hTERT mRNA in GC and DysIII ($P<0.05$) (Table 3).

DISCUSSION

Gastric cancer occurs after a multi-step process of alterations in oncogenes, tumor-suppressor genes, cell-adhesion molecules, telomerase as well as genetic instability at several microsatellite loci. Studies have demonstrated that *H.pylori* infection is closely associated with these abnormal alterations. Konturek's study^[38] showed that *H.pylori* induced apoptosis in gastric mucosa through upregulation of Bax and bcl-2 expression. The bcl-2 gene family plays an important role in regulating apoptosis. In our studies, *H.pylori* enhanced the expression of c-myc and bcl-2 significantly in IMIII ($P<0.05$). The c-myc protein is a critical component for the control of normal cell growth, but the altered c-myc activity by translocation, amplification, overexpression, and mutation is widespread in tumor cells and important for multi-step carcinogenesis^[39,40]. C-myc is a strong inducer of proliferation and it is believed to be critical for the oncogenic properties. Some studies showed that the abnormal c-myc expression derived cells inappropriately through the cell cycle, leading to uncontrolled proliferation, a characteristic of neoplastic cells. From our study we found that *H.pylori* infection caused a higher proliferation and a lower apoptosis in IMIII than in CG and IMI-II and accelerated cell proliferation, leaving a good chance for all kinds of genes and proteins to mutate or overexpress, presumably heightening the genetic instability consistent with the development of carcinoma^[41,42].

Mutations in the tumor suppressor genes p53 and Rb are common events in human cancers that exert their control on the cell cycle at the G1-S phase transition through independent but interconnected pathways^[43-50]. Williams' studies showed that germ-line mutation in p53 and Rb might have cooperative tumorigenic effects in mice^[51]. It has been generally accepted that p53 and Rb tumor-suppressor system, including p53, Rb, p16, p15, p14 and p21waf1^[52-60], play an important role in carcinogenesis. Some studies observed this phenomenon that NO (nitric oxide) generated by *H.pylori* caused p53 mutation at the spot C:G to A:T and at the same time p53 was found mutated at the same spot in IM, Dys and GC, thus *H.pylori* probably caused p53 mutation. In our study, we found that the expressions of p53-Rb were continually enhanced from chronic gastritis (3/42) to gastric cancer (76/84) and in the DysIII and

GC which had a close association with *H.pylori* ($P<0.05$). Chen^[61] reported that the mRNA levels of p53-Rb in gastric cancer were significantly lower than those in their non-cancerous tissues using quantitative analysis method. Some studies favored the view that c-myc drove initial proliferation and subsequent differentiation, concomitant with the activation of the p53 G2 checkpoint and also demonstrated that inactivation of the p53-Rb pathway is required for immortalization through overexpression of Myc^[62,63]. Although c-myc and p53-Rb had no direct association in our study, *H.pylori* infection might initially provoke the c-myc and bcl-2 more than in non-infection group in IMIII and then inactivate the p53-Rb tumor-suppress system in Dys and they collaborated in GC.

Telomerase activity has been found in 85-90 % of all human cancers but not in adjacent normal cells^[27]. It has thus been hypothesized that for a cancer cell to undergo sustained proliferation beyond the limits of cell senescence, it must reactivate telomerase or an alternative mechanism in order to maintain telomeres. This makes telomerase a target not only for the novel etiology agent but also a mark for cancer diagnosis. Many studies showed that telomerase activity was higher in cancers than in non-cancerous tissues and higher in IM than in CG^[64-69], which was similar to our results. The association between *H.pylori* infection and telomerase activity is still controversial. Suzuki's study^[67] indicated that hTERT mRNA which was expressed in precancerous lesions and gastric cancer could be induced at an early stage of gastric carcinogenesis, but it was not correlated with *H.pylori*. Kuniyasu^[70] found that *H.pylori* evidently caused the release of reactive oxygen species (ROMs) and reactive nitrogen species (NO) which might be strong triggers for "stem cell" hyperplastic in IM, followed by telomere reduction and increased telomerase activity as well as hTERT overexpression. We found in GC hTERT expression was significantly higher in infection group (47/48) than in non-infection group (30/36) but had no association in Dys or IM, maybe because there exist two different genetic pathways to two histological types: intestinal-type and diffuse-type gastric cancer. Some studies showed c-myc could stimulate expression of hTERT and thereby enhance telomerase activity which was an important step in carcinogenesis^[71-80]. In our study c-myc had an association with hTERT in Dys and GC, which suggests that *H.pylori* stimulates telomerase directly or indirectly by the overexpression of c-myc. We did not find the association between hTERT and p53-Rb or bcl-2.

There maybe exit this mechanism of gastric carcinogenesis relating to chronic *H.pylori* infection, which leads to imbalance of proliferation and apoptosis in the early stage, and furthermore p53-Rb tumor-suppressor system mutation, telomerase reactivation and finally gastric cancer generation. Hence this molecular pathology mechanism should be applied in routine diagnostic procedures, classification systems, disease monitoring, and even prognostic assessment.

ACKNOWLEDGMENTS

The authors thank the faculty of Department of Pathology and Wang Zhifeng of Stomatology of hospital for their excellent technical assistance throughout this investigation.

Abstract

AIM: To explore the influence of angiostatin up-regulation on the biologic behavior of gastric cancer cells *in vitro* and *in vivo*, and the potential of angiostatin gene therapy in the treatment of human gastric cancer.

METHODS: Mouse angiostatin cDNA was subcloned into the eukaryotic expression vector pcDNA3.1(+) and identified by restriction endonucleases digestion and sequencing. The recombinant vector pcDNA3.1(+)-angio was transfected into human gastric cancer cells SGC7901 with liposome and paralleled with the vector control and the mock control. Angiostatin transcription and protein expression were examined by RT-PCR and Western blot in the stable cell lines selected by G418. Cell proliferation and growth *in vitro* of the three groups were observed respectively under microscope, cell number counting and FACS. The cells overexpressing angiostatin, vector transfected and untreated were respectively implanted subcutaneously into nude mice. After 30 days the size of tumors formed was measured, and microvessel density count (MVD) in the tumor tissues was assessed by immunohistochemistry with the primary anti-VWF antibody.

RESULTS: The recombinant vector pcDNA3.1(+)-angio was confirmed with the correct sequence of mouse angiostatin under the promoter CMV. After 30 d of transfection and selection with G418, macroscopic resistant cell clones were formed in the experimental group transfected with pcDNA 3.1(+)-angio and the vector control. But no untreated cells survived in the mock control. Angiostatin mRNA transcription and protein expression were detected in the experimental group. No significant differences were observed among the three groups in cell morphology, cell growth curves and cell cycle phase distributions *in vitro*. However, in nude mice model, markedly inhibited tumorigenesis and slowed tumor expansion were observed in the experimental group as compared with the controls, which was paralleled with decreased microvessel density in and around tumor tissues ($P < 0.05$).

CONCLUSION: Angiostatin does not directly inhibit human gastric cancer cell proliferation and growth *in vitro*, but exerts its anti-tumor functions through antiangiogenesis in a paracrine way *in vivo*.

INTRODUCTION

Angiogenesis is indispensable for various physiological processes including reproduction, development, wound repair, and tissue regeneration. However, abnormal neovascularization is also involved in the development and progression of pathogenic processes in a variety of disorders, including diabetic retinopathy, psoriasis, chronic inflammation, lepra alphas, rheumatoid arthritis and cardiovascular diseases. Since Folkman put forward the hypothesis that malignant tumor is angiogenesis dependent, direct and indirect evidences have shown that tumor growth and metastasis are accompanied by the growth of new blood vessels, which proves the rationality and feasibility of anti-angiogenic therapy in treatment of cancer^[1,2]. Shifting the balance within the tumor microenvironment from overproduction of angiogenic stimulators toward an overproduction of angiogenic inhibitors represents one potential anti-angiogenic strategy^[3,4]. To date, a number of angiogenic inhibitors have been demonstrated to inhibit experimental tumor growth in animal models, and some of them have already entered clinical trials^[5].

Gastric cancer is a malignant neoplasm, for which the common treatment is suboptimal and the prognosis of patients remains dismal. It is suggested that tumor-mediated angiogenesis due to high levels of angiogenic stimulators and down-regulation of endogenous angiogenic inhibitors play a fundamental role in the pathogenesis of malignant gastric cancer^[6,7]. Molecular mechanisms of angiogenesis in gastric cancer have indicated an attractive therapeutic strategy by targeting those angiogenic regulators^[8].

Angiostatin, a potent specific inhibitor of proliferating endothelial cells, shows significant antiangiogenic and anticarcinogenic efficacies on various tumors *in vivo*. It specifically inhibits the proliferation, migration, and formation of capillary tubes *in vitro* or *in vivo*, and induces apoptosis in endothelial cells^[9-11]. Although no directed inhibition on tumor cell growth *in vitro* is observed, evidence shows that angiostatin inhibits the occurrence of the primary as well as metastatic tumor, and remains dormant. Systemic delivery of purified angiostatin protein, however, raises a number of difficult practical problems which make the large-scale implementation inefficient and/or inefficacious. And these problems also make it unavailable logically and pharmaceutically, including difficulties in producing large quantities of biologically active protein, the short half-life of such proteins *in vivo*, and the requirement for long-term intermittent or continuous treatment. The transfer of angiostatin gene, therefore, may represent a useful alternative delivery strategy. Transducing tissues at risk for tumor progression *in vivo* with genes encoding antiangiogenic proteins offers the potential of creating a local antiangiogenic microenvironment that can be stably maintained through continuous expression of the transduced transgene

from surrounding tumor cells.

We have constructed and administered eukaryotic vector encoding mouse angiostatin into human gastric cancer cells to further characterize the antitumor function of angiostatin and explore the potential activity in gene therapy for gastric cancer. Our data demonstrated statistically significant inhibition of tumor formation and growth in nude mice accompanied by decreased microvascular density and upregulation of angiostatin, meanwhile no cytostatic effect on gastric cancer cells was observed *in vitro*. These results suggested that the delivery of angiostatin gene may represent a potentially new treatment modality for malignant gastric cancer, accounting for antiangiogenic activity in a paracrine way on surrounding endothelial cells.

MATERIALS AND METHODS

Cell culture and reagents

The human gastric cancer cell line SGC7901 was obtained from the Japanese Cancer Research Resources Bank (Tokyo, Japan). Cells were cultured in RPMI1640 (Gibco) supplemented with 10 % fetal bovine serum (FBS) (Sijiqing, Hangzhou, China), penicillin (100 units/ml) and streptomycin (100 mg/ml) in a humidified atmosphere of 5 % CO₂ at 37 °C. Liposome (Tfx™ Reagent) was purchased from Promega Company; total RNA Isolation System (Sino-American Biotechnology Company) G418 from Gibco company; and bicinchoninic acid (BCA) protein assay kit was obtained from Pierce Chemicals (Rockford, Illinois).

Recombinant eukaryotic expression vector pcDNA3.1(+)-angio construction and transfection

Mouse angiostatin cDNA fragment encoding for the NH₂-terminal secretory signal sequence(SS) and kringle1-4(K1-4) regions of mouse plasminogen, fused with an antigenic epitope tag HA(HA tag) to the COOH terminus of kringle 4 was inserted into eukaryotic expression vector pcDNA3.1(+). The structure of the recombinant vector pcDNA3.1(+)-angio was confirmed by the restriction enzyme digest and DNA sequencing.

Gastric cancer cells SGC7901 in logarithmic growth phase were planted in 6-well plates at 5×10⁵ cells/well, and reached approximately 80 % confluent after overnight incubation on the day of the transfection. DNA/liposome (Tfx™ Reagent) complexes were prepared and transfected according to the protocol provided by the manufacturer. The experimental group was transfected with pcDNA3.1(+)-angio 2 µg/liposome 10 µL, the vector control with pcDNA3.1(+) 2 µg/liposome 10 µL and the mock control with liposome 10 µL. After 48 h of transfection, the selective medium containing G418 (400 mg/L) was used to culture cells for 30 d. Then the isolated resistant cell clones were then selected and amplified.

RNA dot blot analysis of angiostatin transcription

Total RNA was extracted with total RNA isolation system, resuspended in DEPC-treated water, quantitated with OD260 and OD280, and dotted onto nitrocellulose filters. The linear mouse angiostatin cDNA fragment was released from the vector pcDNA3.1(+)-angio and labeled with [α -³²P] in nick translation reaction as the probe. The specific activity of the probe was examined by TCA method. Hybrid was performed sequentially: prehybridized at 42 °C for 3 h, the probe denatured in water-bath at 100 °C for 10 min and cooled on ice for 5 min, hybridized at 42 °C overnight, washed in 2×SSC and 0.2×SSC at RT, and then hybrid signals were detected by autoradiograph.

Western blot analysis of HA-tagged protein

The cells were cultured in conditioned media for 5 d. Cell

supernatants was mixed with Lysine-sepharose and incubated at 4 °C overnight. The resin was washed with 50 mM Tris-HCl (pH8.0), and protein was eluted and stored at -20 °C. Protein concentration was determined by bicinchoninic acid assay (BCA) with bovine serum albumin as standard. Equal aliquots (40 µg) of protein from cell supernatants were subjected to electrophoresis on a 10 % sodium dodecyl sulfate (SDS)-polyacrylamide gel, followed by transfer to PVDF membranes (mMILLIPORE) using the transfer buffer for 2 hours and detection with the rabbit polyclonal anti-HA antibody (diluted 1:500; Santa Cruz Biotechnology, Santa Cruz, CA) overnight at 4 °C and a secondary peroxidase-conjugated goat anti-rabbit antibody (Santa Cruz Biotechnology, Santa Cruz, CA). Final detection was performed by the enhanced chemiluminescence (ECL) Western blotting analysis system.

Viable cell number counting and FACS analysis of cell cycle

Cell viability and cell growth *in vitro* were determined by cell number counting. Briefly, the three groups of cells were plated on 24-well plates at 1×10⁴ cells/well and cultured for 7 d. Everyday viable cell numbers of the three groups were counted under microscope.

Three groups of cells 3×10⁵ in the logarithmic growth phase were collected and fixed in 70 % ethanol overnight. After being dyed with PI at 4 °C avoid of light for 30 minutes, the cells through screening were checked in FACS to estimate the changes in cell cycle.

Animal studies

In vitro tumorigenesis assay. BalBc nude mice were randomly divided into three groups, 5 in each group and injected subcutaneously with gastric cancer cells SGC7901 at 1.2×10⁷ cells/mouse, the experimental group with pcDNA3.1(+)-angio/SGC7901, the vector control with pcDNA3.1(+)/SGC7901 and the mock control with SGC7901 untransfected. After 30 d, the mice were sacrificed to measure the size of tumor formed and calculate the percentage of inhibition on tumorigenesis *in vivo*.

Quantitative analyses for microvessel densities (MVD)

The tumor tissues were fixed and embedded in paraffin and MVD were detected by SABC method. Briefly, the sections were incubated with 0.3 % H₂O₂ and methanol for 30 min, blocked with normal goat serum at RT for 2 h, stained with a primary anti-mouse vWF monoclonal antibody at 4 °C overnight and then biotin-conjugated anti-mouse IgG antibody at RT for 1 h. After being incubated with ABC compounds for 40 min, DAB was used to develop color reaction. Under light microscope, MVD was counted in 4 fields (400×) selected randomly.

Statistical analysis

The results were verified by variance analysis and χ^2 analysis with SPLM statistical software offered by the Department of Statistics, the Fourth Military Medical University.

RESULTS

Identification of the recombinant eukaryotic expression vector encoding angiostatin cDNA

Angiostatin cDNA was cloned into an eukaryotic expression vector pcDNA3.1(+), under the cytomegalovirus promoter, encoding for the NH-terminal secretory signal sequence (SS), the preactivation peptide (PA), and kringle1-4(K1-4) regions of mouse plasminogen, and an antigenic epitope tag derived from the influenza HA fused to the COOH terminus of kringle4 (Figure 1). As shown in electrophoresis, the linear recombinant plasmid was about 7.0kb, and a fragment 1.4kb was released by restrictive digest with HindIII and XbaI, which confirmed

that the targeted gene was cloned into pcDNA3.1(+)-angio successfully (Figure 2). Gene sequencing showed that it had the same sequence as supposed.

Vector-mediated expression and secretion of angiostatin in vitro

To determine the level of transgene-encoded angiostatin transcription and protein expression and secretion, gastric cancer cells SGC7901 transfected with the corresponding vectors were selected by G418 for 30 d and formed macroscopic cell clones in the experimental and vector control groups (Figure 3). The mock group of cells, however, were dead completely after 7 d of selection. Strong RNA hybrid signals of angiostatin mRNA were detected in the experimental group of cell clones genetically engineered but not in the controls (Figure 4). Western blot analysis of cell supernatants (Figure 5) revealed the detected protein of the size consistent with angiostatin in the experiment group, whereas no specific band was observed in the controls.

Biological activity of angiostatin proteins expression *in vitro*

To assay for biological activity of the encoded angiostatin *in vitro*, tumor cells transduced with and without the corresponding vectors were cultured for 7 d to make cell growth curve (Figure 6). Under microscope, no obvious difference was observed in the cell morphology among the three groups of cells. And cell growth curves indicated no change in cell growth speed and doubling time among the three groups. Comparing the cell cycle of the three groups, no significant differences were found in the distribution of G0/G1, S and G2/M (Figure 7). These results indicated that up-regulated angiostatin expression neither directly inhibits cell growth and proliferation nor affects cell cycle *in vitro*.

Biological activity of angiostatin proteins expression *in vivo*

The macroscopic tumors were observed on day 7 after injection and expanded fast in the vector and mock control groups of nude mice. However, no tumors were observable until day 10 after injection in the experimental group of nude mice, and tumors expanded slowly. After 30 d of injection, no mice died in the three groups and the tumors were resected and measured. Small, pale tumor nodules were observed in the angiostatin-transfected tumors, whereas large, red and hypervascularized tumors were present in the vector-transfected control and mock control tumor cells. The average size of tumors in the experimental group was $2.11 \times 0.53 \text{ cm}^3$, much less than the average size of the vector control $4.32 \times 1.00 \text{ cm}^3$ and the mock control (Figure 8). The inhibition by angiostatin overexpression reached 72 %.

The tumor tissues in the experimental group showed more typical symptoms of poor vascularization than the control groups. More markedly diminished microvascular densities were detected by immunohistochemical staining in the tumors in the experimental group than in the vector or mock control

groups respectively ($P<0.01$) (Figure 9), which indicated that overexpression of angiostatin probably decreased tumorigenesis by inhibiting neovascularization in tumors *in vivo*. And angiostatin exerted its inhibitory actions in some paracrine ways on ECs surrounding tumor tissues and indirectly inhibited tumorigenesis.

DISCUSSION

Since Dr. Folkman raised the hypothesis of tumor angiogenic dependence, experimental evidences have validated that tumor growth requires the company of new blood vessel growth. At the prevascular stage, the tumor is unable to grow to a size beyond $2\text{--}3 \text{ mm}^3$ and remains in its dormant state. However, once the angiogenic phenotype of the tumor is switched on, tumor growth rate changes from linear to exponential^[12-14]. Metastases are also dependent on angiogenesis in at least two steps of the metastatic events^[15]. First, metastatic tumor cells must exit from a primary tumor which has been vascularized. Second, upon arrival at their target organ, metastatic tumor cells must undergo neovascularization in order to grow to a clinically detectable size. It is speculated that complete inhibition of tumor angiogenesis may result in a loss of survival factors essential for tumor cells from the endothelial cell as paracrine factors^[16]. The regulation of tumor angiogenesis is a complex process involving enzymatic and signal-transduction cascades that function in fibrinolysis, matrix remodeling, inflammation, hemodynamic control of oxygenation, and growth regulation^[17-19]. The local balance between positive and negative factors determines the net tendency toward angiogenesis or angiostasis^[20].

Angiogenesis is closely related to gastric cancer as a pertinent predictive factor in addition to having prognostic value^[21]. The average number of blood vessels is significantly higher in gastric cancer specimens than in normal gastric specimens, higher in advanced disease than in early-stage disease, higher in specimens with metastases or blood vessel invasion than in those without such metastasis or invasion^[22,23]. VEGF positive immunostaining is observed in the gastric tissues with different severities of lesions, the positive rates increased with the lesion progressing from CAG to IM to DYS^[24]. And its expression is associated with hematogenous invasion, metastasis, and clinical prognosis of gastric cancer^[25]. As a malignant disease with the highest mortality rates in China, gastric cancer is refractory to the routine chemotherapy and radiotherapy, which are mainly adopted as the adjunctive therapy during and/or post operation to prolong the survival rates^[26,27]. Moreover, chemotherapy has obvious toxicity and is subject to drug resistance in the treatment of gastric cancer^[28]. Until now the only method possible to cure gastric cancer is surgical resection, despite its importance for the late-stage cancer and various types of high-rate recurrences. Meanwhile the chromosomal instability in DNA of gastric cancer cells unfavorably obstructs the curative effects of the methods directly attacking tumor cells.

Thus antiangiogenic treatment may be necessary and potential for gastric cancer, which has been validated in many experiments. In *in vivo* experiments, antiangiogenic agents with cytotoxic anticancer drugs formed a highly effective modulator combination for the treatment against primary and metastatic carcinoma. The combination of anti-VEGF antibody with mitomycin C markedly enhanced anti-tumor and anti-metastasis effects in nude mice transplanted with human gastric cancer SGC-7901^[29]. The VEGF receptor KDR/Flk-1 antisense strategy significantly increases the number of gastric cancer cells undergoing apoptosis, and decreases tumor dissemination^[30]. Angiogenesis inhibitor endostatin inhibits both tumor growth and metastasis of human gastric cancer in nude mice^[31]. And

octreotide inhibits the migration and invasion of SGC-7901 gastric cancer cells *in vitro* and the metastasis of cancer *in vivo* through down-regulation of MMP-2 expression and tumor angiogenesis^[32]. And the clinical applications of antivasular, anti-angiogenic and angiostatic agents for the treatment of gastric carcinoma may be valuable for long-term administration to maintain tumor dormancy because drug resistance does not develop, and these agents have a sustained effect with less side effects than the traditional methods.

Angiostatin was firstly isolated as a circulating angiogenesis inhibitor, whose sequence has greater than 98 % identity with an internal fragment of plasminogen, containing the first four of five triple loop disulfide-linked kringle structures. Purified angiostatin specifically and reversibly inhibits proliferation of endothelial lineages in a dose-dependent manner, but not proliferation of normal and neoplastic nonendothelial cell lines^[9-11]. Systemic administration of human angiostatin potently inhibits the growth of transplanted human breast carcinoma by 95 %, colon carcinoma by 97 % and prostate carcinoma by almost 100 % in mice, without obvious weight loss or other toxicity observed^[33,34]. It causes human primary carcinomas to regress to a dormant state by a net balance of tumor cell proliferation and apoptosis. And in the presence of angiostatin, metastatic tumor cells form microscopic perivascular cuffs around the pre-existing microvessel, rarely expanding beyond 0.3 mm in diameter^[35-37]. Although angiostatin is a potent inhibitor of angiogenesis and tumor growth, the need of high dosages, repeated injections and long-term administration of this protein into the body have made it less attractive for clinical trials.

In order to develop alternative strategies for therapy, the potential of angiostatin in gene therapy has been investigated. In our study, human gastric cancer cells SGC7901 are transfected with mouse angiostatin cDNA and stable cell lines expressing the secreted form of angiostatin are established. Despite the high levels of its expression in cell clones, angiostatin has no direct influence on tumor-cell growth *in vitro*. Implantation of the stable cell clones in nude mice produces inhibition of primary tumor growth by an average of 72 %. Inhibition of tumor growth is correlated with reduced vascularization, suggesting that angiostatin exerts the antitumor effects through antiangiogenesis. These results are similar to the previously report that angiostatin cDNA transfection into the murine T241 fibrosarcoma cells inhibits primary tumor growth by an average of 77 % in C57Bl6/J mice^[38]. Thus angiostatin gene therapy is possibly available for gastric cancer, especially for its simple manipulation, highly specificity, wide-spectrum inhibitory effects on various tumors. It has been observed that retroviral transduction of angiostatin in rat glioma cells inhibits tumor growth by 70 % *in vivo*, however, a relatively ineffective process^[39]. Stable gene transfer of the angiostatin cDNA by retroviral vectors in Kaposi' s sarcoma KS-IMM cells resulted in delayed tumor growth in nude mice, which was associated with reduced vascularization^[40]. Direct injections of replication-deficient angiostatin-expressing adenoviral vector inhibit tumor growth, and represent a potentially new treatment modality for malignant ascites, which are efficient and capable of transducing dividing cells as well as non-dividing cells *in vivo*^[39,41]. The specific targeting of tumors to inhibit angiogenesis using an adenovirus expressing angiostatin, may deliver localized concentrations of protein having a greater impact on inhibition of tumor growth^[42]. AAV-mediated antiangiogenesis gene therapy offers efficient and sustained systemic delivery of the therapeutic product, which in turn effectively suppresses glioma growth in the brain^[43]. Considering the possibility of viral immunoreaction and toxicity, non-viral angiostatin-delivery system has also been explored. Intravenous injection of cationic liposome-

angiostatin cDNA complex produced a significant antimetastatic effect on murine B16 melanoma compared to either reporter gene-treated and untreated controls^[44]. These results support that angiostatin-gene therapy is a potential strategy in the clinical treatment of gastric cancer.

In order to modify the specificity, we are exploiting gastric cancer specific single-chained antibodies to guide the angiostatin-gene therapy. Another potential pathway is delivering angiostatin gene directly into gastric cancer tissues under the endoscope. Because neovascularization in tumors is a multi-step process, the key molecules involved in various steps are potentially combined to improve anti-cancer efficacy of angiogenic gene therapy, including inhibition of endothelial cell proliferation, migration, invasion and matrix degradation. More effective inhibition has been observed in the combined gene therapy of angiostatin and endostatin than the angiostatin-or endostatin-therapy respectively^[45]. Meanwhile, angiogenic genes are possibly combined with other curative molecules, such as immunoregulators, suppressors of oncogene, enzymatic precursor drugs. When angiostatin-mediated antiangiogenic therapy is used in combination with intratumor delivery of the IL-12 gene, this produces a synergistic therapeutic effect^[46]. It has been validated the potential of combining a destructive strategy directed against the tumor cells with an anti-angiogenic approach to fight cancer. The combination of radiotherapy and angiostatin intratumoral injection reveals a significant inhibition of tumor growth as compared with either treatment^[47]. These combined therapies will open new possibilities of being less toxic and more effective than the traditional therapies in the clinical treatment of gastric cancer.

In conclusion, it is the first time that approves the potential of angiostatin anti-cancer effect has been proved on gastric cancer and its functional mechanism of antiangiogenesis in tumor has been revealed. And these data offers a new way to comeover the disadvantages in traditional therapies in clinic.

Abstract

AIM: To illustrate the possible role of cell differential agent-II (CDA-II) in the apoptosis of hepatoma cells induced by arsenic trioxide (As_2O_3).

METHODS: Hepatoma cell lines BEL-7402 and HepG2 were treated with As_2O_3 together with CDA-II. Cell surviving fraction was determined by MTT assay; morphological changes were observed by immunofluorescence staining of Hoechst 33 258; and cell cycle and the apoptosis index were determined by flow cytometry (FCM).

RESULTS: Cytotoxicity of CDA-II was low. Nevertheless, CDA-II could strongly potentiate arsenic trioxide-induced apoptosis. At 1.0 g/L CDA-II, IC_{50} of As_2O_3 in hepatoma cell lines was reduced from 5.0 μ mol/L to 1.0 μ mol/L ($P < 0.01$). The potentiation of apoptosis was dependent on the dosage of CDA-II. FCM indicated that in hepatoma, cell growth was inhibited by CDA-II at lower concentrations (< 2.0 g/L) primarily by arresting at S and G_2 phase, and at higher concentrations (> 2.0 g/L) apoptotic cell and cell cycle arresting at G_1 phase increased proportionally. The combination of two drugs led to much higher apoptotic rates, as compared with the either drug used alone.

CONCLUSION: CDA-II can strongly potentiate As_2O_3 -induced apoptosis in hepatoma cells, and two drugs can produce a significant synergic effect.

INTRODUCTION

It has been reported that arsenic trioxide (As_2O_3), a newly found apoptosis inducer, possesses a greater apoptotic effect on hepatoma cells as compared with some drugs used in chemotherapy^[1-5]. However, because of its toxicity and the drug resistance of cancer cells, it has not been widely used in the treatment of cancers^[6-10]. As a biological preparation purified from human urine, cell differential agent-II (CDA-II) can

effectively induce cell differentiation and reverse drug resistance of cancer cells against chemotherapeutic agents^[11,12]. Clinical application of CDA-II has demonstrated its low toxicity and satisfactory therapeutic effect^[13-15]. This report is intended to investigate the effect of CDA-II on As_2O_3 -induced apoptosis of hepatoma cells in an attempt to find a better combination therapy for hepatoma.

MATERIALS AND METHODS

Materials

Human hepatoma cell lines HepG2 and Bel-7402 were obtained from the cell laboratory in the Medical School of Zhongshan University; cell differential agent (CDA-II) was provided by Everlife Pharmaceutical Co. Ltd, Hefei; arsenic trioxide (As_2O_3 , $M_r=197.84$), MTT, Hoechst 33 258 and PI were purchased from Sigma Co., USA; PRMI 1 640 was purchased from GIBCO, USA; agar, RNase, proteinase were purchased from Huamei Company; DEME purchased from Evergreen Company, Hangzhou, dimethyl sulfoxide (DMSO) was imported and individually packed, and λ -DNA Marker VII was purchased from Roche Company, USA.

Experimental group

The preliminary experiment showed that 1.0-5.0 μ mol/L of As_2O_3 could induce apoptosis in hepatoma cells to various degrees, and 1.0-5.0 g/L of CDA-II could inhibit proliferation and induce differentiation of hepatoma cells. The experiment was divided into 4 groups: group A, control without any drug; group B, As_2O_3 was added only to final concentrations of 1.0, 2.0, 3.0, 4.0 and 5.0 μ mol/L; group C, CDA-II was added to final concentrations of 1.0, 2.0, 3.0, 4.0 and 5.0 g/L; and group D, 1.0 g/L of CDA-II + various concentrations of As_2O_3 used in the group A.

Cell culture and survival rate tested with MTT

Cells were cultured in PRMI1640 with 10 % calf serum, 100 U/ml penicillin and 100 μ g/ml streptomycin in a humidified atmosphere of 5 % CO_2 at 37 °C. With a density between 2×10^6 and 6×10^6 , two cell lines grew in the same way as typical epithelial cells, and reproduced once every two days. During the experiment, the density of cells was adjusted to 1×10^6 /mL with culture medium PRMI1640, and transferred to 96-well plates, 100 μ L cell suspension per well, to incubate for 24 hours. Drugs of different concentrations were added to the plate, 4 plate wells for each drug concentration according to the aforementioned group division: 100 μ L drug and 100 μ L culture medium were added to each well with a total volume of 200 μ L for group B and C; 100 μ L of two drugs each was added with a total volume of 200 μ L for group D; and 200 μ L culture medium was added to each well of control group. All the groups had concentrations of 4 compound wells. After incubation for 24 h, 48 h, 72 h and 96 h, 20 μ L of 0.5 % MTT was added to each well and incubated for another 4 hours. The supernatant was discarded and 200 μ L of DMSO was added. When the stain was dissolved, the optical density ABS value of each well was read on MinireaderII at 570 nm. Cell survival

rate was calculated with the following equation: average A value of experimental group/average A value of control group $\times 100\%$. Each experiment was repeated at least three times.

The rate of apoptosis tested by fluorescence of live cells

After the aforementioned cells were cultured with drugs for 72 h, cells were harvested and fixed with 1:3 glacial acetic acid/methanol twice, first for 5 min and then 10 min and washed with phosphate buffer solution (PBS). Hoechst 33 258 was put into cell suspension to a final concentration of 1.0 mg/L and the cells were stained fluorescent for 15 minutes away from light. An Olympus BH-2 fluorescence microscope was used to observe the fluorescent associated with DNA of cells nuclei. Graphs were drawn based on different concentrations of drugs and apoptotic rate of cells.

Agarose gel electrophoresis of DNA

Cells treated with drugs for 96 h were collected. After lysis with Nicoletti lysis buffer, DNA was extracted with an equal volume of phenol, phenol/chloroform and chloroform once each, incubated with RNase and precipitated with ethanol and sodium acetate. DNA was sedimented by centrifugation, air dried and dissolved in Tris-EDTA buffer. Each DNA sample was analyzed by gel electrophoreses in 1.2 % agarose gel for 1.5 h and visualized under ultra-violet light.

Apoptosis index (PI) determined by flow cytometry (FCM)

The cells described above were harvested, and 1×10^6 cells were centrifuged to get rid of supernatant, fixed with ethanol, and incubated with 200 μ L RNase A at 37 $^{\circ}$ C for 1 h; 800 μ L PI staining solution was mixed into it and the subsequent mixture was stored in the refrigerator at 4 $^{\circ}$ C for 30 minutes. Flow cytometry was then used to analyze the cell cycle. The cells with content of DNA in sub G_1 were apoptotic cells.

Statistics

Software SPSS 10.1 was employed to process the data with test of index deviation, and to analyze the causes of the deviation in data concerning multiple factors of the experimental design.

RESULTS

Effects of CDA-II and As_2O_3 on the growth of hepatoma cells

Cytotoxicity of CDA-II was low. At 1.0 g/L, the respective survival rate of cell lines HepG2 and BEL-7402 were 92 % and 89 %. When the concentration was increased to 3.0 g/L, the survival rate dropped to 76 % and 65 % respectively. The combined usage of two drugs markedly increased the cytotoxicity of As_2O_3 on the two cell lines. The addition of 1.0 g/L CDA-II caused IC_{50} of As_2O_3 to fall from 5.0 μ mol/L to 1.0 μ mol/L ($P<0.01$, Table 1).

Effect of two drugs on apoptosis in hepatoma cells

Under fluorescent microscope, cell nuclei of the control group displayed fluorescence evenly. Treated by the two drugs in combination, a large proportion of cells underwent apoptosis. Uneven and more dense particulate fluorescence could be observed in cell nuclei (Figure 1). The rate of apoptosis of 500 cells was calculated. The result showed (Figure 2) that when As_2O_3 was employed at 1.0 μ mol/L, the number of apoptotic cells was only slightly above that of control, and the difference was not significant ($P=0.063$). However, the apoptotic rate rose greatly with the increase of drug concentrations above 1.0 μ mol/L, and the significance of differences became obvious as against the control ($P<0.01$). When CDA-II was used alone, the concentration must be above 3.0 g/L showed significant difference from the control ($P<0.015$). CDA-II greatly potentiated the apoptosis induced by As_2O_3 . The apoptotic rate of 1.0 μ mol/L of As_2O_3 together with 1.0 g/L of CDA-II approached that of 4.0 μ mol/L As_2O_3 .

Figure 1 Immunofluorescence staining of Hoechst 33 258 72 h after 1.0 μ mol/L As_2O_3 +1.0 g/L CDA-II administrated in HepG2 cells ($\times 400$). \rightarrow : dispersive fluorescences in normal cells nuclei; \triangle : compact particulate fluorescences in apoptosis cell nuclei

Figure 2 Comparison of different groups on numbers of BEL-7402 cell apoptosis. A. Main effect(As_2O_3): $F=0.387$, sig.=0.063, $P>0.05$; B. Main effect(CDA-II): $F=0.670$, sig.=0.785, $P>0.05$; C. Interaction (As_2O_3 + CDA-II): $F=22.450$, sig.=0.000, $P<0.05$

DNA of cells undergoing apoptosis showed a ladder pattern in agarose gel electrophoresis. In the present study, DNA ladders were characteristically identified in the cells treated with 5.0 μ mol/L As_2O_3 or 1.0 g/L CDA-II+1 μ M As_2O_3 for 72 h as shown in Figure 3.

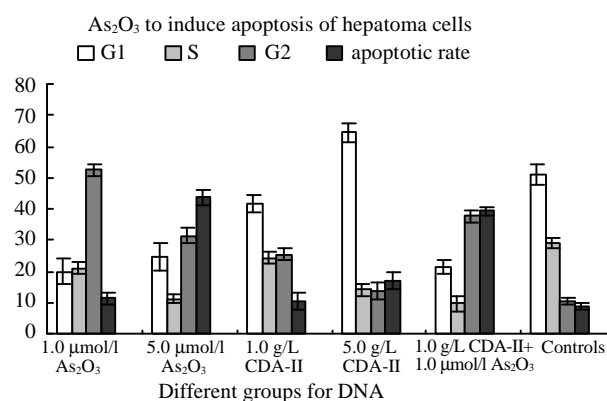

Figure 4 Comparison of DNA in various groups 4 days after medicinal treatment. $P < 0.05$ Compared with the controls

Flow cytometry study of cell apoptosis

Four days after treatment with As_2O_3 , sub- G_1 cells, namely apoptotic cells, became evident in HepG2 and BEL-7402, and the number of apoptotic cells was in direct proportion to drug concentration (Figure 4). As_2O_3 at $5.0 \mu\text{mol/L}$ induced 46.7 % of HepG2 and 53.1 % of BEL-7402, respectively to undergo apoptosis. When CDA-II was employed alone below 2.0 g/L , the apoptotic rate of hepatoma cells was not significantly different from that of the control. At such low concentration ($< 2.0 \text{ g/L}$), the cells arrested in G_2 exceeded those in the control, whereas at concentrations above 2.0 g/L , both apoptotic cells and cells arrested in G_1 increased. The combination of $1.0 \text{ g/L} \text{CDA-II}$ and $1.0 \mu\text{mol/L} \text{As}_2\text{O}_3$ in hepatoma cells resulted in reduced vitality of the two cell lines, and the apoptotic rate rose from 11.3 % in the presence of $1.0 \mu\text{mol/L} \text{As}_2\text{O}_3$ alone to 40.2 % (Figure 5). The potentiation of As_2O_3 -induced apoptosis by CDA-II was concentration-dependent. The percentage of sub- G_1 cells induced by $3.0 \text{ g/L} \text{CDA-II}$ and $1.0 \mu\text{mol/L} \text{As}_2\text{O}_3$ reached 63 %, as against 57 % caused by $5.0 \mu\text{mol/L} \text{As}_2\text{O}_3$. All these findings indicated that CDA-II could synergistically potentiate As_2O_3 to induce apoptosis of hepatoma cells.

DISCUSSION

Toxicity of cell apoptotic agents and drug resistance of cancer cells are major factors contributing to the failure of chemotherapy. It has been reported by Cai *et al.*^[16], that one-third of 47 patients with normal liver function but suffering from recurrent acute promyelocytic leukemia who were treated with As_2O_3 , had their livers damaged. Obviously, the patients with damaged liver function must choose smaller dosage of As_2O_3 . In this regard it particularly fits the recommend combination therapy with CAD-II, because CAD-II is a very effective drug to protect liver from hepatotoxin-induced injuries^[17-20]. In vitro, hepatoma cell growth and proliferation were only inhibited by arsenic trioxide at lower concentrations ($0.25\text{--}2.0 \mu\text{mol/L}$), with no significant apoptosis, at higher concentration ($> 2.0 \mu\text{mol/L}$) can induce cell apoptosis^[21-26]. According to the sensitive standard of chemotherapeutic agents devised by Abe *et al.*^[27,28], hepatoma cells in this experiment are sensitive to the dosage of $5.0 \mu\text{mol/L} \text{As}_2\text{O}_3$. Based on the following formula^[29]: drug concentration (mg/L) = [(drug $\text{mg} \times \text{surface size}$)/body weight] $\times (100/60)$, the sensitive dosage in clinical application is 20 mg/m^2 . In the presence of 1 g/L of CDA-II, IC_{50} of As_2O_3 can be reduced from $5.0 \mu\text{mol/L}$ to $1.0 \mu\text{mol/L}$. That means 4 mg/m^2 is equally as effective in the combination protocol as 20 mg/m^2 of single As_2O_3 . CAD-II is a biological preparation purified from human urine which is a selective inhibitor of abnormal cancer methylation enzymes^[16,30,31]. DNA hypermethylation attributable to abnormal methylation enzymes is related to the evolution of drug resistance of cancer cells^[32,33]. It is likely that the modulation of abnormal

methylation enzymes is responsible for the reverse of drug resistance and the potentiation of As_2O_3 -induced apoptosis. Shen *et al.* reported that abnormal DNA methylation plays an important role in the process of hepatocellular carcinogenesis. DNA methylation level is closely correlated with the biological characteristic of liver cancer, the lower the level of DNA methylation, the stronger the infiltration and metastatic capacity^[34-36]. Animal experiments on have demonstrated that CAD-II could effectively prevent the growth and metastasis of xenografted hepatoma^[37].^[38] Analysis of cell cycle revealed that CAD-II at low concentrations could arrest more hepatoma cells in G_2 and S, and at high concentrations could bring about more apoptosis and relatively more cells arrested in G_1 . It is remarkable that CAD-II at a low dosage is not capable to induce apoptosis, nevertheless, it can strongly potentiate As_2O_3 -induced apoptosis. With 1.0 g/L of CAD-II, the apoptosis-inducing capability of As_2O_3 can be reduced from 5.0 to 1.0 $\mu\text{mol/L}$. Therefore, only 4.0 mg/m^2 of As_2O_3 is needed in clinical treatment giving an equivalence of 20 mg/m^2 of As_2O_3 . Thus, the combined therapy of As_2O_3 and CAD-II offers a great advantage to reduce toxic side effect and to improve the therapeutic efficacy for hepatoma.

Abstract

AIM: The imaging features of MRI and DSA, using the models of implanted and induced hepatoma, were investigated in rats.

METHODS: CBRH3 cancer cells were implanted for different liver site of rat liver and the diethylnitrosoamine was given orally to rats in order to induce liver cancer. Both experimental groups were detected by magnetic resonance imaging (MRI), digital subtraction angiography (DSA) and morphologic assay.

RESULTS: Hypointensity on T1WI and homogenous high signal intensity on T2WI in MRI, and ring-like abnormal stain on DSA were found in implanted cancer. Induced cancers appeared as homogeneous or heterogeneous hypointensity on T1WI (10 cases), and equal or slight high intensity on T2WI (8 cases), but some as hypointensity on T2WI (2 cases).

CONCLUSION: The imaging features of implanted cancers were similar to that of human liver metastases. Therefore, it could serve as an experimental model of human liver metastatic tumor. The imaging feature of induced cancers, whereas, were similar to that of human primary liver cancer. It could be use as an experimental model of human primary liver cancer.

INTRODUCTION

It is important to investigate the relationship between the biologic properties of liver tumor and the findings with modern imaging techniques. MRI affords the possibility in coronal and sagittal views, which are very helpful in liver surgery because surgical techniques are described in these planes^[1-2]. In addition, targeted gene therapy, for instance, cytokines gene therapy, angiogenesis inhibitor and granulocyte-macrophage colony-stimulating factor (GM-CSF) gene-transduced tumor vaccine for patients, may be useful in developing anticancer drugs that prolong or stabilize the progression of tumors with minimal systemic toxicities. These drugs may also be used as novel imaging and radiomunotherapeutic agents in cancer therapy^[3-7].

However, little is known on experimental work of both scan imaging and liver cancer. The present study, using the model of

implanted and induced hepatoma of rats, was undertaken to investigate the relationship between the morphologic alterations and imaging characteristics of magnetic resonance imaging (MRI) and digital subtraction angiography (DSA), and more to improve level of diagnostic and treatment for liver cancer. Finally, interleukin 2 was therapeutic effect on liver tumors^[8], so the our further study of interleukin gene therapy for liver cancer was based on the present outcome of implanted and induced hepatoma.

MATERIALS AND METHODS

Imaging Instruments

MRI equipment was produced by Siemens AG (1.0 T). Its SE rank, 128*128 matrix, T1-weighted sequence (T1WI) were TR/TE 350-480/15 ms; T2-weighted sequence (T2WI) was TR/TE 2 200/90 ms. Slice thickness was 2 mm and scan space was 0.5 mm. Both of coronal and sagittal scanning was fulfilled. Hepatic artery was scanned by DSA (Toshiba DFP-0.3A) with perfusing iodized oil (Lipiodol). Instruments and drugs were sterilized routinely.

Animals and Hepatoma cell

Male Wister rats (200-250 g wt) were obtained from Animal Center of Chinese Academy of Sciences. Animals were maintained on a standard diet. Cellular strains of hepatoma CBRH3 were provided kindly by Prof. Xie Hong (Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Science).

Implanted liver cancer model in rat

Hepatoma CBRH3 cells were injected into abdominal cavity of rat. Rats were sacrificed and tumors were removed from abdominal cavity 7-9 days late. The tumors were cut into pieces of 0.05-0.75 cm and then was inoculated into rat liver for one or more locations respectively. The tumor was grown up to diameter in 0.6-1 cm after 7-10 days of inoculation.

Induced liver cancer model in rat

Male Wister rats (age for 8 weeks) took orally 1:10 000 diethylnitrosamine for 80 days to induce liver cancer. The micro-nodules of hepatoma were developed 14 weeks late and 0.2-1 cm of tumor masses were observed 16-18 weeks late. There were poly-cysts in rat liver. This model was used to study for poly-nodules of hepatoma. The success rate of induced cancer was 100 %^[9,10].

Experimental procedure

Both of 10 implanted tumor rats (age of 9 days) and 10 induced tumor rats (age of 16-18 weeks) was divided to experimental group and control group, randomly. While rats were scanned by MRI, they were anesthetized by injecting ketamine into muscle. In addition, the hepatic artery and gastroduodenal artery were isolated carefully and micro-catheter was inserted into these artery for injection of iodine oil before DSA^[11].

RESULTS

A stable model of rat hepatoma was established by either implanted tumor with cancer piece or inducing tumor with diethylnitrosamine.

Imaging features of the implanted tumors in MRI and DSA and the pathology: The 10 implanted models showed 18 nodules of tumor in MRI and DSA. 11 nodules of them were round shape and 7 of them were ellipse. The margin of tumors was smooth. Implanted cancer showed homogeneous hypointensity on T1WI (Figure 1) and homogeneous hyperintensity on T2WI. The rat liver showed normal signal and normal organ shape.

Figure 1 MR imaging showed low signal on T1WI in implanted hepatoma of rat

In DSA, the tumors showed no stain for blood vessels in the center of tumor (vacancy of vessel) and abnormal ring-like staining of vessel around tumor. The liver tissues were normal. Necrosis and colliquational cavity were shown on the core of tumors in all of 18 tumor mass and the yellow-gray tissue could be seen in cross section of tumors. The cancer cells were small or mediate in size with great nucleus. The parenchyma of liver was normal (Figure 2).

Figure 2 Distribution of microscopy ($\times 200$) in implanted liver cancer that abnormal type and arrangement of cancer cell. There were abundant vascular proliferation and lymphocyte infiltration growth around tumor

The scanning pictures of MRI and DSA and the pathological alteration in induced cancer: Liver cirrhosis with different degree and multiple nodules of cancer were observed in 10 tumor cases. Eight among 10 tumors showed homogeneous slight hypo-intensity on T1WI (Figure 3) and inhomogeneous slight hyper-intensity on T2WI with different shapes, but some of them were with normal signal or more contrast enhancement (Figure 4). Two among 10 tumor livers were shown inhomogeneous slight low signal on T1WI, but equal signal was found in interval. Hypointensity was observed on T2WI.

In DSA the distribution of internal hepato-vascularity was disorder and the angio-clumps were different in sizes in tumor (Figure 5). Pathology: Tumor liver showed poly-nodules, tumor diffusion and inequality of size. The tumor was light yellow. In microscopy examination, distribution of tumor and liver tissue was in interval. The cancer tissue showed plenty and dilation of vessel. The cell plasma of cancer was not abundant. The arrangement of tumor cell was nest and bunch. Liver tissue was

easy for proliferation of nodule with acid-like change and water-alteration. The dilation of lymphatic tube and the proliferation of bile duct were shown between hepato-lobule. Hepato-lobule was divided by proliferation of fibre. The artery and vein were not distinguished because of dilation of vessel (Figure 6).

Figure 3 Homogeneous slight hypointensity on T1WI was found in poly-nodules of tumor

Figure 4 Inhomogeneous slight hyperintensity was indicated on T2WI in different shape, but some of them were showed normal signal or more contrast enhancement in interval

Figure 5 The disorder of distribution of internal hepato-vascularity was found and the angio-clump showed different size in tumor in DSA

Figure 6 Distribution of microscopy ($\times 100$) in induced liver cancer that tumor and liver tissue was in interval. There was plenty and dilation of vessel

DISCUSSION

Characterization of image technique of rat

The available MR image photos were taken because technique is as follow. (1) Technique of eye surface loop: To avoid disturbing factors for image definition that focus on the location of rat liver, this technique was used. (2) Folium technique keeps away the cabin effect on conceal of small tumor nodules. (3) False shadow caused by move of body act and breath was prevented by suitable anesthesia for rats. On DSA image, deep anesthesia and careful anatomy of hepatic artery with catheter were necessary. But it is difficulty to puncture femoral artery. In order to find available condition of exposure time, we try to test more times^[12].

The relation of image and pathology in implanted cancer

The component of tumor is of long longitudinal relaxation time (T1) and long transverse relaxation time (T2) since the implanted cancer show low signal on T1WI and equal signal on T2WI in MRI. Equal signal intensity implies that there are no tissue component in the core of tumor apart from necrosis, liquefaction and cystic change. Therefore, the situation of blood supply was not described due to no-contrast enhancement of Gadolinium-DTPA^[13,14].

On DSA, the imaging of blood vessel around tumor was found such as folium annularity, whereas central liquefaction and necrosis were existed in tumor. Thus, cancer cell on the border of tumor grows actively because of blood supply in plenty and cancer cell in center of tumor does not grow because of insufficient blood supply. There is no liver cirrhosis because signal intensity of liver tissue in MRI and distribution of blood vessel in DSA are normal compared to normal liver parenchyma^[19].

Necrosis at core of tumor and the proliferated nodule of tumor cell were found around blood sinus and dilation of blood vessel after 9 days of implanted cancer^[16,17]. The change in MRI and DSA was accord to pathology.

The relation of image and pathology in induced cancer

Resent study has suggested that a random clonal origin of hepatocyte carcinoma from mature hepatocytes is seen in the diethylnitrosamine model of hepatocarcinogenesis^[18].

Induced cancer is of two different signal intensities including 1. slight low signal intensity on T1WI and slight high signal intensity on T2WI in 8 cases and 2. inhomogeneous low signal on T1WI and low signal on T2WI with regular appearance in 2 cases. We hypothesize that both signals is caused by the difference in hepatoma component and hepatoma cellular arrange. Amount of fibrocyte, apart from tumor cells, is found in these 2 cases which result in extended longitudinal relaxation time (T1) and contracted transverse relaxation time (T2) with low signal on T1WI and low signal on T2WI. Irregular liver shape and liver nodule proliferation in deferent degree with liver cyst could be manifested on MRI because of liver cirrhosis and degeneration resulting from taking carcinogen for long time. To differentiate with cirrhosis nodules and tumor nodules, some investigators reported that the early-enhancing single nodule with cirrhosis is high predictive to hepatocyte cancer in patient. This phenomenon is also seen in our data of photo and microscopy examination^[20,21]. On DAS, the tumor stain is displayed by reason of disorder of blood vessel and angio-clamp^[22].

Comparison imaging of implanted, induced and human hepatoma

Primary liver cancer Based on the liver cirrhosis, primary liver cancer display the slight low signal intensity on T1WI and equal or slight high signal intensity following extended echo time without raise of signal in MRI^[23]. In DSA, the plenty

amateur vessel is observed^[24].

Liver metastases MRI shows the low signal intensity on T1WI, high signal on T2WI and annular enhancement by Gadolinium. In DSA, annular staining is displayed without background of cirrhosis^[15].

Compared with manifestation of MRI and DSA, studies confirm that implanted hepatoma lead that the signal intensity is high following the extended echo time and annular staining around tumor is occurred without liver cirrhosis^[25].

In induced cancer, liver cirrhosis with slight high signal or low signal due to extended echo time without raise of signal is observed in MRI. The abundant malignant vessel stain is indicated that it is similar to human primary liver cancer^[26].

In conclusion, the imaging features of implanted cancers were similar to human liver metastases in manifestation of MRI and DSA. Therefor, it could serve as an experimental model of human liver metastatic tumor. The imaging feature of induced cancers, whereas, were similar to that of human primary liver cancer. It could be use as an experimental model of human primary liver cancer.

Abstract

AIM: This study investigated the anti-cancer effect of combined quercetin and a recombinant adenovirus vector expressing the human p53, GM-CSF and B7-1 genes (designated BB-102) on human hepatocellular carcinoma (HCC) cell lines *in vitro*.

METHODS: The sensitivity of HCC cells to anticancer agents was evaluated by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay. The viability of cells infected with BB-102 was determined by trypan blue exclusion. The expression levels of human wild-type p53, GM-CSF and B7-1 genes were determined by Western blot, enzyme-linked immunosorbent assay (ELISA) and flow cytometric analysis, respectively. The apoptosis of BB-102-infected or quercetin-treated HCC cells was detected by terminal deoxynucleotidyl transferase (TdT) assay or DNA ladder electrophoresis.

RESULTS: Quercetin was found to suppress proliferation of human HCC cell lines BEL-7402, HuH-7 and HLE, with peak suppression at 50 μ mol/L quercetin. BB-102 infection was also found to significantly suppress proliferation of HCC cell lines. The apoptosis of BB-102-infected HCC cells was greater in HLE and HuH-7 cells than in BEL-7402 cells. Quercetin did not affect the expression of the three exogenous genes in BB-102-infected HCC cells ($P>0.05$), but it was found to further decrease proliferation and promote apoptosis of BB-102-infected HCC cells.

CONCLUSION: BB-102 and quercetin synergetically suppress HCC cell proliferation and induce HCC cell apoptosis, suggesting a possible use as a combined anti-cancer agent.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most malignant diseases known. Surgical resections are incapable of removing

all HCC cells and the disease is very resistant to anticancer agents, making chemotherapy an equally ineffective option^[1]. Therefore, anti-tumor gene therapy strategies seem a good future option for the treatment of HCC^[2]. Numerous studies have shown that tumor occurrence and progression are often related to mutations in tumor suppressor genes or loss of host anti-tumor immunity^[3-9]. Therefore, a promising approach is transfer of tumor suppressor genes to cause tumor cell growth arrest or apoptosis, combined with cytokine genes to induce an effective immune response directly against both the genetically modified and the parental tumor cells^[10].

In HCC, mutation or loss of tumor suppressor gene p53 is associated with malignancy and chemoresistance^[11-13], making the wild-type p53 (WT-p53) gene a good candidate for replacement by gene therapy. Granulocyte-macrophage colony stimulating factor (GM-CSF) has been proven to be a potent, long-lasting inducer of antitumor immunity that promotes maturation of dendritic cells and enhances the function of antigen-presenting cells and natural killer (NK) cells^[14-17]. In addition, the expression of members of the B7 gene family has been shown to be important in antitumor responses in both mice and humans^[18-20]. However, most tumor cells, including HCC cells, lack B7-1 molecules on their surface, and as a result they escape recognition by the immune system^[21]. Kim *et al.* found an increased antitumor effect with the combined expression of GM-CSF and B7-1 in athymic nude mice, suggesting that coexpression of GM-CSF and B7-1 may enhance antitumor activity^[22]. Recombinant adenovirus vector BB-102, which expresses p53, GM-CSF and B7-1 genes^[23], has been shown to inhibit the growth of various human carcinoma cells, such as hepatocellular carcinoma, lung cancer^[24], and laryngeal cancer^[25], and enhances carcinoma cell chemosensitivity to anti-cancer agents.

Quercetin (3,3',4',5,7-pentahydroxyflavone) is one of most widely distributed bioflavonoids in the plant kingdom and is a common component of most edible fruits and vegetable. Humans consume approximately 1 g of dietary flavonoid daily. This compound has been shown to inhibit the growth of various human cancer cell lines^[26-34], including leukemia, hepatocellular carcinoma, and estrogen-receptor positive breast carcinoma MCF-7, suggesting that quercetin may have anti-cancer and anti-metastasis potential^[35-39]. The growth inhibitory effect of quercetin on tumor cells is found to be consequence of its ability to interfere with the enzymatic processes involved in the regulation of cellular proliferation: DNA, RNA and protein biosynthesis^[40-43]. Quercetin also has shown to down-regulate or inhibit the phosphatidylinositol (PI) and phosphatidylinositol phosphate (PIP) kinase activities in human carcinoma cells, leading to a marked reduction of second messengers IP3 concentration and cell death^[44,45]. Therefore, quercetin may be useful in the treatment of carcinomas with increased or down-regulated signal transduction capacity^[45-47].

These results suggest that the combination of quercetin with BB-102 may synergetically suppress the growth of carcinoma cells. Accordingly, this study addressed the synergetic action of quercetin combined with BB-102 against HCC cells *in vitro*.

MATERIALS AND METHODS

Agents

Quercetin was purchased from Sigma (St Louis, MO). Western blot detection system ECL+plus Kit was purchased from Amersham Pharmacia Biotech (Arlinton Heights, IL). GM-CSF ELISA kit was bought from Genzyme (Cambridge, MA). The TdT FragEL™ DNA fragmentation detection kit was from Calbiochem (Cambridge, MA). Ad-GFP (Ad5 vector expressing green fluorescence protein) was kindly provided by the Gene Therapy Unit, Baxter Healthcare Corporation, USA. BB-102 was reconstructed by Dr ZH Qu. Quercetin was dissolved in medium containing 0.1 % dimethyl sulfoxide (DMSO), and the same concentration of DMSO was used in control experiments.

Quercetin inhibits the growth of HCC cells

The BEL-7402, HLE and HuH-7 cell lines were seeded in 96-well plates at a density of 5×10^3 cells/well. After 24 h, the cells were exposed to various concentrations of quercetin from 3.125 $\mu\text{mol/L}$ to 100 $\mu\text{mol/L}$. After 72 h, the number of viable cells was determined by MTT assay.

Growth suppression in BB-102-infected HCC cells

HCC cell lines were seeded in six-well plates at a density of 5×10^5 cells/well. Twelve hours later, the cells were infected with BB-102 and Ad-GFP at a MOI of 50 pfu/cell. Culture medium was used for mock infection. Triplicate wells of each treatment group were counted every 2 days for a total of four times after infection. The viability of the cells was determined by trypan blue exclusion.

Assay of apoptosis

Apoptosis induced by BB-102 was analyzed by terminal deoxynucleotidyl transferase (TdT) assay. Briefly, HCC cells were seeded in 12-well plates at a density of 5×10^5 cells/well. After 24 h, they were infected with BB-102 or Ad-GFP at a MOI of 50 pfu/cell. Culture medium was used for mock infection. Seventy-two hours later, cell monolayers were fixed with 4 % formaldehyde diluted in phosphate-buffered saline (PBS) for 15 min at room temperature. Apoptosis of the cells was detected using a TdT FragEL™ DNA fragmentation detection kit according to the protocol.

Cellular apoptosis induced by quercetin or quercetin combined with BB-102 was analyzed by agarose gel-electrophoresis as described based on the pattern of DNA cleavage. Briefly, cells (1×10^6) were lysed with 0.5 ml lysis buffer, followed by the addition of RNase A to a final concentration of 200 $\mu\text{g/ml}$, and incubated for 1 h at 37 °C. Cells were then treated with 300 $\mu\text{g/ml}$ of proteinase K for 1 h at 37 °C. After addition of 4 μl loading buffer, 20 μl samples in each lane were subjected to electrophoresis on a 1.5 % agarose at 50 V for 3 h. DNA was stained with ethidium bromide and laddering was visualized under UV light.

p53 gene expression by western blot

Three cell lines were seeded in 6-well plates at a density of 1×10^5 cells/well. Group II was treated with 100 $\mu\text{mol/L}$ quercetin, group III was infected with BB-102 at a MOI of 50 pfu/cell, group IV was infected with BB-102 and then treated with 100 $\mu\text{mol/L}$ quercetin, and group I was mock-infected with culture medium infected with empty adenovirus vector as control. After 48 h incubation, cells were washed with phosphate buffered saline, disrupted by addition of lysing buffer (100 mmol/L Tris·Cl pH 6.8, 200 mmol/L DTT, 4 % SDS, 0.2 % bromophenol blue, 20 % glycerol), and electrophoresed. Western blot detection system ECL+plus Kit was used to determine p53 expression according to the instruction manual.

ELISA of GM-CSF gene expression

Expression of human GM-CSF was detected by enzyme-linked immunosorbent assay. Briefly, the cells were seeded in 6-well plates at a density of 1×10^6 cells/well. After 24 h, the cells were infected with BB-102 at a MOI of 50 pfu/cell for 1 h, then BB-102 suspensions were replaced with either culture medium alone, or culture medium containing 100 $\mu\text{mol/L}$ quercetin. After 48 h, the suspension was collected. The GM-CSF present in each suspension was quantified using the ELISA kit according to the protocol.

FCM of B7-1 gene expression

HCC cells were seeded in 6-well plates at a density of 5×10^5 cells/well. After 24 h, the cells were either treated with 100 $\mu\text{mol/L}$ quercetin, infected with BB-102 at a MOI of 50 pfu/cell, or infected with BB-102 at a MOI of 50 pfu/cell then treated with 100 $\mu\text{mol/L}$ quercetin. Culture medium was used for mock infection. After 48 h incubation, the cells were collected. Cells were washed twice in PBS and resuspended in PBS containing 1 % bovine serum albumin (BSA) prior to incubation with anti-human B7-1 monoclonal antibody (MoAb) for 30 min at 4 °C in the dark, followed by two washes in PBS/BSA. The cells were stained with FITC-conjugated goat anti-mouse IgG for 30 min at 4 °C. Nonspecific binding was controlled by incubation with isotypic controls. Fluorescence was measured with FACSCalibur flow cytometer (Becton Dickinson).

Proliferation of cells treated with both quercetin and BB-102

HCC cells were seeded in 96-well plates at a density of 5×10^3 cells/well. After 24 h, cells were infected with Ad-GFP or BB-102 at a MOI of 50 pfu/cell. Culture medium was used for mock infection. After 48 h, cells were treated with various concentrations of quercetin from 3.125 to 50 $\mu\text{mol/L}$. Culture medium was used for mock treatment. After 72 h, the viable cell numbers were tested by MTT assay.

RESULTS

Antitumor effect of quercetin on HCC cells

Quercetin was shown to inhibit HCC proliferation and induce HCC apoptosis *in vitro* in a dose-dependent manner until it reached peak inhibition at 50 $\mu\text{mol} \cdot \text{L}^{-1}$ (Figure 1).

Figure 1 The suppressive effect of quercetin on the proliferation of BEL-7402, HLE and HuH-7 cell lines *in vitro*.

BB-102 inhibit the growth of HCC cells

Introduction of p53, GM-CSF and B7-1 through BB-102 infection led to significant suppression of growth proliferation in BEL-7402, HLE and HuH-7 cells compared with those infected with Ad-GFP or mock infected (Figure 2). Among them, there was a lower suppression in BEL-7402 cell line compared with HLE and HuH-7 cell lines ($P < 0.05$), which might be related

to the fact that BEL-7402 expresses an endogenous wild-type p53, while HLE and HuH-7 both express endogenous mutant p53, resulting in BEL-7402 being less sensitive to the effects of the exogenous p53 protein expressed by BB-102.

Figure 2 Proliferation inhibition of HCC cell lines transduced with BB-102.

BB-102 induces HCC cells apoptosis

As measured by TdT assay, apoptotic rates in BEL-7402, HLE and HuH-7 cells lines were 12.75 %, 57 % and 49.5 %, respectively. This suggests that HLE and HuH-7 cells were more sensitive to BB-102 than BEL-7402 cells.

Quercetin induces apoptosis of HCC cells

DNA laddering (Figure 3) suggests that quercetin induces HCC cell apoptosis, and that BB-102 further promoted the quercetin-treated cell apoptosis.

Figure 3 The promotion of Que on HCC cell apoptosis induced by BB-102.

Quercetin does not affect exogenous gene expression in BB-102-infected cells

Expression of exogenous P53 in BB-102-infected cells By using Western blot analysis, high levels of p53 protein were detected in BB-102-infected HCC cell lines. These levels were not affected by treatment with quercetin (Figure 4).

Figure 4 Effect of Que on the p53 expression in HCC cell lines transferred with BB-102. (lane1: control; lane2: with Que; lane3: with BB-102; lane4: with Que and BB-102).

Figure 5 Synergistic effect of BB-102 on quercetin suppression of growth of HCC cell lines.

Expression of exogenous GM-CSF protein in BB-102-infected cells

ELISA assay showed that a high-level expression of GM-CSF was detected in the culture suspension of BB-102-infected cells 48 h after infection. There was no statistical difference in GM-CSF level between the cells treated with quercetin and untreated cells (Table 1).

Expression of exogenous B7-1 protein in BB-102-infected cells

B7-1 gene expression was observed flow cytometric analysis 48 h after BB-102 infection (Table 2). There was no

significant difference in B7-1 expression between cells treated with quercetin and untreated cells.

Quercetin enhances the inhibition of the proliferation in BB-102-infected HCC cell lines

The proliferation suppression pattern of HCC cells treated with quercetin was not significantly different between Ad-GFP-infected cells and Ad-mock infected cells. In contrast, BB-102-infected cells showed a significant increase of suppression when treated with quercetin. This implies that BB-102 transduction and quercetin treatment synergistically suppress HCC proliferation (Figure 5). The control data indicates that it was the exogenous gene expression that induced this effect, not the adenovirus.

DISCUSSION

Gene therapy, the introduction of functional genes into cells to treat or prevent a disease, is a promising approach for the treatment of human cancer. In an effort to explore potential gene therapy approaches to the treatment of stubborn HCC, we investigated the synergetic effects of dietary component (quercetin) plus gene transfer (BB-102 infection). BB-102 is a recombinant adenoviral vector expressing the genes for human wild-type p53, GM-CSF and B7-1^[23]. Our study showed that BB-102 infection arrested the growth of HCC cells lines BEL-7402, HLE, HuH-7, and induced their apoptosis by the expression of exogenous wild-type p53 (a transcriptional activator that induces cell cycle arrest and apoptosis^[48-50]). BB-102 also enhanced immunogenicity of HCC cells and improved host antitumor immune reaction.

We then examined the possible synergy between these exogenous genes and quercetin, which is thought to have a long-term preventive effect on chemical carcinogenesis, especially in people who eat a diet rich in fruits and vegetables^[30,31,36,51,52]. Previously, we had found that antineoplastic drug concentrations exerting cytotoxic activity were markedly lower when cells were pretreated with quercetin^[28,35]. In addition, quercetin has been shown to inhibit the growth of human breast cancer cell line MDA-MB468 in a dose-dependent fashion by specifically inhibiting the expression of mutant p53 in cellular transformation^[53]. Because HCC patients are generally resistant to chemotherapy (possibly due to the loss of a functional p53 gene^[54], which is known to occur in 50 % of cancers^[55-58]), we

questioned whether quercetin could reverse the multi-drug resistance of HCC cells, perhaps through down-regulation of mutated p53 or glycoprotein^[53,59,60]. In addition to its possible role in adjusting p53 levels, quercetin is also known to inhibit the synthesis of HSP70 (heat shock protein 70) and change its intracellular distribution. HSP70 is involved in apoptosis, and the link between the two suggests that quercetin may be involved in the induction of apoptosis^[35,61].

We found enhancement of apoptosis and inhibition of the proliferation of BB-102-infected HCC cell lines treated with quercetin, suggesting that there is a synergetic anticancer effect between quercetin and BB-102. There was no change in p53, GM-CSF and B7-1 gene expressions in BB-102-infected HCC cell lines following quercetin treatment, indicating that quercetin did not affect exogenous gene expression in BB-102-infected HCC cells. We believe it is possible that this synergetic effect might be due to BB-102 transduction promoting the chemosensitivity of HCC cells to quercetin, but this and other mechanisms will need further study.

BEL-7402 cells were more sensitive to quercetin than HLE and HuH-7 cells. At a concentration of 50 μmol/L quercetin (peak proliferation inhibition), proliferation inhibition was 78 %, 33 % and 24 % for BEL-7402, HLE and HuH-7, respectively. Our previous studies have shown that the doubling time of BEL-7402 is the shortest among these cells. This suggests that the cells that proliferate quickly are more sensitive to quercetin in this study. In addition, quercetin induced apoptosis in HCC cells at G1 and S in a dose- and time-dependent manner, and the effect was enhanced by BB-102 infection. This enhancement was less in BEL-7402, possibly due to its wild-type endogenous p53 status^[62]. Overall, HCC cells treated with both quercetin and BB-102 showed inhibition of proliferation and increased apoptosis, suggesting that quercetin may be useful as an adjuvant in chemotherapy treatment of HCC patients. The combination of quercetin and BB-102 transduction is a promising new strategy for the treatment of typically chemo-resistant hepatomas.

Abstract

AIM: To construct interleukin-2 gene-modified human hepatocyte line (L-02/IL-2) and investigate the changes of the function of liver cells and IL-2 secretion in culture with microcarrier, laying the foundation for further experimentation on hepatocyte transplantation.

METHODS: hIL-2 gene was transduced into L-02 hepatocytes by recombinant retroviral vector pLNCIL-2, and the changes of morphology and clonogenicity rate of the transduced cells were observed, the secretion levels of hIL-2 in cultural supernatant were detected by ELISA and NeoR gene was amplified by PCR. The growth of L-02/IL-2, the special biochemistry items and the levels of IL-2 were detected after cultivation with microcarrier.

RESULTS: The clonogenicity rate of the L-02/IL-2 cells was lower than that of L-02/Neo cells and L-02 cells. The levels of hIL-2 could reach 32 000 pg/10⁶ cells per day and kept secreting for more than ten weeks. NeoR gene segment was respectively obtained by PCR from both L-02/IL-2 and L-02/Neo cell's genomic DNA. At the 6th day in culture with microcarrier, the matrix-induced liver cell aggregates were formed, the number of alive L-02/IL-2 cell were 16.8±0.53 ×10⁶/flask and the levels of ALB and UREA were 52.54±1.28 mg/L and 5.29±0.17 mmol/L, respectively. These data had not significantly changed as compared with those of L-02 cells (*P*>0.05); However, the levels of IL-2 in IL-2/L-02 cells remarkably exceeded that in L-02 cells in the whole culture process (*P*<0.001).

CONCLUSION: The IL-2 gene-modified hepatocyte line has been successfully constructed. The L-02/IL-2 cellular aggregates cultured with microcarrier have a high capacity of IL-2 production as well as protein synthesis and amino acid metabolism.

INTRODUCTION

Gene therapy has become an important therapeutic alternative in recent years, thanks to the growing improvement of gene-transduction techniques in eukaryotic cells. There are a large number of proteins expression in hepatocyte with high levels, and many genes that are involved in metabolism also express in hepatocytes, so hepatocyte is one of the crucial tools for gene therapy^[1], for example, the therapeutic implement for patient with hyperbilirubinemia by hepatocyte transplantation after gene modification *in vitro*, which was approved by FDA^[2].

As an important approach for inhibiting the growth of tumor, immune therapy of cytokines further broadens the prospect of clinical application of hepatocytes and gene therapy of cytokines. Recent studies have demonstrated the feasibility of cytokine gene transference to enhance the antitumor activities of host immune cell^[3]. With regards to therapy for hepatocarcinoma, there are many good results obtained from the study of hepatocarcinoma cells modified by cytokine genes^[4-11], especially using IL-2 gene modified hepatocarcinoma cells that conquered the substantial toxicity from administration of high doses of IL-2^[9,12]. However, few studies focus on the antitumor immune function of hepatocyte transduced with cytokine gene in hepatocyte transplantation. In this study, IL-2 gene was transduced into human hepatocyte line L-02 by recombinant retroviral vector. The experiments of its biologic activities and cultivation with microcarriers were performed, laying the foundation for further experimentation on hepatocyte transplantation.

MATERIALS AND METHODS

Material

Human hepatocyte line L-02, amphotropic packaging cell PA317 and mouse fibroblast cell line NIH3T3 were purchased from Shanghai Cell Biology Institute, Chinese Academy of Science and grown in DF medium (DMEM: Ham's F12=3:1) containing 100 mL·L⁻¹ fetal calf serum, penicillin 1×10⁵U·L⁻¹ and streptomycin 100 mg·L⁻¹. The cells were kept at 37 °C in a 50 mL/LCO₂ humidified atmosphere and subcultured from one to three when the cells proliferated into a full monolayer. Recombinant retroviral vector, LNCX and LNCIL-2, were kindly provided by Prof. Joo Hang Kim from Yonsei University in Korea. Plasmid extraction and purification kit, Wizard® Plus SV Minipreps DNA, and transfection kit TransFast™ were from Promega. hIL-2 ELISA kit was purchased from Jingmei Biological Engineering, Shenzhen. Microcarrier Cytodex3 was from Pharmacia. Poly-HEMA, DMEM and Ham's F12 medium were the products of Sigma. Calf serum were purchased from Four Season Green Biological Co., Hangzhou, China.

Methods

Construction of recombinant retrovirus producer cell line
Transformation of recombinant retroviral vector was performed as previously described^[13]. The extraction and purification of the product was operated according to the manufacturer's protocol. The purified products were quantitated by spectrophotometer (DU 640), digested with *Hind* III at 37 °C for 2 h and identified by electrophoresis through a 10 g/L

formaldehyde agarose gel. The amphotropic packaging cells PA317 were plated into 12-well plates and cultured till nearly 60-70 % confluence. Then LNCX or LNCIL-2 transduction to PA317 cell line was made with lipo-transfection technique. The PA317/Neo and PA317/IL-2 cell clones which produced pLNCX and pLNCIL-2 were respectively selected by G418 and subcultured for amplification in G418-free DF media for 24 h. Furthermore, the supernatant of above cells containing recombinant retrovirus were collected, and the retrovirus titer was detected by NIH3T3 cells according to that described^[14], quantitated highest titer was kept at -70 °C.

Transduction of IL-2 gene into the hepatocyte cell line The L-02 hepatocyte line were grown to a confluence of 60-70 % in 24-well plate. The supernatant were discarded and replaced with 1 mL recombinant retroviral supernatant supplemented with 8 µg of Polybrene. Two hours later, 2 mL fresh DF media containing 800 mg/L were added and cultured at 37 °C for 24 h. The whole process of the cell clone against G418 selection lasted 15 days followed by amplified cultivation.

Growth of transfected cells The growth of transfected cells were observed and photographed, total of 3×10^3 L-02, L-02/Neo and L-02/IL-2 cells were put into the media respectively with a final volume of 200 µL, and then plated on a 96-well plate and incubated at 37 °C in 5 mL/LCO₂ humidified atmosphere for 7 days. Each group had six wells. The assay of cell proliferation was performed by MTT every 24 h. Briefly, 20 µL of 5 g/L MTT were added into each well and cultured for another 4 h. The supernatant was discarded and replaced with 200 µL of dimethyl sulfoxide (DMSO). When the crystals were dissolved, the absorbance (A) value of the slides was read at 490 nm. In addition, 1×10^3 cells per well of the three kinds of cell were plated into 24-well plate in 1 mL media and cultured for 7 days, respectively. The colonogenicity rate (CR) of transferred cells were calculated by using the following equation: $CR = (\text{average clones per well} / 1000) \times 100 \%$.

NeoR gene analysis of the transfected cells by PCR The total genomic DNA were extracted from 1.0×10^6 of L-02, L-02/Neo and L-02/IL-2 cells in 200 mL TE buffer respectively, then quantitated by spectrophotometer and digested with *Bam*HI. The NeoR gene was amplified under following conditions: denaturation at 94 °C for 5 min followed by 94 °C 1 min, 62 °C 1 min and 72 °C 1 min 15 s for 30 cycles. The sequence of NeoR gene primers and length of PCR products were as follows: forward-5' -CAAGATGGATTGCACGCAGG-3' and reverse-5' -CCCGCTCAGAAGAAGCTCGTC-3', size, 790 bp. For analysis, 10 µL of reaction product were checked in 10 g/L agarose gel with ethidium bromide staining and followed by camera photographing.

Detection of the levels of hIL-2 secreted by the transduced cells The supernatant of 1.0×10^6 of L-02, L-02/Neo and L-02/IL-2 cells that cultured in flask for 24 h were obtained and stored at -70 °C after centrifugation. L-02/IL-2 cells were especially cultured for 10 wk and the supernatants were collected every week. The levels of hIL-2 were measured by ELISA according to the manufacturer's protocol.

Cultivation with microcarriers All glassware with which Cytodex3 came into contact, should be siliconized before use. The hydration of Cytodex3 was carried out as the protocol. Briefly, 200 mg Cytodex3 were dipped in Ca²⁺ and Mg²⁺-free PBS in a siliconized container overnight and sterilized by autoclaving, then replaced with fresh DF media; The flasks were covered with 0.1 mL/cm² 120 g/L Poly-HEMA dissolved in ethanol and then air-dried sterilizedly. The hydrated Cytodex3, 20 mg a flask, along with L-02 and L-02/IL-2 cells, 3.0×10^6 a flask in 2 mL media, were seeded into Poly-HEMA covered flasks, respectively. Each group had five bottles. They were all cultured in incubator at 37 °C for 4 h following shakes twice for 1 min every 4 h, the media were replaced every 24 h,

and the supernatants were kept at -70 °C after centrifugation at 1000r/min.

Morphologic observation and cell proliferation The culture process was observed and photographed. The cell samples at 6th day were fixed by 25 g/L glutaraldehyde and observed by HU-12A electronmicroscope. The proliferation was performed as follows: (1) 100 µL cell suspension were taken out from every flask at day 2, 4, 6, 8 and 10 in culture and added into a new flask without Poly-HEMA; (2) When all microcarriers went down, the supernatants were discarded, 100 µL 2.5 g/L trypsinase were added and cultured at 37 °C for 5 min; (3) After 100 µL DF media were added for termination of trypsinization, the flasks were put up slowly with all microcarriers anchored to the bottom of the flask, and the supernatant were rapidly dipped out for cell calculation with trypan blue dye exclusion method.

Measurement of biochemical items and IL-2 in the supernatant With γ calculator (SN-682), the concentration of human ALB was detected by RIA kit from North Biotechnique Institute, Beijing, others as UREA (BUN $\times 2.14$), AST and LDH were measured by biochemical autoanalyzer (CX Δ 7, Beckman).

RESULTS

Identification of amplified retroviral vector

The amplified products of LNCX and LNCIL-2 were digested with *Hind* III, and then checked with 20 g/L agarose gel electrophoresis (Figure 1). The length of LNCX (6 620 bp) and LNCIL-2 (7 293 bp) were identical with that predicted, showing the success of amplification, extraction and purification.

Figure 1 Restriction enzyme analysis of pLNCX and pLNCIL-2

Cultivation of virus producer cell and measurement of viral concentration

21 and 25 anti-G418 clones appeared after PA317 cells were transduced by LNCX and LNCIL-2 and cultured in media containing 800 mg/L of G418 for 2 weeks. 10 clones selected were performed amplified culture, respectively. The titer of retrovirus of all collected supernatants was between 5.4×10^7 cfu/L and 1.4×10^9 cfu/L.

Morphological changes

Under the light microscope, L-02 cells were seen flake-like growth (Figure 2A), L-02/Neo and L-02/IL-2 cells represented the trend of island-like growth with clear margin (Figure 2B). The growing speed of L-02/IL-2 cells was slightly slower than that of L-02 and L-02/Neo cells (Figure 3). Clonogenicity rate of the L-02 /IL-2 cells were significantly lower than those of L-02/Neo and L-02 cells ($P < 0.01$) (Table 1).

PCR analysis of NeoR gene

NeoR gene segment (790 bp) was amplified by PCR from genomic DNA of L-02/Neo and L-02/IL-2 cells and tested with 20 g/L agarose gel electrophoresis, but none from L-02 cells

(Figure 4). These suggested that LNCX and LNCIL-2 were successfully integrated into the genome of L-02 cells.

IL-2 secretion from IL-2 transduced hepatocyte line

After IL-2 transduction and G418 selection using LNCX and LNCIL-2 retroviral vector, maximal amount of IL-2 production in L-02/IL-2 cells was 32 000 pg/10⁶ cells·24 h, remarkably exceeding 56 pg/10⁶ cells·24 h in L-02 cells and 48 pg/10⁶ cells·24 h in L-02/Neo cells. Moreover, more than ten weeks later the levels of hIL-2 could rise to 27 500 pg/10⁶ cells·24 h.

Morphology and proliferation of cells in culture with microcarrier

After cultivation with microcarrier for 4 h, all the cells anchored to microcarriers. At the 4th day 70 % of microcarriers were filled with cells, at the 6th day all microcarriers' s surface were full of cells or cellular mass (Figure5), at the 8th day some dead cells could be seen shedded from microcarriers. Under the electronmicroscope, L-02 and L-02/IL-2 cells had normal super-microstructure, such as integral cell membrane, affluent mitochondria, glycogen and rough endoplasmic reticulum (Figure 6); 3) L-02 and L-02/IL-2 began an exponential growth after two days in culture. At the 6th day, the number of alive L-02 was 17.1±0.76×10⁶/flask and L-02/IL-2 was 16.8±0.53×10⁶/flask. At the day of 10, the number of alive cells were 6.1±0.34×10⁶/flask and 5.9±0.52×10⁶/flask, respectively.

^bP<0.001, vs L-02 cells.

levels of AST and LDH elevated slowly before the 6th day and rapidly increased with the cell death after the peak of growth. These data had not significantly changed as compared with L-02 cells. However, the levels of IL-2 in IL-2/L-02 cells remarkably exceeded that in L-02 cells in the whole cultural process ($P<0.001$) (Table 2).

DISCUSSION

IL-2, an important regulatory factor in immune network, can induce proliferation of T cell and enhance the immune response function of T cell, B cell, NK cell and monocytes. It plays an important role in antitumor and antiinfection immune function in the body^[15-17]. As one of the most therapeutically effective genes, IL-2 gene has been transduced into a varieties of cells in research^[8,12,18]. Recently, there were some reports about direct injection of viral vector that expressed IL-2 gene for therapy of hepatocarcinoma^[7]. Worldwide, 80 % of gene-therapy projects that were applied clinically with approval were using retroviral vector, for example, LNCX, LXCX, LXSX, etc.^[19,20]. LNCX, which contained the immediate early promoter of human cytomegalovirus (CMV), was not limited by cell type or animal species and it was more powerful than the other types of enhancer^[21]. In our study, LNCX, and its derivation LNCIL-2 were transduced into human hepatocyte line L-02. Clonogenicity rate of the L-02 /IL-2 cells were obviously lower than that of L-02/Neo cells and L-02 cells, due to the change of function of IL-2 as an inhibited signal in cell proliferation. The levels of IL-2 in supernatant of L-02/IL-2 cells were remarkably higher than that of L-02/Neo cells and L-02 cells, and the L-02/IL-2 cells could secrete IL-2 for more than ten weeks. These data showed that IL-2 gene was successfully integrated into the genome of L-02 cells.

