Abstract

Diverticular disease of the colon is a common disease worldwide. Although the disease is asymptomatic in about 70-80 % of patients, it represents, at least in Western countries, one of the most important gastrointestinal diseases in terms of direct and indirect health costs. Pathogenesis of the disease is still unknown. However, it is the result of complex interactions between colonic structure, intestinal motility, diet and genetic factors. Whilst efficacious preventive strategies remain to be identified, fibre supplementation in the diet is recommended. Why symptoms develop is still unclear. Results of recent experimental studies on irritable bowel syndrome speculated that low grade inflammation of colonic mucosa, induced by changes in bacterial microflora, could affect the enteric nervous system, which is crucial for normal gut function, thus favouring symptom development. This hypothesis could be extrapolated also for diverticular disease, since bacterial overgrowth is present, at least in a subgroup of patients. These perspectives on symptom development are reviewed and new therapeutic approaches are hypothesized.

INTRODUCTION

Diverticular disease (DD) of the colon is very common especially in the elderly[1]. Although DD is present worldwide, a higher incidence has been reported in developed countries, compared to underdeveloped countries[2]. DD has important socioeconomic implications on the health system, due not only to its worldwide distribution, but also to the lack of knowledge concerning its natural history and the risk factors involved in development of symptoms. As a consequence, it is difficult to define efficacious preventive strategies.

According to a recent report by the American Gastroenterological Association on the burden of digestive diseases in the United States[3], DD represents, in terms of direct and indirect costs, the 5th most important gastrointestinal disease, with a mortality-rate of 2.5 per 100 000 per year.

DD is a manifestation of an acquired deformity of the colon wall and is characterized by the development of pseudodiverticula, i.e., protrusions of the mucosa and submucosa through the muscular wall. These protrusions occur in weak areas of the wall where blood vessels penetrate due to the high pressure inside the colon[4].

No uniform definition of DD exists as yet. However, according to a recent Consensus Development Conference[5], colonic DD can be defined as a condition involving primarily the sigmoid region of the colon. This condition may be either asymptomatic, and is referred to as "diverticulosis", or associated with symptoms, and termed "diverticular disease", which may, in turn, be either complicated or non-complicated. The term diverticulitis is used to indicate inflammation of the bowel wall.

A brief review is made herein of the epidemiology, pathogenesis and treatment of DD, and in accordance with recent experimental results, some hypotheses on pathogenesis of symptom development are advanced, which may be usefully taken into consideration in defining more effective preventive strategies.

EPIDEMIOLOGY

Epidemiological studies have demonstrated that the prevalence rates differ considerably from one country to another. Indeed, the disease is very common in Western developed countries, with a much higher frequency (30-40 %) than that in Eastern and developing countries (1-4 %)[2, 6-8].

Furthermore, in Western countries, about 90 % of the patients have diverticula in the sigmoid segment, while in Asian populations the caecum and the right colon are most frequently involved[9-12].

Recent studies, however, indicate an increase in the prevalence rate of DD also in Eastern populations, possibly due to increasing globalization and the fact that lifestyle has become increasingly similar in various parts of the world[11-13].

No definitive data have emerged, so far, on the prevalence rate of DD, mainly because the majority of patients are asymptomatic, and are hence difficult to identify. The most important risk factor appears to be aging, the prevalence rate increases with age and varies from <10 % in subjects <40 years old to an estimated 50-66 % in patients >85 years[1, 14, 15].

Some studies have reported a slightly higher frequency in females, however, no sex-related predominance has been demonstrated[16, 17].

PATHOGENESIS

The pathogenetic mechanisms of DD are still poorly understood, however it is generally recognized that these are probably related to complex interactions between colon structure, intestinal motility, diet as well as genetic features[18].

DD has been correlated with "a low residue diet"[2], and furthermore, the prevalence of diverticulosis is higher with a reduced dietary intake of raw fibres[19] and lower in vegetarians[20]. These data are supported by studies both in

animals[21, 22] and humans[23-28]. However, although the fibre deficiency hypothesis has been widely quoted, conflicting evidence and much controversy still exist[29, 30]. The exact mechanism involved remains to be defined, even if prolonged colonic transit time and decreased stool volume in subjects on a low residue diet, seem to induce an increase in intraluminal pressure, which in turn, predisposes to diverticular herniation[31, 32]. Furthermore, the lower faecal bile acid output in patients with DD suggests a pathogenetic role of these compounds which stimulate colon motor activity and as a result reduce colonic transit time[33]. Albeit, these hypotheses have not been confirmed by controlled clinical studies comparing healthy subjects with DD patients[1].

As far as colonic structure is concerned, early surgical and autopsy studies demonstrated an association between muscular hypertrophy of the colon and presence of DD[34, 35], thus suggesting that increased muscle bulk plays a role in enhancing intraluminal pressure.

Furthermore, electron microscopy evidence of a two-fold increase in elastin content in the taenia coli[36] suggests a further pathogenetic mechanism. The elastin content in the taenia results in contraction and bunching of the circular muscle, giving the appearance of a hypertrophic muscle with narrowing of the bowel lumen.

The increased prevalence of DD with aging could be due to a progressive, age-related accumulation of elastin in the taenia coli[36, 37]. In fact, in the elderly, the bowel wall is invariably increased in thickness with reduced elasticity[1] and thus, intraluminal pressure increases and, according to Laplace' s law, formation of diverticula is more likely.

The tendency to elastin accumulation in the taenia coli could be resulted from a low residue diet that extends the bowel intermittently and incompletely, thus favouring prolin (an elastin precursor) uptake[1].

Whilst several pathogenetic hypotheses have been advanced to explain the development of colon diverticula, the fact remains that the pathologic aspects of the disease are resulted from lifelong exposure to a low residue diet and a complex interaction between colonic structure, intestinal motility and genetic factors[18].

CLINICAL ASPECTS OF DIVERTICULAR DISEASE

Clinical classification

Current classifications of DD are based on localization, distribution, symptoms, clinical presentation and pathology[1, 5, 38-40]. Two different types of classification have been proposed: a clinical classification and the Hinchey classification[41], which is used to describe the stages of perforated DD. For the purposes of the present article, the clinical classification is taken into consideration here (Table 1).

Table 1 Classification of diverticular diseases of the colon

Clinical classification (modified from ref. 5)
· Symptomatic uncomplicated disease
· Recurrent symptomatic disease
· Complicated disease (haemorrhage, abscess, phlegmon, perforation, purulent and faecal peritonitis, stricture, fistula, small-bowel obstruction due to post-inflammatory adhesions)
Modified Hinchey classification (modified from refs. 41, 71)
· Stage I: pericolic abscess
· Stage IIa: distant abscess amenable to percutaneous drainage
· Stage IIb: complex abscess associated with / without fistula
· Stage III: generalized purulent peritonitis
· Stage IV: faecal peritonitis

However, the hallmark of painful DD is abdominal pain in the absence of any indications of inflammation. Pain is usually colicky, but may also be steady. It is exacerbated by eating, and is typically relieved by flatus or bowel movements. Associated symptoms vary considerably: diarrhoea, constipation, flatulence, heartburn, nausea and vomiting, palpable abdominal mass, abdominal distension[1, 5, 38].