Highly differentiated liver cell line were easy to proliferate in culture *in vitro*, and had many features of normal hepatocyte, so the construction of hepatocyte line is a very significant subject^[22]. Japanese scholars had constructed immortalized hepatocyte lines and used them for hepatocyte transplantation and bioartificial liver system with high efficacy^[23-26]. In this study, the hepatocyte line we used, L-02, was histologically originated from normal human liver tissue and immortalized. High levels of ALB and UREA reflected the cell's good

biological activity in protein synthesis and amino acid metabolism. When IL-2 gene was inserted, these characteristics were not notably changed.

As a alternative for amplifying the number of cells, the technique of cultivation with microcarrier is increasingly playing an important role in bio-engineering. For example, researchers can use it to produce monoclonal antibody^[27], hormone^[28], vaccine^[29], cytokine^[30] and even viral vector for gene therapy^[31], and moreover use it to culture hepatocyte for bioartificial liver system^[32,33] or hepatocyte transplantation^[34,35] for clinical use. Regardless of the type of liver cell, two requirements must be considered: First, the number of cell is adequate and easily available. Second, the cells should form congeries, because the work of hepatocytes depends on the contact between the cells or cell and the matrix. With charges-free, Cytodex3, formed by chemically coupling a thin layer of denatured collagen to the cross-linked dextran matrix, has a good adhesive character. So Cytodex3 became the core of hepatocyte aggregation and gradually formed the matrix-induced liver cell aggregates (MILCA)^[36].

The significances of construction of L-02/IL-2 cell are as follow. Theoretically, if hepatocytes modified by IL-2 gene can be transplanted into a patient with HCC who is subjected to operation, these cells might provide some functions of hepatocyte as well as antitumor immune function of IL-2 that can induce the regression of cancer cells and inhibit the metastasis, due to the activation of T-cell and other effector cells. Of course, the immune rejection of transplantation should be taken into account, two strategies are available. (1) The fetal hepatocytes, which are poor in immunogenicity and susceptible to retrovirus^[25,37], can be selected to be transfected by target-gene and cultured with microcarrier. (2) Microencapsular technique can be used to encapsule transgenetically immortalized hepatocytes, realizing the continuous expression of exogenous gene^[38,39], which can be testified by further animal experimentation.

Abstract

AIM: To investigate the effects of p16 gene on biological behaviour in hepatocellular carcinoma cells.

METHODS: HCC cell lines SNU-449 and HepG2.2.15 were infected respectively by a replication defective, recombinant retrovirus capable of producing a high level of p16 protein expression (pCLXSN-p16). G418 resistant stable P16 protein expression cell lines were selected. And the biological behaviours of the p16 gene transfected HCC cells were observed.

RESULTS: Initial *in vitro* experiments in HCC cell line SNU-449 with loss of p16 protein expression demonstrated the pCLXSN-p16 treatment significantly inhibited cell growth. But there was no treatment effect when the pCLXSN-p16 was used in another HCC cell line HepG2.2.15 which has positive p16 protein expression. Subsequent study in a nude mouse model demonstrated that the p16 gene transfected SNU-449 had a lower succeeding rate in the first time establishment of tumors and grew more slowly in the nude mice when compared with non-transfected SNU-449. Moreover, the nude mice inoculated with transfected SNU-449 had a longer surviving time than those inoculated with non-transfected SNU-449.

CONCLUSION: Our results show that the p16INK4a gene transfer can inhibit the proliferation and reduce the invasion ability of hepatocellular carcinoma.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common malignant tumor with a increasing incidence^[1], and the treatment has been extremely difficult. HCCs are generally highly resistant to chemotherapeutic agents and radiotherapy. Despite a variety of treatment options including surgical resection, chemoembolization, percutaneous injection of ethanol or acetic acid, and liver transplantation, the prognosis of HCC patients is poor^[2]. Thus, new treatment strategies are necessary

to improve the survival rate. It is believed that molecular changes that occur during carcinogenesis, such as overexpression of the multidrug resistant gene and the loss of tumor suppressor genes may allow many kinds of tumor cell populations to become resistant to most therapeutic approaches. Gene therapy may offer certain advantages in the treatment of HCC.

P16 gene encoded for a protein that was initially identified as a specific inhibitor of the CDKs, CDK4 and CDK6. By binding to and inhibiting CDK4 and CDK6, p16 prevents both pRb phosphorylation and subsequent progression into the S phase of the cell cycle. P16 gene alterations were found in many kinds of cancers^[3-13]. Our previously study has showed that the frequency of P16 gene inactivation was high (36 %)^[14] in HCC. Other's Reports have also showed frequent P16 gene inactivations^[15-21]. Thus, P16 gene may be an ideal candidate for the treatment of HCC. In this study, we constructed the retrovirus p16 expression vector and then investigated whether it could control the proliferation of HCC cell lines.

MATERIALS AND METHODS

P16 cDNA subcloning and construction of pCLXSN-p16

The original P16 cDNA was amplified from the total RNA of normal human lymphocytes by reverse transcription PCR. The PCR product was subcloned into pCLXSN expression vector, a deficient retrovirus vector which derived from pLXSN (IMAGENEX). Then the recombinant p16 expression vector was cotransfected with the pCL-Ampho packaging construct into 293 cells by using a modification of the HEPES-buffered saline calcium phosphate method^[22]. Two days after infection the 293 cells were placed under G418 selection (800 µg/ml) and grew for 10 days. Then the G418 resistant 293 cells were amplified and the supernatant which contained the pCLXSN-p16 pseudo retrovirus were collected and filtered through a 0.45 µm pore size filter. The pseudo retroviruses were tited through infecting NIH 3T3 cells^[22]. We also packaged a reporter gene expression vector pCLMFG-LacZ as a control. The viral titer was 1.6×10⁵CFU/ml.

Cell lines

Human HCC cell lines SNU-449 (with loss of p16 expression) and HepG2.2.15 (with p16 expression) were kindly provided by Dr. Zhang Mingyi (Tumor Hospital of Sichuan Province, Chengdu, China,) and Dr. Gao Yong (the Union Hospital, Tongji Medical University, Wuhan, China) respectively. They were grown in RPMI 1640 containing 10 % fetal bovine serum.

Infection of retroviral vectors and selection of stable expression cell lines

SNU-449 and HepG2.2.15 cell lines were seeded and cultured in two 6 cm plates at a density of 2×10⁵ cells for 24hs respectively. Immediately before infection, the culture medium was replaced and 1 ml viral supernatant of pCLXSN-p16 or pCLMFG-LacZ (control) was added. Then the polybrene was added to the medium in 8 µg/ml. The infected cells were grown for 24hs and split into 10 cm plates at 1:10 dilution, then grown in the medium containing G418 in 800 µg/ml. The

medium was replaced every 3-4 days and the G418 resistant cells were selected and named SNU-449/pCLXSN-p16, HepG2.2.15/pCLXSN-p16, SNU-449/pCLMFG-LacZ and HepG2.2.15/pCLMFG-LacZ, respectively.

Immunohistochemical analysis and western blotting

SNU-449 cells were collected 24hs after infected by pCLXSN-p16. The stable G418 resistant SNU-449/pCLXSN-p16 cells were also collected. Both of them were examined for p16 expression immunohistochemically by the labeled streptavidin-biotin method. The SNU-449/pCLXSN cells were also screened for p16 expression by Western blotting. The cells for immunochemical analysis were grown on the glass slides.

Immunohistochemical detection procedure was carried out according to the manufacture's recommendations. Western blotting was performed as previously described^[23].

Growth curves

The effect of p16 expression on cell growth was examined in all six cell lines, including SNU-449, SNU-449/pCLXSN-p16, SNU-449/pCLMFG-LacZ, HepG2.2.15, HepG2.2.15/pCLXSN-p16, and HepG2.2.15/pCLMFG-LacZ. Triplicate samples of log phase cells were seeded at a density of 1×10^4 in 6 holes culture plates. Cells were harvested for counting by digestion with trypsin/EDTA for 3 min, followed by the addition of fresh media to inhibit further digestion. Cells were then pelleted by centrifugation at 1000rpm for 5 min, followed by resuspension in fresh media. Triplicate sets of cells were counted at 1, 3 and 5 days after seeded. The mean cell number for each harvesting was calculated, and cell growth curves were determined.

Cell cycle and apoptosis analysis

The effect of pCLXSN-p16 expression on cell cycle dynamics and cell apoptosis was examined in both the SNU-449/pCLXSN-p16 and HepG2.2.15/pCLXSN-p16 cell lines using FACS analysis. In the meanwhile, the cell cycle distribution and apoptosis analysis of SNU-449, SNU-449/pCLMFG-LacZ and HepG2.2.15 cells were also examined for controls. Briefly, 1×10^6 cells of each cell line were collected by centrifugation at 1000 rpm for 5 min, followed by two washes in ice-cold PBS. Cells were then fixed in 2.0 ml of 70 % ethanol and stored at 4 °C for a minimum of 1 h. Prior to FACS analysis, cells were washed twice with ice-cold PBS, and the cell pellet was resuspended in 10 µg/ml of propidium iodide (Sigma Chemical Co.). Add 100 µg/ml of RNase (Sigma Chemical Cop.) and incubated at 37 °C for 30 min. Then the FACS analysis was performed.

In vivo studies

Nude mice were used at the weight of 23-27 grams. Log phase SNU-449/pCLXSN-p16 and SNU-449 cells were harvested and centrifuged at 1000 rpm for 5 min, then resuspended in 0.9 % salt solution at 1×10^8 , respectively. Cells were immediately implanted subcutaneously into the right flank of nude mice (1×10^7 cells for each animal). Tumor formation and subsequent growth were monitored. The tumor volume at 23 days after implantation and the survival rate of the mice at 52 days after implantation were also observed. Statistical significance was assessed by Mann-Whitney statistical analysis (Statmost for windows).

RESULTS

Detection of p16 protein expression

SNU-449 cells exhibited a loss of p16 protein expression (Figure 1), and HepG2.2.15 cells showed positive p16 staining. About 20 % SNU-449 cells showed positive p16 staining 24 hours after infected by pCLXSN-p16 pseudo virus. All the

G418 resistant SNU-449/pCLXSN-p16 cells exhibited p16 protein expression (Figure 2). Western blot analysis also confirmed that SNU-449 cells showed loss of p16 protein expression and SNU-449/pCLXSN-p16 cells could express p16 protein (Figure 3).

Figure 1 SNU-449 cells show negative p16 staining (original magnification $\times 400$).

Figure 2 SNU-449/pCLXSN-p16 cells show positive p16 staining (original magnification $\times 200$).

Figure 3 Western blot analysis. Lanes 1 and 3: SNU-449/pCLXSN-p16 cells; Lane 2: SNU-449 cells.

Figure 4 *In vitro* growth curves of SNU-449/pCLXSN-p16, SNU-449/pCLMFG-LacZ and SNU-449 cell lines.

Cell growth curves

As shown in Figure 4, *in vitro* growth rates of SNU-449/pCLXSN-p16 cell line, a selected stable p16 protein expression cell line, were significantly inhibited when compared with cell lines SNU-449 and SNU-449/pCLMFG-LacZ in which p16 protein expression was lost. Nearly equal growth rates were observed in both HepG 2.2.15 and HepG 2.2.15/pCLXSN-p16 cell lines.

Cell cycle distribution and cell apoptosis status

The underlying mechanism of *in vitro* growth inhibition seen in the pCLXSN-p16 treated cell line SNU-449/pCLXSN-p16 was investigated by cell cycle analysis using flow cytometry. As shown in table 1, SNU-449/pCLXSN-p16 cell line exhibited significant increase in the percentage of cells in G₀-G₁ phase (68 %), consistent with a cell cycle arrest at the G₁ transition when compared with cell lines SNU-449 and SNU-449/pCLMFG-LacZ. However there was no obvious cell cycle difference between cell lines HepG2.2.15/pCLXSN-p16 and HepG2.2.15.

Table 1 Cell cycle analysis

Cell type	Cell cycle(%)		
	G ₀ -G ₁	G ₂ -M	S
SNU-449	37	36	27
SNU-449/pCLXSN-p16	68	21	11
SNU-449/pCLMFG-LacZ	39	38	23
HepG2.2.15	29	42	29
HepG2.2.15/pCLXSN-p16	32	43	25

Cell apoptosis analysis was performed in cell lines SNU-449, SNU-449/pCLXSN-p16, HepG2.2.15 and HepG2.2.15/pCLXSN-p16 and showed no difference between these cell lines.

Effects of pCLXSN-p16 treatment on HCC tumor growth in vivo

The therapeutic potential of pCLXSN-p16 to treat HCC tumors *in vivo* was studied in nude mice. Tumors were created by injecting 1×10⁷ SNU-449 or SNU-449/pCLXSN-p16 cells in 100 μl 0.9 % salt solution into the right flank of nude mice as described above. The succeed rate of tumor establishment at the first time injection of tumor cells SNU-449/pCLXSN-p16 in nude mice was 70 % (7/10). At the same time only 40 % (4/10) nude mice succeeded to establish tumors at the first time injection of SNU-449 cells. Animals who were succeeded to establish tumors were observed over a period of 52 days from the day of injecting tumor cells. During the observing period animals injected with SNU-449/pCLXSN-p16 cell line survived significantly longer than those injected with SNU-449 (*P*<0.05). The mean survival time of animals injected with SNU-449/pCLXSN-p16 and SNU-449 were 42.1±9.0 days and 32.7±6.7 days, respectively (Table 2). The survival rate of nude mice injected with SNU-449/pCLXSN-p16 cell line was higher than that of those injected with SNU-449. Figure 5 was the survival curves of nude mice injected with cell lines SNU-449/pCLXSN-p16 and SNU-449, respectively.

Two groups of nude mice with each of 6 animals were established with tumors by injection of cell lines SNU-449/pCLXSN-p16 and SNU-449, respectively and were observed for a period of 23 days. All the animals survived during the observing period. At 23th day after injection of tumor cells they were all sacrificed for measurement of tumor volumes. The tumor volume in nude mice injected with SNU-449/

pCLXSN-p16 was 234±125 mm³, significantly smaller than that in those injected with SNU-449 cell line (726±513 mm³).

Figure 5 Survival curves of nude mice.

Table 2 The survival time and survival rate of nude mice

Group	animal number	survival time(d)	survival rate
Salt solution	5	52.0±0.0	100%
SNU-449	7	32.7±6.7	0%
SNU-449/pCLXSN-p16	7	42.1±9.0 ^a	28.6%

^a*P*<0.05 Compared with group SNU-449

DISCUSSION

The hypothesis that the inactivation or loss of certain genes, specially tumor suppressor genes, leads to both tumor growth and progression is now well established and provides a unique opportunity in cancer gene therapy. The decision to use p16 gene as a therapeutic agent against human hepatocellular carcinoma was based on our earlier work where we had found p16 gene was frequently inactivated in HCCs^[14]. In the fact, P16 gene was widely used in the study of tumor gene therapy and showed obvious tumor suppressing effects in many kinds of tumors^[23-31]. In the present study we cloned human p16 cDNA and constructed a replication-defective, recombinant retrovirus that express high levels of the tumor suppressor protein p16.

The pCLXSN vector was modified from pLXSN vector. It's more safe and can produce higher titers of retrovirus when cotransfected with the pCL-Ampho packaging construct into 293 cells than its' prototype pLXSN. It permits the expression of a number of cell cycle-regulatory proteins such as p16 that are otherwise difficult to study in retroviruses because of their potent cytostatic or cytotoxic effects^[22]. In this study we cotransfected a report gene LacZ expression vector pLMFG-LacZ and packaging constructs pCL-Ampho into 293 cells. The transfecting efficiency was determined and only 1 % (data not shown), much lower than reported 30 %^[15]. Considering the lower transfecting efficiency we selected a stable virus-producing cell lines after the p16 protein expression vector pCLXSN-p16 was cotransfected with pCL-Ampho into 293 cells. The titer of pCLXSN-p16 retrovirus produced by the stable virus-producing cell line was determined to be 1.6×10⁵CFU/ml. It is much lower than reported 5×10⁵-2×10⁶^[22]. Only 20 % SNU-449 cells showed positive p16 protein expression 24hs after infected by the pCLXSN-p16 pseudo retroviruses. We then determined to select a SNU-449 cell line which stably expresses p16 protein after infected by the pCLXSN-p16 and use it to study the treatment effect of p16 gene transfer to the HCC cells.

Initial *in vitro* experiments demonstrated that the reintroduction of p16 gene significantly inhibited cell growth

by inducing G1-S cell cycle arrest in the SNU-449 HCC cell line in which p16 gene was originally inactivated. In contrast, no inhibition of cell growth was found when wild type p16 gene was transfected into another HCC cell line HepG2.2.15 in which p16 protein was normally expressed. This suggested that inactivation of p16 gene and its downstream gene may contributed to the carcinogenesis of HCC. Our results were similar to others' reports about treatment study of some tumors using p16 gene transfer^[32-35]. No changes of tumor cell apoptosis were found when wild type p16 gene was introduced to cell lines SNU-449 or HepG2.2.15. This suggested that introduction of p16 gene may not cause apoptosis of HCC cells.

Subsequent *in vivo* studies showed that the first time establishment of tumors in nude mice was more difficult using p16 gene treated SNU-449 cells (SNU-449/pCLXSN-p16) than using the cells without treatment. This suggested that reintroduction of p16 gene could reduce the invasion ability of HCC tumor cells. Further observation demonstrated that reintroduction of p16 gene into tumor cells significantly inhibited tumor growth rate in tumor-established animals and extended the survival time and survival rate of these animals during the observing period. The results of *in vitro* and *in vivo* study were consistent.

Our results support the use of retrovirus-mediated p16 gene treatment for HCC and provide an important foundation from which to build future preclinical studies and initiate future human clinical trials. If pCLXSN-p16 is proved to be effective in the clinical setting, it will offer a much useful addition to present therapeutic regimens. PCLXSN-p16 may potentially develop into an important adjuvant therapy, expedient in treating unresectable HCC or microscopic residual disease after surgical resection. However, the titer of pCLXSN-p16 pseudo retrovirus must be boosted in the future studies.

Abstract

AIM: To find the point mutations meaningful for inactivation of liver-related putative tumor suppressor gene (LPTS) gene, a human novel liver-related putative tumor suppressor gene and telomerase inhibitor in hepatocellular carcinoma.

METHODS: The entire coding sequence of LPTS gene was examined for mutations by single strand conformation polymorphism (SSCP) assay and PCR products direct sequencing in 56 liver cancer cell lines, 7 ovarian cancer and 7 head & neck tumor cell lines and 70 pairs of HCC tissues samples. The cDNA fragment coding for the most frequent mutant protein was subcloned into GST fusion expression vector. The product was expressed in *E.coli* and purified by glutathione-agarose column. Telomeric repeat amplification protocol (TRAP) assays were performed to study the effect of point mutation to telomerase inhibitory activity.

RESULTS: SSCP gels showed the abnormal shifting bands and DNA sequencing found that there were 5 different mutations and/or polymorphisms in 12 tumor cell lines located at exon2, exon5 and exon7. The main alterations were A(778)A/G and A(880)T in exon7. The change in site of 778 could not be found in HCC tissue samples, while the mutation in position 880 was seen in 7 (10 %) cases. The mutation in the site of 880 had no effect on telomerase inhibitory activity.

CONCLUSION: Alterations identified in this study are polymorphisms of LPTS gene. LPTS mutations occur in HCC but are infrequent and of little effect on the telomerase inhibitory function of the protein. Epigenetics, such as methylation, acetylation, may play the key role in inactivation of LPTS.

INTRODUCTION

Human hepatocellular carcinoma (HCC), the predominant histological subtype of primary liver cancer is one of the most common malignancies of the liver worldwide. The development of human cancer results from the clonal expansion of genetically modified cells that acquired selective growth advantage through accumulated alterations of proto-oncogenes and tumor suppressor genes^[1]. Chromosomal analysis using polymorphic DNA markers that distinguish different alleles has revealed loss of heterozygosity (LOH) of specific chromosomal regions in various types of cancers and mapping of regions with a high frequency of LOH has been critical for identifying negative regulators of tumor growth, which will be of great help in positional cloning of tumor suppressor genes^[2].

We have cloned a novel human liver-related putative tumor suppressor gene, LPTS by means of allelic-loss mapping and positional candidate cloning^[3]. LPTS gene mapped to chromosome 8p23, a locus with high-frequency LOH and a hot spot of tumor suppressor in HCC^[2, 4]. The expression of LPTS was ubiquitous in normal human tissues, whereas levels appeared to be significantly reduced, or sometimes undetectable in HCC cells and neoplastic tissues. The gene for LPTS is a growth-arrest gene that acts directly or indirectly to control the proliferation of cells, and might be a tumor suppressor gene^[3]. LPTS gene has 7 exons totally and encodes two transcripts, one is LPTS-S, lacking exon6 and encoding a 174-a.a. protein; the other is LPTS-L, encoding a 328-a.a. protein with entire 7 exons. The LPTS-L is highly homologous to PinX1 identified recently^[5]. LPTS-L and PinX1 have quite different 3' -untranslated region and encode a same protein, referred to LPTS-L/PinX1. LPTS-L/PinX1 has strong telomerase inhibitory activity both *in vivo* and *in vitro*.

In this study, we collected 56 HCC cell lines, 7 ovarian cancer cell lines and 7 head & neck tumor cell lines to perform single strand conformation polymorphism (SSCP) assay^[6,7] to screen the point mutations in LPTS gene. Then we detected those mutations identified from SSCP assay in 70 pairs of HCC tissues to confirm the existence of real mutations in HCC tissue samples. Finally, telomerase activity assay was done to study the effect of the point mutation on the function of protein *in vitro*.

MATERIALS AND METHODS

Tumor cells and HCC tissue samples

The cell lines, including 56 liver cancer cell lines, 7 ovarian cell lines and 7 head and neck tumor cell lines, were from mainland of P.R. China, Japan, France, Taiwan, Hongkong and America separately. The cell lines were cultured in Dulbecco's Modified Eagle Medium (DMEM, Life Technologies Inc., Grand Island, NY) or in RPMI medium 1 640 (Life Technologies Inc.),

supplemented with 10 % fetal calf serum (FCS, Life Technologies Inc.) with or without non-essential amino acid (Life Technologies Inc.) according to suppliers. All the samples of primary HCC (Ks), adjacent samples of nontumorous tissues (Ls), were obtained from Shanghai Eastern Hepatobiliary Surgery Hospital (Shanghai, P.R. China), with the agreement of each patient. The serial numbers were those recorded by the hospital. All tissues were placed in liquid nitrogen immediately after surgical resection.

Point mutation assay

According to the genome sequence of LPTS gene, we synthesized 11 pairs of primers covering 7 exons of the gene, with length of each PCR product around 170 to 250 bp (Table 1). Genomic DNA was separated as described^[8]. PCR was performed in a 25-μL reaction mixture that contained 2 μL Genomic DNA (around 50 ng) from each cell line as template, 2 μL primers mix (20 μM each), 0.4 μL dNTP mix (12.5 mM each), 4.75 μL H₂O, 0.25 μL Taq DNA polymerase (Life Technologies Inc.), and 15.6 μL premix (16 mM TrisHCl pH8.4, 80 mM KCl, 2.4mM MgCl₂ and 0.16 % Tween-20). PCR reaction conditions were described in Table 1. In Table 1, SD referred to the step-down PCR, the annealing temperature was declined 3 °C every 3 cycles for 94 °C 45 sec, annealing temperature 1 min and 72 °C 1 min from 68 °C until the indicated temperature and then for another 25 cycles of standard PCR reaction. The products of PCR were separated by electrophoresis on 2 % agarose gel to check the specificity of each PCR reaction. The PCR products were sequenced directly or performed SSCP assay as described below.

Table 1 Primer sequences for the coding region of the LPTS gene

SD: step-down PCR

For SSCP assay^[9,10], 3 μL PCR product, added with 4 μL denaturing buffer (95 % formamide, 10 mM NaOH, 0.25 % bromophenol blue and 0.25 % xylene cyanol), were kept at 95 °C for 5 min and then loaded 5 μL denatured mixture sample

directly into each of sample wells of GeneGel Excel, 0.5 mm thin, pre-cast polyacrylamide ready-to-run gel for DNA electrophoresis (Amersham Pharmacia Biotech Inc.). Electrophoresis was done on GenePhor DNA separation system (Amersham Pharmacia Biotech Inc.) at 150 Voltage for 10 min and then 600 Voltage for 2 hours at 4 °C. At the end of running, silver stained the gel with DNA silver staining kit (Amersham Pharmacia Biotech Inc.) in accordance with the manufacturer's protocol.

Expression and purification of GST fusion protein

The coding sequence of protein fragment for expression was cloned in frame into the *E.coli* GST fusion expression vector pGEX-4T2 (Amersham Pharmacia Biotech Inc.), then transfected the construct into *E.coli* BL21(DE3). The protein was expressed with IPTG induction for 3 hours and purified by glutathione-agarose (Sigma) column.

TRAP telomerase activity assay

HCC cells SMMC-7721 were lysed in lysis buffer (10 mM TrisHCl pH7.5, 1 mM MgCl₂, 1 mM EGTA, 0.1 mM PMSF, 5 mM 2-mercaptoethanol, 0.5 % CHAPS, 10 % glycerol) on ice for 30 min and then centrifuged at high speed for 30 min, the suspension containing telomerase was used for TRAP assay. The GST-fused protein was incubated with cell extract for 10 min at 4 °C before subjecting to telomerase extension according reference^[11]. Telomerase products were separated on 10 % polyacrylamide gels, which were stained with silver nitrate.

RESULTS

5 alterations were found in 12 tumor cell lines

We mainly screened the point mutations of LPTS gene in 56 liver cancer cell lines by means of SSCP. For chromosome 8p23 is a hot spot containing tumor suppressor in many types of tumors except for liver, including ovarian cancer and head and neck tumors, we checked LPTS gene in another 7 ovarian cancer cell lines and 7 head and neck tumor cell lines altogether. Among the cell lines analyzed, about half of those are homozygous in region between D8S550 and D8S518 on chromosome 8p23, covering the LPTS gene, by fine mapping of allele deletion (loss of heterozygosity) in Chromosome 8p.

After PCR amplification the fragment, PCR products were checked for specificity on 2 % agarose gel. Only the good specific amplification could be used in the latter assay (Figure 1). The specific PCR products were separated in PAGE gel and stained with silver nitrate. The abnormal band patterns, such as loss or gain of extra bands, different migration of bands, comparing to the negative and positive controls which had been sequenced in advance, suggested this sample might have point mutations (Figure 2). The products with abnormal migration pattern were sequenced and determined. The point mutations as shown in Table 2, were mainly located in exon 2, exon 5 and exon 7. In exon 2, there were two types of alterations, C (161) changed to T, predicted effect was the change from alanine to valine in cholangiocarcinoma cell CCLP1, and the other was C (183) to T, which was silent at the protein level and might therefore be considered as a polymorphism. In exon 5, only one point mutation of A (497) to G in HCC cell line PLCPRF5 was found, causing the encoded amino acid changing from tyrosine to cysteine. Two frequent mutations clustering at positions 778 and 880 were found in exon 7. The A778G changed the threonine residue to an alanine. All cell lines harboring this polymorphism were heterozygous at position 778 with the second allele retaining the wild type. The second mutation cluster A880T caused a change from serine to cysteine.

Table 2 The alterations of LPTS-S and LPTS-L in tumor cell lines

Cell line	Cell type	Mutation	Exon	Codon	Predicted effect

**Figure 1** Agarose gel analysis of PCR products for SSCP assay. Agarose gel separation was used to determine the specificity of PCR reaction. PCR products with only one specific band of right size in the gel can be used to SSCP assay. M: 100 bp ladder.**Figure 2** Some different electrophoresis patterns in SSCP assay of each exon. Arrows showed the differences, including extra bands, differential bands shifting, and so on.

Figure 3 The sequences of mutation site of 880 in two pairs of HCC tissues. (A) HCC sample 91K, 91L; (B) HCC sample C64K, C64L. 'K' represents HCC tissue and 'L' represents adjacent nontumorous liver tissue. Arrow indicated the site of 880.

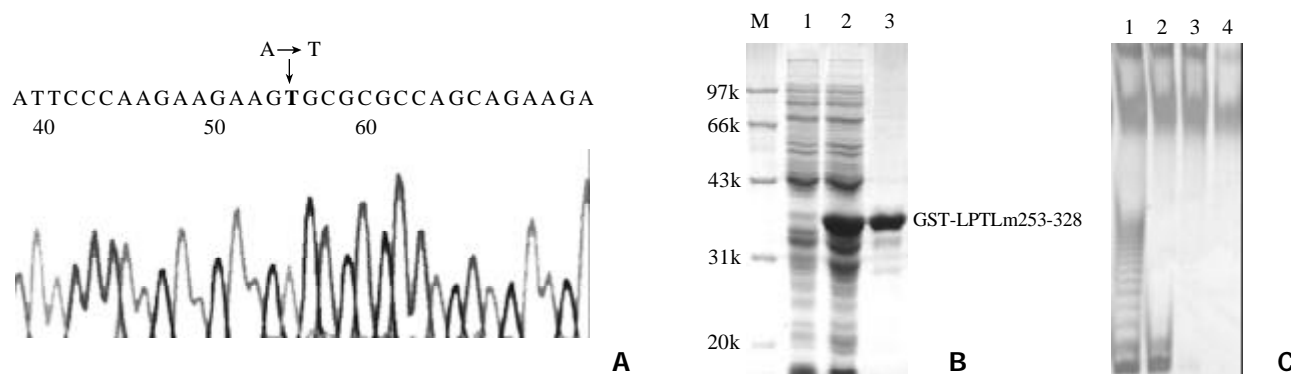

Figure 4 The point mutation in position 880 has no effect on the telomerase inhibitory activity of LPTS-L. A. The 'A' in position 880 of LPTS-L transcript was mutated to 'T'; B. The expression and purification of GST-LPTLm253-328, 1, without IPTG induction; 2, IPTG induction; 3, purified protein. C. The telomerase inhibiting activity assay in vitro of mutant protein LPTLm253-328 in SMMC-7721 cell extract. 1-4 were 0.1, 0.5, 1, 5 μg protein added in cell extract for 10 min, respectively.

Position (880) A to T was identified in 7 patients (10 %)

From the assay in HCC and other tumor cell lines, we can see that the major point mutations are in exon 7. The point mutation in 778 and 880 nt caused threonine and serine which being the candidate sites for phosphorylation changed to alanine and cysteine. The mutation in 880 nt turned to the cysteine, which might form disulfide bond and affect the conformation of the protein. It would be very important to confirm the existence of these two mutations in HCC tissues. Next, we collected 70 pairs of HCC samples, amplified the exon 7 and sequenced directly. In all 70 pairs samples, we could not find the point mutation in position 778, whereas the mutation in site of 880 was detected in 7 HCC samples and the mutation frequency was 10 %. The mutation in the site of 880 was also A/T heterozygous, which was shown double pits in sequence reaction (Figure 3).

The significance of A(880) mutation

LPTS-L/PinX1 possessing strong telomerase inhibitory activity had been determined by *in vivo* and *in vitro* experiments. To

study the effect of telomerase inhibitory function of A(880) mutant, we designed PCR primer with point mutation at the site of 880, 5'-GAA TTC CCA AGA AGA AGT GCG CGC CA-3', the mutated site of 'T' was indicated in italic type. We subcloned the mutated cDNA fragment (from amino acid subunit 253 to 328) into GST fusion expression vector pGEX-4T2 and purified the GST-fused mutant protein. After TRAP telomerase activity assay, we found that the mutant protein still had strong telomerase inhibitory activity in HCC cell line SMMC-7721 cell extract (Figure 4). From these results, we concluded that the point mutation in position 880 of LPTS gene had no effect on telomerase inhibition.

DISCUSSION

Somatic inactivation of a tumor suppressor gene is usually achieved by intragenic mutation in one allele of the gene, with subsequent by loss of a chromosome region that spans the second allele, showed loss of heterozygosity (LOH). Among the various deleted chromosome regions identified by several laboratories, chromosome 8p has a particularly high frequency

of LOH^[2, 12-14] and a growing body of evidence suggests that chromosome 8p is active in many types of carcinogenesis and metastasis including liver, breast, colorectal, prostate, lung, head and neck, pancreatic and urinary bladder carcinomas^[14-18]. However, there have been no reports of the identification of a tumor suppressor gene on 8p.

LPTS gene is a possible candidate tumor suppressor localized in 8p23 region, which is a negative regulator in cell proliferation^[3]. According to Kundson's tumor suppressor "two-hit" model^[19], one tumor suppressor needs to be hit twice to be inactivated. To clarify the relationship between LPTS gene and HCC, we searched for point mutations in all seven exons of LPTS gene in HCC tissue samples and HCC cell lines. In 70 tumor cell lines and 70 pairs of HCC tissues analyzed, there were mainly two point mutations in exon 7, position 778 and 880. The mutation at the site of 778 was found only in several HCC cell lines, but not in clinical HCC tissues. The mutation at the site of 880 has the mutation frequency of 10 % in HCC tissues, but the mutation has no effect of the telomerase inhibitory activity of LPTS-L/PinX1 protein, suggesting that this position is a polymorphism site of LPTS gene.

During our preparation of this manuscript, another research group in Korea reported their research work of genetic analysis of LPTS gene in HCC sample from South Korea. They also found that LPTS gene indeed had very high LOH frequency (34.5 %) in HCC patients, but also no point mutations could be found in HCC patients from South Korea, same with our results in Chinese HCC patients^[20]. Taken the above data together, LPTS gene has high frequency of LOH in HCC, but has no point mutation in the last allele, suggesting that inactivation of LPTS gene may not be caused by point mutation. However, we cannot rule out completely the epigenetic inactivation, such as methylation, acetylation etc^[21-23]. Indeed, we found that there were two CpG islands, about 1.2 kb in length, in the upstream of LPTS gene transcription initiating site. Study of the methylation status in the regulation of LPTS gene is being performed now.

Abstract

AIM: To characterize the gene expression profiles in different stages of carcinogenesis of esophageal epithelium.

METHODS: A microarray containing 588 cancer related genes was employed to study the gene expression profile at different stages of esophageal squamous cell carcinoma including basal cell hyperplasia, high-grade dysplasia, carcinoma *in situ*, early and late cancer. Principle component analysis was performed to search the genes which were important in carcinogenesis.

RESULTS: More than 100 genes were up or down regulated in esophageal epithelial cells during the stages of basal cell hyperplasia, high-grade dysplasia, carcinoma *in situ*, early and late cancer. Principle component analysis identified a set of genes which may play important roles in the tumor development. Comparison of expression profiles between these stages showed that some genes, such as P160ROCK, JNK2, were activated and may play an important role in early stages of carcinogenesis.

CONCLUSION: These findings provided an esophageal cancer-specific and stage-specific expression profiles, showing that complex alterations of gene expression underlie the development of malignant phenotype of esophageal cancer cells.

INTRODUCTION

Cancer development is a complex multi-step process, involving various genetic and epigenetic changes. Progress of phenotypes from normal to advanced carcinoma is controlled by a transcriptional hierarchy that coordinates the action of hundreds

of genes. Conventional approaches investigating one or several candidate genes at a time can not show the whole story of carcinogenesis. The generation of vast amounts of DNA sequence information, coupled with advances in technologies developed for the experimental use of such information, allows the description of biological processes from a view of global genetic perspective. One such technology, DNA microarray, permits simultaneous monitoring of thousands of genes^[1,2]. Fuller *et al*^[3] and Sgroi *et al*^[4] have used this new technique in analyzing gene expression profiles in human glioblastoma, human breast cancer and matched normal tissues. However, little is known about the exact expression changes in each stage of tumorigenesis, which will help us identify the exact series of events that leads to the initiation and progression of cancer development.

In this study, esophageal cancer was chosen as a model to analyze the changes of expression profiles in different stages of carcinogenesis. By using microarray membranes, expression of 588 known cellular genes were profiled in normal esophageal tissues, basal cell hyperplasia, high-grade dysplasia, carcinoma *in situ*, early and advanced cancer. Our results revealed some genes differently expressed in a certain stage, and some kept up or down regulated in all stages toward cancer.

MATERIALS AND METHODS

Biopsy specimens and primary esophageal cancer tissues

Biopsy specimens were collected from the individuals who were more than 35 years old, underwent endoscopy examination in a screening for early cases of esophageal cancer in Henan province in North China, where has the highest incidence rate of this fatal cancer in the world. Agreements have been obtained from all individuals informed consents issued. In each case, 4 pieces of tissues with the size of 0.01 cm³ were separately removed from the mucosa, two of them were instantly frozen and kept in liquid nitrogen until use, and the other two underwent pathologic diagnosis according to the criteria of Riddell and associates. Specimens of normal esophagus, basal cell hyperplasia, high-grade dysplasia, carcinoma *in situ*, and early carcinoma were obtained in this study. Every tissue specimen was mostly composed of normal or abnormal epithelial cells.

Cancer and adjacent almost normal tissues with size of about 0.5 cm³ were collected from patients with primary esophageal cancer in Cancer Hospital of the Chinese Academy of Medical Sciences after informed consent was obtained. Fresh samples were dissected manually to remove mixed connective tissue and stored in liquid nitrogen. Pathological diagnosis showed that the cancers were from squamous cell at medium to high grade differentiation, the matched almost normal mucosa did not show any invasion of cancer cells.

Human cancer cDNA expression array

Human cancer cDNA expression array membrane was purchased from Clontech Laboratories Inc. (Palo Alto, CA), each membrane contains of 588 well characterized genes along with 9 housekeeping genes as internal control. During this study, membranes of the same lot were used to ensure the reproducibility.

RNA extraction

The biopsy specimens of the same histological diagnosis were pooled and the total RNA of different kinds of samples was extracted with Micro RNA isolation kit (Stratagene, La Jolla, CA). Before labeling, 5 µg total RNA of each type was treated with 2 µl DNase I (10 unit/ml, Boehringer Mannheim, Mannheim, Germany), 1 µl RNasin (40 units/µl, Promega) at 37 °C for 15 min to remove contaminated DNA.

Hybridization and exposure

Following the recommendation of the manufacturer, ³²P-labelled cDNA probes were generated by reverse transcription from 5 µg of RNA sample in the presence of [α -³²P]dATP (3 000 ci/mmol, Du Pont). Each cDNA probe was then hybridized to a membrane at 65 °C overnight. The membranes were washed twice in 2×SSC, 0.5 % SDS at 65 °C for 30 minutes, then twice in 0.2×SSC, 0.5 % SDS at 65 °C for 30 minutes, then exposed to X-ray film at -80 °C for 2-3 days.

Hybridization pattern analysis

Images of individual autoradiography for each stage of carcinogenesis were digitalized by Fluor-STM MultiImager System (Bio-Rad Laboratories, Inc.) The hybridization pattern of arrays was analyzed and compared using AtlasImageTM 1.01 software (Clontech). To normalize the relative gene expression, beta-actin and alpha tubulin were used as internal references whose expression level was found stable in different developmental stages in our study. These genes were preferred also because they are conventionally used as internal references for measuring gene expression levels in Northern blot, RNase protection and semi-quantitative RT-PCR.

Confirmation by semi-quantitative RT-PCR analysis

To validate the expression pattern identified on the expression arrays, 5 genes were randomly picked and semi-quantitative RT-PCR was performed to confirm their differential expression with cDNA template from esophageal cancer and adjacent almost normal tissues. First strand cDNA was synthesized from 5 µg RNase-free DNase treated total RNA using the SuperscriptTM Preamplification system for First Strand cDNA Synthesis (Life Technologies, Inc) as described by the manufacturer. An aliquot of 1/20 of the reverse transcribed product was used as template in the following PCR amplification. Reactions undergone in 25 µl total volume containing 1×PCR buffer, 1.5 mmol/L MgCl₂, 200 µmol/L dNTPs, 1.5 u Taq Polymerase (Life Technologies, Inc) and 40 µmol/L gene specific primers under the conditions: 94 °C 5 min, followed by 25-28 cycles each of 94 °C 20 sec, 58 °C 30 sec, 72 °C 1 min. Amplification of beta actin with same aliquot of cDNA template was used as internal reference to determine the relative gene expression.

Gene specific primers: Rho8 5' -GGACACTTCGGGTTCTCCTTAC-3', 5' -TGTGGCTCTCTGTGATTTGTTTC-3'; IL-1 beta 5' -GCAGAAAGGGAACAGAAAGGTT-3', 5' -AAGGAGGCACACCAGTCCAAAT-3'; Interleukin 1 receptor antagonist 5' -ACTCTCCTCCTCTTCTGTTC-3', 5' -GCTTGTCTGCTTTCTGTTCTC-3'; Cytokeratin 4 5' -GGGAACAAAGCATCTCCAT-3', 5' -ATCTCAGGGTCAATCTCCAC-3'; Wnt-13 5' -GCCAAAGTTAGATGGGACAAAG-3', 5' -TTGAACAGGCAGCAAGTAAGC-3'.

Principle component analysis

A principle component analysis was used to explain the variance-covariance structure of the gene expressions in 6 stages of tumor development. The purpose of principle component analysis is data reduction, and interpretation through a few linear combinations of the original variables (gene expressions)^[5].

Principle component analysis starts with k variables which

represent the expression profiles of k genes. The t th element of the j variable corresponds to the expression level of the j th gene in the t stage of the tumor development. Principle component analysis intends to replace the k variables by p principle components where p is smaller than k , while minimizing loss of information. The principle component is a linear combination of the variables x_1, x_2, \dots, x_k and can be constructed by the eigenvector e_i ($i=1,2,\dots,k$) of the covariance matrix V of the variables x_1, x_2, \dots, x_k , where the eigenvector e_i of the matrix V is defined as any vector satisfying the equation $V e_i = \lambda_i e_i$, and λ_i is called the corresponding eigenvalue associated with the eigenvector e_i . The elements of the eigenvector measure the importance (loading score) of the genes to the principle component and the eigenvalue measures the variance of the corresponding principle component explaining variations of expressions of a linear combination of genes represented by the principle component. The first principle component with the largest eigenvalue has the largest variance, the second principle component with the second largest eigenvalue has the second largest variance and so on. It can be shown that λ_i is equal to the variance of the i th principle component.

Although k variables are required to reproduce the total system variability, often much of this variability can be accounted for by a small number of principle components with larger eigenvalues (variances) which explain large proportions of variations of gene expressions underlying some biological processes. Principle component analysis was used to identify a set of genes which may contribute to the tumor development.

RESULTS

Expression pattern of 588 known genes in progression of carcinoma

High quality total RNA was isolated from biopsy specimens. The RNA was reverse-transcribed into ³²P-labeled cDNA probe and hybridized to AtlasTM Human Cancer cDNA expression array to profile the expression of 588 known genes. The hybridization patterns were imaged by the Fluor-STM MultiImage System and analyzed by AtlasImageTM 1.01 software. Genes with adjusted intensity difference >20 000 or ratio >2 between two stages were supposed to be regulated differentially. Figure 1 showed the cDNA array images along with color charts indicating up-regulated genes with red, down-regulated ones with blue, and non-changed with green.

There were more than 100 genes up or down regulated substantially in every abnormal stage when compared to human normal mucosa. In stage of basal cell hyperplasia II, there were 122 genes up regulated and 17 down regulated; in stage of high grade dysplasia, there were 134 genes up regulated and 33 down regulated; in stage of squamous cell carcinoma in situ, there were 114 genes up regulated and 10 down regulated; in stage of early cancer, there were 169 genes up regulated and 13 down regulated; In stage of late cancer, there were 77 genes up regulated and 60 down regulated. As shown in the color charts of Figure 1 the types as well as expression level of genes are different among each stage.

Validation of Array Data with RT-PCR

To further investigate the reliability of our array data, we randomly picked 5 differentially expressed genes and measured the expression of the genes in the paired cancer and adjacent almost normal tissues using RT-PCR. Figure 2 showed that the different expression pattern of each of the five genes as determined by RT-PCR were similar to those observed with cDNA array in more than half of 12 pairs of matched tissues (squamous esophageal cancer and matched adjacent almost normal tissue), confirming the reliability of our array data. Our observed correlation between the cDNA array and RT-PCR are consistent with that observed by others^[6,7].

Figure 1 Expression patterns of genes in esophageal tissue of normal, basal cell hyperplasia, high-grade dysplasia, carcinoma in situ, early and advanced cancer. Total RNAs were isolated from these tissues, reverse-transcribed into ^{32}P -labeled cDNAs and hybridized to AtlasTM Human Cancer cDNA expression arrays. A complete list of names and location of the arrayed gene can be

found in the instruction manual and website from Clontech. Data was analyzed by AtlasImage™ 1.01 software. A,B,C,D,E,F showed hybridization result of normal cells, basal cell hyperplasia, high-grade dysplasia, carcinoma in situ, early and advanced cancer; G, H, I, J, K showed the color charts indicating up-regulated genes with red, down-regulated genes with blue, and non-changed genes with green in the later 5 stages when compared to normal tissue; L, M, N, O, P showed the pathological image of normal, basal cell hyperplasia, high-grade dysplasia, carcinoma in situ, early and advanced cancer respectively.

Figure 2 Validation of array data with RT-PCR: Rho8, Wnt 13, IL-1 beta, IL-1 receptor antagonist and cytokeratin 4 were chosen to further investigate the reliability of the array data using RT-PCR. The figures showed part of the RT-PCR results of five genes in cancer (designated T) and matched almost normal tissues(designated N). P means positive control.

Principle component analysis Identified a set of genes which may play Important roles in cancer development

Principle component analysis showed that there were 5 principle components in the 6 stages of cancer development. The three principle components with eigenvalues 233.52, 121.59 and 101.34 respectively, accounted 92 % of total variations of gene expressions in 6 stages. Table 1 showed a set of genes with largest loading score (negative or positive) in the first three principle components in the ascending order. The loading scores are highly correlated with the expression level of genes. In Table 1 we also listed the ratio of the gene expressions in the corresponding stages of the tumor development. From Table 1 we can see that the first principle component roughly describes the changes of the gene expression level in the first and last stage of tumor development. Nine genes in the upper of the table were up-regulated in the stages of basal cell hyperplasia and early cancer, meanwhile seven genes in the bottom of the table were down-regulated in these stages. Genes GAF, CAPR, CASP8, BMP5, MIF and MYC may play important roles in the esophagus tumorigenesis. GAF (Glia-activating factor) is a novel heparin-binding growth factor purified from the culture supernatant of a human glioma cell line with growth-stimulating effect on glial cells *in vitro*. GAF domains are ubiquitous motifs present in cyclic GMP (cGMP)-regulated cyclic nucleotide phosphodiesterases and form a new class of cyclic nucleotide receptors distinct from the regulatory domains of cyclic nucleotide-regulated protein

kinases and ion channels^[8], the role of GAF in tumor development has not been characterized yet; CAPR is cadherin-associated protein related, also named as alpha 2 catenin, the abnormal expression of adhesion molecules (E-cadherin, alpha-catenin) has been reported as markers of high malignant potential in esophageal cancer^[9], and it was suggested that alpha catenin has prognostic significance in colorectal and prostate cancer^[10]; The human CASP8 gene, whose product is also well known as caspase 8, encodes an interleukin-1beta converting enzyme (ICE)-related cysteine protease that is activated by the engagement of several different death receptors. Caspase 8 is a cysteine protease regulated in both a death-receptor-dependent and -independent manner during apoptosis, it is well characterized in apoptosis and tumor development^[11]; BMP5 (Bone morphogenetic protein-5) is a signaling molecule which have the ability to induce ectopic bone when placed under the skin of an animal^[12]; MIF (macrophage migration inhibitory factor) is involved in tumorigenesis via promotion of angiogenesis^[13], it is an ubiquitary cytokine whose expression has been investigated in tumors, showing a correlation between tumor aggressiveness and production of this protein by neoplastic cells. MIF is known to function as a cytokine, hormone, and glucocorticoid-induced immunoregulator, it is likely that MIF may function as a novel growth factor that stimulates incessant growth and invasion of melanoma concomitant with neovascularization; Myc is a well known oncogene which was involved in most of tumorigenesis, and

obviously it plays an important role in esophageal cancer development.

The second component involves three stages of the tumor development: basal cell hyperplasia, dysplasia and carcinoma in situ. Table 1 listed nine genes which were up-regulated and eight genes which were down-regulated in the stages of basal cell hyperplasia and dysplasia. The third principle component reflects the changes of the gene expression level in the transition from normal to basal cell hyperplasia and from basal cell hyperplasia to dysplasia. The table listed genes may play an important role in these transitions.

Table 1A Ratio of expression level for a set of genes with the largest loading scores in the first two principal components

Component 1			Component 2		
Gene	Ratio ELCA/LaCa	Ratio BCH/N	Gene	Ratio BCH/N	Ratio DYS/CAIN

Table 2 Genes up or down regulated in all five stages of grade II basal cell hyperplasia, high-grade dysplasia, carcinoma in situ, early and advanced squamous cell carcinoma. Position indicates the gene position on the microarray membrane

Position	Gene Name
Up Regulated Genes	
A2k	G1/S-specific cyclin C
A4i	ERK5
A4j	ERK6
A5b	ERK activator kinase 1
A5l	transcription factor DP2
B3g	caspase-8 precursor
B3i	caspase-9 precursor
B3j	caspase-10 precursor (CASP10)
C1a	DNA-dependent protein kinase
C2c	DNA-repair protein XRCC1
C2j	RAD1
C4b	Wnt-5A
C4k	DVL1
C6m	CCK4
C7k	retinoic acid receptor epsilon
C7l	retinoic acid receptor gamma 1
C7m	retinoic acid receptor beta
D4b	integrin alpha 8
D4j	integrin beta 7 precursor
D4k	integrin beta 8 precursor
D5g	ezrin; cyto villin 2; villin 2
D5j	CD56 antigen
D7f	placenta growth factor 1
E1f	MMP9
E2a	MMP18
F3j	early growth response protein 1
F4l	IL-6
F5e	IL-13
F5k	interferon gamma precursor
F5l	leukocyte interferon-inducible peptide
Down regulated Genes	
C6c	insulin-like growth factor binding protein 2 (IGFBP2)
F4d	interleukin-1 receptor antagonist protein precursor (IL-1RA; IRAP)

Some genes are activated in particular stages

According to their specificity to stages, differentially expressed genes fall into two main categories. The first category contains genes that are up or down regulated in the same way in all 4 abnormal stages. 77 genes belong to this category, including G1/S-specific cyclin C, proliferating cyclic nuclear antigen (PCNA), E2F dimerization partner 2, Wnt5A, retinoic acid receptors (epsilon, gamma 1, beta), early growth response protein 1 (hEGR1), etc. Part of these genes are listed in Table 2. Most of which are genes related to cell proliferation or differentiation. These expression profiles are accordant with the generality of characteristic phenotype of all of the 4 abnormal stages, i.e. decrease in extent of differentiation and increase in rate of proliferation.

The second category contains genes that were up or down regulated in particular stages, some of them seemed to be activated in early stages of carcinogenesis, p160ROCK is one of such genes. Figure 3 showed the expression level of

p160ROCK in 5 stages. P160 ROCK peaked its expression level in the stage of high grade dysplasia, down-regulated rapidly after this stage, recovered its expression level in early and late cancer, which revealed that this gene was transcriptionally activated at pre-cancerous stage.

Figure 3 Expression level of p160ROCK (3A) and JNK2 (3B) in 6 different stages, p160ROCK peaked its expression at stage of high-grade dysplasia and JNK2 peaked its expression at stage of carcinoma in situ. The column chart indicated expression levels of p160ROCK and JNK2 in stages of normal mucosa (designated normal), basal cell hyperplasia II (designated BCH), high grade dysplasia (designated Dys), squamous cell carcinoma in situ (designated CAIN), early cancer (designated ELCA) and late cancer (designated LaCa).

p160ROCK belongs to a family of Rho-associated serine/threonine kinase isozymes and has been identified as a new class of Rho effectors. Its main function is participating the reorganization of the cytoskeletal, and plays an important role in signal transduction from Rho to cytoskeletal^[14] and also get involved in cell motility and morphological changes^[15]. In human hepatocellular carcinoma cells, dominant active p160ROCK transfectants showed increased motility, and dominant negative p160ROCK transfectants showed reduced motility under stimulation. Furthermore, implantation of dominant negative p160ROCK transfectants resulted in a reduced metastatic rate *in vivo* compared with the parent cells or a control transfectant^[16]. In this study, p160ROCK was found transcriptionally activated at the stage of high grade dysplasia, a pre-malignant stage, which imply that activation of the gene may be one of the early events during progress of esophageal carcinogenesis and may be one of the events responsible for morphological changes and increase in cell motility in early stages of carcinogenesis.

JNK2 is another representative gene which peaked its expression level in the stage of carcinoma in situ. Its expression levels in the 5 stages were shown in Figure 3. JNK2, c-Jun N-terminal kinase 2, also named as protein kinase mitogen-activated 9, is a proline-directed serine/threonine kinase activated by dual phosphorylation on threonine and tyrosine residues in response to a wide array of extracellular stimuli. Multiple research showed that JNK2 plays a critical role in coordinating the cellular response to stress and has been

implicated in regulating cell growth and transformation, antisense JNK2 induced growth inhibition which correlated with significant apoptosis^[17]. It was shown that JNK2 plays an important role in cell transformation and carcinogenesis. In this study, JNK2 was found activated at stage of carcinoma in situ, and down regulated in early and late cancer, which showed that this may also be an early events of carcinogenesis and one of the forces pushing the cell from pre-malignancy to malignancy.

DISCUSSION

Tumorigenesis is a complex and multistage process with many genes involved in. As a step toward understanding the complicated changes between normal and malignant cells, this report focused on gene expression profile variations among normal and abnormal esophageal epithelium tissues. Analyzing alterations of gene expression profiles in different stages of neoplasia is necessary for establishing the preventive, diagnostic, therapeutic, and prognostic potential of each related gene. To illustrate the mechanisms controlling malignant changes at molecular level may provide a further understanding of tumorigenesis, as well as new approaches in early detection and treatment of esophageal cancer. Furthermore, since it is impossible to get tissue samples of different stages from one patient, we got the biopsy specimens from different patients and pooled the samples with same pathologic diagnosis together to avoid the individual differences, and semi-quantitative RT-PCR was performed to confirm the reliability of the data. Moreover, we observed that many genes expressed abnormally in this complicated process and those changes mainly involved in cell proliferation, apoptosis, DNA repair, growth factors and cytokines. These genes and their expression alteration constitute a molecular atlas that is stage-specific and esophageal cancer-specific, and possibly being an important supplement to the traditional morphological diagnosis.

Principle component analysis identified a set of genes which plays important role in different stages of tumor development. Although many genes were related to tumorigenesis and development of esophageal cancer, further investigation is still needed to elucidate which gene (s) is the most critical one (s) to this complex process.

Abstract

AIM: To introduce an animal model of hepatocellular carcinoma (HCC) in ACI-rats, and to evaluate the therapeutic effects of Poly-lactide-co-glycolide(Plcg)-microspheres in the transarterial chemoembolization (TACE) in this model, as well the value of this model in the experiments of interventional therapy.

METHODS: Subcapsular implantation of a solid Morris Hepatoma 3 924A (1 mm³) in the livers was carried out in 11 male ACI-rats. The tumor volume (V1) was measured by magnetic resonance imaging (MRI) (13 days after implantation). After laparotomy and retrograde placement of catheter into the gastroduodenal artery (14 days after implantation), the following protocols of interventional treatment were performed: (A) mitomycin C+Poly-lactide-co-glycolide(Plcg)-microspheres ($n=4$); (B) 0.9 % NaCl (control group, $n=7$). 13 days after these therapies the change of the tumor volume (V2) was determined by MRI again.

RESULTS: The success rate of tumor implantation reached to 100 %. The mean tumor volume before TACE (V1) were 0.082 cm³ in group A and 0.096 cm³ in group B respectively. The mean tumor volume after TACE (V2) were 0.230 cm³ in group A and 1.347 cm³ in group B respectively. The mean V2/V1 were 2.860 in group A and 27.120 in group B respectively. Compared to the control group (group B), groups A showed a significant reduction of tumor growth ($P=0.004$) in the period of observation.

CONCLUSION: The growth of liver tumor could be obviously prevented by utilizing Plcg-mitomycin-microspheres in TACE in animal model. This rat model of HCC is suitable for the experimental studies of interventional therapy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies in the world, responsible for an estimated one million deaths annually^[1,2]. In China, HCC has been ranked second of cancer mortality since 1990s^[3]. It has a poor prognosis due to its rapid infiltrating growth and complicating liver cirrhosis^[4]. Surgical resection is still the only potentially curative treatment for HCC, particularly for small HCC^[3]. To date, the resection rate for HCC is unfortunately less than 30 %^[5, 6]. Transarterial chemoembolization (TACE) is currently the first choice of treatment for most unresectable HCC and improve the survival rate in selected patients^[7-13]. However, the technical variants of TACE have often been chosen on an empirical basis and it is not always safe and effective^[14-16]. Although TACE advantageously combines arterial embolization of the vascular supply of HCC with controlled intra-arterial infusion of chemotherapeutic drugs, its application is limited by the lack of appropriate and reliable embolization materials^[15,16]. Recently, poly-lactide-co-glycolide (Plcg)-microspheres has been proved to be a new promising embolic agent^[17,18]. In order to study the interventional therapeutic strategies for HCC, it is necessary to establish a suitable and reproducible animal model. The aim of the present study was to introduce an animal model of HCC with the technique of tumor implantation in ACI-rats, and to evaluate the therapeutic effect of different methods of TACE, including the efficiency of Plcg-microspheres in this animal model. MRI was performed for measuring the tumor volume before and after the TACE in this study.

MATERIALS AND METHODS

Tumor

Morris hepatoma 3 924A, a rapidly growing, poorly differentiated hepatocellular carcinoma, was induced by dietary administration of N-2-fluorenyldiacetamide in an ACI rat. The hepatoma specimens were obtained from the German Cancer Research Center in Heidelberg (DKFZ).

Animal

Inbred male ACI-rats weighing 200 to 220 g ($n=15$) were obtained from the company of Harlan Winkelmann in Germany. The animals were kept under conventional conditions with a temperature of 22 ± 2 °C, a relative humidity of 55 ± 10 %, a dark-light rhythm of 12 hr, and were fed standard laboratory chow and tap water ad libitum.

Anesthesia

All interventional and imaging procedures were carried out under intraperitoneally applied anesthesia with ketamine hydrochloride (Ketanest, Parke-Davis, Germany; 100 mg·kg⁻¹), Xylazinehydrochlorid (Rompun, Bayer, Germany; 15 mg·kg⁻¹) and atropine sulfate (Atropinsulfat Braun, Braun, Germany; 0.1 mg·kg⁻¹).

Tumor implantation (At day 1)

The technique for tumor implantation was basically similar to that described by Yang *et al*^[19,20] with minor modifications^[21].

The Morris Hepatoma 3 924A tumor tissue, recovered from the passaged animals 2 weeks after subcutaneous implantation (corresponding to 5×10^6 tumor cells), was cut into small cubes about 1 mm^3 .

The recipient ACI-rats were intraperitoneally anesthetized, and the upper abdomen was shaved. A small subcapsular incision on the left lateral lobe of the liver was made. The tumor fragment was gently placed into the pocket with a small cotton swab on the liver surface as hemostasis and the abdominal wall was then closed.

Catheterization and TACE (At day 14)

A PE-10 polyethylene catheter (inner diameter 0.28 mm, outer diameter 0.61 mm; Wenzel/Heidelberg, Germany) was used for experiments of TACE under a second laparotomy. By using a binocular operative microscope (M651, Leica/Wetzler, Germany), the catheter was retrograde inserted into the gastroduodenal artery (Figure 1). After slightly drawing the thin rope around the common hepatic artery, the following different agents were injected through the catheter: Group A ($n=4$): TACE with mitomycin C ($0.25 \text{ mg} \cdot \text{kg}^{-1}$) and Plcg-microspheres ($200 \text{ mg} \cdot \text{kg}^{-1}$, diameter: $40 \mu\text{m}$; Institute of Pharmacological Technology, Philipps University, Marburg/Germany).

Group B (control group, $n=7$): injection of 0.9 % NaCl alone.

Figure 1 Catheterization of the gastroduodenal artery *in vivo*

MRI

MRI was performed in a 1.0 Tesla Magnetom superconducting system (Siemens, Erlangen, Germany) supplemented by a commercial coil (Small Field of View) before and after the catheterization (At day 13 and 27). T1-weighted (TR/TE, 400/14 ms) and T2-weighted (TR/TE, 3 000/96 ms) axial SE images with spatial presaturation for controlling the flow artifact were acquired. Slice thickness was 2.0 mm, Matrix was 192×256 . There was no gap between sections. The findings on T1- and T2-weighted SE images were examined in all 11 rats. Tumor volume was determined and evaluated according to the formula: Tumor volume (mm^3) = $\text{Length}(\text{mm}) \times \text{Width}^2(\text{mm})^2 / 2^{[22]}$.

RESULTS

In all the rats receiving tumor implantation with Morris Hepatoma 3 924A, the rate of tumor implantation reached 100 %. None of the animals died during implantation or in the postoperative period.

The sensitivity of MRI for detecting HCC reached 100 %. HCC showed a hypointense pattern on T1-weighted images and a hyperintense pattern on T2-weighted images in the left lateral lobe of the liver (Figure 2, Figure 3). Necrosis,

hemorrhage and metastase of the tumor were not observed. The liver tumor was well discernible from the surrounding liver tissue on each image.

Figure 2 MR images of HCC before the application of Plcg-Mitomycin-microspheres: (a) T1-weighted image (400/14 ms) showed a hypointense pattern in the left lateral lobe of the liver, (b) T2-weighted image (3 000/96 ms) showed a hyperintense pattern in the liver. Necrosis, hemorrhage and metastase of the tumor were not observed.

Figure 3 MR images of HCC after the application of Plcg-Mitomycin-microspheres: (a) MRI T1WI (400/14 ms); (b) MRI T2WI (3 000/96 ms). The tumor volume after the application of Plcg-Mitomycin-microspheres was not changed compared to that before the application.

The efficiencies of Plcg-Mitomycin-microspheres in the interventional therapy of HCC in ACI-rats were shown in Table 1.

Table 1 The efficiencies of Plcg-Mitomycin-microspheres in the interventional therapy of HCC in ACI-rats

	Group A (Plcg)	Group B (control group)
Mean volume (V1) before TACE (cm ³)	0.082	0.096
Mean volume (V2) after TACE (cm ³)	0.230	1.347
Mean V2/V1	2.86	27.12

Compared to the control group (group B), groups A showed a significant reduction of tumor growth ($P=0.004$) in the period of observation by *t*-test.

DISCUSSION

In order to investigate the efficiency of TACE for HCC, it is necessary to have a suitable and reproducible animal model. Various animal models of liver tumor have been established. The diethylnitrosamine model for hepatic tumor induction was simple, and provided a more representative range of tumors for experimental evaluation. However, the high mortality of the animals and various localization/number/size of the tumor in the liver were the major shortcomings. Therefore, the application of this model was extremely limited. The technique with a needle injection of tumor cells into hepatic parenchyma often caused tumor spill from the puncture channel and might result direct injection of the tumor cells into the circulation^[19]. Although a relative high tumor take rate could be obtained by using the Walker-256/VX2 model in rats or rabbits with the technique of tumor implantation, these animal models belonged to carcinosarcoma or adenocarcinoma and were usually utilized for the study of liver metastases^[23-27]. It is well known that the metastasis way and the therapeutic strategies as well the related effects of HCC and sarcoma are quite different from the aspect of histopathology, and a characteristic of HCC which distinguishes it from most metastases to the liver is that it is a highly vascular tumor^[28], so that these animal models are unsatisfactory and not suitable for studying the interventional therapy.

In our present study, an animal model of HCC with the technique of tumor implantation previously described by Yang *et al*^[19,20] was established. The rate of tumor implantation reached 100 %^[17]. Necrosis, hemorrhage and metastases of the tumor were not observed. Histopathologically, Morris hepatoma 3 924A was a poorly differentiated hepatocellular carcinoma, mimicking the Edmondson grade-III hepatoma in humans^[20] (Edmonson's classification is based on the degree of differentiation of HCC). The appropriate growth speed of the liver tumor made it easy for MRI examination^[29]. The blood supply of the tumor mainly came from hepatic arteries which was similar to that in human liver cancers^[19, 29]. As is known to all, HCC was usually hypervascular except for differentiated HCC and TACE was usually effective only for hypervascular HCC^[30-33]. Compared to other animal models, our rat model was more suitable for the study of interventional therapy of HCC, and the related conclusion of the study was more convincing.

MRI examination for measuring the tumor volume without utilizing contrast media was carried out in our experiments. There was no single parameter better than tumor growth rate that could give information on the effects of different therapeutic maneuvers on tumor growth^[22]. In another study of ours, we have demonstrated that MRI as an invasive imaging modality was superior to CT, DSA in the diagnosis of HCC in experiments^[29]. It was supported by histological examination that MRI was also superior to ultrasonography for judging the tumor dimensions^[29]. Another advantage of MRI was its

excellent soft-tissue contrast resolution^[34]. T1-weighted imaging was superior to T2-weighted imaging in depicting early HCC, but the latter could be useful in evaluating the progression of HCC in the histopathologically early stages^[35]. The signal intensity on T2-weighted images correlated with the histological grade and histopathological change of HCC^[35-37]. The detectability of MRI was 100 % in the present study. HCC showed a hypointense pattern on T1-weighted images and a hyperintense pattern on T2-weighted images in the left lateral lobe of the liver. Necrosis, hemorrhage and metastase of the tumor were not observed. The contrast between the tumor and surrounding normal liver parenchyma was clear to observe. Based on these results, we concluded that MRI was useful in the assessment of the therapeutic effects of TACE in HCC.

TACE is one choice of the palliative treatment for unresectable HCC, particularly for patients with multifocal HCC and with acceptable liver functions. TACE caused tumor necrosis by occlusion of the feeding artery of HCC, and its clinical efficiencies have been generally recognized^[38-41]. By using TACE with a combination of cytostatic drugs (mitomycin, doxorubicin, epirubicin, cisplatin, 5-Fu), a reduction of vital tumor tissue could be achieved^[42-44], although the prolongation of survival remained questionable^[45, 46]. As stated before, although TACE advantageously combined arterial embolization of the vascular supply of a neoplasm with controlled intra-arterial infusion of chemotherapeutic drugs, its application was limited by the lack of appropriate and reliable embolic agents. The major problem with embolic agents are twofold^[47]: first, they could often completely obstruct the hepatic artery, leading to difficulties in administration of subsequent courses of hepatic artery chemotherapy. With a relative short half-life of embolic agents, the effectiveness of TACE was not significantly improved; and second, it was easy to aggravate the liver cirrhosis and lead to hepatic failure after repeated TACE. The optimal treatment modality of TACE was unknown^[14, 48].

Recently, Plcg-microspheres have been proved to be a new promising embolic agent in TACE in experiments^[17,18]. Verrijk and co-workers^[49,50] reported that TACE with Plcg-microspheres and CDDP significantly improved the delivery of cytotoxic drugs to liver tumor and simultaneously reduced systemic toxicity in animals. Plcg-microspheres are biodegradable polymers with high molecular size and possess a good tissue compatibility. The degradation rate of polylactides is known to depend on the polymer microstructure that may be of the L, D or D, L type. The polyester lifetime could be controlled in a range of a few days or months^[49-51]. It has been suggested that this drug could slowly release into the tumor tissues principally by a diffusion mechanism. It has also been indicated that the microspheres size of 40 μ m allows a distal and homogeneous migration of the embolic agent within the targeted organ, without passing through the capillary filter^[18], it is this reason that Plcg-microspheres with the size of 40 μ m were chosen in our experiments. Verrijk *et al*^[49,50] also demonstrated, that the absence of a burst effect and an adequate CDDP release from Plcg-CDDP-microspheres then significantly prolonged the first-pass effect, with the result that low systemic platinum levels were maintained while a liver platinum concentration was achieved which was high enough for an antitumor effect. The results of our present studies indicated that Plcg-microspheres could effectively retard the growth of HCC. Compared to the control group (group B), groups A (Plcg) showed a significant reduction of tumor growth ($P=0.004$) in the period of observation by *t*-test. The therapeutic efficiencies of Plcg-mitomycin-microspheres was similar to Gelform+Mitomycin+Lipiodol in our another study (Mean V2/V1=2.86, $P=0.748$, unpublished results).

To conclude, the growth of liver tumor was markedly

prevented by the use of Plcg-mitomycin-microspheres in the TACE in an animal model. This effective and reliable embolic agent might be useful in clinic in future. However, the mechanism of effect of Plcg-microspheres is not clear so far. Data on a large number of animals and the test of application of various cytotoxic agents in the TACE, as well the repeated TACE will be required.

Abstract

AIM: To investigate the risk factors of colon cancer and rectal cancer.

METHODS: A nested case-control study was conducted in a cohort of 64 693 subjects who participated in a colorectal cancer screening program from 1989 to 1998 in Jiashan county, Zhejiang, China. 196 cases of colorectal cancer were detected from 1990 to 1998 as the case group and 980 non-colorectal cancer subjects, matched with factors of age, gender, resident location, were randomly selected from the 64 693 cohort as controls. By using univariate analysis and multivariate conditional logistic regression analysis, the odds ratio (OR) and its 95 % confidence interval (95 %CI) were calculated between colorectal cancer and personal habits, dietary factors, as well as intestinal related symptoms.

RESULTS: The multivariate analysis results showed that after matched with age, sex and resident location, mucous blood stool history and mixed sources of drinking water were closely associated with colon cancer and rectal cancer, OR values for the mucous blood stool history were 3.508 (95 %CI: 1.370-8.985) and 2.139 (95 %CI: 1.040-4.402) respectively; for the mixed drinking water sources, 2.387 (95 %CI: 1.243-4.587) and 1.951 (95 %CI: 1.086-3.506) respectively. All reached the significant level with a *P*-value less than 0.05.

CONCLUSION: The study suggested that mucous blood stool history and mixed sources of drinking water were the risk factors of colon cancer and rectal cancer. There was no any significant association between dietary habits and the incidence of colorectal cancer.

INTRODUCTION

Colorectal cancer is one of the most common malignant tumors^[1-6]. During the past decades, the incidence of colorectal cancer was increased all around the world, more than 500 000 cases were diagnosed as colorectal cancer per year. In the east

of China, there has been a higher incidence of colorectal cancer. In Jiashan County, the mortality rate of colorectal cancer was the highest among China, which is about 20/100 000 per year^[7].

The causes of colorectal cancer are generally regarded as two aspects: heredity and environment^[8-10]. The former includes family history of cancer, intestinal polyp history, and so on. The later includes particularly dietary habit and physical activity.

Nested Case-Control Study (NCCS), an analytical epidemiological study method, was first presented by Mantel N, an American epidemiologist, in 1973^[11], and it was widely used after 1980's^[12-21]. All the subjects in such study are selected from a whole cohort, which is generally called cohort set. Compared with the cohort study, NCCS has the privilege of time-saving, money-saving, and trouble-saving; while compared to case-control study, since the exposure data are collected before the incident of disease, it is certain of the causes and time consequences relationship, and observational bias could be controlled efficiently. All of these characteristics of NCCS are suitable to the study of chronic disease, such as cancer.

There are many reports on the risk factors of colorectal cancer using classical case-control study method, however, few studies used nested case-control study method^[22-29]. The purpose of this study is to explore the risk factors of colorectal cancer, providing evidence for the prevention of colorectal cancer.

MATERIALS AND METHODS

Selection of cases and controls

A colorectal cancer screening program beginning on 1st May 1989 and ending on 30th April 1990 was conducted in ten countries which belonged to Jiashan county, Zhejiang province, China, including Weitan town, Yangmiao country, Xiadianmiao country, *et al*. From 75 842 eligible subjects aged 30 years and over, 64 693 subjects were enrolled as the base cohort set, the response rate was 85.3 %. Moreover, Jiashan county has founded cancer registration system and colorectal cancer report system, monitoring new cancer cases, including colorectal cancer. The cases in this study, who had participated in the 1989-1990 screening program, were the new colorectal cancer patients reported by Institute of Cancer Research and Prevention of Jiashan county. Up to 1998, the total number was 196 cases. Of which, 151 cases were pathological diagnosed, account for 77.1 %, 20 cases were diagnosed in the operation, 10.2 %, 23 cases were diagnosed by endoscopy, 11.7 %. Under the principle of same-country or town, same-sex, and no more than 3 years age disparity, 980 non-colorectal cancer subjects in the cohort set were selected as controls, resulting the final study subjects of 196 cases and 980 controls.

Contents of the study

The study contents composed of three parts as follow: (1). General characteristics: including age, sex, job types, educational levels, address *et al*; (2). Personal habits: including dietary habits, drinking water sources, alcohol consumption and cigarette smoking, *et al*; (3). Symptoms and disease history related with colorectal cancer: including changes of stool status, abdominal operation history, intestinal disease history, asthma history and allergy history, family cancer history, ancylostomiasis history, drug using history, psychic stimulation history, and so on.

Investigation methods and quality control

In the 1989-1990 screening investigation, a well-built *Investigation Manual* as the uniform criteria for inquiring the subjects and filling up the constructed questionnaire was used. All interviewers were trained focusing on the skills of inquiring. No subjects refused to be interviewed except that they were out of towns. For building the database, the questionnaires were coded and put into computer twice to control bias. The data used in this study were taken from this database.

Statistical analysis

Classical analysis methods of case-control study can be used to NCCS data, usually calculating OR value. In this study, Chi-square test was used in the univariate analysis of the data; conditional logistic regression was used in the multivariate analysis. The SPSS 10.0 for windows and the SAS system for windows, version 6.12, were used for completing all the statistical analyses.

RESULTS

General information

In this study, there were 196 cases (84 colon cancer, 112 rectal cancer) and 980 controls. The distribution of age between cases and controls for male and female was shown in Table 1.

Table 1 The distribution of subjects by age and sex

age	male		female	
	case	control	case	control
30-	3	15	7	35
35-	9	49	3	15
40-	14	69	3	19
45-	11	52	14	66
50-	21	110	14	78
55-	24	114	22	104
60-	11	57	13	63
65-	11	54	3	15
70-	2	10	5	26
75-	2	10	3	14
80-	0	0	1	5
Total	108	540	88	440

The average age of case group was 54.5 ± 10.6 years, while that of the control group was 54.3 ± 10.6 year, there was no statistically significant difference ($t=0.127$, $P=0.899$). For sex, there was also no difference statistically ($\chi^2=0.001$, $P=0.979$).

Univariate analysis

In order to control the possible confounding bias the age, sex and resident location were matched in the study design. Given that the risk factors of colon cancer might be different from that of rectal cancer, the analysis of the risk factors were separated into colon cancer and rectal cancer, instead of colorectal cancer. The OR and its 95 % confidence intervals (95 %CI), χ^2 and P values in the univariate analysis were showed respectively in Table 2 and Table 3 (the variables showed $P>0.20$ were excluded).

Table 2 Results of univariate analysis for colon cancer (cases $n=84$, controls $n=420$)

factors	OR	95 % CI	χ^2	P
pork eating($y=1, n=0$)	1.481	0.846 2.593	1.890	0.169
drining mixed water source* ($y=1, n=0$)	2.273	1.255 4.117	7.332	0.007
drining gutter water ($y=1, n=0$)	1.639	0.777 3.457	1.680	0.195
drining well water ($y=1, n=0$)	0.542	0.338 0.870	6.445	0.011
chronic diarrhea history($y=1, n=0$)	2.018	1.003 4.060	3.871	0.049
constipaton history($y=1, n=0$)	0.483	0.171 1.363	1.888	0.169
appendicitis history($y=1, n=0$)	1.697	0.966 2.981	3.386	0.066
appendix operating history($y=1, n=0$)	1.707	0.873 3.334	2.446	0.118
intestinal polyps history($y=1, n=0$)	6.503	2.009 21.049	9.762	0.002

*drinking mixed water source refers to the subjects drinking different type of water sources through his/her lifetime, mostly drinking river water and gutter water. So is Table 2,3 and 4

Table 3 Results of univariate analysis for rectal cancer (cases $n=112$, controls $n=560$)

factors	OR	95 % CI	χ^2	P
drining mixed water source ($y=1, n=0$)	2.021	1.170 3.491	6.363	0.011
mucious blood history ($y=1, n=0$)	2.138	1.122 4.072	5.335	0.021
defaecation drug using ($y=1, n=0$)	2.280	0.711 7.312	1.923	0.166
cholecyst excision history ($y=1, n=0$)	2.294	0.715 7.352	1.195	0.163

In Table 2, it was showed that four variables, well water drinking, mixed water source drinking, chronic diarrhea history and intestinal polyp history, were significantly associated with colon cancer ($P<0.05$). The factor of appendicitis history showed an OR value close to significant level ($P=0.066$). For rectal cancer in Table 3, there were two variables reached the significant level of $P=0.05$, which were mixed water source drinking (OR=2.02) and mucous blood stool history (OR=2.14).

Multivariate analysis

The variables showing associations with the risk of colon cancer and rectal cancer at $P<0.15$ level were further tested in forward stepwise conditional logistic regression models. The final model consisted of those variables showing a significant association with the risk of colorectal cancer at $P<0.05$ level. Results were showed in Table 4 and Table 5 for colon and rectal cancers, respectively.

Table 4 Results of multivariate analysis for colon cancer

factors	OR	95 % CI	P
drining mixed source water ($y=1, n=0$)	2.387	1.243 4.587	0.009
mucous blood history ($y=1, n=0$)	3.508	1.370 8.985	0.009

Table 4 and Table 5 illustrated that, at $P=0.05$ level, both for colon cancer and rectal cancer, the final logistic regression model comprised two factors: mixed water source drinking and mucous blood stool history.

Table 5 Results of multivariate analysis for rectal cancer

factors	OR	95%CI	P
drinking mixed water source ($y=1, n=0$)	1.951	1.086 3.506	0.025
mucous blood history ($y=1, n=0$)	2.139	1.040 4.402	0.039
factors	2.870	1.117 7.371	0.029

DISCUSSION

It is generally believed that colorectal cancer is the combined outcome of heredity and environment^[8-10,30]. Despite uncertainties regarding the underlying association between heredity and colorectal cancer, the genetic factors may affect the individual sensitivity to cancer^[3,30-37]; many documents had reported that the environmental factors might also influence colorectal cancer^[37-49]. On the secondary prevention for colorectal cancer, symptoms and/or disorders of pre-cancer, such as intestinal polyps, ulcerative colitis, should be considered^[50,51].

Univariate analysis results of this study showed that drinking well water is a protective factor for colon cancer, OR value was 0.542, ($P < 0.05$); drinking mixed water, mostly drinking river water and gutter water, was a risk factor both for colon cancer and rectal cancer, OR values were 2.387 (95 %CI: 1.247-4.587) and 1.951 (95 %CI: 1.086-3.506) in multivariate conditional logistic model, respectively. The association between drinking mixed water and colorectal cancer is consistent with former study. In this study, country subjects account for about 75 %, most of the mixed water drinking aggregated in country. In the local country, people usually were drinking river water and well water. It reflects that uncertainty of drinking water source, especially mixed drinking river water and gutting water would increase the incidence of colon cancer and rectal cancer. The findings in this study resembled other study reports^[47,52].

Chronic diarrhea, mucous blood stool and constipation history are the pre-clinical symptoms of colorectal cancer^[53-56]. This study has found the positive association between mucous blood stool history and colorectal cancer. In final colon cancer logistic model and rectal cancer logistic model, the OR values of mucous blood stool history were 3.508 (95 %CI: 1.370-8.985) and 2.139 (95 %CI: 1.04-4.402) respectively, both reached statistical significant level. Univariate analysis also showed that, for colon cancer, the OR value of chronic diarrhea history was 2.018 (95 %CI: 1.023-4.06), $P < 0.05$, but did not enter the final logistic regression model.

Intestinal polyp history commonly regarded as a high risk factor for colorectal cancer^[57-65]. Although the univariate analysis result showed a positive association between intestinal polyp history and colon cancer, OR=6.503 (95 %CI: 2.009-21.049), $P < 0.05$, after being matched with age, sex and location, the factor did not enter the final logistic regression model. However, the association between intestinal polyp history and rectal cancer could not reach the significant level even in the univariate analysis.

Although the association between dietary habits and colorectal cancer has been reported^[35,38,39,41,45,49, 66,67], this study was not able to confirm such a positive association. It was reported that increasing fat while reducing fibrous in diet would increase the incidence of colorectal cancer^[68-70]. In this study, after merging the two variables, pork eating and vegetable eating, into one variable by cross-difference method, we got a negative association. Red meat eating, such as fish cooked with soy souse, was reported to be the risk factor of colorectal cancer^[71], but the result of this did not agree with that. Moreover, recent reports were not consistent with each other about the association between cigarette smoking and colorectal cancer, nor does the alcohol consumption^[71-76]. This study did not find any statistical association between cigarette smoking, nor was alcohol consumption and colorectal cancer.

Nested case control study, namely case control study within cohort, is based on a cohort set. After baseline investigation for the cohort set, including population structure, exposure factors and pertinent factors, the study subjects are divided into two groups: the disease individuals form the case group and the individuals of control group need to be randomly

selected from the non-disease subjects. This kind of study can be analyzed statistically as a case-control study. The risk factors found in nested one are certain in cause and time consequence. In addition, the number of case in this study was abundance after ten years of follow-up; the controls were randomly selected from the whole disease-free cohort set and can represent the normal public population well. All of these endue the results with persuasion.

It should be noted that, after ten years of follow-up, some exposure factors may have changed, factors such as dietary habits, drinking water sources, intestinal disease history may be different from the primate investigation. All the changes may discount the preciseness of the conclusion. That the association between dietary habits and colorectal cancer could not be put forward any positive evidence might be explained by such changes.

Abstract

The liver is the commonest site of distant metastasis of colorectal cancer and nearly half of the patients with colorectal cancer ultimately develop liver involved during the course of their diseases. Surgery is the only therapy that offers the possibility of cure for patients with hepatic metastatic diseases. Five-year survival rates after resection of all detectable liver metastases can be up to 40 %. Unfortunately, only 25 % of patients with colorectal liver metastases are candidates for liver resection, while the others are not amenable to surgical resection. Regional therapies such as radiofrequency ablation and cryotherapy may be offered to patients with isolated unresectable metastases but no extrahepatic diseases. Hepatic artery catheter chemotherapy and chemoembolization and portal vein embolization are often used for the patients with extensive liver metastases but without extrahepatic diseases, which are not suitable for regional ablation. For the patients with metastatic colorectal cancer beyond the liver, systemic chemotherapy is a more appropriate choice. Immunotherapy is also a good option when other therapies are used in combination to enhance the efficacy. Selective internal radiation therapy is a new radiation method which can be used in patients given other routine therapies without effects.

INTRODUCTION

Colorectal cancer is one of the commonest solid tumors in human beings and is responsible for approximately 10 percent of the cancer death in Western world^[1-5]. The incidence of colorectal cancer is also increased recently in China^[6-8]. The liver is the commonest site of distant metastasis in this disease and nearly half of the patients with colorectal cancer ultimately develop liver involved during the course of their diseases. Treatment of primary colorectal cancer with surgical resection, combined with chemotherapy and radiotherapy in some cases, is effective in many patients. But, about 10-25 % patients had liver metastases at the time of primary diagnosis and another 20-25 % patients developed metachronous liver metastases^[9-12].

Death of colorectal cancer is often a result of liver metastases. Over half patients died from their metastatic liver diseases.

Surgical resection of distant metastases in colorectal cancer can produce long-term survival and cure in some selected patients. Surgery is the only therapy that offers any possibility of cure for the patients with hepatic metastatic diseases. The five-year survival rates after resection of all detectable liver metastases can reach up to 40 %. Unfortunately, only 25 % of the patients with colorectal liver metastases are candidates for liver resection, while the others are not amenable to surgical resection. Chemotherapy and some newer therapies are expected to raise the survival time for the unresectable colorectal liver metastases^[13-15].

This article reviews the natural history of colorectal cancer liver metastases, pretreatment assessment of patients, surgical resection of liver metastases, systemic and hepatic artery chemotherapy (hepatic artery infusion, HAC, HAI), hepatic artery chemoembolization, portal vein embolization, immunotherapy and selective intra-artery radiation therapy (SIRT), and other regional therapies, including cryotherapy, radiofrequency ablation (RFA).

NATURAL HISTORY

Understanding the natural history of colorectal cancer is useful to assess the value of various treatments. About 60 % patients who underwent curative surgery for colorectal cancer will develop local, regional, or distant recurrence. Nearly 85 % of tumors recurrence are detected within 2.5 years after resection of primary colorectal cancer, and the remaining 15 % are detected within the next 2.5 years. Median survival for these patients was found to be between 5 and 9 months^[16,17]. However, the majority of patients in former studies had advanced diseases diagnosed without modern imaging techniques. Several previous studies have retrospectively determined the survival of patients with potentially resectable colorectal cancer liver metastases that left untreated. It was found that a 0 % five-year survival for patients with untreated but potentially resectable liver metastases compared with a 28 % five-year survival for operated patients with resected liver metastases^[18]. Another study found that patients untreated but potentially resectable liver metastases had a mean survival of 21.3 months^[19]. Other study found patients with an untreated single liver metastasis had a median survival of 19 months, with no patients surviving 5 years, while patients with a resected single liver metastasis had a median survival of 36 months with 25 % of patients surviving five years^[20]. It is well known that resection of colorectal cancer liver metastases improves long-term survival.

PRETREATMENT ASSESSMENT

Synchronous liver metastases from colorectal cancer may be detected before operation or during operation. Suspicious liver lesions should be biopsied and send to freezing pathology during the operation. Metachronous liver metastases may be found after the operation of colorectal cancer by physical examination, blood test, and radiological imaging. Further evaluation of patients with colorectal cancer liver metastases depends on the available treatment procedures. If the patients are not suitable to operation, confirmation of the presence of metastatic lesions by ultrasound and CT scan is sufficient, no

matter of number and size of the lesions. If patients are candidates for surgical resection of liver metastases, a series of examinations should be done to determine the liver function and general condition to tolerate liver resection, to delineate exactly the anatomy of the lesions including the number, size and relationship with vessels and bile ducts, and to exclude the presence of extrahepatic disease.

Candidates for surgical resection of colorectal cancer liver metastases should be under a detailed history and physical examination, hematology test, liver function test, chest X-ray, and abdominal and pelvic CT scans. Patients should undergo colonoscopy to rule out the recurrence of the original primary colorectal cancer or development of a second primary colorectal cancer, if they had not already done within the past 6 months. A range of imaging techniques, including transabdominal ultrasound, CT scan, CT arteriography (CTAP), magnetic resonance imaging (MRI), and positron emission tomography (PET) can provide information of liver metastases and extrahepatic diseases^[21]. Transabdominal ultrasound examination of liver correctly identifies around 52-58 % of patients who had liver metastases. Ultrasound may be most appropriately used because it is cheapest and readily available. But transabdominal ultrasound plays no role in the preoperative evaluation of potential liver resection candidates^[22-24]. Abdominal CT scan is mostly used for the assessment of liver metastases, in which images are usually hypoattenuated relative to normal liver. The use of intravenous contrast increases the detectability of liver metastases because normal liver is perfused primarily by portal vein and liver metastases are perfused mostly by hepatic artery. Hypoattenuated liver metastases are more easily recognized following the intravenous contrast on CT scan during the portal venous phase. The sensitivity of helical CT of liver metastases was 80 %^[25,26]. We often used more sensitive CT arteriography (CTAP) which is an invasive method to investigate the metastatic liver lesions. We firstly placed a catheter into the superior mesenteric artery and then captured the liver CT images during the arterial and portal venous phase following contrast injection. The overall sensitivity for detection of liver metastases helical CTAP exceeded 90 %. But, perfusion abnormalities and pseudolesions were frequently observed with CTAP, thereby significantly reducing the specificity of this technique^[27-29]. Magnetic resonance imaging (MRI) is increasingly utilized for the diagnosis and characterization of liver lesions, particularly the liver-specific contrast agents and dynamic scanning have been incorporated. One liver-specific contrast agent, manganese-pyridoxal diphosphate (Mn-DPDP), is a paramagnetic agent taken up preferentially by hepatocytes and excreted in the bile. The popularity of MRI is also due to its non-invasiveness in some centers^[30,31]. PET is a newer technique which can scan the whole body. It is mainly used to rule out the potential extrahepatic diseases which could not be identified by other methods before operation^[32,33].

Laparoscopy is usually used for preoperative evaluation of metastatic liver diseases. Laparoscopy with laparoscopic ultrasound may be the most sensitive imaging technique for detection of liver metastases. Laparoscopy can prevent laparotomy in some unresectable cases with liver metastases which were judged resectable preoperatively by conventional imaging studies^[34]. But it is still an invasive procedure which need general anesthesia. Therefore, laparoscopy was not routinely used unless the resectability of the lesions was not determined by other methods.

SURGERY

Patients without extrahepatic diseases and with good liver function and general condition are candidates for surgical

resection, while all liver metastases can be resected with at least 1 cm tumor-free margin. Up to 75 % of the liver can be removed if the liver function is normal. Recognition of the segmental basis of liver anatomy led to the evolution of the segment-based resection. This has had a particular influence on surgery for colorectal metastases because it allows excision of bilateral or multiple liver lesions that might previously have been deemed unresectable. Staged resection is another means and may be useful for bulky bilateral lesions. In fact, one or more segmental resections can often spare more normal liver than a major resection or allow resection of metastases not encompassed by a traditional major resection^[35-39].

The surgical resection of liver metastases from colorectal cancer first involves an exploratory laparotomy through a right subcostal incision. The abdominal cavity is explored for signs of extrahepatic disease, and suspicious areas are biopsied. The liver is fully mobilized by dissection of its supporting ligaments and palpated to identify lesions. Intraoperative ultrasound is used at this point to identify nonpalpable lesions and delineate vascular anatomy. No matter traditional liver resection or segmental resection is performed, the goal of the operation is complete removal of all metastases with at least a 1cm tumor-free margin. Although there are various methods of dividing hepatic parenchyma, I prefer using ultrasonic surgical aspirator in normal liver and a combination of ultrasonic surgical aspirator and clamp fracture in cirrhotic liver. Small vessels are controlled with electrocautery or hemoclips, and large vessels are controlled with sutures. An argon beam coagulator can also be used to achieve hemostasis in resection margin^[40-42].

Vascular occlusion techniques, particularly the Pringle maneuver, have had a major impact in minimizing blood loss and reducing the morbidity associated with liver resection. Selective vascular occlusion has been popularly accepted in segment resection in patients with limited liver function. Total vascular exclusion has become widely accepted as a means of minimizing blood loss when we operated on difficult lesions. Although few surgeons use total vascular exclusion routinely, it is a technique that facilitates excision of lesions involving the vena cava or those lying near the junction of the hepatic veins and the vena cava. Some lesions which were previously been thought unresectable can now be resected with the reconstructed segments of hepatic inflow or outflow vascular structure. Replacement of hepatic vein and vena cava with autologous vein and prosthetic grafts respectively had been fasciated by the use of total vascular exclusion and a number of techniques of liver transplantation. The use of venovenous bypass in combination with *in situ* hypothermic perfusion and *ex situ* resection and autotransplantation, have both been important additions to the liver surgeons^[43,44].

The operative mortality for major liver resections has declined with improved operative techniques and postoperative care, but still significant. Operative mortality ranged from 0 % to 7 %. The causes of death include hemorrhage, sepsis, and liver failure. The Morbidity of liver resection was between 22-39 %, and the causes of morbidity included hemorrhage, biliary leak or fistula, liver failure, abscess around liver, wound infection, and pneumonia. Median survival ranged from 28 to 46 months. The five-year survival was between 24 % and 38 %^[45-48].

How many lesions are too many in colorectal cancer liver metastases underlying liver resections? Many surgeons consider four or more tumors in the liver to be a contraindication for surgical resection before. But more and more authors think that the number was not a limitation in liver resection of colorectal cancer liver metastases with the use of new techniques. The follow-up showed that there was no significant difference in the mortality, morbidity and five-year survival between patients whose lesions more than four and those less than four^[49].

RADIOFREQUENCY ABLATION (RFA)

The so-called RF thermal ablation works by converting RF waves into heat. A high-frequency alternating current (100 to 500 kHz), mostly 460kHz, passes from an uninsulated electrode tip into the surrounding tissues and causes ionic vibration as the ions attempt to follow the change in the direction of the rapidly alternating current. This ionic vibration causes frictional heating of the tissues surrounding the electrode, rather than the heat being generated from the probe itself. The goal of RFA is to achieve local temperatures to make tissue destruction occur^[50-55]. Tissue heating also drives extracellular and intracellular water out of the tissue and results in further destruction of the tissue due to coagulative necrosis. Besides these, different studies have shown that hyperthermia can cause accelerated emigration and migration of peripheral blood mononuclear cells, activation of effect cells, induction and secretion of cytokines, expression of heat shock proteins, and increased induction of apoptosis^[56-58].

Most of the early reports on the use of RFA for colorectal cancer liver metastases came from Rossi in Italy. In 1996, they reported their results with percutaneous RFA in 50 patients, of whom 11 patients had 13 metastases ranging from 1 to 9 cm in diameter. Monopolar and bipolar needles were utilized and multiple probe insertions and treatment sessions were performed. There were no associated complications or deaths. Of the 11 patients with metastases, two underwent subsequent surgical resection, one of them had complete tumor necrosis by histopathologic examination. At a median follow-up of 22.6 months, 10 (90 %) of 11 patients were alive, two (18 %) had a local recurrence and seven (64 %) had persistent or distant disease. Only one (9 %) patient, therefore, was alive without disease. These studies suggested that although RFA was effective in preventing local recurrence of metastases, it may not affect the progressive course of the cancer^[59].

Wood TF reported 231 tumors in 84 patients treated with 91 RFA procedures. The majority of the patients had metastatic lesions (213 lesions in 73 patients). RFA was given in 51 of the 91 treatments alone. The other 40 included RFA combined with surgical resection, cryoablation, and hepatic artery infusion of chemotherapy. Of the 91 RFA treatments, 39 were ablated at laparotomy, 27 by laparoscopy and 25 percutaneously. Tumors ranged in size from 0.3 to 9.0 cm. Three deaths occurred, one (1 %) of which was directly related to the RFA procedure. Ten patients underwent a second RFA procedure (sequential ablations). It is due to progressive (seven patients), and recurrent (three patients) lesions. A third RFA procedure for large was performed in one patient. At a median follow-up of 9 months (range 1-27 months), 15 (18 %) patients had developed a local recurrence. Of the remaining 69 patients, 34 were alive without disease, 14 were alive with disease, and 21 died. New hepatic tumors or extrahepatic diseases occurred in 35 patients. The average hospital stay was 3.6 days^[60].

Although RFA has a lot of advantages in the treatment of metastatic liver tumors, it still has a few disadvantages and complications. These complications included symptomatic pleural effusion, fever, pain, subcutaneous hematoma, subcapsular liver hematoma, and ventricular fibrillation. The severe complication is treatment-related death. Interms of the methods related to tumors, the outcome of RF thermal ablation involves the skill of a surgeon performing the procedure. Exact placement of the ablation needles requires considerable skill and some degree of guess work by the radiologist and surgeon, who may be the most experienced in interventional procedures. Recurrence at the treatment margin may result from an inability to adequately kill the tumor the hepatic parenchyma adjacent to the treated tumors. The abundant portal venous blood flow present in normal hepatic parenchyma acts as a heat pump, which makes the creation of thermal injury in normal liver

more difficult than that it is in liver tumors. RF also caused skin burn in percutaneous procedures, hemorrhage, diaphragmatic necrosis, hepatic abscess, hepatic artery injuries, bile duct injuries, renal failure, coagulopathy and liver failure, which were severe and eventually fatal^[61-64].

Although long-term observations are not available, RFA will definitely give the surgeon a helpful hand and bring the patients a better prognosis. But, RFA is unlikely to be curative for most patients, it can relieve the symptoms of patients and improve the quality of life of patients. RFA has been shown to be safer and better tolerated as compared with other ablative techniques, such as cryotherapy, laser ablation and microwave ablation. RFA has been associated with fewer local recurrence. RFA for unresectable liver tumors provides a relatively safe, highly effective method to control local disease in some liver metastatic patients who are not candidates for liver resection. RFA also showed some better respect in combination with surgical resection, hepatic artery chemotherapy. The most interesting feature of RFA is the minimal-invasiveness with zero mortality rate, significantly lower complications, reduced costs and hospital days compared with surgery and other therapies. Furthermore, in combination with other procedures, RFA will improve the survival of patients with colorectal cancer liver metastases^[65,66].

CRYOTHERAPY

Cryotherapy has been mostly used as a regional therapy all over the world for a long time^[67,68]. Hepatic cryotherapy involves the freezing and thawing of liver tumors by means of a cryoprobe inserted into the tumors. During freeze/thaw cycles, intracellular and extracellular ice formation occurs in an area termed "the iceball", leading to tumor destruction. Hepatic cryotherapy is generally reserved for patients with liver metastases from colorectal cancer in whom one or more lesions are not surgically resectable. Some centers offer liver cryotherapy as an alternative to surgical resection^[69-71]. Cryotherapy can treat multiple lesions and salvages more uninvolved liver parenchyma than surgical resection. Cryotherapy may also be used to treat tumors intimately associated with major vessels. But, major vessels may serve as "heat-sinks" and prevent adequate freezing of immediately adjacent tumors. Hepatic inflow occlusion may reduce the incidence of inadequate freezing of tumors adjacent to large blood vessels. Cryotherapy can also treat patients who are left with a positive surgical margin after hepatic resection which is called "edge cryotherapy". Cryotherapy can also be used in patients in whom underlying illness or hepatic insufficiency precludes surgical resection^[72-74].

Hepatic cryotherapy is performed by making an abdominal incision, followed by exploration of the abdomen to search for extrahepatic metastases. Intraoperative ultrasound is used to identify and assess intrahepatic lesions^[75,76]. For superficial lesions, a cryoprobe can be placed into the center of the lesion under direct vision. For deeper lesions, the probe can be inserted into the center of the tumor under ultrasound guidance. Sometimes two or three probes may be used for large lesions. Freezing is continued until the iceball is at least 1 cm beyond the tumor. Two or three cycles should be performed or combine freezing with occlusion of hepatic inflow to increase tumor destructive ice ball and negative edge of ice ball in some lesions. It can also be done percutaneously under the guide of ultrasound and CT scan^[77].

The complications of cryotherapy include subsequent hemorrhage of cracking frozen liver, bile collection, biliary fistula, right-sided pleural effusion, liver abscess, thrombocytopenia, myoglobinuria, arrhythmia, acute renal failure, and cryoshock due to multi-organ failure with DIC.

Overall morbidity rates range from 6 % to 29 %. Mortality rates range from 0 % to 8 %, with an overall mortality rate of 1.6 %. Median survival ranged from 8 to 43 months. New or improved liquid nitrogen delivery systems and together with intraoperative ultrasound have led to significant advances in cryotherapy over the past few years and its feasibility and safety are now well accepted. Although long-term survival following hepatic cryotherapy for liver metastases from colorectal cancer is unclear, hepatic cryotherapy is still an option for patients who are not candidates for surgical resection but enough to cryoablation of all lesions. Cryotherapy is also an important supplement of surgical resection and beneficial to the patients with liver metastasis from colorectal cancer when combined with surgery^[78,79].

HEPATIC ARTERY CHEMOTHERAPY

Following resection of liver metastases from colorectal cancer, recurrence will occur in 60-70 % of patients, most commonly in the liver, so effective postoperative adjuvant treatment is also required, during which chemotherapy is the main method. Chemotherapy is also required in unresectable liver metastases to sustain the survival rate^[80-83]. However, the optimum regimen and route of delivery should be clarified. As most drugs have a steep dose-dependent curve, it is a basic pharmacokinetic principle that if drug delivery is increased to tumors, the response rates can be elevated. An alternative approach to liver metastases is therefore, to deliver the drug intra-arterially^[84,85]. Hepatic artery catheter chemotherapy has been a therapeutic possibility for unresectable liver metastases for many years. The rational for hepatic artery catheter chemotherapy is based on the fact that liver metastases over 1 cm derive most their blood supply from hepatic artery. The other rational is the high first pass hepatic extraction of the drug used for this approach. Both factors cause high local drug concentrations with reduced systemic toxicity and allow relatively higher dosages as compared with intravenous treatment^[86,87].

Some studies compared intra-arterial chemotherapy with conventional systemic chemotherapy and showed consistently higher response rates in patients receiving intra-arterial chemotherapy^[88]. In the United Kingdom, patients were randomized to receive intra-arterial chemotherapy through a totally implantable infusion device; patients were given systemic chemotherapy in other group. Survival was significantly longer in the intra-arterial group (median survival 405 days compared with 226 days). The intra-arterial group also had a better quality of life than those received systemic chemotherapy^[89]. Other studies showed that the response rate was 43 % in the intra-arterial group compared with 9 % in the systemic chemotherapy group. Furthermore, the intra-arterial group showed a significant increase in the one-year survival (64 % vs 44 %) and two-year survival (23 % vs 13 %). Other studies also showed a higher response rates in intra-arterial chemotherapy than in systemic chemotherapy^[90].

In all studies, 5-FU and FUDR were chosen for the arterial route of administration. As 84-99 % of FUDR is extracted by the liver on first pass, it seemed logical to use FUDR to achieve the dual objective of high levels within the tumor and low plasma levels, thereby increasing the probability of the tumor's response while minimizing the systemic toxicity^[91]. But 55 % of patients using FUDR in the UK and French studies developed extra-hepatic progress, suggesting that these patients may have had occult extra-hepatic disease at the time of entry into the trial or during the intra-arterial chemotherapy. The lower plasma level of drugs has been misplaced, while 5-FU, which has a higher plasma level than FUDR, should be preferred. Although there are some complications in HAC, it is still a feasible method for liver metastases from colorectal cancer.

Most complications was related to the technique of surgery and care of patients^[92].

Comparison of intra-arterial with systemic chemotherapy is an important topic that has not been resolved adequately. Some groups were unable to detect any difference in recurrence of hepatic colorectal metastases after liver resection among groups treated with systemic, intra-arterial or intra-portal chemotherapy. There are a lot of new agents such as Xeloda, currently being assessed as adjuvant treatment for both primary colorectal cancer and following resection of metastatic liver lesions^[93-102].

HEPATIC ARTERY CEMOEMBOLIZATION

Hepatic artery chemoembolization (HACE) was developed to treat unresectable non-disseminated liver tumors^[103,104]. Although HACE has not shown any benefit on survival, it increased the response rate compared with systemic administration of cytotoxic agents. HACE has been studied mostly in the treatment of hepatocellular carcinoma, which was also used in colorectal cancer liver metastases for some clinical trials^[105]. Preoperative HACE has been proposed as a possible means of decreasing perioperative tumor dissemination, but only in a small number of patients. Some centers reported that HACE in patients with borderline resectable tumors caused sufficient tumor shrinkage to allow resection. Routine HACE produced no survival benefit on patients with resectable tumors. It was only used in unresectable tumors as an adjacent treatment^[106,107].

PORTAL VEIN EMBOLIZATION

Preoperative portal vein embolization induced hypertrophy in the normal liver which will be remnant and decreased the likelihood of liver insufficiency occurring after extensive liver resection^[108,109]. It has not only mostly used in cholangiocarcinoma but sometimes used in liver metastases from colorectal cancer. Portal vein embolization may be performed either by percutaneous ultrasonographically guided puncture of a portal vein radical or by operative exposure of an ileocolic vein to access portal vein. It can not only be performed in the right portal vein to allow the left side hypertrophy in those who will receive right hepatectomy, but also in left portal vein to allow the right side hypertrophy in those who will receive extend left hepatectomy. Portal vein embolization was well tolerated and produced a less severe systemic reaction than intra-arterial chemoembolization^[110-113].

IMMUNOTHERAPY

Immunotherapy is mainly used in advanced diseases which have failed to respond to conventional therapy. Levamisole, a non-specific immune stimulate, was used in adjunctive treatment with 5-FU as a immune modulator^[114]. More exploration of different combinations may provide new adjuvant regimens. Some scientists have recently reported a phase I-II clinical trial of neoadjuvant immunotherapy with interleukin 2 before hepatectomy for liver metastases from colorectal cancer in 19 patients. Pretreatment with interleukin 2 prevented the postoperative immunodepression seen in the control patients^[115,116]. Clinical trials have also shown that the monoclonal antibody 17-1A was effective in increasing the survival following resection of Dukes C primary colorectal tumors. It can also be used as an adjuvant treatment before or after liver resection for liver metastases from colorectal cancer^[88,117-119].

RADIOTHERAPY

Traditional external beam irradiation has found little place in

the management of liver tumors because of the particularly radiosensitive nature of normal liver tissues, which limits the total dosage to 30-35 Gy^[120-122]. Selective internal radiation therapy (SIRT) is a new modality that may be valuable in colorectal cancer liver metastatic patients which was not suitable to resection, RFA and cryotherapy. SIRT is a technique that allows high average doses of radiation of 200-300Gy to liver tumors with minimal serious effects on the non-tumorous liver. The treatment entails delivery of usually a single dose of ⁹⁰Yttrium microspheres into the hepatic artery, which by virtue of the almost exclusive arterial supply to liver tumors compared with the predominant portal supply to normal liver, resulting in selective tumor uptake and irradiation. ⁹⁰Yttrium is a particularly suitable isotope for medical use in this situation. As a pure beta emitter, it is simpler to handle and use than gamma or mixed beta and gamma emitters such as ¹³¹Iodine^[123,124]. In addition, its half-life of 2.7 days and maximum penetration in soft tissues of 11 mm both are suitable for the purpose. The microspheres do not degrade and are of a size of 29-35 µm that means they are trapped in the arteriolar capillaries. To avoid the potential radiation pneumonitis and pancreatitis and ulceration of stomach and duodenum caused by inadvertent perfusion. The placement of a hepatic artery port is particularly important in terms of safety and efficacy. The high rate of response and encouraging survival from SIRT have been reported for hepatocellular and liver metastases from colorectal cancer^[125,126].

CONCLUSION

Patients with liver metastases from colorectal cancer that are potentially resectable should be evaluated by experienced surgeons and radiologists, because surgical resection remains best treatment for long-term survival, although a minority of patients are amenable to the resection. Patients who are not suitable to surgical resection and who have no extrahepatic disease can be considered for regional therapies such as RFA and cryotherapy. Patients with extensive liver metastases, Hepatic artery catheter chemotherapy and chemoembolization can be considered as an alternative to systemic chemotherapy. Portal vein embolization may be combined in the treatment of patients with huge metastases. SIRT should be used for patients without extrahepatic metastases who failed in the treatment with 5-FU and other cytotoxic agents prefer. Systemic chemotherapy should be administered in patients with extrahepatic diseases. Immunotherapy can only be used to amplify the efficacy of antitumor cytotoxic agents in combination.

Abstract

Stem cells are not only units of biological organization, responsible for the development and the regeneration of tissue and organ systems, but also are units in evolution by natural selection. It is accepted that there is stem cell potential in the liver. Like most organs in a healthy adult, the liver maintains a perfect balance between cell gain and loss. It has three levels of cells that can respond to loss of hepatocytes: (1) Mature hepatocytes, which proliferate after normal liver tissue renewal, less severe liver damage, etc; they are numerous, unipotent, "committed" and respond rapidly to liver injury. (2) Oval cells, which are activated to proliferate when the liver damage is extensive and chronic, or if proliferation of hepatocytes is inhibited; they lie within or immediately adjacent to the canal of Hering (CoH); they are less numerous, bipotent and respond by longer, but still limited proliferation. (3) Exogenous liver stem cells, which may derive from circulating hematopoietic stem cells (HSCs) or bone marrow stem cells; they respond to allyl alcohol injury or hepatocarcinogenesis; they are multipotent, rare, but have a very long proliferation potential. They make a more significant contribution to regeneration, and even completely restore normal function in a murine model of hereditary tyrosinaemia. How these three stem cell populations integrate to achieve a homeostatic balance remains enigmatic. This review focuses on the location, activation, markers of the three candidates of liver stem cell, and the most importantly, therapeutic potential of hepatic stem cells.

INTRODUCTION

The considerable excitement surrounding the stem cell field is based on the unique biological properties of these cells and their capacity to self-renew and regenerate tissue and organ systems^[1-3]. Although the existence of a liver stem cell has been debated for many years, it is now generally accepted that the liver contains cells with stem-like properties and that these cells can be activated to proliferate and differentiate into mature hepatic epithelial cells under certain pathophysiologic circumstances^[4-8]. Cellular therapy with liver stem cells and their progeny is a promising new approach which will contribute to gene therapy of liver diseases^[9-11].

HEPATOCYTES AS HEPATIC STEM CELLS

It has been estimated that the liver is replaced by normal tissue renewal approximately once a year. The participation of putative liver stem cells has never been demonstrated in this process^[12,13]. Replacement of lost liver tissues is accomplished by proliferation of mature hepatocytes (and supporting sinusoidal cells)^[14]. In the classic partial hepatectomy (PH) experiments, the loss of two-thirds of the rat liver is replaced within 2 weeks by proliferation of hepatocytes^[15-17]. Although periportal hepatocytes appear to proliferate early after PH, all hepatocytes, including those immediately adjacent to the central vein, may undergo mitosis and proliferate promptly, continuously replenish the lost cells. Overturf *et al*^[18] performed serial transplantation of a limited number of unfractionated adult parenchymal hepatocytes in fumarylacetoacetate hydrolase (FAH) deficiency mice. The results document that such cells can divide at least 69 times without loss of functions. So it can be concluded that hepatocytes are highly proliferative and have growth potential similar to that of hematopoietic stem cells.

A cell population that has an extensive self-maintaining capacity is the definition of stem cells. In this context, the adult liver, having the extensive capacity of maintaining parenchymal cell number throughout the life span of the organism, can be considered as a single lineage stem cell system in which the hepatocyte is the stem cell. Potten and Loeffler^[19] proposed stem cells as actual stem cells, potential stem cells, and committed stem cells. So hepatocytes appear to be "committed stem cells" that are normally quiescent, but can be activated to produce progeny whose only differentiation option is hepatocytic.

HEPATIC STEM CELLS IN CANAL OF HERING

In the development of liver, the early fetal hepatocytes or hepatoblasts are progenitors for both adult hepatocytes and bile epithelial cells, which suggests that hepatoblasts are at least bipotential precursors^[20]. The question then arises whether either or both of the cell lineages derived from the hepatoblast retain the "bipotential capacity" of the precursor cells. There is at present no substantial evidence indicating that adult hepatocytes are more than a unipotential committed stem cell system, while adequate data have been accumulated to show that there really exist so-called "oval cells" in adult liver. Oval cells have lineage options similar to those displayed by hepatoblasts in early stages of liver development^[21]. As such, oval cells can be regarded as "bipotential precursors" for the two hepatic parenchymal cell lineages. They are able to differentiate into mature hepatocytes or cholangiocytes in response to various types of stress or injury.

Morphologically, oval cells are small in size (approximately 10 μ m), with a large nucleus-to-cytoplasm ratio, with an oval-shaped nucleus (hence their name). Oval cells are heterogeneous, and may display features of both bile duct cells and hepatocytes. Oval cells are activated to proliferate after hepatocyte loss in the mature liver if liver damage is extensive and chronic, or if proliferation of hepatocytes is inhibited, such as by viral infection. Then their progeny extended across the liver lobule and differentiated into either hepatocytes or bile duct cells, ultimately rebuilt the liver^[22,23]. In rodents, the concept of the bipotential cell, the so-called oval cell, is now

widely accepted, the existence of a human equivalent remains controversial. In Heather's experiments^[24], immunolocalization of OV-6 and two biliary markers, cytokeratin 19(CK19) and human epithelial antigen 125(HEA-125) was compared in normal adult human livers and in primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) liver sections. It is proposed that the small OV-6-positive oval cells are analogous to those seen in rat models and may represent human liver progenitor cells that may differentiate into OV-6-positive ductal cells or lobular hepatocytes. The most commonly recognized tissue reaction in support of oval cells in human is the appearance of "ductular reactions"^[25]. Ductular reaction is the proliferative response to many types of liver injury in human, characterized by an increase of bile duct-like structures. In a number of morphological studies, the presence of cells with a distinctive "small" or oval cell-like appearance have been reported in diseased human liver tissue^[26,27]. This includes severe hepatic necrosis, alcoholic cirrhosis, focal nodular hyperplasia, hepatoblastoma, and biliary diseases such as primary biliary cirrhosis or biliary atresia. These oval cell-like cells are proliferative and can differentiate into hepatocytes and cholangiocytes.

The anatomic location of oval cell has also been a subject of controversy. Results from a detailed time course study of activation of hepatic stem cells in the AAF/PH model, utilizing a combination of immunohistochemistry with OV-6 and desmin antibodies and autoradiography after [³H]thymidine administration shortly after the PH, indicate that the earliest population of proliferating OV-6 positive cells is located in the small bile ductules. In addition, these early population of OV-6 positive cells express albumin and α -fetoprotein(AFP)^[28]. Therefore, it seems likely that the major source of oval cells, at least in the AAF/PH model, is derived from the lining cells of the biliary ductules and that these cells constitute the dormant/facultative hepatic stem cell compartment. Theise *et al*'s experimental work^[29] suggests that oval cells lie within or immediately adjacent to the canal of Hering(CoH), which is the anatomic juncture of the hepatocyte canalicular system, and the terminal branches of the biliary tree.

Oval cells express similar markers to hepatocytes or bile duct cells, like AFP, certain keratin markers (e.g., cytokeratin 19 [CK19]), and γ -glutamyl transpeptidase. Monoclonal antibodies such as OV-6, OC2, and BD1 also aid in their characterization. High levels of certain mRNAs like AFP and stem cell factor (SCF) can also be expressed by oval cells. OV-6 identifies a cytokeratin of molecular weight 56 000, with epitopes shared on cytokeratins (CKs) 14 and 19. It is present in rat liver on bile ducts, oval cells, and nodular hepatocytes as well as transitional hepatocytes^[30]. In human liver, OV-6 identifies cells in the ductal plate, oval cells and bile ducts and ductules in fetal tissue, and oval cells found in focal nodular hyperplasia^[31,32]. AFP is an abundant serum glycoprotein in developing mammals. During embryonic development, AFP is first detected in the yolk sac and later in the fetal liver. The full-length AFP RNA and protein are highly expressed in the primitive hepatoblasts and postnatal hepatocytes^[33]. Full length AFP has been shown to be expressed in oval cells and small basophilic hepatocytes during the early stages of carcinogenesis^[34]. Hence, AFP expression can be used as an indicator for an early hepatic lineage, and has also served as an important marker for the activation of the hepatic stem cell compartment. SCF, also called c-kit ligand, encodes a transmembrane tyrosine kinase protein and belongs to the subfamily of platelet derived growth factor. The SCF/c-kit system is believed to play an important role in stem cell biology during hematopoiesis, gametogenesis, and melanogenesis^[35,36]. Studies have shown that both SCF and c-kit are expressed in the bile duct cells and the expression of both the genes is increased in

oval cells in the 2-acetylaminofluorene and partial hepatectomy model^[37].

HEPATIC STEM CELLS FROM BONE MARROW

In the experiment by Yavorkovsky *et al*^[38], periportal necrosis of allyl alcohol toxicity resulted in a "null cell" proliferation that was negative not only for hepatocyte markers, but also for cholangiocyte markers. This phenomenon suggests that oval cells are not the only source of hepatic stem cells. This hypothesis might be correct as suggested by the research in transdifferentiation of marrow stem cells^[39]. The ability of marrow stem cells to give rise to cells of different organs is being increasingly identified, for example, bone marrow turning into skeletal muscle^[40,41], renal^[42], or into brain^[43].

Correlation between bone marrow and liver has been discovered. (1) Hematopoiesis and hepatic development share common stages^[44]. During fetal development, hematopoietic stem cells move out of the yolk sac and into the developing liver. The liver remains hematopoietic during the entire fetal period and for approximately the first week after birth in the neonates. Simultaneously with the appearance of hematopoiesis, hematopoietic stem cells (HSCs) can be detected in the fetal liver. In the latter part of gestation and after birth, the hematopoietic function of the liver is considerably reduced, if not totally absent. Although the liver loses its hematopoietic functions, hematopoiesis often returns in adult life in disease states. (2) Some studies show that hepatic oval cells and hematopoietic stem cells share CD34, Thy-1, and c-kit mRNA and protein^[45-49]. Oval cells also express mRNA for the flt-3 receptor, previously reported to be restricted to hematopoietic stem cells^[50]. (3) In Theise ND *et al*'s research work^[51], a cohort of lethally irradiated female mice received whole bone marrow transplants from age-matched male donors. Fluorescence *in situ* hybridization (FISH) for the Y-chromosome was performed on liver tissues. Y-chromosome positive hepatocytes were identified in all animals sacrificed 2 months or longer post-transplantation. Simultaneous FISH for the Y-chromosome and albumin messenger RNA confirmed male-derived cells were mature hepatocytes. The experiments show that bone marrow cells transplanted from male donors to syngeneic recipients are able to localize in the two largest lobes of the liver, differentiating into mature hepatocytes carrying the Y-chromosome. In human experiment, biopsy and autopsy liver specimens from recipients of therapeutic bone marrow or liver transplants were analyzed for marrow-derived hepatocytes and cholangiocytes^[52,53]. In view of these bone marrow-liver inter-relationships, it is expected that a closer relationship might exist in the two lineages^[54]. Hepatocytes and cholangiocytes could derive from bone marrow stem cells. In both of human subjects and in the experimental animals, engraftment by bone marrow cells as hepatocytes could be seen in the absence of severe injury, suggesting that such movement might occur as a low level, baseline, physiologic phenomenon.

The mechanism of entry and differentiation of the transplanted bone marrow cells within the liver cell plates might also occur in different ways. First, circulating. Marrow-derived cells might enter the liver plates directly from the sinusoidal circulation. These cells are most often scattered throughout the parenchyma and intercalate randomly into pre-existent liver cords directly as hepatocytes. On the other hand, given previous demonstrations that oval cells derive from CoH, and that not only hepatocytes, but oval cells derive from marrow cells^[55-57], we can speculate that marrow cells might enter into liver through the circulation, then translocate across basement membranes into CoH and/or the terminal branches of the biliary tree, and differentiate into cytokeratin 19-positive small cholangiocyte-like cells. Proliferation and differentiation into

hepatocytes would follow in proportion to the type and extent of hepatocyte injury. Thus, hepatic regeneration through marrow cells may have multiple and perhaps overlapping pathways to accomplish cell replacement and organ repair.

MSCs are not only highly self-regenerative, but also can transdifferentiate into liver endogenous stem cells and liver parenchymal cells. So MSCs can repair damaged liver. Compared with liver transplantation and hepatocyte transplantation, there are much more marrow donors than liver and liver cells donors. If we utilize a patient's own MSCs as a new therapeutic option to treat liver diseases, immunological rejection will be avoided completely. Now MSCs has been used in animal experiments and clinical trials^[68,59]. Orlic *et al*^[60,61] sorted lineage-negative (Lin⁻) bone marrow cells from transgenic mice expressing enhanced green fluorescent protein by fluorescence-activated cell sorting on the basis of c-kit expression. Then they injected these Lin⁻c-kit^{pos} cells into the contracting wall bordering the infarct shortly after coronary ligation. The results show that newly formed myocardium occupied 68 % of the infarcted portion of the ventricle 9 days after transplanting the bone marrow cells. The developing tissues comprised proliferating myocytes and vascular structures. Their studies indicate that it is possible to rebuild heart-attack-damaged hearts with adult stem cells from bone marrow. Also, in order to determine whether bone marrow contains cells that can correct liver diseases, Lagasse *et al*^[62] used bone marrow transplantation in the fumarylacetoacetate hydrolase (FAH)-deficient mouse, an animal model of fatal hereditary tyrosinemia type I. The results show that bone marrow transplantation rescued the mouse and restored the biochemical functions of its liver.

PROSPECT

The liver is an organ known to have tremendous regenerative capacity. It is confirmed that liver stem cells exist in humans and that they can be of endogenous (hepatocytes or oval cells) or exogenous (most likely bone marrow) origin. The marked degree of hepatic engraftment from extrahepatic cells in cases of severe liver injury indicates that there may be therapeutic utility for bone marrow transplantation to correct defects in hepatocyte metabolic or synthetic function. The researches mentioned above represent significant advances in liver stem cell biology. However, questions regarding some respects of liver stem cells remain open and need to be resolved: how to activate liver stem cells^[63,64]? How to isolate and characterize a plenty of liver stem cells with high purification^[65,66]? How to set up a tracking system to make clear the ultimate fate of liver stem cells *in vivo*^[67,68]? How to develop a stable *ex vivo* culture system of liver stem cells and adjust their differentiation^[69,70]? Excellent *in vitro* and *in vivo* researches will pave the way for a much broader understanding of the biological properties and clinical use of liver stem cells.

Abstract

AIM: To study the expression pattern of ETS2 (erythroblastosis virus oncogene homolog 2) in human esophageal squamous cell carcinoma (ESCC).

METHODS: Reverse transcription polymerase chain reaction (RT-PCR) and Northern blot were performed to examine the expression level of ETS2 mRNA in 37 pairs of ESCC tissue samples. Western blot and immunohistochemistry were carried out to check the expression level of ETS2 protein in 30 pairs of ESCC tissue specimens.

RESULTS: RT-PCR and Northern blot analysis showed that ETS2 mRNA upregulated in 75.7 % (28/37) examined ESCC tissues relative to matched normal tissues. From those 37 cases, 14 cases were randomly selected to perform Western blot and the results revealed that ETS2 protein overexpressed in 71.4 % (10/14) checked ESCC tissues compared with the corresponding normal tissues. Moreover, the expression patterns of ETS2 protein in those 14 cases were identical to those of ETS2 mRNA displayed by RT-PCR or Northern blot. Immunohistochemistry analysis showed that the expression level of ETS2 protein rose in 75 % (12/16) tumor epithelial cells contrasted to the normal cells. Altogether the expression level of ETS2 protein increased in 73.3 % (22/30) checked ESCC tissue samples contrary to their normal counterparts.

CONCLUSION: The results suggested that ETS2 overexpressed in paired human ESCC tissue samples at both mRNA and protein levels and may be associated with the tumorigenesis of esophagus.

INTRODUCTION

Erythroblastosis virus oncogene homolog 2 (ETS2) is a pro-

oncogene, which is located in human chromosomal region 21q22.3 and encodes a 56 kD protein that is phosphorylated by a Ca²⁺-dependent mitogenic signal process^[1,2]. ETS2 gene expresses in various tissues, including blood, breast and prostate. ETS2 may be involved in the regulation of cellular proliferation and differentiation and may play a critical role in T-cell activation and cytokines production^[3-6].

As a member of ETS oncogene family, ETS2 gene has the oncogenic potential. It is similarly transposed as a consequence of nonrandom chromosomal translocations; especially, the *t* (8;21)(q22;q22) translocation is the most frequently noted breakpoint involving chromosome 21 for acute myelogenous leukemia^[7]. An acute non-lymphoblastic leukemia with a complex *t* (6;18;21) chromosomal translocation, has so far been associated with higher expression level of ETS2^[8]. It had been reported that ETS2 gene was associated with the growth and invasion of breast carcinoma cells and was required to maintain the transformed state for human prostate cancer cells^[9,10].

Esophageal cancer ranks among the 10 most frequent cancers in the world, with a predominant distribution in developing countries. Our previous study showed that genetic susceptibility to esophageal cancer was one of the important causes for the high prevalence and familial aggregation of this disease in some areas of northern China^[11]. We observed the upregulation of ETS2 gene in human esophageal squamous cell carcinoma (ESCC) using cDNA microarray technique^[12]. To our best knowledge, this study first investigated the expression patterns of ETS2 gene and ETS2 protein in ESCC by reverse transcription polymerase chain reaction (RT-PCR), Northern blot, Western blot and immunohistochemistry. Both the expression levels of ETS2 gene and ETS2 protein increased in ESCC tissues contrary to their normal counterparts. The results were consistent with the microarray results. Therefore, it indicated that ETS2 gene might be related to the formation of human ESCC and its further study may provide the insight into the mechanisms of carcinogenesis of esophagus.

MATERIALS AND METHODS

Human tissues

Samples of ESCC and matched normal esophagus tissues were collected from 37 patients who had not receive chemotherapy or radiotherapy before surgery. The tissues were immediately stored in liquid nitrogen until analysis and each sample was confirmed by histological examination. Total RNA and total protein of the samples were extracted using Trizol solution (Life Technologies, Rochville, ML) per manufacturer's protocol. Total RNA was quantitated and assessed for purity by means of UV spectrophotometry and electrophoresis in denaturing formaldehyde gel. The standard curve of protein was prepared to determine the protein concentration of tissue samples with Bicinchoninic Acid Protein Assay Kit (SIGMA, St. Louis, MO). Sixteen pairs of ESCC paraffin slides were obtained from Department of Pathology, Cancer Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College.

RT-PCR

Before reverse-transcription, 5 µg total RNA of each sample was treated with 20 units DNase I (Promega, Madison, WI), 40 units RNasin (Promega, Madison, WI) at 37 °C for 15 min to remove contaminated genomic DNA. Then first strand cDNA was synthesized with SuperScript Preamplification System For First Strand cDNA Synthesis kit (Life Technologies, Rochville, ML). Two microliters of reverse-transcription product were used as the template to amplify specific fragment of ETS2 gene. PCR conditions were as follows: initial denaturation at 94 °C for 3 min, followed by 28 cycles of 94 °C for 30 s, 58 °C for 30 s and 72 °C for 1 min. The expression of housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), was used to normalize the template input. The sequences of the PCR primer pairs of ETS2 and GAPDH were as follows: ETS2, 5'-GTGGACCTATTTCAGCTGTGG-3', 5'-TTCCCCGACGTCTTGTGGAT-3'; GAPDH, 5'-ACCACAGTCCATGCCATCAC-3', 5'-TCCACCACCCTGTTGCTGTA-3'.

Northern blot

Briefly, 30 µg total RNA of each sample was dissolved in loading buffer containing formamide and formaldehyde, heated at 70 °C for 10 min, electrophoresed on the 2 % formaldehyde agarose gel and transferred to a positively charged nylon membrane. The membrane was prehybridized in 5 ml hybridization solution (6×SSC, 2×Denhart's solution, 0.1 % SDS, 100 µg/ml denatured salmon sperm DNA) at 68 °C for 2 h. Then ³²P-labelled probe (bases 1202-1952) was added and hybridization was performed at 68 °C for 18 h. The membrane was washed twice at room temperature in 2×SSC, 0.1 % SDS for 20 min, once at 65 °C in 0.5×SSC, 0.1 % SDS for 20 min and exposed to X-ray films at -70 °C for 72 h.

Western blot

Anti-ETS2 antibody was purchased from Santa Cruz biotechnology, Inc (Santa Cruz, CA). Thirty-microgram total protein of each sample was mixed with 20 µl sample buffer (100 mM Tris·Cl, 200 mM DTT, 4 % SDS, 20 % glycerol and 0.2 % bromophenol blue) before separation by SDS-PAGE (10 %) electrophoresis system. Samples were then transferred to PVDF membrane and nonspecific binding was blocked with 5 % nonfat dry milk for 1 h at room temperature. Then the filter was incubated with anti-ETS2 antibody (1:500) for 2 h at room temperature. An enhanced chemiluminescence system (Santa Cruz, Santa Cruz, CA) was used for signal detection.

Immunohistochemistry

Four-micron paraffin-embedded slides were dewaxed in xylene, rehydrated in ethanol and treated with H₂O₂ to block the endogenous peroxidase activity. Antigen retrieval was achieved by microwaving in a citrate buffer (pH 6.0) for 15 min. The slides were incubated with anti-ETS2 antibody at a 1:50 dilution for 2 h at 37 °C. Biotinylated secondary antibody and peroxidase-conjugated streptavidin steps were performed using UltraSensitive™ S-P kit (Maxim Biotech, Fujian, China) according to the manufacturer's protocol. DAB was used as the chromogen and hematoxylin as the counterstain. Negative control was performed by substituting PBS for the primary antibody.

RESULTS

Overexpression of ETS2 in paired ESCC tissue samples at mRNA level

RT-PCR and Northern blot were performed to confirm the differential expression of ETS2 in ESCC at transcriptional level.

RT-PCR analysis showed that ETS2 gene overexpressed in 24 pairs of tumor versus normal tissues among a total of 31 tested cases (Figure 1). Northern blot analysis showed that the expression level of ETS2 gene increased in 4 of 6 cases of tumor tissues relative to the matched normal tissues (Figure 2).

Figure 1 RT-PCR analysis of ETS2 expression in ESCC tissues (Lanes C) and matched normal esophagus tissues (Lanes N). Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an internal control. PCR product sizes were 229bp for ETS2 and 452bp for GAPDH.

Figure 2 Northern blot results of ETS2 gene in ESCC tissues (designated as C) and matched normal esophagus tissues (designated as N). Thirty-microgram total RNA of each sample was resolved by formaldehyde gel electrophoresis, transferred to a nylon membrane, and hybridized with ³²P-labelled ETS2 probe.

Upregulation of ETS2 in paired ESCC tissue samples at protein level

Western blot and immunohistochemistry were conducted to verify the differential expression of ETS2 in ESCC at translational level. From the above mentioned 37 cases, 14 pairs of ESCC tissue samples were randomly selected to carry out Western blot and the results showed that ETS2 protein was upregulated in 71.4 % (10/14) examined ESCC tissues relative to the corresponding normal tissues (Figure 3). The expression patterns of ETS2 protein in those 14 cases were identical to those of ETS2 mRNA revealed by RT-PCR or Northern Blot.

Figure 3 Elevation of ETS2 protein expression in paired ESCC tissue samples detected by Western blot. Total protein was extracted from the tissues and equal amounts of total protein of each sample (30 µg) were loaded. Blots were hybridized with anti-ETS2 antibody (1:500). An enhanced chemiluminescence system (ECL) was used for signal detection. The molecular weight of ETS2 protein is 56 kD.

Immunohistochemistry results displayed that 75 % (12/16) checked ESCC cases existed diffuse and strong staining in the nucleus of tumor cells, while sporadic and weak staining was observed in the nucleus of the matched normal esophageal epithelial cells (Figure 4).

Figure 4 Immunohistochemistry analysis for ETS2 protein in paired ESCC tissue samples using anti-ETS2 antibody (1:50). Diffuse and strong staining was detected in the nucleus of the ESCC epithelial cells (A), while sporadic and weak staining was observed in the nucleus of matched normal esophageal epithelial cells (B). No positive staining was observed in negative controls (C, D). (original magnification $\times 400$).

DISCUSSION

The understanding of the molecular basis of tumor development has progressed dramatically in the last two decades. It is well known that tumor is essentially a genetic disease. So it is important to demonstrate what genes are and how they work in carcinogenesis. Identifying the genetic differences between normal and tumor cells or tissues will discover the genes that directly cause tumor or be associated with tumorigenesis and provide novel markers for early detection and appropriate therapy.

In our previous study, ETS2 gene showed upregulation in

human ESCC tissue^[12]. To verify this differential expression, we explored the expression pattern of ETS2 in paired ESCC tissue samples at both mRNA and protein levels. The results of RT-PCR and Northern blot revealed that ETS2 overexpressed in 75.7 % (28/37) examined tumor tissues relative to the corresponding normal tissues. From those 37 cases, 14 cases were randomly selected to perform Western blot and the results showed that the expression level of ETS2 protein elevated in 71.4 % (10/14) checked ESCC tissues compared with the corresponding normal tissues. Moreover, the expression patterns of ETS2 protein in those 14 cases were identical to those of ETS2 mRNA displayed by RT-PCR or Northern Blot. Immunohistochemistry analysis showed that the expression level of ETS2 protein raised in 75 % (12/16) examined tumor epithelial cells contrasted to the normal counterparts. Altogether ETS2 protein overexpressed in 73.3 % (22/30) tested ESCC tissues relative to the matched normal tissues. Therefore, the data suggested that ETS2 abnormally expressed not only in the transcriptional level but also in the translational level for human ESCC and the increasing transcription of ETS2 mRNA in ESCC may result in increasing translation of ETS2 protein.

As a transcription factor, ETS2 protein controls the transcription of some important genes participating in a number of biological processes including cell growth and apoptosis. Although many studies have been done, the accurate function of ETS2 in biological and pathophysiologic state is still unclear. Previous studies showed that the overexpression of ETS2 led to different results in different cells. Some promoted tumorigenesis^[13,14], while others were arresting^[15]. So it indicated that ETS2 could mediate multiple different signal pathways and might be involved in carcinogenesis with some unlike ways. In the present study, we found the overexpression of ETS2 in ESCC at both mRNA and protein levels. It suggested that ETS2 might be associated with the formation of ESCC. But how ETS2 acts during the neoplasia of esophagus and whether its function is tissue-specific or organ-specific are still unknown. Although a lot of work was focused on the chromosomal aberrations of human ESCC^[16-18] and even in several studies frequent loss of 21q was observed^[19,20], 21q had not yet been investigated in detail. Hence the variation of 21q22.3 in human ESCC, and which ETS2 gene is located in remain unclear. Further investigations will help us to make clear whether the overexpression of ETS2 is caused by the gain of 21q22.3 in human ESCC. As mentioned above, the higher expression level of ETS2 was found in an acute non-lymphoblastic leukemia with a complex *t* (6;18;21) chromosomal translocation^[8]. Another speculation is that the upregulation of ETS2 in human ESCC may be associated with the chromosomal translocation of 21q22.3. More studies about chromosomal aberrations will be helpful to demonstrate the precise function of ETS2 and its molecular mechanisms in tumorigenesis of esophagus.

Abstract

AIM: To describe the incidence of esophageal cancer (EC) in Cixian, a county of Hebei province during 1974-1996. We analyzed the sex and age characteristics as well as the geographic distribution of EC, in order to determine the impact so that methods of preventing and controlling EC in Cixian can be put in place.

METHODS: Since the early 1970s, the cancer registry system has been established, which collects the cancer incidence in Cixian county. The malignant tumors were coded according to International Classification of Disease IX (ICD-9). All the data were checked and analyzed using EPIINFO.

RESULTS: The trend of the incidence rate of EC from 1974 to 1996 had declined, (229.9/100 000 vs 178.5/100 000, Odds ratio=1.47, 95 % CI:1.32~1.63, $\chi^2=52.89$, trend $\chi^2=26.54$, $P<0.001$). The incidence rate of males declined significantly (281.81/100 000 vs 157.96/100 000, Odds ratio=1.61, 95 % CI: 1.41~1.84, $\chi^2=47.85$, Trend $\chi^2=44.86$, $P<0.001$), whereas, the females remained steady (157.96/100 000 vs 133.41/100 000, odds ratio=1.28, 95 % CI:1.17~1.49, $\chi^2=9.26$, trend $\chi^2=2.69$, $P>0.05$). Male average annual incidence rate was 142.80/100 000 and the female's was 95.18/100 000. The sex ratio (males to females) was 1.50:1. The incidence rate was increasing along with the age. As to the geographic distribution, the incidence rate in mountainous areas and hilly areas showed a significantly declining trend (mountainous areas, trend $\chi^2=149.93$, $P<0.001$; hilly areas, trend $\chi^2=42.70$, $P<0.001$). The incidence rate of EC in plain areas had increased (trend $\chi^2=22.39$, $P<0.001$).

CONCLUSION: The incidence rate of EC in Cixian county shows a trend and has declined after two decades, especially in mountainous area. But compared to other regions in the world, Cixian county still had a high incidence rate of EC.

INTRODUCTION

Cixian county is one of the highest incidence rates of

esophageal cancer (EC) in China, as well as in the world^[1-7]. At the start of the 1970s, a field study of EC prevention and treatment was set up^[8]. At the same time the population-based cancer registry system, so called the three-level prevention web, was established. Each clinic doctor in every township was required to report each new case of cancer occurring in the township using a standard card, then the cards were sent to the clinic of the rural administration unit. The unit sorted the cards and sent them to the Cixian Cancer Registry. To this day the Cixian Cancer Registry continues to collect incidence data. This present report came from "A study of incidence, mortality and surveillance method of risk factors of common carcinoma" carried out in the Cixian county of Hebei province, which is adjacent to the Linxian county of Henan province. This study was one of The National Ninth-Five-Year Scientific Championship Project.

MATERIALS AND METHODS

Materials

Cixian is located at latitude 36° 30' North and longitude 114° 40' East. It is situated on the east side of the Taihang Mountain, along the Zhanghe River and it lies in the south of the Handan City. Across the Zhanghe River to the south is the Anyang City of Henan Province. Cixian county occupies an area about 951 square kilometers, composed of 35 districts, and its population is 574 828, consisting of 289 391 males and 285 437 females. There is a remarkable variation in the earth stratum of the county, with mountainous, hilly, and level land each constituting about one-third of its total area. The climate is influenced mainly by the warm mainland seasonal winds. The temperature range is between 18-25 °C and the rainfall range is between 600-700 millimeters. The major soil there is brown and light colored weed earth. Farm products include wheat, corn, millet, rice, red potato and beans. Iron and coal are the main minerals, and coal is the main local fuel of the county.

Cixian Cancer Registry is a population-based registry that was established in 1974. Its aim is to collect and analyze data on every new case of cancer occurring in Cixian county. Initially, it was mainly concerned with collecting data on the incidence and mortality rates of EC in Cixian. However, from 1988, it began to also collect information on the histopathology of the cancers reported.

Methods

The register was conducted by the three-level prevention web. Each clinic doctor in every township (prevention web I) was required to report each new case of cancer occurring in the township by a standard card, then the cards were sent to the clinic of the rural administration unit (prevention web II). They were sorted and sent to the Cixian Cancer Registry (prevention web III) once a month, these cards were checked, analyzed, coded and stored there. At the end of each year, a sample survey was conducted, to check the quality of the registration.

The carcinoma were coded according to International Classification of Disease IX (ICD-9)^[9]. All the data was checked and analyzed by EPIINFO software. Age-standardized

rates (ASR) were standardized to the world population using the direct method and the statistical analysis was carried out by using χ^2 and U-test, a probability value of less than 0.05 was considered statistically significant.

RESULTS

Incidence of esophageal cancer

Between the years 1974 and 1996 there were 14 207 cases of EC in the county. The annual average incidence rate was 119.43/100 000, the ASR was 167.22/100 000. In 1974, the incidence rate of EC was 165.81/100 000. It declined to 113.49/100 000 in 1996, representing a decline of 31.5 percent. From Table 1 and Figure 1, we can see that the incidence rate of EC in Cixian had a trend of gradual decline. The trend test revealed that $\chi^2=26.54$, $P<0.001$. The incidence rate among males declined significantly ($\chi^2=44.86$, $P<0.001$), whereas, the females remained steady ($\chi^2=2.69$, $P>0.05$). In total, the incidence rate between 1970s and 1990s showed significant differences (U test: $P<0.01$). While the difference between 1980s and 1990s was not significant.

The sex and age distribution

During the period there were 8 559 males and 5 648 females with EC. The incidence rate among males was 142.80/100 000, while females was 95.18/100 000. The sex ratio was 1.50:1. The sex ratios (males to females) in 1970s, 1980s and 1990s

respectively was 1.57:1, 1.56:1 and 1.35:1.

The minimum age group of incidence was 1-year group over 23 years. The incidence rate of EC increased with age after 30 years old. It reached the highest at 80 years old group. In 1970s, the minimum age group was 25 years old group. The incidence rate had significantly increased after 35 years of age, and reached the highest level at 70 years old, then declined in 75-year old group. In 1980s, the minimum incidence group was one-year group. The incidence rate increased with age after that 25-year old group. The male incidence rate reached the highest at 80-year-old group. In females at the 60-year-old group it declined a little and reached the highest at 80-year-old group. In 1990s the minimum incidence group was 10-year-old group. The incidence rate increased with age after 25-year-old group and reached the highest at 80-year-old group. The male incidence rate reached the highest at 80 years old group, while the female declined little at 60-year-old group and reached the highest at 80-year-old group.

Geographic Distribution

In the mountainous area there were 2 106 EC cases from 1974 to 1996. The annual average incidence rate was 112.14/100 000. The incidence rate of EC in 1974 was 213.60/100 000, which declined to 82.55/100 000 in 1996. Decreased by 131.05/100 000, and the decline rate was 61.35 percent. From Table 2 and Figure 3 we could find that the incidence rate of EC in mountainous

area had significantly decreased. The result of trend test was $\chi^2=149.93$, $P<0.001$. The incidence rates of EC in 1970s, 1980s, and 1990s were 150.44/100 000, 109.85/100 000 and 75.55/100 000, respectively. The U test result between 1970s and 1990s, between 1980s and 1990s was $P<0.01$. Both of them had significant difference.

In the hilly area there were 4 633 EC cases. The annual average rate was 117.16/100 000. From 1974 to 1996, the incidence rate changed from 165.71/100 000 to 96.33/100 000. Decreasing in number was 69.38/100 000. And declining rate was 41.86 percent. The result of trend test was $\chi^2=42.70$, $P<0.001$. From Table 2 and Figure 3, we could see that from 1970s to 1980s the incidence rate of EC declined significantly, from 141.62/100 000 to 106.30/100 000 (U test: $P<0.01$). While comparing the incidence rate of EC of 1980s with that of the 1990s', it increased from 106.30/100 000 to 111.24/100 000 (U test: $P<0.01$).

On level land there were 7 416 EC cases over 23 years. The annual average incidence rate was 122.30/100 000. According to Table 2 and Figure 3 we can see that during the past 23 years incidence rate of EC increased steadily. The result of trend test was $\chi^2=22.39$, $P<0.001$. Comparing 1970s' incidence rate with 1990s', it increased from 116.14/100 000 to 130.09/100 000. The increasing in number was 13.95/100 000 and the increasing rate was 12.01 percent (U test: $P<0.01$). Comparing the incidence rate of 1980s with the 1990s', which increased from 120.50/100 000 to 130.09/100 000. The increasing in number was 9.59/100 000 and the increasing rate

was 7.95 percent (U test: $P<0.01$). We could see that the incidence rate of EC in level land was increasing steadily.

There are 35 townships in Cixian County. In the 1970s, Linfeng township had the highest incidence rate of EC, which was 211.90/100 000. While Dudang township had the lowest, which was 66.57/100 000. The highest male incidence rate existed in Linfeng and the number was 298.02/100 000. While the highest female incidence rate existed in Guanglu township and the number was 164.49/100 000. The lowest incidence rate of EC of both male and female existed in Dudang, which was 79.71/100 000 and 51.51/100 000, respectively. The highest rate was 3.18 times as much as the lowest. Cixian County had two high risk areas, one was the mountainous area which was centered around Baitu district (132.23/100 000), the other was hilly area which was centered around Lintan district (128.64/100 000). Level land had the lowest incidence rate (116.01/100 000). After 1980s, the highest incidence rate existed in Guanglu township (232.04/100 000) and the lowest existed in Dudang (55.08/100 000). Linfeng had the highest male incidence rate of EC (285.37/100 000). While Cizhou town had the lowest (64.77/100 000). Guanglu had the highest female incidence rate of EC (214.28/100 000), while Dudang had the lowest (38.65/100 000). The highest EC incidence rate was 4.21 times as much as the lowest. There were 20 townships whose incidence rate were higher than the average of county wide, forming a high-risk hilly area, which was centered around Lintan district. After 1990s, Ducun township had the highest EC incidence rate of 275.80/100 000. While Dudang township

had the lowest whose number was 45.92/100 000. The highest male incidence rate existed in Ducun township which was 341.08/100 000. The highest female incidence rate existed in Guanglu which was 213.26/100 000. While the lowest male incidence rate lay in Wuhe township which number was 36.20/100 000. The lowest female incidence rate lay in Huangsha township which was 26.98/100 000. The highest EC incidence rate was 6.01 times as much as the lowest. There were 19 townships whose incidence rate were higher than the average of county wide, forming a high-risk level land area which was centered around Ducun township.

In the 1970s, the high incidence area existed in mountainous areas which are centered around Baitu district and in hilly area which was centered around Lintan district. After 1990s, the incidence rate of EC in Cixian declined significantly. But the hilly area still had high incidence rate, declining slowly. While the level land area had increasing trend, forming a high risk area which was centered around Ducun township.

Figure 1 Cixian EC Incidence Rate State from 1974 to 1996.

Figure 2 Cixian EC Incidence Rate of Groups from 1983 to 1997.

Figure 3 The Geography Distribution of Cixian EC Incidence from 1974 to 1996.

DISCUSSION

Cixian county is one of the highest EC incidence rate areas in China, as well as in the world. Since the early 1970s, cancer registry system has been established where began to collected the cancer incidence in Cixian county^[10-21]. Until now Cixian Cancer Registry have piled up the incidence data of more than twenty years. In this study we found the trend of the incidence rate of EC from 1974 to 1996 had declined after two decades. As for the possible causes of EC^[22-27], we advocate the inhabitant to take follow prevention: (1) To improve the quality of the drinking water condition; (2) To administer the farm products storage, not to eat the food with mold; (3) Eating more vegetables and fruits, changing the bad life style; (4) Conducting screening survey to find the carcinoma in situ or intramucosal carcinoma especially esophageal epithelium dysplasia (EED). EED is a precancerous lesion which can either develop further into a more severe stage or cancer, stay unchanged, or reverse back to normal again for a period of several years or even a decade^[28-34]. It is therefore very promising to detect patients with EED and treat the precancerous lesions before they transform into the irreversible malignant stage. There are several techniques and chemicals or nutrients that have been reported to be effective in blocking precancerous lesions from transforming into cancer^[35-38].

The incidence rate among males declined significantly however, females remained steady. As to the geographic distribution, the incidence rate in mountainous area and hilly area showed a declining trend. The incidence rate of EC in level land area had increased. The reasons why these happened needs to be further studied and analysed.

In conclusion, the trend of the EC incidence rate in Cixian county had declined after two decades, especially in mountainous areas. But compared to the other regions in the world Cixian county still had a high incidence rate of EC. By using a register the information can provide the scientific data for cancer prevention and control.

Abstract

AIM: The incidence of gastric cardia cancer has greatly increased in the past 2-3 decades, however, the risk factors for the disease are still not clearly understood. The investigations among Chinese population on the risk factors of gastric cardia cancer were also scarcely reported. We therefore conducted a case-control study in Fujian province, China, to investigate the potential risk and protective factors of this disease.

METHODS: 191 cardia and 190 non-cardia gastric cancer cases, and a total of 222 control cases were included in this study. Standard questionnaires were used in collecting epidemiological factors and the data were then analyzed by the unconditional logistic regression model.

RESULTS: As the factors such as age, gender, smoking, alcohol consumption, and family history of gastric cancer were controlled, a multivariable analysis was conducted, which revealed that there was a significant correlation between the dietary habits such as irregular meal, over and fast eating, and the gastric cardia cancer with the odds ratios (ORs) of 4.2 (95 % confidence interval: 2.3-7.7), 4.7 (2.1-10.8), and 2.7 (1.3-5.3) respectively. Other correlations were also observed between the gastric cardia cancer and the consumption of salty fish or pickled vegetable, smoking, and the family cancer history with the ORs of 5.5 (1.4-19.5), 1.8 (1.0-3.0), 2.1 (1.3-3.5), and 3.8 (2.3-6.2) respectively. In contrast, the negative correlations were found existing between the intake of fresh vegetables and fruits, the use of refrigerator, and the gastric cardia cancer, with the ORs of 0.4 (0.2-0.9), 0.2 (0.1-0.5), and 0.2 (0.1-0.4), respectively. However, dietary habits were associated less with non-cardia gastric cancer compared with its cardia counterpart.

CONCLUSION: Dietary habits might be one of the risk factors for the cardia carcinogenesis among Chinese population.

INTRODUCTION

While the total incidence and mortality of gastric cancer manifested a declining trend world wide, the incidence of gastric cardia cancer has increased considerably in the past few decades^[1-4]. The explanations for this phenomenon, however, have not been fully elucidated yet^[5-6]. Although certain dietary factors have been suggested to be associated with the gastric carcinogenesis, there are few investigations performing the etiological analysis further on the anatomical sub-site of the cancer^[7-11], whose divergent carcinogenesis patterns suggested that there might exist differences in etiological factors between the cardia and non-cardia gastric cancers. To verify this hypothesis, we have conducted a case-control study in Fujian Province, China.

MATERIALS AND METHODS

Subjects

191 cardia and 190 non-cardia primary gastric cancer cases, which were pathologically confirmed or diagnosed through surgical operation between April 2000 and June 2001 in six hospitals in Fuzhou, were employed as the observation group and the cancer controls respectively. The 222 cases of normal control, which came from the department of orthopedics in the same hospitals, were selected without cancers or gastric diseases and frequency-matched to the observation cases by age (± 3 year) and gender. All subjects in our study must have resided in Fujian Province for more than 20 years and can answer questions clearly.

Investigation

Face-to-face interviews were conducted in the hospitals by trained interviewers, in which a structured questionnaire containing socio-demographic characteristics, personal medical history, tobacco and alcohol consumption habits, family cancer history, dietary history and dietary habits was used. As for the dietary habits, the exposure time of 10 years before the interview was emphasized to ensure the assessment of potential risk factors with a reasonable latent period before the onset of cancer. Although the dietary habits could be changed presently by the course of the disease, they would never be influenced 10 years earlier. With the agreement to be interviewed, the observed case and his or her control counterparts were investigated by the same interviewer.

Statistical analysis

The data were statistically evaluated with Epi-info by the univariate and multivariate analysis. The relationship between the putative risk factors and the sub-sites of gastric cancer was assessed by odds ratios (ORs) and their 95 % confidence intervals (CIs) derived from unconditional logistic regression model. Multivariate logistic regression analysis was used to evaluate simultaneously the effects of multiple factors and other potential confounding factors.

RESULTS

A total of 603 subjects from 30 to 79 years old were included

in this study. In the observation group, there were 156 male and 35 female with the average age of 61.2 (± 9.7) and 57.3 (± 10.9) years old respectively. Table 1 shows the demographic characteristics of age and gender for the observed cases and controls. To minimize the possible confounding effects on the investigation results, the age and the gender were taken as the confounding factors to be controlled in all of our analyses.

The relationship between the dietary habits and gastric cancers are shown in Table 2 with the factors such as age, gender, smoking, alcohol consumption and family cancer history being controlled. Irregular meal, over and fast eating could increase the risk of cardia carcinogenesis. Intake of salty fish, pickled vegetables, lard oil and drinking of the well water were also the risk factors for the cardia cancer. In contrast, the intake of fresh vegetables and fruits and the use of refrigerator were belong to the protective factors against the cancer. Besides, it was found that low income, poor education and bearing a family cancer history in the first-degree relatives were associated with the cardia cancer risk. However, the dietary habits

were associated less with non-cardia cancer compared with its cardia counterpart. Alcohol consumption was not observed relating to the cardia cancer risk in the present study.

Table 3 shows the interrelation between cardia cancer and smoking. In smokers, the odds ratio for cardia cancer is 2.09 after adjusted by age, gender, alcohol drinking and family cancer history. For those who smoke more than 20 cigarettes a day, the risk for cardia cancer was 2-fold or more compared with non-smokers. We also noted a significant dose-risk relationship existed between the daily consumed cigarettes, smoking duration and the cardia cancer. However, it was not existed between smoking and the non-cardia gastric cancer.

Unconditional logistic analyses were made by a backward elimination approach to select a possible best subset of risk factors for cardia cancer. The results showed that the best subset of risk factors included family cancer history, irregular meal, fast eating, well-water drinking, smoking, and poor-educated. Fresh fruit intake and the use of refrigerator have protective effect against cardia cancer.

DISCUSSION

Epidemiological studies have indicated that while the overall incidence of gastric cancer has been decreasing, the morbidity of cardia gastric cancer has constantly gone up, which might reflect a different etiology for the cardia gastric cancer^[12-14]. However, little attention has been paid to the risk factors for this increasing trend of cardia gastric cancer. The correlation between the risk factors and the location of gastric cancer has also seldom been investigated^[15-17].

In our study the dietary habits were identified as the risk factors for cardia cancer. Irregular meal, over-eating, and the fast eating may cause injuries to the digestive tract mucosa and promote the carcinogenesis. The protective effects of taking in fresh vegetables and fruits against gastric cancer may be mediated by anti-oxidants such as ascorbic acid. Therefore, intake of more fresh fruits and vegetables may significantly lower the risk of gastric cancer, which is consistent with the former epidemiological studies^[18-21]. The present study also showed that the more the pickled vegetables and salty fish were taken in, the more the risk for cardia cancer were increasing, which might be attributed to the potential carcinogens, such as nitroso compounds contained in these foods, and may also involved the increased cell replication and susceptibility to carcinogenesis from salt intake^[22-24]. Lard oil intake was also associated with the increased risk of gastric ca cancer, probably because of excessive exposures of people to the saturated fatty acids. We found that in comparison of the cardia with non-cardia cancer, the carcinogenic risk with specific food or food groups were similar; however, the dietary habits associated more closely with the cardia cancer than with the other stomach carcinomas.

Long-term use of refrigerators could decrease the risk of both cardia and non-cardia gastric cancer with the adjusted OR of 0.242 (95 % CI: 0.143-0.409) and 0.426 (95 % CI: 0.263-0.693) respectively. Refrigerator may keep foods and vegetables fresh for longer period of time, reduce the possibility of generating nitroso compounds, and maintain vitamins and other antioxidants at a higher level, which in turn protect the individuals from exposure to nitroso compounds and other carcinogens. Effective food preservation, which slows down the conversion of nitrates ions to highly carcinogenic nitrites, has been suggested to be at least partially responsible for the overall decreasing trend of gastric cancer incidence.

Well-water, especially shallow well-water may be more easily polluted than tap water. In this study, the fact that well-water drinking was related to an increased risk of cardia cancer suggested that potentially detrimental materials in polluted drinking water might be involved in the cardia carcinogenesis.

After adjusted by age, gender, drinking water and family cancer history in the first-degree relatives, cigarette smoking manifested as a risk factor for the cardia cancer in this study. There was a longer smoking exposure history in the cardia cancer cases than in both cancer-free controls and non-cardia gastric cancer patients. Significant positive dose-effect relationship was found both in the daily cigarette consumption ($P < 0.001$) and the smoking duration ($P < 0.001$). These findings suggested that the smoking exposure was a specific risk factor for the cardia cancer, and the results were influenced less by the recall bias, as it is implausible that patients with cardia cancer would recall smoking exposure more accurately than the non-cardia gastric cancer cases. It is also impossible for the cardia cancer patients to think the more about smoking as the possible cause of their illness than the non-cardia gastric cancer patients, even though cancer cases were aware of their disease status. Therefore, taking multiple controls of different types can be valuable for exploring alternate hypotheses and for taking into account possible potential bias such as recall bias^[25].

Low socio-economic status and poor education were also related to the gastric cancer risk^[26]. The cancer-free controls tended to be better educated than the cancer cases in this study. Family aggregation of the cardia gastric cancer has been confirmed in this study with adjusted OR of 2.09. The correlation between the cardia gastric cancer and family cancer history in the first-degree relatives suggested that inherited genetic susceptibility and shared environmental risk factors might contribute to the cardia carcinogenesis^[27, 28].

In conclusion, our study indicated that dietary habits and family cancer history are the risk factors both for cardia and non-cardia gastric cancer. However, dietary habits and smoking were associated more with the cardia cancer than the non-cardia carcinomas. The different epidemiological features between the cardia and the non-cardia gastric cancer suggested that these tumors might have different etiologic profiles. Therefore, further studies on environmental and host determinants of gastric cardia cancer are needed. Our study also suggested that interventions against cigarette smoking and bad dietary habits may be important for the prevention of gastric cancer. As part of the strategy for the cancer control, healthy lifestyle should be emphasized as every one's responsibility^[29, 30]. Daily intake of fresh vegetables and fruits should be encouraged^[31-33].

Abstract

AIM: To evaluate the value of miniprobe sonography (MPS), spiral CT and MR imaging (MRI) in the tumor and regional lymph node staging of esophageal cancer.

METHODS: Eight-six patients (56 men and 30 women; age range of 39-73 years, mean 62 years) with esophageal carcinoma were staged preoperatively with imaging modalities. Of them, 81 (94 %) had squamous cell carcinoma, 4(5 %) adenocarcinoma, and 1(1 %) adenoacanthoma. Eleven patients (12 %) had malignancy of the upper one third, 41 (48 %) of the mid-esophagus and 34 (40 %) of the distal one third. Forty-one were examined by spiral CT in whom 13 were co-examined by MPS, and forty-five by MRI in whom 18 were also co-examined by MPS. These imaging results were compared with the findings of the histopathologic examination for resected specimens.

RESULTS: In staging the depth of tumor growth, MPS was significantly more accurate (84 %) than spiral CT and MRI (68 % and 60 %, respectively, $P < 0.05$). The specificity and sensitivity were 82 % and 85 % for MPS; 60 % and 69 % for spiral CT; and 40 % and 63 % for MRI, respectively. In staging regional lymph nodes, spiral CT was more accurate (78 %) than MPS and MRI (71 % and 64 %, respectively), but the difference was not statistically significant. The specificity and sensitivity were 79 % and 77 % for spiral CT; 75 % and 68 % for MPS; and 68 % and 62 % for MRI, respectively.

CONCLUSION: MPS is superior to spiral CT or MRI for T staging, especially in early esophageal cancer. However, the three modalities have the similar accuracy in N staging. Spiral CT or MRI is helpful for the detection of far-distance metastasis in esophageal cancer.

INTRODUCTION

Patients with esophageal cancer have a poor prognosis because

on the onset of symptoms and the final diagnosis, most tumors have reached an advanced stage^[1-5]. Resection of esophageal cancers is the only curative method, but is limited to the early stages of the disease^[6-10]. Therefore, the early diagnosis and an accurate staging are very important for the surgery.

Esophageal tumor is a common disease in China^[11-17]. Shantou is a high-risk region. The incidence of the disease ranges from 60-150 per 100 000 population and the mortality is as high as 90-134 per 100 000 population^[18,19]. Currently, several cross sectional imaging techniques, such as endoscopic ultrasonography (EUS), computed tomography (CT) and magnetic resonance imaging (MRI) have been widely used to provide preoperative staging and follow-up information in these patients^[1, 20-26]. Unfortunately, all these techniques have their limitations.

Miniprobe endosonography (MPS) is a new intracavitary technique^[27], especially in China^[28,29]. In staging esophageal tumors, previously most studies used the 1987 TNM classification system^[30]. In this study, we adopted the new (1997) TNM classification standard^[31]. The purpose of our study is to compare the accuracy of the three different modalities in preoperative TN staging in patients with esophageal tumors and to analyze their advantages and limitations.

MATERIALS AND METHODS

Patients

From February 1997 to May 2001, 86 patients (56 men and 30 women; age range of 39-73 years, mean 62 years) with esophageal carcinoma were staged preoperatively with imaging modalities. All patients were operated on and staging was done either by histopathological assessment of the resected specimens, or by intraoperative findings, or both. The findings of histopathologic examination were as a gold standard and compared with the results of MPS, spiral CT, and MRI. Of the 86 patients, 81 (94 %) had squamous cell carcinoma, 4(5 %) adenocarcinoma, and 1(1 %) had adenoacanthoma. Eleven patients (12 %) had malignancy of the upper one third, forty-one (48 %) of the mid-esophagus and thirty-four (40 %) of the distal one third. Forty-one patients were examined by spiral CT in which 13 were co-examined by MPS, and 45 patients were examined by MRI in whom 18 were also co-examined by MPS. Of the 22 stenotic tumors in this group, 12 were examined by MPS and the others by spiral CT or MRI.

Imaging procedure

Miniprobe sonography system (Sp-501, Fujinon Co. Ltd, Japan) was used to obtain ultrasound images. A miniprobe (2.6 mm in diameter, 2.05 m in length, 12 MHz or 15 MHz in frequency) was passed through the biopsy channel of a video-endoscope (Olympus XQ-200) during routine endoscopy. Examinations were performed by one endoscopist using the following technique. Premedication with 5 mg midazolam was administered intravenously to 31 patients. First, a standard endoscopy was performed to determine the exact location and size of the tumor. Then the tip of the endoscope was placed 2 to 3 cm proximally to the tumor. The lumen was filled with 50-300 ml of deaerated water to achieve acoustic coupling

between transducer and wall. The normal esophageal wall is known to be visualized by MPS as a five-layer structure: (1) mucosa (hyperechoic), (2) muscularis mucosa (hypoechoic), (3) submucosa (hyperechoic), (4) muscularis propria (hypoechoic), and (5) adventitia (hyperechoic). TN staging of MPS was modified according to the 1997 standard of TNM classification^[31]. Depth of invasion of the primary tumor was assessed as follows: T1, tumor invading the lamina propria or submucosa; T2, tumor invading the muscularis propria and leading to complete or nearly complete loss of the layer structure, but with a smooth outer margin; T3, tumor invading the adventitia and surrounding fat tissues; and T4, tumor invading adjacent structures. The criteria for the assessment of lymph node metastasis were used according to our previous standard^[28]. In short, the hypoechoic pattern, clearly defined boundaries, especially the direct extension from the primary tumor were considered malignant nodes. In contrast, the hyperechoic pattern and fuzzy borders were considered benign nodes.

Spiral CT scans were obtained by means of a commercially available unit (Tomoscan AV EP-Plus, Phillip) with 10-mm thick contiguous sections from the pulmonary apices to the adrenal region. Enhanced CT scan was performed in a biphasic mode with a rapid intravenous injection of 50 ml iohalamate meglumine (Ultravist) in 38 patients. Three hundred ml of water was administered to the patients with distal neoplasms before the CT scanning in order to assess gastric extension. Spiral CT images were reviewed by an experienced radiologist, and TN stages were evaluated using the same criteria described below for MR examinations.

MR imaging was performed with a permanent magnet operating at 0.15T (ASP-015, Annke) with a 128×256 acquisition matrix. Multiple spin-echo pulse sequences were obtained in the transaxial plane at repetition times (TR) of 500, 1 800, or 2 500 msec and echo times (TE) of 35, 90 or 120 msec. In some patients, the sagittal and coronal images were obtained. T₁-weighted images were obtained at repetition times (TR) of 500msec and echo times (TE) of 30 msec, and T₂-weighted images were obtained at TR of 1 500-1 800 msec and TE of 90-120msec. Transaxial images with contiguous 8-10 mm sections were obtained from the pulmonary apices, including supra clavicular fossas to the upper abdomen, including the entire liver. Coronal and sagittal images with contiguous 8-10 mm sections were obtained in 37 patients, and 0.5 % Gd-DTPA was orally administered to distend the stomach before the MR examination. ECG-gated scans were not used in all patients. Five mm esophageal thickness was used as the upper limits of normal esophageal wall. Any increase beyond this was considered abnormal. Since CT or MRI cannot differentiate each layer of the esophageal wall, according to Botet *et al* standard^[32], thickening of the wall greater than 5 mm and less than 15 mm was diagnosed as modified T2, thickening of the wall greater than 15 mm with irregularity of the outer margin as T3, and tumor invasion of adjacent structures such as the trachea, aortic pericardium, or vertebral body as T4. Lymph nodes greater than 10 mm in shortaxis diameter were considered abnormal. In contrast, lymph nodes less than 10 mm in diameter were considered benign nodes.

Statistics

The accuracy, sensitivity and specificity of MPS, spiral CT and MRI were calculated using histopathologic staging as a gold standard. For T stage, the sensitivity is a measure of the ability of the three modalities to correctly stage T1/T2 and not overstage tumors as T3/T4, and conversely the specificity is a measure of the ability of the three modalities to correctly stage T3/T4 and not understage tumors as T1/T2^[30]. A Chi-squared test was performed to assess the differences in staging accuracy

by different methods. A *P* value of less than 0.05 was considered to be statistically significant.

RESULTS

Evaluation of tumor growth (T stage)

Tables 1 shows the accuracy of the three modalities for predicting the T category. Of the 86 patients, 4 patients had T1 tumor, 8 T2, 34 T3 and 40 T4 by final histopathologic examination.

Thirty-one patients were examined by MPS. It correctly diagnosed all 4 (100 %) T1 tumors, 5 of 7 (71 %) T2, 8 of 9 (89 %) T3, and 9 of 11 (82 %) T4. In stage T2, one was understaged and another was overstaged. In stage T3, only one tumor was misdiagnosed as T2. In stage T4, two tumors were understaged. The sensitivity and specificity were 82 % and 85 %, respectively. The overall accuracy of MPS was 84 %.