Natural history

The natural history of DD remains to be elucidated and the few prospective studies carried out so far[9, 42-44] indicate that 80-85 % of patients with DD remain asymptomatic. Of the 15-20 % of patients presenting abdominal pain, approximately 75 % have a painful DD whilst the remainder have diverticulitis, as well as complications of diverticulitis and haemorrhage[1]. Furthermore, about 1-2 % will require hospitalisation and 0.5 % will require surgery[1, 45, 46]. Unfortunately, due to the lack of prospective studies, factors predicting the development of symptoms remain to be identified. However, it has been suggested[47] that evaluation of the colonic motility index (pressure amplitude exceeding 120 mmHg), together with a brief history of left lower quadrant pain, a short segment of involved colon and a relatively younger age (about 50 years), may be useful in recognizing a group of patients at risk of developing symptoms.

Moreover, investigations[48, 49] have suggested that lack of physical activity is independently associated with an increased risk of symptomatic DD, while smoking, caffeine and alcohol intake are not associated with a substantially increased risk of asymptomatic disease. Furthermore, a significant inverse association has been found between insoluble dietary fibre intake (especially fruit and vegetables, e.g. cellulose fibre) and the risk of subsequently developing symptomatic DD[24]. In contrast, a study on the efficacy of fibre supplementation in symptomatic patients with DD did not lead to an improvement in symptoms[50].

Since few data exist on risk factors, preventive measures for the development of diverticula are only speculative, and can be aimed only at preventing development of symptoms. Despite controversial data, fibre supplementation is recommended[1, 38].

Symptom development

The causes of symptom development, in some patients, are still unclear. Since it has been observed that DD patients who have a history of diverticulitis have more episodes of recurrent abdominal pain and impaired bowel function[6, 51, 52], a possible role of previous episodes of intestinal inflammation may be hypothesised. This finding is not unlike that which has been recently demonstrated in other gastrointestinal diseases such as infectious enteritis and inflammatory bowel disease[53, 54] and, as also speculated[55] in irritable bowel syndrome (IBS). In these patients, the presence of a chronic, low-grade intestinal inflammation would induce a sensory-motor dysfunction, leading to symptom development and/or persistence[53-56].

Changes in intestinal microflora could be one of the putative mechanisms responsible for low grade inflammation, at least in IBS[55]. In patients with DD, bacterial overgrowth may be present[57]. This bacterial overgrowth aided by the faecal stasis inside the diverticula, could contribute to chronic low-grade inflammation which sensitises both intrinsic primary efferent and extrinsic primary afferent neurons. These alterations could lead to smooth muscle hypertrophy, and increased sensitivity to abdominal distension[56,58], and finally, to symptom development. This hypothesis is based mainly on experimental studies, investigation in man, being limited at present. However, an increased level of the neuropeptide substance P, which may be related to impaired visceral sensation, has been

demonstrated in patients with DD with abdominal pain but without inflammation[59]. This finding is not unlike that observed by Di Sebastiano *et al*[60] who documented a role of neuroproliferation within the appendix, associated with an increased concentration of substance P and vasoactive intestinal polypeptide, in the pathophysiology of right iliac fossa pain in the absence of inflammation. Moreover, in patients with diverticulitis, abnormal nerves with axonal sprouting have been observed[61], suggesting previous injury. These findings would appear to be compatible with post-inflammatory neural and muscle dysfunction, probably induced also by intestinal bacterial overgrowth, which would contribute to symptom development.

Further studies, both experimental and in man, are obviously needed to confirm the pathogenetic role (which is summarized in Figure 1) of intestinal infection and low grade inflammation, in the development of symptoms in patients with DD.

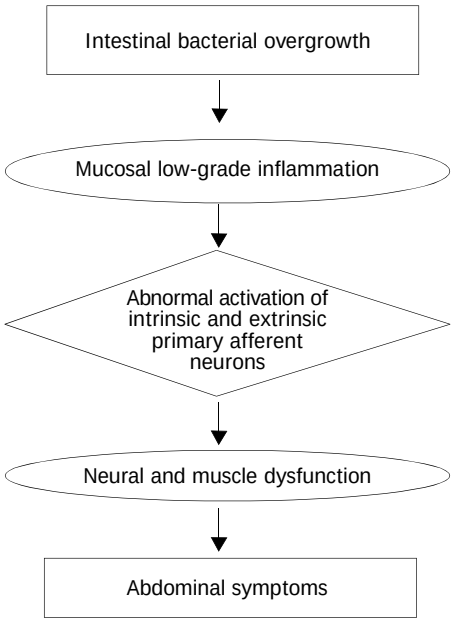

Figure 1 Diverticular disease: putative role of intestinal bacterial overgrowth in symptom development. Altered intestinal microflora could contribute to chronic low-grade inflammation (supported by both immunocytes and mast cells) which abnormally sensitised both intrinsic primary efferent and extrinsic primary afferent neurons. This condition could lead to neural and muscle dysfunction (i.e. altered intestinal motility and visceral sensitivity) and, finally, to symptom development.

Non-surgical treatment

There is a general consensus that conservative treatment is indicated in cases with newly onset uncomplicated diverticulitis[5, 38, 62, 63]. The rationale for this strategy is that about 50-70 % of patients treated for a first episode of acute diverticulitis will recover and have no further clinical problems. Furthermore, only about 20 % of these patients will develop symptoms whilst those with recurrent symptoms have a 60 % risk of developing disease complications[5, 44].

In patients with uncomplicated diverticulosis, a diet with abundant fruit and vegetables is recommended since it seems that this protective effect reduces symptom development and prevents major complications as demonstrated in uncontrolled studies. Nevertheless, recent guidelines[38] advise the use of a high fibre diet, which should be prescribed also for the well-known potential health benefits.

Anticholinergic and antispasmodic agents may be effective in some cases of uncomplicated DD. However, their use remains to be confirmed by controlled studies.

Although the role of antibiotics in uncomplicated DD is still debated[38], recent clinical studies[64-66] have demonstrated that cyclic administration of rifaximin (Normix®, Alfa Wassermann S.p.A., Alanno Scalo, Chieti, Italy) (a broad-spectrum poorly absorbable antibiotic) is more effective in reducing symptoms than fibre supplementation alone (Table 2).

Latella *et al*[66] performed a large, multicentre, prospective, randomized study, enrolling 968 outpatients with symptomatic diverticulosis. Among them, 595 patients received fibre supplement (glucomannan 4 g/day) plus rifaximin 400 mg bid for 7 days, per month, and 373 patients received glucomannan alone. After 12 months, a significant reduction in the occurrence rate of symptoms was documented in the group treated with rifaximin and fibre. 56.5 % of the patients were asymptomatic as compared to 29.2 % of the fibre group. Moreover, the incidence of major complications was lower in the rifaximin plus fibre group *vs* the group treated with fibre alone. The mechanism of of rifaximin in reducing the frequency of symptoms and the rate of complications of DD is only speculative. It has been suggested that rifaximin reduces the metabolic activity of intestinal bacterial flora, the degradation of dietary fibres, and the production of gas. The latter effect is important since an increased production of intestinal gas and of gas-related symptoms such as pain and bloating have recently been documented, in patients with IBS[67]. Furthermore, treatment with non-absorbable antibiotics was shown to reduce symptoms frequency and intensity in these patients. Similar results were obtained by others[68] who documented an association between small intestinal overgrowth and functional intestinal disorders. Moreover, eradication of bacterial overgrowth seems to be related to a reduction in intestinal symptoms.