Spiral CT was performed in 41 patients. Among them, 2 had T1 tumor, 3 T2, 14 T3 and 22 T4 by final histopathologic examination. In 5 T1/T2 tumors, 2 were overstaged, and 3 were staged as modified T2 correctly (75 %). In stage T3, 2 tumors were understaged as T2 and 1 was overstaged, 11 of 14 were staged correctly (79 %). In stage T4, 8 were misdiagnosed, and only 14 of 22 were staged correctly (64 %). The sensitivity and specificity of T staging by spiral CT were 60 % and 69 %, respectively. The overall accuracy was 68 %.

MRI was performed in 45 patients. Among them, 5 had T2 tumor, 20 T3 and 20 T4 by final histopathologic examination. No T1 tumor was examined by MRI. In stage T2, one was understaged and 2 were overstaged, only 2 T2 were staged correctly (40 %). In stage T3, 2 tumors were understaged as T2 and 4 were overstaged, 14 of 20 were staged correctly (70 %). In stage T4, 9 were misdiagnosed, and only 11 of 20 were staged correctly (55 %). The sensitivity and specificity were 40 % and 63 %. The overall accuracy of MRI was 60 %.

Table 1 Accuracy of T classification in esophageal cancers: MPS, spiral CT, MRI compared with histopathologic staging

Histopathology	n	Accuracy (%)		
		MPS	Spiral CT	MRI
T1	4	4/4 (100)		
T2	8	5/7 (71)	3/5 (75)	2/5 (40)
T3	34	8/9 (89)	11/14 (79)	14/20 (70)
T4	40	9/11 (82)	14/22 (64)	11/20 (55)
Total	86	26/31 (84)	28/41 (68)	27/45 (60)

Evaluation of lymph node involvement (N stage)

Tables 2 shows the accuracy of the three modalities for predicting the overall N category differentiated as N0 or N1. Among the 86 patients, 47 had histopathologically proved lymph node involvement.

In 31 patients investigated by MPS, 19 had lymph node involvement and 12 had not by histopathologic examination. MPS correctly diagnosed 13 patients in 19 positive nodes. In 12 patients without lymph node involvement, MPS diagnosed 9 patients correctly. There were 3 false-positive and 6 false-negative. The sensitivity, specificity and accuracy were 68 %, 75 %, and 71 %, respectively.

Of 41 patients examined by spiral CT, 22 had lymph node involvement. Spiral CT showed 17 patients had regional lymph node metastasis in 22 positive patients. In 19 patients without lymph node involvement, spiral CT diagnosed 15 patients correctly. There were 4 false-positive and 5 false-negative.

The sensitivity, specificity and accuracy were 77 %, 79 %, and 78 %, respectively.

Among 45 patients examined by MRI, 26 had lymph node involvement. MRI showed 16 had regional lymph node metastasis in 26 positive patients. In 19 patients without lymph node involvement, MRI diagnosed 13 patients correctly. There were 6 false-positive and 10 false-negative. The sensitivity, specificity and accuracy were 62 %, 68 %, and 64 %, respectively.

Table 2 Accuracy of N classification in esophageal cancers: MPS, spiral CT, MRI compared to histopathologic staging

Histopathology	n	Accuracy (%)		
		MPS	Spiral CT	MRI
N0	39	9/12 (75)	15/19 (79)	13/19 (68)
N1	47	13/19 (68)	17/22 (77)	16/26 (62)
Total	86	22/31 (71)	32/41 (78)	29/45 (64)

DISCUSSION

It was reported that accuracy rates of EUS were approximately 52-92 % in the assessment of the infiltration depth of esophageal cancer^[33-39]. In our study, the overall accuracy of T staging was 84 %. We think that the high resolution of MPS contributes the good results, 12MHz translator made it possible to differentiate esophageal histological structures and delineate the entire margins of tumors, especially in the superficial esophageal cancer. The penetration depth of good resolution ultrasound was about 6-8 cm, which could clearly visualize the tumor and the adjacent organs^[40]. In some reports, T1 tumors were often overstaged as T2 because of the resultant obliteration of the submucosa and the muscularis propria^[33]. Although one study reported no benefit of miniprobe in esophageal cancers^[41], Menzel *et al* carefully compared the effects of higher frequency miniprobe with conventional probes and concluded that MPS had a higher accuracy for T staging and similar accuracy for N staging in esophageal tumors^[42]. Akaoshi *et al* also demonstrated the benefit of MPS in early gastric cancers^[43]. In this series, 4 T1 tumors (including one superficial mucosal carcinoma) were all correctly diagnosed because the tact border of muscularis propria was clearly visualized. In T2 tumor, the accuracy was 71 %. One T2 tumor was overstaged as T3 because the inflammation and fibrosis were mistakenly interpreted as tumor extension through the muscularis propria. Another T2 tumor was understaged because the microscopic invasion beyond the submucosa was not discerned. For T3 tumors, only one was understaged due to inexperience. The tumor was larger and the invasion outside the muscularis propria was interpreted as an irregular outer margin of the muscularis propria. In T4 stage, two tumors were understaged because the adjacent malignant stricture (tracheal or bronchial invasion) was not discerned in a limited field of view. We thought that endosonographic wall penetration was a critical factor. Richards *et al* also observed that ultrasound attenuation was a commonest reason which led to the error of diagnosis in the advanced tumor^[44], in particular in stenotic tumors^[45]. In addition, artifacts due to oblique scanning may also give rise to misrepresentation of the true depth of penetration, which was another deficient of MPS.

CT or MRI has been widely used in staging tumors of the upper intestinal tract. However, their diagnostic accuracy in evaluating esophageal carcinoma is controversial. Both of them have the same limitations, i.e. unable to discriminate the layer of the esophageal wall and to detect tumor spread through the muscular wall into adjacent tissues^[32]. Evaluation of direct invasion by CT or MRI is based on two criteria: mass effect

and loss of fat planes. When the trachea or bronchial wall is indented or displaced away by a tumor mass, the mass effect is present and invasion is presumed. The loss of fat plane between tumor and adjacent tissues is commonly used to predict aortic and pericardial invasion. According to the reports, the accuracy of CT or MRI in staging the local tumor infiltration ranged from 45 % to 73 %^[46-51]. Quint *et al* compared MRI with CT in the staging of esophageal tumors^[52]. In 12 patients evaluated, they found that both CT and MRI were 100 % accurate in prediction of tracheobronchial invasion with an accuracy rate of 75 % for aortic invasion and 88 % for pericardial invasion. In a late review, Kelly *et al* reported that the sensitivity of CT ranged from 40 % to 80 % and the specificity from 14 % to 97 %^[30]. In present study, the sensitivity of the three modalities ranged from 40 % to 82 % and the specificity from 63 % to 85 %. Three patients misdiagnosed by spiral CT and five patients by MRI were staged correctly by MPS, especially in T1-T2 tumors, which demonstrated the superiority of MPS. Spiral CT is an inspiring new technique. Our primary data showed that spiral CT was not optimistic, although spiral CT had a higher accuracy than MRI, no significant difference was found ($P>0.05$). MPS appeared more accurate (84 %) than spiral CT or MRI (68 % or 60 %, respectively, $P<0.05$). Although strictly blinded approach was not taken in this study, our results continue to support the hypothesis that endosonography is superior to CT or MRI in the T staging of esophageal cancer^[53-55].

MPS can only visualize lymph nodes close to the esophageal wall whereas CT and MRI can demonstrate both regional and distant lymph node metastases. For MPS, the differentiation of malignant lymph nodes from benign nodes could be made according to its size, distance from tumor and echo features. The round hypoechoic lymph nodes with a smoothly demarcated border and size greater than 5 mm had the greatest probability of malignancy^[56]. Murata *et al*^[57] used MPS to evaluate lymph nodes in different periesophageal areas and the accuracy being 88 %. Other reported that the accuracy of EUS ranged from 68 % to 92 %^[29,58-60]. In this study, the overall accuracy of MPS for diagnosing the N category was 71 %, with a sensitivity of 75 % and a specificity of 68 %. Our results were consistent with these reports.

We think that the lack of reliable criteria in N staging may be the main reason of low accuracy for MPS. The judging value of node size is still controversial. Some authors reported that nodes larger than 5 mm were not inflammatory in the resection specimens^[33, 61-64]. Tio *et al* thought that enlarged lymph nodes were not necessarily cancerous and small nodes might be involved by tumors^[33]. We also observed that lymph nodes larger than 5 mm were inflammatory by pathological examination^[28]. However, we believed that nodes greater than 10 mm, especially close to the primary tumor, rounder, darker, and more homogeneous had much more possibility of malignancy^[20]. In addition, the morphology of tumors would also be another important factor affecting these results.

Holscher *et al*^[65] thought that MPS was more accurate than CT or MRI in the diagnosis of lymph node metastases. Tio *et al*^[33], however, pointed out that CT was superior to EUS for evaluating celiac lymph nodes due to nontraversable stenoses. In this series, the accuracy of spiral CT (78 %) was higher than that of MPS or MRI (68 %, 64 %, respectively), but without significant difference ($P>0.05$). The cause was not clear. We think that methodologies of study designs are related to these results, because different assessment conditions, such as technical parameters, anatomical location of tumors and patient characteristics could lead to different results^[66]. For example, stenotic tumors were not included or accounted for different percentages in some studies^[65]. Hordijk *et al* assessed the influence of tumor stenosis on T staging accuracy of

miniprbes. A lower accuracy (46 %) was obtained with stenotic tumors than those with nontraversable tumors (82 %). They postulated that the main reason lay in the short focal distance between the ultrasonic transducer and tumor hampered clear visualization of the wall layers and tumor penetration depth^[45]. On the other hand, Kallimanis *et al*^[66] reported that the degree of esophageal stenosis was an important criteria for lymph node involvement. Brugge *et al* pointed out that T3 and T4 tumors were significantly thicker than T1 and T2 tumors^[67]. In our previous reports, about half of severe stenotic tumors were T3 and the other half T4^[18]. Tio *et al* indicated that the incidence of positive lymph nodes in the advanced tumors (T3/T4) was higher than the intramural tumors (T1/T2)^[33]. In this study, 23 (27 %) patients had stenotic tumors, in whom 10 patients had T3 and 13 had T4 and all had the lymph node involvement. No one had T2 or T1 stage. In other words, stenotic tumors had more possibilities of advanced stage and lymph node metastasis^[18, 68-72]. Our results strongly supported Brugge's view^[67]. However, in 12 stenotic tumors examined by MPS, only 5 (42 %) were correctly diagnosed. In another 10 stenotic tumors, 5 (5/6) were correctly diagnosed by Spiral CT and 3(3/4) by MRI. Spiral CT and MRI appeared more accurate than MPS in stenotic tumors^[30,71].

In clinical practice, two methods are commonly used to improve the accuracy of diagnosis. One is the use of contrast material, such as Ultravist on spiral CT or Gd-TDPA on MR imaging. Enhanced imaging can provide useful information of the blood supply of the lesions, which is helpful to distinguishing the malignant from the benign mass. The other one is the regulation of the section thickness. A section gap of 1-2 mm can help discover micro-lesions. However, Gd-DTPA has several disadvantages, such as non-specific distribution and slightly nephrotic toxicity^[73]. To develop new tissue-specific contrast material would further improve the accuracy of spiral CT and MRI in TNM staging of gastroesophageal carcinoma. In addition, it should be taken into consideration that in our study the MR equipment was of (first generation), which was also a reason for its low accuracy.

We think that the experience is an important factor to improve the accuracy of diagnosis^[28]. Some problems such as the lack of training facilities, EUS courses and EUS laboratories limit the wider use of MPS. No atlas of endosonography for different diseases has been published in the world so far. The interpretation of endosonographic images is dependent on the ultrasound knowledge or the results of animal experiments. The lack of experience in transabdominal ultrasonography hinders the reasonable interpretation for some complex image patterns. The ultrasound images are also unsteady. We observed that the esophageal wall can be visualized as a five-layer structure, but sometimes as a three-layer structure^[28]. Other authors also reported the similar results^[35,57]. The reason remains to be demonstrated. Many hospitals diagnosed the disease in cooperation between endoscopists and ultrasoundists. In addition, many surgeons have still doubted the role of endosonography. They would rather believe the results of spiral CT or MRI. In fact, CT or MRI plays an increasing role in ruling out the intra-abdominal metastasis so as to avoid unnecessary surgery^[74]. We also think it unnecessary to make MPS examination for those patients who have lost the operation chance. To our knowledge, surgeons in our hospital make the therapeutic plans for the patients with advanced tumors mainly relying on the results of spiral CT or MRI. As a matter of contrast, they select the surgical procedures for the patients with stage T1 and T2 much more depending on the results of MPS. As a matter of fact, MPS appears superior to CT or MRI mainly in staging early tumors and the latter have much higher accuracy in determining the presence or extent of more distant metastases. A combination of endoscopic ultrasound including

computer-assisted analysis and spiral CT or MRI are expected to provide a higher TNM accuracy^[75].

Abstract

AIM: To elucidate the expression of E-cadherin and β -catenin correlating with its clinical outcome in patients with esophageal squamous cell carcinoma (ESCC), by analyzing their interrelationship with clinicopathological variables and their effects on progress and prognosis.

METHODS: Expression of E-cadherin and β -catenin was determined by SP immunohistochemical technique in patients with ESCC consecutively, their correlation with clinical characteristics was evaluated and analyzed by multivariate analysis.

RESULTS: The rate of expression of E-cadherin decreased to 66.03 % (70/106) in ESCC and the protein level was negative correlated with histologic grade, tumor size, clinical staging, lymph node metastasis and venous invasion. Whereas the expression rate of β -catenin was reduced to 69.8 % (74/106) and the level of protein expression correlated only with histologic grade. There obviously existed inverse correlation between level of E-cadherin protein and survival, especially in stage I, IIa, IIb ($P=0.0033$). Patients with low-expressing tumors for β -catenin and non-expressing tumors for E-cadherin/ β -catenin had lower survival period than those with normal-expressing ones ($P=0.0501$ and $P=0.0080$, respectively). Patients with diminished expression of E-cadherin as grade II or III had shorter survival period than those with normally expressing and grade I, no significance existed between grade I and grade II or III with respect to different status of E-cadherin expression. Furthermore, Correlation analysis showed level of E-cadherin correlated with that of β -catenin ($P=0.005$). Cox proportional hazards model analysis suggested downregulation of E-cadherin was an important factor indicating poor prognosis.

CONCLUSION: As a probable independent prognostic factor, it correlates with overall and disease free survival period, expression of E-cadherin but not β -catenin may predict prognosis in patients with ESCC.

INTRODUCTION

Esophageal carcinoma is generally considered as one of the most extremely aggressive carcinomas with dismal prognosis identified thus far^[1-5]. In recent years, postoperative survival of the patients with esophageal carcinoma have been improved. However, 5-year survival rate of operative advanced esophageal carcinoma is still 20-25 %. Early diagnosis and treatment are still important^[2,3,6-9]. TNM system is always considered as a classic criterion to provide treatments and evaluate prognoses. Unfortunately tumor heterogeneity and individual differences influence its accurate estimation^[10]. Therefore, to establish a "molecular staging" system based on materials combining biomarkers and clinical parameters including histologic grade and tumor stage may be helpful to guide individuated treatment and evaluate prognosis. Then some potential molecules remain to be identified^[16,8,9,11-15].

Invasion and metastatic processes themselves consist of sequential multi-stage, multi-step involving host-tumor interactions^[16]. Some studies showed status of intercellular adherens junction plays a pivotal role in tumor growth, invasion, metastasis and prognosis and the suppression of cell-cell adhesiveness may trigger the release of cancer cells from the primary cancer nests and confer invasive properties on a tumor^[16-18]. Detecting expression of adhesion molecules may reflect biological behavior and characteristics of tumor and are conducive to predict and evaluate risk of relapse and metastasis of the patients with postoperative esophageal carcinoma, thus having realistic significance to guide individuated treatment.

The cadherins that exist in many kinds of cells, belong to a family of transmembrane glycoproteins responsible for homophilic interaction of calcium-dependent cell-cell adhesion. Among them, E-cadherin (120 kDa, chromosome 16q22.1) is a classical cadherin and forms the functional component of adherens junctions between epithelial cells, and β -catenin, a multifunctional cytoplasmic protein which links E-cadherin and α -catenin to cytoskeleton constituted E-cadherin-catenin complex, both have important roles in maintaining integrity of cellular structure^[16-20]. Reduction and loss of expression in cancer cells may destroy the junctional structure which can affect the intercellular adhesion, and facilitate tumor differentiation, infiltration and metastasis. Their expression are related to survival and prognosis in a portion of cancer. It had been formed that E-cadherin might be an independent predictor of occult lymph node or micrometastasis in nodes classified as N₀ by routine histopathological methods. However, only few studies were available in ESCC^[18,21,22].

β -catenin has recently been found as a member in Wnt signaling^[23-25]. In the absence of a mitotic signal outside the cell, β -catenin is sequestered in a complex with the APC (adenomatous polyposis coli) gene product, a serine threonine glycogen synthetase kinase (GSK-3 β) and an adapter protein axin (or a homologue conductin), enabling phosphorylation and degradation of free β -catenin by the ubiquitin-proteasome system^[23-25]. When a mitotic signal is delivered by the Wnt pathway, by association of the Wg/Wnt family of secreted glycoproteins and their membrane receptors frizzled, it leads

to activation of the dishevelled (Dsh) protein, which is recruited to the cell membrane. The activated Dsh downregulates the protein complex, so that it can no longer phosphorylate β -catenin. The release of β -catenin from the phosphorylation and degradation complex promotes β -catenin stabilization and signaling. This results in an increase of free cytosolic β -catenin which translocates to the nucleus and directly binds the transcription factors Lef and Tcf, leading to activation of gene expression^[26,27].

Here, we performed E-cadherin and β -catenin expression analysis in a 106 ESCC in order to elucidate whether the expression of E-cadherin and β -catenin correlate with clinicopathological variables and clinical outcome, by analyzing their interrelationships and effects on progression of cancer and their prognostic evaluations in ESCC. Furthermore, may provide some considerable suggestions for clinical treatments.

MATERIALS AND METHODS

Clinicopathologic data

The specimens of cancer tissues and non-cancerous adjacent tissues were taken from 106 consecutive patients with esophageal squamous cell carcinoma who had undergone esophagectomy from January 1990 to December 1995 at Cancer Hospital of Tianjin Medical University, Tianjin, China. None of them received irradiation or chemotherapy preoperatively. The patients included 76 men and 30 women with a mean age of 59 (range 37-76) years. Ten tumors were in the upper segment, 68 in the middle segment and 28 in the lower segment. With respect to their growth pattern, they were 20 medullary type, 42 fungating, 34 ulcerative, 9 scirrhous and 1 other type. Of seventy-three patients underwent left thoracic approach esophagectomy, 60 cases had esophagogastric anastomosis above the aortic arch, 10 below the aortic arches and 3 cervical esophagogastric reconstruction, 25 patients underwent right thoracic posteriolateral, abdominal and cervical approach esophagectomy and 8 with other approach. Tumors were staged again according to the TNM classification (UICC1997): 2 patients with stage I, 31 IIa, 10 IIb, 60 III and 3 IV. Postoperative radiotherapy was performed in 12 patients and chemotherapy in 15. Survival periods were calculated from the date of operation to death from recurrence of the disease. Follow-up period ranged from 2 to 117 months with an average of 32.4 months.

Immunohistochemical staining

For parallel analyses of staining characteristic of the tumor and normal mucosa, representative tissue section comparing the most part of the tumor and adjacent normal mucosa were selected after the H&E stained slides were reviewed. In brief, Four micrometers thick sections prepared from 100 ml \cdot l⁻¹ neutral buffered formalin-fixed and paraffin-embedded tumor tissue on the slides were deparaffinized, dehydrated and blocked from removing endogenous peroxides activating with 3 ml \cdot l⁻¹ H₂O₂ in methanol for 30 min. The sections were microwaved in 0.1 mol \cdot l⁻¹ citrate buffer pH 6.0 at 750 W for 12 min. After incubation with 10 % normal goat serum to block non-specific binding and were then incubated with the primary antibodies such as mouse monoclonal anti-human E-cadherin (4A2C \times 7, Santa Cruz Biotechnology, USA, ready to use) and polyclonal rabbit anti- β -catenin (Sigma Chemical Company, USA, diluted 1:1 000 in PBS) overnight at 4 $^{\circ}$ C. After washing antibody with the SP kit (Zymed, USA) the peroxides reaction was performed using 3, 3' -diaminobenzidine tetrahydrochloride (DAB) (Zhongshan Biological Technology, Beijing, China) as chromogen. Tissues were counterstained with hematoxylin.

The slides were washed between each step three times with PBS. Negative control was obtained by replacing the primary antibody with PBS. Adjacent normal squamous epithelium served as an internal positive control.

Evaluation of immunohistochemical staining

Tumor sections were scored by light microscopy by 3 independent observers (Chen H, Li H and Liu XS) without knowledge of the stage and patient profiles. Based on the previous immunohistochemical studies^[28], the membranous staining of cells were positively stained by the antibody. Calculating the percentage of positively stained cells evaluated for each tissue section after counting 100 cells at more than 5 high-power (\times 200) fields. The expression of E-cadherin and β -catenin were classified into 3 grades, as follows: -, If less than 10 % of the tumor cells were positively stained; +, If more than 90 % of the tumor cells were positively stained, the expression was judged to be positive; and \pm , between 10 % and 90 % of the tumor cells were evaluated as heterogeneous. The specimens graded + stand for normal expression, \pm and - were taken together and classified as reduced expression.

Statistical analysis

The χ^2 test and Spearman rank correlation coefficient analysis were used to assess the univariate association between the immunohistochemical status and the clinicopathological characteristics. The survival rate was calculated by life table and cumulative survival curves were constructed according to the Kaplan-Meier method, and differences in survival were estimated with the Log-rank test. Cox proportional hazards model was used for multivariate survival analysis. A *P* value less than 0.05 was considered significant. All the statistical analyses were performed using the SPSS 10.0 V for Windows software.

RESULTS

Expression of E-cadherin and β -catenin in normal esophagus

Normal esophageal epithelium showed strong expression of E-cadherin and β -catenin at the membrane of cell and the intercellular junctions. Expression of these molecules was more marked in the prickle cell layer and para-basal cell layers. No or weak cytoplasmic staining of E-cadherin and no cytoplasmic staining of β -catenin were seen in normal esophageal epithelium. Esophageal glands and their duct also showed expression of these molecules at cell membranes, Whereas non-epithelial cells such as muscular tissue and infiltrating lymphocytes did not.

Expression of E-cadherin and β -catenin in esophageal carcinoma

Reduced homogenous and heterogeneous staining of E-cadherin and β -catenin were found in esophageal carcinoma (Figure 1). In well/moderately differentiated carcinomas, cancer cells from the tumor nest peripheries showed weaker expression of these molecules than those in the centers showing zonal differentiation (Figure 2). Although reduced expression and loss of them were always present in poorly differentiated carcinomas, some showed normal expression of these molecules in neoplastic nests. Reduced membranous expression of E-cadherin and β -catenin were found in 66.0 % (70/106) and 69.8 % (74/106), respectively.

Expression of E-cadherin and β -catenin and clinicopathologic variables

Significant inverse correlation existed between the intensity of E-cadherin expression and histologic grade, tumor size,

Figure 1 Expression of E-cadherin in esophageal squamous carcinoma tissue, brownish membrane and cytoplasm were shown in part of the tumor cells (A, B positive, C heterogeneous, D negative expression Original magnification $\times 200$; B, Original magnification $\times 400$).

clinical staging and venous invasiveness, No significant differences were seen in age, gender, location of tumor, growth pattern and invasion depth ($r_s=0.020\sim0.156$, $P=0.084\sim0.118$). Expression of β -catenin correlated significantly only with histologic grade, Whereas no differences were observed in age, gender, location of tumor, tumor size, clinical staging, growth pattern, venous invasiveness and invasion depth ($r_s=0.060\sim0.1569$, $P=0.541\sim0.104$), shown in Table 1. In carcinomas with lymph node metastasis, reduced expression of E-cadherin and β -catenin were seen in 76.59 % (36/47) and 72.34 % (34/47) versus 57.63 % (34/59) and 67.79 % (40/59) in carcinomas without lymph node metastasis, respectively. The staining of E-cadherin correlated only with lymph node status ($P=0.040$) and no significant differences for β -catenin.

Relationships between E-cadherin and β -catenin

As summarized in Table 2, the expression of both E-cadherin and β -catenin were evaluated in consecutive sections. The correlation between E-cadherin and β -catenin was statistically significant ($P=0.005$). 17.92 % (19/106) of tumors were E-cadherin(+)/ β -catenin($\pm \sim -$), and 14.15 % (15/106) of tumors were E-cadherin($\pm \sim -$)/ β -catenin(+), statistically significant differences were observed in different expression of these molecules (Pearson $\chi^2=6.086$, $P=0.014$).

Expression of E-cadherin and β -catenin and survival

The median survival was 28.64 months and overall 1-, 3-, 5-year survival rates were 57.13 %, 34.89 % and 29.59 %, respectively. There obviously existed inverse correlation between intensity of E-cadherin protein and survival ($P=0.0532$), even in the group without receiving postoperative chemotherapy or radiotherapy ($P=0.0067$ and $P=0.0295$, respectively). Patients with loss of E-cadherin expression had lower survival at 1-, 3-, 5-year than those with expression tumors, and Patients with reduced E-cadherin expression had shorter disease-free survival than those with normal expression ($P=0.0278$). No significant correlation was apparent between abnormal expression of β -catenin and overall survival. But patients with low-expressing tumors for β -catenin and non-expressing tumors for E-cadherin/ β -catenin had shorter median survival period than those with normal expressing tumors ($P=0.0501$ and $P=0.0080$, respectively) in the group without receiving postoperative chemotherapy or radiotherapy ($P=0.0735$ and $P=0.0205$, respectively).

Expression of E-cadherin and survival stratified for tumor stage

In patients with stage I, IIa, IIb, the median survival for normal, heterogeneous and negative E-cadherin expressing groups were 106.59, 46.59 and 28.50 months, respectively. Statistically significance existed in different level of E-cadherin and overall survival ($P=0.0033$), Survival curves were shown in Figure 3, and disease-free survival ($P=0.0002$) in different E-cadherin expressing groups whose median survival were 78.56, 32.00 and 14.00 months. In contrast, as for stage III or IV, no significance existed in different level of E-cadherin ($P=0.2152$ and $P=0.3397$, respectively). Survival curves were shown in Figure 4.

expressing ones and grade I, no significance existed between grade I and grade II or III with respect to different status of E-cadherin expression. In the patients with grade I, Statistically significant relationships existed between level of E-cadherin and overall survival ($P=0.0125$). The survival curves were shown in Figure 5.

**Figure 5** Kaplan-Meier survival curves for patients with ESCC stratified for histologic grade according to E-cadherin expression

Multivariate analysis of survival

Multivariate survival analysis was performed by means of the Cox proportional hazards model by entering the following covariates: age, gender, location of tumor, tumor size, invasion depth, venous invasiveness, histologic grade, clinical stage, lymph node status, E-cadherin and β -catenin expression. Covariates were selected in a stepwise fashion by using method of Backward: Wald. The significant prognostic factors influencing survival were location of tumor, venous invasiveness, clinical stage, lymph node status, E-cadherin expression. The results were shown in Table 3.

DISCUSSION

Previous studies reported that the reduction rate of E-cadherin expression was observed to be 18.2-87 % in specimens from the patients with ESCC^[28-34]. While 66 % of ESCC examined showed reduced expression of E-cadherin in our investigation. This is not in accordance with references reported. It is our

logical thoughts that selection of the patients entering into the study, immunohistochemical method, antibody origination, tumor heterogeneity and differences in staining evaluation may be individually or in combination held responsible. As a marker associated with squamous cell differentiation^[35], the level of E-cadherin expression had inverse correlation with histologic grade. It suggested that normal function of E-cadherin molecule mediated cell-cell adherens junction to induce cell aggregates, which was consistent with histologic morphogenesis of tumor nest in well-differentiated tumors showed zonal differentiation. That phenomenon consists of a mechanical stretching and compression between adjacent cell and requires active contraction of the actin tethered to the cadherin intercellular contacts^[36]. But normal expression of E-cadherin was found in poorly-differentiated tumors, accounting for 15.0 % in our study. Several studies were available about this phenomenon, Nakanishi *et al* reported 14.58 % of the patients with poorly-differentiated ESCC also appeared normal expression of E-cadherin, of catenins (α , β and γ), so did 3.22 % of the patients with moderated or poorly-differentiated tumors from reports of Tamura *et al*^[29]. Then this showed simply reduced expression of E-cadherin was not independent factor impact on adherens junction. On the other hand normal function of adherens junction relate to cytoplasm protein expression and its normal function. Expression of E-cadherin was closely associated with size of tumor, lymph node metastases and venous invasion in our study. These were not identical to the results of Nakanishi *et al*, Tamura *et al*. However, diminished expression of E-cadherin facilitate tumor dedifferentiation, invasion and metastases, indeed, the tumor cells of solid tumor with high metastatic potentials are often focally dissociated at the invading fronts^[28,29,31]. Of particular interest is the finding in some studies in recent years that expression of E-cadherin might be used to predict micrometastasis in lymph node of the patients without signs of lymph node or distant metastases classified as N₀ and M₀ by routine histopathological methods^[22,37]. Based on these findings, in the present study, The relationship between reduced expression of E-cadherin and haematogenous metastasis in postoperative patients had also come under investigation. Hematogenous metastasis frequently occurred in the patients with reduced expression of E-cadherin, but multivariate analysis revealed the finding need further evaluation (data not shown). It seemed to accept that more intercellular adhesion

molecules such as integrins, selectins and immunoglobulin were involved in the process.

It appears to possess both irreversible and reversible mechanisms for inactivating the cell-cell adhesion system. Several studies revealed heterogeneous methylation patterns exhibit a remarkably unstable, allele-to-allele variability that, like the dynamic expression of E-cadherin during metastatic progression, can be modulated or selected for in relation to the tumor microenvironment^[38]. There have been several reports on E-cadherin gene mutations in human cancer^[16,18], however, mutations are rare in esophageal carcinoma, E-cadherin promoter hypermethylation is associated with decreased expression^[39,40], moreover, recent studies showed that, despite the frequent LOH of the E-cadherin locus, mutations in the E-cadherin gene are rare events and can not be held responsible for down regulation of E-cadherin observed in the majority of adenocarcinomas of the esophagus^[41]. Further studies demonstrated abnormal phosphorylation of cytoplasm protein regulated by tyrosine kinases and tyrosine phosphatases affected expression of E-cadherin and its function^[42].

Significant difference in survival existed in patients with different level of E-cadherin protein and a trend towards better survival was found in patients having normal E-cadherin expression. But discrepancy resulted from studies on the kinds of tumors. Inada *et al* reported 5-year survival rate of the patients with ESCC ranged from 87.8 % in normal E-cadherin expression to 19.1 % in absent expression of E-cadherin^[30], but some coworkers did not acquire the same results^[32,33]. Nakanishi *et al* demonstrated no significant correlations between survival and reduced E-cadherin expression, however, in univariate analysis survival of the patients with reduced α -catenin expression was significantly shorter than that of those with normal expression, and the loss of α -catenin expression from cancer tissues might be attributable to loss of E-cadherin function, which reflected more serious dysfunction of the cadherin-mediated cell-cell adhesion system. In our study there obviously existed inverse correlation between the patients with reduced level of E-cadherin expression and survival, especially in tumors with stage I, II, and in group with absent expression of E-cadherin shorter survival period was observed. Multivariate analysis revealed E-cadherin expression was an independent factor impacted on prognosis of the patients with ESCC. These findings were consistent with the reports of Tamura *et al*, and recently a multicenter investigation supported this viewpoint^[34]. In view of the association between E-cadherin and histologic grade, furthermore, we analyzed and tried to elucidate whether these factors played different roles in combination or individually. Although several studies approved the discrepancy of survival could be partly explained by the histologic grade, owing to other clinicopathologic features and grading categories not to be precisely defined, the results of studies remain controversial. In our present investigation, no significance existed between grade I and grade II or III with respect to different E-cadherin status. But in group with grade I, survival of the patients with normal E-cadherin expression was statistically significantly higher than that of those with diminished one, suggesting an apparent difference in the effect of downregulation of E-cadherin between different histologic grade. Therefore, E-cadherin expression as an independent prognostic factor had more significance to predict prognosis for the patients at early stage and with similar histologic grade, might provide some suggestions for clinical treatments.

β -catenin played an important role in the interactions between cadherins and other transmembrane receptor proteins and regulated cellular differentiation and proliferation. Reduced and absent expression of β -catenin were also frequently in tumors might disrupt stability and integrity of the E-cadherin-catenin complex and disturb cellular adherens junction,

resulting in cell proliferation, migration, and invasion. Reduction of β -catenin expression was 73 % in ESCC from Nakanishi *et al* and 40.9 % from Ninomiya *et al*^[43]. Similarly, 69.8 % of patients with β -catenin expression were judged to be reduced in our study, whereas reduced expression of β -catenin significantly correlated only with the histologic grade. Also, an association between abnormal expression of E-cadherin and β -catenin was found, suggesting that loss of E-cadherin binding may cause a redistribution of β -catenin from the cell membrane to the cytoplasm.

It remains unclear that β -catenin expression is associated with lymph node status, invasion depth, tumor stage, hematogenous metastasis and histologic grade. Many believe as a member of oncogenes and signaling molecules, β -catenin plays an important role in tumor progression and carcinogenesis, and there exists relation with cytoplasmic protein such as α -, γ -catenin, p120^{cas}, APC^[23,24], Dsh, Tcf, Axin, β -Trcp, G12^[44], PP2A^[45], IQGAP1^[23] and Smad4^[46]. Since so intricate signaling network and multifunctional molecules are involved in regulating cellular function, it is difficult to explain abnormal expression of β -catenin and its functional abnormalities, thus negating correlation with clinicopathologic parameters^[47]. But undoubtedly β -catenin as a member of adhesion molecule should be imprudently considered in prognostic value of ESCC. To some extent absent expression of β -catenin reflects dysfunction of E-cadherin mediated cellular adherens junction, which may cause weak cell-cell adhesion and confer invasive properties on a tumor^[26,27,48].

To our knowledge, reduced β -catenin expression indicated poor prognosis in some kinds of tumor in addition to esophageal squamous cell carcinoma^[49,50]. We found that patients with low-expression tumors for β -catenin and non-expression tumors for E-cadherin/ β -catenin had shorter survival period than those with normally expressing ones. But in group with normal E-cadherin expression, no significant relation was found between β -catenin and prognosis. It was apparent that the prognostic value of β -catenin is lower than that of E-cadherin, this may be explained by their roles in the E-cadherin-catenin complex, E-cadherin influences redistribution and function of β -catenin, and γ -catenin might substitute for β -catenin as a component of the complex^[51], in other tumors several studies showed aberrant expression of β -catenin or γ -catenin does not necessarily lead to a nonfunctional complex^[52].

In conclusion, as a probable independent prognostic factor, it correlates with overall and disease free survival period, expression of E-cadherin but not β -catenin may predict prognosis in patients with ESCC, Further studies are needed to elucidate function of β -catenin by combining other cytoplasmic proteins.

Abstract

AIM: Cancer gene therapy has received more and more attentions in the recent decade. Various systems of gene therapy for cancer have been developed. One of the most promising choices is the suicide gene. The product of thymidine kinase (TK) gene can convert ganciclovir (GCV) to phosphorylated GCV, which inhibits the synthesis of cell DNA, and then induces the cells to death. Cytokines play an important role in anti-tumor immunity. This experiment was designed to combine the TK gene and mIL-2/mGM-CSF genes to treat gastric cancer, and was expected to produce a marked anti-tumor effect.

METHODS: TK gene was constructed into the retroviral vector pLxSN, and the mIL-2 and mGM-CSF genes were inserted into the eukaryotic expressing vector pIRES. The gastric cancer cells were transfected by retroviral serum that was harvested from the package cells. *In vitro* study, the transfected gastric cancer cells were maintained in the GCV-contained medium, to assay the cell killing effect and bystander effect. *In vivo* experiment, retroviral serum and cytokines plasmid were transfected into tumor-bearing mice, to observe the changes of tumor volumes and survival of the mice.

RESULTS: *In vitro* experiment, 20 % TK gene transduced cells could cause 70-80 % of total cells to death. *In vivo* results showed that there was no treatment effect in control group and TK/GCV could inhibit the tumor growth. The strongest anti-tumor effect was shown in TK+mIL-2+mGM-CSF group. The pathologic examination showed necrosis of the cancer in the treated groups.

CONCLUSION: TK/GCV can kill tumor cells and inhibit the tumor growth *in vivo*. IL-2 and GM-CSF strongly enhance the anti-tumor effect. Through the retrovirus and liposome methods, the suicide gene and cytokine genes are all expressed in the tissues.

INTRODUCTION

Gastric cancer is a common malignancy in China. However, all the efforts of conventional treatments including extended resection, radiation and chemotherapy have a little influence on the improvement of its survival. In searching for a new way to the treatment of such a malignant disease, the gene therapy was introduced and displayed its promising. One of the landmark discoveries is the application of suicide gene to cancer cells. It converted a nontoxic prodrug into a cell-killing compound. The herpes simplex virus type I thymidine kinase (HSV-tk) and the *Escherichia coli* cytosine deaminase (CD) was popularly used as transfected suicide gene.

The expressed products of these genes are enzymes, which can convert the nontoxic anti-ancer drugs into toxic ones, and disrupt the synthesis of target DNA. The product of TK gene can phosphalate the ganciclovir (GCV), and it was further phosphalated by endogenous kinase that leads to the formation of cytotoxic ganciclovir triphosphate. Interestingly, neighbor tumor cells that do not express the suicide gene were also killed in the presence of prodrug. This phenomenon is called the "bystander effect"^[1-10].

Cytokines play important roles in the anti-tumor immune responses. IL-2 can activate the NK, LAK cells and CD₈⁺ T lymphocytes. The activated CD₈⁺ T lymphocytes can kill tumor cells directly. GM-CSF can promote the antigen presentation to macrophage and dendritic cells in the anti-tumor immune reaction^[11-14].

The aim of this study was to boost the anti-tumor effect to achieve long- term survival and tumor eradication in model by the combination of TK/GCV with IL-2 and GM-CSF.

MATERIALS AND METHODS

Materials

The retroviral vector pLxSN was purchased from the Genetech, the HSV-TK gene was provided by Dr. Bingya Liu. LacZ gene was purchased from Promega. MFC cell line was derived from the 615 murine carcinoma of proximal stomach, and obtained from the Drug Research Institute of Chinese Science Academy. PA317 cell and NIH3T3 cells were cultured in this laboratory. Ganciclovir was purchased from Shanghai Roche Company, DMEM from Gibco, and G 418 from Promega.

Methods

Vectors and cell lines The retroviral vector is pLxSN. TK gene was inserted into the multiple cloning site between EcoR I and BamH I, which was under the control of long terminal repeat (LTR), and the neomycin resistance gene was driven by an SV40 promoter. The report gene LacZ was inserted as same as TK gene. The murine IL-2 (Mil-2) and murine GM-CSF (mGM-CSF) were cloned from murine spleen tissue, and was confirmed by DNA sequencing. They were inserted into multiple cloning site of the pIRES vector through the EcoR I and BamH I, and driven by the cytomegalovirus (CMV) promoter.

MFC cells were maintained in DMEM (Dubecco's modified essential medium), supplemented with 10 % FBS (Hangzhou

Sijiqing Biotech Company), 2 mM L-glutamine, 100 units/ml penicillin and 100 ug/ml streptomycin. PA317 cell was used as the packaging cell, and NIH 3T3 cell was used to assay the virus titre.

Packaging cells transfection, clone selection and supernatant preparation The retrovirus plasmids containing TK and LacZ gene were transfected into the PA317 packaging cell line by lipofectamine (Gibco). Clones were isolated by G418 selection. After 48hs of lipofection, the media was replaced by the media contain G418 (600 ug/ml). The media was changed every 3 days. Most cells died after 2 weeks and the transfected cells survived. Culture and generate the selected anti-G418 cells. Collect virus suspension of four generations. To infect the NIH 3T3 cell with the virus suspension in different titres. Calculate the virus titres.

Infection of MFC gastric carcinoma cell line Infection was performed in suspension by a 30 minutes incubation of MFC cells with virus dilutions in 1 ml of PBS, supplemented with 4 ug/ml polybrene. To change the medium with DMEM which contained G418 48hs later, and repeated it every 3 days. Cells started to die after one week. The infected cells survived ultimately and formed cell clones.

In vitro experiment

1. *In vitro* sensitivity to GCV: Transfected MFC cells were planted in the 96 wells plate in 1×10^4 /well. The medium containing various concentration of GCV. Cells were cultured for 7 days, and the survival rate of cells was counted by MTT method. The result was calculated by the following formula,

$$\text{Survival rate} = \frac{\text{Value of experimental group} - \text{value of control group}}{\text{The max value} - \text{value of control group}} \times 100\%$$

2. *In vitro* evaluation of the bystander effect: The transfected MFC cells were mixed with untransfected MFC cells at varying ratios, and planted in 96 wells plate at a density of 1×10^4 /well. Cells were then cultured at 37 °C for 7 days in the present of 50 µg/ml GCV. The survival rate of cells was measured by MTT method.

In vivo experiments

The mouse MFC gastric cancer models were established by injecting of 5×10^5 cells (in 100 µl saline) into the flanks of 60 6-week-old female 615 mice (the Animal Laboratory of the Institute of Drugs, Chinese Academy of Science). Five days late, when tumors became palpable, the mice were randomized in a blinded manner into 5 groups: the control group, TK, TK/GCV, TK/GCV+mIL-2, TK/GCV+mGM-CSF, and TK/GCV+mIL-2+mGM-CSF.

The test supernatant containing retrovirus was injected into tumors, 100 µl/time, twice a week, for 2 weeks. The control group was injected with saline. The cytokine plasmids were transduced with liposome. The quantity of DNA was 50 µg/time/day and the volume ratio of DNA versus liposome was 5:1. The DNA/liposome mixture was injected for 4 consecutive days. Three days after the virus infection, the animals were treated with i.p. injection of GCV (500 ng/kg/d) or saline (control group). The treatment was maintained for 3 weeks. Measure the longest radius (A) and the shortest radius (B) of tumors at every 5 days. The tumor volumes were calculated in mm^3 using the formula $1/2AB^2$.

In vivo expression of the transfected genes

RNA from tissues of mice receiving TK and cytokine genes were extracted and examined by RT-PCR and agarose gel electrophoresis.

All the primers were designed by ourselves. The forward primer of TK gene was 5' -GTGAATTCACAATGGCTT-CGTACCCCTGCCAT-3', and the reverse primer of TK gene was 5' -AGTGGATCCTCAGTTAGCTCCCCCATCTCC-

3'. The forward primer of mβ-actin was 5' -TAGCGGGGTCACCCACAC-3', and the reverse primer of mβ-actin was 5' -CTAGAAGCACTTGCAGTGCACG-3'.

The reaction condition of TK gene was denaturation in 95 °C for 1 minute, annealing in 60 °C for 1 minute, and extension in 72 °C for 3 minutes, for 39 cycles. The PCR conditions for β-actin were denaturation in 95 °C for 1 minute, annealing in 55 °C for 1 minute, and extension at 72 °C for 1 minute, for 39 cycles. The products of RT-PCR were analyzed by 1 % agarose gel electrophoresis and visualized by ethidium bromide staining.

To assess the expression of mIL-2 and mGM-CSF, the mRNA was extracted from the tumor surrounding tissues of mice and examined by RT-PCR. The forward primer of mIL-2 was 5' -TCGAATTCTGTACAGCATGCAGCTC-3', the reverse primer was 5' -TGGATCCGGTACATAGTTATTGAGGGC-3'. The forward primer of mGM-CSF was 5' -CGGAATTCATGTGGCTGCAGAAT-3', and the reverse primer was 5' -CGGAATTCTTCAGAGCTGGCCTG-3'. The reaction condition was denaturation in 95 °C for 1 minute, annealing in 55 °C for 55 seconds, and extension in 72 °C for 1 minute, for 30 cycles. The products were analyzed by 1 % agarose gel electrophoresis and visualized by ethidium bromide staining.

Histological analysis and immunohistochemical studies

Samples of tumor and surrounding tissues were fixed with formalin for 24 h, wax embedded. Sections were obtained with a microtome, and stained with haematoxylin-eosin for histological analysis. The frozen samples were fixed with cold acetone for 10 minutes and immunostain with specific antibodies using peroxidase method to detect the expression of CD3⁺, CD4⁺ and CD8⁺ in infiltrating cells. The sections were incubated for 15 minutes in phosphate buffered saline (PBS), 1 % bovine serum albumin (BSA), and then overnight at 4 with monoclonal antibodies diluted in PBS/1 % BSA.

Statistical analyses

The tumor volumes were performed using the variance analysis. $P < 0.05$ was considered to be statistically significant.

RESULTS

Plasmid transduction and virus supernatant collection

The TK gene retrovirus vector plasmid was transduced into packaging cells with lipofectamine and maintained for 5-7 days in culture medium containing G418 600 mg/ml, and many cells started to death. After cultured for 2-3 weeks, some adhesive cells formed cell clones contrasted with the dead cells.

The supernatants of every clone were collected and filtered after the cell clones were selected and expanded, the number of retroviral particles produced by the different cell clones was measured by NIH 3T3 cells. The maximum titer was 2×10^5 cfu/ml.

In vitro cytotoxicity and bystander-effect

After infected by the virus supernatant, many MFC cells began to die. Some adhesive cells immersed 3 weeks later, and formed cell clones.

MFC cells expressing TK gene were assayed for sensitivity to GCV. From the second day of culture with the medium containing GCV, the TK gene transfected cells began to die, and almost all the cells died at the seventh day. The untransfected cells in control group had no marked death.

The TK gene transfected MFC cells expressing marked bystander effect. A few transfected cells can cause many co-cultured cells to death combined with GCV (50 u/ml), Twenty percent of the TK gene transfected cells could kill 70-80 % of total cells (Figure 1).

Figure 1 The bystander effect of TK transfected MFC cells.

In vivo experiment

In vivo analyses of TK/GCV and cytokines were performed in 615 mice implanted with the mouse carcinoma MFC cell line in proximal stomach. The retrovirus supernatant was injected into the tumors, and the cytokine genes were injected into the tumor surrounding tissues as indicated in the “materials and methods”. There has no significant inhibition of tumor growth in control group although treated with peritoneum injection of GCV. The group of TK gene without use of GCV also had no inhibition effect on tumor growth. In the TK/GCV group, tumor growth was significantly suppressed ($P < 0.01$). In the animal groups treated with both TK/GCV and mIL-2 or mGM-CSF, there was a further significant reduction of the residual tumor size as compared to the group treated with TK/GCV ($P < 0.05$). There was further more decrease of tumor size in the group of TK/GCV combined with both cytokines. The tumors diminished in 7 mice of this group (Figure 2).

Figure 2 Compare of tumor volumes in every group.

Histological and immunohistochemical analyses

There were great many tumor cells with mitoses in the sections of control group. The TK/GCV group showed lots of necrotic cells, and some of them accompanied by bleeding. But active tumor cells could also be seen in this group. There was massive infiltration of inflammation cells surrounding the necrotic area of the tumor treated with TK + cytokine, but not in those area of animals treated with TK alone. Tumor cells diminished in most animals treated with TK/GCV+ mIL-2 + mGM-CSF. There were a few residue tumor tissues in part of these animals, but few mitoses phase can be seen, with great many of inflammatory cells.

Immunohistochemical analyses revealed that the infiltrates were mainly CD₈⁺ lymphocytes in the tumor boundary area of animals treated with TK+mIL-2 or TK+ mIL-2 + mGM-CSF. The number of CD₄⁺ lymphocytes was approximately equal in the TK + mGM-CSF and TK+mIL-2 + mGM-CSF groups.

In vivo expression of transfected genes

By RT-PCR analyses, TK gene and cytokine genes all can be expressed *in vivo* by virus transfection or liposome transduction.

DISCUSSION

Transfer suicide genes into tumors has emerged as an attractive gene therapy for the selective elimination of cancer cells. The suicide genes encode non- mammalian enzymes that can convert nontoxic prodrugs into cellular toxic metabolites. The most widely used suicide gene is HSV-tk, which confers prodrug GCV into phosphorylated GCV. The GCV monophosphate is further phosphorylated by cellular kinase, forming GCV triphosphate, which inhibits cellular DNA synthesis and lead to cell death. The “bystander effect” caused by TK gene can strongly enhance its killing capacity^[15-20]. Many researchers believe that necrosis of tumor cells is the mechanism of tumor killing effect caused by the metabolites of prodrugs, but the activated CTL can kill tumor cells as well. There also have many people think that apoptosis take an important role in the procession^[21-24]. In our studies, necrosis was shown in the prodrug used tumor tissues, some of them with bleeding. This might be the vascular endothelials transfected by suicide genes. *In vitro* experiment showed that 20 % gene transfected cells rendered 80 % of total cells to death. The mechanism of bystander effect has unclear. It has been hypothesized that the following factors may be concerned with the mechanism. (1) Gap junction: the toxic product of suicide gene was transferred from transfected cells into the surrounding untransfected ones^[25-27]. Studies demonstrated that the bystander effect of TK gene was via the gap junction. The converted phosphorylated GCV can get into the contact cells by gap junction, which needs the direct cell contact^[28-33]. (2) Apoptosis: the apoptotic acetes that released by the transfected cells engulfed by the surrounding cells^[34-37]. (3) Immune mechanism: tumor cells killed by TK/GCV can release tumor antigens. The tumor cell derived antigens were taken up by APCs (antigen presenting cells), and then presented to the CD₄⁺ T lymphocytes. It in turn activated tumor-specific CD₈⁺ cytolytic T cells. The immunohistochemistry shows tremendous aggregation of CD₄⁺ and CD₈⁺ lymphocytes surrounding the tumor tissue^[38-42].

Chen *et al* reported that cytokine gene IL-2 acted synergistically with the suicide gene to induce a systemic antitumor immunity. The immunity resulted in regression of local tumor and protection against distant site challenge of parental tumor cells. The antitumor immunity was attributed to IL-2 mediated activation and proliferation of CD₈⁺ CTLs^[43].

TK/GCV gene therapy led to death of the tumor cells. The tumor antigens were then available to the immune system, and might activate an anti-tumor immune response. The local expression of mGM-CSF enhanced the inflammatory response and antigen presentation. Expressed mIL-2 activated and enhanced the proliferation of T lymphocytes. Combination of mIL-2 with mGM-CSF can synergistically stimulate the anti-tumor immune response^[44-48].

The experimental results confirmed that TK/GCV gene therapy could kill tumor cells markedly. If combined with mIL-2 and mGM-CSF genes, they could boost the anti- tumor reaction, and produce powerful anti-tumor effects.

Abstract

AIM: To investigate the expression of 1A6 gene in the lesions during the development of intestinal gastric carcinoma.

METHODS: One hundred and thirty-six cases of intestinal metaplasia (IM) from surgical resections and biopsy were classified by mucous staining. Expression of 1A6 in all cases was detected using immunohistochemical S-P method.

RESULTS: The positive rates of 1A6 in normal and superficial gastritis (SG), severe atrophic gastritis (SAG), type I, II, III IM, dysplasia (Dys) and intestinal gastric carcinoma (IGC) were 12.2 %, 16.7 %, 7.1 %, 22.6 %, 47.8 %, 46.9 % and 60.8 %, respectively. A significant difference among type III IM and SG, SAG, type I and II IM was found ($P < 0.01$), the difference between type III and Dys, IGC being not significant.

CONCLUSION: As a new tumor-related gene, expression of 1A6 may be an effective parameter to predict the malignant transformation of precancerous lesion to gastric carcinoma.

INTRODUCTION

Gastric cancer is a major health problem in the world^[1-3]. Clinical statistics have shown that 50 % of gastric cancer in China are intestinal type adenocarcinoma^[4]. The phenotypic events in intestinal gastric carcinoma have been well recognized as normal gastric mucosa, chronic superficial gastritis, severe atrophic gastritis, intestinal metaplasia, dysplasia, intramucosal ("early") carcinoma and invasive carcinoma^[5,6]. A considerable number of oncogenes and antioncogenes involved in this process have been described, such as c-met, p53, c-erbB-2, APC, PCNA, p16, akt etc^[7-12]. Unfortunately, they are not gastric carcinoma-specific. No significant progress has been made in the existing studies concerning special genotypic abnormalities in the premalignant

lesions of gastric carcinoma. 1A6 is a novel tumor-related gene. In this study, immunohistochemistry was used to detect the expression of 1A6 protein in IGC, its premalignant lesions and normal counterparts.

MATERIALS AND METHODS

Patients and specimens

Paraffin-embedded archival materials from surgical resections and biopsy performed during 1998 to 2001 in our department were retrieved. There were 92 cases of gastric carcinoma (62 men and 30 women; aged 29-81 years), among them 51 cases were IGC, and 41 cases were diffuse gastric carcinoma (DGC). The criterion for classifying gastric carcinoma was derived largely from the observations of Lauren^[13]. The 23 sarcoma patients consisted of 15 men and 8 women, their ages ranged from 20 to 81 years, the histopathologic types included malignant fibrohistiocytoma, leiomyosarcoma, liposarcoma, fibrosarcoma, malignant stromal tumor and malignant peripheral nerve sheath tumor. According to the updated Sydney system^[14] and the Padova International Classification for Gastric Dysplasia^[15], 198 cases from biopsy (109 men and 89 women; age ranged from 27-82 years) were divided into four groups: normal mucosal and chronic superficial gastritis (41 cases), severe atrophic gastritis without IM (24 cases), IM (136 cases) and dysplasia (32 cases).

Mucin histochemistry

We performed mucin histochemical studies on 136 cases of IM to classify them using HID/AB/PAS staining described previously^[16-19]. The variants fell into three main groups: type I (complete type) shows features of mature small intestinal epithelia, type II (incomplete small intestinal type) had features of both gastric and small intestinal epithelia, whereas type III (incomplete colonic type) has characteristics of large intestines. Neutral mucins appeared magenta in color (PAS positive), sialomucins, blue color (AB positive) and sulphomucins brown (HID positive), respectively. The criteria for classifying IM are given in Table 1.

Table 1 Classification of IM

	PAS	AB	HID
Type I	-	+	-
Type II	+	+	-
Type III	+	+	+

Immunohistochemical staining

To investigate the expression of 1A6 protein, we adopted the standard S-P immunohistochemical method^[20]. The 1A6 monoclonal antibody was provided by the Laboratory of Genetics, Beijing Institute of Cancer Research, its dilution was 1:500. The SP kit was provided by Beijing Zhongshan Biotechnology Company. All the slides were treated with PBS and were microwaved for antigen retrieval. 1A6 protein was located in nucleus. Only the samples with more than 10 % cells stained could be considered positive.

Statistical analysis

The difference of 1A6 protein expression among different lesions was analyzed by χ^2 square test. A *P* value of less than 0.05 was considered statistical significantly.

RESULTS

Expression of 1A6 protein in gastric carcinoma and sarcoma

The positive expression rate of 1A6 protein in all types of gastric carcinoma was 48.9 % (45/92). In contrast, 1A6 protein was negative in all cases of sarcoma (Figure 1). In comparison of IGC and DGC, there was significant difference ($P < 0.01$). In IGC, the positive rate was 60.8 % (31/51), whereas the positive rate in DGC was 34.1 % (14/41). Most positive cells showed a nuclear and plasmatic staining (Figure 2).

Figure 1 The expression of 1A6 protein in sarcoma. The cells were negative staining. Immunohistochemical stain, $\times 100$.

Figure 2 The expression of 1A6 protein in intestinal type gastric carcinoma. The tumor cells showed a nuclear staining. Immunohistochemical stain, $\times 400$.

Expression of 1A6 protein in intestinal metaplasia

According to the mucin histochemistry, there were 14 cases of type I IM, 53 cases of type II IM and 69 cases of type III IM. The expression of 1A6 protein in all kinds of IM is shown in Table 2 (Figures 3,4,5). The positive rate of type III was significantly higher than that of the other two types. A nuclear and plasmatic staining was also found in most positive cases (Figure 6).

Table 2 Expression of 1A6 protein in IM

	<i>n</i>	1A6(+) (%)	1A6(-) (%)
Type I	14	1 (7.1)	13(92.9)
Type II	53	12 (22.6)	41(77.4)
Type III	69	33 (47.8)	39(52.2) ^a

^a $P < 0.005$ ($\chi^2 = 7.965, 8.167$), vs type I IM, type II IM, respectively.

Figure 3 Type I intestinal metaplasia. The mucins in cells were stained blue. HID/AB/PAS stain, $\times 200$.

Figure 4 Type II intestinal metaplasia. The mucins in cells were stained blue and magenta. HID/AB/PAS stain, $\times 200$.

Figure 5 Type III intestinal metaplasia. The mucins in cells were stained blue and brown. HID/AB/PAS stain, $\times 200$.

Figure 6 The expression of 1A6 protein in type III intestinal metaplasia. The metaplastic cells showed a nuclear and plasmatic staining. Immunohistochemical stain, $\times 200$.

Expression of 1A6 protein in normal mucosa and SG, SAG, type III IM, Dys and IGC

As the stomach mucosa changed from benign lesion to malignant tumor, the positive expression of 1A6 protein became higher and higher (Table 3). The positive rate of type III, Dys and IGC were higher than SG and SAG, the difference being statistically significant ($P < 0.01$). On the contrary, there were no significant differences among type III IM, Dys and IGC.

Table 3 Expression of 1A6 in different lesions of stomach

	<i>n</i>	1A6 + (%)
Normal mucosa and SG	41	5(12.2)
SAG	24	4(16.7)
Type III IM	69	33(47.8) ^a
Dys	32	15(46.9) ^b
IGC	51	31(60.8) ^c

^a $P < 0.01$ ($\chi^2 = 7.494$), vs normal mucosa and SG; ^b $P < 0.01$ ($\chi^2 = 10.067$), vs normal mucosa and SG; ^c $P < 0.01$ ($\chi^2 = 16.298$), vs normal mucosa and SG.

DISCUSSION

Recently, many investigations concerning intestinal metaplasia of stomach have been made in different aspects such as epidemiology, pathology and molecular biology^[21-23]. Although there were controversies about the phenotypic and genotypic events of IM, it has been widely accepted that the incomplete colonic type IM plays an important role in the histogenesis of gastric carcinoma and it is considered as the premalignant lesion of intestinal gastric carcinoma^[21, 24-28].

Gene 1A6 is a novel tumor-associated gene cloned from malignant cell line MC, which is an MNNG-treated human fetal gastric epithelial cell line. 1A6 is located in chromosome 12q23.2-23.3. Its cDNA is about 3kb. There are HEAT motif and nucleus-located sequence in 1A6 protein by molecular sequence analysis. 1A6 protein nucleus localization was further confirmed by immunofluorescence and immuno-electron microscopy. It was found in nucleole and heterochromatin. It suggested that 1A6 protein could interact with other proteins and may play a role as a nuclear transcription factor. Immunohistochemical studies in different tumors indicated that 1A6 was expressed not only in gastric carcinoma, but also in esophageal and breast cancers^[29-31].

As mentioned above, type III IM is thought to be the premalignant lesion of gastric carcinoma^[32-35]. In our study, the positive expression rate of 1A6 protein was very high in type III IM, which suggests that the overexpression of gene 1A6 maybe an early event in gastric malignant transformation. It can be an important index for predicting the carcinogenesis of stomach. How 1A6 protein functions in transformation of the intestinal metaplasia tissue into malignant tumor and the interaction between other oncogenes and antioncogenes need further investigation and the work is undergoing.

In this study, it was found that although the positive expression rate of 1A6 protein in DGC was much lower than that of IGC, one third of them were positive too. These results indicate that as gastric carcinoma, IGC and DGC may share some common characteristics, although their biological characteristics and etiological molecular mechanism are very different. In 23 cases of sarcoma, the positive rate was 0 %, it is no doubt that 1A6 protein is epithelial-tumor-specific.

In this study, many positive cells showed both nuclear and plasmatic staining. There are three possibilities: (1) The synthesis of nuclear proteins takes place in cell plasma, and then transmit into the nucleus, the plasmatic positivity might

reflect the newly synthesized 1A6 protein. (2) Non-specific binding of 1A6 Ab with other plasmatic proteins. (3) Non-specific secondary Ab binding with the proteins in the plasma.

In conclusion, 1A6 is a new tumor-related gene, its expression may play an important role in the early stage of gastric carcinogenesis. The detection of 1A6 protein in the premalignant lesions of intestinal gastric carcinoma may be a very valuable index to predict the malignant transformation of these lesions.

Abstract

AIM: To study the influence of chemotherapy on proliferation activation of tumor cell by observing the change of chemiluminescence (CL) and cell cycle in various tumor cell lines after mitomycin C treated.

METHODS: BGC823 and LoVo cell lines were all cultured in RPMI-1640, and then were adjusted to a concentration of 1×10^5 cells/ml in fresh media and incubated for 24 h. Mitomycin C ($100 \text{ ng} \cdot \text{ml}^{-1}$) was added to each bottle. All indeses were examined after 24 h. No Mitomycin C was added in control group. Each group contained 8 samples. Flow cytometric analysis and luminol-dependent CL were used to investigate the effect of mitomycin C on two gastrointestinal carcinoma cell lines.

RESULTS: BGC823 and LoVo cell lines incubated with MMC for 24 h. We discovered that the emergence of peak of CL stimulated by PHA was postponed significantly (BGC823: 12.63 ± 3.21 vs 4.50 ± 1.04 , LoVo: 13.25 ± 2.96 vs 5.12 ± 1.36 , $P < 0.01$) and the peak intension of CL was reduced significantly (BGC823: 120.25 ± 16.61 vs 248.38 ± 29.17 , LoVo: 98.13 ± 10.49 vs 267.50 ± 18.56 , $P < 0.01$). The PI of cell lines was decreased significantly (BGC823: 51.87 ± 4.82 vs 25.44 ± 2.26 , LoVo: 47.11 ± 1.04 vs 24.23 ± 0.37 , $P < 0.01$) and the apoptotic fractions changed by contraries (BGC823: 26.25 ± 5.29 vs 9.83 ± 2.51 , LoVo: 33.50 ± 3.68 vs 9.63 ± 1.44 , $P < 0.01$).

CONCLUSION: CL can be used to measure activation of tumor cells. We discovered that the ground CL intensions of two cell lines were not high but increased rapidly after stimulation of PHA. The CL peak ranged from 4-5 minutes, and then decreased gradually. The results were not reported before. CL of tumor cell has close correlativity with the dynamics of cell cycle and can reflect the feature of oxidation metabolism and proliferation activation of tumor cell. So it can be used to observe the influence of chemotherapy drug on metabolism and proliferation activation of tumor cell and screen out chemotherapy drugs to which tumor cells are sensitive.

Chen C, Liu FK, Qi XP, Li JS. The study of chemiluminescence in gastric and colonic carcinoma cell lines treated by anti-tumor drugs. *World J Gastroenterol* 2003; 9(2): 242-245

INTRODUCTION

Chemiluminescence (CL) is a natural phenomenon of creatures^[1]. As other cells, tumor cells also have the ability of CL. So the vigor of tumor cells could be measured by CL. At present, there were few reports about the CL of tumor cells^[2]. We used gastric and colonic carcinoma cell lines to study the CL of tumor cells and to investigate the dynamics of CL and the influence of drugs on CL.

MATERIALS AND METHODS

Cell line

BGC823 is a kind of human gastric carcinoma cell line^[3-5]; LoVo is a kind of human colonic carcinoma cell line^[6,7]. We bought them from Shanghai Cell Biology Institute of the Chinese Academy of Sciences.

Cell culture and mitomycin C treatment

Two cell lines were all cultured in RPMI-1640 (GIBCO) containing $100 \text{ g} \cdot \text{L}^{-1}$ newborn calf serum (Sijiqing, Hangzhou), penicillin ($100 \text{ U} \cdot \text{ml}^{-1}$), and streptomycin ($100 \mu\text{g} \cdot \text{ml}^{-1}$). Log phase cells were adjusted to a concentration of 1×10^5 cells/ml in fresh media and incubated for 24 h. Mitomycin C ($100 \text{ ng} \cdot \text{ml}^{-1}$)^[8] was added to each bottle. All indeses were examined after 24 h. No Mitomycin C was added in control group. Each group contained 8 samples.

CL analysis

Media was removed and cells were washed in phenol red free D-Hank's solution three times and adjusted to a concentration of 1×10^3 cells $\cdot \text{ml}^{-1}$ in the same solution. Aliquots (0.1 ml) of this cell suspension were placed into a cuvette, to which 0.7 ml of phenol red free D-Hank's solution and 0.1 ml of luminol ($1 \text{ mmol} \cdot \text{L}^{-1}$) were added. All cuvettes were put into sample chamber of SHG-1 bio-luminometer (Shangli measure instrument factory). CL of tumor cell was measured using T-2 procedure, configuring measure times were 30 and interval was 60 seconds. At first background of CL was measured, then 0.1 ml of phaseolus vulgaris agglutinin (PHA, $4 \text{ mg} \cdot \text{L}^{-1}$) was added and shaken up rapidly. CL PHA stimulated was measured continuously for about 30 minutes. All assays were made at 37°C . After measurements completed, CL kinetics curve, peak value, peak time, slope function and integral were calculated using the computer. Unit of intension of CL was scintillation counting per minute^[9] (Figure 1).

Flow cytometric analysis

Cells were harvested and washed in D-Hank's solution three times and adjusted to a concentration of 1×10^6 cells $\cdot \text{ml}^{-1}$ in the same solution. The nuclei were stained with propidium iodide at a concentration of $50 \mu\text{g} \cdot \text{ml}^{-1}$ and then filtered through $40 \mu\text{m}$ nylon mesh before flow cytometric analysis^[10]. The nuclear DNA content was analyzed with a flow cytometer (Epics XL; Coulter Co. U.S.A); 1×10^6 cells were examined in each sample. The cell cycle distribution, i.e., G_0/G_1 , S, G_2/M were analyzed using a computer program (Multicycle). The mean coefficient of variation (CV) for the G_0/G_1 peak was less than 8.0 in all

cases^[11]. We assessed the proliferation index (PI) to evaluate the changes of cell cycle distribution caused by treatment of MMC.

$$PI = \frac{S+G_2M}{S+G_2M+G_0G_1} \times 100\%$$
 We used the fraction of subdiploid peak in front of DNA histograms as apoptotic fraction^[12].

Statistical analysis

Statistical analysis, i.e., one-way ANOVA, unpaired *t*-test, correlate analysis, was performed using SPSS 8.0. Data were presented as means \pm standard deviation (S.D.). The level of significance was $P < 0.05$.

RESULTS

CL analysis

Figure 1 and Table 1 show the time-course of CL change in control and treatment groups of BGC823. In control group a CL signal was noted almost immediately that peaked within 3-5 minutes and returned to baseline after about 10-15 min. In contrast treatment group cells responded slowly and the peak CL did not occur until after 11-18 min. The CL peak value in treatment group decreased significantly ($P < 0.01$) when compared with control group. The same changes were detected in all two cell lines.

Figure 1 Time-course of CL change in control and treatment groups of BGC823.

Table 1 Effects of MMC treatment on CL of two cell lines

	BGC823 (n=8)		LoVo (n=8)	
	Control	Treatment	Control	Treatment
Peak value (cpm)	248.38 \pm 29.17	120.25 \pm 16.61 ^a	267.50 \pm 18.56	98.13 \pm 10.49 ^a
Peak time (minute)	4.50 \pm 1.04	12.63 \pm 3.21 ^a	5.12 \pm 1.36	13.25 \pm 2.96 ^a

^a $P < 0.01$, vs control.

Flow cytometric analysis

The PI in treatment group decreased significantly and the apoptotic fraction increased significantly when compared with control group ($P < 0.01$). There was no significant difference in the change of cell cycle contribution between two cell lines (Table 2).

Table 2 Effects of MMC treatment on cell cycle distribution of two cell lines

	BGC823		LoVo	
	Control	Treatment	Control	Treatment
PI (%)	51.87 \pm 4.82	25.44 \pm 2.26 ^a	47.11 \pm 1.04	24.23 \pm 0.37 ^a
Apoptosis (%)	9.83 \pm 2.51	26.25 \pm 5.29	9.63 \pm 1.44	33.50 \pm 3.68

^a $P < 0.01$, vs control.

Correlations between CL and cell cycle distribution

There was positive correlation between CL and PI (BGC823: $r = 0.92$, $P < 0.01$; LoVo: $r = 0.90$, $P < 0.01$), and there was negative correlation between CL and apoptotic fraction (BGC823: $r = -0.91$, $P < 0.01$; LoVo: $r = -0.95$, $P < 0.01$) (Figures 2-5).

Figure 2 Correlations between CL and PI in BGC823.

Figure 3 Correlations between CL and apoptotic fraction in BGC823.

Figure 4 Correlations between CL and PI in LoVo.

Figure 5 Correlations between CL and Apoptotic fraction in LoVo.

DISCUSSION

Oxygen radicals (OR) are intermediary products in the biochemical metabolism of cells, including O_2^- , H_2O_2 , OH^\cdot , 1O_2 , OCI^- and lipid peroxidation oxygen radical^[13]. They are produced mainly by aerobic respiration in mitochondrion and glycolysis^[14,15]. OR reacts to excitable substance in cells and produces CL ^[16]. So we can observe activation of cells by the measurement of CL ^[17,18].

In the present study, luminol-dependent chemiluminescence was used as a measure of CL of human gastric carcinoma cell line BGC823 and human colonic carcinoma cell line LoVo. We discovered that the ground CL intensions of two cell lines were not high but increased rapidly after stimulation of PHA. The CL peak ranged from 4-5 minutes, then decreased gradually. The results were not reported before.

Mitomycin C is a cycle-nonspecific anti-tumor agent. The mechanism of anti-cancer effect is its alkylation which makes DNA incorporation and DNA replication inhibition and single strand rupture. MMC affects mainly G1 and early S phases. However the influence of MMC on cell cycle *in vitro* may be different in different cells^[19-22]. MMC also up-regulated EpCAM and LewisY antigen expression in LoVo cell line^[23]. Cell cultures were growth arrested by exposure for 5 minutes to MMC^[24], and MMC retains its antiproliferative effect for at least 6 weeks^[25].

The CL of BGC823 and LoVo cell lines were decreased significantly after incubated with MMC for 24 hours. We also discovered that the peak of CL was postponed significantly and the peak intension of CL was reduced significantly after the stimulation of PHA. At the same time, the proliferation index (PI) was decreased significantly and apoptotic fractions changed by contraries^[26]. There was positive correlation between CL and PI, and there was negative correlation between CL and apoptotic fraction. These results revealed that the proliferation activation of tumor cell reduced, the apoptosis of cells increased and the reaction to stimulation of PHA weakened when the concentration of oxygen radicals in tumor cell decreased^[27-29]. So the decrease of concentration of oxygen radicals in low range depressed the mitochysis of tumor cell^[30] and prompted the apoptosis of tumor cell. These results also suggest the CL of cell can reflect change of proliferation activation of tumor cell treated by chemotherapy drugs.

In conclusion, the CL of tumor cell can reflect the feature of oxidation metabolism and proliferation activation of tumor cell, can be used to observe the influence of chemotherapy drug on metabolism and proliferation activation of tumor cell and screen out chemotherapy drugs to which tumor cells are sensitive. Compared with other methods cell chemiluminescence is more sensitive, more accurate, more rapid, less pollution and need fewer samples.

Abstract

AIM: To observe the expression of cyclooxygenase-2 (COX-2) and to investigate the association between COX-2 expression and infection with cytotoxic-associated gene A (*cagA*) positive strain *Helicobacter pylori* (*Hp*) in human gastric cancer, and subsequently to provide fresh ideas for the early prevention of gastric cancer.

METHODS: 32 Specimens of gastric cancer and corresponding adjacent normal gastric mucosa were obtained from patients who had undergone surgical operations of gastric cancer. All the samples including 1 case of stomach malignant lymphoma and 31 cases of gastric adenocarcinoma were confirmed by pathology diagnosis. The expression of COX-2 in 32 specimens of gastric cancer and corresponding adjacent normal gastric mucosa was quantitatively determined and analyzed with Flow Cytometry, and the levels of COX-2 protein were compared between specimens with *cagA*⁺ *Hp* infection and those without *cagA*⁺ *Hp* infection. The *cagA* gene in 32 specimens of gastric cancer was detected by polymerase chain reaction (PCR) method.

RESULTS: Twenty-seven of 32 (84 %) specimens of gastric cancer showed over-expression of COX-2, compared with the adjacent normal gastric mucosa. *cagA*⁺ gene were detected from 19 specimens of gastric cancer, but not from the other 13 specimens. The levels of COX-2 protein in 19 specimens of gastric cancer with *cagA*⁺ *Hp* infection (the number of positive cells was 73.82±18.2) were significantly higher than those in the 13 specimens without *cagA*⁺ *Hp* infection (the number of positive cells was 35.92±22.1).

CONCLUSION: COX-2 is overexpressed in gastric cancer and *cagA*⁺ *Hp* infection could up-regulate the expression of COX-2 in gastric cancer in human. There may also exist another way or channel to regulate the expression of COX-2 in gastric cancer in addition to *cagA*⁺ *Hp* infection. Therefore, applying COX-2 selective inhibitors could be an effective and promising way to prevent gastric cancer.

INTRODUCTION

The mortality rate of gastric cancer still takes the first place in eastern Asia, particularly in China. So it is important to study the mechanism of gastric carcinogenesis and to explore the effective and reasonable methods for early prevention of gastric cancer, subsequently reducing the mortality rate of gastric cancer.

Epidemiological studies show that gastric cancer is closely linked to *Helicobacter pylori* (*Hp*) infection^[1-5], because the incidence of gastric cancer increases 4-9 times after *Hp* infection, and more than 60 % patients with gastric cancer had been infected with *Hp*^[6]. Recent studies indicate that infection with *cagA*⁺ *Hp* possesses a potent toxin and high risk for causing gastric cancer^[7, 8]. There is a close association between *cagA*⁺ *Hp* and precancerous stage, even gastric cancer^[9-12]. But the mechanism that how *cagA*⁺ *Hp* actually leads to gastric cancer still remains unclear.

Cyclooxygenase-2 (COX-2) is one isoform of COX enzyme family, which is the rate-limiting enzyme for prostaglandin H synthesis. It is an inducible enzyme, and normally absent in cells, but its expression is rapidly and transiently induced in response to growth factors, tumor promoters or cytokines^[13, 14]. Recent studies indicate that COX-2 not only involves in inflammatory responses but also relates to carcinogenesis. Since COX-2 is overexpressed in many tumors, such as colon-rectum cancer^[15-17], esophageal cancer^[18, 19] etc., it may play an important role in the development and progression of cancers^[20-22].

It is well documented that *Hp* infection can cause inflammation, and COX-2 is often involved in inflammatory responses and also related to carcinogenesis. However, it is not clear whether *cagA*⁺ *Hp* infection induces COX-2 expression and whether there is an association between them during gastric cancer development and progression.

To investigate the possible association between the COX-2 expression level and *cagA*⁺ *Hp* infection, in this study, Flow Cytometry technique was employed to quantitatively determine the expression level of COX-2 in specimens of gastric cancer and adjacent normal gastric mucosa and PCR method was used to amplify the *cagA* gene in specimens of gastric cancer.

MATERIALS AND METHODS

Materials

Specimens of gastric cancer and corresponding adjacent normal gastric mucosa were obtained from 32 patients who had undergone surgical operations of gastric cancer at the Department of Tumor Surgery of the first affiliated hospital of China Medical University. All samples including 1 case of stomach malignant lymphoma and 31 cases of gastric adenocarcinoma were confirmed by pathology diagnosis. The 32 patients were made up of 19 males and 13 females ranging in age from 46 to 73 years old.

Methods

Flow cytometry determination (1) Obtaining single cell solution: 0.5 cm³ specimen of gastric cancer and tissue of adjacent normal gastric mucosa were put on separate 400 pore cleaning copper nets on top of small cups, and the samples

were cut into very small chips and washed with 0.9 % NaCl, then single cell solution was collected and confirmed with microscope that over 90 % cells were single cells. (2) Permeabilizing cells: after being washed 2 times with PBS, the single cells were resuspended with 2 mL 1×FACS permeabilizing solution (Becton Dickson), and incubated at R.T. for 10 min before being washed 1 time with PBS containing 0.5 % bovine serum albumin. The cells were then divided in 2 flow cytometer tubes, and made sure the number of cells in each tube is 10^6 . (3) Immunofluorescence staining: COX-2 was indirectly immunofluorescence stained and 2 tubes were set for each specimens of gastric cancer and tissues of adjacent normal gastric mucosa. 1 tube of each set was stained with FITC (polyclonal anti-rabbit IgG Becton Dickson-Pharmingen company), which was a second fluorescent antibody, as a second antibody self contro l. 2 μ L anti-COX-2 rabbit polyclonal IgG (Santa Cruz Biotechnology, Inc.) were added to the other 1 tube of cells and mixed. The cells were incubated at R.T. for 30 min before being washed 1 time with PBS containing 0.5 % bovine serum albumin. 2 μ L secondary FITC antibody were then added and the cells were incubated in the dark at 2-8 °C for 30 min. After being washed 2 times with PBS, the cell pellet was resuspended in 500 μ L PBS for COX-2 detection by Flow Cytometer (FACScan Becton Dickson). (4) FACS detection and analysis: Laser excitation was at 488nm, the data was obtained and analyzed with Cell Quest multiple function software, and the fragment interference was eliminated by drawing a gate.

PCR amplification The template from specimen of gastric cancer was amplified by polymerase chain reaction. The *cagA*-*Hp* primers used were: upstream: 5'-GTG CCT GCT AGT TTG TCA GCG; and the downstream: 5'-TTG GAA ACC ACC TTT TGT ATT AGC. (obtained from Dr Berg, Washington University). PCR reaction: the 20 μ L reaction mixture including 5 μ L template, 2 μ L PCR buffer, 2 μ L dNTP, 2 μ L MgCl₂, 0.5 μ L upstream and 0.5 μ L downstream primers, 0.25 μ L Taq DNA polymerase and dH₂O was subjected to denaturation at 94 °C for 5 min; 35 cycles of 1 min at 94 °C, 1 min at 50 °C, 1 min at 72 °C; with a final extension at 72 °C for 10 min. The amplification reaction was proceeded in a PerkinElmer Cetus Thermocycler (PE-9600).

Assay of PCR production 10 μ L of reaction mixture were loaded to 1.5 % agarose gel containing 0.5 μ g/ml ethidium bromide for electrophoresis, the gel was then placed under ultraviolet ray for detection. The amplified *cagA* gene product was about 390 bp.

Statistical analysis

The expression of COX-2 protein in gastric cancer was analyzed by paired T test with Excel 2000; the association between the levels of COX-2 expression and *cagA*-*Hp* infection in gastric cancer was analyzed with T test between the two groups.

RESULTS

Expression of COX-2 protein in gastric cancer

27 cases of gastric cancer (in 32 cases) expressed high levels of COX-2 with an average of 67.51 % \pm 21.11 % positive cells and the range was between 30.36-98.56 % (Figure 1: A₁, A₂, A₃), in contrast, the corresponding 27 cases of adjacent normal gastric mucosa only showed a weak expression of COX-2 with an average of 12.41 % \pm 8.16 % positive cells and the range between 3.55-29.16 % (Figure 1: B₁, B₂, B₃). The percentage of positive cells in gastric cancer was significantly higher than that in the normal gastric mucosa beside cancers ($P < 0.001$). Out of the 5 remaining cases, 3 did not show the expression of COX-2 in both specimen of gastric cancer and adjacent normal gastric mucosa, whereas in the other 2 cases, the percentage

of positive cells in specimen of gastric cancer was not higher than that in the adjacent normal gastric mucosa. In total, 27 cases of 32 gastric cancer overexpressed COX-2 protein and the positive rate was 84.4 %.

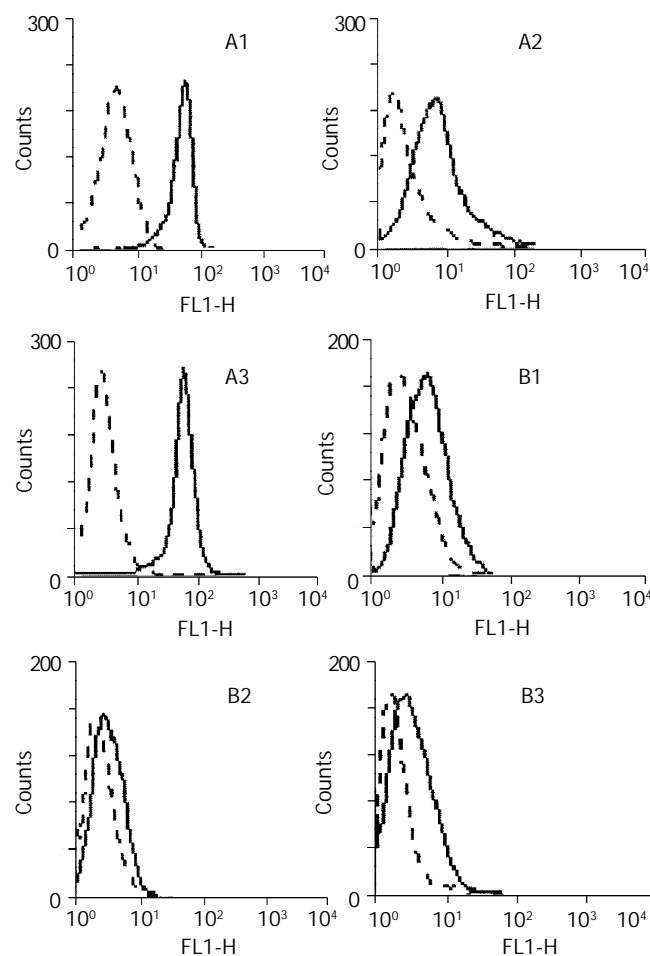

Figure 1 Analysis of COX-2 expressions in gastric cancer tissues and relevant adjacent normal gastric tissues by FACS. A₁, A₂, A₃: Gastric cancer tissues; B₁, B₂, B₃: Relevant adjacent normal gastric tissues. Dotted lines represent results generated with anti-rabbit-FITC; Solid lines represent results generated with rabbit-anti COX-2 and anti-rabbit-FITC.

Figure 2 Agarose gel electrophoresis of PCR products of *cagA* gene in gastric cancer tissues. M: DNA marker; 1, 4, 5, 6 and 7: positive PCR products; 2 and 3: negative PCR products.

The association between the levels of COX-2 expression and *cagA*-*Hp* infection in gastric cancer

The *cagA*⁺ *Hp* was detected in 19 out of 32 (59.3 %) gastric cancers (Figure 2). According to the *cagA* detection results, 32 cases of gastric cancer were then divided into two groups, the *cagA* positive group and *cagA* negative group, so that we could analyze the difference in the levels of COX-2 expression between the two groups. As shown in Table 1, the levels of COX-2 expression in *cagA* positive group were much higher than those in *cagA* negative group, and *cagA* gene was not

detected in the 5 cases with no obvious COX-2 expression. The results suggest that the expression of COX-2 is associated with the *cagA*⁺ *Hp* infection in gastric cancer and *cagA*⁺ *Hp* infection can up-regulate the expression of COX-2.

Table 1 The expression of COX-2 protein in gastric cancer

Grope	n	Cells expressed COX-2($\bar{x}\pm s$)%
Gastric cancer	32	67.51 \pm 21.11 ^a
Normal gastric mucosa	32	12.41 \pm 8.16

DISCUSSION

Cyclooxygenases (COXs) are the key enzyme in arachidonate metabolism and catalyze the biosynthesis of prostaglandin H₂, which is the precursor for prostanoids. COX family consists of the classical COX-1 enzyme, which is constitutively expressed in many tissues, and involved in the homeostasis of various physiologic functions, and its isozyme COX-2, which was discovered in 1991^[13] and is involved in many inflammatory reactions with its expression rapidly induced by growth factors, tumor promoters or cytokines. Under normal conditions, COX-2 is absent in tissue cells. Since *Hp* infection causes inflammatory reaction, it may also induce the expression of COX-2. Romano and associates incubated MKN28 gastric mucosal cells with broth culture filtrates or bacterial suspensions from wild-type *Hp*, after 24 hours COX-2 mRNA levels increased by 5-fold and the synthesis of PGE₂, the main product of COXs, increased by 3-fold, whereas COX-1 mRNA levels remained unchanged^[23]. This effect was specifically related to *Hp* because it was not observed with *Escherichia coli*. This study indicates that *Hp* could induce the expression of COX-2 in gastric mucosal cells *in vitro*. However, whether *Hp* induces the expression of COX-2 *in vivo*, particularly in gastric cancer, and whether there is an association between *cagA*⁺ *Hp* infection and the expression of COX-2 still remain unclear. Our results showed that 27 out of 32 cases (84 %) of human gastric cancer expressed COX-2, which was similar to the status in colon-rectum cancer^[24], and indicated that the expression of COX-2 was closely associated with gastric cancer. The average percentage of cells that positively express COX-2 was 73.82 % in 19 cases of gastric cancer with *cagA*⁺ *Hp* infection; whereas it was 35.92 % in 13 cases of gastric cancer without *cagA*⁺ *Hp* infection. The levels of COX-2 expression in gastric cancer with *cagA*⁺ *Hp* infection were much higher than those without *cagA*⁺ *Hp* infection (*P*<0.001). 5 cases of gastric cancer did not show expression of COX-2 also were not detected for *cagA* gene PCR product. The result indicates that *cagA*⁺ *Hp* infection can up-regulate the expression of COX-2 in gastric cancer, and *cagA*⁺ *Hp* infection may play an important role during gastric carcinogenesis by mediating the expression of COX-2. McCarthy *et al*^[25] analyzed the COX-2 expression in gastric antral mucosa before and after eradication of *Hp* infection by immunohistochemistry and the results indicate that acute and chronic antral inflammation is associated with *Hp* as well as the expression of COX-2 protein in epithelial cells. The expression of COX-2 was reduced, but not eliminated, in the epithelium after successful eradication of *Hp*. Despite the reduction in COX-2 expression after *Hp* eradication, expression of COX-2 in epithelial cells remained and strongly correlated with the extent of the chronic inflammatory cell infiltration. This conclusion supports our

results that COX-2 was also expressed in some cases of gastric cancer without *cagA*⁺ *Hp* infection and that the expression of COX-2 in gastric cancer without *cagA*⁺ *Hp* infection is weaker than that with *cagA*⁺ *Hp* infection. Recent studies indicate that *Hp* can induce COX-2 expression in gastritis^[26-30], and COX-2 expression in gastric cancer with *Hp* infection has also been reported recently^[31,32], but most of the studies were conducted with immunohistochemistry, Western blot and RT-PCR methods^[26-32], and to quantitatively determinate COX-2 expression and to divide *Hp* into subtypes for analysis has seldom been reported so far.

Recently, evidence has been presented that COX-2 is induced in human colorectal cancers and in the polyps of mouse FAP models. When the COX-2 gene is inactivated in FAP model mice, both the number and size of polyps are reduced dramatically. In addition, selective inhibitors of COX-2 cause results similar to those caused by COX-2 gene knockout mutations. These genetic and pharmacological data open up the possibility of effectively treating human FAP and various human cancers with COX-2 selective inhibitors^[33-35].

The fact that COX-2 is overexpressed in gastric cancer and that the expression of COX-2 in gastric cancer infected by *cagA*⁺ *Hp* is much higher than that without *cagA*⁺ *Hp* infection indicates that *cagA*⁺ *Hp* infection up-regulate the expression of COX-2 in human gastric cancer, and the expression of COX-2 is closely associated with gastric cancer. But the fact that the specimens of gastric cancer without *cagA*⁺ *Hp* infection also express COX-2 at different levels implies that there may exist another way or channel to up-regulate the expression of COX-2 in gastric cancer besides *cagA* positive strain infection. Therefore, with the successful eradication of *Hp* infection, applying COX-2 selective inhibitors could be an effective and promising way to prevent gastric cancer.

Abstract

AIM: To study the expression of cyclooxygenase-2 (COX-2) gene in gastric cancer and the relationship between COX-2 expression and clinicopathologic features of gastric cancer.

METHODS: With reference to the expression of β -actin gene, COX-2 mRNA level was examined in cancerous tissues and adjacent noncancerous mucosa from 33 patients by semiquantitative reverse transcription- polymerase chain reaction (RT-PCR). Quantitation of relative band Adj volume counts was performed using molecular Analyst for windows software. The COX-2 index was determined from the band Adj volume counts ratio of COX-2 to constitutively expressed actin.

RESULTS: The COX-2 index in gastric carcinoma was significantly higher than that in normal mucosa (0.5966 ± 0.2659 vs 0.2979 ± 0.171 , $u=5.4309$, $P<0.01$). Significantly higher expression of COX-2 mRNA was also observed in patients with lymph node involvement than that in those without (0.6775 ± 0.2486 vs 0.4105 ± 0.2182 , $t=2.9341$, $P<0.01$). Furthermore, the staging in the UICC TNM classification significantly correlated with COX-2 overexpression ($F=3.656$, $P<0.05$), the COX-2 index in stage III and IV was significantly higher than those in stage I and II ($q=3.2728$ and $q=3.4906$, $P<0.05$). The COX-2 index showed no correlation with patient's age, sex, blood group, tumor location, gross typing, depth of invasion, differentiation, and the greatest tumor dimension ($P>0.05$).

CONCLUSION: Expression of COX-2 mRNA in gastric carcinoma was significantly higher, which may enhance lymphatic metastasis in patients with gastric carcinoma. The staging in the UICC TNM classification was significantly correlated with COX-2 over-expression. COX-2 may contribute to progression of tumor in human gastric adenocarcinoma.

INTRODUCTION

Cyclooxygenase-2 (COX-2) is a rate-limiting enzyme in

conversion of arachidonic acid to prostaglandins, also referred to as prostaglandin endoperoxide synthase (PGHS). Epidemiological and clinical results have suggested that non-steroidal anti-inflammatory drugs (NSAIDs) may reduce the risk of digestive tract carcinomas, including gastric and colon lesions. COX-2, which has been identified as being overexpressed in colorectal and gastric cancers, is one of the major targets of NSAIDs. Not only specific inhibitors of COX-2 significantly suppressed proliferation of gastric cancer cell lines^[1,2], but also a recent in-vitro study suggested that specific inhibitors of COX-2 significantly suppressed proliferation of gastric cancer xenografts in nude mice^[3]. This evidence supports the hypothesis that COX-2 is an important factor in the growth and development of gastric cancer. We used the semiquantitative reverse transcription- polymerase chain reaction (RT-PCR) to examine the expression of COX-2 mRNA in gastric cancerous tissues and adjacent noncancerous mucosa, and to study the relationship to the clinicopathologic features.

MATERIALS AND METHODS

Patients and samples

Thirty-three patients undergoing surgery for primary gastric cancer at the Third Clinical Hospital of Harbin Medical University from 2001 to 2002 were examined. Of these, 27 were male and 6 were female. The mean age was 58.6 years (range, 32-76). The clinicopathologic features showed in Table 1. Paired samples of cancer tissue and normal gastric mucosa (the distance to border of tumor is beyond 5 cm) were obtained from each patient at the time of surgery. The samples were immediately frozen in liquid nitrogen. All specimens were verified by the same pathologists.

Methods

Total RNA was isolated from 50-100 mg of the tissues according to the method of User Manual TRIzol reagent (Life Science) and was quantitated by reading absorbance at 260 nm. The total RNA solution was subjected to RT-PCR analysis using the TITANIUM™ one-step RT-PCR kit (CLONTECH Laboratories, Inc, USA). The total RNA specimens (1 μ g) were reverse transcribed and amplified in 25 μ l of reaction mixture, and the reaction conditions for COX-2 and β -actin was identical.

Oligonucleotide primers for COX-2 used were 5'-TGA AAC CCA CTC CAA ACA CAG-3' (sense) and 5'-TCA TCA GGC ACA GGA GGA AG-3' (antisense), the PCR product length was 232 bp; those for β -actin were 5'-GTT TGA GAC CTT CAA CAC CCC-3' (sense) and 5'-GTG GCC ATC TCT CTT GCT CGA AGT C-3' (antisense), the PCR product length was 320 bp. The RT-PCR procedures were as following: reverse transcription at 55 °C for 60 min, inactivation of reverse transcriptase at 94 °C for 5 min, amplification for 30 cycles of denaturation at 94 °C for 30 sec, annealing at 55 °C for 30 sec, and extension at 68 °C for 60 sec.

The PCR products were electrophoresed in 2 % agarose gels with 0.5 μ g/ml ethidium bromide and visualized under UV light. Quantitation of relative band volume counts was

performed using Molecular Analyst for windows software. To estimate COX-2 expression levels, a COX-2 index was designated as a band volume counts ratio of COX-2 to constitutively expressed β -actin, because β -actin mRNA is expressed constitutively in both the normal gastric mucosa and tumor tissues. The higher COX-2 index showed the higher expression level of COX-2 mRNA in tissues.

Statistical analysis

Statistical significance was calculated with the Students *t* test, Students *u* test, one-way ANOVA and Student-Newman-Keuls. $P < 0.05$ was selected as the statistically significant value. All results are shown as means \pm SE.

RESULTS

The total RNA was electrophoresed in 1 % agarose gels with 0.5 μ g/ml ethidium bromide and visualized under UV light, then showed three bands: 5s, 18s and 28s. The total RNA was quantitated by reading absorbance at 260 nm, and A260/280 that ranged from 1.7 to 2.0.

COX-2 mRNA and β -actin mRNA were amplified by RT-PCR, and their products length were 232bp and 320bp. The β -actin mRNA expressed constitutively in all tissues, including normal gastric mucosa and tumor tissues (Figure 1). COX-2 mRNA expressed in 29 of 33 (87.88 %) human gastric cancer specimens, over-expression was seen in 26 of 33 (78.79 %) cases (COX-2 index was 0.5966 ± 0.2659), and weak or negative COX-2 expression was seen in 25 of 33 (75.8 %) normal mucosa (COX-2 index was 0.2979 ± 0.171) (Figure 2). COX-2 index in gastric carcinoma was significantly higher than that in normal mucosa ($u = 5.4309$, $P < 0.01$). Significantly higher expression of COX-2 mRNA was also observed in patients with lymph node involvement than that in those without (0.6775 ± 0.2486 vs 0.4105 ± 0.2182 , $t = 2.9341$, $P < 0.01$). Furthermore, the staging in the UICC TNM classification (1985) significantly correlated with COX-2 overexpression ($F = 3.656$, $P < 0.05$), COX-2 index in stages III and IV was significantly higher than those in stages I and II ($q = 3.2728$ and $q = 3.4906$, $P < 0.05$). COX-2 index showed no correlation with patient's age, sex, blood group, tumor location, gross typing, depth of invasion, differentiation, and the greatest tumor dimension ($P > 0.05$, Table 1).

DISCUSSION

Two isoforms of COX have been identified: COX-1 expressed constitutively in a number of cell types, which take part in sustaining physiologic function of body; COX-2 is a inducing immediate-early gene, and human gastric mucosa normally expresses detectable levels of COX-2. COX-2 is induced by a variety of cytokines, hormones, and tumor promoters, leading to more PGs producing. Initial association of COX-2 with tumor has shown in studies for colorectal cancer, and then for other tumor^[4-10]. A series of studies confirmed that COX-2 levels elevated in colorectal carcinoma, and over-expression of COX-2 in colorectal cancer was associated with carcinogenesis, development^[11-17] and poor prognosis^[18, 19]. In recent years, a lot of researchers studied the association of COX-2 expression with gastric carcinoma^[20-26], but those conclusions were not identical, with a variety of causes.

In the current study, we found that elevated levels of COX-2 mRNA in human gastric adenocarcinoma tissues, and the COX-2 index in gastric carcinoma was significantly higher than that in normal mucosa ($u=5.4309$, $P<0.01$), which is identical to the data published^[20-26]. The mechanism of the COX-2 involved in the pathogenesis of tumor is that over-expression of COX-2 may promote PGs biosynthesis in gastric cancer cells, and PGs shows a potent immunosuppression effect by inhibiting the T-cell or natural killer cell activity^[27]. PGs thus provide a selective advantage for cancer cell survival; in addition, COX-2 can also suppress cell apoptosis^[28-32], prolong cell cycle G1^[33,34], and decrease level of cyclin D1^[35,36], which lead to that cells can not enter the cycle and proliferate continuously. Meantime, COX-2 enhances adhesion of cells^[37,38] and promotes tumor angiogenesis^[22,39], which may finally lead to the carcinogenesis and progression of the tumor.

Many researchers^[20-40] found that COX-2 mRNA expression in gastric carcinoma is correlated closely with depth of invasion, indicating that COX-2 is involved in the growth of the tumor. But, our studies did not find a correlation between COX-2 expression and the extent of primary tumor invasion. Our recent studies have found a correlation between the level of COX-2 expression and lymph node metastasis in patients with gastric carcinoma. Murata *et al*^[21] and Leung *et al*^[41] found that tumor with the overexpression of COX-2 protein by Western blot and immunohistochemical analysis was associated significantly with invasion into gastric wall lymphatic vessels as well as with metastasis to lymph nodes ($P<0.05$). Uefuji *et al*^[40] detected level of COX-2 mRNA expression by RT-PCR analysis, and the conclusion was in agreement with this study. We demonstrated that significantly higher expression of COX-2 mRNA was also observed in patients with lymph node involvement than that in those without ($t=2.9341$, $P<0.01$). It is suggested that COX-2 may influence lymphatic involvement by the way of increasing tumor invasiveness. Some studies have found that over-expression of COX-2 decreased the expression of both E-cadherin and the transforming growth factor- β receptor, which has been linked to enhancing tumorigenic potential and increasing tumor invasiveness^[37,38,42-45]. Meantime, the overexpression of the COX-2 promotes invasiveness in gastric cancer through the induction of metalloproteinase-2 and membrane-type metalloproteinase^[11,21,46].

Although several investigators^[20] reported that the COX-2 level was not associated with UICC TNM stage, but majority of them^[21,23] have reported a significant relation between the levels of COX-2 protein over-expression and UICC TNM stage. Our results are in agreement with previous ones. The COX-2 level in Stage III and IV was significantly higher than in Stage I and II ($q=3.2728$ and $q=3.4906$, $P<0.05$); but the difference of COX-2 level between Stages III and IV showed no statistical significance ($q=0.3702$, $P>0.05$). Consequently, we can infer that COX-2 may be independent or synergistic with other factors to promote growth of gastric cancer, and to enhance the lymph node metastasis and involvement. But, in advanced gastric cancer, when COX-2 expression is up-regulated to a certain level, COX-2 can not increase continuously, which suggests that there are some much more complicated mechanisms in the regulation of COX-2 expression.

In conclusion, COX-2 mRNA shows elevated expression in gastric carcinoma tissues, and the degree of COX-2 mRNA elevation is related to the lymphatic metastasis, UICC TNM stage, and poor prognosis. These findings suggest that COX-2 is involved in the carcinogenesis and growth of gastric carcinoma and that the inhibition of COX-2 activity may prove to have an important therapeutic benefit in the control of gastric carcinoma.

Abstract

AIM: Current study was aimed to evaluate the usefulness of EUS in TNM staging of gastric cancer by comparing EUS preoperative staging with pathological findings, and the preliminary exploration of possible reasons for overstaging and understaging phenomenon was especially intended.

METHODS: A total of 35 patients with histologically confirmed gastric adenocarcinoma were referred to EUS and staged preoperatively by using the TNM system. The preoperative endosonographic results were compared with the histopathological staging.

RESULTS: The overall accuracy of EUS for determination of the T stage was 80.0 %, and for T1, T2, T3, and T4 was 100 %, 71.4 %, 87.5 % and 72.7 %, respectively. For N stage, EUS had the accuracy of 68.6 %, with sensitivity and specificity of 66.7 % and 73.7 %, respectively. Resectability was predicted with sensitivity and specificity of 87.5 % and 100 %, respectively.

CONCLUSION: EUS is an accurate staging modality in most cases, with a few exceptions of overstaging and understaging. Patients with gastric cancers can benefit from preoperative EUS staging for establishing individualized therapy. However, EUS criteria to differentiate benign from malignant nodes still need to be further defined by future studies.

INTRODUCTION

Gastric cancer is one of the most encountered gastrointestinal malignances. The overall 5-year survival rates are still not encouraging, although many advances in diagnostic modalities and therapeutic regimens have been achieved during last a few decades. The improvement of survival rates depends primarily on early detection and treatment of the tumor. Many large-scale clinical trials indicate that the majority of patients are in

advanced stage at time of diagnosis and the outcome is dismal. It has been well accepted that accurate preoperative staging is not only important for prediction of the prognosis, but also essential to establishment of individualized cancer therapy^[1]. The staging was previously made by analysis on the bases of clinical presentations, laboratory test results, and various imaging findings such as trans-abdominal B-mode Ultrasonography, computed tomography (CT) or magnetic resonance imaging (MRI). However, precise conclusion was often difficult to obtain due largely to limitations on or local unavailability of these techniques themselves^[2,3].

Endoscopic ultrasonography (EUS) was first introduced by a German doctor in the early 1980s and is now used worldwide. Without interference by abdominal fat, bones and gut gases, the probe can be placed in where is nearest to the target organ or tissue of interest and the more accurate imaging can be obtained. Because of the use of transducers of high frequency, it facilitates the early detection of minute lesions and the TNM staging of tumors^[4,5]. The ability of EUS to accurately visualize and differentiate the different layers of the gut wall makes it possible to determine the penetration depth of a gastrointestinal cancer more precisely. Simultaneously, the observation of the involvement of lymph nodes and other organs adjacent to the cancer within the range of EUS scanning can provide more detailed additional information to the disease. Currently, EUS is becoming one of the routine methods in staging of gastrointestinal cancers, including gastric carcinoma^[6-8]. Published data showed that the accuracy of T and N staging for gastric cancer is 78-92 % and 63-78 %, respectively^[9,10], being imperative in prognostic prediction and especially in decision-making regarding to individualized therapeutic regimens^[11,12].

It has been noticed that overstaging and understaging are the common problems encountered in current EUS practice, and accuracy for lymph node staging exhibits discrepancy between observers^[9,13]. Current study was aimed to evaluate the usefulness of EUS in TNM staging of gastric cancer by comparing EUS preoperative staging results with pathological findings, and the preliminary exploration of possible reasons for above-mentioned phenomenon was especially intended.

MATERIALS AND METHODS

Patients

Thirty-five patients with gastric cancer proven pathologically underwent EUS preoperative T and N staging, including 25 male, 10 female, aged 28-78 years with average of 61.7. Of them, 32 were treated surgically (two were found unresectable due to adjacent organ involvement). The diagnosis was reconfirmed and pathological TN staging made. Three cases were diagnosed T4N1M1 based on EUS, B ultrasound, and CT scanning findings and treated unsurgically. Therefore, 32 patients were finally enrolled in this study.

EUS examination procedures

A Pentax 3840T double-channeled video-gastroscope was

employed and Fujinon SP-701 radial scanning probes (with frequency of 7.5MHz, 12MHz, and 20MHz) introduced via one of the working channels. EUS preoperative staging for gastric cancer followed the TNM staging as of the Union Internationale Contre le Cancer (UICC)^[10]. Early cancer is clinically defined as the tumor confined to mucosa or submucosa regardless of lymph node metastasis^[14]. The extension of the cancer into muscularis propria is classified as the advanced. The judgment of local tumor invasion depth by EUS is according to the determination of the outmost involved layer of the gastric wall^[15]. Regional lymph node staging is classified as N0 (no lymph node involvement found) and N+ (perigastric lymph node metastasis confirmed). M refers to distant metastasis, defined as M0 and M1 (with or without distant metastasis).

RESULTS

EUS staging

EUS preoperative staging results were listed in Table 1.

Table 1 Accuracy of EUS preoperative T staging in 35 patients with gastric carcinoma

EUS stage	n	Pathologicstage				Accuracy of EUS (%)
		T1	T2	T3	T4	
T1	1	1	0	0	0	100
T2	7	1	5	1	0	71.4
T3	16	0	2	14	0	87.5
T4	8(3)	0	0	3	5(3)	72.7
Total	32(3)	2	7	18	5(3)	80.0

Surgical findings

Among 32 cases of the current study, cancer located in gastric atrium was found in 18 patients, gastric corpus in 9 and fundus in 5. Radical gastrectomy was performed in 15, total gastrectomy in 13, and palliative surgery in 2. Unresectable tumors were found in 2 patients. The sensitivity and specificity of EUS for predicting resectability were 87.5 % and 100 % respectively.

The comparison between EUS and pathologic T staging

By compared to the postoperative pathology, the overall accuracy of EUS T staging was 80.0 % (Table 1). Much attention should be paid to overstaging and understaging found in T2, T3, and T4. The assessment of tumor invasion in postoperative pathology was mostly consistent with preoperative EUS findings, except seven cases including 4 ulcerated type, 2 protruded type, and 1 flat type. Pathologically, the understaged one was due to micro-tumor invasion undetectable by EUS. The overstaged six cases were owing to local inflammatory reaction, edema, and fibrosis undifferentiable by EUS.

The comparison between EUS and pathologic N staging

The accuracy, sensitivity and specificity of EUS for N staging (Table 2) were 68.6 %, 66.7 %, and 73.3 %, respectively. However, 11 patients had inconsistent pathologic findings compared with EUS. Although four of them were diagnosed N+ by EUS during operation, the pathology confirmed inflammatory lymphadenopathy with no evidence of tumor metastasis. Lymph nodes susceptible of metastasis were not detected in 2 cases both by EUS during operation but confirmed

later pathologically. EUS-undetected lymph nodes in 3 cases were also diagnosed during operation and by postoperative pathology.

Table 2 Accuracy of EUS preoperative N staging in 35 patients with gastric carcinoma

EUS stage	n	Pathologic stage		Accuracy of EUS(%)
		N0	N+	
N0	20	14	6	70.0
N+	12(3)	5	7(3)	66.7
Total	32(3)	19	13(3)	68.6

(NOTES: three cases of T4N+ not surgically treated were included as being the correctly diagnosed).

DISCUSSION

Clinical experience with EUS used as an important preoperative staging tool for gastric cancer has been widely reported. On EUS imaging, early gastric cancer is visualized as hypo-echo masses invading the first, second, and third layers of the stomach, resulting in disruption, thickening, and irregularity of the layers involved. The fourth and fifth layers are often intact. Gastric cancer in advanced stage is usually accompanied by disruption of submucosa and muscularis propria, disappearance and replacement of the normal structures by hypo-echo mass as result of tumor invasion^[16-18]. Willis *et al*^[19] reported that overall accuracy of EUS for T, T1, T2, T3, and T4 staging was 78 %, 80 %, 63 %, 95 %, and 83 %, respectively. Regional lymph node staging was correctly conducted in 77 % of all 116 patients. Our results were similar to Willis' s, with 80.0 % and 68.6 % for T and N staging, respectively. Together with reports elsewhere, it is accepted that EUS is an accurate staging modality in most cases, with a few exceptions of overstaging and understaging. In our study, seven incorrectly staged patients consisted of ulcerated type in 4 cases, protruded type in 2, and flat type in 1. By careful examination and analysis, we found pathologically that reasons contributing to overstaging can be misinterpretation of necrotic tissue overlaying the ulcer surface, scars and fibrosis, inflammatory reaction in the peripheral structure of cancer, thickened gastric wall or ball-balloon alteration. Microscopic cancer invasion or focal destruction of a certain layer undetectable with lower-frequency ultrasound often results in understaging. In general, staging for elevated type may be more readily than that for ulcerated one, being with higher accuracy. To achieve the best visualization of the cancer and improve the diagnostic accuracy, high frequency probes (20MHz) may be more suitable for early cancer, while low frequency transducers (7.5 or 12MHz) for advanced ones^[20,21].

Lightdale^[22] and Zuccaro *et al*^[10] pointed out those lymph nodes of round shape, clear margin, and hypo-echo pattern similar to that of the primary tumor were more likely to be malignant. Heintz *et al*^[23] reported that the sensitivity and specificity could be 85 % and 45-85 % respectively if the followings were taken as the diagnostic criteria for malignant nodes: larger than 10 mm in diameter, heterogeneous echo pattern, and sharp border. EUS accuracy for N staging in this study was 68.6 %. Inaccuracy may be as the result of lack of reliable differential standard for benign and malignant nodes. The diameter, location, and the distance of lymph node to the primary lesion, and the endoscopists' expertise are important as well. Other factors affecting the accuracy may also include the frequency and penetration depth of the transducers used,

and intra-gastric substance. We recommend that based on our experience, visualization of lymph nodes by EUS should start with the site of primary tumor followed by gradual detection of each perigastric lymph node group. The differentiation of lymph nodes from other perigastric structures such as vessels on EUS imaging can be made by moving the probe forward and backward or using linear EUS equipped with color Doppler. Since many factors may influence the detection of nodes, negative EUS does not reliably indicate the absolute absence of nodal involvement and further assessment should be carried out to obtain definite diagnosis. EUS-guided fine needle aspiration (EUS-FNA) is now clinically available and has been accepted as the most reliable cytology for differentiation in this situation^[24,25].

The accurate preoperative staging for gastric cancer is very important in predicting prognosis and in determining individualized therapeutic regimens^[26-28]. Since EUS has its own limitations on accuracy of M staging, it must be emphasized here that precise staging results and proper management decision-making should rely on clinical presentations, laboratory tests and various imaging technologies. Nevertheless, EUS is undoubtedly superior to B ultrasound, CT, and conventional endoscopy in the assessment of primary tumor invasion depth and regional lymph node status^[4]. The therapeutic goals for gastric cancer should be set to maximally prolong the survival time, significantly improve the patient's quality of life, avoid any unnecessary procedure and any operation with no proven benefit, and also, reduce the economic burden on the patient. To achieve those, optimal therapy must be carefully individualized to meet the need of each patient based on precise TNM staging. Because early cancers confined to mucosa can be effectively managed by endoscopic resection and thus laparotomic surgery and its related complications can be avoided^[29-32], these lesions must be recognized clinically prior to the treatment decision-making. The very limited penetration depth of early tumors can be clearly displayed and reliably determined on EUS scanning especially when high-frequency probes are used, as reported by our team^[17]. Although surgery is still recommended as the first line therapy for T1-T3N1M0 cancer^[33], Rohde *et al*^[10] found that 30 % of 1 420 gastric cancer patients undergoing surgery eventually had no curative results because of tumor invasion. For patients with T4 cancers, further investigation should be performed to determine whether there is any hope of surgical cure^[34,35]. Patients with cancer invading into adjacent organs such as the pancreas proven by EUS should not undergo radical management. For them, palliative surgery can be a treatment choice if digestive tract obstruction is present, and radiotherapy or chemotherapy may be instituted when indicated. Treatment plans for three patients initially considered as surgical candidates in this study were eventually amended because of the preoperative staging of T4N1M1. In these patients, the pancreas invasion, large vessel involvement and liver metastases were the major indicators against curative surgery, which were demonstrated clearly by EUS imaging (for pancreas and vessel involvement) and CT scanning (for liver metastases).

In summary, EUS is a useful study for accurate staging of gastric carcinoma. Its unique advantages make EUS become one of the reliable methods in guiding prediction of the prognosis and establishment of cancer therapy regimens, although not likely to replace other imaging modalities used to stage these patients. Further large-scale clinical trails and carefully planned investigations should be conducted to clarify those questions about the ability of EUS to differentiate tumor infiltration from fibrosis or inflammatory tissues, to detect microscopic invasions, and to discriminate the benign from malignant nodes.

Abstract

AIM: To investigate the characteristics of the vascularity of hepatic metastasis.

METHODS: Six New Zealand rabbits, weighing averagely 2.7 ± 0.4 kg, were selected and operated to establish hepatic VX2 tumor carrier model. Hepatic VX2 tumors were then imaged with conventional B mode US, second harmonic imaging (SHI), color Doppler flow imaging (CDFI), power Doppler imaging (PDI) and harmonic PDI by a transducer S8 connected to HP-5 500 ultrasound system. A kind of self made echo contrast agent was intravenously injected at a dose of 0.01 mL/kg through ear vein, and then the venous passage was cleaned with sterilized saline.

RESULTS: Totally, 6 hypoechoic lesions and 3 hyperechoic lesions were found in the six carrier rabbits with a mean size about 2.1 ± 0.4 cm under conventional B mode ultrasound, they were oval or round in shape with a clear outline or a hypoechoic halo at the margin of the lesions. Contrast agent could not change the echogenicity of the lesions under conventional B mode and SHI, however, it could greatly increase the flow sensitivity of the lesions under PDI and harmonic PDI. Nutrient artery of these metastatic lesions might also be well depicted under contrast enhanced PDI and harmonic PDI.

CONCLUSION: Our result suggested that contrast enhanced PDI, especially harmonic PDI, was a promised method in the detection of vascularity of hepatic tumor nodules.

INTRODUCTION

Power Doppler ultrasonography (US) has been shown more sensitive than color Doppler US in the depiction of vascular flow in focal hepatic lesions, such as hepatocellular carcinoma (HCC), focal nodular hyperplasia (FNH) and metastasis (Mets). In addition, a wide variety of US contrast agents have been developed by using different gases and coating materials,

especially those called the third generation contrast agents manufactured through perfluorocarbon gases. These US contrast agents are promised to improve the quality of vascularity in Doppler studies, and its potential role in hepatic US has already been widely investigated. Researches have revealed that power Doppler US performed with the application of the contrast agent depicts more intratumoral vascularity in HCC than non-contrast power Doppler US does. Meanwhile, less knowledge is known about the vascularity of hepatic metastasis by harmonic power Doppler US. In this study, we intended to depict the characterization of the vascularity of hepatic Metastasis.

MATERIALS AND METHODS

Preparation of animal models

Six New Zealand rabbits weighing 2.6-3.2 kg, averagely 2.7 ± 0.4 kg were anaesthetized by Sumianxin (a product of the Changchun Argo-Pastoral University) at 0.2 mL/kg through intramuscular injection. Hairs in the abdominal region were moulted by 8 % sodium sulfide, then the region was cleaned by saline water. Median incision right beneath the metasternum was made to expose the right lobe of liver. A tunnel about 3cm deep at the lobe was established with an ophthalmic nipper. Viable VX2 tumor tissue masses about 2-3 mm³ were implanted into the tunnel, locally stanchied and then the each layer of abdominal wall was sutured accordingly. 2 or 3 weeks later, these rabbits were ready for the experiment. VX2 tumor is a kind of dermatological squamous cancer induced by Shope virus, viable VX2 tumor can be transplanted and generated through New Zealand rabbits, and therefore is used as simulate metastatic hepatic tumor models.

Preparation of echo contrast agent

Self made echo contrast agent was made from 5 % (g/L) human albumin and 40 % (g/L) Dextran in a ratio of 1:3 (v/v), the mixture was then underwent electromechanical sonication (Sonication machine JY92-2D was manufactured by Ninbo Xinzhi Research Institute) for 90 seconds under mechanical energy of 280W. During the sonication process, perfluoropropane gas was mixed into the mixture. Microbubbles manufactured in this way were counted by a Coulter counter, which concentration was about 1.6×10^9 bubbles/L with an average size 4.3 ± 2.1 μ m.

Equipments

A transducer S8 connected to HP-5 500 ultrasound system was used, which fundamental wave frequency was 3MHz and the second harmonic imaging was transmitted at frequency 3MHz receiving at frequency 6 MHz. Power Doppler imaging was tuned to PRF=2.2. During the whole process of experiment, the image depth, color gain and TGC should be kept constant.

Methods

Hepatic VX2 tumors were imaged with conventional B mode US, second harmonic imaging (SHI), color Doppler flow imaging (CDFI), power Doppler imaging (PDI) and harmonic PDI. Echo agent was intravenously injected at a dose of 0.01 mL/kg through ear vein, and then the venous passage was

cleaned with sterilized saline. All images were recorded realtimely by magnetic optics (MO), and they were analyzed further by at least two independent experienced sonographer.

RESULTS

Features of VX2 tumor under conventional and harmonic B mode US

Totally 6 hypoechoic lesions and 3 hyperechoic lesions were found in the six carrier rabbits with a mean size about 2.1 ± 0.4 cm under conventional B mode ultrasound, no even echoic lesions were found. They were oval or round in shape with a clear outline or a hypoechoic halo at the margin of the lesions. These images didn't seem to be improved by SHI. Contrast images under conventional B mode US also showed no improvement at all, meanwhile, SHI revealed a short duration of enhancement of the hepatic arteries and tumor lesions at the early phase, and an enhancement of the liver parenchyma and an decreased echo at the later phase. A pronounced arterial enhancement was also found at one side of the lesion, which may be considered as the nutrient artery of the tumor. (Figures 1-3).

Figure 1 Image of VX2 tumor lesion under conventional B mode US. Arrow indicates the VX2 tumor lesion at the anterior part of the right lobe. It is oval and hypoechoic with a small hyperechoic scar at the center of the lesion.

Figure 2 Image of VX2 tumor lesion under conventional second harmonic imaging. Arrow indicates the same VX2 tumor lesion at the anterior part of the right lobe. The echogenicity of the lesion and the around liver parenchyma seem unchanged at all.

Figure 3 Contrast enhanced second harmonic image. It shows

the enhancement of the liver arteries in the parenchyma, arrows indicate the afferent artery and its branches.

Figure 4 Conventional power Doppler image of the lesion. Arrows indicate the clear afferent blood flow signals of the lesion and its branches.

Figure 5 Contrast enhanced power Doppler image. It shows the enhancement of the afferent arteries in the lesion, arrow indicates especially the pronounced blooming artifacts around the artery and its branches.

Figure 6 Contrast enhanced harmonic power Doppler image. It shows the enhancement of the afferent arteries in the lesion, arrow indicates the newly appeared intralesional blood signals and less blooming artefacts around the artery and its branches.

Figure 7 Contrast enhanced harmonic power Doppler image at a later stage. It shows the enhancement of the afferent arter-

ies in the lesion, where intralesional blood signals and rare blooming artefacts are observable around the artery and its branches.

Changes of intralesional blood flow under CDFI, PDI and harmonic PDI

Color Doppler flow imaging could only reveal a spot-like or short bar-like flow signals around the lesion, and rarely reveal intralesional flow signals (Figure 4). Contrast agent may increase CDFI signals, but not so ideally as we expected. PDI could reveal a clear bar-like flow signal at one side of the lesion, and relatively more signals around and inside the lesions as compared with CDFI (Figure 5). Contrast agent can increase PDI signals quite remarkably from the instant of injection of gas bubbles, and a short duration of blooming artifacts were clearly seen, then the intralesional blood flow signals and even its branches were well revealed (Figure 6). These phenomena may better demonstrated what had been revealed by contrast SHI described above. An interesting fact was shown when tumor lesion was imaged under contrast enhanced harmonic PDI. Under this situation, intralesional and perilesional blood flow was much clearer and blooming artifacts became less (Figure 7).

DISCUSSION

Ultrasound is the most common used imaging modality to scan for focal liver lesions. Populations at a high risk of developing either primary or secondary hepatic tumors are usually followed up with US examination performed every 6 months in order to detect malignant lesions at the early stage. Early detection of either primary or secondary malignancies may greatly enhance the possibilities of curative surgical operation or other ablation treatments. The major limitation of US in the detection of small tumor lesions is its sensitivity. However, the introduction of microbubble contrast agents and the development of contrast specific techniques have revealed many new prospects of US detection and characteristics of focal liver tumor lesions. Hepatic metastasis typically appears as multiple focal discrete but solid lesions, and occasionally appears diffuse infiltrate hepatic involvement. Metastasis^[1-5], under conventional B mode US, has a nonspecific appearance which shows hypoechoic, hyperechoic, or mixed echogenicity. The sensitivity for total tumor detection has been reported as 57 to 92 % with a specificity of 76-96 %^[6-8]. However, the reported sensitivity of US is only about 41 % for accurate detection in the total numbers of intrahepatic lesions^[9]. Color Doppler flow imaging and power Doppler imaging are often used in the differentiation of hepatocellular carcinoma and metastatic liver lesions. Tanaka *et al*^[11] had reported a description of vascular pattern on different hepatic malignancies using CDFI and PDI. In particular, the basket and vessels- within-the-tumor pattern were supposed to be characteristics of HCC, the spot pattern more frequently appeared in hemangioma, and the detour pattern was often seen in metastasis. PDI has already been demonstrated to be superior to conventional CDFI, particularly in depicting vessels in small tumors, and contrast enhanced PDI may even increase the sensitivity of HCC to as high as 100 % in comparison with the conventional techniques^[10-13]. While, metastatic liver lesions were usually considered as hypovascular. Choi *et al*^[8,21] had reported that most of the metastatic lesions were absent of flow signals under both CDFI and PDI. Another report revealed that in a series of 64 metastatic liver lesions 67 % appeared avascular, and only 32 % of these cases appeared intralesional flow signals in comparison to 76 % of HCC^[14-18].

In our study, conventional B mode US and CDFI results are in accord with other researches. However, contrast

enhanced second harmonic imaging and harmonic PDI in this study demonstrated that vascularity of metastasis might overlap with that of HCC. Although metastatic lesion may be considered as avascular under conventional ultrasonography, the introduction of new techniques such as SHI and pulse inversion harmonic imaging and the use of echo contrast agent may greatly increase the sensitivity in cheking of perilesional and intralesional vasculature. Even the nutrient artery of the metastatic lesion could be clearly seen under these new techniques. Therefore, we should reconsider the differentiating criteria of HCC and metastasis, especially when lesions were all less than 3 cm. The major problems in the use of power Doppler were that the detected velocities were too slow in the tumor, there were too many blooming artifacts associated with microbubble injection, the duration of enhancement was short and the were motion artifacts resulted from respiration^[19-26]. Second harmonic imaging (SHI) US technique involves transmitting at frequency f and receiving at frequency $2f$, and contrast enhanced echoes could be therefore obtained at second harmonic frequency because of the non-linear motion of the gas bubbles when destroyed by high acoustic pressures^[27-29]. Thus, harmonic power Doppler US used in accord with contrast agent might provide vascular information in detail, and at the same time decreasing the artifacts associated with the contrast agent^[30-36]. Our findings confirmed that contrast enhanced harmonic PDI could reveal increased color sensitivity of vessels either inside the tumor lesion or in the surrounding liver parenchyma with less blooming artifacts. It was suggested that contrast enhanced harmonic PDI was convinced to be much more superior to conventional CDFI, PDI and contrast enhanced SHI.

Abstract

AIM: To obtain an efficient delivery system for transporting endostatin gene to mouse liver tumor xenografts by administration of aerosol.

METHODS: Recombinant plasmid pcDNA3.0/endostatin containing human endostatin gene together with signal peptide from alkaline phosphatase were transferred into human umbilical vein endothelial cell (HUVEC) by transferrin (TF)-liposome-endostatin complex. Western blot was used to detect the expression of human endostatin in transfected HUVEC cells and its medium. After the tumor-bearing mice were administrated with TF-liposome-endostatin complex, the lung tissue was analyzed by immunohistochemical method for expression of endostatin and the tumors were treated with CD-31 antibody to detect the density of microvessels in tumor tissues. The inhibition of tumor growth was estimated by the weight of tumors from groups treated with different doses of TF-liposome-endostatin complex. DNA fragmentation assay was used to detect the apoptosis of the cells from primary liver tumor.

RESULTS: Western blot analysis and immunohistochemical method confirmed the expression of endostatin protein *in vitro* and *in vivo*. After the tumor sections were treated with CD-31 antibody, the positive reaction cells appeared brown while the negative cells were colorless. The positively stained area of the TF-liposome-endostatin treated group was significantly smaller ($P < 0.01$, $645.8 \pm 55.2 \mu\text{m}^2$) than that of the control group ($1\,325.4 \pm 198.5 \mu\text{m}^2$). The data showed a significant inhibition of angiogenesis. After administration of TF-liposome-endostatin, comparing with the control group administrated with TF-liposome-pcDNA3.0, liver tumor growth in the mice treated with 50, 250 and 500 mg DNA/kg was inhibited by 36.6 %, 40.8 %, and 72.8 %, respectively ($P < 0.01$). And a typical DNA fragmentation of apoptosis was found in the cells from tumor tissues of the mice treated with TF-liposome-endostatin but none in the control group.

CONCLUSION: Endostatin gene could be efficiently transported into the mice with TF-liposome-DNA delivery

system by administration of aerosol. TF-liposome-mediated endostatin gene therapy strongly inhibited angiogenesis and the growth of mouse xenograft liver tumors. It also could promote the development of apoptosis of tumors without direct influence on tumor cells.

INTRODUCTION

Angiogenesis, the process of new blood vessel formation from existing vessels, is essential for tumor progression and metastasis^[1-7]. Tumor cells stimulate angiogenesis by secretion of angiogenic factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF)^[8]. At the same time, tumor cells also produce anti-angiogenic factors, including angiostatin^[9] and endostatin^[10]. Tumor angiogenesis is dependent upon the local balance of these positive and negative regulators^[11]. Inhibition of angiogenesis has been shown to inhibit local tumor growth and metastasis^[12]. Systemic administration of endostatin in tumor-bearing mice has been shown to keep the primary tumors in a dormant state^[10], thereby preventing tumor metastasis.

Clinical trials involving angiostatin and endostatin require large quantities of recombinant proteins, which are difficult to produce. In addition, these proteins do not maintain their bioactivity and are hard to be administered systemically. Gene therapy with endostatin employing a viral delivery system has shown a high efficacy in inhibiting tumor growth and metastasis in mice^[13-15]. However, the safety issues in its usage make this approach less attractive in human clinical trials. Nonviral gene therapy with endostatin was reported^[16, 17], but the efficiency was rather low as compared with viral delivery systems. The use of a cationic liposome-mediated gene transfer system together with a transferrin ligand achieved high transfection efficiency upon delivery of the p53 gene in mice^[18]. In this study, we evaluated the effect of aerosol administration of TF-liposome-endostatin on liver tumor growth in mice. The results indicated that TF-liposome-mediated endostatin gene therapy strongly inhibited angiogenesis and the growth of mouse xenograft liver tumors.

MATERIALS AND METHODS

Plasmid construction

The endostatin gene was obtained by PCR from a human liver cDNA library (Clontech Co). Endostatin was digested with *EcoRI/XbaI* and cloned in the *EcoRI/XbaI* site of pcDNA3.0 (Invitrogen Co). The sequence encoding the signal peptide from alkaline phosphatase^[19] was inserted into the *HindIII/EcoRI* site upstream of endostatin and an epitope tag derived from influenza

virus hemagglutinin A (HA) was fused in the *EcoRI* site between the signal peptide and endostatin. Recombinant plasmid was purified by QIA prep spin miniprep kit (QIAGEN Co).

Preparation of liposomes

Dried lipid films were prepared by solubilizing stearylamine, phosphatidyl choline and cholesterol at a 2:7:1 molar ratio in chloroform and subsequent removal of the chloroform by evaporation^[20]. The films were hydrated for 10 min with sterile water at 60 °C and then vortexed to generate liposomes. After hydration, the liposomes were sonicated on ice and filtered (pore size 0.22 µm). The diameter of liposome was assessed under scanning electron microscopy.

Formation of the TF-liposome-plasmid complex and determination of the encapsulation coefficient

The TF-liposome-plasmid complexes were prepared using 10:1:1, 10:5:1, 10:10:1 or 10:20:1 (mg:nmol:mg) ratios of TF:liposome:DNA. Liposomes and TF were mixed and incubated for 20 min at room temperature. The purified plasmid was then added to the solution, mixed immediately and thoroughly, and incubated for a minimum of 20 min at room temperature. The encapsulation coefficient of the TF-liposome-plasmid complexes was determined by 7.5 g·L⁻¹ agarose electrophoresis. The complexes were dissociated with 4 g·L⁻¹ SDS.

Expression of endostatin in vitro

HUVEC cells were obtained from Shanghai Cellular Research Institute and maintained in 1640 medium supplemented with 100 mL·L⁻¹ fetal bovine serum. HUVEC cells were plated in six-well plates at 2.5×10⁵ cells/well, and transfected with TF-liposome-plasmid complex containing 2 µg of purified plasmid. The conditioned media were collected after 48 h and concentrated in a microconcentrator (Amicon Co). And the cells were harvested by centrifugation, mixed with sample buffer and treated with sonic. The samples were subjected to SDS-PAGE using 120 g·L⁻¹ polyacrylamide gels, followed by Western blot analysis. The primary monoclonal mouse-anti-HA antibody (Babco Co) was used at 1:1 000 dilution followed by goat anti-mouse IgG-HRP (Sino-American Biotechnology Co) at 1:50 dilution. The membrane was stained by DAB.

Treatment of tumor-bearing mice with TF-liposome-pcDNA3.0/endostatin complexes

BALB/c male and female mice (obtained from the Animal Center of Nanjing Medical University, China) weighing about 20 grams were used in this study. Mice were fed with a standard rodent diet. Hep5 mouse liver tumor^[21] (obtained from the Animal Center of Chinese Academy of Sciences in Shanghai, China) was minced thoroughly and cancer cells were obtained at a concentration of 5×10⁶ cells/mL. A total of 1×10⁶ tumor cells were inoculated under the skin of the right thigh for each mouse. After 72 h inoculation, the tumor-bearing mice were treated with the aerosol containing 50, 250 or 500 µg DNA/kg of TF-liposome-pcDNA3.0/endostatin complexes (in 100 µL) or 500 µg DNA/kg of TF-liposome-pcDNA3.0 vector complexes every 72 h, for a total of five administrations. After 72 h of the fifth administration, mice were sacrificed and tumors were excised and weighed. Inhibition of tumor growth was determined using the formula: (Tumor weight of control group - Tumor weight of treatment group)/tumor weight of control group ×100 %.

Detection of expression of endostatin in vivo

Lung tissues were harvested after sacrificing the mice and the

expression of endostatin was assayed by immunohistochemistry. They were then fixed in 40 g·L⁻¹ paraformaldehyde and frozen. The sections of 20 µm were cut and mounted on glass slides. The sections were subsequently treated with 0.1 mol·L⁻¹ PBS (pH 7.0) for 5 min, and methanol mixed with 3 mL·L⁻¹ H₂O₂ for 10 min. The sections were blocked with 10 g·L⁻¹ milk in PBS, incubated at 37 °C for 2 h with a 1:1 000 dilution of a monoclonal mouse anti-HA antibody, followed by 1 h incubation at 37 °C of 1:25 dilutions of goat-anti-mouse IgG-HRP. The sections were stained with 0.5 mL·L⁻¹ DAB mixed with 0.3 mL·L⁻¹ H₂O₂.

Immunohistochemistry

Mice were sacrificed after 18 days of treatment. Tumors were excised and fixed in 40 g·L⁻¹ paraformaldehyde. Tumor tissues were frozen, and 20 µm sections were cut and mounted on glass slides. Sections were treated as described above. The primary CD-31 monoclonal rat anti-mouse antibody (Pharmingen Co) was diluted 200 times. The secondary antibody was a 1:25 dilution of goat anti-rat IgG-HRP (Kirkegaard & Perry Laboratories Co). Sections were stained with DAB as described above.

DNA fragmentation assay

The tumor tissues were excised and homogenized thoroughly. Following centrifugation at 3 000×g at 4 °C for 5 min, the pellets were resuspended in a lysis buffer containing 10 mmol·L⁻¹ Tris-HCl buffer (pH8.0), 10 mmol·L⁻¹ EDTA, 10 g·L⁻¹ SDS, 20 mg·L⁻¹ DNase-free RNase and 200 mg·L⁻¹ of proteinase K. After overnight incubation at 37 °C, the DNA was purified by phenol/chloroform extraction, precipitated, and resuspended in TE buffer (pH 7.4). Ten mg DNA was subjected to electrophoresis on a 15 g·L⁻¹ agarose gel containing 0.5 mg·L⁻¹ ethidium bromide and visualized under UV light. Electrophoresis was carried out in TE buffer (pH 8.0) at 20V for 8 h.

RESULTS

Detection of liposome diameter and encapsulation coefficient of the TF-liposome-plasmid complex

Prepared liposomes were observed under scanning electron microscopy at 10 000 fold magnification. The mean diameter of the liposomes was about 180-220 nm. After formation of the TF-liposome-pcDNA3.0/endostatin complex, the encapsulation coefficient was determined by 7.5 g·L⁻¹ agarose gel electrophoresis (Figure 1). The results showed that the encapsulation coefficient rose with increased ratio of liposome:DNA. Moreover, at a TF:liposome:DNA ratio of 10:10:1 (mg/nmol/mg), the encapsulation coefficient was higher than 98 %.

Figure 1 Determination of encapsulation coefficient. Lane 1: pure pcDNA3.0/endostatin plasmid, lanes 2-5: TF:liposome:DNA (mg:nmol:mg) at a ratio of 10:1:1, 10:5:1, 10:10:1 and 10:20:1. Lanes 6-7: complexes dissociated with 4 g·L⁻¹ SDS.

Expression of endostatin *in vitro* and *in vivo*

The *in vitro* expression of endostatin was detected by Western blot analysis. Distinct bands at around 22 kDa, the predicted molecular weight for the recombinant endostatin, were visualized in the supernatant and HUVEC cells transfected with pcDNA3.0/endostatin but not in the supernatant or HUVEC cells transfected with pcDNA3.0 (Figure 2). The *in vivo* expression of endostatin was detected by immunohistochemistry. After five administrations of the TF-liposome-pcDNA3.0/endostatin complex, the lung tissue was harvested and sectioned. Staining with an anti-HA antibody revealed positive cells containing endostatin in the sections of the treated group, whereas control sections were negative (Figure 3).

Figure 2 Expression of endostatin *in vitro*. Lane 1: HUVEC cells transfected with pcDNA3.0/endostatin; lane 2: supernatant of HUVEC cells transfected with pcDNA3.0/endostatin; lane 3: HUVEC cells transfected with pcDNA3.0; lane 4: supernatant of HUVEC cells transfected with pcDNA3.0.

Figure 3 Expression of pcDNA3.0/endostatin *in vivo*. The lung tissue sections from mice treated with TF-liposome-pcDNA3.0/endostatin (A) and from mice treated with TF-liposome-pcDNA3.0 (B) were treated with anti-HA antibody.

Endostatin inhibits the growth of primary liver tumors

To determine the efficacy of the TF-liposome-endostatin complex on tumor growth, we treated tumor-bearing mice with aerosol containing the complex. Tumor growth in the mice treated with 50, 250 and 500 mg DNA/kg was inhibited by 36.6 %, 40.8 %, and 72.8 %, respectively ($P < 0.01$). We concluded that the growth of primary tumors was significantly suppressed by systemic therapy with TF-liposome-pcDNA3.0/endostatin in a dose-dependent manner (Figure 4).

Endostatin inhibits angiogenesis in primary tumors

Immunohistochemical analysis showed a potent inhibition of angiogenesis in the tumors treated with the TF-liposome-pcDNA3.0/endostatin complex. Blood vessels were counted in three areas of each tumor section. There were significantly ($P < 0.01$) less microvessels in the tumors of treated mice versus control mice after staining of the tumor tissues with a rat anti-mouse CD-31 monoclonal antibody (Figure 5).

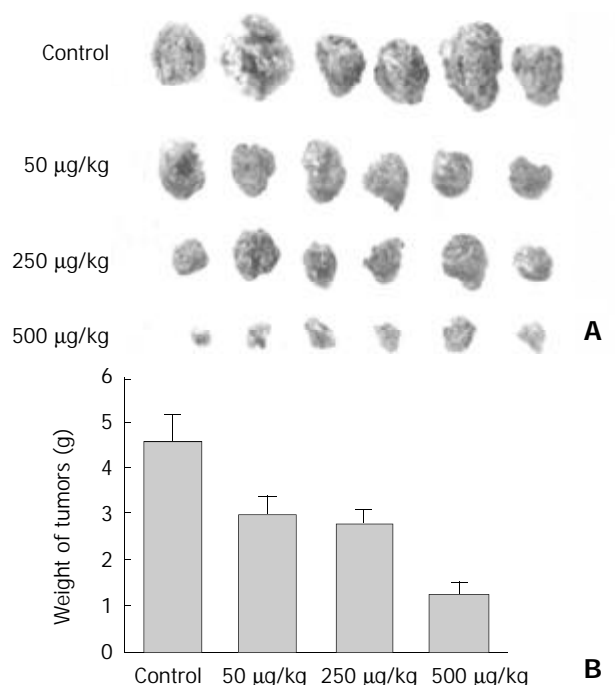

Figure 4 TF-liposome containing endostatin inhibits tumors growth. A: Tumors excised from mice treated with different doses of TF-liposome-pcDNA3.0/endostatin, or with TF-liposome-pcDNA3.0 (negative control). B: Tumor weight of mice treated with TF-liposome-pcDNA3.0/endostatin or TF-liposome-pcDNA3.0 vector. Each bar represents the mean \pm SD for six mice.

Figure 5 Reduced angiogenesis in TF-liposome-pcDNA3.0/endostatin treated tumors. Tumor sections from mice treated with TF-liposome-pcDNA3.0 (A) or treated with TF-liposome-

pcDNA3.0/endostatin (B) were stained with a CD-31 monoclonal antibody. CD-31-positive cells were brown whereas negative cells colorless in stain.

Quantitation of vessel density was determined under microscopy of the areas of brown (positive) and colorless (negative) staining at 432-fold magnification. One unit visual field encompassed 128×128 pixels. The positively stained area of the endostatin-treated group was significantly lower ($P<0.01$, $645.8\pm55.2\ \mu\text{m}^2$, mean \pm SD) than that of the control group ($1\ 325.4\pm198.5\ \mu\text{m}^2$, mean \pm SD), which showed that the TF-liposome-pcDNA3.0/endostatin complex blocked tumor angiogenesis, while the TF-liposome-pcDNA3.0 vector complex, as a negative control, did not block angiogenesis, which indicated that the inhibition of angiogenesis was caused by the introduced endostatin gene.

Induction of apoptosis in tumor cells by introduced endostatin gene

Fragmentation of cellular DNA represents a main change in the nuclei of cells undergoing apoptosis. Administration of the TF-liposome-pcDNA3.0/endostatin complex resulted in the typical DNA ladder pattern in apoptotic cells of tumor tissues (Figure 6). However, no DNA fragmentation could be detected in the tumor tissues from mice treated with the empty vector complex. The results showed that the introduced endostatin gene blocked angiogenesis accompanied by induction of apoptosis in liver tumors.

Figure 6 The introduced endostatin gene induces apoptosis in cells of tumor tissues. DNA was extracted from tumors and DNA fragmentation identified on a 15 g·L⁻¹ agarose gel. Lane 1: the DNA molecular weight marker; lane 2: DNA from mice treated with TF-liposome-pcDNA3.0 vector; lane 3: DNA from mice treated with TF-liposome-pcDNA3.0/endostatin.

DISCUSSION

Inhibition of angiogenesis has recently been acknowledged as a promising strategy to treat cancer. Endostatin, an endogenous angiogenesis inhibitor, specifically suppresses endothelial cell proliferation, thereby acting as a competitor for angiogenesis inducers secreted by tumor cells. The use of endostatin may serve as an attractive new strategy in cancer therapy^[22-25]. However, poor solubility of the endostatin protein together with a high effective dose hampered its widespread application, although high and continuous endostatin expression can be obtained by direct induction of the endostatin gene *in vivo*.

In recent years, great progress has been made in anti-cancer gene therapy and different gene delivery systems, based on retroviruses^[15,26,27], adenoviruses^[14,28] and liposomes have been used in animals. Liposomes are considered to provide a safer gene therapy delivery method, and can be administered intravenously, intramuscularly, intraperitoneally, or by intratracheal injection^[17,18,20,29]. We used a transferrin facilitated liposome delivery of the endostatin gene by aerosol administration in our experiments. This method provides several advantages: (1) Lung tissue and airways cover a large surface area, therefore the introduced gene can be expressed

efficiently in the lung. (2) TF enhances the efficiency of gene expression and transfection by facilitating the entry of DNA into the cells. (3) Recent liposome toxicity studies in the lungs of humans and several animal species show that liposomes cause no or minimal host inflammatory and immune responses^[30,31]. (4) Aerosol administration is convenient and can be performed repeatedly by the patients themselves.

In the TF-liposome-DNA mediated gene transfer system, transferrin facilitated the delivery of DNA by binding to its receptors. The liposomes along with the DNA were internalized by fusion with the plasma membrane and underwent receptor-mediated endocytosis. Following the internalization of the TF-liposome-DNA-TF receptor complex, transferrin may facilitate the escape of DNA from the endosome. So the transfection efficiency was improved by this transfer system^[18,32]. Indeed, the degree of inhibition of tumor growth (72.8 %) in our studies was greater than that reported by another group (49 %)^[17], who used liposomes alone to deliver the endostatin gene.

The potent antiangiogenic effect of endostatin can specifically inhibit the proliferation and migration of endothelial cells and subsequently promote the development of apoptosis and atrophy of tumors without direct influence on tumor cell or nonneoplastic cell growth^[33-35]. Our results demonstrated that typical DNA fragmentation was found in the nuclei of cells from tumor tissues of the mice treated with TF-liposome-pcDNA3.0/endostatin complexes, but not in the control group.

In conclusion, our results showed a strong inhibition of angiogenesis and tumor growth in mice after administration of the TF-liposome-endostatin plasmid complex. This suggests that TF-liposome-DNA complexes can be utilized as an efficient method for anti-angiogenic gene delivery to tumors in the gene therapy for cancers.

ACKNOWLEDGEMENTS

We would like to thank Drs. Sandra Liekens and Yan Chen from New York University School of Medicine for preparing this manuscript.

Abstract

AIM: To investigate the serum level and expression of insulin growth factor II (IGF-II) in liver tissues of rats with early experimental hepatocellular carcinomas (HCC) and its significance in early diagnosis.

METHODS: Early experimental hepatocellular carcinomas were induced by diethylnitrosamine (DENA) in 180 male SD rats. Another 20 male SD rats served as control. The IGF-II serum level was measured by ELISA. Immunohistochemistry and electron microscopic immunohistochemistry were used to observe the expression of IGF-II in normal and tumor liver tissues and its ultrastructural location in malignant hepatocytes. The expressions of IGF-II in human hepatoma cell lines HepG2, SMMC7721 and human embryonic liver cell line L-02 were measured by immunocytochemistry. IGF-II mRNA level was studied by in situ hybridization.

RESULTS: IGF-II was expressed in the cytoplasm of both sinusoidal cells in paracancerous cirrhotic liver tissue and malignant hepatocytes in early experimental HCC tissues. Gold particles were seen on the rough endoplasmic reticulum and the mitochondrion in malignant hepatocytes. IGF-II was expressed in the human hepatoma cell lines. The mRNA level of IGF-II was higher in rat liver tumor tissue than in normal rat liver tissue. The serum IGF-II level of the early experimental HCC group was 34.67 ± 10.53 ng·ml⁻¹ and that of the control group was 11.75 ± 5.84 ng·ml⁻¹. The rank sum test was used for statistical analysis. There was a significant difference between the two groups ($P < 0.01$).

CONCLUSION: During the induction of early experimental HCC by DENA, IGF-II may promote hepatocytic proliferation via a paracrine mechanism in the pre-cancerous stage. When hepatocytes are transformed into malignant cells, they may secrete IGF-II and promote malignant cell proliferation by an autocrine mechanism. IGF-II may be a possible biological marker in the early diagnosis of HCC.

INTRODUCTION

IGF-II is a 67-amino-acid polypeptide growth factor which is mainly produced by liver cells and is crucial in normal fetal growth^[1-2]. The main researches about the relationship between IGF-II and HCC have been focused on: (1) the mechanism of IGF-II in the development of HCC^[3-6], (2) to decrease the expression of IGF-II searching the treatment methods for HCC^[7-9], and (3) its prognostic significance^[10]. Although IGF-II is believed to be implicated in normal and neoplastic liver growth, the mechanism of IGF-II in early hepatocellular carcinomas development and its significance in the early diagnosis of such cancer are unclear. So we used ELISA, immunohistochemistry, electron microscopic immunocytochemistry and in situ hybridization to search for possible answers to the questions.

MATERIALS AND METHODS

Animal model and tissue preparation

180 male SD rats were given DENA (diethylnitrosamine), once every week for 17 weeks in a dose of 70 mg/kg, to induce early experimental HCC. In the control group, 20 male SD rats were maintained on a standard laboratory diet and tap water. From the 4th week, 2 random experimental rats were sacrificed at the end of every week for pathological study of their livers. The remainder were killed at the 17th week for study. Sera were collected and stored at -70 °C. Liver tissues were fixed in 40 ml·L⁻¹ paraformaldehyde or 40 ml·L⁻¹ paraformaldehyde containing 5 ml·L⁻¹ glutaraldehyde for light and electron microscopic studies.

Cell lines culture

Human hepatoma cell lines HepG2 and SMMC7721, and human embryonic liver cell line L-02 (Wuhan University Cell Center) in PRMI 1640 (GIBCO), with 100 ml·L⁻¹ fetal calf serum (GIBCO), and 37 °C, 50 ml·L⁻¹ CO₂.

ELISA detection for the serum level of IGF-II

100 ul of goat anti-IGF-II polyclonal antibody (Santa Cruz Co.) (25 ug/ml in 0.1 mol/L NaHCO₃) was put into each well of a 96-well ELISA plate, and incubated for 36 hours at 4 °C. Nonspecific protein binding was blocked by 100 ul, 10 ml·L⁻¹ bovine serum albumin. Then 100 ul of sera of rat and recombinant human IGF-II (Pepro Tech Co.) were separately added to the wells, 1 hour at 37 °C. The 100 ul of Rabbit anti-IGF-II polyclonal antibody (Santa Cruz Co.) (1:200 dilution) was added to the wells, 1 hour at 37 °C. HRP-conjugated goat anti-rabbit immunoglobulin (Southern Biotech Co.) (1:2 000 dilution), 100 ul, 1 hour at 37 °C. Binding was developed with ortho-phenylene diamine. Absorbance was read at 490 nm. During the performance, washing the plate was according to the ELISA routine method.

Immunohistochemical detection for IGF-II expression in early experimental HCC tissues

Immunohistochemical detection was made using rabbit anti-IGF-II polyclonal antibody (Santa Cruz Co.) by SABC

technique. The experiment was performed following the manufacturer's recommendation of the SABC kit (Beijing Zhongshan Bioech Co.).

Immunocytochemical detection for IGF-II expression in human cell lines

Human hepatoma cell lines HepG2 and SMMC7721 and human embryonic cell line L-02 were cultivated to let them climb on coverslips, which then fixed in acetone at -20 °C for 10 minutes. The antibody, SABC kit and experimental method were the same as those for the immunohistochemical detection.

Electron microscopic immunocytochemistry for IGF-II ultrastructural location in malignant hepatocytes

Early experimental HCC tissues were cut into 500 nm ultrathin sections, and the sections were etched in 10 % hydrogen peroxide solution for 10 minutes at room temperature. After the grids were drained, the sections were placed into 40 mL L⁻¹ BSA solution, and then were treated overnight at 4 °C with rabbit anti-IGF-II polyclonal antibody (1:50 dilution). The sections were incubated with colloidal gold (5 nM) conjugated goat anti-rabbit IgG (Wuhan Best Co.) (1:40 dilution), 37 °C, 10 minutes. The sections were examined with a transmission electron microscopy after counter staining. The solution for diluting antibody replacing the rabbit anti-IGF-II polyclonal antibody for those sections served as the negative control.

In situ hybridization detection for IGF-II mRNA level in early experimental HCC tissues

IGF-II in situ hybridization kit was purchased from the Wuhan Best Co. The experiment was conducted according to the manual of the kit.

Statistical analysis

SAS software and Rank Sum Test were used for statistical analysis.

RESULTS

Microscopic observation and histopathological examination

In the DENA group, the liver surfaces were covered with scattered small white nodules in the 4th week. In the 17th week, the diameter of the largest nodule was 8 mm. These rats were diagnosed as having early experimental hepatocellular carcinomas. The rat livers in the control group showed no pathological changes.

IGF-II serum level of early experimental HCC

The mean \pm standard deviation of IGF-II serum level was 34.67 ± 10.53 ng·mL⁻¹ in the DENA group and 11.75 ± 5.84 ng·mL⁻¹ in the control group. There was significant difference between the two groups ($P < 0.01$).

Expression of IGF-II in early experimental HCC tissues

Strong immunostaining of IGF-II was seen in the cytoplasm of sinusoidal cell in paracancerous cirrhotic tissues (Figure 1) and the malignant hepatocytes in HCC tissues. Only a few hepatocytes in paracancerous tissues had weakly positive expression. In the control group, however, the liver tissues showed no positive results.

Expression of IGF-II in human cell lines

Human hepatoma cell lines HepG2 and SMMC7721 and human embryonic liver cell line L-02 all expressed IGF-II. The positive immunolocalization of the three cell lines was in the cytoplasm. SMMC7721 cell line showed the most strongly positive immunostaining (Figure 2).

Figure 1 IGF-II expression in the cytoplasm of sinusoidal cells in the paracancerous cirrhotic tissues. Immunohistochemical staining, $\times 200$.

Figure 2 IGF-II expression in the cytoplasm of SMMC7721 cell line. Immunocytochemical staining, $\times 200$.

Figure 3 Colloidal gold particles in rough endoplasmic reticulum (ll), mitochondrion (▲), nucleus and paranuclear region (←). Electron microscopic immunocytochemical staining for IGF-II, $\times 16\ 000$.

Figure 4 Expression of IGF-II mRNA in the cytoplasm of malignant hepatocytes. In situ hybridization, $\times 200$.

Ultrastructural localization of IGF-II in malignant hepatocytes of early experimental HCC tissues

Electron microscopic immunocytochemistry confirmed the light microscopic findings. Gold particles were seen in the rough endoplasmic reticulum, mitochondrion and the paranuclear region of malignant hepatocytes. A few gold particles were found in the nuclei of malignant hepatocytes (Figure 3). The negative control sections did not show positive results.

IGF-II mRNA level in early experimental HCC tissues

IGF-II mRNA was distributed in the cytoplasm of hepatocytes in the tissues of early experimental HCC, and IGF-II mRNA was overexpressed in HCC tissues (Figure 4).

DISCUSSION

Among the many growth factors, the insulin-like growth factor, transformation growth factor- α and hepatocyte growth factor are mostly strongly implicated in normal and neoplastic liver growth^[11-17]. IGF-II exerts its effect via two specific high affinity receptors, IGF1R and M6P/IGF2R, in paracrine and autocrine manner^[18-22]. IGF1R is a transmembrane glycoprotein which exists on the surface of hepatocytes with an intracellular tyrosine kinase domain. M6P/IGF2R is a single chain polypeptide associated with a G-protein signal pathway. In the present study, it has clearly been shown that: (1) the sinusoidal cells in paracancerous cirrhotic nodule tissues expressed IGF-II; (2) the malignant hepatocytes in rat early experimental HCC tissues expressed IGF-II. As we know that liver cirrhotic nodules are the pre-cancerous condition of HCC^[23], so it is clearly suggested that, in the pre-cancerous condition, IGF-II mediated hepatocyte proliferation mainly via IGF1R by a paracrine mechanism. However, after the hepatocytes were transformed into malignant cells, they could secrete IGF-II themselves, suggesting that IGF-II mediated malignant hepatocytes proliferation in an autocrine manner at that time and that M6P/IGF2R might be involved. Although several reports have shown that M6P/IGF2R protein and mRNA level were reduced and that the M6P/IGF2R gene had loss of heterozygosity in HCC^[24,25], Gomez-Angelats and Wada reported that no mutation was found in the M6P/IGF2R gene in the model of rat hepatocarcinogenesis and human HCC^[26,27]. By electron microscopic immunocytochemistry, we found that IGF-II existed in the mitochondria of malignant hepatocytes. M6P/IGF2R is a G-protein receptor which is closely related to mitochondrion. So we favor Gomez-Angelats' view that M6P/IGF-II was in an activated condition in the process of rat hepatocarcinogenesis.

Human hepatoma cell lines HepG2 and SMMC7721 expressed IGF-II strongly. This fact confirms the above postulate in another aspect, i.e., IGF-II could be secreted by malignant hepatocytes themselves and stimulate their proliferation via an autocrine mechanism. Human embryonic liver cell line L-02 expressed IGF-II too, suggesting that hepatoma cells may regain some embryonic development characteristics, like α -FP secretion.

α -FP is a diagnostic marker of HCC, but its significance in the early diagnosis of HCC is unclear and the positive rate is not high^[28-30]. In our research, the serum IGF-II level in the rat early experimental HCC group was significantly higher than that of the control group. IGF-II is a polypeptide hormone secreted by many organs of the fetus. After birth, however, it is mainly produced by liver cells^[31,32]. We may postulate that, in rat early experimental HCC, extrahepatic organs may regain the ability to secrete IGF-II and that their intrahepatic cells express IGF-II more strongly than those in normal condition^[33,35]. These might be the main reasons for the increase in serum IGF-II level. Hayakawa reported that the serum level of IGF-II was

significantly lower in primary hepatocellular carcinomas than in control^[36], but we haven't found any report on the serum IGF-II level in early HCC. So it is possible that serum IGF-II level increases temporarily in early HCC and then decreases gradually in the process of HCC development, IGF-II maybe a biological marker in the early diagnosis of HCC.

Abstract

AIM: Many growth factors, such as epidermal growth factor (EGF), are associated with the carcinogenesis. EGF plays its role in the proliferation of hepatoma cells through binding with EGF receptor (EGFR) and a series of signal transduction. But the postreceptor pathway is still not clear. In the present experiment, we studied the effect of tyrosine kinase, protein kinase C, Na^+/H^+ exchange, calmodulin and voltage-dependent Ca^{2+} channel on EGF-induced hepatoma cell proliferation.

METHODS: Hepatoma cell line SMMC7721 was cultured in RPMI1640 serum-free medium. In order to study the effect of tyrosine kinase, protein kinase C, Na^+/H^+ exchange, calmodulin and voltage-dependent Ca^{2+} channel on human hepatoma cell proliferation induced by epidermal growth factor (EGF), DNA synthesis rate of hepatoma cells was measured by the method of ^3H -TdR incorporation.

RESULTS: EGF (10^{-9} M) stimulated the proliferation of hepatoma cells significantly (^3H -TdR incorporation was $1\,880 \pm 281$ cpm/well, $P < 0.05$), and this effect was significantly inhibited by tyrosine kinase inhibitor genistein (^3H -TdR incorporation was 808 ± 209 cpm/well, $P < 0.001$). Calmodulin inhibitor W-7, protein kinase C inhibitor H-7 and Na^+/H^+ exchange inhibitor amiloride individually had significant inhibiting effect on EGF-induced proliferation of hepatoma cells (^3H -TdR incorporation was 978 ± 87.3 cpm/well, $1\,241 \pm 147$ cpm/well, $1\,380 \pm 189$ cpm/well, respectively, $P < 0.001$, $P < 0.01$, $P < 0.05$), but they all had no effect on the basal level proliferation of cultured hepatoma cells (^3H -TdR incorporation was $1\,284 \pm 260$ cpm/well, $1\,179 \pm 150$ cpm/well, $1\,392 \pm 152$ cpm/well, respectively, ^3H -TdR incorporation of the control was $1\,353 \pm 175$ cpm/well, $P > 0.05$). Voltage-dependent Ca^{2+} channel inhibitor verapamil had no inhibition on EGF-induced proliferation of hepatoma cells (^3H -TdR incorporation was $1\,637 \pm 133$ cpm/well, $P > 0.05$), it also had no effect on the basal level proliferation of cultured hepatoma cells (^3H -TdR incorporation was $1\,196 \pm 112$ cpm/well, $P > 0.05$).

CONCLUSION: Our data suggest that tyrosine kinase, Ca^{2+} -calmodulin-dependent pathway, protein kinase C and Na^+/H^+

H^+ exchange play a critical role in EGF-induced proliferation of hepatoma cells and that the effect of EGF is independent of voltage-dependent Ca^{2+} channel.

INTRODUCTION

Most hepatocellular carcinoma (HCC) is associated with cirrhosis, a condition in which liver cell necrosis coexists with inflammation and hepatocellular regeneration. HCC arising in cirrhotic livers is exposed to a number of growth factors mediating hepatocellular regeneration. Epidermal growth factor (EGF) is one of them.

EGF is a single strand polypeptide composed of 53 amino acid and has implicated in the regulation of a wide variety of physiological and pathological processes including embryo genesis, growth, tissue repair, regeneration and neoplasia. EGF inhibits gastric acid secretion and has a cytoprotective effect on stomach tissue, EGF has been of clinical interest for the treatment of acid hypersecretion and the healing of ulcers. EGF has been implicated as a hepatotrophic factor during liver regeneration, has protective effect during hepatic damage through inducing the DNA synthesis of hepatic cells^[1-4]. EGF also induces DNA synthesis of hepatoma cells and promotes the occurrence and expansion of hepatoma^[5,6].

EGF exerts its biologic effects by binding with the EGF receptor (EGFR), a type of transmembrane glucoprotein with a molecule of 170kD. The primary structure of its intramembranous part is associated with the expression of oncogene erb-B. The intracellular part of EGFR has tyrosine kinase activity. EGFR is overexpressed in various carcinoma, such as hepatoma^[7-9], gastric carcinoma^[10-14], colon carcinoma^[15-20], lung carcinoma^[21-23] and prostatic carcinoma^[24-28], and also associated with the histologic types and invasiveness of the tumor^[29-32]. Many growth factors have the effect of promoting cells proliferation and malignant transformation by binding with EGFR such as EGF, heparin binding EGF (HB-EGF)^[33,34], transforming growth factor β (TGF- β)^[35,36] and hepatopoietin^[37,38]. After the integration of HBV-X gene into hepatic cells, EGFR was activated and overexpressed, which induced liver carcinogenesis^[39].

In general, EGF induces tumor cell division and proliferation through a series of signal transduction by binding with EGF receptor (EGFR) and activating its tyrosine protein kinase and phosphorylating itself and its protein substrate^[40]. This postreceptor signal transduction is associated with phosphatidylinositol pathway^[41]. But the exact mechanism is still not clear.

In this report, we have characterized the anti-tumor activity of tyrosine kinase, calmodulin, protein kinase C, Na^+/H^+ exchange and voltage-dependent Ca^{2+} channel inhibitors. The SMMC7721 cell line cultured in serum-free medium was used in this study.

MATERIALS AND METHODS

Reagents

All chemicals were purchased from sigma chemical CO. (St. Louis, Mo. USA) unless otherwise stated. ^3H -TdR was purchased from the Institute of Nuclear Power of China. Verapamil, streptomycin, penicillin and 0.5 % hydrocortisone were clinical medicines.

Cell culture

SMMC7721 cells were stored in our laboratory and cultured in RPMI1640 serum-free medium. Briefly, SMMC7721 cells were grown in RPMI1640 supplemented with 5 $\mu\text{g}/\text{ml}$ transferrin, 20 $\mu\text{U}/\text{ml}$ insulin, 0.4 $\mu\text{g}/\text{ml}$ hydrocortisone and 100 $\mu\text{g}/\text{ml}$ streptomycin and penicillin.

Experiment program

Eleven groups were separated in the experiment: (1) control, (2) EGF (10^{-9}M), (3) W-7, (4) verapamil, (5) W-7+EGF, (6) verapamil+EGF, (7) genistein+EGF, (8) H-7, (9) H-7+EGF, (10) amiloride, (11) amiloride+EGF.

DNA synthesis rate of hepatoma cells

The DNA synthesis rates were measured by the method of ^3H -TdR incorporation. The hepatoma cells were seeded into 96 well plates at a density of $1 \times 10^4/\text{well}$ and incubated with serum-free RPMI1640. After 24 hours, fresh medium was changed, and reagents added. After incubation for 18 hours the medium was then replaced with fresh medium containing ^3H -TdR 0.5 $\mu\text{Ci}/\text{ml}$ for another 6 hours. The cells were finally lysed with 0.33 mol/L HCl, ^3H -TdR incorporation was determined with a β -counter.

Statistical analysis

Two-side t test was used to examine the significant difference between groups.

RESULTS

Effect of genistein on EGF-induced growth of hepatoma cells

Genistein is a tyrosine kinase inhibitor. EGF (10^{-9}M) stimulated the growth of hepatoma cells significantly compared with the control ($P < 0.05$). EGF-induced ^3H -TdR incorporation was reduced from 1880 ± 281 cpm/well to 808 ± 209 cpm/well by genistein ($P < 0.001$, Figure 1).

Figure 1 Effect of genistein on EGF-induced ^3H -TdR incorporation into hepatoma cells. $n=6$, $\bar{x} \pm s$, $^aP < 0.05$, vs control; $^cP < 0.001$, vs EGF 10^{-9}M .

Effect of W-7 on EGF-induced growth of hepatoma cells

W-7 is a calmodulin inhibitor. W-7 (25 $\mu\text{mol}/\text{L}$) alone had no effect on ^3H -TdR incorporation, the incorporation of W-7 group and control were 1284 ± 260 cpm/well and 1353 ± 175 cpm/well, respectively ($P > 0.05$). When W-7 was added with EGF

(10^{-9}M), the effect of EGF on the growth of hepatoma cells was inhibited significantly, the incorporation (978 ± 87.3 cpm/well) was significantly lower than that of EGF (10^{-9}M) group (1880 ± 281 cpm/well) ($P < 0.001$, Figure2).

Figure 2 Effect of W-7 on EGF-induced ^3H -TdR incorporation into hepatoma cells. $n=6$, $\bar{x} \pm s$, $^aP < 0.001$ vs W-7 group; $^cP > 0.05$ vs control.

Effect of verapamil on EGF-induced growth of hepatoma cells

Verapamil is voltage-dependent Ca^{2+} channel inhibitor. As shown in Figure3, verapamil (100 $\mu\text{mol}/\text{L}$) alone had no effect on ^3H -TdR incorporation, the incorporation of verapamil group and control were 1196 ± 112 cpm/well and 1353 ± 175 cpm/well, respectively ($P > 0.05$). When verapamil (100 $\mu\text{mol}/\text{L}$) was used with EGF (10^{-9}M), the incorporation was 1637 ± 133 cpm/well, which was not significantly different from the incorporation with EGF (10^{-9}M) alone (1880 ± 281 cpm/well, $P > 0.05$).

Figure 3 Effect of verapamil on EGF-induced ^3H -TdR incorporation into hepatoma cells. $n=6$, $\bar{x} \pm s$, $^aP > 0.05$ vs EGF 10^{-9}M group; $^cP > 0.05$ vs control.

Effect of H-7 on EGF-induced growth of hepatoma cells

H-7 is a specific inhibitor of protein kinase C. H-7 (50 $\mu\text{mol}/\text{L}$) alone had no effect on the basal level ^3H -TdR incorporation, the incorporation of H-7 group and control were 1179 ± 150 cpm/well and 1353 ± 175 cpm/well, respectively ($P > 0.05$). When H-7 was used together with EGF (10^{-9}M), the effect of EGF on the proliferation of hepatoma cells was inhibited significantly, the incorporation (1241 ± 147 cpm/well) was significantly lower than that of EGF group (1880 ± 281 cpm/well, $P < 0.01$) (Figure4).

Effect of Na^+/H^+ exchange on EGF-induced growth of hepatoma cells

Amiloride is an inhibitor of Na^+/H^+ exchange. As shown in Figure 5, amiloride (0.1 mmol/L) alone had no effect on ^3H -TdR incorporation, the incorporation of amiloride group and control were 1392 ± 152 cpm/well and 1353 ± 175 cpm/well, respectively ($P > 0.05$). When amiloride (0.1 mmol/L) was used

with EGF (10^{-9} M), the effect of EGF on the proliferation of hepatoma cells was inhibited significantly, the incorporation ($1\,380 \pm 189$ cpm/well) was significantly lower than that of EGF group ($1\,880 \pm 281$ cpm/well, $P < 0.05$) (Figure 5).

Figure 4 Effect of H-7 on EGF-induced $^3\text{H-TdR}$ incorporation into hepatoma cells. $n=6$, $\bar{x} \pm s$, $^a P > 0.05$ compared with control; $^b P < 0.01$ vs EGF 10^{-9} M group; $^c P < 0.05$ vs control.

Figure 5 Effect of amiloride on EGF-induced $^3\text{H-TdR}$ incorporation into hepatoma cells. $n=6$, $\bar{x} \pm s$, $^a P > 0.05$ vs control; $^c P < 0.05$ vs EGF (10^{-9} M) group.

DISCUSSION

In this study, we demonstrated that EGF (10^{-9} M) had strong stimulation on the growth of hepatoma cells. It is well documented that EGF binds with the EGFR and activates the tyrosine kinase of the receptor. In this paper, the tyrosine kinase inhibitor genistein effectively blocked the growth of hepatoma cells induced by EGF.