In conclusion, if low grade mucosal inflammation is confirmed in DD patients, and if such inflammation is provoked and maintained by changes in bacterial microflora as in IBD (change IBD with IBS), then these impairments likely play a role in the pathogenesis and symptom development of both diseases, and thus, new preventive approaches could be identified. According to this hypothesis, cyclic administrations of antibiotics, and in particular of non-absorbable antibiotics such as rifaximin, could reverse the process, i.e., intestinal bacterial overgrowth which is held to trigger the cascade of events which starts from intestinal low grade inflammation to reach symptom generation. In fact, rifaximin, which is highly

Table 2 Effects of rifaximin (R) administration on symptoms in patients with diverticular disease

First author (year, ref)	Pts (*n*)	Treatment (type)	Duration (months)	Reduction in symptoms (%)	*P*
Papi (1992, 64)	217	R (400 mg daily) + glucomannan (2 g daily) *vs* glucomannan	12	63.9 *vs* 47.6	<0.001
Papi (1995, 65)	168	R (400 mg daily) + glucomannan (2 g daily) *vs* placebo +glucomannan	12	68.9 *vs* 38.5	<0.001
Latella (2003, 66)	968	R (400 mg daily) + glucomannan (4 g daily) *vs* glucomannan	12	56.5 *vs* 29.2	<0.001

effective against anaerobic bacteria[69], is effective also in intestinal bacterial overgrowth[70,71].

It is important, at this stage, to identify and characterize those DD patients with intestinal bacterial overgrowth and, then, to perform controlled clinical trials to evaluate the effects of antibiotic administration on symptom and complication frequency, i.e., on the natural history of this disease.

Abstract

AIM: To investigate the association of the *NQO1* (C609T) polymorphism with susceptibility to esophageal squamous cell carcinoma (ESCC) and gastric cardiac adenocarcinoma (GCA) in North China.

METHODS: The *NQO1* C609T genotypes were determined by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis in 317 cancer patients (193 ESCC and 124 GCA) and 165 unrelated healthy controls.

RESULTS: The *NQO1* C609T C/C, C/T and T/T genotype frequency among healthy controls was 31.5 %, 52.1 % and 16.4 % respectively. The *NQO1* T/T genotype frequency among ESCC patients (25.9 %) was significantly higher than that among healthy controls (χ^2=4.79, *P*=0.028). The *NQO1* T/T genotype significantly increased the risk for developing ESCC compared with the combination of C/C and C/T genotypes, with an age, sex and smoking status adjusted odds ratio (OR) of 1.78 (1.04-2.98). This increased susceptibility was pronounced in ESCC patients with family histories of upper gastrointestinal cancers (UGIC) (adjusted OR=2.20, 95 % CI=1.18-3.98). Similarly, the susceptibility of the *NQO1* T/T genotype to GCA development was also observed among patients with family histories of UGIC, with an adjusted odds ratio of 2.55 (95 % CI=1.21-5.23), whereas no difference in *NQO1* genotype distribution was shown among patients without family histories of UGIC.

CONCLUSION: Determination of the *NQO1* C609T genotype may be used as a stratification marker to predicate the individuals at high risk for developing ESCC and GCA in North China.

INTRODUCTION

China is a country with high incidence regions of esophageal squamous cell cancer (ESCC) and gastric cardiac adenocarcinoma (GCA). Chemical carcinogenesis existed in consumed alcohol and tobacco or ingested food[1,2], nutrition deficiency[3], unhealthy living habits[2] and pathogenic infections[4-6] are in general considered as the risk factors for developing these two cancers. However, not all individuals exposed to the above exogenous risk factors will develop ESCC or GCA, indicating that the host susceptibility factors may play an important role in the cancer development. The role of a genetic background in developing these cancers was also strongly suggested by the familial clustering of upper gastrointestinal cancer (UGIC) patients in high incidence regions[7,8].

In recent years, many polymorphic genes encoded carcinogen metabolic enzymes have been found to be associated with susceptibility to chemically induced cancers such as esophageal cancer and gastric cancer[9-13]. NAD(P)H: quinone oxidoreductase 1 (NQO1) is a cytosolic enzyme which catalyzes the two-electron reduction of quinone compounds and prevents the generation of semiquinone free radicals and reactive oxygen species, thus protecting cells from oxydative damage[14]. On the other hand, NQO1 catalyzes the reductive activation of quinoid chemotherapeutic agents and of environmental carcinogens such as nitrosamines, heterocyclic amines and cigarette smoke condensate[15]. The activity of the NQO1 enzyme may be influenced by a single C to T substitution at nucleotide 609 of exon 6 of the *NQO1* cDNA that causes the Pro187Ser amino acid change[16]. The homozygous wild-type (C/C) encodes NQO1 protein with complete enzyme activity, whereas the protein encoded by the heterozygous phenotype (C/T) has approximately three-fold decreased activity and the homozygous mutant (T/T) phenotype has a complete lack of enzyme activity[15-18]. The *NQO1* C609T polymorphism is correlated with the susceptibility to several chemical carcinogen induced tumors such as lung cancer[19,20] and leukemia[21,22]. The association of *NQO1* C609T polymorphism with the susceptibility to ESCC and GCA has not been reported so far. Therefore, the current study investigated the *NQO1* C609T genotype distribution in ESCC and GCA patients and healthy controls from North China.

MATERIALS AND METHODS

Subjects

This case-control study recruited 317 patients with histologically confirmed cancers (193 esophageal cancer and 124 gastric cardiac cancer) and 165 unrelated healthy controls. The cancer patients were hospitalized for tumor resection in the Fourth Affiliated Hospital of Hebei Medical University between 2001 and 2002. The histological pattern of the resected samples was determined by pathologists of the same hospital according to the international standard[23]. The healthy controls were unrelated blood donors or voluntary staff of Hebei Cancer

Institute. All of the patients and controls were from Shijiazhuang city or its surrounding regions. The information about sex, age, smoking habits and family history was obtained from the cancer patients by their hospital recordings and from the healthy controls by interview directly after bleeding. The smokers were defined as ex- or current smoking 5 cigarettes per day for at least two years. The individuals with at least one first-degree relative or at least two second-degree relatives having esophageal/cardiac/gastric cancer were defined as having family histories of upper gastrointestinal cancers (UGIC). The informed consent was obtained from all the recruited subjects. The study was approved by the Ethics Committee of the Hebei Cancer Institute. The demographic data of the cancer patients and healthy controls are presented in Table 1.

DNA extraction

Five ml of venous blood from each subject was drawn in vacutainer tubes containing EDTA. The genomic DNA was extracted within one week after bleeding using proteinase K digestion followed by a salting out procedure.