Intracellular Ca^{2+} is one of critical factors maintaining the intracellular homeostasis. The concentration of Ca^{2+} in the cell plasma is about 10^{-7} mol/L, which is far lower than extracellular concentration of 10^{-3} mol/L. The enhancement of the intracellular Ca^{2+} concentration is achieved in two ways: one is the membrane depolarization, the other is the release from the intracellular stores intervened by phosphatidylinositol 1,4,5-triphosphate (IP_3). When the concentration of the intracellular Ca^{2+} rises to 5 folds above normal, the Ca^{2+} pump will be activated and put the Ca^{2+} out of the cell. Intracellular Ca^{2+} is the cofactor of many critical enzymes and functional proteins, and is an important intracellular messenger.

Studies demonstrate that in hepatoma cells EGF and other Ca^{2+} mobilizing hormones stimulate the rapid formation of IP_3 and a concomitant rise in cytosolic Ca^{2+} , apparently mobilized from intracellular stores^[42]. Ca^{2+} -binding protein regucalcin plays a role in the maintenance of intracellular Ca^{2+} homeostasis, and inhibits Ca^{2+} -activated DNA fragmentation. Regucalcin may play a physiological role in the control of over-proliferative cells^[43].

In this experiment, the calmodulin inhibitor W-7 was used

with EGF, and it significantly inhibited the growth of hepatoma cells induced by EGF, but it showed no effect on the growth of hepatoma cell when used alone. On the contrary, voltage-dependent Ca^{2+} channel inhibitor verapamil had no effect on the growth of hepatoma cells induced by EGF. It is suggested that Ca^{2+} -calmodulin-dependent pathway plays a critical role on the proliferation of hepatoma cells induced by EGF, and the effect of EGF is independent of voltage-dependent Ca^{2+} channel.

In the signal transduction pathway of phosphatidylinositol, activators bind with the cell surface receptor and activate phospholipase C (PLC)- β through G protein. PLC catalyzes dehydration of phosphatidylinositol 4,5-bisphosphate (PIP_2) into IP_3 and diglyceride (DG). IP_3 promotes the release of Ca^{2+} from endoplasmic reticulum. With the participation of Ca^{2+} , DG activates PKC, and PKC urges the phosphorylation of tyrosine which activates oncogene erb-B with productions of protein Erb-B2 and Erb-B3^[44]. In this study, PKC inhibitor H-7 used alone had no significant effect compared with control, but when used with EGF, it significantly inhibited the mitogenic effect of EGF on hepatoma cells. The result suggests the activation of PKC is an important link in the effect of EGF, and also implies that the effect of EGF is associated with phosphatidylinositol signaling pathway.

Intracellular pH (pHi) is another critical factor maintaining the intracellular homeostasis. At present, many studies found that pHi is associated with the pathogenesis of many diseases and mitosis of many kind of cells. Na^+/H^+ exchange is an important mechanism of pHi modulation. Activation of Na^+/H^+ exchange is the trigger of cellular protein and DNA synthesis, and is of fundamental importance for tumor growth. An increased influx of Na^+ through the stimulation of Na^+/H^+ exchange plays a key role during early phases of the cell cycle. Na^+/H^+ exchange messenger RNA expression may reach 10 times higher in HepG2 than in normal hepatocytes. EGF can increase baseline pHi in a dose-dependent manner. This effect was completely inhibited by pretreatment with amiloride^[45]. In this experiment, we found that Na^+/H^+ exchange inhibitor amiloride (0.1 mmol/L) alone showed no effect on the basal level $^3\text{H-TdR}$ incorporation of hepatoma cells. On the contrary, when it was used with EGF (10^{-9} M), the stimulatory effect of EGF was significantly inhibited. This suggests that the activation of Na^+/H^+ exchange may be one pathway of the effect of EGF.

Recent studies have shown that Ca^{2+} /calmodulin-dependent protein kinase IV was overexpressed in HCC with high activity and might be involved in the development of HCC^[46]. The effect of EGF on the hepatoma cells was associated with protein kinase C and calmodulin. Protein kinase C can activate Na^+/H^+ exchange. After the phosphorylation of EGFR, the proliferation signal was sent into the nucleus through STAT3 (signal transducers and activators of transcription 3)^[47]. The mechanism of this signal transduction is very complicated. It is connected with the activation of oncogene ras^[48,49], erb-B^[44], cyclinD1 and c-Myc^[50,51]. The effect of cell proliferation induced by EGF is associated with the MAPK (mitogen-activated protein kinase) pathway. The interactions between them demand more intensive studies.

In conclusion, our data suggest that PKC, calmodulin and Na^+/H^+ exchange could play a critical role in the growth of some hepatic tumors and that the inhibition of PKC, calmodulin or Na^+/H^+ exchange activity through pharmacological or genetic interventions, could theoretically be a useful strategy to reduce the growth rate of hepatocellular carcinoma.

Abstract

AIM: To probe the value of γ -glutamyl transpeptidase (GGT) messenger RNA in monitoring canceration of liver cells and for early diagnosis of hepatocellular carcinoma (HCC), by researching the types of GGT messenger RNA (GGTmRNA) in liver tissues and peripheral blood of different hepatopathy.

METHODS: The three types of GGTmRNA (A, B, C) in liver tissues and peripheral blood from the patients with HCC, noncancerous hepatopathy, hepatic benign tumor, secondary carcinoma of liver, and healthy persons were detected by reverse-transcription polymerase chain reaction (RT-PCR).

RESULTS: (1) In normal liver tissues, type A was predominantly found (100.00 %), type B was not found, type C was found occasionally (25.00 %). (2) The distribution of types of GGTmRNA in liver tissues with acute hepatitis, chronic hepatitis, cirrhosis, alcoholic hepatopathy was similar as in normal liver tissues ($P>0.05$), but type B was found in 3 of 18 patients with chronic hepatitis (16.67 %), and also in 3 of 11 patients with cirrhosis (27.27 %). (3) There was no significant difference of types of GGTmRNA between liver tissues with hepatic benign tumor, secondary carcinoma of liver and normal liver tissues ($P>0.05$). (4) Type B was predominant in cancerous tissues with HCC (87.5 %), the prevalence of type B in cancerous tissues was significantly higher than that in normal liver tissues (0/12) ($P<0.05$), but the prevalence of type A in cancerous tissues (46.88 %) was significantly lower than that in normal liver tissues (100.00 %) ($P<0.05$), and the prevalence of type C (6.25 %) in cancerous was the same as that in normal liver tissues (25.00 %) ($P>0.05$). In noncancerous tissues of livers with HCC, the main types were type A and type B, the prevalence of type A (85.71 %, 90.48 %) and type C (14.29 %, 9.52 %) in noncancerous tissues of liver with HCC was similar as that in normal liver tissues (A: 100.00 %; C: 25.00 %) ($P>0.05$), but the prevalence of type B (80.95 %, 76.19 %) in noncancerous tissues of livers with HCC was significantly higher than that in normal liver tissues (0/12) ($P<0.05$). (5) The prevalence of type B (37.5 %) in peripheral blood with HCC was higher than that in normal person (0/12) ($P<0.05$). In peripheral blood, type B was found in 4 of 11 cases of HCC with serum AFP negative.

CONCLUSION: The shift of types of GGTmRNA from A to B in liver tissues may be closely related to the development of HCC, and the analysis of GGT gene may provide a useful tool for early diagnosis of HCC.

INTRODUCTION

HCC is one of common fatal malignant tumors^[1-5]. About 90 percent of tumors originated from liver are HCC^[6-10]. There are more than 250 000 patients of HCC in the world every year, 44.7 percent of these patients are Chinese^[11-15]. The pathogenic mechanism, early diagnosis, and efficient treatment of HCC are very important. Many studies concerning GGT in HCC have suggested that changes in hepatic GGT expression may be closely related to the development of HCC. It has been reported that HCC in humans expresses GGT enzymes with unique carbohydrate moieties compared with normal liver enzymes. The presence of the unique GGT isoform for HCC in patient sera was used as a marker for the diagnosis of HCC. However, the genomic changes in GGT relating to the development of HCC are not known, and genomic analysis of the specific GGT to HCC is also lacking. In this study, the specific primer sets for reverse-transcription polymerase chain reaction corresponding to the 5'-noncoding human GGTmRNA of fetal liver (type A), HepG2 cells (type B), and placenta (type C) were prepared. in order to clarify the type of GGTmRNA in human liver and the relationship between alterations in GGTmRNA expression and the development of HCC, we detected the types of GGTmRNA in normal liver tissues and diseased liver tissues with or without HCC.

MATERIALS AND METHODS

All cases were divided into 8 groups by type of diseases: (1) healthy control group 12 cases, male 9 cases, female 3 cases. (2) HCC group 32 cases, male 26 cases, female 6 cases, small sized HCC (size ≤ 3 cm) 8 cases, large sized HCC (size 3-10 cm) 16 cases, enormous sized HCC (size >10 cm) 8 cases. 11 HCC patients with serum alpha fetoprotein (AFP) negative, 21 HCC patients were treated with surgery. (3) Acute hepatitis group 15 cases, male 11 cases, female 4 cases, hepatitis A 4 cases, hepatitis B 3 cases, hepatitis E 5 cases, drug hepatitis 3 cases. (4) Chronic hepatitis group 18 cases, male 12 cases, female 6 cases, hepatitis B 14 cases, hepatitis C 4 cases. (5) Cirrhosis group 11 cases. The diagnosis of acute hepatitis, chronic hepatitis and cirrhosis meet the standard of National Academic Conference about infectious disease^[16]. (6) Alcoholic hepatopathy group 13 cases, male 13 cases. (7) Hepatic benign tumor group 10 cases, male 8 cases, female 2 cases, hepatic hemangioma 6 cases, hepatic cyst 4 cases. (8) Secondary carcinoma of liver 13 cases, male 8 cases, female 5 cases, primary carcinoma of stomach 4 cases, primary carcinoma of colon 4 cases, primary carcinoma of lung 2 cases, primary carcinoma of prostate 1 cases, primary carcinoma of ovary 2 cases.

Sample collection

Collection of liver tissues: Cancerous tissues, adjacent

paracancerous tissues (to the brim of carcinoma 3-5 cm) and distal cancerous tissues (to the brim of carcinoma >5 cm) were respectively obtained during surgery from 21 patients with HCC, and the cancerous tissues and noncancerous tissues were obtained by needle liver biopsy with help of ultrasound B from the other patients of HCC (11 cases). Liver tissues were obtained by needle liver biopsy in the other groups, non-tumor tissues were merely obtained in hepatic benign tumor and secondary carcinoma of liver. All the tissue specimens were immediately refrigerated by liquid nitrogen for 1 hour, and then were transferred to refrigerator at -80°C for future use.

Blood samples: peripheral blood was obtained from each person at morning before breakfast, anticoagulated by sodium citrate solution, and then peripheral blood mononuclear cells (PBMC) were separated from blood, total RNA was extracted from PBMC, cDNA was synthesized with reverse transcription, and then reserved in refrigerator at -80°C .

Total RNA extraction

Total RNA was extracted by using TRIzol (from TECH-LINE company) and the purity of RNA was tested with ultraviolet spectrophotometer of DAOJUN UR-2201.

Detection of the types of GGTmRNA by RT-PCR

cDNA was synthesized with RNA, reverse transcriptase (M-MLV) and random primer (OligodTs). then cDNAs of GGTmRNA were amplified by PCR using polymerase and three different primer sets which were specific for the three GGTmRNA types. Nucleotide sequences of the primer sets to each type of GGTmRNAs are: type A sense 5' - CAC AGG GGA CAT ACA GTG AG-3', Antisense 5' - GAA ATA GCT GAA GCA CGC GC -3'; type B sense 5' - GGA TTC TCC CAG AGA TTG CC -3', antisense 5' - GAA GGT CAA GGG AGG TTA CC -3'; type C sense 5' - GCC CAG AAG TGA GAG CAG TT -3', antisense 5' - TCC AGA AAG CAG CTA GAG GG -3'. The condition of reaction: in advance denaturalization of 94°C for 3 min, and then PCR was performed with 30 cycles consisting of a denaturing step of 94°C 30 s, an annealing step of 58°C for 30 s and an elongation step of 72°C for 30 s. the final step at 72°C was extended to 8 min. The expected size of each PCR product is 308bp in type A, 300bp in type B, 386bp in type C. Products after gel electrophoresis by 1.3 % gelose were observed under ultraviolet radiation comparing with stander DNA.

Statistical analysis

The statistical software SPSS was used for statistical analysis, the level of significance was $P < 0.05$.

RESULTS

GGTmRNA in tissues

In normal liver tissues (12 cases), type A was the main type, it was found in all livers (100 %), type B was not found, type C was found in 3 cases, the GGTmRNA expression was monogenic (type A) in 9 livers and polygenic (type A + type C) in 3 cases (Table 1).

In liver tissues with acute hepatitis, chronic hepatitis, cirrhosis or alcoholic hepatopathy, type A was the main type (81.82-93.33 %), type C was found occasionally (13.33-23.08 %), the distribution of types of GGTmRNA was similar as in normal liver tissues ($P > 0.05$), type B was found in 3 cases with chronic hepatitis, 3 cases with cirrhosis, the prevalence of type B was higher than normal livers, but it was not significantly different ($P > 0.05$).

In 32 cancerous tissues with HCC, type B was the main type, it was found in 28 cases, the prevalence of type B in

cancerous tissues (87.5 %) was significantly higher than in normal livers ($P < 0.05$); type A was found in 15 cases, its prevalence in cancerous tissues (46.88 %) was lower than in normal livers ($P < 0.05$); the type C was not significantly different between cancerous tissues and normal liver tissues ($P > 0.05$). In 21 adjacent paracancerous tissues, 21 distal cancerous tissues and 11 noncancerous tissues, the main type was type A and B, the prevalence of type A (87.51 %, 90.48 %, 81.82 %) was similar as in normal livers ($P > 0.05$); however the prevalence of type B (80.95 %, 76.19 %, 72.73 %) was significantly higher than in normal liver tissues ($P < 0.05$); the prevalence of type C was similar as in normal livers ($P > 0.05$).

In nontumor tissues of livers with hepatic benign tumor and secondary carcinoma of liver, the distribution of GGTmRNA was similar as in normal livers ($P > 0.05$).

The relation between types of GGTmRNA and size of HCC: The prevalence of type A in cancerous tissues of larger sized HCC is lower than in that of smaller sized HCC, the monogenic pattern of type B tended to be found more frequently in larger sized HCC, but the difference was not significant ($P > 0.05$). Table 2.

Table 1 Incidence of Different GGTmRNA types in Livers of Each Group

Group	No. of Samples	Type of GGTmRNA		
		A (%)	B (%)	C (%)
1. Normal	12	12 (100%)	0	3 (25.00%)
2. Acute hepatitis	15	14 (93.33%)	1 (6.67%)	2 (13.33%)
3. Chronic hepatitis	18	16 (88.89%)	3 (16.67%)	4 (22.22%)
4. Cirrhosis	11	9 (81.82%)	3 (27.27%)	2 (18.18%)
5. Alcoholic hepatopathy	13	12 (92.31%)	1 (7.69%)	3 (23.08%)
6. Hepatic benign tumor	10	10 (100%)	0	1 (10.00%)
7. Secondary carcinoma of liver	13	11 (84.62%)	0	3 (23.08%)
8. HCC	32			
Cancerous tissues	32	15 (46.88%) ^a	28 (87.5%) ^a	2 (6.25%)
Adjacent Paracancerous tissues	21	18 (85.71%)	17 (80.95%) ^a	3 (14.29%)
Distal Cancerous tissues	21	19 (90.48%)	16 (76.19%) ^a	2 (9.52%)
Noncancerous tissues	11	9 (81.82%)	8 (72.73%) ^a	1 (9.09%)

^a $P < 0.05$ vs. normal liver.

Table 2 GGTmRNA and the size of HCC

	cases	Cancerous tissues type A	Cancerous tissues type B	Non cancerous tissues type B	Peripheral blood type B
Small sized HCC	8	5 (62.50%)	6 (75.00%)	5 (62.50%)	2 (25.00%)
Large sized HCC	16	7 (43.75%)	15 (93.75%)	14 (87.50%)	6 (37.50%)
Enormous sized HCC	8	3 (37.50%)	7 (87.50%)	7 (87.50%)	4 (50.00%)

GGTmRNA in peripheral blood

In peripheral blood of 32 patients with HCC, type A was found in 2 cases (6.25 %), type B was found in 12 cases, the prevalence of type B (37.5 %) was significantly higher than normal ($P < 0.05$), type C was found in 1 case (3.13 %). In peripheral blood of patients with acute hepatitis, type A was found in 2 cases. In chronic hepatitis group, type A was found in 1 case. Type B and C were not found in acute and chronic hepatitis group. In the other groups, GGTmRNA was not found. In 8 cases of small sized HCC, type B was found in 5 noncancerous tissues (62.5 %) and in peripheral blood of 2 cases (25 %). In the 8 cases, there were 3 patients with serum

AFP positive (37.5 %). Table 2.

In 21 cases of HCC with AFP positive, type B was found in peripheral blood of 8 cases (38.1 %). In 11 cases of HCC with AFP negative, type B was found in peripheral blood of 4 cases (36.36 %). Type B was not significantly different between them ($P>0.05$). Therefore the prevalence of type B in peripheral blood was not related to the prevalence of AFP.

DISCUSSION

Hepatocellular carcinoma is one of the common malignant tumor^[17-29], because of its severe malignance, quick development, early intrahepatic metastasis, mostly being combined with cirrhosis, frequent recurrence, the prognosis of HCC still remains dismal^[30-41]. By now, surgery is still the most efficient treatment for HCC, but about 70 percent of patients with HCC lost the opportunity of surgery, since they did not go to see a doctor until the tumor reached an advanced stage, and HCC reoccurred more frequently after surgery, on the other hand, HCC is not susceptible to radiotherapy, chemotherapy and other synthetic treatments^[42-44], so it is imperative to clarify the pathogenic mechanism of HCC and to find efficient methods for early diagnosis of HCC. The epidemiological studies suggested that the prevalence of HCC in patients with hepatopathy had been obviously increasing in China. At present, the pathogenic mechanisms of HCC are not well known, it is reported that the occurrence and evolvement HCC may be a process of polygenic and multiple steps, which related to polygenic expression, such as repair of DNA, signal transduction, cell cycle regulation etc^[45-52].

It is still difficult to monitor the canceration of liver cells in preneoplastic stage and early stage of HCC^[53]. If we could monitor the changes of the structure and function of some genes, we would find the patients with high risk of HCC, forecast the possibility of occurrence of HCC before cytological changes, and then we could prevent, make a diagnosis and give treatment on molecular level.

It has been reported that HCC synthesizes and secretes many proteins, polypeptides or isoenzymes such as AFP, GGT etc. they may be used as important marks for the diagnosis of HCC. GGT is closely relate to biotransformation, metabolism of nucleic acid, and the occurrence of carcinoma, it may be used as a mark for detection of bibulosity and the canceration of liver cells. In humans, the activity of GGT is at a very high level in embryo period, after birth it declines to a very low level quickly, HCC expresses a large amount of GGT and unique GGT isoenzyme. However, its mechanisms are not known. Human GGT gene is linked to a BCR gene-related segment that is located on band q11→qter of chromosome 22, maybe there is a family of GGT genes, it could suit for the various expressions of physiological aberrance and physiological state. Many studies concerning GGT complementary DNA (cDNA) sequences indicated that the cDNA sequences from fetal liver, HepG2 cells, and placenta showed identical open reading frame (ORF) consisting of 1707 nucleotide acids and GGT protein structure. The most significant difference among these cDNAs exists in the 5' -noncoding region^[54]. In the present study, polymorphisms of GGT mRNAs at the 5' -noncoding region from normal liver tissues and diseased liver tissues were analyzed with RT-PCR method.

In normal liver tissues, the main type of GGT mRNA was type A, the expression was monogenic in most cases (type A), but was polygenic in some cases (typeA+C).

In livers of acute hepatitis, chronic hepatitis, and cirrhosis, the distribution of types of GGT mRNA was nearly the same as in normal livers, but in livers of chronic hepatitis and cirrhosis, the prevalence of type B was higher than in normal livers ($P>0.05$).

In cancerous tissues with HCC, type B was predominant. In noncancerous tissues of livers with HCC, the main types were type A and B. The prevalence of type B was significantly higher in both cancerous and noncancerous tissues of livers with HCC than in normal livers and diseased livers without HCC. The prevalence of type A in cancerous tissues, but not in noncancerous tissues, was significantly lower than in normal livers and diseased livers without HCC. The prevalence of type A in noncancerous tissues of livers with HCC was similar as in livers without HCC. These results strongly suggest that the GGT mRNA expression in human liver may shift from type A to type B during the development of HCC. The prevalence of type B in noncancerous tissues of livers with HCC was significantly higher than in livers without HCC, and was similar as in cancerous tissues of livers with HCC. These suggest that the shift of the GGT mRNA may occur from the preneoplastic stage of hepatocytes. Type B was detected in livers of 3 cases with chronic active hepatitis and 3 cases with cirrhosis. It was not sure whether or not some liver cells in liver tissues of these 6 cases had developed to the preneoplastic stage or changed to cancerous cells, and whether or not these 6 patients would developed to HCC in the future. It need further follow-up study to answer these questions.

Among the patients of hepatic benign tumor and secondary carcinoma, the distribution of GGT mRNA in livers tissues but not tumor tissues was similar as that in normal livers. The results suggested that the shift from type A to type B did not exist in liver tissues with benign tumor and secondary carcinoma.

The serum level of GGT is mostly higher in patients with alcoholic hepatopathy, but the distribution of types of GGT mRNA in these liver tissues was similar as in normal liver tissues. This result suggested that alcohol did not induce the shift of GGT mRNA.

Studies about small sized HCC have been the important incident in the history of HCC in the past 20 years. Early diagnosis and treatment are the keys to increase survival rate and decrease recurrence rate. The detection of serum alpha-fetoprotein (AFP) is an important method for early diagnosis of HCC, especially in patients with high risk of HCC^[55,56]. However, the negative rate of AFP is higher in patients with small sized HCC. In present study, among the 8 patients with small sized HCC, type B was detected in noncancerous liver tissues of 5 patients, and in peripheral blood of 2 cases, however, AFP was positive in serum of only 2 patients. Moreover, in peripheral blood, type B of GGT mRNA was found in 4 of 11 HCC patients with AFP negative (36.36 %). These results suggested that the detection of unique type B of GGT mRNA may provide a useful tool for the diagnosis of the small sized HCC and HCC with AFP negative.

Since there are lots of RNA enzymes in blood plasma, RNA will be degraded by RNA enzymes as soon as it appears in plasma, so there are not dissociative GGT mRNAs in blood plasma in normal blood plasma. In this study, GGT mRNAs were not found in normal peripheral blood, however, among 32 cases of HCC, type B of GGT mRNA was found in peripheral blood of 12 cases (37.5 %). GGT mRNAs were not found in peripheral blood in other groups. So it may be inferred that cancerous cells exist in peripheral blood of this 12 patients. These results suggest that the shift of type of GGT mRNA are closely related to the development of HCC, and that analysis of GGT mRNA expression may provide a useful fool for early diagnosis of HCC.

Abstract

AIM: To study the effect of TNP-470 on cell growth, proliferation and apoptosis in human colon cancer xenografts in nude mice.

METHODS: Human colon cancer xenografts were transplanted into 20 nude mice. Mice were randomly divided into two groups. TNP-470 treated group received TNP-470 (30 mg/kg, s.c) every other day and the control group received a sham injection of same volume saline solution. They were sacrificed after 4 weeks and their tumors were processed for histological examination. The expression of proliferating cell nuclear antigen (PCNA) in tumors was detected using immunohistochemical method with image analysis, and apoptosis in tumor cells was measured by TdT-mediated biotinylated-dUTP nick end labeling (TUNEL) staining.

RESULTS: Comparing with controls, tumor growth was significantly inhibited in TNP-470 treated group, the inhibitory rate being 54.4 %. Expression of PCNA in tumors of TNP-470 treated group ($PI\ 54.32 \pm 11.47$) was significantly lower than that of control group ($PI\ 88.54 \pm 12.36$), $P < 0.01$. Apoptosis index (AI) of TNP-470 treated group (18.95 ± 1.71) was significantly higher than that of control group (7.26 ± 1.44), $P < 0.001$, typical morphological change of apoptosis in tumor cells was observed in TNP-470 treated group.

CONCLUSION: Besides the anti-angiogenic effects, TNP-470 can inhibit tumor growth by inhibiting the proliferation and inducing apoptosis of tumor cells.

INTRODUCTION

The worldwide incidence of colorectal cancer is estimated at 945 000 patients per year. Many of these patients present with metastases. The past decade has seen several extensive

investigations into advanced colorectal cancer. However, Most patients have limited improvement in long-term prognosis^[1]. Therefore, new therapeutic methods are needed to treat and improve the survival rate in colorectal cancer patients.

Tumors are always dependent on the development of an adequate blood supply through angiogenesis for growth at both primary and secondary sites, and colon cancer would not be an exception^[2-9]. The concept of anti-angiogenesis therapy was first proposed by Folkman^[10,11]. The implications of angiogenesis for tumor biology and therapy were investigated, and some anti-angiogenesis agents have been developed^[12-14]. TNP-470 is a potent angiogenesis inhibitor and an analogue of fimagillin, which is a natural antibiotic secreted by *Aspergillus fumigatus fresenius*^[15,16]. This agent shows a marked inhibitory effect on tumor growth and metastasis *in vivo*^[17-19]. Its target is not only the endothelial cells but also the cancer cells of the host, and the tumor is affected directly^[20-22]. In this study, we examined the inhibitory effect of TNP-470 on tumor growth of human colon cancer xenografts in nude mice. The expression of proliferating cell nuclear antigen (PCNA) in tumors was examined by immunohistochemical method and apoptotic cancer cells were measured by TUNEL assay.

MATERIALS AND METHODS

Drug and reagents

TNP-470 was a generous gift from Takeda Chemical Industries (Osaka, Japan). Its structure and characteristics have been reported. TNP-470 was suspended in a vehicle composed of 0.5 % ethanol plus 5 % gum Arabic in saline. RPMI 1640 and heat-inactivated fetal calf serum (FCS) were purchased from Gibco (Grand Island, NY).

Cell line

Human colon adenocarcinoma cell line Lovo was kindly provided by the Department of Pathology, Cancer Center, First Military Medical University (FIMMU). Cells were cultured in RPMI 1640 supplemented with 10 % FCS, and were maintained at 37 °C in 5 % CO₂. A single cell suspension of approximately 5×10^6 cells in 0.5 mL of culture medium was inoculated subcutaneously in two Balb/c nude mice to make source tumors. These source tumors were excised when they grew to approximately 1 cm³, and then 2 to 3 mm³ of minced tumor tissue was implanted subcutaneously into the left axial region of the cervix of each balb/c nude mouse on day 0.

Animals

Female Balb/c nude mice were obtained from the Experimental Animal Center, FIMMU, and reared under specific pathogen-free conditions. Four-week-old mice weighing 17-22 g were used in the experiments. On day 1 after implantation, tumor-bearing nude mice were randomly divided into a control group ($n=10$) and a TNP-470 treated group ($n=10$). In the TNP-470 treated group, TNP-470 of 30 mg/kg was injected subcutaneously every other day from day 1 until sacrifice. In the control group, mice received a sham injection of the same volume of saline. The average tumor volumes and animal

weights in the treatment and control groups were almost equal at the beginning of treatment.

Tumor growth and animal weights

The tumor dimensions were measured every 3 days with a dial caliper. The tumor volumes were calculated with the formula width 2 length 0.52. Mice were weighed every 3 days. The animals were painlessly killed on day 30. All animals were weighed before autopsy, at which time, the tumor weight and volume were obtained. The tumor volume was also expressed by the rate of the mean tumor volume in that treated animals to the mean tumor volume in that of control animals (T/S rate). Tumor tissues were resected and fixed intact with 10 % formalin solution, and then cut into four-micrometer-thick sections for PCNA immunohistochemical assay and TUNEL staining.

Immunohistochemical detection of PCNA

Four-micrometer-thick sections were incubated with mouse monoclonal antibodies against PCNA (Gibco, Grand Island, NY) as the primary antibody, followed by biotinylated anti-mouse immunoglobulin and avidin-biotin complex. The PCNA indices were calculated with image analysis system as the percent rate of positively stain Lovo cell nuclei to the total of Lovo nuclei. A minimum of 500 cells was counted in triplicate^[23].

TUNEL staining detection of apoptotic Lovo cells

We stained tumor tissue sections with terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick end labeling (TUNEL) to identify apoptotic cells^[24]. Briefly, the sections (after being dewaxed in xylene and rehydrated in ethanol) were incubated with 20 µg/L proteinase K at room temperature for 15 minutes. After quenching of endogenous peroxidase, sections were rinsed in TdT buffer (30 mM Tris, 140 mM sodium cacodylate, 1 mM cobalt chloride), pH 7.2, and incubated with TdT (Pharmacia Biotech, Piscataway, NJ, USA) 1:50 and biotinylated dUTP (Gibco, Grand Island, NY, USA) 1:50 in TdT buffer for 60 min at room temperature. Labeled nuclei were detected with DAB in PBS and counterstained with methyl green for 10 minutes and 5 minutes, respectively. The slides were then mounted and examined under light microscope. Negative controls were tissues processed with omission of the TdT reaction step. Cells were defined as apoptotic if the whole nuclear area of the cell labeled positively. The apoptotic cells and bodies were counted in 10 high-power fields, and this figure was divided by the number of cells in the high-power fields with image analysis system.

Statistical analysis

Data were expressed as mean ± standard deviation. Comparison between two groups was made by the independent samples *t* test. *P* < 0.05 was considered statistically significant. All statistics were carried out using SPSS10.0 statistics software.

RESULTS

Antitumor effects

Before treatment, the mean tumor volumes in the two groups were approximately the same. The mean tumor volume and tumor weight of two groups at the end of the experiment are shown in Table 1. Tumor growth curve is illustrated in Figure 1. Significant inhibitory efficacy was obtained in TNP-470 treated group.

Proliferation and apoptosis of lovo cells

In PCNA immunohistochemical analysis and TUNEL staining, the number and extent of apoptotic cells were considerably increased and PCNA positive cells were decreased in the TNP-

470 treated group compared with those on the control group. The proliferation index and apoptosis rate of Lovo cells in two groups are shown in Table 2.

Figure 1 Tumor growth curve.

Table 1 Tumor weight and tumor volume in two groups ($\bar{x} \pm s$)

Group	n	Tumor weight (g)	Tumor volume(mm³)	T/C(%)
Control	10	1.423±0.169	1345.24±38.46	100
TNP-470	10	0.830±0.123 ^a	731.66±40.42 ^b	54.4

^a*P* < 0.05; ^b*P* < 0.01, vs control.

Table 2 Proliferation index (PI) and apoptosis index (AI) in two groups ($\bar{x} \pm s$)

Group	n	PI (%)	AI(%)
Control	10	88.54±12.36	7.26±1.44
TNP-470	10	54.32±11.47 ^a	18.95±1.71 ^b

^a*P* < 0.01; ^b *P* < 0.001, vs control.

DISCUSSION

TNP-470 has been reported to be highly effective against a wide variety of tumors and metastases. This agent mainly exerts its anti-tumor effect by preventing tumor neovascularization^[25-27]. Angiogenesis is essential for the growth of solid tumors at primary and at secondary sites^[28]. It is thought that the new blood vessels in tumor are highly permeable and provide a route for cancer cells to enter the circulation^[29]. Therefore, anti-angiogenesis agents may have the potential to be clinically useful for the prevention of cancer progression.

TNP-470 is well described to antiproliferate the activity against endothelial cells and anti-angiogenic properties *in vivo*. In the recent study, TNP-470 was found to suppress DNA synthesis and cause an increased proportion of cells to go into the G0/G1 phase^[30-32]. A molecular target recently identified that TNP-470 is the mammalian protein MetAP-2. TNP-470 covalently attaching MetAP-2 in endothelial cells may prevent the myristylation of signaling components specific to cell cycle regulation of these cells, and inhibited the proliferation of endothelial cells^[33-35]. Other studies^[36,37] described that cell cycle inhibition by TNP-470 is mediated by p53 and p21^{WAF/CIP}.

TNP-470 has been reported to inhibit various tumor cell proliferation at concentrations much higher than those required to inhibit endothelial cells, yet the exact mechanisms underlying these effects are unclear. In contrast, there are reports that TNP-470 has no significant effect on primary tumors transplanted *s.c.*^[38]. These differences may arise because of organ-site-dependent differences in tumorigenesis and on cancer-cell properties. In addition, sensitivity to TNP-470 varied from tumors possibly due to the tumors' biological malignancy, the growth activity,

the metastasis rate, the adhesive activity to extracellular matrix and the production of VEGF^[10, 39, 40].

The antitumor activity of TNP-470 on a variety of tumors was evaluated *in vitro* and *in vivo*, but not in human colon cancer Lovo cells. In the present study, we found that TNP-470 inhibited the growth of human colon cancer cell line Lovo *in vivo* with an inhibitory rate (T/C) of 45.6 % and no weight loss was observed. Another important discovery in the present study was that TNP-470 could inhibit the expression of PCNA in tumors and induce apoptosis of cancer cells *in vivo*. But mechanisms of effect are not clear. Further studies *in vitro* will be necessary.

In conclusion, the present *in vivo* results demonstrated that treatment with TNP-470 could be efficient to inhibit the growth of colon cancer. Further investigation on the mechanism of the apoptosis-inducing effect of TNP-470 will help understand the mechanisms of tumor growth and metastasis.

Abstract

AIM: To study the clinical characteristics of hereditary nonpolyposis colorectal cancer (HNPCC) in the Chinese population and discuss the identification and management of the patients with HNPCC.

METHODS: A series of 140 patients with colorectal cancers (CRC) and HNPCC associated tumors from 30 families fulfilling the Amsterdam criteria were analyzed.

RESULTS: A total of 118 patients had CRC. Average age at diagnosis of the first CRC was 45.7 years, 56.8 % and 23.4 % of the first CRC were located proximal to the splenic flexure and in the rectum respectively. Twenty-three (19.5 %) had synchronous and metachronous CRC. Twenty-seven patients were found to have extracolonic tumors. Gastric carcinoma was the most common tumor type in our series (44.4 %).

CONCLUSION: The frequency of HNPCC was 2.6 % in our series of patients. The main features are an excess of early onset with a propensity to involve the proximal colon, and high frequency of multiple foci. Management and surveillance for these patients should be different from sporadic CRC. Contrary to American and European reports, gastric cancer seems more frequent than endometrial cancer in Chinese. It is necessary to formulate a new HNPCC criterion for Chinese patients.

INTRODUCTION

Hereditary nonpolyposis colorectal cancer (HNPCC), also known as Lynch syndrome, is a distinct autosomal dominant syndrome. It accounts for 1-10 % of the total colorectal cancer population^[1-9]. On the basis of the absence or presence of extracolonic malignancies, it can be subdivided into Lynch syndrome I (hereditary site specific colorectal cancer) and

Lynch syndrome II (colorectal cancer in association with extracolonic cancer)^[10,11].

The criteria for clinical diagnosis of HNPCC were established by the International Collaborative Group on Hereditary Nonpolyposis Colorectal Cancer (ICG-HNPCC) in 1991. These criteria known as the "Amsterdam criteria" are as follows: (1) Histologically verified colorectal cancer in three or more relatives, one of whom is a first-degree relative of the other two; (2) Colorectal cancer involving at least two generations; (3) One or more colorectal cancers diagnosed below age of 50 years. In the present study, 30 Chinese HNPCC families fulfilling the Amsterdam criteria were studied.

MATERIALS AND METHODS

Materials

From September 1994 to December 2001, 30 Chinese HNPCC families that fulfilled the Amsterdam Criteria were registered at the Department of Abdominal Surgery in the Shanghai Cancer Hospital / Institute. Of the 30 identified patients, 8 were found to have colorectal cancer before October 1998 and 5 were diagnosed and treated from June 2000 to December 2001. From October 1998 to May 2000, we consecutively investigated 392 patients with colorectal cancer (CRC) for their detailed family history. The remaining 7 cases were diagnosed on follow-up in the clinic.

Methods

When the probands were verified, we investigated the more detailed family history of patients in the hospital or in the clinic through inquiry by telephone and mail. The tree of each family pedigree was drawn. And these HNPCC patients are being followed up.

RESULTS

Tumor frequency

From October 1998 to May 2000, we investigated 392 patients with CRC for their detailed family history and 10 families with the clinical features of HNPCC were identified, resulting in an overall incidence rate of 2.6 %. The 30 families included 14 Lynch type I families and 16 Lynch type II families. A total of 140 patients developed malignant tumors, 118 (65 males and 53 females) of whom had CRC. The median age at diagnosis of the first colorectal cancer was 45.7 years (range from 20 to 79 years). Eighty-eight patients (74.6 %) developed CRC below 50 years, including 10 patients (8.5 %) under 30 years of age, 56.8 % and 23.4 % of the first colorectal cancers were located in the colon proximal to spleen flexure and in rectum, respectively. Synchronous and metachronous colorectal cancer occurred in 23 (19.5 %) patients.

Extracolonic colorectal cancer

Twenty-seven extracolonic tumors were found, including 10 stomach cancers, 4 endometrial carcinomas, 3 esophageal cancer, 2 hepatic cancers, one renal carcinoma, one pancreatic cancer, one breast cancer, one laryngeal cancer, one lymphoma

and one leukemia. Gastric cancer is the most frequent extracolonic cancer in our series, accounting for 44.5 %.

Pathology of colorectal cancers

We reviewed the HE of 18 cases available. Five (27.8 %) cases of mucinous adenocarcinoma or signet cell type carcinoma were found. Four (22.2 %) tumors had lymphocyte infiltration.

DISCUSSION

Amsterdam criteria I was adopted to diagnose HNPCC in this study. As the widely accepted criteria for diagnosis of HNPCC, the Amsterdam criteria were established by the International Collaborative Group on Hereditary Nonpolyposis Colorectal Cancer (ICG-HNPCC). But as clinical criteria, the Amsterdam criteria are too restrictive, thus leading to a number of limitations: (1) The failure to acknowledge the contribution of endometrial cancer and other extracolonic cancer to the HNPCC diagnosis. (2) Small family size or poor documentation of disease and cause of death limits the identification of many affected families^[12]. (3) New mutations are not likely to be identified. Estimates of HNPCC frequency varied from country to country. On the one hand, a difference actually exists among different areas, ethnics, nationalities, etc. On the other hand, these studies were not based on uniform criteria. Amsterdam criteria I and II, Japanese criteria and other criteria for suspected HNPCC were used in different studies. According to the Amsterdam criteria, many population-based studies in foreign countries yielded the frequency at 1-10 %. In 1999, a national epidemiological research done in Italy indicated a frequency of HNPCC of 7 %^[13]. Nevertheless, suspected HNPCC cases were included in this study. The actual frequency of HNPCC will be lower than 7 % obviously with Amsterdam criteria I. Another study by Peel *et al.* showed that the frequency of HNPCC was nearly 1 %^[14]. In China, Bo Zhao reported that HNPCC accounted for 5.2 % of the Chinese population^[15]. However, this study included 11 HNPCC families fulfilling Amsterdam criteria I and 5 HNPCC families according to Japanese criteria. The actual frequency of HNPCC was 3.6 % excluding the 5 families fulfilling Japanese criteria. The frequency of HNPCC was found to be 2.6 % in our study, which agrees with previous studies.

To solve this problem, many investigators developed additional criteria, such as the Japanese criteria for HNPCC. They include class A, in which there are three or more colorectal cancers within first-degree relatives, and class B, in which there are two or more colorectal cancers within first degree relatives, and any of the following: (1) early onset of colorectal cancer (age <50 years). (2) Right colon involvement, or (3) synchronous or metachronous colorectal and/or extracolonic cancers. Among our 392 patients, 24 families were found according to these criteria, accounting for 6.1 % of the total colorectal cancers. Compared with the Amsterdam criteria, the Japanese criteria are relatively looser, thus increasing the frequency for diagnosis of HNPCC. But there still remain some problems: (1) It does not give enough attention to extracolonic cancer in the diagnosis. (2) The early age of onset and transmissibility of HNPCC, which are the most striking characteristics of HNPCC, have not been emphasized. These weaknesses make it easy to diagnose sporadic colorectal cancers as HNPCC.

In 1998, new selection criteria for collaborative studies, called revised ICG-HNPCC or the Amsterdam criteria II, were proposed by ICG-HNPCC (The classic Amsterdam criteria were kept as Amsterdam criteria I). The new criteria include: (1) There should be at least three relatives with a histologically verified HNPCC-associated cancer (colorectal cancer, cancer of endometrium, small bowel, ureter, or renal pelvis), one of

whom is a first-degree relative of the other two. (2) At least two successive generations should be affected. (3) At least one should be diagnosed below 50 years of age. The new criteria raised the diagnostic value of some extracolonic cancers. Considering the risk of gastric and hepatic cancers is not high in the relatives, they excluded stomach cancer and hepatic cancer^[16], which were the most prevalent cancers in HNPCC families and in the general population of some Asian countries, including China, Korea, etc. The incidence of cancers of endometrium and small bowel is relatively lower than that of western countries. So the Amsterdam criteria II may be more applicable to western countries than to Asian countries. In our 392 consecutive colorectal cancer patients, except for the 10 families fulfilling the criteria I, no families met the Amsterdam criteria II. However, if we included other HNPCC-associated cancers in the criteria, 24 additional families would be found. Including the 10 families for criteria I, they accounted for 8.7 % of the 392 colorectal patients. We think that the specificity and sensitivity of the Amsterdam criteria II are not wholly suitable for the diagnosis of HNPCC in China. We have performed the detection of microsatellite instability, sequence analysis of mismatch repair genes and the detection of hMLH1 and hMSH2 protein on the probands of these 24 kindreds and 18 HNPCC patients. If we can detect the alteration of mismatch repair genes in these HNPCC families, we may include gastric and hepatic cancers in HNPCC related extracolonic tumors. Further epidemiological and genetic studies in China will advance our knowledge on HNPCC. The variance and similarity between Chinese and western countries should be evaluated. It is necessary to establish the Chinese criteria for HNPCC.

HNPCC is a syndrome that affects a distinct percentage of the total colorectal cancer population. It is characterized by the development of cancer at an early age^[17-19], predominance of proximal colonic cancer^[20-23], excess of multiple cancers^[24-27], an increased risk for selected extracolonic adenocarcinomas^[28], early occurrence of colonic adenomas^[16] and better prognosis^[29-31]. *In vitro* experiments showed that HNPCC is resistant to 5-Fluorouracil (5-FU), Cis-diaminedichloroplatinum (DDP) and Nitrogen mustard. By contrast, HNPCC is more sensitive to γ-rays. Identifying individuals afflicted with HNPCC has implications for early diagnosis, surgical management, chemotherapy, prognosis, follow-up, and surveillance of HNPCC patients and family members at risk. We have noticed that patients with HNPCC inherit a germline mutation in one of the genes responsible for repair of DNA mismatch errors^[32,33]. However, given the clinical unavailability for widespread application of gene test and the enormous cost for gene mutation hunting, selection of patients with HNPCC based on suspicious family history is still the most important approach^[34-36].

Early age of cancer onset is one of the most striking features about HNPCC. The average age to develop colorectal cancer was 45 years, 20 years earlier than the sporadic colorectal cancer. The study involving 43 HNPCC kindreds and 140 HNPCC patients by Bertario *et al* showed that the average age of onset was 49 years^[36]. Bo Zhao *et al* reported the mean age of cancer onset in 16 Chinese HNPCC families, which was 50.8 years in 68 patients^[15]. Another 13 HNPCC kindreds in China were reported by Sheng *et al* whose median age at diagnosis was 41 years. In Sheng's study, 68.75 % of the colorectal cancer developed below age of 50 years, and 90.63 % before 60 years of age^[37]. In the present study, the median age of onset of the first colorectal cancer was 45.7 years, with 74.6 % under age of 50 years and 8.5 % under 30 years of age.

Another important clinical characteristic of HNPCC is that the cancer is inclined to be located in the proximal colon. A Swedish national investigation in 2001 demonstrated the proportion of cancers located in the proximal colon was 51 %

of the total^[38]. Similar to the other reports, the colorectal cancer is more commonly found proximal to the splenic flexure (58.3 %) in our study. So a relatively young patient, especially younger than 50, with a proximal colon lesion is a clue to be noted. Special attention must be paid while inquiring into the family history. However, there were contrary reports. The percentage of cancers proximal to the splenic flexure was only 25 % in Peel's research^[14]. Given the early age of onset of the cancer and most of the tumor will develop in the proximal colon, we recommend that colonoscopy be performed for the family members with HNPCC and repeated annually or biannually thereafter from the age of 25 years. Flexible sigmoidoscopy is not an effective screening approach in this disease.

HNPCC also predisposes individuals to multiple synchronous and metachronous colon cancer. The prevalence rate of synchronous and metachronous colorectal cancer was about 35 %^[16]. Peel *et al* reported that 12.5 % of the patients had synchronous and metachronous cancers in the colon. Although the rate was not high, it was still higher than that of the patients without family cancer history and non-HNPCC cases with positive family cancer history, being 2.6 % and 5.9 % respectively. And the difference was statistically evident ($P=0.023$)^[14]. A domestic investigation in China showed the percentage of synchronous and metachronous colorectal cancers was 39.5 %. All of them developed within ten years after surgery and needed reoperations^[15]. In our series, 23 (19.5 %) of 118 patients presented with multiple cancers in the colorectum. The high incidence of multiple cancers implies that subtotal colectomy is an appropriate management when colon cancers are found in affected patients. It can reduce the chance of developing synchronous colorectal cancer and simplify the endoscopic examination^[39]. But considering the effect on the quality of life after subtotal colectomy and the psychological attack on the patients, we usually chose segmental resection for colorectal carcinoma and give intensive follow-up. Only when the patients were diagnosed with multiple cancers or adenomas at other segments, would subtotal colectomy be performed.

Individuals in HNPCC families had an increased risk of developing extracolonic carcinomas including endometrium, stomach, ovary, small intestine, pancreaticobiliary system, upper urological tract, and other sites. Fourteen Lynch type I families and 16 Lynch type II families were found in the 30 HNPCC families (0.88:1). There were 3 Lynch type I families and 13 Lynch type II families in a total of 16 HNPCC kindreds in Bo Zhao's study (0.23:1)^[15]. So extracolonic tumors are frequently seen in HNPCC patients and may contribute to the diagnosis of HNPCC. For this reason, extracolonic cancers were included in the Amsterdam criteria II. According to the reports of western countries, the endometrial and stomach cancers are the first and the second most common tumor in HNPCC, respectively. A study in Portugal revealed that endometrial carcinoma was most frequent in HNPCC extracolonic tumors, the prevalence among women patients even reached 25 %^[40]. In our series, of the 81 patients in the 16 Lynch syndrome II families, 27 developed extracolonic carcinomas. The three most common tumors were stomach cancer (12/27), endometrial carcinoma (4/27) and esophageal neoplasm (3/27). Different from the western countries, the incidence of stomach carcinoma was significantly higher than endometrial cancer ($P<0.05$). Bo Zhao *et al* in China reported 34 cases of extracolonic cancer in 16 HNPCC families. He also found stomach cancer was the most common extracolonic tumor in HNPCC (11 cases of stomach cancers) and endometrial cancer was less common (7 of 34) than gastric cancer^[15]. The difference in extracolonic tumor spectrum between China and western countries may lie in many aspects. The small size of our sample may be one of the reasons. Besides, different types of mutation or mutation loci and

interaction between environment, life style, ethnics and genotype may also contribute to the observed variation.

ACKNOWLEDGEMENTS

We are indebted to Professor Mo SJ for his critical advice for this study and assistance in collecting partial HNPCC cases. We also appreciate the help from Professor Shi DR for his pathological diagnosis and providing pathological data of patients.

Abstract

AIM: To evaluate the role of preoperative angiography in the diagnosis and treatment of colorectal cancer.

METHODS: The authors performed selective arterial cannulation by Seldinger's method in 47 patients to locate the primary cancer and to diagnose metastasis to the liver. Each patient was then given intra-arterial regional chemotherapy, and received 5-fluorouracil (5-Fu, 1 000 mg), mitomycin C (MMC, 20 mg), and cisplatin (CDDP, 80 mg).

RESULTS: The location and shape of each tumor were observed, including metastatic tumors in the liver, in 42 of the 47 (89.4 %) patients. The site of the primary tumor was difficult to identify in 5 cases because the patients had a recurrence of cancer. Arterial chemotherapy was performed successfully in all patients. The authors recorded no partial or significant morbidity resulted from angiography. The only incident was bleeding from the artery puncture site in one patient, which was successfully stopped by general medication.

CONCLUSION: Preoperative selective arterial angiography can help the diagnosis and locate primary tumors and to detect liver metastasis. At the same time, regional arterial chemotherapy can be an important form of preoperative therapy.

INTRODUCTION

Colorectal cancer is one of the three leading causes of worldwide cancer mortality^[1]. It is the second leading cause of cancer-related deaths in the Western world^[2]. Because of changes in life style and nutritional habits, the incidence of colorectal cancer is increasing in China. From 1972-1989, the incidence of colorectal cancer increased 85 % in men and 79 % in women. The average rate of increase in incidence was 4.2 % per year since 1970's. Of all cancers in China, colorectal cancer ranks the fifth in incidence. Although 80 % of patients initially can have the primary tumor completely resected, the cancer invades the serosa or involves the regional lymph nodes in

almost half of patients, predisposing them to a high risk of recurrence^[3]. Recurrent cancer of the large intestine is second in cancer-related deaths only to lung cancer^[4,5].

Colorectal cancers are detected mainly by endoscopic and radiological examination. However, endoscopy is unsuccessful in some patients who have a low tolerance for the procedure and in patients, especially elderly ones, who are physically unable to undergo a barium enema. In the United Kingdom a complete colonoscopic examination to the caecum is achieved in only 70 % of cases^[6].

Angiography has been used to define sites of gastrointestinal bleeding when endoscopy has been unsuccessful^[7]. To our knowledge, there have been no reports describing the significance of angiography to help diagnosis in colorectal cancer. Our present study assessed the clinical value of the angiography for colorectal cancer.

MATERIALS AND METHODS

Materials

Between Jan.1997 and Jan 1999, we enrolled in this study 47 consecutive patients (25 men, 22 women, age range, 37-81) with histologically or clinically proven colorectal cancer. All patients had normal cardiopulmonary, renal, and hepatic function. In addition, no patient had evidence of coagulopathy or had been previously treated with chemotherapy or any other anti-cancer treatment. Carcinoma was located in the rectum in 26 patients, in the sigmoid colon in 10, in the ascending colon in 7, in the descending colon in 1 and in the transverse colon in 3. Of the 47 tumors, 6 were classified on histologic study as mucinous adenocarcinoma and 41 were adenocarcinoma, of which 3 were poorly differentiated, 31 moderately to well differentiated, and 7 well differentiated. No case was defined as Dukes' s stage A; 3 were stage B1, 26 were stage B2, 13 were stage C, and 5 were stage D. Acute obstruction of the colon was seen in 6 patients, and 7 cases were postoperative recurrent tumor. In this group, 3 cases were colorectal cancer with hepatic metastases.

Methods

The groin was sterilized and prepared with local anesthesia. The abdominal aorta was catheterized through the femoral artery by Seldinger's method^[8].

In each patient, we selectively advanced the catheter into the vessel that supplied the tumor: the ileocolic artery for cancer of the ileoceum, right colic artery for cancer of the ascending colon, left colic artery for cancer of descending colon, sigmoid artery for cancer of the sigmoid colon, superior rectal artery and bilateral iliac arteries for cancers of the anus and most distal rectum^[9].

When these arteries could not be located, we placed the catheter into the superior mesenteric artery for the right half of the colon and the inferior mesenteric artery for the left half of the colon. Digital subtraction angiography (PHILIP INTEGERIS V 3 000, PHILIPS LTD, Holland) and the use of contrast dye of Ultravist 370 yielded a "Tumor flush" caused by the abnormal capillary mass of the tumor, which gave the exact location of the tumor. Then we infused chemotherapeutic agents into the tumor through the same artery; each patient received 5-fluorouracil (5-Fu 1 000 mg), mitomycin C (MMC,

20 mg), and cisplatin (CDDP, 80 mg).

Both the hepatic and superior rectal arteries were cannulated in one patient who had rectal cancer with multiple liver metastases.

RESULTS

We performed a digital subtraction angiography procedure (DSA) in 47 patients with colorectal cancer. We were able to locate the exact tumor site in 42 of 47 (89.4 %) angiographic studies, including six patients with acute obstruction of the colon (Figures 1-3). The location of the primary tumor was difficult to identify in 5 cases because the patients had a recurrence of cancer and liver metastases that were found at the same time of the DSA during angiography. Regional chemotherapy for primary colorectal cancer was successfully completed in 47 patients, and 3 patients received chemotherapy for metastatic tumors in the liver at the same time (Figure 4).

Figure 1 Detection of the tumor site by angiography. Carcinoma of the descending colon can be visualized.

Figure 2 Detection of a tumor in the rectum by angiography.

Figure 3 Angiography showing the tumor site in a patient with rectal carcinoma associated with liver metastasis.

Figure 4 Angiography showing multiple liver metastases in the same patient as in Figure 3.

DISCUSSION

In patients with symptoms of colorectal cancer, flexible colonoscopy or barium enema are usually performed, for definitive diagnosis. Cathartics are usually necessary to prepare for the barium enema. However, if plain radiographs of the abdomen show a dilated colon and acute colonic obstruction is suspected, a barium enema (or water-soluble contrast study) may be obtained without preparation to define the location and nature of the obstructing lesion. Some patients, especially older patients, are not able to finish rolling on the table during the examination. Although flexible colonoscopy is the most accurate and complete examination for the large bowel, some patients cannot tolerate the procedure. In addition, technical limitations, such as the inability to evaluate the splenic or hepatic flexures or the cecum, compromise the diagnostic usefulness of colonoscopy. Furthermore, colonoscopy is contraindicated in patients with suspected perforation or obstruction of the large bowel^[10,11]. Angiography is a safe and accurate technique for localizing acute gastrointestinal hemorrhage^[12]. Since 1996, we have used angiography to diagnose colorectal cancer and to deliver regional chemotherapy^[13,14]. Our rate of locating tumors with is 89.4 %, and we have simultaneously detected cases of colorectal cancer with metastatic liver tumors using angiography. During this procedure, patients have been able to lie comfortably on the table, even those in pain with an acute bowel obstruction induced by colorectal cancer. We had difficulty to find the site of the tumor of recurrent colorectal cancer by angiography because the vessels supplied the tumor had been ligated during the last operation. Regional chemotherapy has been widely used to treat solid tumors^[15,16]. The rationale for arterial chemotherapy is that arterial administration allows for high local levels of the drug without corresponding systemic toxicity^[17-20]. After intraarterial infusion of 5-Fu, drug levels at the tumor site has been reported to be 9-to 69-fold higher than those obtained during intravenous administration^[21]. Few studies have been published on intraarterial chemotherapy in primary colorectal cancer. In our study, chemotherapeutic agents were infused after angiography into vessels supplying the colorectal cancer. As we were reporting short-term results (less than 3 years), we did not see a statistical survival benefit in this study.

Distant metastases develop in 10-15 % of patients despite complete resection of the primary colorectal tumor^[22]. Colorectal cancer commonly metastasizes through lymphatic pathways and portal venous vessels to the liver^[23-25]. Thus, hepatic arterial chemotherapy is an attractive treatment option for bilobar non-resectable liver metastases in patients in whom the liver is the sole site of distant disease and recurrence^[26-31]. Furthermore, angiography and intra-hepatic artery infusion chemotherapy may be used simultaneously we make it possible

to be finished at the same period.

Local recurrence and distant metastasis are the most common reasons for treatment failure after surgical resection for colorectal cancer. Local recurrence of rectal cancer, with extension through the wall and with regional lymph node involvement, occurs in 50 % of patients. In patients with unresectable lesions, pain and organ obstruction are distressing and potentially devastating symptoms^[32]. It was reported that intraarterial infusion of 5-Fu and MMC by percutaneous placement of an infusion catheter in the bilateral internal iliac arteries relieved the pain in 50 % of patients with unresectable, recurrent rectal cancer^[33]. In our study, one patient with recurrent cancer having severe pelvic pain underwent angiography for diagnosis and then received intraarterial chemotherapy in the bilateral internal iliac arteries. After treatment, the pain was relieved, and the bowels were more easily evacuated. We are not sure of the mechanism underlying these treatment effects.

Abstract

AIM: To study hepatic virus C (HCV) RNA and HCV protein expression in peripheral blood mononuclear cells (PBMCs) of patients with HCV infection, and explore the relationship between the HCV RNA in the PBMCs and response to interferon (IFN) therapy.

METHODS: Type-specific primers were designed and RT-nested PCR was used to detect the plus- and minus- strands of HCV RNA in PBMCs of 54 patients with HCV infection; Indirect immunofluorescence assay was applied to identify HCVNS5 protein expression in PBMCs; 6 month-, 3 MU-IFN regimen was administered to observe the responses to IFN in 35 chronic hepatitis C patients with different HCV RNA status in PBMCs.

RESULTS: HCV plus strand RNA was found in 10 of 19 (52.6 %) acute hepatitis C patients and 22 of 35 (62.9 %) chronic hepatitis C patients. HCV minus strand RNA was detected in 14 of 35 (40.0 %) chronic hepatitis C patients, but only one patient (5.3 %) with acute HCV infection was found to be minus HCV RNA positive. Though no HCV NS5 protein expression was found in the examined 10 cases of acute HCV infection, it was positive in 17 of 20 (85.0 %) chronic hepatitis C patients by indirect immunofluorescence assay. There are significant differences of positive rate of the minus-strand and HCVNS5 protein between acute and chronic hepatitis C groups ($u=2.07$, $P<0.05$ and $u=4.43$, $P<0.01$ respectively). The patients with minus-strand HCV RNA showed a significantly lower 6-month sustained response (SR-6) to IFN compared to those without minus-strand HCVRNA in PBMCs (biologically 14.3 % vs 42.8 %, $\chi^2=4.12$, $P<0.05$ and virologically 7.1 % vs 23.9 %, $\chi^2=4.24$, $P<0.05$).

CONCLUSION: HCV is capable of infecting and replicating in PBMCs, and HCVNS5 protein was expressed in PBMCs. The patients with minus strand HCV RNA in PBMCs showed a significantly lower 6-month sustained response to IFN, suggesting that minus-strand HCV RNA in PBMCs may be one of the factors influencing response to IFN therapy.

INTRODUCTION

Hepatitis C virus (HCV), a single positive-strand RNA, belongs to the Flaviviridae family, and is the major cause of post-transfusion hepatitis. Infection with HCV usually results in chronic hepatitis, which may progress to cirrhosis and finally to hepatocellular carcinoma. The mechanisms responsible for the chronicity are unclear, one of which is supposed to be that HCV has the ability to escape the host immunity by mutations in genome. There are numerous genotypes of HCV worldwide, and genotype 1b is found to be responsible for the most cases of HCV infection in southern China^[1]. IFN has been a widely accepted drug for the treatment of patients with HCV infection for more than 10 years, and now combination of IFN with ribavirin becomes the choice of therapy^[3,4]. Reinfection of HCV after orthotopic liver transplantation has postulated that there exists extrahepatic sites suitable for HCV replication^[5,6]. The possible extrahepatic cells for HCV replication may be PBMC, cells in pancreas, adrenal gland, bone marrow and spleen, even in the cerebrospinal fluid^[2,7-9], among them, PBMCs have been the most controversial, in which the minus strand HCV RNA, a replicative intermediate of HCV, has been found. It still remains unclear whether HCV replication in PBMC is a factor influencing IFN therapy response. In this study, we not only detected the minus strand HCVRNA and HCVNS5 protein expression in PBMC of patients with hepatitis C, but also analyzed the relationship between minus strand HCVRNA in PBMC and IFN response.

MATERIALS AND METHODS

PBMC preparation

Blood samples were collected from 54 patients with hepatitis C virus infection from January of 1994 to January of 1998, all of them are positive for anti-HCV by ELISA (Sino-American Biotech. Company, China) and HCV RNA by RT-PCR (Sino-American Biotech. Company, China). PBMCs were separated from 10 mL of whole blood mixed with sodium citrate by density gradient centrifugation with ficoll-hypaque. The separated PBMCs were washed four times in 10 mL of RPMI-1640 and then frozen and stored at -70 °C until use.

Cellular total RNA extraction and RT-PCR

Total RNA of the PBMCs was extracted with an RNA isolation kit (Shanghai Huaxun Company, China) according to the manufacturer's instructions. Primers P1: 5' - CGCGCGACTAGGAAGACTTC-3' and P2: 5' - ATGTACCCCCATGAGGTTCGGC-3' (as the external pair), and P3: 5' -AGGAAGACTTCCGAGCGCGGTC-3' and P4: 5' -GAGCCATCTGCC CACCCCA-3' (as the internal pair) for RT-PCR were designed according to Okamoto *et al*^[10]. 5 μ l of PBMC RNA and 1 μ l of P1 (for producing cDNA of minus HCVRNA) or 1 μ l of P2 (for producing cDNA of plus HCVRNA) were added to the reverse transcription system (Promega, USA). The reverse transcription system includes 10 \times buffer 2 μ l, 25 mmol/L MgCl₂ 4 μ l, RNasin 1 μ l, AMVRT 15 U, 10 mmol/L dNTP 2 μ l with a total volume of 20 μ l by adding ddH₂O. After incubation for 30 min at 42 °C, the synthesized HCV RNA cDNA was exposed at 95 °C for 30 min to destroy AMVRT. The first PCR was performed with the

above synthesized HCV RNA cDNA as a template. The external primers (P1 and P2) were added into the PCR reaction mix. After pre-denaturing for 5 min, the reaction mix denatured at 94 °C for 60sec, annealed at 55 °C for 60sec and extended at 72 °C for 90sec for 35 cycles. The second PCR was performed same as in the first PCR except the production of the first PCR was used as the template and with the internal primers (P3 and P4). A total volume of 7 μ l the second PCR product was loaded onto 2 % agarose gel containing 0.5 μ g/mL EB. After electrophoresis, the gel was placed under ultraviolet ray to analyze the results (Figure 1).

Figure 1 Analysis of HCV RNA plus-strand (A) and minus-strand (B). Lane 1, 2, 3, 4, 5: Serum Samples from the patients with hepatitis C. 144bp means plus of minus strand HCV RNA. Lane 6: DNA marker (pGEM-7 HindIII/EcoRI).

Immunofluorescence assay

After being separated, PBMCs were suspended (1×10^7 cell \cdot mL⁻¹) in RPMI-1640, dropped on to slides, and air dried. The slides were then fixed in acetone for 20 min at -20 °C, washed with PBS, and air-dried. Mouse anti-human HCV NS5 McAb (1:400, Virostat, U.S.A) was added onto the slides. After 30 min incubation at 37 °C, the slides were washed three times in PBS, and then isothiocyanate-conjugated rabbit anti-mouse IgG was added and incubated for 30 min. Slides were then washed and observed under microscope (Figure 2).

Figure 2 Indirect immunofluorescent assay for detection of HCV NS5A protein. HCV NS5A was stained in green and distributed mainly in the cytoplasm of PBMCs.

Treatment with IFN

Three MU of Interferon α -2b (Tianjing Hualida, China) was administered intramuscularly three times a week for 6 months. The efficacy of interferon therapy is defined biochemically as normalization of serum (adding full term of ALT here!!!) (ALT) and virologically as serum conversion of HCV RNA. End-treatment response (ETR) refers to the response to IFN

when the treatment ends, and the sustained response (SR) refers to the response after the ending of treatment, i.e., SR-6 means response at 6 months after the ending of treatment.

RESULTS

HCV RNA and HCV NS5 protein in PBMCs of patients with hepatitis C virus infection

HCV plus-strand RNA was found in 32 of 54 (59.26 %) patients with HCV infection, among them 10 of 19 (52.63 %) with acute hepatitis C and 22 of 35 (62.85 %) with chronic hepatitis C were positive respectively, and there is no statistically significant difference between the two groups. HCV minus-strand RNA was detected positive in 14 out of the 35 patients with chronic hepatitis C (14 of 35, 40 %) and 1 of 19 patients with acute hepatitis C and a significant difference was found between these two groups ($u=2.07$, $P<0.05$). Regarding to HCV NS5 expression in PBMCs of patients with hepatitis C, 17 out of 20 patients with chronic hepatitis C were found positive, but all the 10 patients with acute hepatitis C were found negative, and there is a remarkable statistically significant difference between the two groups ($u=4.43$, $P<0.01$. see Table 1).

Table 1 HCV plus and minus RNA and HCV NS5 in PBMCs

	HCV RNA		HCV NS5
	Plus	minus	positive
Acute hepatitis C	10/19 (52.6%)	1/19 (5.3%) ^b	0/10 (0%) ^d
Chronic hepatitis C	22/35 (62.9%)	14/35 (40.0%) ^b	17/20 (85%) ^d

^bComparison of the detection rates of HCV minus-RNA between acute and chronic hepatitis C, $u=2.07$, $P<0.05$;

^dComparison of the detection rates of HCV NS5 protein between acute and chronic hepatitis C, $u=4.43$, $P<0.01$.

The influence of HCV RNA status in PBMCs on therapy response to IFN

Six-month regimen with 3MU of IFN- α 2b was completed in 35 patients with chronic hepatitis C, and the biochemical and virological ETR and SR-6 were evaluated. There is a tendency to have a lower response to IFN treatment in the patients with plus-strand HCV RNA positive in PBMCs, although no statistically significant difference was found when compared with the negative group. The patients with minus-strand HCV RNA in PBMCs showed a significantly lower SR-6 to IFN therapy than those without HCV RNA minus-strand, both biochemically (SR-6: 14.3 % vs 42.8 %, $\chi^2=4.12$, $P<0.05$), and virologically (SR-6: 7.1 % vs 23.9 %, $\chi^2=4.24$, $P<0.05$) (Table 2).

Table 2 The influence of HCV RNA in PBMC on interferon response

	HCV RNA plus strand		HCV RNA minus strand	
	Positive	Negative	Positive	Negative
ETR (Biochemical)	13 (59.1%)	7 (53.7%)	8 (57.1%)	13 (61.9%)
ETR (Virological)	11 (50.0%)	9 (69.2%)	6 (42.9%)	12 (57.1%)
SR-6 (Biochemical)	8 (36.7%)	6 (46.2%)	2 (14.3%) ^a	9 (42.8%) ^a
SR-6 (Virological)	6 (27.3%)	5 (38.5%)	1 (7.1%) ^c	7 (33.3%) ^c

^aComparison of biochemical SR-6 between HCV minus-RNA positive and negative groups, $\chi^2=4.12$, $P<0.05$; ^cComparison of virological SR-6 between HCV minus-RNA positive and negative groups, $\chi^2=4.24$, $P<0.05$.

DISCUSSION

Extrahepatic HCV replication has long been a controversial topic since the finding of the high rate of re-infection of grafts after orthotopic liver transplantation in the patients with the end-stage HCV induced liver diseases. Whether PBMCs is suitable for HCV replication is still uncertain. The detection of the minus strand HCV RNA is thought to be reasonable for the discovery of HCV replication because the minus strand RNA is the replicative intermediate of HCV. In recent years, several reports on the detection of HCVRNA in PBMCs have been published^[12-14]. Cribier *et al* incubated PBMCs healthy donors with HCV positive sera, and detected HCV RNA plus-strand and minus-strand using RT-PCR and *in situ* hybridization^[15]. Our results showed that HCV RNA plus-strand were common in the PBMCs of patients, in both acute and chronic infection patients. This high rate of plus-strand HCV RNA is usually thought to be resulted from the contamination of plasma, therefore, minus-strand HCV RNA was explored in the PBMCs from hepatitis C patients, which indicates the replication of HCV in PBMCs. In acute HCV infection, HCV RNA minus-strand is rare in PBMCs, but in the chronic group, the minus-strand HCV RNA is not uncommon in the PBMCs (14 of 35, 40.0 %), which is similar to what Chang *et al* reported^[16]. The ratio of HCV RNA minus-strand detected in chronic hepatitis C is much higher than that in acute hepatitis C, suggesting that the replication of HCV in PBMCs may play an important role in the processes of chronicity, and the mechanism could be that HCV in PBMCs can escape from clearance resulting from host immunity, and make the infection of HCV persistent. On the other hand, the dysfunction of the HCV infected PBMCs leads to immune function decline or in disorder, and this becomes more difficult for the host to clear intrahepatic HCV, so that the injure of hepatocytes persists^[17]. Although minus-strand HCV RNA is the replicative form and not found in patient's serum or plasma, indicating that is a more convincing parameter for HCV replication, some authors are still arguing that the minus-strand HCV RNA in the blood cells including PBMC may be artifacts from self-priming or mispriming during PCR reaction^[18,19], or contamination or passive absorption by circulating virus^[20,21]. To overcome that point, the expression of HCV related proteins in extrahepatic cells has become the key point for the identification of HCV replication. Sansonno *et al*, found HCV exists and replicates mainly in plasma of PBMCs, and the viral proteins, such as core protein, NS3 were found to be expressed in PBMCs^[22]. Chen *et al*, analyzed the relationship between HCV core expression in PBMCs and the diseased state of hepatitis C patients and found that the core protein was more intensely expressed in the nucleus of PBMCs from advanced chronic hepatitis C patients than that from the moderate patients^[11]. We further performed an indirect immunofluorescent assay for HCVNS5 protein and its expression was found mainly in cytoplasm of PBMCs from patients with chronic hepatitis C. Our results indicate that HCV not only replicates but also produces its related protein in PBMCs.

IFN is known to possess both immunomodulatory and antiviral activities. It is tempting to postulate that IFN therapy may enhance the host immune response to promote the clearance of HCV infection. IFN is currently the only approved efficient drug for hepatitis C infection, and combined with ribavirin, its antiviral activity will be increased^[3,4,23]. Serum HCV load and the HCV subtypes have been considered as the major factors to influence the response to IFN therapy^[28,29]. Others influencing factors include the increased amount of Mxα mRNA, the higher complexity of HCV quasispecies and the frequency of mutations in NS5A region^[30-33]. The extrahepatic HCV replication, especially in the PBMCs, acts

as a predictor for the response to IFN therapy needs to be explored. Omata *et al*, reported a prospective IFN study, in which most of patients treated with IFN obtained normalization of serum aminotransferase, whereas only 3 cases from the control showed such change ($P < 0.02$); serum hepatitis C virus RNA became undetectable in 10 of 11 treated cases, but in only 1 of 12 patients of control group. IFN prevents the progression of acute hepatitis C to chronicity by eradicating HCV. The response of patients with chronic hepatitis C to IFN treatment was significantly lower than that of patients with acute hepatitis C. That the detection ratio of HC VRNA minus in PBMC of chronic hepatitis C is significantly higher than that of acute hepatitis C suggests that the replication of HCV in PBMCs is an important factor influencing the response to IFN treatment^[24]. Löhr *et al*, reported that there was no relationship between HCVRNA minus-strand in PBMC and the response to IFN treatment^[25]. Others reported that the replication of HCVRNA in PBMC may be the source of relapse after IFN treatment in chronic hepatitis C^[26,27]. The different HCV quasispecies in liver or PBMC may response to IFN differently and the quasispecies in PBMCs should be considered to predictor in response to IFN therapy^[34-36]. Our results show the replication of HCV RNA in PBMC can influence the response to IFN. The patients with HCVRNA minus-strands in PBMC had a significantly lower 6-month sustained response to IFN, both biochemically and virologically, than those without minus-strand, suggesting HCV replication in PBMCs may be one reason for relapse after treatment with IFN.

Abstract

AIM: To study the effect of a novel targeted ribonuclease (TN), the fusion protein of HBVc and human eosinophil-derived neurotoxin (hEDN), on the HBV replication *in vitro*.

METHODS: The gene encoding the targeted ribonuclease was cloned into pcDNA3.1 (-) to form recombinant eukaryotic expression vector p/TN. Control plasmids, including p/hEDN, p/HBVc, and p/TNmut in which a Lys113→Arg mutation was introduced by sequential PCR to eliminate the ribonuclease activity of hEDN, were also constructed. Liposome-mediated transfection of 2.2.15 cells by p/TN, p/TNmut, p/hEDN, p/HBVc, and pcDNA3.1 (-), or mock transfection was performed. After that, RT-PCR was used to verify the transgene expression. Morphology of the transfected cells was observed and MTT assay was performed to detect the cytotoxicity of transgene expression. Concentration of HBsAg in the supernatant of the transfected cells was measured using solid-phase radioimmunoassay.

RESULTS: Transgenes were successfully expressed in 2.2.15 cells. No obvious cytotoxic effect of transgene expression on 2.2.15 cells was found. The HBsAg concentration in the p/TN transfected cells was reduced by 58 % compared with that of mock transfected cells. No such an effect was found in all other controls.

CONCLUSION: The targeted ribonuclease can inhibit HBV replication *in vitro* while it has no cytotoxicity on host cells. The targeted ribonuclease may be used as a novel antiviral agent for human HBV infection.

INTRODUCTION

Hepatitis B virus (HBV) infection is still a major health concern around the world. Globally, more than 350 million people are infected by HBV, and some of them will evolve into liver cirrhosis and hepatocellular carcinoma (HCC)^[1-3]. Although vaccination can elicit effective immunity in about 95 % of inoculated people, the non-responders to vaccination who may contact HBV infection in their life, the threat of escape mutants,

and the huge amount of currently infected people call for an effective treatment^[4-6]. Interferon- α (IFN- α) is the first choice for the treatment of chronic HBV infection. However, the sustained response rate to IFN- α treatment is only about 30 %^[7]. IFN- α can also cause many adverse effects, such as fatigue, fever, neutropenia, autoimmune disease, psychological problems, and so on^[8]. Nucleotide analogues such as lamivudine can inhibit replication of HBV *via* inhibiting the synthesis of minus-strand DNA of HBV, but cease of the treatment usually leads to relapse of the infection and drug-resistant virus variants have emerged^[9-11]. Antisense nucleotides and ribozymes have been reported to suppress HBV replication *in vitro*^[12-17]. However, up to now, antisense nucleotides and ribozymes can generally only moderately inhibit HBV replication intracellularly. In a word, the limited efficacy of current treatment for HBV infection justifies the search for new treatment strategy.

Capsid-targeted viral inactivation (CTVI), first proposed by Natsoulis and Boeke in 1991, is a conceptually powerful antiviral approach^[18]. The principle of CTVI is to construct a fusion protein of viral capsid protein and some degradative enzyme. The capsid part of the fusion protein serves to target the degradative enzyme to virions and the degradative enzyme can specifically destruct the component of the virions. The degradative enzymes used presently are nucleases though other enzymes such as lipases and proteinases can also be used in CTVI in principle. CTVI has been thoroughly investigated in the experimental treatment for retrovirus, such as Moloney murine leukemia virus (MMLV) and HIV, showing a promising prospect as an antiviral treatment^[19-26].

The replication of Hepadnavirus, including HBV, is unique in DNA virus in that it needs a RNA intermediate and a reverse transcription process^[1]. This 3.5 kb RNA intermediate contains all genetic information of HBV and is so called pregenomic RNA (pgRNA). The pgRNA is first translated to both the capsid, or core, protein (c protein) and the DNA polymerase protein (P protein). Then the pgRNA is bound first by P protein and cellular chaperones to form a complex which is then encapsidated by C protein^[27-29]. Inside the nucleocapsids, P protein catalyzes the synthesis of minus-strand DNA via reverse transcription and then the incomplete plus-strand DNA. The nucleocapsids containing minus- and plus-strand DNA can reenter nucleus or bud into endoplasmic reticulum and then be released via secretory pathway out of host cells^[30]. C-terminal 144-164 amino acids of C protein, rich in arginine, is necessary for pregenome encapsidation since particles formed by C mutant deleting this domain contain no pgRNA^[31].

The replication characteristic of HBV hints CTVI can also be applied to this malicious virus. Previously, we reported the construction of a fusion protein of HBV C protein and a ribonuclease, human eosinophil-derived neurotoxin (hEDN)^[32-34]. In this paper, we found that this fusion protein, which was named as targeted ribonuclease in this paper, could effectively inhibit the replication of HBV, while had no cytotoxicity on host cells.

MATERIALS AND METHODS

Cell culture

2.2.15 cell line, human hepatoblastoma Hep G2 cell line stably transfected by HBV genome^[35-37], was kindly provided by Dr.

Cheng (Chinese PLA 302 Hospital) and cultured in Dulbecco's modified Eagle's medium (DMEM, purchased from Gibco Life Technologies, Grand Island, NY) supplemented with 100 mL/L fetal calf serum (Sijiqing Biotech Company, Hangzhou).

Plasmid construction

Targeted ribonuclease eukaryotic expression plasmid p/TN (Figure 1) and control plasmids p/hEDN and p/HBVc were constructed with the method previously reported^[34]. Briefly, cDNA coding for hEDN or HBVc was amplified by RT-PCR from the total RNA isolated from HL60 cell line (kindly provided by Professor Boquan Jin, Department of Immunology, Fourth Military Medical University) or 2.2.15 cell line. Then, the PCR product was cloned into pUC18. After verification of the correctness of the open reading frames of the cloned hEDN and HBVc by sequencing, they were subcloned into pcDNA3.1 (-) (Gibco Life Technologies), to generate p/hEDN and p/HBVc, respectively, or they were ligated together by T4 ligase (Gibco Life Technologies) and the ligated DNA fragment was cloned into pcDNA3.1 (-) to form p/TN. To construct control plasmid p/TNmut in which the DNA fragment encoding hEDNmut (hEDN mutated for just one amino acid, Lys113→Arg, which eliminates the ribonuclease activity^[38]) substituted for hEDN in p/TN, sequential PCR was used to obtain hEDNmut-encoding DNA fragment (Figure 2). For the first round of two separate PCR reactions, primers M1, N2 and M2, N1 (all synthesized by Sangon Company, Shanghai) were used, respectively, and pUC18/hEDN was used as template. The sequences of the primers are as follows:

N1: 5'-GCA GAA ACC AAA ATA CTT TCC T-3'

N2: 5'-TCT GCA TCG CCG TTG ATA ATT-3'

M1: 5'-GCG CGG ATC CAC CAT GAA ACC TCC ACA GTT TAC-3'

M2: 5'-GCG CGA GCT CGA TGA TTC TAT CCA GGT G-3'

The underlined nucleotides in N1 and N2 were used to introduce the mutation. The PCR products of the two reaction were mixed together. Two μ L of the mixture was used as the template, M1 and M2 were used as primers for the next round of PCR. The PCR product of this round amplification was cloned into pUC18 and sequenced for confirmation of the mutation. Then the hEDNmut gene was subcloned into p/TN to substitute hEDN gene to generate recombinant plasmid p/TNmut. pcDNA3.1(-)/GFP was generated by transferring green fluorescent protein (GFP) gene from pEGFP-N3 MCS (Clontech, Palo Alto, CA) into pcDNA3.1(-).

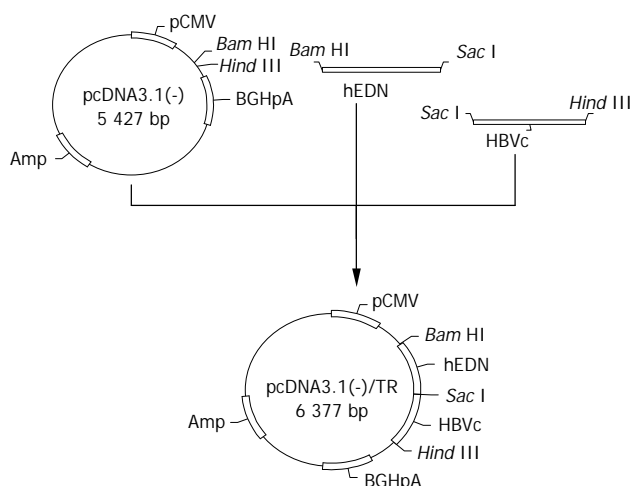

Figure 1 Construction of p/TN. cDNA coding for hEDN or HBVc was amplified by RT-PCR, ligated together, and then cloned into pcDNA3.1 (-) to form p/TN.

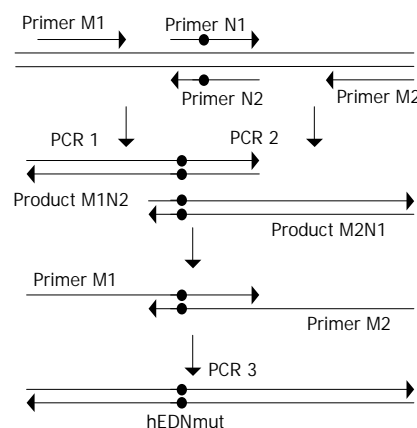

Figure 2 Generation of hEDNmut gene by sequential PCR. For PCR 1 and 2, pUC18/hEDN was used as template. Primers pair M1 and N2 were used in PCR 1 and N1 and M2 in PCR 2. For PCR 3, the mixture of PCR 1 and 2 product was used as template and M1 and M2 as primers. The black dots in the figure denote the nucleotides introducing the Lys113→Arg mutation which eliminates the ribonuclease activity.

Transfection

Twenty-four h before transfection, 2.2.15 cells were seeded into the culture plate at a density of 2×10^5 /L. LipofectamineTM 2000 reagent (Gibco Life Technologies) was used for the transfection of 2.2.15 cells by p/TN, p/TNmut, p/hEDN, p/HBVc, pcDNA3.1 (-), or mock solution (DMEM plus LipofectamineTM 2000 reagent containing no plasmid) according to the manufacturer's protocol. The amount of LipofectamineTM 2000 reagent (approximately 3.1 μ L/cm² surface area in this study) and the concentration of DNA (approximately 1 μ g/cm² surface area in this study) were first optimized in a preliminary transfection of 2.2.15 cells by pcDNA3.1(-)/GFP in which GFP gene was used as a reporter gene.

Confirmation of transgene expression by RT-PCR

Forty-eight h after the transfection, total RNA was isolated from transfected 2.2.15 cells using Trizol[®] reagent (Gibco Life Technologies) according to the manufacturer's protocol. One μ L of total RNA was used as template. RT-PCR was performed using SuperScriptTM One-step RT-PCR kit (Gibco Life Technologies) as recommended by the manufacturer. Forward primer was T7 promoter primer which is upstream to the multicloning site of pcDNA3.1 (-). Reverse primer was complementary to pcDNA3.1/BGH reverse priming site which is downstream to multicloning site of pcDNA3.1 (-). The sequences of the two primers are as follows:

Forward primer: 5'-TAA TAC GAC TCA CTA TAG GGA GA-3'

Reverse primer: 5'-TAG AAG GCA CAG TCG-3'

The condition of RT-PCR was: 50 °C 30 min, 94 °C 2 min, then 40 cycles at 94 °C 30 s, 60 °C 30 s, and 72 °C 2 min. To ensure that the amplified product was from RNA, but not DNA, a control was set up for each RT-PCR reaction, in which the reverse transcriptase was omitted.