NQO1 genotyping

NQO1 genotyping of healthy controls and ESCC patients was performed at the Molecular Laboratory of the Institute of Pathology, Heinrich-Heine University, Duesseldorf. The genotyping of the GCA patients was performed at the Molecular Biology Laboratory of the Hebei Cancer Institute with the same reagents and the same methods. The base change (C to T) at nucleotide 609 of *NQO1* cDNA created a *Hinf I* restriction site. Therefore, the *NQO1* C609T genotyping was performed by PCR and subsequent restriction fragment analysis. PCR was performed in a 25 μl volume containing 100 ng DNA template, 2.5 μl 10×PCR-buffer, 1 U Hotstar Taq-DNA-polymerase (Qiagen, Hilden, Germany), 200 μmol dNTPs and 10 pmol sense primer (5' AAGCCCAGACCAACTTCT-3') and antisense primer (5' -ATTTGAATTCGGGCGTCTGCTG-3'). Initial denaturation for 14 min at 94 ℃ was followed by 40 cycles at 94 ℃ for 1 min, at 56 ℃ for 1 min, and at 72 ℃ for 2 min. The PCR products were subsequently digested with 20 units of *Hinf* I (Boehringer, Mannheim, Germany) for 3 h at 37 ℃ and separated on a 2 % agarose gel (Figure 1). The *NQO1* wild-type allele showed a 172-bp PCR product resistant to enzyme digestion, whereas the null allele showed a 131-bp and a 41-bp band. For quality control, each PCR reaction used distilled water instead of DNA as a negative control, and 10 % of the samples were analyzed twice.

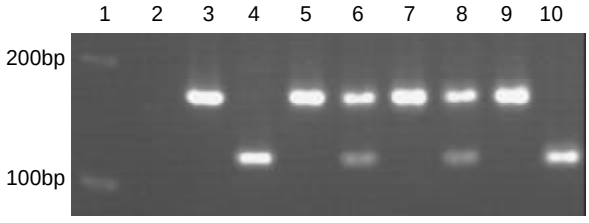

Figure 1 Genotype patterns for *NAD(P)H: quinone oxidoreductase 1 (NQO1)* C609T polymorphism analyzed by PCR-*Hinf I* digestion. Lane 1, 100bp molecular marker; lane 2, negative control; lane 3, PCR fragment containing *NQO1* C609T polymorphism; lanes 4,10, homozygous null genotype (T/T); lanes 5,7,9, homozygous wild genotype (C/C); lanes 6,8, heterozygous genotype (C/T).

Statistical analysis

The comparison of *NQO1* genotype distribution in the study groups was performed by means of two-sided contingency tables using Chi-square test. Hardy-Weinberg analysis was performed to compare the observed and expected genotype frequencies using Chi-square test. A probability level of 5 % was made as statistically significant. The odds ratio (OR) and 95 % confidence interval (CI) were calculated and adjusted for age, sex and smoking status with the unconditional logistic regression model. Statistical analysis was made using SPSS software package (10.0 version).

RESULTS

As shown in Table 1, the composition of gender, age and the proportion of smokers in ESCC and GCA patients were compared with the healthy controls. Eighty-six (44.6 %) of the ESCC and 45 (36.3 %) of the GCA patients had family histories of UGIC. The proportion of age, sex and smoking status in ESCC and GCA patients with and without family histories of UGIC was also not significantly different (data not shown). None of the healthy controls had a family history of UGIC.

The *NQO1* C609T genotyping was successfully performed in all study subjects. The observed *NQO1* genotype frequencies were not significantly deviated from those expected from Hardy-Weinberg equilibrium in the healthy controls (χ^2=0.061; *P*=0.970), ESCC patients (χ^2=0.166; *P*=0.920) and GCA patients (χ^2=0.832; *P*=0.660). The *NQO1* C609T genotype distribution among healthy controls was 31.5 % (C/C), 52.1 % (C/T), and 16.4 % (T/T) respectively (Table 1). The genotype distribution was not correlated with gender, age and smoking status in each study group (data not shown).

Table 1 Demographic characteristics and *NQO1* polymorphism among ESCC, GCA patients and controls

Groups	Control *n* (%)	ESCC *n* (%)	GCA *n* (%)
Sex			
Male	109(66.1)	124(64.3)	92(74.2)
Female	56(33.9)	69(35.7)	32(25.8)
Mean age ±SD (yrs)	52±7.16	59±8.73	60±8.24
Smoking status			
Smoker	82(49.7)	104(53.9)	68(59.8)
Non-smoker	83(50.3)	89(46.1)	46(40.2)
Family history of UGIC			
Positive	0	86(44.6)	45(36.3)
Negative	165(100)	107(55.4)	79(63.7)
Genotype			
C/C	52(31.5)	51(26.4)	40(32.3)
C/T	86(52.1)	92(47.7)	55(44.3)
T/T	27(16.4)	50(25.9)[a]	29(23.4)
Allele type			
C	190(57.6)	194(50.3)	135(54.4)
T	140(42.4)	192(49.7)[b]	113(45.6)

Note. ESCC: esophageal squamous cell carcinoma; GCA: gastric cardiac adenocarcinoma; *NQO1: NAD(P)H: quinone oxidoreductase 1;* UGIC: upper gastrointestinal cancer; a. The genotype frequency was significantly higher than that in healthy controls (χ^2=4.79, *P*=0.028); b. The allele frequency was marginaly higher than that in healthy controls (χ^2=3.83, *P*=0.05).

The overall *NQO1* null-allele frequency among ESCC patients (49.7 %) was marginally higher than that among healthy controls (42.4 %) (χ^2=3.83, *P*=0.05). There was no difference in allele distribution between GCA patients and healthy controls (χ^2=0.567, *P*=0.451) (Table 1). The distribution of *NQO1* C/C and C/T genotypes among ESCC and GCA

patients was not significantly different from that among healthy controls (P>0.05) (Table 1).

Interestingly, in ESCC patients, the *NQO1* T/T genotype was significantly more frequent (25.9 %) than that among healthy controls (χ^2=4.79, P=0.028) (Table 2). The relative risk of the T/T genotype for the ESCC development was increased by about 1.8 fold compared with the combination of the C/C or C/T genotypes, with an age, sex and smoking status adjusted odds ratio of 1.78 (95 % CI=1.04-2.98). When stratified for the family history of UGIC, the *NQO1* T/T genotype was significantly more common among patients with family histories of UGIC (30.2 %) than that among healthy controls (χ^2=6.53, P=0.011). The T/T genotype significantly increased the risk for developing ESCC among patients with family histories of UGIC, compared with the C/C and C/T genotypes (adjusted OR=2.20, 95 % CI=1.18-3.98). In contrast, the *NQO1* T/T genotype frequency was not significantly different between ESCC patients without family history of UGIC (22.4 %) and healthy controls (χ^2=1.49, P=0.223) (Table 2).

In line with the result of ESCC, the *NQO1* T/T genotype significantly increased the risk for developing GCA compared with the C/C and C/T genotypes. However, this increased risk was only demonstrated when stratified for the family history. Thus, among GCA patients with family histories of UGIC, the T/T frequency (33.3 %) was significantly higher than that among healthy controls (χ^2=6.36, P=0.012). In this patient group, the relative risk of the T/T genotype for developing GCA was more than two-fold higher compared with the combination of C/C and C/T genotypes (adjusted OR=2.55, 95 % CI=1.21-5.23), whereas the *NQO1* T/T genotype frequency among the overall GCA patients (23.4 %) and GCA patients without family histories of UGIC (17.7 %) remained similar to that of the healthy controls (P>0.05) (Table 2).

Table 2 Relative risk of the *NQO1* C609T homogenous null for ESCC and GCA development

Groups	*NQO1* genotype		aOR (95%CI)[d]
	C/C+C/T *n* (%)	T/T *n* (%)	
Healthy controls	138(83.6)	27(16.4)	
ESCC patient	143(74.1)	50(25.9)[a]	1.78 (1.04-2.98)
Family history of UGIC			
Positive	60(69.8)	26(30.2)[b]	2.20 (1.18-3.98)
Negative	83(77.6)	24(22.4)	1.46 (0.79-2.63)
GCA patient	95(76.6)	29(23.4)	1.44 (0.86-2.30)
Family history of UGIC			
Positive	30(66.7)	15(33.3)[c]	2.55 (1.21-5.23)
Negative	65(82.3)	14(17.7)	1.10 (0.80-1.34)

Note. ESCC: esophageal squamous cell carcinoma; *NQO1:NAD (P)H: quinone oxidoreductase 1*; UGIC: upper gastrointestinal cancer; a,b,c. The genotype frequency was significantly higher than that in healthy controls (a. χ^2=4.79, P=0.028; b. χ^2=6.53, P=0.011; c. χ^2=6.36, P=0.012); d. The age, sex and smoking status adjusted relative risk of the *NQO1* C609T homogenous null genotype (T/T) against the combination of the heterozygote (C/T) and homozygous wild type (C/C).

To observe the different influence of the *NQO1* C609T polymorphism on the ESCC or GCA development among smokers and non-smokers, the genotype distribution was also stratified according to the smoking habits. No difference in *NQO1* genotype distribution among smoking or non-smoking ESCC and GCA patients was observed as compared with that of the healthy controls (data not shown).

DISCUSSION

Both of ESCC and GCA are characterized by a particularly poor prognosis since most of patients are diagnosed at advanced stages. Endoscopic examination is the only feasible way to detect ESCC and GCA at early and/or precancerous stages. However, the wide application of this method is limited by the high cost and painfulness of the examination. The laboratory identification of high-risk individuals, in combination with the clinical detection, will provide a promising way to detect the early tumors.

The present hospital based case control study suggests that *NQO1* C609T homozygous null genotype may increase the susceptibility to ESCC and GCA in the northern Chinese population. This result is consistent with the previous investigations, which showed that the *NQO1* homozygous null genotype increased the susceptibility to other tumor types such as lung cancer[19], leukemia[21,22] and cutaneous cancers[24]. The underlying mechanism of the correlation of *NQO1* C609T polymorphism with increased risk for developing various tumors may be related to the different enzyme activities encoded by the different *NQO1* genotypes. Thus, lack of NQO1 activity encoded by the homozygous null genotype results in a reduced detoxification of exogenous carcinogens and leads cells to be easily damaged by oxidation, and thereby increasing the susceptibility to chemically induced cancers such as ESCC and GCA. In addition, the recessive effect of the *NQO1* C609T null allele on the development of ESCC and GCA was suggested by the current study, since the heterozygous genotype frequency among tumor patients was similar to that among healthy controls. The result indicates that although the *NQO1* heterozygous genotype results in a three-fold decrease of the NQO1 enzyme activity, it may be sufficient for protecting cells from damage by exogenous carcinogens.

In this study, the increased risk of the *NQO1* C609T homozygous null genotype for developing both of ESCC and GCA was only evident in patients with family histories of UGIC, indicating that in families aggregated with UGIC patients, a predisposition to ESCC and GCA may be inherited by lack of *NQO1* enzyme activity. A strong association of increased risk for esophageal cancer with a positive family history of UGIC in the first-degree relatives has been reported in the high incidence regions of China[7,8]. The segregation analysis on the high-risk nuclear families suggested that the ESCC occurrence was best fit to the autosomal recessive Mendelian inheritance[8]. However, the underlying molecular mechanisms for the familial clustering of UGIC patients have not been elucidated so far. Our results suggested, that the *NQO1* C609T polymorphic gene, together with other possible susceptible genes, might give an opportunity to challenge the genetic mechanisms of cancer development in the UGIC clustered families and provide a chance to predict high-risk individuals in the high-incidence regions. In addition, the consistent association of *NQO1* C609T polymorphism with the susceptibility to ESCC and GCA, as shown in this study, supports that there might be a common genetic background in the development of these two tumor types. However, the result should be interpreted cautiously, since the number of cases, especially in the subgroup analyses, was probably too small to draw a final conclusion.

In summary, our preliminary data suggest that the *NQO1* C609T gene polymorphism may influence the susceptibility to ESCC and CAC in a northern Chinese population. Determination of *NQO1* C609T genotype may provide a useful genetic marker in predicating high-risk individuals for the development of ESCC and CAC. It is worthwhile conducting additional population-based studies including enlarged subjects before its clinical application.

Abstract

AIM: To characterize cytochrome P4501A1 (CYP1A1), glutathione S-transferases (GSTs) and microsomal epoxide hydrolase (mEH) polymorphisms in Chinese esophageal cancer patients.

METHODS: Multiplex polymerase chain reaction (PCR) and PCR based restriction fragment length polymorphisms (PCR-RFLP) were used to detect polymorphism changes of CYP, GSTs and mEH on esophageal cancerous and precancerous lesions as well as in case control group. All the examination samples were obtained from Linzhou (formerly Linxian), Henan Province, the highest incidence area for esophageal cancer.

RESULTS: The frequency of CYP1A1 3' polymorphism in case control group (26/38, 68 %) was significantly higher than in esophageal squamous cell carcinoma group (ESCC) (29/62, 47 %) ($P<0.05$). A significant difference in the incidence of mEH slow allele variant was observed between case control group (15/38, 39 %) and esophageal dysplasia group (22/32, 69 %) or ESCC group (39/62, 63 %) ($P<0.05$). However, no significant difference was observed among different groups in the polymorphisms of CYP1A1 exon 7, GSTM1, GSTT1, GSTP1 and mEH fast allele.

CONCLUSION: The present results suggest that CYP1A1 3' polymorphism may be one of the promising protective factors and its wild gene type may be an indicator for higher susceptibility to esophageal cancer. mEH slow allele variant, associated with the progression of esophageal precancerous lesions, may contribute to the high susceptibility to esophageal carcinoma.

INTRODUCTION

It has been revealed that carcinogenesis may be resulted from mutations or deletions in cancer-related genes. Meanwhile, a large proportion of human cancers is associated with diet, tobacco smoking and other environmental factors[1], suggesting that a combination of endogenous and exogenous factors is responsible for human carcinogenesis. In recent years, a relatively new field of cancer research has focused on the interaction between genes and enrironment to understand the aetiology of cancer[2]. Primary candidates for gene-environment interaction studies are those which encode enzymes related to the metabolism of established cancer risk factors. It has been known that most carcinogens require metabolic activation in the human body for the carcinogenic effects. There are two major enzyme systems that metabolize potential carcinogens, either synthetic or naturally occurring in the body, which have been classified as phase I and phase II. Generally, phase I enzymes can activate the carcinogen directly and produce more active metabolites. Phase II enzymes can detoxify and process the activated metabolites for final breakdown or excretion. Therefore, the genotypes with high phase I enzyme activity and low phase II enzyme level are considered to pose a high risk to cancer development[3].

Cytochrome P450 (CYP) isoenzymes are one major kind of phase I enzymes and play an important role in the oxidation of chemical compounds, such as polycyclic aromatic hydrocarbons (PAH), often resulting in the formation of highly reactive compounds that are the ultimate carcinogens[4]. Glutathione S-transferases (GSTs) are phase II enzymes and responsible for catalyzing the biotransformation of a variety of electrophiles, and have a central role in the detoxification of activated metabolites of procarcinogens produced by phase I reactions. GSTP1 is the main GST isoform expressed in esophageal mucosa[5,6]. Microsomal epoxide hydrolase (mEH) plays a dual role both in detoxication and activation of procarcinogens because it is not only involved in detoxication reaction but also generates some trans-dihydrodiols that could be metabolized to highly toxic, mutagenic and carcinogenic polycyclic hydrocarbon diol epoxides[7].