Quantification of HBsAg in supernatant of cell culture

Forty-eight h after the transfection, the supernatant of the cell culture was collected, and HBsAg in the supernatant was quantified using the Solid Phase Radio-immunoassay Kit for Quantification of HBsAg (Beimian Dongya Biotech Institute, Beijing) according to the manufacturer's protocol. Briefly, 200 μ L of the supernatant was incubated with plastic bead coated by anti-HBs Ab at 45 °C for 1.5 h. After thorough washing, the bead with deionized water, 200 μ L of ¹²⁵I-labelled secondary antibody was added and incubated at room

temperature overnight. The bead was thoroughly washed, and cpm was measured. The concentration of HBsAg of each sample was obtained by comparing the cpm of each sample with a standard curve.

MTT assay

Forty-eight h after the transfection, 20 μ L of MTT solution (the concentration of MTT was 5 g/L) was added to each well and the culture plate was incubated at 37 °C for 4 h, then 150 μ L of DMSO was added to each well and the plate was shaken for 10 min. The A_{490} value of each well was obtained by an ELISA reader.

Statistical analysis

Variance analysis and Student's *t* test were used for data analysis. Differences were considered significant when $P < 0.05$.

RESULTS

Transgene expression in 2.2.15 cells

As shown in Figure 3, the results of the RT-PCR indicated that the transgenes were expressed in transfected 2.2.15 cells.

Figure 3 Confirmation of transgenes expression in transfected 2.2.15 cell line. Forty-eight h after the transfection, total RNA was isolated from transfected 2.2.15 cells and RT-PCR was performed to confirm the expression of transgenes. The RT-PCR products were then electrophoresed in 1.2 % agarose gel. Lanes 1-5 represent the RT-PCR results for total RNA isolated from 2.2.15 cells transfected by p/TN, p/TNmut, p/HBVC, p/hEDN, and pcDNA3.1 (-), respectively. Lanes 6-10 represent controls corresponding to lanes 1-5, respectively, in which reverse transcriptase was omitted in RT-PCR. M: DNA Marker (2000, 1000, 750, 500, 250, 100bp from top to bottom).

The effect of targeted ribonuclease on cell viability

The morphological alterations of the transfected 2.2.15 cells were observed under microscope. There were no discernible morphological differences of 2.2.15 cells transfected with p/TN, as compared with the controls (Figure 4). To further analyze the effect of targeted ribonuclease on cell viability, MTT assay was performed. The A_{490} value of 2.2.15 cells transfected with p/TN, p/hEDN, p/HBVC, p/TNmut, pcDNA3.1 (-), and mock transfection was 0.425 ± 0.065 , 0.465 ± 0.050 , 0.410 ± 0.075 , 0.438 ± 0.042 , 0.413 ± 0.063 , and 0.430 ± 0.065 , respectively ($\bar{x} \pm s$, $n=4$).

There were no significant differences between A_{490} value of 2.2.15 cells transfected with p/TN and those of controls ($P > 0.05$). Taken together, these results indicated that the targeted ribonuclease had no adverse effects on cell viability and proliferation.

Inhibition of HBV replication by targeted ribonuclease

As shown in Figure 5, the concentration of HBsAg in the supernatant of 2.2.15 cells transfected with p/TN was significantly lower than controls ($P < 0.05$), while that of 2.2.15 cells transfected with p/TNmut, p/hEDN, p/HBVC, pcDNA3.1 (-), or mock transfection did not significantly different from each other ($P > 0.05$). Compared with that of mock transfected

2.2.15 cells, the concentration of HBsAg in the supernatant of 2.2.15 cells transfected with p/TN was decreased by 58 %.

Figure 4 Morphology of 2.2.15 cells 48 h after transfection. A-F represent 2.2.15 cells transfected by p/TN, p/hEDN, p/HBVC, p/TNmut, pcDNA3.1 (-), or mock transfection, respectively. There were no discernible morphological differences of 2.2.15 cells transfected with p/TN, as compared with the controls.

Figure 5 The HBsAg concentration in supernatants of transfected 2.2.15 cells. Groups A-F represent 2.2.15 cells transfected by p/TN, p/hEDN, p/HBVC, p/TNmut, pcDNA3.1 (-), or mock transfection, respectively. The concentration of HBsAg in the supernatant of 2.2.15 cells transfected with p/TN was decreased by 58 % as compared with that of mock transfected 2.2.15 cells.

DISCUSSION

Theoretically, CTVI has many advantages in the treatment of viral infection^[39]. First, CTVI is highly specific. This high specificity is conferred by the encapsidating capacity and self-assembly property of the viral capsid protein which is used as a targeting molecule in CTVI. Second, CTVI is highly efficient. The nuclease, which is used as an effector molecule in CTVI, is a protein enzyme, and its catalytic efficiency is higher than ribozyme. Third, escape mutants may rarely if not impossibly arise in case of CTVI since viral capsid proteins generally play important roles in virus assembly and infection. Fourth, while

ribozyme and antisense RNA can only be used clinically in the form of gene therapy, CTVI can be used in the form of either gene therapy or recombinant protein drug. The results of experimental research also indicate that CTVI is a promising antiviral strategy. Boeke *et al.* reported that the fusion protein of Gag of murine Moloney leukemia virus (MMLV) and staphylococcus nuclease could reduce the infection titer of MMLV by 20-60 %, while that of Gag and ribonuclease H1 of *E. coli* could inhibit the production of MMLV by 97-99 %^[21,24]. Recently, Schumann *et al.* tested the antiviral effect of CTVI *in vivo* using transgenic murine models^[26]. They found Gag-nuclease fusion protein could significantly inhibit MMLV replication, ameliorate the symptoms, and increase the life span up to 2.5 fold in transgenic mice. Furthermore, they found that the fusion protein was nontoxic for transgenic mice, confirming the previous *in vitro* cell culture results^[19-25]. In this report, we demonstrated that targeted ribonuclease constructed by us (the fusion protein of HBVc and hEDN) could reduce the concentration of HBsAg in the supernatant of the transfected 2.2.15 cells by 58 %. Although it is controversial that the decrease of HBsAg concentration is caused by some factors other than the inhibition of HBV replication by targeted ribonuclease, our results strongly disprove this argument. First, the fact that transfection of p/TN decreased HBsAg concentration in the supernatant while p/HBVc and p/TNmut, which are identical to p/TN except for only one amino acid mutation but lose ribonuclease activity, indicates that the reduction of HBsAg is dependent on the activity of the ribonuclease in the fusion protein targeted ribonuclease. Second, transfection of p/hEDN did not affect the HBsAg concentration, showing that the reduction of HBsAg relies on the existence of HBVc in the fusion protein. Our present results are most consistent with a model that the targeted ribonuclease encapsidates the pgRNA together with wild type capsid protein and then degrades it (also see below). This model has been corroborated by some recent research reports^[19-26, 40]. On the other hand, 58 % reduction of HBsAg in the supernatant of 2.2.15 cells caused by the targeted ribonuclease might be an underestimate for the inhibition of HBV replication since besides present in mature virions as envelope protein, a large amount of HBsAg was synthesized and secreted as 22 nm spherical and filamentous particles by 2.2.15 cells using 2.1kb HBV mRNA as transcript which, unlike pgRNA, can not be encapsidated and therefore may not be degraded by the targeted ribonuclease^[35,37]. Therefore, even if the targeted ribonuclease can strongly inhibit HBV replication, there might still be a large amount of HBsAg secreted extracellularly. The mechanism for the decrease of HBsAg concentration caused by the targeted ribonuclease might be as follows: the degradation of HBV pgRNA by targeted ribonuclease leads to the decrease of P and C protein of HBV since pgRNA also acts as mRNA for the translation of both proteins. The reduction of pgRNA, P and C protein will impair the assembly of viral capsid and then reduce the mature virions released from host cells. Further analysis including Northern and Southern blot is being performed in this laboratory to clarify the degree of inhibition on HBV replication by the targeted ribonuclease and to elucidate at what stage of HBV replication the targeted ribonuclease exerts its antiviral role.

In the process of this study, Beterams and Nassal reported their CTVI application for inhibition of HBV replication *in vitro*^[40]. Although both their research and ours used the same strategy against HBV replication and both used HBVc as the target molecule, the effector molecules adopted were different. Bererams *et al.* used staphylococcal nuclease (SN) and we used hEDN. Compared with SN, hEDN may be more suitable for the treatment of HBV infection in human beings because as a human-origin molecule, hEDN will not induce specific

immunity which may not only decrease the efficacy of CTVI but also induce immunopathological response. The difference of the effector molecules also means the targets of CTVI in the two studies were different. SN is generally believed to be active only extracellularly because it requires a high Ca^{2+} concentration present extracellularly but not intracellularly for its activity^[41]. Therefore, SN-capsid protein incorporated into the virion is only active in degrading the viral nucleic acids upon release of the virion from the cell into an extracellular milieu^[18-19, 21, 23, 25-26]. According to this scheme, the targeted SN in Beterams *et al.*'s study can only degrade the relaxed circular (RC) DNA of mature virion released from the cell. Although they suggested in their reports that targeted SN might be mildly activated intracellularly by somewhat unknown mechanism and then cut pgRNA and minus-strand DNA of HBV, their results showed targeted SN had no significant effect on pgRNA. In contrast, the effector molecule in our study, hEDN, is a ribonuclease. Therefore, the target molecule degraded by the targeted ribonuclease constructed by us is most probably HBV pgRNA, the only RNA stage in the replication of HBV. As stated above, this notion is also supported by our experimental results, since the ribonuclease activity of hEDN is necessary for the anti-HBV effect of targeted ribonuclease. Similarly, onconase, an amphibian ribonuclease was reported to inhibit HIV replication intracellularly by degrading HIV RNA^[42]. The degradation of HBV pgRNA will not only lead to less mature virions released from host cells, which means secreted viral particles had lower infectivity, but also inhibit the amplification of HBV closed circular DNA (cccDNA) which is downstream to pgRNA in HBV replication^[43]. This inhibition on HBV cccDNA amplification is of pivotal significance for the treatment of chronic HBV infection since the amplification of cccDNA, the template for all HBV transcripts, plays a major role in the persistence of HBV in infected hepatocytes^[1, 30].

In summary, we constructed a novel targeted ribonuclease which can specifically inhibit HBV replication but has no cytotoxicity for host cells. Our results raise the possibility of using the targeted ribonuclease as a therapeutic agent for human HBV infection. For this purpose, we are generating recombinant adenovirus vector carrying the targeted ribonuclease to test its antiviral efficacy in HBV murine model.

Abstract

AIM: To investigate the interaction between hepatitis C virus core protein and translin protein and its role in the pathogenesis of hepatocellular carcinoma and lymphoma.

METHODS: With the components of the yeast two hybrid system 3, "bait" plasmids of HCV core the gene was constructed. After proving that hepatitis C virus core protein could be firmly expressed in AH109 yeast strains, yeast two-hybrid screening was performed by mating AH109 with Y187 that transformed with liver cDNA library plasmids - pACT2 and then plated on quadruple dropout (QDO) medium and then assayed for α -gal activity. Sequencing analysis of the genes of library plasmids in yeast colonies that could grow on QDO with α -gal activity was performed. The interaction between HCV core protein and the protein we obtained from positive colony was further confirmed by repeating yeast two - hybrid analysis and coimmunoprecipitation *in vitro*.

RESULTS: A gene from a positive colony was the gene of translin, a recombination hotspot binding protein. The interaction between HCV core protein and translin protein could be proved not only in yeast, but also *in vitro*.

CONCLUSION: The core protein of HCV can interact with translin protein. This can partly explain the molecular mechanism for hepatocellular carcinoma and lymphoma caused by HCV.

INTRODUCTION

The core protein of hepatitis C virus (HCV) is the structural protein of the virus^[1-4]. However, some evidences suggested

that this protein has a pleiotropic nature. In addition to having a packaging function, the core protein has been shown to act *in trans* on the viral and cellular promoters and it is also capable of transformation of rat embryonic fibroblasts through cooperation with the *ras* oncogene. Previous studies showed that the core protein could interact with several proteins such as lymphotoxin- β Receptor, heterogeneous nuclear ribonucleoprotein K, RNA helicase^[5-8]. In order to understand the pathogenesis of HCV infection we examined the possibility that the HCV core protein interacts with cellular proteins.

MATERIALS AND METHODS

Material

Bacterial, yeast strains and Plasmids All yeast strains and plasmids for yeast two-hybrid experiments were obtained from Clontech (Palo Alto, Calif., USA) as components of the MATCHMAKER Two Hybrid System 3. Yeast strain AH109 (MAT α , *trp1-901*, *leu2-3,112*, *ura3-52*, *his3-200*, *gal4* Δ , *gal80* Δ , *LYS2::GAL1_{UAS}-GAL1_{TATA}-HIS3*, *GAL2_{UAS}-GAL2_{TATA}-ADE2 URA3::MEL1_{TATA}-lacZ MEL1*) containing pGBKT7-53, coding for DNA-BD/mouse p53 fusing protein and AH109 used for cloning of bait plasmids, yeast strain Y187 (MAT α *ura3-52*, *his3-200*, *Ade2-101*, *trp1-901*, *leu2-3, 112*, *gal4* Δ , *gal80* Δ , *met-*, *URA3::GAL1_{UAS}-GAL1_{TATA}-lacZ MEL1*) containing pTD1-1, in which pACT2 coding for AD/SV40 large T antigen fusing protein and Y187 used for cloning of library plasmids. Pretransformed cDNA liver cell library Y187. Bacterial strain DH5 α used for cloning of every shuttle plasmid. Yeast-*Escherichia coli* shuttle plasmids pGBKT7 DNA-BD cloning plasmid, pGADT7 AD cloning plasmid, pGBKT7-53 control plasmid, pGADT7, pGBKT7-Lam control plasmid, pCL1 plasmid from Clontech L.T.D Company(K1612-1). pGEM T vector from Promega Company, USA.

Chemical agents and cultural media Taq DNA polymerase purchased from MBI Company, T4 DNA ligase, EcoRI and BamHI restriction endonuclease from Takara. c-Myc monoclonal antibody secreted by 1-9E10.2 hybridoma (ATCC), goat anti-mouse IgG conjugated with horseradish peroxidase from Zhongshan Company, China. Lithium Acetate, semi-sulfate adenine, Acrylamide and N, N' -Bis-acrylamide from Sigma, TEMED from Boehringer Mannheim. Tryptone and yeast extracts from OXOID. X- α -Gal and Cultural media: YPDA, SD/-Trp SD/-Leu, SD/-Trp/-Leu, SD/-Trp/-Leu/-His, SD/-Trp/-Leu/-His/-Ade from Clontech L.T.D Company. protein-G agarose from Roche. RT-PCR kit and TNT[®]Coupled Reticulocyte Lysate Systems from Promega. [³⁵S]-methionine (.1 000 Ci/mmol; 10 mCi/ml) from Isotope company of china. Amplify Fluorographic Reagent (#NAMP100) from Amersham Life Sciences. Others from Sigma company.

Methods

Construction of "bait" plasmid and expression of HCV core protein Plasmid pGBKT7-core (Figure 1) containing full-

length HCV core gene was constructed by insertion of HCV core gene in-frame into EcoRI/BamHI site, which could direct expression of DNA binding domain, *c-myc* and core fusion protein. After the plasmid was transformed into yeast strain AH109 by using Lithium Acetate method^[9]. Western blotting was performed to confirm the expression of the fusion protein by using *c-myc* monoclonal antibody. Transformed AH109 was cultured on quadropole dropout media to exclude the auto-activity.

Figure 1 "bait" plasmid pGBKT7-core.

Two-hybrid library screening using yeast mating One large (2-3-mm), fresh (<2 months old) colony of AH109[bait] was inoculated into 50 ml of SD/-Trp and incubated at 30 °C overnight (16-24 hr) with shaking at 250-270 rpm. Then the cells were spun down by centrifuging the entire 50-ml culture at 1 000×g for 5 min and supernatant Decanted the cell pellet was resuspended in the residual liquid by vortexing. The entire AH109[bait] culture and the 1-ml library were combined and cultured in a 2-L sterile flask and Add 45 ml of 2X YPDA/Kan was added and swirl gently. After 20 h mating, the cells were spun down and resuspended then spreaded on -50 large (150-mm) plates, containing 200 ml of SD/-Ade/-His/-Leu/-Trp (QDO). After 6-18 days grew, the yeast colonies were transferred onto the plates containing X-a-Gal to check for expression of the MEL1 reporter gene(blue colonies).

Plasmid isolation from yeast and transforming *E.coli* with yeast plasmid Yeast plasmid was isolated with Lyticase method (provided by Clontech), and transformed into *E. coli* by using electroporation^[10], transformants were plated on ampicilin LB selection media, then, isolating plasmids from *E.coli* and sequencing analysis.

To confirm the true interaction in yeast To confirm the true protein-protein interaction and exclude false positives, the plasmids of positive colonies were transformed into yeast strain Y187, next mating experiments were carried out by mating with yeast strain AH109 containing pGBKT7-core or pGBKT7-Lam. After mating ,the diploids yeast were plated on QDO covered with X-α-gal (Figure 2).

Figure 2 To confirm the interaction.

Bioinformatic analysis After sequencing the positive colonies, the sequences blasted with GenBank to analogize the function of the genes.

RT-PCR In order to clone the full-length gene, RT-PCRs were conducted by using PCR primers the designing based on the information of GenBank. The genes amplified by RT-PCR were ligated into yeast plasmid pGADT7.

In vitro translation Mixture of TNT®reticulocyte 25 µl, TNT®reactio buffer 2 µl, T7 TNT®RNA polymerase 1µl, amino acids mixture (minus methionine, 1 mM) 1µl, [³⁵S]methionine 2 µl, Rnasin®nuclease inhibitor (40u/µl) 1µl, DNA template (pGBKT7-core or pGADT7-library gene) (0.5 µg/µl) 2 µl, ddH₂O 50 µl, 30 °C incubated 90 minutes.

Coimmunoprecipitation The following reactants were combined in a 1.5-ml microcentrifuge tube on ice: Five µl *in vitro* translated bait protein, 5 µl *in vitro* translated library protein. The control only added 10 µl pGBKT7-core plasmid. The mixtures were incubated at 30 °C for 1 hr. Then, the following reagents added into the reaction tubes: 470 ml coimmunoprecipitation buffer (20 mM Tris-HCl (pH 7.5), 150 mM NaCl, 1 mM DTT, 5 µg/ml aprotinin, 0.5 mM PMSF, 0.1 % Tween 20), 10 µl Protein-G Agarose Beads, 10 µl c-Myc Monoclonal Antibody. Incubated at 4 for 2 hr with continuous rocking. The tubes were centrifuged at 14 000 rpm for 1-2 min. The supernatants were removed. 0.5 ml TBST added to the tubes. Rinse steps were repeated three times. 15 ml SDS-loading buffer were added. The samples was heated at 80 °C for 5 min. The tubes were placed on ice. Briefly centrifuged, and 10 µl loaded onto an SDS-PAGE minigel to begin the electrophoretic separation. After electrophoresis, the gel was transferred to a tray containing Gel Fixation Solution, and placed on a rotary shaker for 10 min at room temperature. Rinsed the gel with H₂O, then Amplify Fluorographic Reagent was added shaken for 20 min at room, then dried at 80 °C under constant vacuum. The gel was exposed to a X-ray film overnight at room temperature. The film was developed by using standard techniques.

RESULTS

Expression of the "bait" fusion protein

Yeast strain AH109 transformed with pGBKT7-core could stably express the fusion protein at high level (Figure 3) and could only grow on SD/-Trp medium and could not grow on QDO medium. Thus, the transformed yeast could be used for yeast hybrid analysis.

Figure 3 Western blotting showed the expression of HCV core protein in yeast (arrow indicated). lane 1 is HCV core protein and lane 2 is negative control.

RT-PCR experiments The yeast two hybrid analysis showed 30 blue colonies grew on QDO plates containing X-α-Gal. After confirming the true interaction in yeast, we isolated the plasmids from the blue colonies containing only pGBKT7-core and one library plasmid other than other plasmids. Sequencing the gene and blasted with the data from GenBank, a gene is translin. To further prove the interaction between HCV core protein and translin protein (Translin), a pair of primer were designed based on the gene of translin (Forward: 5' -GAA TTC ATG TCT GTG AGC GAG ATC TTC GTG G -3', down: 5' -GGA TCC CTA TTT TTC AAC ACA AGC

TGC TGC C-3'), up and down primers containing EcoRI and BamHI restriction endonuclease site, respectively. Total RNAs were prepared from HepG2, A 687bp fragment was amplified by using RT-PCR (Figure 4A). After cut by EcoRI/BamHI, the fragment was in-frame ligated into pGADT7 EcoRI/BamHI site (Figure 4B).

Figure 4 a 687bp fragment-translin, amplified by RT-PCR. (A) pGADT7-translin cut by EcoRI/BamHI (B).

In vitro coimmunoprecipitation

HCV core protein containing 192 aa, $M_r=20\ 968$, is smaller than Translin containing 228aa, $M_r=26\ 182$. Lane 1 showed two protein could interact with each other, lane 2 was only HCV core protein.(Figure 5).

Figure 5 lane 1 HCV core protein and translin protein, lane 2 HCV core protein.

DISCUSSION

Hepatitis C virus infects an estimated 170 million persons worldwide and thus represents a viral pandemic. Progression to chronic disease occurs in the majority of HCV-infected persons^[11-17], and some patients can develop to hepatocellular carcinoma^[18] and lymphoma. Infection with the virus has become the main indication for liver transplantation. Although research advances have been impeded by the inability to grow HCV easily in culture, there have been some insights into pathogenesis of the infection and improvements in treatment options. The core protein of HCV is a multifunctional protein involved in several processes; it is phosphorylated and has both cytoplasmic and nuclear localization and thus it may play multiple roles in the viral life cycle^[3,4]. Several studies also suggested that it has regulatory roles for viral and cellular genes^[19,20] and possesses transformation activity. More recent studies revealed that the core protein can interact with tumor necrosis factor receptor-1, lymphotoxin β -R and viral envelope protein 1 (E1) and also forms a complex with apolipoprotein AII of the lipid droplet^[21]. A recent report showed that the HCV core protein can suppress the cisplatin- and c-Myc-mediated apoptotic effect, supporting its role in the establishment of persistent HCV infection^[22]. But there have reverse results that the core protein also has the ability to enhance cell death triggered by LT- β R ligand or anti-Fas monoclonal antibody. Some research considered that the core protein of HCV can induce steatosis and hepatocellular carcinoma in transgenic mice^[23,24].

Thus, the molecular mechanism by which the HCV core protein and HCV induce hepatocellular carcinoma is not clear. Recent epidemical research indicated that a significant increase in the prevalence of HCV infection in a group of B-cell non-Hodgkin's lymphoma(NHL)^[25-29].

In this study, yeast two-hybrid system was used to clone oncogenic gene. Yeast two-hybrid system 3 based on the system originally designed by Fields and Song^[30] is developed by Bendixen^[31], which is commercially available from Clontech Company L.t.d. In this system, the promoters controlling *HIS3*, *ADE2*, and *MEL1* expression in AH109 have significantly fewer false positives and the simple mating protocol significantly reduces the labor and time involved in performing a two-hybrid library screening and improves the chances of finding rare protein-protein interactions and leads to more reproducible results.

The "bait" plasmid pGBKT7-core was transformed into yeast strain, After mating with liver cDNA library yeast strain Y187, the diploid yeast cells were plated on QDO media containing X- α -gal, 30 true positives were obtained. Sequencing analysis of isolated library plasmids, we find one of the genes is translin^[32] - a recombination hotspot binding protein. In order to further conform the interaction between the expressed protein and HCV core protein, we performed the experiment of coimmunoprecipitation of both proteins. A strong interaction between the HCV core protein and Translin protein *in vitro* was observed.

A number of studies have shown that chromosomal translocations either result in the activation of proto-oncogenes by joining them to immunoglobulin (Ig) or T-cell receptor genes or lead to the creation of tumor-specific fusion proteins. In man, such translocations consistently occur at particular sites in the genome. Translin protein, which specifically binds to the consensus sequences ATGCAG and GCCC (A/T) (G/C) (G/C) (A/T) found at the breakpoint junctions in many cases of chromosomal translocations, is a unique DNA binding protein^[33]. The nuclear translocation of translin protein only happened in the time when the cells were treated with mutagen. translin protein may be a typical DNA end binding protein, which is in contrast with one of the other DNA binding proteins, the Ku antigen, that initially binds to DNA ends and then moves to internal positions within the DNA molecule^[34]. Previous report showed that translin protein was not found in liver tumors. But in this study, we found the gene expressed in liver tumor cell HepG2 and in liver cDNA library. And the interaction between translin protein and HCV core protein not only existed in yeast, but also *in vitro*. The results suggested that translin protein may play a role in hepatocellular carcinoma. But there has had no report giving the evidence that the patients infected with HCV other than HBV have the chromosomal translocation, whether the hepatocellular carcinomas caused by infection of HCV have chromosomal translocation worthy of further studying.

The effects of translin protein on normal lymphocytes need the induction by some factors such as mutagens or biological factors (HCV infection). In lymphoproliferative disorder patients infected with HCV, some reports showed chromosomal translocation happened in B-cell^[35,36]. Therefore, our report indicated a molecular mechanism that the interaction between HCV core protein and translin protein may trigger the B-cell progressing into lymphoma in patients infected with HCV. How the interaction between the HCV core protein and translin protein causes chromosomal translocation or rather, causes lymphoma, more experiments are necessary to elucidate it.

Abstract

AIM: Hepatitis B surface antigen (HBsAg) mutant of hepatitis B virus (HBV) is one of the important factors that result in immune escape and cause failure of immunization. In this study we reported and characterized a novel HBV mutant with A-to-G at nt551 and intended to provide theoretical data for prevention of HBV infection in China.

METHODS: A methodology comprising polymerase chain reaction (PCR) amplifying, M13 bacteriophage cloning and nucleotide sequencing was used to analyze the sera of the pediatric patient who was hepatitis B (HB) immune failure. Expression plasmids containing the mutant S gene and a wild-type (*adr*) S gene were constructed respectively and the recombinant HBsAg were expressed in COS-7 cells under the regulation of SV40 early promoter. The recombinant proteins were investigated for their immunological reactivity with different monoclonal antibodies (mAb) against 'a' determinant and vaccine-raised human neutralizing antibodies.

RESULTS: It was found that there was a new point mutation at nt551 of the HBV (*adr*) genome from A to G, leading to a substitution of methionine (Met) to valine (Val) at position 133 in the 'a' determinant of HBsAg. Compared to the wild-type HBsAg, the binding activity of the mutant HBsAg to mAbs (A6, A11 and S17) and to vaccine-raised human anti-hepatitis B surface antibody (anti-HBs) decreased significantly.

CONCLUSION: According to the facts that the patient has been immunized with HB vaccine and that the serum is anti-HBs positive and HBsAg negative, and based on the nucleotide sequence analysis of the mutant HBV S gene and its alteration of antigenicity, the HBV is considered to be a new vaccine-induced immune escape mutant different from the known ones.

INTRODUCTION

From late 1980's, there has been increasing number of reports on hepatitis B (HB) patients with atypical HBV serological markers. Analysis of HBV in those patients demonstrated

mutants^[1-6]. Mutations could be found within the C gene, S gene, P gene and X gene^[7,8]. HBsAg encoded by the S gene carries the common determinant 'a', as well as 'd' or 'y' and 'w' or 'r' subtype determinant, and is classified into four major subtypes, i.e. *adw*, *adr*, *ayw*, *ayr*. Two amino acid (aa) residues encoded by S gene at codon positions 122 and 160 have been postulated to determine the different antigenic subtypes^[9]. The most important S gene mutations are those affecting the antigenicity of HBsAg 'a' determinant (aa 124 to 147) to which the major immune-target of neutralizing polyclonal antibodies reacted. In this way, the HBsAg mutants can escape detection by current methods and influence the effect of HBV vaccines.

There have been several reports on HBV S gene mutants affecting amino acid positions 126, 129, 131, 141, 144 and 145 of HBsAg^[10-12]. In this report, we described a rare variant of HBV isolated from a pediatric patient whose serum was negative for HBsAg and positive for anti-HBs. Sequence analysis revealed the substitution at position 133 (Met to Val) in the 'a' determinant within S gene. Using a panel of three mAbs (A6, A11 and S17) against 'a' determinant and vaccine-raised anti-HBs, the recombinant mutant HBsAg showed less binding activity than the wild-type HBsAg. Taken together, the data we presented clearly demonstrated that the substitution results in antigenic alteration and may allow the mutant virus to escape the detection by standard HBsAg assays.

MATERIALS AND METHODS

Patient

The patient, male, 4 years old, was born to a HBV carrier mother. He had been immunized with HBV vaccine on a conventional 0-1-6 schedule, i.e., 3 injections of HBV vaccine were given at 0, 1 and 6 month (s) old respectively. The virus markers of his serum were anti-HBs positive, HBsAg negative and HBeAg positive, as well as positive for HBV DNA by PCR and high level of alanine transaminase (ALT) 200 IU·L⁻¹.

Extraction and amplification of HBs DNA

The viral DNA was extracted from the serum sample using the standard method. Briefly, 100 µl serum was treated with proteinase K, phenol and chloroform, and then DNA was precipitated with ethanol. The resulted DNA was resuspended in 20 µl distilled water for later use. A nested PCR method^[13,14] was used to amplify HBV S gene fragment. The external primers were 5' -ACATACTCTGTGGAAGGC-3' (nt2 756 to nt2 773, forward) and 5' -TATCCCATGAAGTTAAGG-3' (nt884 to nt867, reverse). The internal primers were 5' -CGGGATCCATATTCTTGGGAACAAG-3' (nt2 826 to nt2 844, forward, underlined is a BamHI site) and 5' -CACTGCAGGGTTTAAATGTATACCCA-3' (nt839 to nt821, reverse, underlined is a PstI site). The PCR was carried out for 30 cycles, each cycle including 94 °C denaturation for 1 minute, 50 °C annealing for 1 minute and 72 °C chain elongation for 2 minutes.

Nucleotide and amino acid sequence analysis

The PCR-amplified HBV S gene fragments (about 1.2 kb) were

cleaned with a QIAquick spin column (Qiagen). The DNA was digested with both BamHI and PstI, and then ligated by T4 DNA ligase with M13mp18 RF DNA cut with the same restriction enzymes. The ligated DNA was used in the transformation of *E. coli* JM105 cells and the recombinant phages were recognized by loss of β -galactosidase activity in the culture plate containing X-gal and IPTG. The single-stranded recombinant DNA was prepared according to the standard protocol^[15]. The S gene sequence was determined on an ABI PRISM™ 377XL sequencer (PE Applied Biosystems, USA) and sequence analysis was performed using Release 6.70 of the PCGENE package (IntelliGenetics Co.). The HBsAg 'a' determinant coding regions of 48 defined HBV genotypes downloaded from National Center for Biotechnology Information (NCBI) were analyzed comparatively.

Construction of expression plasmids and transient protein expression

The process followed the reference^[16-18]. Briefly, the construction of recombinant wild-type and mutant HBsAg expression plasmids started with a plasmid pS300 which was constructed from pSP65 carrying the SV40 early promoter sequence, the preS/S gene and the poly (A) signal sequence of HBV. For construction of the major HBsAg expression plasmid, the preS1 and preS2 regions were deleted by restriction enzyme digestion. COS-7 cells were cultured in DMEM/HG medium supplemented with 5 % fetal calf serum, two million units/ml of ampicillin and one million units/ml of kanamycin under the condition of 5 % CO₂, 37 °C. The cells in 60-mm dishes were transfected with 10 µg of the expression plasmids using calcium phosphate precipitation method. 72 hours later, the transfected cells were collected into 1.5-ml Eppendorf tubes, washed with 10 mM PBS (pH7.4) and resuspended with 500 µl (for each dish) of 10 mM PBS (pH7.4). The cells were disrupted by freezing and thawing for 5 times, and then centrifuged at 8 000 rpm for 5 minutes. The supernatants contained the recombinant HBsAg proteins.

Recombinant HBsAg antigen immunoassay and epitope analysis

A solid phase radioimmunoassay (RIA) method was applied for detecting the binding activity of the expressed HBsAg with mAbs. In brief, polystyrene beads were coated with mAbs against different epitopes of HBsAg respectively and then incubated with the expressed HBsAg overnight at room temperature. The beads were washed thoroughly and incubated with ¹²⁵I-labeled anti-HBs (Beijing Atomic Energy Institute). Bound antibodies were detected as counts per minute (cpm) in LKB 1 272 gamma counter. To evaluate the reactivity of vaccine-raised human anti-HBs to recombinant wild-type HBsAg and mutant HBsAg, an enzyme-linked immunosorbent assay (ELISA) was established as follows^[19-21]: plates were coated with size filtrated and volume concentrated antigen from expression cell culture; Plasma from five HBV vaccinated individuals were pooled and serially diluted human anti-HBs was incubated in the plates at 37 °C for 90 minutes. Bound human IgG was detected by a second incubation with horseradish peroxidase (HRP) conjugated murine monoclonal anti-human IgG; The reactivity was determined by enzyme catalyzed OPD colour development and the results were expressed as absorbance units at 490 nm.

RESULTS

HBs variant nucleotide and amino acid sequence analysis

The HBs DNA sequence of the novel mutant was shown in Figure 1. The adenosine (A) at nt519 and the guanosine (G) at nt633 indicated that the mutant belonged to *adr* subtype^[22]. Sequence comparison between the mutant and 48 defined HBs genotypes revealed a new nucleotide mutation at nt551 from A to G, leading to the amino acid alteration at position 133 from Met to Val in the 'a' determinant. The mutant was first reported and its sequence data have been deposited with GenBank DNA databases under the accession number AF052576. The comparative analysis of HBsAg 'a' determinant coding regions of different HBV genotypes was shown in Figure 2.

Figure 1 The complete nucleotide sequence of the mutant S gene. The A-to-G mutation site at nt551 of HBV genome is in bold letter. The underlined are the EcoRI-like site, the initiation codon of HBsAg and the amino acid codon (ATG to GTG) respectively. The first C of the EcoRI-like site (GAACTC) is counted as nt1. The GenBank accession number of the sequence is AF052576.

Figure 2 Comparative analysis of the HBsAg 'a' determinant coding regions of different HBV genomes. HBsAg 'a' determinant is a conformational epitope which has a special two-loop construction kept by the disulfide bonds between Cys124 and Cys137, Cys139 and Cys147, respectively. 48 HBV genome sequences were downloaded from National Center for Biotechnology Information (NCBI), USA (<http://www.ncbi.nlm.nih.gov>). "Gene names" are their names in the original gene databases. Here the ※ labeled ones are from DDBJ, the labeled are from EMBL, and the § labeled are from GenBank.

Recombinant HBsAg transient expression in COS-7 cell

The recombinant wild-type HBsAg and mutant HBsAg were expressed under the regulation of SV40 early promoter in COS-7 cells in a transient fashion. Only secreted HBsAg in culture supernatant was examined for expression. There was no obvious expression yield difference between the wild-type and mutant recombinant HBsAg based on protein silver staining on SDS-PAGE.

Immunoreactivity analysis

To compare the reactivity of recombinant wild-type HBsAg and mutant HBsAg to antibodies, the quantity of the antigens must be the same. Because both the wild-type and mutant HBV were known to be adr subtypes, an anti-‘d’ determinant mAb, S4 (Shanghai Institute of Biological Products), was used for the standardization of the HBsAg. After series of dilution and detection, both HBsAg preparations were adjusted to a protein concentration of 2.1 ng/ml. Three different anti-‘a’ determinant mAbs, A6, A11 and S17, were selected to characterize the binding activity of the expressed HBsAg. In the condition of the same concentration of HBsAg proteins determined by anti-‘d’ mAb, the reactivity of the mutant HBsAg to three anti-‘a’ mAbs were unexceptionally weaker than that of the wild-type HBsAg, as shown in Table 1. The recombinant wild-type and mutant HBsAg were also tested for their relative reactivity to vaccine-raised human anti-HBs. Clearly, pooled human HBV vaccinated antisera decreased its binding strength to the mutant HBsAg by about 5-fold by ELISA assay, as shown in Table 2. As control, the cell culture supernatant without recombinant plasmid transfection did not bind to human antisera in this assay. The results demonstrated that the Met-to-Val substitution at amino acid position 133 of HBsAg led to the antigenic alteration.

Table 1 Detection of immunoreactivity of the expressed HBsAg to anti-‘a’ monoclonal antibodies by radioimmunoassay^a

Anti-‘a’ monoclonal antibodies	Wild-type HBs (133Met)	Mutant HBs (133Val)
A6	1118 (5.82)	774 (3.93)
A11	932 (4.80)	744 (3.76)
S17	945 (4.87)	630 (3.14)

^aCounter per minute (cpm), the number in the parentheses is P/N value. According to the solid RIA kit producer’s recommendation, P/N=(sample cpm-background)/(negative control cpm-background). Untransfected cells were used as negative control, average cpm was 240. Blank polystyrene beads were used as background, average cpm was 58. P/N \geq 2.10 is considered to be positive reactivity. The more the P/N value, the stronger the reactivity.

Table 2 Immunoreactivity of vaccine-raised human anti-HBs to recombinant wild-type HBsAg and to recombinant mutant HBsAg in an ELISA assay

Plate coated with	Wild-type rHBsAg				Mutant rHBsAg				Control
Vaccine-raised anti-HBs	1:1	1:2	1:4	1:8	1:1	1:2	1:4	1:8	1:1
Absorbance at 490 nm	2.45	1.32	0.71	0.28	0.53	0.28	0.15	0.06	0.04

DISCUSSION

The hepatitis B virus has three envelope proteins, and the major envelope protein is S protein, consisting of 226 amino acids. A hydrophilic region in S protein (aa 124 to 147) is designated as ‘a’ determinant, an antigenic determinant common to all HBV subtypes. ‘a’ determinant is a conformational epitope

which is made up of a special two-loop structure kept by the disulfide bonds between Cys124 and Cys137, Cys139 and Cys147, respectively. This structure projects out from the surface of the HBV particle^[23]. The HBV DNA template is transcribed by cellular RNA polymerase to pregenomic RNA, which in turn is reverse transcribed to DNA by virus polymerase. This unique way of HBV replication means a significant tendency to mutation^[8,19]. On the other hand, the pressure of immunoprophylaxis with HB immunoglobulin and/or vaccines is another important cause to result in escape mutants^[23-28]. Up to date, in the reports about HBV vaccine-induced escape mutants, the most popular one is that with glycine to arginine at aa145 of HBsAg. The mutation decreased the binding activity of HBsAg to mAbs^[23,29]. There was another vaccine-induced escape mutant of HBV from an immunized child with anti-HBs positive. The aspartic acid at aa144 was substituted by an alanine in HBsAg, and anti-‘a’ monoclonal antibody assay showed the mutant HBsAg had weak reactivity^[12]. We also reported a different mutant of HBV with isoleucine at aa126 replaced by serine^[30]. It seemed that the Ser126 mutant was not an antibody-induced escape mutant since anti-HBs was not detected in the patient. Besides, the mutations, situated closely adjacent to the ‘a’ determinant, could also change the entire immunodominant region structure and therefore weaken the antigenicity even though no mutations were found within this ‘124-147’ region^[31]. Hence, the classical definition of the ‘a’ immunodominant region may need to be extended to require adjacent amino acids to support its conformation^[32-34].

In this report, we characterize a novel HBV mutant with A-to-G at nt551. The substitution of Met to Val at position 133 in the ‘a’ determinant of HBsAg results in the decrease of reactivity of the recombinant HBsAg to anti-‘a’ mAbs and vaccine-raised human anti-HBs. Since the major B-cell antigenic epitope resides in the group specific ‘a’ determinant region, which is reported to be conformational^[35], the data we presented clearly demonstrated that the mutation affects the conformation of the ‘a’ determinant and alters the antigenicity of HBsAg, leading to HBsAg escape from the detection by standard HBsAg assays. Our observations further indicate that the mutation in the HBV surface gene may lead to a considerable decrease of properly folded surface antigens which may render the virus particle less immunogenic in producing an effective neutralizing anti-HBs to clear the virus. According to the fact that the patient has been immunized with HBV vaccine and that the serum is anti-HBs positive and HBsAg negative, the HBV variant we report here is considered to be a new vaccine-induced immune escape mutant.

This antigenically divergent HBV mutant is important for both clinical and diagnostic reasons^[36,37]. Therefore, further studies using expressed mutant HBs proteins and accumulation of additional cases will be required for elucidation of the mechanism of the loss of antigenicity.

Abstract

AIM: *Helicobacter pylori* can be diagnosed by invasive or non-invasive tests but to obtain bacteria for culture and antibiotic susceptibility testing, an upper GI endoscopy is often required. The string test may be a minimally-invasive alternative method of obtaining *H. pylori* samples. This study evaluates the sensitivity and specificity of the string test in the diagnosis of *H. pylori* in comparison with endoscopic means of diagnosis.

METHODS: This was a prospective open comparative study of patients with dyspepsia with endoscopy-based tests as gold standard (defined as a positive CLO test and antral histology). Fasting patients swallowed the encapsulated-string (Enterotest *Hp*), which was withdrawn after 1 hour. The gastric juice from the string was plated onto *H. pylori*-selective media for culture. *Helicobacter pylori* was identified by typical colony morphology, gram stain and biochemical test results.

RESULTS: Thirty dyspeptic patients were recruited of whom 21 (70 %) were positive for *H. pylori* according to the gold standard. The sensitivity, specificity, positive predictive value, and negative predictive value for the string test were 38 %, 100 %, 100 % and 41 % respectively, and for endoscopic biopsies 81 %, 100 %, 100 %, 69 % respectively ($P=0.004$). Logistic regression showed that only abundant growth density from endoscopic biopsy cultures to be a predictor of a positive string test ($P=0.018$).

CONCLUSION: The string test is an alternative method to endoscopy in obtaining *H. pylori* but has a low sensitivity compared to endoscopic biopsies.

INTRODUCTION

The diagnosis of *H. pylori* can be made by invasive or non-invasive tests^[1]. While non-invasive methods offer distinct

advantages in terms of cost, ease-of-effort and comfort to patients, the retrieval of *H. pylori* for microscopy, culture, DNA analysis, cytotoxin profiling, strain identification and antibiotic susceptibility testing often require an endoscopy with gastric mucosal biopsies. With a rising incidence in antibiotic resistance, failed eradication therapy now occurs in up to 20 % of all patients^[2,3]. In this situation, obtaining *H. pylori* for antibiotic susceptibility testing may be necessary, with the goal of choosing an appropriate antibiotic regimen that will result in likely successful eradication of resistant organisms^[3,4]. In this regard, there is a growing need to develop a cost effective and minimally-invasive means of obtaining the bacteria for culture and antibiotic susceptibility testing^[4,5].

The string test consists of an encapsulated string that is swallowed and then later withdrawn orally along with gastric juice that may harbor *H. pylori*. It may be a method by which *H. pylori* can be obtained with minimal invasiveness. Studies have shown string test sensitivity as high as 78 % to 97 %^[4,6]. However these results are achieved in highly specialized centers with a dedicated team and expertise in the string test technique. The same high sensitivity may not be reproduced in a standard microbiology laboratory with less experience with this procedure. Other studies used PCR on the string test to improve the sensitivity through the detection of *H. pylori*-specific DNA^[7-10]. However this method does not obtain live *H. pylori* for culture and antibiotic susceptibility testing. We therefore evaluated the utility of the string test compared with endoscopy-based methods and more specifically the sensitivity and specificity of culture from the string compared with culture from endoscopic biopsies.

MATERIALS AND METHODS

Patient selection

Adult patients, 18-80 years of age, with dyspepsia were prospectively recruited from the Endoscopy Department of the Prince of Wales Hospital, prior to oesophagogastroduodenoscopy (OGD). Patients were excluded if they had previous *H. pylori* eradication therapy, recent use of antibiotics, histamine receptor antagonists or proton pump inhibitors within the 4 weeks prior to OGD, a previous endoscopy or diagnostic test for *H. pylori*, predominant reflux symptoms, or previous gastric surgery or gastric malignancy. Signed informed consent was obtained from every patient. The study was in accordance with the declaration of Helsinki.

String test

The string test protocol was based on that described by Samuels *et al*^[6]. The patients had fasted overnight prior to presentation. A 7 mm diameter gelatin capsule, which contained a 90 cm-long nylon string with a weighted end, was used for the string test (Enterotest HP, HDC Corporation, San Jose, CA, USA). A 20 cm-long portion of the string was pulled out from the capsule, and this proximal end was tapped to the patients' cheek to prevent the whole string from being swallowed. The capsule was then swallowed with up to 200 ml of water. The capsule dissolved within the gastric lumen releasing the string to absorb the gastric mucus. After an hour the string was retrieved orally. The proximal 30 cm of the string was cut using sterile scissors

and discarded. The distal gastric acid-impregnated string was flushed with 5 ml of normal saline to reduce contamination by naso- and oropharyngeal organisms, then placed into a sterile specimen bottle containing 3 ml of brain-heart-infusion broth (BHIB) and immediately sent for processing. Gastric juice was squeezed from the string and the juice and approximately 5 microliter aliquot was plated onto each of two different *H. pylori*-selective media-Skirrows agar (containing vancomycin 10 mg/L, trimethoprim 5 mg/L, polymixin B 2 500 IU/L) and Wilkins-Chalgren agar with Dent supplement (vancomycin 10 mg/L, trimethoprim 5 mg/L, cefsulodin 5 mg/L, amphotericin B 5 mg/L). The remaining BHIB/gastric juice was centrifuged at 14 000 rpm for 5 minutes. The supernatant was discarded and the concentrated pellet was resuspended in 200 microliter of BHIB and plated onto another set of the same 2 selective media. Therefore, every patient's string sample was inoculated onto 4 culture plates. The plates were incubated in micro-aerophilic conditions, (37 °C, 10 % carbon dioxide) and 95-100 % humidity. On day 3-4, suspected *H. pylori* colonies were identified and replated onto horse-blood agar and cultured for up to 7 more days. Formal identification was made by typical colony morphology, Gram stain, and positive biochemical test results (oxidase, catalase, and urease tests). Contaminants were gram stained but not formally identified.

Patients underwent OGD and had an antral biopsy taken for rapid urease test (CLO test, Tri-Med, Va, USA), and 2 antral and 2 body biopsies for histopathology, and 2 antral biopsies for culture. The gold standard for the presence of *H. pylori* was defined by a positive CLO test and antral histopathology. Growth of *H. pylori* from antral biopsies was graded as scant, moderate or abundant growth corresponding with the *H. pylori* colonies found in 1, 2 or=3 quadrants of the culture plate respectively. Antral specimens were examined with hematoxylin-eosin stain and Giemsa stain and examined by a pathologist unaware of the patient's *H. pylori* status. *Helicobacter pylori* seen on antral histology was graded according to the Sydney system as normal (no *H. pylori*), mild (focal bacteria), moderate (bacteria in several areas), or marked (abundance of bacteria in most glands)^[11].

Statistics

The Chi square test was used for comparison of categorical data and the Fisher's exact test was used when an expected variable was below 5 %. The McNemar test was used to detect the symmetry of the differences between the string test and other tests. A *P* value of <0.05 was considered significant.

RESULTS

Thirty-three patients were approached to participate in this study. One patient refused participation and 2 patients attempted to but could not swallow the string capsule due to gagging and dry retching. The remaining 30 patients (14 males and 16 females with mean age of 52 years, age range 19-77 years) had both the string test and the OGD. There were no complications from the string test or from the OGD, apart from minor transient discomfort or gagging on swallowing the string test and during withdrawal of the string.

Twenty-one out of 30 (70 %) patients had *H. pylori* infection based on the gold standard definition of a positive CLO test and antral histopathology. The string test detected *H. pylori* in only 8 patients and was negative in 22 patients. The sensitivity, specificity, positive predictive value and negative predictive value for the string test were 38 %, 100 %, 100 % and 41 % respectively. In comparison, the endoscopic biopsy culture method yielded a positive result in 17 patients with a sensitivity, specificity, positive predictive value and negative predictive value of 81 %, 100 %, 100 % and 69 %, respectively. (*P*=0.004).

Figure 1 illustrates this difference. The McNemar test showed that the string test result was significantly different to the gold standard (*P*<0.001), endoscopic biopsy culture (*P*=0.004), CLO test (*P*<0.001) and histopathology (*P*<0.001). The comparison between the string-test and with the OGD-based tests is presented in Tables 1 and 2.

Figure 1 Comparison of the sensitivity and specificity of the culture results by the string test and from the endoscopic biopsies.

Table 1 Results of the 4 tests in detecting *Helicobacter pylori*

<i>Helicobacter pylori</i> status	CLO test	Histology	Antral biopsy culture	String test culture	Number of patients (n=30)
+	+	+	+	+	8*
+	+	+	+	-	9
+	+	+	-	-	4
-	-	+	-	-	1
-	-	-	-	-	8

+ denotes positive test; - denotes negative test. * one patient with a positive CLO test but the antral histopathology was not performed. He was counted as a positive case for this study.

Table 2 The sensitivity, specificity, positive predictive value, negative predictive value and the accuracy of the string test compared to endoscopy-based tests

	Sensitivity %	Specificity %	PPV %	NPV %	Accuracy %
CLO test	100	100	100	100	100
Antral histology	100	95	89	100	97
Antral biopsy culture	81	100	100	69	77
String test culture	38	100	100	41	57

The string test was more likely to be positive when there was also abundant growth of *H. pylori* from endoscopic biopsies, and less likely to be positive for moderate, scant or no growth (string test positive in 80 % and 16 % respectively, *P*=0.011, Table 3). However, the string test result was not statistically associated with the density of *H. pylori* organisms on antral histopathology (string test positive in 50 % of cases of marked density and 18 % of moderate or lower density, *P*=0.158, Table 4). Logistic regression showed that abundant growth from endoscopic biopsy cultures to be the only significant predictor of a positive string test (OR: 23.1, 95% CI: 1.71-310, *P*=0.018).

Overall on OGD, 18 (60 %) patients had endoscopic findings (5 patients with peptic ulcer disease and 13 patients with gastroduodenitis). The string test was positive in 4 out of 5 (80 %) patients with peptic ulcers, 3/13 (23 %) of patients with gastroduodenitis, and 1/12 (8 %) of patients with no pathology (*P*=0.009).

The concentrated Skirrow medium provided the best result

for the string test and grew *H. pylori* in all 8 patients who had a positive string test result. In contrast the Wilkins-Chalgren medium was positive in only 2 of these patients. Contamination of the plates with naso- and oropharyngeal organisms was the main reason for the low string test sensitivity, and occurred in 37/60 Wilkins-Chalgren plates, and 18/60 of the Skirrow plates. The contaminants were predominantly gram positive cocci and gram negative rods. A few plates had fungal contaminants. The plates with the concentrated BHIB were more likely to grow *H. pylori*, but also tended to have more contaminants. We attempted to reduce the load of oropharyngeal commensals by having the patients gargle their throats with water just prior to string extraction. However this did not improve the overall sensitivity of detecting *H. pylori* (data not presented). Contamination of the batch BHIB was excluded by the use of a fresh BHIB sample as a negative control. There was no growth of contaminants from this negative control. Also no contamination was reported from the antral biopsy cultures, which were also transported in BHIB.

Table 3 The results of the string test according to the growth rate of cultures from endoscopic biopsies

	Cultures of endoscopic biopsies and growth rate of <i>Helicobacter pylori</i>			
	Abundant	Moderate	Scant	No growth
String test negative (n=22)	1	2	6	13
String test positive (n=8)	4	1	3	0
Total	5	3	8	14

Table 4 The results of the string test according to the density of *Helicobacter pylori* on antral histology

	Antral histology and density of <i>Helicobacter pylori</i>			
	Marked	Moderate	Mild	None present
String test negative (n=22)	4	8	2	8
String test positive (n=8)	4	2	2	0
Total	8	10	4	8

DISCUSSION

The string test demonstrated only 38 % sensitivity in detecting *H. pylori* at our center contrasting previous results^[4,6]. In contrast, direct endoscopic mucosal biopsy cultures yielded a significantly higher sensitivity of 81 %. This low sensitivity of the string test could be attributable to either overgrowth of contaminants, or failure to collect sufficient *H. pylori* onto the string, or death of the organisms during handling.

To prevent oropharyngeal and nasopharyngeal organisms from overgrowing the culture plates require the use of *H. pylori*-selective media. We only used 2 types of *H. pylori* selective media (total of 4 plates per patient) whereas 3 types were used in Samuel's study^[6]. Samuel's study showed that there was no clear superiority of any one selective medium over another and that different strains of *H. pylori* may unpredictably preferentially grow in a certain medium and not the others. Therefore the use of all 3 media may improve the pick up rate^[6]. However, other experts have advocated on the use of only 2 types of selective plates for identifying *H. pylori*^[12].

Helicobacter pylori may have been successfully collected on the string but plate contaminants or improper handling may have resulted in the negative culture. PCR can be performed to detect *H. pylori*-specific DNA sequences and this may

increase the positive results. Previous studies have shown the high sensitivity of PCR-based string test^[7-10]. In one study the string test sensitivity increased from 37 % with culture to 93 % when PCR was utilized^[8]. However PCR testing is not a practical alternative in many centers and this will add to the overall cost of diagnosis. Also the main purpose of *H. pylori* culture in adults is to determine antibiotic susceptibility and this information is not determined by PCR.

The string test reported by Samuels *et al* with very high sensitivity rate of 97 % requires intensive laboratory methods, is labor-intensive, and requires the use of many culture plates. A vacuum hood was used when plating the selective media and this might reduce airborne contamination. String tests were processed immediately without refrigeration and this may improve the viability of the *H. pylori*. Six plates, instead of 4, were used and this may have also improved the yield of culture^[6]. Therefore, while the string test is an alternative method to an OGD for obtaining samples of *H. pylori*, the low sensitivity coupled with the demanding methodology may mean that it is not a realistic or possible option in many laboratories at present. Modifications of the methodology are required.

In conclusion, the string test is a minimally-invasive test to obtain *H. pylori*. As with other *H. pylori* culture techniques it has 100 % specificity but in contrast to previous studies, a low sensitivity was demonstrated. Despite the use of *H. pylori*-selective media, overgrowth of commensal organisms remains the major obstacle with this technique.

Abstract

AIM: To verify the expressing efficiency and angiogenesis effect after administration of expression vector encoding for vascular endothelial growth factor D in normal and ischemic rat liver.

METHODS: Ten female S-D rats were administrated with liver tissue dot injection of naked PCHO/hVEGF-D, 50 µg/dot, three dots for each. The same amount of physiological saline was used as control in the neighboring lobe. Fourteen S-D rats, using inflow occlusion of left lateral lobe, were divided into two groups, seven rats in each group. One was ischemic plasmid group, which received naked plasmid PCHO/hVEGF-D injection of 150 µg. The other received the equal amount of natural saline injection and designed as control. The expressions of hVEGF-D in mRNA and protein levels were identified by *in situ* hybridization and immunohistochemistry, respectively. Endothelial cells were labeled by the factor VIII immunohistochemically. The average number of perisinusoidal capillaries of each group was calculated and compared statistically 8 days after injection.

RESULTS: A large amount of hVEGF-D in mRNA level was found in both normal and ischemic plasmid groups and but none in their corresponding control groups. The protein of hVEGF was also highly expressed in both normal and ischemic plasmid groups than in the controls. The mean number of capillaries under microscopy (×200) of the plasmid group and control was 10.2±2.78 vs 7.1±2.02 ($P<0.05$), and those of ischemic plasmid group and ischemic control were 7.43±1.72 vs 4.71±1.11 with statistical difference ($P<0.05$).

CONCLUSION: The naked PCHO/hVEGF-D dot injection to normal, ischemic rat liver can produce comparatively high expression of hVEGF in both protein and mRNA levels, and prominently increase the number of new capillaries around hepatic sinuses. Therefore, it could be another ideal choice for the treatment of ischemic liver diseases.

INTRODUCTION

Nowadays, the liver has become the most important target organ for gene therapy because of its unique structure and complex functions. Owing to its particular situation with respect to the blood circulation, the liver can serve as a secretory organ for the systemic delivery of therapeutic proteins. The liver parenchyma is readily accessible to large molecules such as DNA fragments or recombinant viruses present in the blood on account of its peculiar endothelium. Great progress has been achieved in various gene transfer protocols aimed at delivering genes to the normal or the pathologic liver in the last decade^[1,2].

Angiogenesis is a process of new blood vessel development from pre-existing vasculature. It plays an essential role in embryonic development, normal growth of tissues, wound healing, the female reproductive cycle, as well as a major role in many diseases. One of the most important growth and survival factors for endothelium is vascular endothelial growth factor (VEGF). VEGF induces angiogenesis and endothelial cell proliferation and it plays an important role in regulating vasculogenesis^[3-5]. Many previous studies also proved the antiangiogenic effect of VEGF antisense gene therapy for hepatic carcinoma and the killing effect of suppression of VEGF on gastric cancer cells^[6,7].

Most of the liver conditions were proved to be involved in the morphological and pathological changes of intra-hepatic vessels^[8-11]. Previous studies demonstrated that, when liver under the state of chronic inflammations, chronic necrosis and fibrosis, the density of microvessels were presumed to reduce probably due to the decreased expression of angiogenesis-related growth factors such as VEGF, insulin-like growth factor, and over expression of transforming growth factor beta, platelet-derived growth factor^[12-15]. The expression vector for VEGF has been used to treat various ischemic diseases both experimentally and clinically for nearly ten years^[16-20].

In order to verify the expression efficiency and angiogenesis effect after administration of expression vector for VEGF-D, we carried out experimental studies on normal and ischemic rat livers.

MATERIALS AND METHODS

Large scale preparations of plasmid

Eukaryotic expression plasmid PCHO/hVEGF-D was kindly presented by Prof. Miyuki Shimane (Chugai Institute, Japan). After transformation to E Coli DH5alpha, large scale plasmid was prepared, purified into TE at the concentration of 1 g/L, according to the instruction of Megaprep kit (Promega Co Ltd., German).

A 2.0 kb fragment was cut from PCHO/hVEGF-D by restriction enzymes, *EcoR I* and *BamH I*, as the probe for this hVEGF-D. The probe was labeled using randomly primed labeling method (Shanghai Sangon Co.Ltd, China).

Animal operations and groups

Studies on normal rat livers 10 healthy female Sprague-Dawley rats, weighing 200-220 g, were bought from the Experimental Animal Center of Tongji Medical University. After anaesthetized by pentobarbital ($40 \text{ mg} \cdot \text{kg}^{-1}$ intraperitoneally), all the rats were laparotomized and given liver tissue dot injection of naked PCHO/hVEGF-D, $50 \mu\text{g}/\text{dot}$, three dots for each. The same amount of NS (natural saline) was used as self-control in the neighboring lobe.

Study on ischemic rat liver Fourteen S-D rats, using inflow occlusion of left lateral lobe, were divided equally into two groups. One is study group, each received naked plasmid PCHO/hVEGF-D injection in the amount of $150 \mu\text{g}$ by dot injection as above. The other group received the equal amount of natural saline injection for each and designed as control.

All the rats were sacrificed 8 days after the operation and liver samples with injection were collected and fixed in 10 % neutral-buffered formalin, embedded in paraffin and cut into 4-6 μm sections.

Immunohistochemical method

The sections were deparaffinized, rehydrated, and treated with anti-VEGF antibody (Santa Cruz, Britain) and Factor VIII related antibody (Zymed, USA), their proteins were identified according to the instructions of SABC kit (Zhongshan Bio. Co. Beijing, China).

Positive rate was evaluated by Integral Score method from three aspects: positive cell distribution, intensity and pattern, as reported before^[21]. The positive integral scores of VEGF protein were compared between plasmid group and controls, ischemic group and ischemic controls.

Microvessel density was compared between groups. First choose three most abundant areas under microscopy $\times 100$, count effective vessels under microscopy $\times 200$ and calculated the average number in each group and compare their difference.

In situ hybridization

The investigation procedure was referred to related references^[22]. The *in situ* hybridization kit was purchased from Boshide Biological Technology Limited Company (Wuhan, China). *In situ* hybridization was performed according to the manufacturer's instructions.

Statistical analysis

Student's *t* test was used for comparison of results among different groups. Values were expressed as means \pm SD. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

Results in normal rat liver

A large amount of hVEGF-D mRNA was identified in plasmid group but none in control group. The hVEGF-D mRNA was located in the cytoplasm of hepatocytes, vascular endothelium, and some Kupffer cells. In the areas around vessels, there were relative more positive cells.

The protein of hVEGF was expressed in cytoplasm mainly in hepatocytes and some endothelial cells in both plasmid and control groups. The stain integral scores of plasmid group and control were 6.0 ± 1.63 and 3.7 ± 2.31 respectively. The difference between the two groups was significant (Student *t* test, $T=2.74 > 2.62$, $P < 0.05$) (Figure 1).

The mean numbers of capillaries under microscopy ($\times 200$) of the plasmid group and control were 10.2 ± 2.78 and 7.1 ± 2.02 , respectively, with very significant difference (paired Student *t* test, $T=3.59 > 3.25$, $P < 0.01$) (Figure 2).

Figure 4 Immunohistochemistry. Normal rat liver injected by PCHO/hVEGF-D, VEGF protein stained positive hepatocytes, $\times 400$.

Results in ischemic rat livers

The mRNA of hVEGF-D was found in the study group, but none in the control. The positive cells and location were similar to the normal rat liver studies.

The average expression score of VEGF protein in plasmid group was higher than that of control ones (5.84 ± 1.72 vs 3.69 ± 1.53 , $P < 0.05$), (Figure 3). The average number of vessels under microscope ($\times 200$) was 7.43 ± 1.72 in plasmid group and 4.71 ± 1.11 in control group with statistical difference ($P < 0.05$).

DISCUSSION

VEGF-D (also known as c-fos-induced growth factor or FIGF) was first cloned by Yamada in 1997 from human lung cDNA library^[23]. It is 2 028bp long and encodes for 354 amino acid most closely related to VEGF-C^[23]. It shares structural homology and receptor specificity with VEGF-C, suggesting that VEGF-C and VEGF-D represent a subfamily of the VEGFs. VEGF-D is initially synthesized as a precursor protein containing unique N- and C-terminal propeptides in addition to a central receptor-binding VEGF homology domain (VHD). Similar to VEGF-C, VEGF-D binds, the cell surface receptor tyrosine kinases VEGF receptor 2 (VEGF R2/Flk-1/KDR) and VEGF R3 (Flt-4). VEGF R2 and VEGF R3 were localized in vascular and lymphatic endothelial cells and signal for angiogenesis and lymphangiogenesis^[24]. The gene for VEGF-D maps existed in the chromosome XP22.31 in human^[23].

Numerous techniques and approaches have been investigated for gene transfer to the liver. For the gene therapy of hepatic diseases in animal experiments, exogenous genes were usually delivered to the liver through the portal vein, bile duct injection and by direct liver injection^[25-30]. The most simple is direct DNA injection. More than 20 years ago, studies pioneered the use of DNA, either naked and complexed with calcium phosphate, for gene transfer to various organs including the liver^[31]. Dr. M Anner Hickman presented studies on the direct injection of plasmid DNA, which resulted in significant gene expression in the liver. The cats injected with a plasmid for a reporter gene were noted to exhibit peak expression of the gene 24-48 hours after intrahepatic injection. Residual reporter gene expression could be noted up to 6 weeks later^[32]. In our studies, 8 days after gene PCHO/hVEGF-D injection, VEGF proteins were markedly expressed in liver tissues.

The PCHO/hVEGF-D was specifically designed for mammal expression. It not only cloned the full length of VEGF-D cDNA, but also inserted a special promoter Efalpha. Therefore, it could have a relatively high expression efficiency. In our first part of studies, we tried to ascertain its expression efficiency *in vivo* with naked gene transfer. The result was the same as we anticipated, and the microvessel density of the injected tissue was promoted as an effect of VEGF protein.

Early in 1999, Marconcini L reported that Figf/Vegf-D was a potent angiogenic factor in rabbit cornea *in vivo* in a dose-dependent manner. *In vitro* Figf/Vegf-D induced tyrosine phosphorylation of VEGFR-2 and VEGFR-3 in primary human umbilical cord vein endothelial cells (HUVECs) and in an immortal cell line derived from Kaposi's sarcoma lesion (KS-IMM). The treatment of HUVECs with Figf/Vegf-D induced dose-dependent cell growth^[33]. Recently Byzova TV demonstrated *in vitro* that VEGF-D Delta N Delta C encoded by the adenovirus (Ad-VEGF-D Delta N Delta C) was capable of inducing endothelial cell proliferation and migration and that the latter response was primarily mediated by VEGF receptor-2. The proangiogenic effect of Ad-VEGF-D Delta N Delta C was evident as early as 5 days after injection into the rat cremaster muscle^[17].

From our studies in ischemic livers, naked plasmid PCHO/hVEGF-D direct injection could also produce a comparatively

high expression of hVEGF in both protein and mRNA levels, and prominently increased the number of new capillaries around hepatic sinuses.

In fact, absolute and relative ischemia of hepatic cells are very common in various situations such as chronic hepatitis, liver fibrosis or cirrhosis and portal thrombosis. Lots of previous studies on liver cirrhosis had already proved that the expression of VEGF was reduced and closely related to the state of liver function or portal hypertension degree^[9,10,12-15,34,35]. Assy N studied the serum VEGF levels between cirrhotic patients and normal controls. The results showed that the mean serum VEGF levels in all cirrhotic patients were significantly lower than those of healthy controls and acute hepatitis. These studies give much support for the angiogenesis treatment in chronic liver diseases^[12]. Therapeutic angiogenesis has already widely used to treat many ischemic diseases^[16,18-20]. By stimulating angiogenesis in liver by gene transfer method, hepatocytes would have more nutrition and oxygen and thus could preserve the liver function to some extent. Therefore, angiogenesis through gene transfer, by naked plasmid DNA PCHO/hVEGF-D injection, is a ideal method for the treatment of ischemic liver diseases especially for liver fibrosis and cirrhosis.

Abstract

AIM: To investigate the inhibition effects on the production of collagen type I, III secreted by activated rat hepatic stellate cells (rHSCs) by antisense tissue inhibitors of metalloproteinase 1 (TIMP-1) recombinant plasmid through elevating interstitial collagenase activity.

METHODS: rHSCs were extracted from normal rat liver by pronase and collagenase digestion and purified by centrifugal elutriation, and were cultured on plastic dishes until they were activated to a myofibroblastic phenotype after 7-10 days. RT-Nest-PCR and gene recombinant techniques were used to construct the rat antisense TIMP-1 recombinant plasmids which can express in eucaryotic cells. The recombinant plasmid and the pcDNA3 empty plasmid were transfected in rHSCs by Effectene (QIAGEN) separately. Cells were selected after growing in DMEM containing 400 µg/ml G418 for 2-3 weeks. Expression of exogenous gene was assessed by Northern blot, and expression of TIMP-1 in rHSCs was determined by Northern blot and Western blot. We tested the interstitial collagenase activity with FITC-labeled type I collagen as substrate. Ultimately, we quantified the type I, III collagen by Western blot.

RESULTS: The exogenous antisense TIMP-1 recombinant plasmid could be expressed in rHSCs well, which could block the expression of TIMP-1 greatly, the ratio of TIMP-1/GAPDH was 0.67, 2.41, and 2.97 separately at mRNA level ($P<0.05$); the ratio of TIMP-1/ β -actin was 0.31, 0.98 and 1.32 separately at protein level ($P<0.05$); It might elevate active and latent interstitial collagenase activity, the collagenase activity was 0.3049, 0.1411 and 0.1196 respectively. ($P<0.05$), which led to promotion the degradation of type I, III collagen, the ratio of collagen I/ β -actin was 0.63, 1.78 and 1.92 separately ($P<0.05$); and the ratio of collagen III/ β -actin was 0.59, 1.81 and 1.98 separately ($P<0.05$).

CONCLUSION: These data shows that the antisense TIMP-1 recombinant plasmid has the inhibitory effects on the production of type I, III collagens secreted by activated rHSCs in vitro. It could be a novel method to reverse hepatic fibrosis in the future.

INTRODUCTION

The incidence of liver fibrosis and cirrhosis is still high in China^[1-4], and fibrosis is the common pathological basis of chronic hepatic disease^[5]. Many factors inducing liver injury and inflammation may lead to hepatic fibrosis^[6,7]. At present, the common sense is that hepatic fibrosis could be reversed effectively when the right therapeutic strategy was applied^[8].

Recently, studies on the role of tissue inhibitors of metalloproteinases (TIMPs) in the process of hepatic fibrosis have attracted more attentions^[9-14]. Roeb *et al*^[15] reported that there were no expression of TIMP-3, 4 mRNA in normal and fibrotic liver tissues; the expression of TIMP-1, 2 mRNA could be detected in normal liver tissue at lower level^[15,16]. The expression of TIMP-1 increased greatly in liver tissues of experimental rat hepatic fibrosis models induced by CCl₄ or bile compared to TIMP-2^[15].

Hepatic stellate cells (HSCs) represent up to 15 % of the resident cells of the liver and play a pivotal role in hepatic fibrosis^[17]. In response to liver injury of any etiology, the normally quiescent HSC undergoes a progressive process of trans-differentiation into a proliferating myofibroblast-like activated HSC^[17]. Through increased secretion of extracellular matrix proteins and the tissue inhibitor of metalloproteinases (TIMP)-1, activated HSCs are responsible for deposition and accumulation of the majority of the excess extracellular matrix in the fibrotic liver^[18]. Furthermore, activated HSCs can contribute to the fibrogenic process through their ability to secrete and respond to a wide range of cytokines and growth factors^[19].

It had been considered that the antisense technique was used to inhibit the target genes and proteins expressed in experimental rat hepatic fibrosis. The main aim of our study is to try to block the gene and protein expression of TIMP-1 in rHSCs *in vitro* and investigate the effects of antisense-TIMP-1 recombinant plasmid on the production of collagen type I, III of activated rHSCs, so as to find out the possible mechanism of reversing hepatic fibrosis.

MATERIALS AND METHODS

Isolation and culture of rat hepatic stellate cells

rHSCs were isolated from normal male Sprague-Dawley rats (300±30 g) by sequential perfusion with Pronase and collagenase as previously described^[20]. rHSCs were separated and purified from the cell suspension by single-step density gradient centrifugation with gradient buffer (Ficoll and glycan 1.053, Pharmacia). The purity of cell was assessed by light microscopic appearance and vitamin A autofluorescence at 295nm. rHSCs were activated at day 7 after seeding on the plastic surface and became myofibroblast (MFB) phenotype.

The cells were cultured in Dulbecco's modified Eagle medium (DMEM, GIBCO U.S.A) containing 4 mM L-glutamine and 10 % fetal calf serum (GIBCO U.S.A). Additionally, all culture media were supplemented with penicillin (100 IU/ml) and streptomycin (100 µg/ml) respectively. They were maintained at 37 °C in an atmosphere of 5 % CO₂.

Transfection of rat hepatic myofibroblast cells

rHSCs were transfected 8 days after seeding with pcDNA3/antisense-TIMP-1 recombinant plasmid. Briefly, total RNAs were extracted from rat liver with Trizol (Life Tech, U.S.A) reagent. According to the full-length cDNA sequence that encoded rat TIMP-1, we designed special sense and antisense primers and obtained target sequence with the RT-NEST-PCR technique, which were linked into T4 vector with T4 DNA ligase. After transformation, selection, and appraisal with restriction enzymes *Eco*RI and *Xho*I, the resulting insert was subcloned into the plasmid pcDNA3 (Invitrogen CA) and sequenced (PE377 Auto sequencer). One day before transfection, cells were dispersed with trypsin-EDTA solution and counted, then the cells were pipetted into 6-well dishes at a density of 1×10⁴ cells per well so they would attain 70 % confluence the next day. Transfection was performed with the commercially available cationic liposome reagents Effectene (Qiagen, Germany), using pcDNA3/antisense-TIMP-1 recombinant plasmid (1.0 µg/well) and pcDNA3 empty plasmid, following essentially the instructions of the manufacturers. Transfecting cells were selected after growing in DMEM containing 400 µg/ml G418 for 2-3 weeks. Following selection, 10 drug-resistant (neo⁺) clones of pcDNA3/antisense-TIMP-1 recombinant plasmid transfecting cells were picked randomly from different plates and studied after expansion; in the meantime, eight neo⁺ clones were picked from rMFB transfected with the pcDNA3 vector lacking the antisense sequences and eight non-transfected rMFB were studied as controls.

RNA isolation and Northern analysis for TIMP-1 and exogenous gene

The cells were rinsed with ice cold HBSS, the total RNAs were extracted from rMFBs with Trizol (Life Tech, Grand Island, NY) reagent. The concentration of RNA was determined by absorbance at 260 nm. For Northern analysis, 30 µg of total cellular RNAs were separated by electrophoresis in a 1 % denaturing agarose gel, transferred to a Hybond-N membrane (Amersham, UK) and fixed by baking for 2 h at 80 °C. The probe for pcDNA3 according to the special T7 promoter sequence (the probe sequence 5'-CAGAGGGATATCACTCAGCATAAT-3') and TIMP-1 cDNA probes were labeled with [α -³²P] dCTP (Amersham, UK) by random primer labeling method to detect exogenous gene and TIMP-1 expression. Blots were pre-hybridized for at least 3 h, and then hybridized for 20 h at 37 °C in a buffer containing 50 % formamide, 6×SSC, 5×Denhardt's solution [0.1 % Ficoll 400, 0.1 % BSA, 0.1 % polyvinylpyrrolidone], 5 mM EDTA, 0.5 % SDS, and 100 µg/ml sheared denatured herring sperm DNA (Roche, Germany). The filters were washed once at 55 °C for 20 minutes in a solution containing 2×SSC, 1 mM EDTA, and 0.1 % SDS, then twice at 50 °C for 20 minutes in a solution containing 0.4×SSC, 1 mM EDTA, and 0.1 % SDS. Autoradiographs were exposed to indicated times to Kodak films at -70 °C for 7 days. As an internal standard (loading control) the blots were re-hybridized with a GAPDH specific cDNA.

Western blotting for TIMP-1 and type collagen I, III

Rat TIMP-1 and collagen type I, III proteins in total cell extracts of transfected and non-transfected rMFBs were subjected to

Western-blot analyses. rMFB cells (1×10⁶) were pelleted by centrifugation, washed twice with ice-cold PBS, and lysed on ice in RIPA buffer [30 mM HEPES, 150 mM NaCl, 1 % Triton X-100, 0.1 % SDS and 1 % deoxycholic acid (pH 7.6)], with added proteinase inhibitors, pepstatin A (1.0 µg/ml), aprotinin (3.5 µg/ml), leupeptin (10 µg/ml) and 0.2 mM PMSF. Cell lysates were centrifuged at 3 000 g for 10 min at 4 °C, and BCA protein assay was performed. Protein samples (100 µg) were heated for 5 min at 100 °C and were separated on 12 % SDS-PAGE and transferred to PVDF membranes (Schleicher&Schuell Germany) in Tris-glycine buffer (pH 8.5) plus 20 % methanol. The membranes were blocked overnight in 5 % non-fat dried milk in Tris-buffer containing 0.1 % Tween-20 and then washed with Tris-buffer. The blots were incubated for 2 h at room temperature with mouse TIMP-1 monoclonal IgG (Oncogene) and rabbit anti-collagen type I, III diluted 1:500 in Tris-buffer. The blots were washed and then incubated with AP-conjugated secondary antibodies (Santacruz California U.S.A) at 1:2 000 dilution. The protein bands were visualized with BCIP/NBT (Wuhan, China) system. β -actin as the internal control.

Sample preparation and Enzyme assays

After transfection and selection, rMFBs were seeded into 6-well plates with 10⁵ cells/well and incubated for 2 weeks; the medium was changed twice a week. The media were harvested. Prior to assays, 225 µl of each medium was treated with 25 µl DTT(100mM) to give a final concentration of 10 mM for 30 min at 35 °C to inactivate endogenous collagenase inhibitors. Collagenase activity was determined by Type I Collagenase Activity Assay (Chemicon, Temecula CA). Briefly, the medium had been preincubated at room temperature for 30 min with APMA to obtain 1 mM final concentration to activate latent collagenase. The reaction mixture contained 50 µl (1 µg/µl) FITC-labeled type I collagen in a final volume of 100 µl, was further incubated at 37 °C for 3 h. The reaction was terminated by adding 200 µl enzyme stop reagent/extraction (0.05 M Tris-HCl pH9.5, ethanol containing NaCl, *o*-phenanthroline). After centrifugation at 4 000 rpm for 10 min, fluorescence in the supernatant was measured by Fluorometer (Hitachi Japan) at an excitation wavelength of 490 nm and an emission wavelength of 530nm. These experiments were performed in triplicate for each tissue sample.

One unit (U) of collagenase was defined as the amount of enzyme that hydrolyzed 1 µg of collagen substrate per min. The results shown in the figures were expressed as the mean with standard deviations of collagenase activity of samples.

Statistics

All values were expressed as mean \pm SD, ANOVA was used to determined the significance of differences among the three groups. A values of *P*<0.05 was considered statistically significant.

RESULTS

Expression level of exogenous gene and TIMP-1 gene in rMFB

The exogenous gene expression could be detected in transfection groups (pcDNA3/antisense-TIMP-1 recombinant group and pcDNA3 empty vector group) by Northern blot, but not in non-transfected rMFB (Figure 1); the expression of TIMP-1 was much higher in pcDNA3 empty vector group and non-transfected rMFB control group than pcDNA3/antisense-TIMP-1 recombinant group at mRNA level (Figure 2), the ratio of TIMP-1/GAPDH was 0.67, 2.41, and 2.97 separately (*P*<0.05); There was no significant difference (*P*>0.05) between pcDNA3 empty vector group and non-transfected rMFB control group.

Figure 1 The expression of exogenous gene in rMFB detected by Northern blot after transfection and selection. 1: pcDNA3/antisense-TIMP-1 transfecting group; 2: pcDNA3 vector control group; 3: non-transfecting rMFB control group.

Figure 2 The expression of TIMP-1 mRNA in rMFB detected by Northern blot after transfection and selection. 1: pcDNA3/antisense-TIMP-1 transfecting group; 2: pcDNA3 vector control group; 3: non-transfecting rMFB control group.

Figure 3 The expression of TIMP-1 protein level in rMFB detected by Western blot after transfection and selection. 1: pcDNA3/antisense-TIMP-1 transfecting group; 2: pcDNA3 vector control group; 3: non-transfecting rMFB control group.

Figure 4 The expression of type I, III collagen in rMFB detected by Western blot after transfection and selection. 1: pcDNA3/antisense-TIMP-1 transfecting group; 2: pcDNA3 vector control group; 3: non-transfecting rMFB control group.

Antisense-TIMP-1 recombinant plasmid treated rMFB have reduced the content of TIMP-1 protein and type I, III collagen
The content of TIMP-1 protein and collagen type I, III in recombinant transfection group was lower than those of the

control groups ($P < 0.05$) as shown by the SDS-PAGE. (Figure 3,4). the ratio of TIMP-1/ β -actin was 0.31, 0.98 and 1.32 separately at protein level ($P < 0.05$); the ratio of collagen I/ β -actin was 0.63, 1.78 and 1.92 ($P < 0.05$); and the ratio of collagen III/ β -actin was 0.59, 1.81 and 1.98 ($P < 0.05$). Moreover, there was no significant difference ($P > 0.05$) between pcDNA3 empty vector group and non-transfected control group.

Collagenase activity of rMFB in response to antisense-TIMP-1 recombinant plasmid

The collagenolytic results were shown in Figure 5. Conditioned media from control groups showed low levels of collagenolytic activity; on the contrary, collagen degradation activity of the recombinant plasmid transfection group was significantly elevated, the collagenase activity was 0.3049, 0.1411 and 0.1196 respectively. ($P < 0.05$). Experiments were repeated twice separately.

Figure 5 The enzymatic activity of MMP-1 in conditioned media from rMFB detected by Type I Collagenase Activity. Assay after transfection and selection. A: pcDNA3/antisense-TIMP-1 transfecting group; B: pcDNA3 vector control group; C: non-transfecting rMFB control group.

DISCUSSION

Liver fibrosis represents the final common pathological outcome for the majority of chronic liver insults^[21]. Pathological accumulation of extracellular matrix (ECM) in cases of liver fibrosis reflects imbalance of production and degradation of matrix proteins. At present, the common sense is that it is a reversible process. Matrix metalloproteinases (MMPs) are a family of secreted zinc proteases capable of degrading collagen and other ECM components. Recent studies suggest that MMPs may participate in pathological responses involved in liver fibrosis. Especially, interstitial collagenase (MMP-1) plays a key role in degrading collagen type I, III. (the main component of ECM). MMP-1 is tightly regulated by tissue inhibitors of matrix metalloproteinases (TIMP-1).

Current evidence indicates that the central mediator of liver fibrosis is the hepatic stellate cell (HSC)^[18]. During fibrotic injury, these retinoid-rich perisinusoidal cells proliferate and undergo a phenotypic transformation to myofibroblast (MFB)-like cells, a process termed activation^[22]. Previous work has demonstrated that activated HSC can express TIMP-1, leading to the hypothesis that matrix degradation is inhibited during progressive fibrosis^[23]. This hypothesis is supported by findings that overexpression of TIMP-1 enhances experimental fibrosis^[24] and that spontaneous recovery from liver fibrosis is associated with a diminution of TIMP-1 expression and an increase in collagenase activity with consequent matrix degradation^[25]. Nucleic acid complemented with DNA/RNA of genome is called antisense nucleic acid, including antisense DNA, antisense RNA, and ribozyme^[26]. According to these theories, we designed a special antisense sequence which may complement with the mRNA of TIMP-1, constructing the rat

pcDNA3/antisense-TIMP-1 recombinant plasmid which can express in eucaryotic cells. After transfection and selection, we observed that the exogenous antisense-TIMP-1 recombinant plasmid could be expressed in rMFB well by Northern blot analysis. In order to evaluate the intervening or blocking effects on the expression of TIMP-1, Northern and Western blots were used. The results showed that antisense-TIMP-1 recombinant plasmid could block the expression of TIMP-1 greatly in rMFB compared to that of the control groups ($P < 0.05$); though the expression of TIMP-1 could not be blocked thoroughly, there maybe existed other factors which regulated the expression of TIMP-1.