Esophageal cancer is one of the most common malignant diseases worldwide with a sharp variation in its geographic distribution[8]. The ratio in incidence between high- and low-risk areas could be as great as 500:1. The high incidence in special areas indicates the importance of environmental factors in esophageal carcinogenesis. However, only a small part of individuals in the high-risk area for esophageal cancer develop into esophageal cancer, although all the residents in that area share very similar environment-related risk factors and lifestyle,

suggesting that host susceptibility factors, such as the polymorphisms of phase I and phase II enzymes, may play an important role in increased risk for esophageal cancer. Thus, the present study was undertaken to assess the genetic polymorphisms of CYP1A1, GSTM1, GSTT1, GSTP1 and mEH in esophageal precancerous and cancerous lesions as well as in case control group from the subjects in high-incidence area for esophageal cancer in Henan to correlate these genetic polymorphisms and susceptibility to esophageal cancer.

MATERIALS AND METHODS

Patients and controls

Sixty-two cases of esophageal squamous cell carcinoma (ESCC), including 32 males with a mean age of 55 (55±9.8) and 30 females with a mean age of 60 (66±10.5) were recruited from Yaocun Esophageal Cancer Hospital in Linzhou, who were histopathologically confirmed in 1999. All the cases were from Linzhou district and were interviewed to exclude other simultaneous malignancies. Thirty-eight subjects with matched age and sex frequencies were randomly selected as control group from the same region during the field surveys between 1998 and 1999. Thirty cases of esophageal basal cell hyperplasia (BCH), including 20 males with a mean age of 52 (52±8) and 10 females with a mean age of 54 (54±7) and thirty-two cases of esophageal dysplasia (DYS), including 18 males with a mean age of 54 (54±8) and 14 females with a mean age of 55 (55±7) were also randomly recruited from the same region during the field surveys between 1997 and 1999.

PCR analysis of CYP1A1 gene polymorphism

Genomic DNA was extracted from surgically resected ESCC specimen, BCH and DYS biopsies and buccal smear (for control group). The PCR was performed in a total volume of 25 μL with GeneAmp 9700 (Perkin-Elmer Corp., Norwalk. CT) in this study. The concentration of primers for GSTT1 was 0.3 μM, and others were 1.0 μM. The A to G transition polymorphism in exon 7 of the CYP1A1 gene was analyzed by primers 5' GAAAGGCTGGGTCCACCCTCT and 5' CCAGGAAGAAA GACCTCCCAGCGGGCCA. Briefly, 100 ng of the DNA sample was amplified in buffer (10 mM Tris-HCl, 50 mM KCl, 1.5 mM MgCl2 pH 8.4) with 0.1 mM of each dNTP (Pharmacia, Piscatoway, NJ) and 1.25 U Taq polymerase (Perkin Elmer Corp., Norwalk. CT). Pre-heated at 80 ℃ for 3 sec, then initial denaturation was performed at 95 ℃ for 10 min, followed by 35 cycles of annealing for 1 min at 55 ℃, extention for 1 min at 72 ℃ and denaturation for 1 min at 95 ℃, finally extention for 5 min at 72 ℃. The PCR products were digested with NcoI (New England Biolabs, Inc., Beverly, MA) at 37 ℃ overnight, subjected to electrophoresis in an ethidium-bromide-stained 3 % agarose gel (Nusieve 3: 1; American Bioanalytical, Natick, MA) in TBE buffer (89 mM Tris-HCl, 0.89 mM boric acid and 2 mM EDTA, pH 8.0). PCR-RFLP analysis resulted in the following genotype classification: A predominant homozygote (Ile/Ile), a heterozygote (Ile/Val) and a rare homozygote (Val/Val).

For 3'-flank region polymorphism of CYP1A1, PCR was performed using the primers 5' CAGTCAACAGGTGTAGC and 5' GAGGCAGGTGGATCACTTGAGCTC. After preheated for 3 sec at 80 ℃, initial denaturation was performed at 94 ℃ for 1 min, followed by 37 thermal cycles consisting of denaturation for 25 sec at 94 ℃, annealing for 25 sec at 62 ℃, extention for 25 sec at 72 ℃ and a final extention for 5 min at 72 ℃. The PCR products were digested with MspI (New England Biolabs, Inc., Beverly, MA) at 37 ℃ overnight and subjected to electrophoresis on a 3 % agarose gel. The genotypes of CYP1A1 3' were classified as follows: Wild-type, heterozygous variant and homozygous variant.

GSTM1 and GSTT1 genotyping

GSTM1 and GSTT1 genotyping for gene deletion was carried out by a multiplex PCR using primers 5' GAACTCCCT GAAAAGCTAAAGC and 5' GTTGGGCTCAAATATACG GTGG for GSTM1, which produced a 219 bp product, primers 5' TTCCTTACTGGTCCTCACATCTC and 5' TCACCGGATCATGGCCAGCA for GSTT1, which produced a 480 bp product. At the same time, amplification of the b-globin gene (5' ACACAACTGTGTTCAC TAGC and 5' CTCAAAGAACCTCTGGGTCC) was used as an internal control and produced a 299 bp product. PCR was performed in a 25 μL mixture consisting of 100 ng sample DNA, 10 mM Tris-HCl, 50 mM KCl, 1.5 mM $MgCl_2$ pH 8.4, 0.1 mM of each dNTP and 1.25 U Taq polymerase. After initial denaturation for 3 min at 94 ℃, 35 cycles were performed at 94 ℃ for 1 min (denaturation), at 62 ℃ for 2 min (annealing) and at 72 ℃ for 2 min (extention), followed by a final step for 5 min at 72 ℃. The amplified products were visualized by electrophoresis in ethidium-bromide-stained 3 % agarose gel in TBE buffer. For null deletions of GSTM1 and GSTT1, no amplified product could be observed.

PCR-RFLP analysis of GSTP1 gene polymorphism

The primers 5' GTATTTTGCCCAAGGTCAAG and 5' AGCCACCTGAGGGGTAAG were used to amplify exon 5 of GSTP1 gene that includes the BsmAI enzyme recognition site. The same reaction mixture as above was used, after digestion with BsmAI at 55 ℃ overnight, the following genotypes could be shown: Wild type (one restriction site yielded two fragments of 329 bp and 113 bp), variant with 2 restriction sites, heterozygous variant yielded 3 fragments (329, 216, 113 bp), homozygous one yielded 2 fragments (216, 113 bp).

Analysis of mEH gene polymorphism

Primers 5' GATCGATAAGTTCCGTTTCACC and 5' ATCCTTAGTCTTGAAGTGAGGAT were used to amplify mEH slow allele (113 code). Primers 5' ACATCCAC TTCATCCACGTT and 5' ATGCCTCTGAGAAGCCAT were used to amplify mEH fast allele (139 code). After two separate PCR reactions, the varant, correlated with decreased mEH activity (His 113) was identified through the presence of EcoR V restriction site, and the allele correlated with increased activity (Arg 139) was identified through the presence of RsaI site.

Statistical analysis

The χ^2 test was used to examine the differences in genotype distribution between patients and controls. The difference was considered significant in case of a two-tailed *P* value less than 0.05.

RESULTS

CYP1A1 genetic polymorphism (Table 1)

DNA samples subjected to PCR and enzymatic digestion with MspI revealed the expected fragment lengths and resulted in three genotypes of CYP1A1 3' noncoding area (Figure 1). The frequency of combined heterozygous and homozygous variant genotype detected in the groups of control, BCH, DYS and ESCC was 68 %, 63 %, 62 %, 47 %, respectively (Table 1), the difference was significant between control group and ESCC group ($P<0.05$). However, no significant difference was observed for heterozygous and homozygous variant incidence among the different groups ($P>0.05$). CYP1A1 exon 7 polymorphisms in the groups of control, BCH, DYS and ESCC were observed with an incidence of 47 %, 53 %, 50 % and 52 %, respectively, but there was no significant difference

among these groups (P>0.05). The corresponding heterozygous and homozygous variant frequency did not show a significant difference among these groups.

Table 1 Distribution of CYP1A1 genetic polymorphism in controls and subjects with cancer and different severity of lesions *n*(%)

	Control (*n*=38)	BCH (*n*=30)	DYS (*n*=32)	ESCC (*n*=62)
CYP1A1 3'				
Wild type	12(32)	8(27)	9(28)	33(53)
Heterozygous	22(58)	16(53)	17(53)	25(40)
Homozygous variant	4(10)	3(10)	3(9)	4(6)

Val/Ile + Val/Val	18(47)	16(53)	16(50)	32(52)

[a]P<0.05, *vs* case control group.

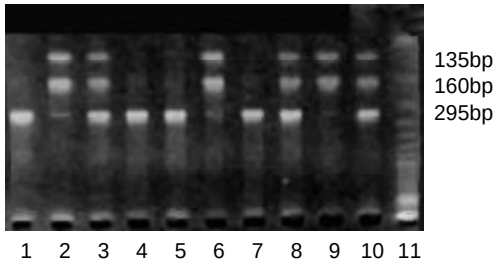

Figure 1 Examples of CYP1A1 3' polymorphism. The RFLPs of PCR-amplified fragments obtained using MspI and subjected to agarose gel electrophoresis. Wild type without MspI restriction site shows a 295 bp band (lanes 1, 4, 5, 7), variant with MspI restriction site results in two bands of 135 and 160 bp (homozygous variant, lanes 2, 6, 9) or all three bands (heterozygous variant, lanes 3, 8, 10).

GSTs genetic polymorphism (Table 2)

Table 2 shows the homozygous deletion of GSTM1 and GSTT1. A similar percentage (around 50 %) for GSTM1 and T1 homozygous deletion in the groups of control, BCH, DYS and ESCC was observed. GSTP1 polymorphism incidence in control group (37 %) was a little lower than that in other groups (about 50 %), but the difference was not significant (P>0.05). There was also no apparent difference for their corresponding heterozygous and homozygous variant distribution in all groups.

Table 2 Genotypes of GSTM1, GSTT1 and GSTP1 in controls and subjects with different severity of lesions and cancer *n*(%)

	Control (*n*=38)	BCH (*n*=30)	DYS (*n*=32)	ESCC (*n*=62)
GSTM1				
+	19(50)	16(53)	18(56)	35(56)
-	19(50)	14(47)	14(44)	27(44)
GSTT1				
+	18(47)	17(57)	15(47)	28(45)
-	20(53)	13(43)	17(53)	34(55)
GSTP1				
Ile/Ile	24(63)	15(50)	15(47)	29(47)
Val/Ile	13(34)	15(50)	16(50)	30(48)
Val/Val	1(3)	0(0)	1(3)	3(5)
Val/Ile + Val/Val	14(37)	15(50)	17(53)	33(53)

mEH genetic polymorphism (Table 3)

mEH polymorphism was observed occurring frequently in exons 3 and 4, which resulted in substitution of amino acid histidine to tyrosine at residue 113 (slow allele) and arginine to histidine at residue 139 (fast allele), respectively. The variant of mEH fast allele was observed with a relatively low frequency in all groups. The homozygous and heterozygous variant for mEH was also detected with a low incidence and no significant difference was observed among different groups (Table 3, P>0.05). However, the different distribution of mEH slow allele variant was observed in the present study. The frequency for mEH slow allele variant (39 %) was the lowest in the control group and increased in BCH (53 %), DYS (69 %) and ECSS (63 %), the difference was significant between control group and BCH, or DYS and ESCC (P<0.05). Figure 2 shows slow allele polymorphism for mEH.

Another interesting result was that none of polymorphic variants of all detected genes was found to be associated with ESCC differentiation in this study.

Table 3 Slow and fast allele polymorphism of mEH in controls and subjects with different severity of lesions and cancer *n*(%)

	Control (*n*=38)	BCH (*n*=30)	DYS (*n*=32)	ESCC (*n*=62)

DISCUSSION

In this study, a similar frequency of CYP1A1 exon 7 polymorphism was observed in the groups of control, ESCC and precancerous lesions, but the CYP1A1 3' flank polymorphic variants most frequently occurred in control group, 1.4 times that in ESCC group (68 % *vs* 47 %), indicating that CYP1A1 3' variants could be a protective factor for ESCC in this population. Two major relevant genetic polymorphisms have been demonstrated in the CYP1A1 gene: One is a T to C substitution in the 3' flanking region altering protein folding, whereas an Ile to Val substitution may occur in exon 7. Both substitutions were considered to result in the enhancement of

enzyme activity[9], but polymorphism in the noncoding region of CYP1A1 was unlikely to have direct functional consequences on CYP1A1 activity[10], even the variant of CYP1A1 exon 7 was not sure to induce an increased enzyme activity[11]. These controversial reports suggest that the effect of CYP1A1 polymorphism on cancer development remains to be characterized.

The second interesting observation in the present study was that a high rate of GSTM1 and GSTT1 null genotype and GSTP1 polymorphic variant occurred not only in the control group but also in ESCC patients and the subjects with different precancerous lesions (BCH and DYS), suggesting that GSTs polymorphism may be responsible for the higher-risk for esophageal cancer in this population. GSTM1 and GSTT1 null genotypes have been reported to enhance the risk of developing gastric, colorectal, and lung cancers[12,13], although other studies did not show such a genetic predisposition[14]. Again, in normal esophageal epithelium, GSTP1 was the mean isoform for GST[5]. An Ile to Val substitution in the GSTP1 gene has been found more often in patients with bladder and testicular cancer[5].

The third interesting observation was that mEH sequence alteration from tyrosine to histidine at residue 113 (slow allele), but not polymorphism at residue 139, was associated with progression of esophageal lesions from normal to BCH to DYS and ESCC, and might contribute to a high susceptibility to esophageal carcinoma. mEH is involved in the metabolism of carcinogens found in cigarette smoke and cooked meat, such as PAH. Expression studies of cDNA *in vitro* indicated that mEH enzymatic activities were decreased by exon 3 polymorphism and increased by exon 4 polymorphism. Reactive and toxic epoxides are frequently generated during PAH oxidative metabolism. Epoxides can be detoxicated partly by mEH, which catalyzes their hydrolysis, thereby yielding the corresponding trans-dihydrolysis. Although hydrolysis is generally considered to represent a detoxication reaction, some trans-dihydrodiols are substrates for additional metabolic changes to highly toxic polycyclic hydrocarbon diol epoxides[7]. It has been suggested that mEH gene His113 variant allele increases the risk of hepatocarcinoma[15] and lung cancer[16] but decreases the risk of ovarian cancer[17]. Further characterization of mEH polymorphism in a larger scale population will be needed to clarify the significance of mEH in high-risk area for esophageal cancer.