We have chosen TIMP-1 as the target gene so as to elevate latent and active interstitial collagenase (MMP-1) activity in rMFB. In our study, we found that the enzymatic activity of MMP-1 in the pcDNA3/antisense-TIMP-1 recombinant transfecting group was 2-3 times higher than that in the control groups. However, the enzymatic activity was lower in the control groups ($P > 0.05$). These results were proven by FITC-labeled type I collagenase Activity Assay.

In healthy human liver, the collagen type I, III account for about 80 % of the total collagen of liver, while it rises up to more than 95 % in fibrotic livers. The collagen type I covers about 60-70 % of the total collagen of fibrotic liver, and type III was 20-30 %^[27-29]. Collagen I, III are the main target of MMP-1. MMP-1 has similar capacity of degrading collagen I, III. Therefore, collagen I, III are regarded as the important parameters to reflect the metabolism of collagen, and thus we can judge the therapeutic effect of the anti-fibrotic strategies of the liver^[30-32].

The content of collagen I, III was lower in the pcDNA3/antisense-TIMP-1 recombinant transfecting group than that in control groups ($P < 0.05$) determined by Western blotting. These data showed that this recombinant plasmid had stronger effects on increasing the degrading capacity of collagen I, III, decreasing the deposition of ECM, and reversing probably the hepatic fibrosis.

In conclusion, our experiment results have demonstrated that the pcDNA3/antisense-TIMP-1 recombinant has anti-hepatic fibrosis effect in vitro strongly through inhibiting the TIMP-1.

Abstract

AIM: To study the effect of leflunomide on immunological liver injury (ILI) in mice.

METHODS: ILI was induced by tail vein injection of 2.5 mg *Bacillus Calmette-Guerin* (BCG), and 10 d later with 10 µg lipopolysaccharide (LPS) in 0.2 mL saline (BCG+LPS). The alanine aminotransferase (ALT), aspartate aminotransferase (AST), nitric oxide (NO) level in plasma and malondialdehyde (MDA), glutathione peroxidase (GSHpx) in liver homogenate were assayed by spectroscopy. The serum content of tumor necrosis factors-α (TNF-α) was determined by ELISA. Interleukin-1 (IL-1), interleukin-2 (IL-2) and Concanavalin A (ConA)-induced splenocyte proliferation response were determined by methods of ³H-infiltrated cell proliferation.

RESULTS: Leflunomide (4, 12, 36 mg·kg⁻¹) was found to significantly decrease the serum transaminase (ALT, AST) activity and MDA content in liver homogenate, and improve reduced GSHpx level of liver homogenate. Leflunomide (4, 12, 36 mg·kg⁻¹) significantly lowered TNF-α and NO level in serum, and IL-1 produced by intraperitoneal macrophages (PMΦ). Moreover, the decreased IL-2 production and ConA-induced splenocyte proliferation response were further inhibited.

CONCLUSION: These findings suggested that leflunomide had significant protective action on ILI in mice.

INTRODUCTION

Earlier studies have identified leflunomide, an isoxazole derivative, as a unique immunomodulatory agent capable of treating rheumatoid arthritis, allograft and xenograft rejection, systemic lupus erythematosus, prostate carcinoma, and neuronal-glial tumours, etc^[1-12]. Our studies indicated that leflunomide had significantly therapeutic effects on the secondary inflammation response of adjuvant arthritis (AA) in rats. Recent evidence suggested the anti-inflammatory and immunoregulatory effects of leflunomide were related to its ability to suppress IL-1 and TNF-α selectively over their

inhibitors in T lymphocyte/monocyte activation, and the activation of nuclear factor kappa B, a potent mediator of inflammation when stimulated by inflammatory agents^[13-16]. Jankovic reported that A₇₇₁₇₂₆, leflunomide's active metabolite, also had inhibitory effect on NO production and iNOS mRNA expression in IFN-γ+LPS-activated murine and rat primary fibroblast^[17, 18].

As we known, the activity of cytokines such as TNF-α, IL-1, IL-6, NO and T cell mediated immunity were closely related to the degree of liver injury caused by virus, endotoxin, ConA, and GalN^[19-21]. Thus, inhibition of proinflammatory cytokines and regulation of host immunity would be beneficial to alleviating liver injury.

Based on the immunological dysfunction in liver injury and leflunomide's immunomodulatory feature with high efficacy and low toxicity, we assumed that leflunomide might have therapeutic effect on ILI. To the best of our knowledge, however, there has been no report so far concerning the effect of leflunomide on ILI. In this study, therefore, we have clarified the therapeutic effect of leflunomide on ILI in mice.

MATERIALS AND METHODS

Animals and reagents

Male Kunming strain mice weighing 18-22 g were purchased from Animal Center of Anhui Medical University. Mice were allowed to take food and tap water *ad libitum*. Leflunomide was kindly donated by Cinkate Co., USA. ConA and LPS from *Escherichia coli* were purchased from Sigma Co., St. Louis, M, USA. 1, 1, 3, 3-tetraethoxypropane (TEP) and 5, 5'-dithiobis-(2-nitrobenzic acid) (DTNB) were purchased from FLUKA Co., Switzerland. BCG was purchased from Institute of Shanghai Biological Products.

Preparation of ILI^[22]

Each mouse was injected with 2.5 mg BCG (viable bacilli) in 0.2 mL saline via tail vein, and 10 d later with 10 µg LPS in 0.2 mL saline. At 0, 4, 8, and 12 h post-injection of LPS, animals received either leflunomide (4, 12, and 36 mg/kg, ig) or appropriate volume (25 mL/kg, ig) of vehicle (3 % prednisone). The mice were anesthetized with ether, then sacrificed by cervical dislocation 16 h after LPS injection and trunk blood was collected into heparinized tubes (50 U/mL) and centrifuged (1 500×g, 10 min, room temperature). Plasma was aspirated and stored at -70 °C until assayed as described below. The liver was also removed and stored at -70 °C until required.

Measurement of plasma ALT, AST, NO and TNF-α

Plasma ALT, and AST were determined using commercial kits produced by Institute of Shanghai Biological Products affiliated to the Ministry of Health. These activities are expressed as an international unit (U/L). Serum TNF-α and NO were measured using commercial kits produced by Sigma Co. and Beijing Biotinge-Tech., Co.Ltd, and their levels were expressed as pg·mL⁻¹ and µmol·L⁻¹ respectively.

Measurement of MDA and GSHpx in liver homogenate

Livers were thawed, weighed and homogenized with Tris-Hcl

buffer (5 mM containing 2 mM EDTA, pH 7.4). Homogenates were centrifuged (1 000×g, 10 min, room temperature) and the supernatant was used immediately for the assays of MDA and GSHpx. MDA was measured by the thiobarbituric acid method according to standard techniques (Gavino VG., 1981). The content of MDA was expressed as nmol per gram liver tissue. GSHpx was measured by the DTNB method, and its content was expressed as U per milligram protein.

Measurement of ConA induced splenocyte proliferation, IL-1 and IL-2

ConA induced splenocyte proliferation was determined according to the report by Yamamoto I in 1982. IL-1 and IL-2 were measured according to the reference (Liang JS, 1989; Ding GF, 1988).

Statistical analysis

Results were expressed by $\bar{x} \pm s$. Statistical significance of differences between groups were determined by ANOVA followed by Student's *t* test. *P* value of less than 0.05 was considered statistically significance.

RESULTS

Therapeutic effects of leflunomide on ILI induced by BCG+LPS in mice

Results are shown in Tables 1 and 2. ALT, AST, and NO in plasma and MDA content in liver homogenate were significantly increased after the interval injection of BCG and LPS. Meanwhile, the GSHpx level in liver homogenate was sharply decreased. Both leflunomide (12, 36 mg/kg) and prednisone (3 mg/kg) could not only significantly decrease ALT, AST, NO and MDA level, but evidently increase GSHpx in mice with ILI.

Effects of leflunomide on TNF-α

As shown in Table 3, when the mice were first injected with BCG and then challenged with LPS, the level of TNF-α was elevated significantly. Leflunomide (4, 12, and 36 mg/kg) obviously decreased the increased TNF-α level in serum.

Table 3 Influences of leflunomide on serum TNF-α induced by BCG+LPS in mice ($n=8$, $\bar{x} \pm s$)

Groups	Dose (mg·kg ⁻¹)	TNF-α (pg·mL ⁻¹)
Normal	-	Under detection limit

Influence of leflunomide on IL-1

IL-1 excreted by PM_φ was significantly increased in the model group. As shown in Table 4, Leflunomide (4, 12, and 36 mg/kg) evidently inhibited PM_φ excreting too much IL-1.

Effect of leflunomide on IL-2 generation and ConA induced splenocyte proliferation

IL-2 and ConA induced splenocyte proliferation were significantly inhibited in the model group (Table 4). Leflunomide (4, 12, and 36 mg/kg) further inhibited IL-2 production and ConA induced splenocyte proliferation response.

DISCUSSION

It has been demonstrated that severe hepatitis could be induced by injecting a small dose of bacterial LPS into BCG-pretreated mice^[22]. In this article, ILI was successfully induced by BCG+LPS. On this basis, leflunomide (4, 12, and 36 mg/kg) could significantly lower the increased plasma transaminase level and MDA content in liver homogenate, meanwhile, GSHpx level rose significantly. All these indicated that leflunomide markedly protected ILI. Leflunomide significantly inhibited the generation of NO, TNF-α and IL-1 excreted by PM_φ, moreover, IL-2 production and ConA induced splenocyte proliferation was further inhibited by leflunomide. Therefore, the protective effects of leflunomide on ILI might be related with its function of balancing cytokine generation and modulating immune.

As it is known, TNF-α is one of the important mediators in liver injury. It has been demonstrated that liver injury induced by endotoxin was conducted by TNF-α, and the

activity of TNF- α was positively related with the extent of liver necrosis^[22-24]. However, TNF- α itself could not directly result in liver injury. The damaging degree of TNF- α on liver might be involved with infection, activity of Kupffer cell, and endogenous serine type protease, etc^[25-30]. TNF- α could act as the first factor of liver injury, its elevation would stimulate a number of proinflammatory mediators including NO, IL-1, IL-6, IL-8 and SIL-2R^[31-36], which further deteriorated the liver injury intoxicated by TNF. Therefore, although the TNF lever was low, liver was damaged significantly.

Leflunomide, an immunomodulatory reagent, is mainly aimed to inhibit the activity of dihydroorotate dehydrogenase (DHODH) involved in *de novo* pyrimidine biosynthesis. But at a higher concentration, it mainly inhibited protein tyrosine kinases initiating signaling^[1,13,14,37,38], and therefore could reduce the cell response to mitogen and cytokine. In the model of ILI induced by BCG+LPS, leflunomide could significantly lower the increased TNF- α level in serum, which agreed with the results of Smith's experiment that leflunomide significantly lowered the increased TNF level in joints from AA rats^[15,16,39]. As it is known, TNF mainly come from Kupffer cell in liver. In this article, leflunomide significantly inhibited TNF- α level in serum of ILI. It deserved further investigation on about whether it is related to leflunomide's effect of regulating the immunological dysfunction through inhibiting the growth and differentiation of Kupffer cell and production of TNF, thus, alleviating liver injury.

As reported in documents, the synthesis of NO was regulated by many immunological factors including TNF- α , IL-1, and IFN- γ , which is composed of a complicated web system, could act on hepatocytes, Kupffer cells and Ito in endotoxemia mice to increase the generation of NO^[31,32,35,40]. Likewise, LPS could also induce Ito cells to express iNOS and synthesis of a large amount of NO^[41,42]. According to our investigation, the effects of leflunomide to inhibit ILI might well be related with its function of decreasing the degeneration of NO.

Although IL-1 itself has no damage on liver, its elevation could stimulate many kinds of immunological and inflammatory cells to excrete cytokine including TNF- α , IFN- γ , IL-6, and IL-8, which mediate the inflammatory and immunological injury. Apart from these, IL-1, TNF- α , IFN- γ and LPS could act on hepatocyte to enhance the expression of iNOS mRNA in synergetic manner, and to increase the generation of NO, thus deteriorating the liver injury. Leflunomide significantly regulated abnormal IL-1 level excreted by PM ϕ in ILI mice *in vivo*, which agrees with Deage's investigation^[43] in effect of leflunomide on AA rats.

Suzuki found that splenectomy could modulate the excretion of inflammatory mediators, which prevented liver injury intoxicated by LPS after hepatectomy. In this study, we discovered that IL-2 production and ConA induced splenocyte proliferation were reduced in ILI induced by BCG+LPS. However, leflunomide further inhibited the production of IL-2 and ConA induced splenocyte proliferation response. Hoskin *et al*^[44] reported that leflunomide inhibited the T lymphatic cell growth and response to IL-2 and production of IL-2. Further studies are needed to elucidate the relationship between the protective effect of leflunomide on ILI and its inhibitory action on cellular immune function.

Abstract

AIM: To determine the feasibility of creating direct intrahepatic portacaval shunt (DIPS) in swine with puncture under sonographic guidance.

METHODS: DIPS was created in 10 domestic swine under sonographic guidance. Liver function, blood ammonia level and portosystemic gradient (PSG) were compared before and after the procedure. Patency of shunt was followed by portography every 7 days after DIPS.

RESULTS: DIPS was successfully established in all 10 swine without any complications. One day after procedure the alanine aminotransferase (ALT), aspartate aminotransferase (AST), and blood ammonia level (BAL) of swine rose from 5.40 ± 0.69 , 16.00 ± 0.79 and 35.66 ± 4.10 to 34.20 ± 3.46 , 59.70 ± 2.22 and 66.94 ± 3.44 respectively. ($P < 0.05$). The PSG decreased from 0.59 ± 0.20 kPa to 0.24 ± 0.11 kPa after DIPS ($P < 0.05$). The shunt of 10 swine was kept patent from 7-28 days (median patency time was 14 days).

CONCLUSION: This initial experience demonstrated that creating intrahepatic portacaval shunt from retrohepatic segment of IVC to portal vein with puncture under sonographic guidance in swine is safe and feasible. Further studies are necessary to perform DIPS in cirrhosis patients.

INTRODUCTION

Since Röschl successfully created an intrahepatic shunt from hepatic vein to portal vein in a canine model in 1969, the transjugular intrahepatic portosystemic shunt (TIPS) procedure has been used increasingly in the management of portal hypertension and its complications^[1-12]. One of the main limitations of TIPS has been the high incidence of shunt malfunction. There is a wide range of shunt malfunction rates reported in the literature from 17-50 % within six months to 23-87 % within the first year^[11-21]. Many experimental and clinical studies^[4,15,23,26] demonstrated that stenosis of the outflow hepatic vein (HV) is the main problem to limit the long-term patency of TIPS and development of HV stenosis after TIPS placement will be minimized by the use of the largest HV (RHV or MHV). The inferior vena cava (IVC) is the largest vein in human being, whose diameter is far wider than that of HV.

Therefore, using IVC as the outflow vein might improve the patency of intrahepatic portosystemic shunt theoretically^[24-28]. To determine the feasibility and safety of creating DIPS in swine under a sonographic guidance, we carried out this study to provide a new route for clinical intrahepatic portosystemic shunt.

MATERIALS AND METHODS

Animals

10 domestic swine, 6-8 weeks old, each weighing 22-25 kg, were used for this study. All animals had a normal liver without portal hypertension.

Pre-procedural preparation

Before procedure, each animal underwent abdominal enhanced CT scan by bolus injection of 80 ml Iopamidol intravenously. The length, diameter and the extent of RHSIVC invested by hepatic parenchyma were measured. The anatomical relationship of the intrahepatic portal vein and RHSIVC was also carefully studied. Liver function and blood ammonia level were checked before procedure to serve as a baseline for further evaluating the damage to swine's liver function after DIPS.

Procedure

Each swine was anaesthetized with ketamine (20 mg/kg) and diazepam (5 mg/kg) intramuscularly. After right femoral vein cut down and dilated, a 10-F-diameter, 41-cm-long sheath (Cook Bloomington, U.S.A) was introduced into swine's IVC and pressure measurement was made. Then, RUPS-100 portal access set modified by increasing the primary curve was passed through the 10-F sheath and placed into swine's RHSIVC. Under sonographic guidance, the tip of modified RUPS set was wedged against the right anterior-lateral wall of the IVC just beneath the level of the portal vein (Figure 1). RUPS-100 set was advanced slightly and orientation of the tip was adjusted ceaselessly. When the posterior-lateral wall of intrahepatic portal vein became "pushed" on sonography the 0.038-inch metal needle and 5-F teflon catheter of modified RUPS set was thrust toward portal vein. After metal needle removed the 5-F teflon catheter was pulled back slowly with intermittent aspiration. When blood can be freely aspirated 5 ml contrast medium was infused as test injection. If portal vein's access was confirmed a 0.035-inch guide wire was passed through the 5-F teflon catheter into the portal vein. Subsequently, a 5-F pigtail catheter was advanced over the guide wire into the portal vein. Then, portography was performed and the pressure of portal vein was measured. After 500 U/kg heparin was intravenously infused a 0.035-inch Amplatz super stiff guide wire was introduced into the portal vein and 5-F pigtail catheter was removed. A 6-mm-diameter, 8-cm-long angioplasty balloon catheter was advanced over the Amplatz guide wire and positioned in the tract between the RHSIVC and portal vein. The balloon was partially inflated and a spot radiography of the partially inflated balloon catheter was used as a road map guide for stent placement. The distal "waist" of the balloon served to mark the portal vein wall and the proximal "waist" marked the wall of the RHSIVC. The distance between the two "waists" is the length of the hepatic parenchymal tract between the portal vein and RHSIVC and is the minimum

length of the stent required to connecting these two structures. The balloon catheter was then fully inflated to predilate the tract. As the balloon was being deflated, the 10-F sheath was advanced over the balloon catheter into the portal vein. With use of the road map image as a guide, the shunt was lined by one or two home-made metal bare stents. Portography was performed immediately after stent placement and pressure measurements were also made. Finally, a 5-F pigtail catheter was retained in animal's IVC for follow-up portography and right femoral vein incision was sutured. No anticoagulant, antibiotics or antiplatelet therapy was administered after procedure. At termination of the study, the animals were sacrificed by overdose ketamine intravenously for pathological examination.

Follow-up

Cross-sectional abdominal contrast-enhanced CT scan was performed 3 days after DIPS to detect any puncture-related complications. Liver function and blood ammonia level were rechecked at 1, 7 and 14 days after procedure. Portography was performed through the 5-F pigtail catheter previously retained in animal's IVC every 7 days after DIPS to evaluate the patency of shunt till the shunt complete occlusion.

Statistical analysis

All measured values were expressed as mean \pm SD. Laboratory values and portosystemic gradient (PSG) before and after DIPS was compared using paired-samples *t* test. The patency of DIPS shunt was evaluated by Kaplan-Meier analysis. If *P* values <0.05 the difference was considered significant.

RESULTS

CT scan

On pre-procedure CT imaging the mean length and diameter of swine's RHSIVC was 47.28 ± 3.65 mm and 19.00 ± 2.24 mm respectively. About 85.83–100 % of swine's RHSIVC was completely invested by hepatic parenchyma (Figure 2). On the CT imaging obtained 3 days after DIPS no hematoma beneath the hepatic integument or intraperitoneal bleeding was revealed. All stents were accurately deployed in the shunt connecting the intrahepatic portal vein and RHSIVC. No thrombosis could be detected in the portal vein or IVC (Figure 3).

Portal vein puncture and stent deployment

The direct RHSIVC to portal vein puncture visualized with real-time ultrasound was successfully made in all 10 swine. 1–5 (mean 2.2) passes were required to complete the puncture. Mean length of the intraparenchymal tract from RHIVC to portal vein was 15.43 ± 3.36 mm. In 8 swine, the shunt linked right branch of portal vein and RHSIVC, in the remaining 2 animals the left branch of portal vein was connected. Mean angles between the axial of shunt and RHSIVC was $29.42 \pm 2.31^\circ$. Totally 14 stents were deployed in 10 animals' shunts. In No. 1 and 6 swine, first stent was deployed too far into the portal vein and a second stent was required to fully cover the tract. In No.2 and 8 swine, the first stent dislodged into animals' RHSIVC and a second stent was necessitated. All stents were dilated to 8 mm in diameter without any contraction. After stents deployment, immediate portography demonstrated rapid flow from portal vein to IVC through widely patent DIPS shunt and no obvious contrast-medium extravasation was observed. The post-procedure PSG was significantly lower than that of before (Table 1) (Figure 4, 5).

Follow-up

On follow-up, no procedure-related death occurred, every

animal grew well and no signs or symptoms of infection could be observed. The patency time of DIPS shunt varied from 7 days to 28 days (median patency time was 14 days) after procedure (Figure 6).

Table 1 Portosystemic Gradient before and after DIPS (kPa)

	Pressure of IVC		Pressure of Portal vein		PSG	
	Before	After	Before	After	Before	After
	1.28 ± 0.28	1.41 ± 0.28	1.86 ± 0.21	1.57 ± 0.17	0.59 ± 0.20	0.24 ± 0.11
<i>P</i> values	0.034		0.001		0.007	

Figure 1 Intrahepatic portal vein, RHSIVC of swine and the modified RUPS-100 set wedging against the anterior-lateral wall of RHSIVC are clearly demonstrated on sonography.

Figure 2 Sectional abdominal enhanced CT scan of swine before DIPS demonstrates the swine's intrahepatic portal vein and retrohepatic segment of IVC clearly.

Figure 3 No hematoma beneath the hepatic integument or intraperitoneal bleeding is detected on sectional abdominal enhanced CT imaging of swine after DIPS. The self-expandable home-made stent is accurately deployed in the shunt connecting the intrahepatic portal vein and RHSIVC.

Figure 4 After intrahepatic portal vein successfully accessed via retrohepatic segment of IVC approach, portography was performed with a 5-F pigtail catheter. Swine's anterior and posterior branch of right portal vein is clearly demonstrated.

Figure 5 The DIPS shunt is lined by an 8 mm-diameter, 6 cm-long home-made metal bare stent. The stent is fully dilated and accurately connected the swine's RHSIVC and anterior branch of right portal vein. Swine's hepatic perfusion is well and animal's IVC was patent. No extravasation of contrast medium can be detected.

Figure 6 Median patency time of 10 DIPS shunt is 14 days. 7, 14, 21 and 28 days after DIPS procedure the cumulative patency rate of shunt is 100 %, 80 %, 50 % and 20 % respectively.

Laboratory examination

One and 7 days after DIPS, animal's alanine aminotransferase (ALT) and aspartate aminotransferase (AST) became significantly higher than the pre-DIPS values but the 7 day's values already became significantly lower than that of the first day after procedure. 14 days after DIPS, ALT and AST of swine returned to their normal pre-DIPS level. Animal's total bilirubin (TB) and combined bilirubin (CB) remained unchanged before and after DIPS. Swine's blood ammonia level increased significantly 1 day after procedure and returned to the its baseline value at 7days after DIPS (Table 2).

Table 2 Laboratory examination before DIPS, 1, 7 and 14 days after DIPS

Laboratory examination	Pre-DIPS	1d after DIPS	7d after DIPS	14d after DIPS
ALT (U/L)	5.40±0.69	34.20±3.46	18.0±2.11	5.80±0.66
AST(U/L)	16.00±0.79	59.70±2.22	23.90±0.90	17.60±0.75
TB(uoml/L)	1.86±0.20	1.94±0.23	2.16±0.17	2.10±0.17
CB(uoml/L)	0.66±0.10	0.86±0.14	0.95±0.12	0.88±0.19
BAL(uoml/L)	35.66±4.10	66.94±3.44	36.08±3.93	43.59±3.91

Note: Compared with the value of pre-DIPS the swine's ALT and AST rose significantly 1 and 7 days after DIPS. But 7 days' value had decreased significantly lower than that of first day after procedure. 14 days after DIPS the swine's ALT and AST returned to their baseline value of pre-DIPS. Swine's TB and CB kept no change before and after DIPS. Animal's blood ammonia level elevated significantly first day after DIPS. 7 days after procedure the animal's BAL returned to its baseline value of pre-DIPS and kept no significant change at 14 days after DIPS.

DISCUSSION

Direct intrahepatic portacaval shunt (DIPS) is to establish a low-resistant pathway between the intrahepatic portal vein and RHSIVC by diverting some of portal flow into IVC to achieve the goal of lowering the portal venous pressure. Compared with conventional TIPS, DIPS links RHSIVC rather than the hepatic vein. The diameter of RHSIVC is much wider than that of hepatic vein and the angle of DIPS shunt-to-IVC is more acute than that of TIPS shunt-to-hepatic vein. Thus, after DIPS the local hemodynamic change, a trigger factor of stenosis or occlusion of the outflow vein, may be less than that after TIPS and the patency time of DIPS may be longer than that of TIPS. In some cirrhosis patients, the hepatic vein drained into IVC with an approximate right angle or the level of intrahepatic portal vein might elevate too close to the level of hepatic vein owing to severe fibrosis of the liver. On these clinical situations, the RUPS-100 set can not be favorably introduced into the hepatic vein and puncture into portal vein is too difficult to be made^[24]. Moreover, to establish a portosystemic shunt in some portal hypertension patients with Budd-Chiari syndrome or hepatic venoocclusive disease the puncture into portal vein can but be made from IVC^[25,29]. Meanwhile, in some patients with previous TIPS shunt occlusion and no suitable hepatic vein could be supported a second parallel TIPS and DIPS seemed to be a rational choice^[30].

Local hematoma or pneumothorax resulted from mispunctures of the carotid artery or the trachea was considered as the serious complication of internal jugular vein puncture^[4,31,32]. Some authors^[31,32] pointed out that a previous TIPS procedure might interfere with the operative management of the subsequent orthotopic liver transplantation by deploying a stent into the suprahepatic portion of IVC, which often occurred at TIPS revision and a second parallel TIPS was established. To completely avoid these puncture-related complications and potential suboptimal stent placement of conventional TIPS we created this DIPS via a femoral vein's approach.

Anatomic construct of swine's liver and its post-trauma's histopathologic response are similar to those of human being^[35,36]. So DIPS can be created in pigs using techniques and equipment identical to that used in humans. The key step of successfully established DIPS is to select a suitable puncture site of IVC. In this study, the mean length of swine's RHSIVC was 47.28±3.65 mm and 85.83-100 % of RHSIVC was completely invested by hepatic parenchyma. These are the anatomic foundation of safely performing DIPS in swine. Mean diameter of swine's RHSIVC is 19.00±2.24 mm which is far

wider than the 10.10 ± 1.58 mm-diameter of swine's hepatic vein. These results demonstrated using RHSIVC as the drain vein of DIPS in swine might improve the patency of intrahepatic portosystemic shunt theoretically.

Portal vein can not be precisely targeted under fluoroscopy. Thus, many major even fatal complications of conventional TIPS procedure are related to the "blind puncture" from hepatic vein into portal vein^[4,31,32]. Meanwhile, the bile duct injury and subsequent bile leak has been implicated as a cause of shunt thrombosis. Mucus in bile, not bile itself, is thought to be the thrombogenic factor of early shunt malfunction^[37,38]. Accordingly, using an effective guiding tool plays a most important role not only in creating DIPS safely but also in achieving a long-term patent shunt owing to improve the accuracy of puncture. We performed DIPS under sonographic guidance because of its free of X-ray and easy to perform. On sonography the location of intrahepatic portal vein and the tip of modified RUPS-100 placed in swine's RHSIVC can be clearly demonstrated. Only should we do is to adjust the angle of RUPS-100 set-to-IVC and advance the set slightly. When the left posterior-lateral wall of intrahepatic portal vein became "pushed", puncture was made. In our study, only 2.2 passes were required to accomplish the puncture, mean distance of puncture was only 15.43 ± 3.36 mm and no puncture-related complications could be detected after procedure. These findings verified the effectiveness of real-time ultrasound to guide puncture in DIPS procedure. By using sonographic guidance to perform DIPS in cirrhosis patient attention should be paid to the interference brought by regenerated nodules, pneumatosis of bowel and ascites to the clarity of sonography. Portosystemic gradient (PSG) decreasing from 0.59 ± 0.20 kPa to 0.24 ± 0.11 kPa after procedure ($P < 0.05$) verified the effectiveness of DIPS to decompress the portal venous pressure. After DIPS, the swine's ALT and AST increased significantly for a time but they finally returned to their normal pre-DIPS levels within two weeks after procedure. This exhibited the damage brought by DIPS to swine's liver function might just be temporary. Animal's TB and CB remained unchanged before and after DIPS. This implicated the injury of bile duct after DIPS is minor, which might attribute to the less number of passes required to complete the puncture and a short distance of intraparenchymal tract. Animal's blood ammonia level elevated significantly first day after DIPS. 7 days after procedure the animal's BAL returned to its baseline value before DIPS. This would be related to the swine used in this study without portal hypertension and portosystemic gradient quickly achieved a dynamic equilibrium after DIPS.

Our DIPS shunt kept patent from 7-28 days (median patency time was 14 days) which were shorter than the results published by Petersen *et al.*^[26]. Except the breed disparity of animals between two studies some factors may be related to this despondent result. (1) All swine underwent DIPS without intubation and the respiratory movement of animals could not be well controlled. 4 stents' unprecisely deployment, 2 deployed far into the portal vein and 2 dislodged into animal's RHSIVC, were attributed to animal's irregular respiratory movement. (2) We created this DIPS via a femoral vein's approach. The direction of flow in shunt is opposite to the flow orientation in IVC. This might form whirlpool or turbulent flow at the outflow venous end of the stent and made it liable to injury from stress of the jet stream of blood. (3) Compared with the Palmaz stents used by Petersen, the high thrombogenicity of home-made stent may lead to early shunt malfunction. Finally, All swine used in this study have a normal liver without portal hypertension. After DIPS, the portosystemic gradient was decreased to 0.24 ± 0.11 kPa which can not maintain the sufficient flow in shunt, using a "bare-stent" that can not effectively prevent the ingrowth of normal liver parenchyma and no anticoagulant

being administered were also related to this early stenosis or occlusion of shunt.

Our initial experience demonstrated creating direct intrahepatic portosystemic shunt in swine was safe and feasible. Carefully studying the anatomic relationship of intrahepatic portal vein and RHSIVC in cirrhosis patients and deploying a low-thrombogenic stent-graft in parenchymal track seem to be necessary for safely performing and achieving a long term patent DIPS in human being.

Abstract

AIM: To study the effects of palmatine, a known inhibitor on delayed rectifier potassium current and L-type calcium current ($I_{Ca,L}$) in guinea pig ventricular myocytes, on the potassium and calcium currents in isolated rat hepatocytes.

METHODS: Tight-seal whole-cell patch-clamp techniques were performed to investigate the effects of palmatine on the delayed outward potassium currents (I_K), inward rectifier potassium current (I_{K1}) and Ca^{2+} release-activated Ca^{2+} current (I_{CRAC}) in enzymatically isolated rat hepatocytes.

RESULTS: Palmatine 0.3-100 μ M reduced I_K in a concentration-dependent manner with EC_{50} of 41.62 ± 10.11 μ M and n_H , 0.48 ± 0.07 ($n=8$). The effect of the drug was poorly reversible after washout. When the bath solution was changed to tetraethylammonium (TEA) 8 mM, I_K was inhibited. Palmatine 10 μ M and 100 μ M shifted the I-V curves of I_K downward, and the block of I_K was voltage-independent. Palmatine 0.3-100 μ M also inhibited I_{CRAC} in a concentration-dependent manner. The fitting parameters were as follows: $EC_{50}=51.19 \pm 15.18$ μ M, and $n_H=0.46 \pm 0.07$ ($n=8$). The peak value of I_{CRAC} in the I-V relationship was decreased by palmatine 10 μ M and 100 μ M. But the reverse potential of I_{CRAC} occurred at Voltage=0 mV in all cells. Palmatine 0.3-100 μ M failed to have any significant effect on either inward or outward components of I_{K1} at any membrane potential examined.

CONCLUSION: The inhibitory effects on I_K and I_{CRAC} could be one of the mechanisms that palmatine exerts protective effect on hepatocytes.

INTRODUCTION

There are many natural drugs for liver diseases currently used in popular medicine. For example, quaternary protoberberine

alkaloids from *Flissitigma* and *Goniiothalamus* have been used in popular medicine for hepatomegaly and hepatosplenomegaly^[1,2]. The uses of alkaloids from *Berberis aristata* for liver injury induced by chemical carcinogenesis and alkaloids from *Enantica* for disorders of bilirubin have also been reported^[3,4].

Palmatine, the protoberberine class of isoquinoline alkaloids, has been found in plants of various families, and mainly presents in the rhizomes of *Fibrorurea Tinctoria Lour.* These medicinal plants have been used as folk medicine in treatment of jaundice, dysentery, hypertension, inflammation and liver-related diseases^[5,6]. The previous studies have shown that palmatine could block the delayed rectifier potassium current and had inhibition effect on L-type calcium current ($I_{Ca,L}$) in guinea pig ventricular myocytes^[7-11]. Pauli *et al* reported a protoberberine alkaloids mixture from *Enantia chlorantha*, called Hepasor, containing palmatine, columbamine and jatrorrhizine prevented liver from chemically induced traumatization and also promoted the healing process in the hepatic injury models selected. Hepasor improved the blood flow and mitotic activity in thioacetamide-traumatized rat livers^[12]. However, the hepatoprotective mechanism of palmatine still remains unknown. And there are no data available to the relationship between ion currents in hepatocytes and the hepatoprotective effect of palmatine.

In the present study, we investigated the effects of palmatine on whole-cell currents recorded from isolated rat hepatocytes to explore its mechanisms against liver injury. We tried to develop not only an effective hepatoprotective agent but also a promising leading compound against liver injury while maintaining a low side-effect profile.

MATERIALS AND METHODS

Cell preparation

The rat hepatocytes were enzymatically isolated from Sprague Dawley (SD) rats of either sex (150 to 200 g) by slightly modified procedures described previously^[13-18]. Briefly, adult animals were anesthetized with an intraperitoneal injection of pentobarbital sodium (30 mg/kg) in strict accordance to the guidelines established by the Institutional Animal Care and Use Committee, which follow all applicable state and federal laws. The portal vein and the inferior vena cava were cannulated. The liver was initially perfused at a flow rate of 25 mL \cdot min⁻¹ with a constant-flow system with modified oxygenated Ca^{2+} , Mg^{2+} -free Hanks' solution containing (in mM): NaCl 137, KCl 5.4, NaH_2PO_4 0.5, Na_2HPO_4 0.58, $NaHCO_3$ 4.16 and Glucose 5.5 (pH 7.3) for several minutes, followed by perfusion with a Ca^{2+} , Mg^{2+} -free Hanks' solution containing collagenase (0.3 g \cdot L⁻¹; type I) for 10 min. The solutions were gassed with 100 % O_2 and warmed to 37 $^{\circ}$ C. After these perfusions, the liver was excised and then minced in Ca^{2+} , Mg^{2+} -free Hanks' solution at 0 $^{\circ}$ C. The cells were filtered through a 200 μ m nylon mesh, and washed three times by centrifugation at 50 g for 2 min. The cell pellets were resuspended in Kraft-bruhe (KB) solution containing (in mM): L-glutamic acid 70, KCl 130, taurine 15, KH_2PO_4 10, $MgCl_2$ 0.5, Glucose 11, 4-(2-hydroxyethyl)-1-piperazine-*N'*-2-ethanesulfonic acid (HEPES) 10 and ethylene glycol-bis (β -aminoethyl ether)-*N*,

N, *N'*, *N'*-tetraacetic acid (EGTA) 0.5 (pH 7.4) that yielded approximately 85 % to 95 % viable hepatocytes. A small aliquot of the medium containing single cell was transferred into a 1 mL chamber mounted on the stage of an inverted microscope (XD-101_{2B}, Nanjing, China). The spherical, smooth cells were used for the whole-cell voltage-clamp studies. All experiments were performed at room temperature (20 to 22 °C).

Voltage-clamp recording

A programmable vertical puller (pp-83, Narishige, Japan) was used to pull the electrodes. The resistance of the capillary glass electrodes (GG-17, Nanjing, China) used was 2 to 4 MΩ when filled with internal solution. A patch-clamp amplifier (PC-II, Wuhan, China) was used to record whole-cell currents with four-pole Bessel filter set at 1 kHz, digitized at 5 kHz. The protocols for voltage clamp and data analysis were established with routines using software (pClamp 6.0, Wuhan, China) and data were stored on computer for subsequent analysis. Drug actions were measured only after steady-state-conditions were reached, which were judged by the amplitudes and time courses of currents remaining constant with further perfusion of drug.

Drugs and solutions

Palmitine hydrochloride was obtained from Zhonglian Pharmaceutical Company of China as base powders, dissolved in distilled water and made a stock solution at 0.1 M. Palmitine was added to bath solution for extracellular application. All drugs were from Sigma Chemical Co unless otherwise indicated.

With studies of I_K , the bath solution was a modified Tyrode's solution contained (in mM): NaCl 144, KCl 4.0, CaCl₂ 1.8, MgCl₂ 0.53, Na₂HPO₄ 0.33, HEPES 5 and Glucose 5.5 (pH 7.3). The patch pipette solution contained (in mM): KCl 130, K₂ATP 5.0, creatine phosphate 5.0 and HEPES 5.0 (pH 7.4).

For experiments on I_{K1} , both the bath solution and the pipette solution contained (in mM): KCl 7, MgCl₂ 2, EGTA 1, K-glutamate 130 and HEPES 10 (pH 7.4).

For I_{CRAC} recording, the bath solution was (in mM): NaCl 140, KCl 2.8, CaCl₂ 10, MgCl₂ 0.5, Glucose 11 and HEPES 10 (pH 7.4). The pipette solution used (in mM): K-glutamate 145, NaCl 8, MgCl₂ 1, MgATP 0.5, EGTA 10 and HEPES 10 (pH 7.2).

Statistics

All values are expressed as mean \pm S.E.M and error bars were plotted as S.E.M. Student's *t* test was used to evaluate the statistical significance of differences between means. A value of $P < 0.05$ was considered to be statistically significant. Concentration-response curves were fitted by the Hill equation: Inhibition of current (%) = $100/[1 + (EC_{50}/C)^{nH}]$

Where EC_{50} is the concentration of palmitine for half-maximum block, *C* is the concentration of palmitine, and n_H , the Hill coefficient.

RESULTS

Effects of palmitine on I_K

I_K was evoked in isolated rat hepatocytes by depolarizing pulse to +140 mV for 900 ms from a holding potential of -50 mV. The current at the end point of the test pulse was measured as the amplitude of I_K ^[19].

To better the concentration of palmitine necessary for half-maximal effect, six concentrations (0.3-100 μ M) were studied. The percentage block of I_K was defined as $(I_{Control} - I_{palmitine})/I_{Control}$ and plotted as a function of logarithm [palmitine] in Figure 1B. At +140 mV, palmitine exerted a concentration-dependent inhibition of the current, which was poorly reversible after washout (Table 1). The data points are fitted according to the Hill equation with an EC_{50} for palmitine on I_K is $41.62 \pm 10.11 \mu$ M

and n_H , 0.48 ± 0.07 ($n=8$). When the bath solution was changed to tetraethylammonium (TEA) 8 mM, I_K was inhibited.

Figure 1C shows the effects of palmitine 10 μ M and 100 μ M on the steady-state I-V relationship for I_K generated by applying 12 depolarizing pulses from +30 mV to +140 mV for 900 ms with a 10 mV increment from a holding potential of -50 mV. In the presence of palmitine 100 μ M, the amplitude of I_K was significantly reduced from +70 mV through +140 mV ($n=8$, $P < 0.05$ or $P < 0.01$ vs control). The currents were inhibited in a voltage-independent manner at the potentials tested. For example, at +100 mV, I_K was reduced by palmitine 100 μ M from 1319.52 ± 192.60 to 575.37 ± 133.29 pA (56.40 % reduction), and at +140 mV, current was reduced from 1861.42 ± 215.76 to 879.37 ± 172.30 pA (52.76 % reduction). The relative reductions of I_K were illustrated in Figure 1D. Currents after addition of 10 μ M and 100 μ M palmitine were normalized to currents under control conditions at a given voltage, and it can clearly be seen that the currents were inhibited to the same degree at all potentials tested.

Table 1 Effects of palmitine on I_K at a test potential of +140 mV and I_{CRAC} at -100 mV

Concentration (μ M)	Inhibition of I_K (%)	Inhibition of I_{CRAC} (%)
0.3	3.36 ± 1.96	3.81 ± 0.40
1	11.04 ± 3.03	10.19 ± 2.03
3	23.97 ± 4.62	21.42 ± 3.22
10	36.75 ± 5.12	37.39 ± 3.95
30	49.58 ± 7.98	47.50 ± 4.38
100	55.40 ± 8.97	52.10 ± 5.98

Effects of palmitine on I_{K1}

Hyperpolarizing and depolarizing potentials over a range from -200 mV to +175 mV were applied from a holding level of 0 mV^[20]. The absolute value at the end of test pulse was measured as the amplitude of I_{K1} . Palmitine 0.3-100 μ M failed to have any significant effect on either inward or outward components of I_{K1} at any membrane potential examined.

Effects of palmitine on I_{CRAC}

When the holding potential was 0 mV, and the cells were depolarized to -100 mV for 200 ms at a frequency of 0.2 Hz, the I_{CRAC} was evoked^[21]. As shown in Figure 2, I_{CRAC} also was blocked by palmitine in a concentration-dependent fashion, and the current was less sensitive to palmitine than I_K with an EC_{50} of $51.19 \pm 15.18 \mu$ M and $n_H = 0.46 \pm 0.07$ ($n=8$). Table 1 also showed the effects of palmitine on I_{CRAC} at a test potential of -100 mV. Figure 2C showed the effects of palmitine on the steady-stated I-V relationships generated by applying a series depolarizing pulses from a holding potential of 0 mV to different membrane potentials (-100 mV to +80 mV) with a 20 mV increment. The peak value of I_{CRAC} in the I-V relationship was decreased by palmitine 10 μ M and 100 μ M ($n=8$, $P < 0.05$ or $P < 0.01$ vs control). But the reverse potential of I_{CRAC} occurred at voltage=0 mV in all cells.

DISCUSSION

In this study we have, for the first time, characterized the effects of palmitine on the hepatocyte I_K , I_{K1} and I_{CRAC} by patch-clamp techniques and demonstrated that palmitine effectively inhibited I_K and I_{CRAC} in isolated rat hepatocytes.

Membrane potential is important in regulating metabolic processes in the liver, including gluconeogenesis, amino acid transport, and the rate of uptake of bile salts^[22,23]. Changes in

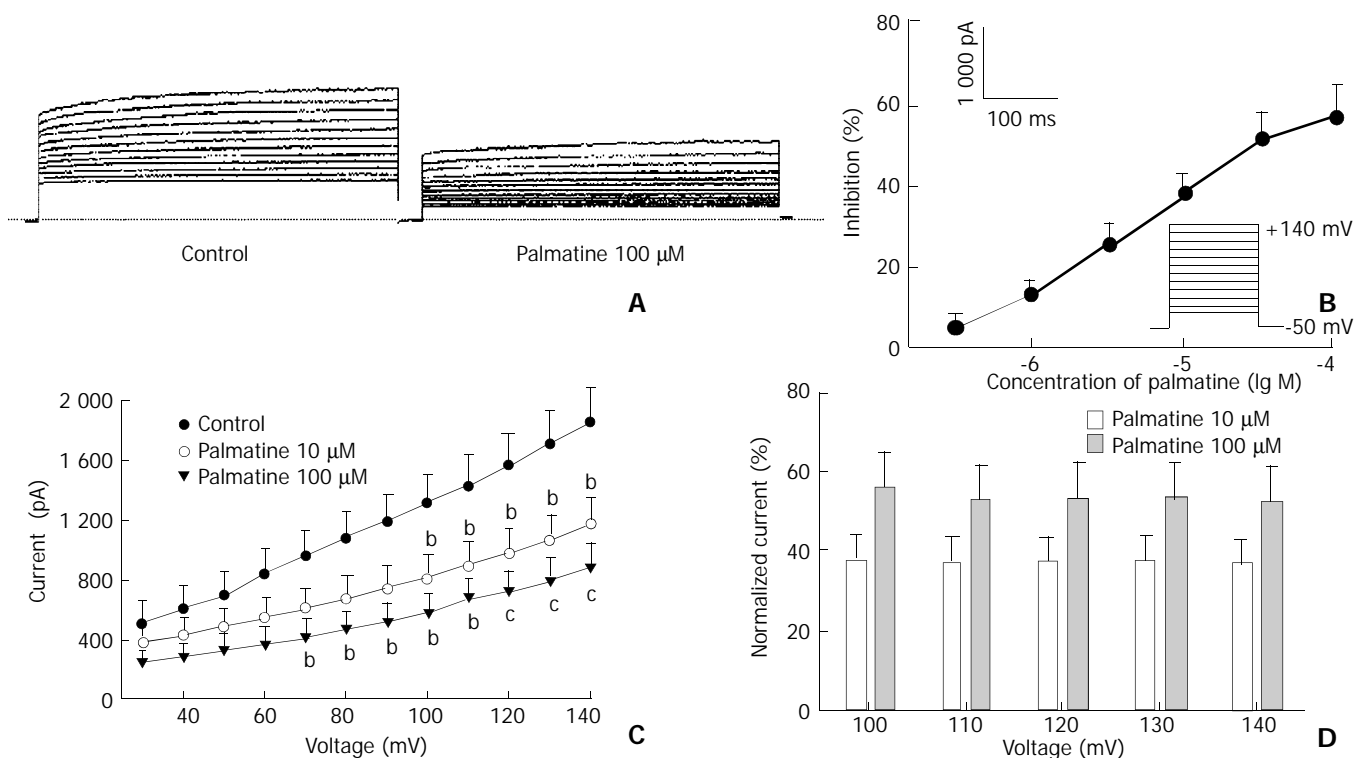

Figure 1 Effects of palmatine on I_K . (A) Family of I_K recorded with changes in the absent or present of palmatine 100 μ M. Dotted line indicates zero current level. (B) Dose-response curve for the effects of palmatine on I_K . The data are mean values from $n=8$ cells. (C) I-V relationship of I_K under control (●) and palmatine 10 μ M (○), 100 μ M (●). The voltage steps used to elicit I_K are shown in the inset of panel (B). ^b $P<0.05$, ^c $P<0.01$ vs control ($n=8$). (D) Dependence of palmatine effects on test potential. The values for the mean percentage reductions in I_K induced by palmatine 10 μ M (□) and 100 μ M (■) are plotted against the corresponding test potential. No significant voltage-dependence was observed for the blocks induced by palmatine.

(B) Dose-response curve for effects of palmatine on I_{CRAC} . The data are mean values from $n=8$ cells. (C) I-V relationship of I_{CRAC} under control (●) and palmatine 10 μ M (○), 100 μ M (●). The voltage steps used to elicit I_K are shown in the inset of panel (B). ^b $P<0.05$, ^c $P<0.01$ vs control ($n=8$).

K⁺ permeability can affect the transmembrane potential. Transcellular bile acid transport is integrated in the regulation of intracellular pH, K⁺ homeostasis and membrane potential. Hepatocellular K⁺-depletion can result in inhibition of bile acid secretion despite rising intracellular concentration^[24-26].

During ischemia and hypoxia, hepatocellular volume and K⁺ conductance are increased. It was reported that the extracellular K⁺ increase would result in hyperpolarization and

hyperexcitability of cells. This would lead to cell death^[27-29]. Nietsch *et al* demonstrated membrane potential change by modulation of K⁺ channel activity might be involved in the mechanism of apoptosis in human hepatoma cells^[30,31]. The inhibition of K⁺ channels could delay hepatocyte apoptosis and death.

Calcium has been demonstrated to play an important role in hepatocyte damage. Elevation of intracellular Ca²⁺

concentration was associated with the development of cell damage and apoptosis^[32-35].

Recent developments suggest that an early disturbance in hepatocellular Ca^{2+} homeostasis might be involved in the hepatocellular damage induced by CCl_4 ^[36-38].

Hepatocytes as the nonexcitable cells are short of the voltage-dependent Ca^{2+} channels but possess plasma membrane Ca^{2+} channels that have a high selectivity for Ca^{2+} , and are activated by a decrease in the concentration of Ca^{2+} in intracellular stores, which named I_{CRAC} ^[39,40]. The gating of I_{CRAC} is independent of membrane voltage, there is, nevertheless, a strong dependence of Ca^{2+} influx on the driving force exerted by the membrane potential, ie, the influx rate increases with hyperpolarization and decreases with depolarization, which is different from cardiac myocytes that Ca^{2+} influx increases with depolarization and decreases with hyperpolarization^[41].

Palmitine inhibits I_{CRAC} with EC_{50} of 51.19 μM , which is higher than the EC_{50} of $\text{I}_{\text{Ca,L}}$ in cardiac myocytes^[42]. The differential drug sensitivity of the two currents also provides further support for the idea that I_{CRAC} is different from voltage-gated Ca^{2+} channel.

In conclusion, palmitine blocks K^+ channel and decreases the extracellular K^+ to regulate the metabolic processes in the liver. Palmitine also inhibits I_{CRAC} effectively and protects hepatocytes from calcium overload via the inhibition of I_{CRAC} . The inhibitory effects on I_{K} and I_{CRAC} may partly contribute to the hepatoprotective action of palmitine.

Abstract

AIM: To observe the localization of TRAIL/TRAILR (DR4, DR5, DcR1, DcR2) in the fetal pancreas.

METHODS: Fetal pancreas of 32 weeks of pregnancy were obtained from induced abortions, embedded in paraffin, and 4- μ m sections were prepared. The localization of TRAIL/TRAILR in fetal pancreas was investigated by fluorescence immunohistochemical method combined with laser scanning confocal microscopy.

RESULTS: TRAIL immunoreactive cells were mainly located on the periphery of the pancreas islets. There were a few DcR1 and DcR2 positive cells whereas there were no immunoreactive cells of DR4 and DR5 in the pancreas islets. In the acini and the ducts of the exocrine pancreas there were no TRAIL/TRAILR immunoreactive cells.

CONCLUSION: This study not only describes the distribution of TRAIL/TRAILR in the fetal pancreas, but also provides a morphological basis for deducing the function of TRAIL/TRAILR in pancreas, suggesting that in normal pancreatic islets, the pancreatic cells are resistant towards apoptosis too.

INTRODUCTION

Being an important endocrinology organ, the pancreas plays an important role in many physical and pathological processes^[1-11]. The pancreatic islets could secrete not only the classical endocrinology substances such as insulin, glucagons, somatostatin and so on, but also could secrete some neuropeptides and cytokines^[12,13].

Tumor necrosis factor related apoptosis inducing ligand (TRAIL)/TRAILR is a group of molecules belong to TNFSF/TNFRSF identified from 1995 and displays very important biological function^[14-20]. Despite the widespread interest in TRAIL and its receptors to date, studies on TRAIL/TRAILR

are mostly stayed on mRNA level just for the lack of monoclonal antibodies. Fortunately, a series of antibodies against TRAIL/TRAILR system have been prepared and identified successfully by our department and Screation group recently and these provided a useful way to detect the expression of TRAIL/TRAILR in many organs and tissues^[21]. In this experiment, we detected the localization of TRAIL/TRAILR in fetal pancreas.

MATERIALS AND METHODS

Reagents

The mouse anti-human DR4, DR5, DcR1, and DcR2 antibodies and the rabbit anti-human TRAIL antibody were prepared in our department. Biotin conjugated horse anti-rabbit IgG, FITC conjugated goat anti-mouse IgG and Texas red-conjugated streptavidin were purchased from Sigma.

Preparation of tissue sections

Five fetal pancreas of 32-week pregnancy were surgically obtained. They were washed with physiological saline at 4 °C and a 6-mm³ piece was taken from each before fixed in Bouin's solution overnight. Each piece was embedded in paraffin and 4- μ m sections were prepared.

Immunohistochemistry

Four-micrometer sections from fetal pancreas of 32-week pregnancy were employed in the fluorescent immunohistochemical analysis of TRAIL/TRAILR. Several dilutions of the antibody were tested to find the optimal staining concentration before the entire series was processed. The staining procedure was carried out as previous reports, without protease treatment^[22]. Briefly, the steps included: (1) the sections were deparaffinized in xylene, hydrated in ethanol, and washed in 0.01 mol/L PBS, then pretreated with 30 mL/L normal goat serum for 40 min and rinsed in 0.1 mol/L PBS; (2) incubation at 4 °C for 24 h in the primary antibodies, mouse anti-human DR4, DR5, DcR1 and DcR2 antibody (1:200 dilution, final concentration of 25 mg/L) was performed respectively, and then in rabbit anti-human TRAIL antibody (1:300 dilution in 10 mL/L BSA-PBS); (3) the secondary antibody, biotin-labeled horse anti-rabbit IgG (1:200 dilution), was incubated at room temperature for 1 h; (4) simultaneous incubation with 1:200 FITC conjugated goat anti-mouse IgG and Texas red-conjugated streptavidin (1:1 000 dilution) for 30 min. The sections were washed three times for 10 min each after incubation from steps 2 to 4, respectively, and were finally mounted in 50 g/L glycerin. The sections were examined with Bio-Rad 1024 LSCM. The specimens were excited with a laser beam at wavelengths of 568 nm (Texas Red) and 488 nm (FITC) and the emission light was focused through a pinhole aperture. The full field of view was scanned in square image formats of 512x512 pixels.

Controls

Primary antibodies were substituted by irrelevant antibodies and normal rabbit or goat serum as specific antibody control. PBS was substituted for primary antibody as negative control. Primary antibody was omitted as blank control.

Figure 1, 4, 7, 10 Distribution of TRAIL in fetal pancreas. The positive reactivities are mainly distributed in membrane (red). TR-labelled $\times 400$.

Figure 2, 5, 8, 11 Localization of DcR1, DcR2, DR4 and DR5 respectively in fetal pancreas. There are a few DcR1 (Figure 2) and DcR2 (Figure 5) positive cells and the positive substances locate in membrane mainly (green). There is no DR4 (Figure 8) and DR5 (Figure 11) positive cells distributed in fetal pancreas. FITC-labelled $\times 400$.

Figure 3, 6, 9, 12 Coexpression of TRAIL/TRAILR in fetal pancreas. Some TRAIL positive cells coexpress with DcR1 or DcR2, whereas there is no coexpression of TRAIL and DR4, TRAIL and DR5 in fetal pancreas. The positive cells distribute in disperse (yellow). TR-labelled TRAIL, FITC-labelled TRAILR (DcR1, DcR2, DR4 and DR5) $\times 400$.

RESULTS

Localization of TRAIL in fetal pancreas

Fluorescent immunohistochemistry showed that TRAIL positive cells located on the periphery of pancreatic islets mainly. In the acini and the ducts of the exocrine pancreas there were no TRAIL immunoreactive cells. The positive cells distributed in disperse or patch pattern. The positive reactivity was mainly distributed in membrane and cytoplasm, while nuclei remained immunonegative (Figures 1, 4, 7 and 10).

Localization of TRAILR in fetal pancreas

Figures 2, 5, 8 and 11 showed the localization of DcR1, DcR2, DR4 and DR5 respectively in fetal pancreas. There were a few DcR1 (Figure 2) and DcR2 (Figure 5) positive cells and the positive reactivity located in membrane mainly (green). There was no DR4 (Figure 8) and DR5 (Figure 11) positive cells distributed in fetal pancreas.

Coexpression of TRAIL and TRAILR in fetal pancreas

Some TRAIL positive cells coexpressed with DcR1 or DcR2, whereas there was no coexpression of TRAIL and DR4, TRAIL and DR5 in fetal pancreas. All DcR1 and DcR2 immunoreactive cells showed TRAIL immunoreactivity (Figures 3, 6, 9 and 12).

DISCUSSION

Members of the TNF and TNF superfamilies of proteins are involved in the regulation of many important biological processes, including development, organogenesis, and innate and adaptive immunity^[23]. The TNF-related apoptosis-inducing ligand (TRAIL, also known as Apo-2L) is a newly identified TNF superfamily member with high homology to FasL. In the TRAIL/TRAILR system, control over apoptosis relies on differential display of receptors (TRAILR). These include DR4 (TRAIL-R1) and DR5 (TRICK2/TRAIL-R2), which transduce apoptotic signals, as well as DcR1 (TRID/LIT/TRAIL-R3) and DcR2 (TRUNDD/TRAIL-R4), which lack functional death domains and act as decoys. Osteoprotegerin (OPG), a soluble decoy receptor for OPGL/RANKL/TRANCE, which is involved in osteoclast function, has also been reported to bind to TRAIL^[24-36].

There were some reports on the distribution of TRAIL/TRAILR in human pancreas and pancreatic cancer. Liao *et al* found that TRAIL-R3 mRNA and protein expression were generally weak in pancreatic cancers and normal pancreatic tissues. In contrast, TRAIL-R4 mRNA and protein were expressed at moderate to high levels in human pancreatic cancer tissues, but demonstrated weak to negative expression in the normal pancreas by Northern blotting, Western blotting and

immunohistochemistry^[37]. Satoh *et al* detected the expression of TRAIL and its receptors other than osteoprotegerin in normal pancreatic tissues using RT-PCR^[38]. In our experiment, we found for the first time that in fetal pancreatic islets, there was strong distribution of TRAIL protein. The TRAIL immunoreactive substances mainly located on the membrane and cytoplasm with negative nuclei. Some TRAIL immunoreactive cells also showed DcR1 or DcR2 positive immunostaining, whereas there were no expression of DR4 and DR5 in fetal pancreas. Our results show some consistence with what Liao *et al* and Satoh *et al* have found.

We all know that pancreatic cancer is one of the most aggressive cancers, partly due to the general resistance of pancreatic cancer cells towards apoptosis. Ibrahim *et al* demonstrated that pancreatic carcinoma cells evaded the immune system in two mechanisms. One is the expression of nonfunctional receptors, decoy receptors, and molecules that block cell death, such as bcl2 and bcl-XL. The other is the expression of apoptosis-inducing ligands, such as TRAIL, that could induce cell death of immune cells^[39]. In our experiment, we found that in fetal pancreatic islets, some cells expressed TRAIL. At the same time, DcR1 and DcR2 also colocalized with TRAIL in some cells, but there was no expression of DR4 and DR5. Our findings suggest that in fetal pancreatic islets, the pancreatic cells are resistant towards apoptosis too. The characteristics of the fetal pancreas are consistent with those of pancreatic cancer.

It is well known that there are some kinds of cell types in human pancreatic islets such as A cells, B cells, D cells and PP cells. Although we found that TRAIL was located in some endocrine cells, we could not conclude which kind of cell types it existed in. This still needs to be clarified further.

Abstract

AIM: To determine whether Platelet activating factor (PAF) has a regulation role in the expression of adhesion molecules and accumulation of neutrophils in a murine model of acute pancreatitis.

METHODS: One hundred twenty-eight Kunming mice were divided into four groups. Group 1 received 0.1 ml saline s.c. every hour for three hours (sham). Group 2 received cerulein (50 µg/kg dose s.c.) every hour for three hours. Group 3 received AP and additional challenge of PAF (50 mg/kg in absolute ethanol) (AP/PAF). Group 4 received AP, plus therapeutic treatment with GAB (25 mg dose i.p.) immediately after the first challenge of cerulein (AP/GAB). Animals were sacrificed at 12 h after the first challenge of saline or cerulein. Adhesion molecules of pancreas were semi-quantified by SP methods. Standard assays were performed for serum amylase and myeloperoxidase activity (MPO) of pancreas. Histology of pancreas was scored in a blind manner. Water content of pancreas was also measured at the same time.

RESULTS: Control pancreata showed negligible adhesion molecule expression and neutrophil accumulation. There were evident adhesion molecules expression and neutrophil accumulation in AP and AP/PAF compared with sham ($P < 0.05$). AP/GAB had a lower level of adhesion molecules, neutrophils, and water content versus AP and AP/PAF ($P < 0.05$). Histology showed a trend toward improvement in AP/GAB, but did not reach statistical significance.

CONCLUSION: PAF can induce the expression of adhesion molecules that mediate neutrophil accumulation. The PAF antagonist reduces the expression of adhesion molecules and the severity of inflammation when given immediately after the induction of mild AP in mice. These results suggest that PAF antagonism may be useful in the treatment of mild pancreatitis after its clinical onset.

INTRODUCTION

Acute pancreatitis (AP) was characterized as local and systemic

inflammatory reactions. Adhesion molecules play a pivotal role in neutrophil immigration and accumulation^[1]. Platelet activating factor (PAF) is a biologically active phospholipid which is thought to function as one of the proximal mediators in the inflammatory cascade of AP. However, the relationship between PAF and the expression of adhesion molecules in AP remains largely unknown, although Blackstone MO has ever speculated^[2].

The present study was conducted to determine whether PAF has a regulatory role in the expression of adhesion molecules and the accumulation of neutrophils. To examine this effect, a murine model of edematous pancreatitis was established by overdose administration of cerulein, as described by Tani *et al*^[3]. PAF and its antagonist (GAB) were also used in this experiment.

MATERIALS AND METHODS

Materials

Cerulein and PAF were purchased from Sigma Chemical Co. (St. Louis, Missouri). GAB (Ginkgolide AB) was a generous gift from associate professor Di-Qing Zhang in Guizhou University. MPO assay kit was purchased from Nanjing Jiancheng Bioengineering Co. Ltd. China. Rabbit anti-rat E-selectin polyclonal antibody and Rabbit anti-rat ICAM-1 polyclonal antibody were purchased from Boster Bioengineering Co. Ltd. China. SP assay kit was purchased from Maixin Bioengineering Co. Ltd. China. Cerulein was dissolved in normal saline at the concentration of 10 µg/ml. PAF was first dissolved in absolute ethanol, and then diluted with normal saline when it was to be used. GAB was dissolved in 30 % Dimethyl Sulfoxide (DMSO).

128 six-week-old Kunming mice, weighing 34-36 g each, were purchased from the experimental animal center of Wuhan University. The animals were randomly divided into 4 groups (described in methods) and fed standard laboratory chow. All animals were allowed to acclimatize for a minimum of 1 week prior to experimentation. Before the day of the experiment, animals were fasted overnight, but allowed free access to water.

Animals model

Acute pancreatitis was established in 32 mice (AP group) by subcutaneous injection of cerulein (50 µg/kg dose) every hour for three hours. Sham group (32 mice) received subcutaneous injection of normal saline every hour for three hours. AP/PAF group (32 mice) received subcutaneous injection of cerulein (50 µg/kg dose) every hour for three hours, plus PAF (50 µg/kg dose) injected peritoneally immediately after the first cerulein challenge. AP/GAB group (32 mice) received subcutaneous injection of cerulein (50 µg/kg dose) every hour for three hours, plus therapeutic treatment with GAB (25 mg/kg i.p.) immediately after the first cerulein challenge.

The animals were sacrificed at 12 h after the first cerulein challenge or saline injection. Some mice (eight in every group) were decapitated and the blood was collected in vials for the analysis of serum amylase. Pancreata were dissected. Some were weighted and grounded for the analysis of MPO, and the others were fixed with formalin for histological scoring and

immunohistochemical staining. Some left pancreatic tissues were dried and weighted.

MPO measurement

MPO assay of pancreas was performed according to the instructions of commercial kit.

Amylase

Serum amylase levels were measured using starch-iodine method.

Water content

Pancreas was dissected from its attachment and the fluid on its surface was dried with filter paper. Then the pancreas was placed in oven at a temperature of 90-92 °C for 10 hours. Water content = $(\text{Weight}_{\text{wet}} - \text{Weight}_{\text{dry}}) / \text{Weight}_{\text{wet}} \times 100\%$.

Histological grading

Pancreatic sections were stained with hematoxylin and eosin and graded in a blind manner by two investigators. Severity of pancreatitis was scored on a scale of 0 to 4 (normal to severity) in the categories (vacuolization, inflammation, edema) for a total score of 0 to 12, as described by J.Schmidt^[4].

Immunohistochemical staining

Pancreata were fixed in formalin for 12 h and then embedded in paraffin wax. Sections were cut at 4 µm in thickness and mounted on slides. They were deparaffinized by passing them through two changes of xylene and graded series of ethanol, followed by rinses in tap water and 0.01 mmol·L⁻¹ phosphate buffered saline (PBS), respectively. Endogenous peroxidase activity was quenched by treating the section with 3 % hydrogen peroxide for 10 minutes. Nonspecific binding was blocked by incubating sections in 1 % bovine albumin in PBS for 10 minutes, and then incubated for an hour in primary antibody (rabbit anti-E-selectin or rabbit anti-ICAM-1 polyclonal antibody). After rinsing in PBS, the sections were treated sequentially with biotinconjugated second antibody for 10 minutes and then with streptavidin-peroxidase for another 10 minutes with PBS rinsing after each step. Sections were stained subsequently with freshly prepared DAB reagent for 3 minutes, and terminated by rinsing in water. then the sections were immersed in hematoxylin for 3-5 minutes and 0.5 mmol·L⁻¹ HCl for 10 seconds. Finally, when passed through two changes of xylene and graded series of alcohol, the sections were covered with coverslip for light analysis. Every slice was counted on ten different fields by two investigators independently. Vessel stained brown was considered positive vessel. (-), score 0, means no positive vessel was observed. (+), score 1, means 1-2 positive vessels were observed. (++) , score 2, means 3-4 positive vessels were observed. (+++) , score 3, means more than 5 positive vessels were observed.

Statistical analysis

Numerical variables are reported as means ± SEM and compared between groups using *Newman-Keuls* method. Rank data are reported as means and analyzed with *Nemenyi* method. Difference with $P < 0.05$ are considered significant.

RESULTS

Expression of adhesion molecules

In control group there was no staining of E-selectin and ICAM-1 in pancreatic venules. Expression of the two adhesion molecules was eminent in AP and AP/PAF. But there was no difference between the two groups. AP/GAB has a lower level of E-selectin and ICAM-1 expression compared with AP (Table 1, Figures 1-4).

Figure 1 12 h, sham group showed negative expression of adhesion molecules. (×400).

Figure 2 E-selectin was evident in AP at 12 h. (×400).

Figure 3 ICAM-1 was evident in AP at 12 h. (×400).

Figure 4 ICAM-1 expression in AP/GAB at 12 h. (×400).

Amylase and water content

Serum amylase levels and water content was used to evaluate the severity of pancreatic injury. Amylase rose at 12 h in AP and AP/PAF group against control group, but there was no difference between the two groups. GAB treatment significantly reduced the amylase level at 12 h ($P<0.05$). Water content reflects the extent of pancreatic edema. At 12 h AP and AP/PAF showed a higher level of water content against sham and AP/GAB. AP/GAB still has a higher level of water content than sham (Table 2).

MPO activity

Measurement of neutrophil accumulation by MPO activity revealed that AP and AP/PAF had an increase of MPO activity almost 10-fold greater than sham. AP/GAB showed significantly lower level of MPO Activity than AP ($P<0.05$). And this level did not return to the values seen in sham treated animals (Table 2).

Pancreatic histological analysis

Sham group was microscopically intact, with normal histological structure. Pancreatic lesions, such as edema, vacuolation and infiltration of PMN were found in AP, AP/PAF and AP/GAB. There was a trend toward improvement in histological parameters in AP/GAB, but it failed to reach statistical significance. (Data not shown).

Table 1 Expression of adhesion molecules in pancreas. ($\bar{x}\pm s$)

Group	E-selectin	ICAM-1
Sham	0	0
AP	2.1 ^a	2.3 ^a
AP/PAF	2.3 ^a	2.4 ^a
AP/GAB	1.1 ^b	1.1 ^b

^a $P<0.05$ vs sham, ^b $P<0.05$ vs AP.

Table 2 Measurement of amylase, MPO activity, water content. ($\bar{x}\pm s$).

Group	Amylase ($\times 10^3$ U/L)	MPO activity (AU/g)	Water content (%)
Sham	4.2 \pm 0.2	2.14 \pm 0.011	71.0 \pm 0.1
AP	22.1 \pm 2.7 ^a	2.213 \pm 0.035 ^a	81.0 \pm 0.2 ^a
AP/PAF	22.9 \pm 0.9 ^a	2.325 \pm 0.067 ^a	79.8 \pm 0.2 ^a
AP/GAB	10.9 \pm 0.8 ^{b,c}	0.795 \pm 0.004 ^{b,c}	75.3 \pm 0.1 ^{b,c}

^a $P<0.05$, ^b $P<0.05$ vs sham, ^c $P<0.05$ vs AP.

DISCUSSION

Platelet activating factor, 1-O-octadecyl-2-acetyl-Sn-glycero-3-phosphocholine, is a potent inflammatory mediator produced by endothelial cells, platelets, monocytes, neutrophils, and basophils. It has been widely studied that PAF played an important role in the pathogenesis of AP, and its local and systemic effects on AP have also been revealed. The systemic effects cause circulatory disturbances and multiple organ failure. Local effects include platelet aggregation, neutrophil accumulation, microvascular ischemia and increasing of capillary permeability^[5-7]. Moreover, PAF itself also can induce pancreatitis when injected in peritoneal or superior pancreaticoduodenal artery^[8-10].

Accordingly, treatment of experimental pancreatitis with PAF antagonist has consistently shown significant local and systemic protection to reduce inflammatory changes^[11-15]. But the mechanism of its protection has not been fully classified.

One kind of PAF antagonist, lexipafant, has been studied in clinical trials in acute pancreatitis. In phase II and phase III clinical studies lexipafant showed better protection against AP, although a phase III clinical trial in UK showed little protection in the treatment of severe acute pancreatitis^[16-18].

In vitro PAF can induce the expression of adhesion molecules^[19], there was little information whether PAF and its antagonist could regulate the expression of adhesion molecules in AP. So, we conducted this experiment to testify the hypothesis.

Leukocyte accumulation from circulating blood to the site of inflammation includes multiple steps involving different kind of adhesion molecules on the endothelial cell. There are four steps in the adhesion cascade: (1) tethering, (2) triggering, (3) firm adhesion and (4) diapedesis- and these steps must occur in ordered sequence. Tethering interactions are the first step in the adhesion cascade. The molecules involved in this reaction come from the selectin family, such as E-selectin and P-selectin. The firm-binding phase involves superimmunoglobulin family, such as ICAM-1 and VCAM-1. Both E-selectin and ICAM-1 have shown to be necessary for transendothelial migration of polymorphonuclear leukocytes^[20]. In AP, neutrophils and adhesion molecules elevate and play an important role^[21,22]. Treatment of severe acute pancreatitis with ICAM-1 monoclonal antibody reduces the severity of pancreatic and lung injury. The severity of AP is partially decreased in mice deficient in ICAM-1^[22].

In our study adhesion molecules were elevated in AP. But additional PAF challenge couldn't increase the expression of adhesion molecules. PAF antagonist (GAB) can reduce the expression of adhesion molecules and reduce the accumulation of neutrophils in pancreas in AP. The mechanism may be that internal PAF has enough capability to induce the expression of adhesion molecule, and exogenous PAF do not have accelerating ability to induce more expression of adhesion molecules. PAF antagonist may have different ways in AP to reduce the expression of adhesion molecules: (1) reduce the concentration of cytokines, such as TNF- α and IL-1 β ^[23,24]. (2) reduce oxidative stress in pancreas^[24,25]. (3) repress the activation of NF- κ B directly.

In conclusion, PAF plays an important role in the expression of adhesion molecules and accumulation of neutrophils in AP. PAF antagonist can be used early in mild AP. Further studies are necessary to determine whether PAF antagonist can prevent mild AP to transform into severe AP.

ACKNOWLEDGEMENT

We gratefully acknowledge associate Prof. Di-Qing Zhang for his precious PAF antagonist (GAB).

Abstract

AIM: To study the effect of co-expression of *ppsA*, *pckA*, *aroG*, *pheA* and *tyrB* genes on the production of L-phenylalanine, and to construct a genetic engineering strain for L-phenylalanine.

METHODS: *ppsA* and *pckA* genes were amplified from genomic DNA of *E. coli* by polymerase chain reaction, and then introduced into shuttle vectors between *E. coli* and *Brevibacterium flavum* to generate constructs pJN2 and pJN5. pJN2 was generated by inserting *ppsA* and *pckA* genes into vector pCZ; whereas pJN5 was obtained by introducing *ppsA* and *pckA* genes into pCZ-GAB, which was originally constructed for co-expression of *aroG*, *pheA* and *tyrB* genes. The recombinant plasmids were then introduced into *B. flavum* by electroporation and the transformants were used for L-phenylalanine fermentation.

RESULTS: Compared with the original *B. flavum* cells, all the transformants were showed to have increased five enzyme activities specifically, and have enhanced L-phenylalanine biosynthesis ability variably. pJN5 transformant was observed to have the highest elevation of L-phenylalanine production by a 3.4-fold. Co-expression of *ppsA* and *pckA* increased activity of DAHP synthetase significantly.

CONCLUSION: Co-expression of *ppsA* and *pckA* genes in *B. flavum* could remarkably increase the expression of DAHP synthetase; Co-expression of *ppsA*, *pckA*, *aroG*, *pheA* and *tyrB* of *E. coli* in *B. flavum* was a feasible approach to construct a strain for phenylalanine production.

INTRODUCTION

L-phenylalanine, one of the essential amino acids in human, is used as a major component of amino acid in infusion

clinically. For the past two decades, biosynthesis of L-phenylalanine has attracted more and more attentions due to the increasing demand of Aspartame, a dipeptide sweetener containing L-phenylalanine^[2,3].

Production of L-phenylalanine by microbes has clear advantages over chemical synthesis, e.g., the biological processes are more environmentally sound and utilize renewable resources^[4-8]. In bacteria, the biosynthesis of aromatic amino acids starts from condensation reaction of central carbon intermediates phosphoenolpyruvate (PEP) and erythrose-4-phosphate (E4P) to form 3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP), which is catalyzed by DAHP synthetase (DS)^[9,10]. DAHP is then converted to chorismate, the branch point of aromatic amino acid biosynthesis. L-phenylalanine is synthesized from chorismate by three continuous steps catalyzed by chorismate mutase (CM), prephenate dehydratase (PD) and aromatic-amino-acid transaminase (AT). In *E. coli*, *aroG* and *tyrB* genes encode DS and AT, respectively^[11-17], whereas CM and PD are encoded by a single gene *pheA*^[18-21].

Since the genes coding for amino acid biosynthesis are well characterized in *E. coli* and other microbes, it is possible to make metabolic pathway engineering via recombinant DNA approach to increase the productivity of phenylalanine in bacteria. As reported previously, introduction of a single gene *pheA* into *Corynebacterium glutamicum* resulted in a 35 % increase of L-phenylalanine production^[22]. In our previous work, co-expression of *aroG*, *pheA* and *tyrB* in *Brevibacterium lactofermentum* with pCZ-GAB gave a 2-fold increase in L-phenylalanine yield^[11]. On the other hand, elevation of intracellular levels of the precursor PEP is considered to be essential to channel more carbon flux into aromatic flux in order to get higher yield of L-phenylalanine. In *E. coli*, two enzymes are involved in the formation of PEP. PEP synthetase (PpsA) catalyzes the synthesis of PEP from pyruvate by transphosphorylation reaction^[23], whereas PEP carboxykinase (PckA) catalyzes the synthesis of PEP from oxaloacetate by decarboxylation reaction^[24-26]. PpsA and PckA are encoded by *ppsA* gene and *pckA* gene, respectively. Overexpression of *ppsA* gene in *E. coli* has been shown to elevate DAHP level by a 1.9-fold^[27]. PckA over-expression in *E. coli* cells showed a 20 % increase in molar conversion yields for L-phenylalanine production^[15].

In this study, the *ppsA* and *pckA* genes in *E. coli* were amplified from genomic DNA by polymerase chain reaction (PCR), and then introduced into a *B. flavum*-*E. coli* shuttle vector with *aroG*, both *pheA* and *tyrB* genes were used as operons. The constructs were transformed into *B. flavum* for L-phenylalanine fermentation, and the specific activities of each enzyme as well as the L-phenylalanine yield were measured.

MATERIALS AND METHODS

Bacterial strains and plasmids

All the strains and plasmids used in this study are listed in Table 1. *E. coli* XL1-Blue-G and *B. flavum* 311 are mutants resistant to phenylalanine analogue fluorophenylalanine. XL1-Blue-G was used as donor of *ppsA* and *pckA*.

Table 1 Bacterial strains and plasmids

Strain or plasmid	Relevant characteristics	Source or reference
<i>E. coli</i> XL1-Blue-G	Fp ^r (donor of <i>ppsA</i> , <i>pckA</i>)	Ref. 28
<i>E. coli</i> P2392	(strain for expression)	Stored by our lab
<i>B. flavum</i> 311	Nx ^r , Fp ^r (strain for expression and fermentation)	Stored by our lab
pλP _R	Ap ^r (<i>E. coli</i> expressing vector)	Ref. 28
pλP _R -pps	pλP _R inserted with <i>ppsA</i>	This study
pλP _R -pck	pλP _R inserted with <i>pckA</i>	This study
pλP _R -2p	pλP _R inserted with <i>ppsA</i> and <i>pckA</i> tandemly	This study
pSK-P _{BF}	pBluscript SK- inserted with promoter P _{BF}	Structured by our lab, unpublished
pCZ	Km ^r (<i>B. Flavum-E. coli</i> shuttle vector)	Stored by our lab
pCZ-GAB	pCZ inserted with tandem <i>aroG pheA tyrB</i>	Ref. 1
pJN2	pCZ inserted with tandem <i>ppsA pckA</i>	This study
pJN5	pCZ-GAB inserted with tandem <i>ppsA pckA</i>	This study

Fp^r, resistance to fluorophenylalanine; Nx^r, resistance to nalidixic acid; Ap^r, resistance to ampicillin; Km^r, resistance to kanamycin.

Media and growth conditions

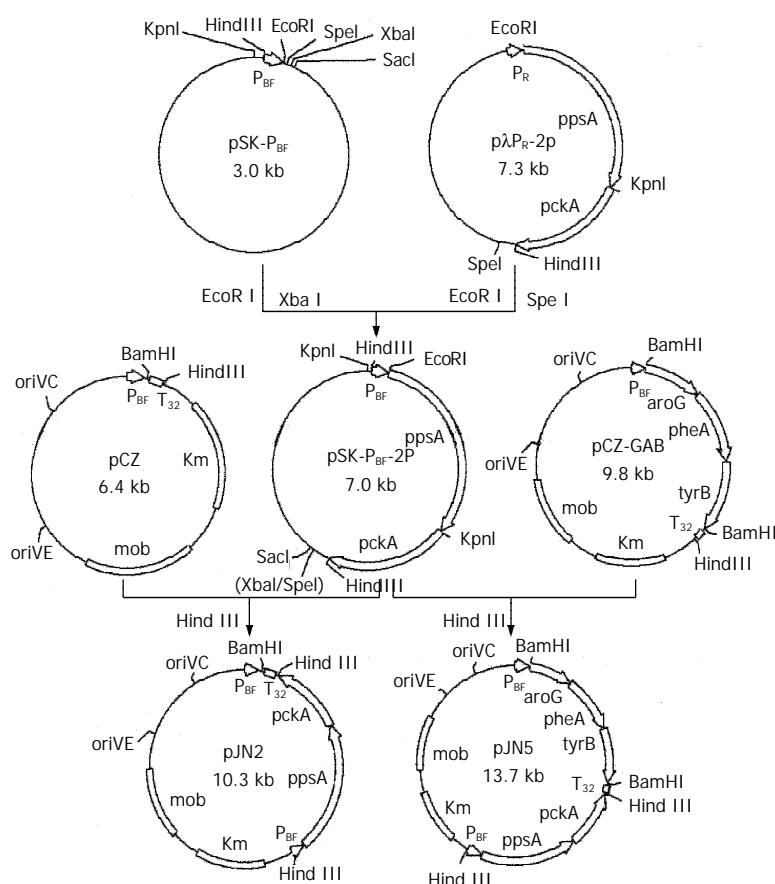

E. coli and transformants containing plasmid were grown at 37 °C in Luria-Bertani medium. *B. flavum* and plasmid-containing transformants were grown in complete medium at 31 °C for DNA manipulation and expression, and were grown in production medium for fermentation as described previously^[1]. Media were supplemented with the following antibiotics as required: fluorophenylalanine (1 mg/mL), nalidixic acid (10 µg/mL), ampicillin (100 µg/mL), kanamycin (20 µg/mL).

Construction of recombinant plasmids

Primers for amplification of *ppsA* gene were synthesized according to Ref. 29 with addition of restriction enzyme sites of *EcoRI* for forward primer (5' -GCATGAATTCGATGTCC AACAATGGCTCGTC-3') and *KpnI* for reverse primer (5' -GCATGGTACCGATTTCGATTGCGATGCAGGT-3'). Primers for amplification of *pckA* gene were designed according to Ref. 30 with addition of restriction enzyme sites of *KpnI* for forward primer (5' -GCATGGTACCATATTGG CTAAGGAGCAGTG-3') and *HindIII* for reverse primer (5' -TACGAAGCTTATCCAGCGAACCCTG-3'). The genes were amplified by PCR and cloned on pBlueScript II SK(+) and transferred on to expression vector pλP_R in a tandem arrangement as showed in Figure 1. The fragment containing tandem *ppsA* and *pckA* was then inserted into shuttle vector pCZ and pCZ-GAB to obtain pJN2 and pJN5.

Enzymatic activity assay

Crude lysates used for enzymatic activity assays were prepared as described previously^[1]. The total protein level was determined by the method of Bradford^[31]. PpsA activity was determined by method^[32] described with modification. In brief, each PpsA assay mixture contained 1.5 µmol/L pyruvate, 10 µmol/L ATP, 10 µmol/L MgCl₂, 100 µmol/L Tris-HCl (pH 8.0), and 200 µL crude lysates. The reaction was terminated by adding 0.3 mL 100 g/L TCA and 0.1 mL 1 g/L 2,4-dinitro phenylhydrazine, and was monitored by measuring the consumption of pyruvate at 520 nm. PckA activity was determined as publication^[33] with modification. In brief, each PckA assay mixture contained 10 µmol/L PEP, 50 µmol/L NaHCO₃, 4 µmol/L ADP, 80 µmol/L MgCl₂, 100 µmol/L Tris-HCl (pH 7.5), and 100 µL crude lysates. The reaction was terminated by adding 0.75 mL ethanol and 20 µL 20 g/L Fast

**Figure 1** Construction of recombinant plasmids

Violet B Salt, and was monitored at 520 nm. DS and AT activities were assayed as described previously^[28]. CM activity was determined as the method of Xia^[34]. PD activity was assayed as the method of Ref. 35.

Fermentation and analysis of phenylalanine

Fermentation of *B. flavum* 311 was carried out and the fermentation yields of L-phenylalanine were determined by the method of Ref. 1.

RESULTS

Expression of *ppsA* and *pckA* genes in transformed *E. coli* cells