Finally, it is noteworthy that the genetic variants of all detected genes in this study were not associated with ESCC differentiation, suggesting that genetic polymorphism may represent susceptibility to ESCC.

Abstract

AIM: To systematically study the expression of carbonic anhydrase (CA) isozymes IX and XII in gastric tumors.

METHODS: We analyzed a representative series of specimens from non-neoplastic gastric mucosa and from various dysplastic and neoplastic gastric lesions for the expression of CA IX and XII. Immunohistochemical staining was performed using isozyme-specific antibodies and biotin-streptavidin complex method.

RESULTS: CA IX was highly expressed in the normal gastric mucosa and remained positive in many gastric tumors. In adenomas, CA IX expression significantly decreased towards the high grade dysplasia. However, the expression resumed back to the normal level in well differentiated adenocarcinomas, while it again declined in carcinomas with less differentiation. In comparison, CA XII showed no or weak immunoreaction in the normal gastric mucosa and was slightly increased in tumors.

CONCLUSION: These results demonstrate that CA IX expression is sustained in several types of gastric tumors. The variations observed in the CA IX levels support the concept that gastric adenomas and carcinomas are distinct entities and do not represent progressive steps of a single pathway.

INTRODUCTION

The carbonic anhydrases (CAs) catalyze the reversible hydration of carbon dioxide, $CO_2 + H_2O \Leftrightarrow HCO_3^- + H^+$, and participate in various physiological processes, including respiration, bone resorption, renal acidification, gluconeogenesis, and formation of cerebrospinal fluid and gastric acid. At present, 11 functionally active CA isozymes, differing in their tissue distribution and enzymatic activity, have been identified in mammals[1-3].

CA IX was initially described as a tumor-associated integral plasma membrane antigen (MN)[4]. It has been reported to contain an extracellular domain with the essential structural features and high activity of CAs[5-7]. CA IX has been detected in the normal gastric, intestinal, and biliary mucosa[8]. Because CA IX is more strongly expressed in the proliferating cryptal epithelium than in the upper part of the mucosa, it may play a role in the control of proliferation and differentiation of intestinal epithelial cells[9]. Cell proliferation is abnormally increased in premalignant and malignant lesions, and therefore CA IX has been considered as a potential biomarker for tumor progression[10]. Previous studies have shown that CA IX is expressed in a high percentage of human epithelial tumors, including carcinomas of uterine cervix, lung, kidney, biliary tract, colon, and breast[11-20]. Most of these tumors arise from tissues with no or low CA IX expression. On the other hand, it has been proposed that CA IX is absent or reduced in most tumors originating from CA IX-positive tissues[8].

CA XII is another transmembrane CA isozyme, whose expression has been demonstrated in normal human kidney, colon, prostate, pancreas, ovary, testis, lung, and brain[21, 22]. By immunohistochemistry, CA XII has been detected at the basolateral plasma membrane of the superficial epithelial cells of the colon and rectum, while the small intestine has remained negative[23]. CA XII protein has also been located in the epithelial cells of endometrium[24], renal tubules[25], and efferent ducts[26]. CA XII shows a clear association with some tumors, which was first reported by Türeci *et al.*[27]. They showed that in 10 % of patients with renal cell cancer, the CA XII transcript was expressed at much higher levels in the tumor than in the surrounding normal kidney tissue. These results have been recently confirmed by immunohistochemical staining showing CA XII expression in most cases of clear cell carcinomas and oncocytomas[25]. In addition to renal tumors, CA XII is expressed in a number of colorectal tumors[23] and in ductal carcinomas of the breast[19].

CA IX and XII seem to be regulated by similar mechanisms. First, Ivanov *et al.*[21] identified the *CA9* and *CA12* genes as von Hippel-Lindau (VHL) target genes. They observed that the wild-type VHL protein down-regulated the transcription of CA IX and XII mRNA, indicating that these isozymes may have a potential role in VHL-mediated carcinogenesis. Second, both isozymes have been induced under hypoxic conditions in tumors and cultured tumor cells[22,28]. Hypoxia activates transcription through hypoxia inducible factor-1 (HIF-1), which is composed of two subunits (HIF-1α and HIF-1α)[29]. It is also known that VHL gene product (pVHL) interacts with HIF-1α and is required for the destruction of HIF-1α under normoxic conditions[30]. Taken together, it seems plausible that

CA IX and XII are functionally connected to neoplastic processes controlled by HIF-1 and pVHL[22]. Furthermore, high expression of CA IX and XII in tumors has suggested that they may functionally participate in the invasion process, which is facilitated by acidification of extracellular space. In favor of this hypothesis, it has been shown *in vitro* that CA inhibitors can reduce the invasion capacity and/or proliferation of cancer cells[31-34].

The present study was designed to examine the expression of CA IX and XII in gastric tumors. Even though gastric mucosa is known to be the predominant site of CA IX expression, tumors originating from this area have not been comprehensively studied for the expression of these isozymes.

MATERIALS AND METHODS

Antibodies

The polyclonal rabbit antibodies against human CA XII have been produced earlier[24]. The monoclonal antibody M75 against human CA IX has also been described earlier[4]. Both antibodies have been characterized for specificity and they have shown no cross-reactivity with other CAs[9,24].

Immunocytochemistry

The tissue samples from the non-neoplastic gastric mucosa and the corresponding benign and/or malignant neoplastic samples were obtained alongside routine histopathological specimens collected at Oulu University Hospital (Oulu, Finland). The numbers of samples in each histological category are shown in Table 1. The study was approved by the Ethics Committee of Oulu University Hospital and performed according to the guidelines of the Declaration of Helsinki.

Table 1 Number of gastric specimens analyzed for CA IX and XII expression

Diagnosis	CA IX (*n*)	CA XII (*n*)
Nonneoplastic cardia	7	5
Nonneoplastic corpus	21	15
Nonneoplastic antrum	26	17
Hyperplasia	13	3
Adenoma, slight dysplasia	11	4
Adenoma, moderate dysplasia	8	3
Adenoma, severe dysplasia	3	1
Adenocarcinoma, grade I	11	8
Adenocarcinoma, grade II	16	15
Adenocarcinoma, grade III	16	15
Diffuse carcinoma	18	15
Metastasis of gastric carcinoma	13	13
Intestinal metaplasia	33	20

The specimens were fixed in 4 % neutral-buffered formaldehyde for 24-48 h. Then they were dehydrated, embedded in paraffin in a vacuum oven at 58 ℃, and 5 μm sections were placed on Superfrostä microscope slides (Menzel Gläser, Braunschweig, Germany). The CA isozymes were immunostained by the biotin-steptavidin complex method, employing the following steps: (a) Pretreatment of sections with undiluted cow colostrum (Biotop Ltd, Oulu, Finland) for 30 min and rinsing in phosphate-buffered saline (PBS). (b) Incubation for 1 h with anti-CA XII serum (1:100), normal rabbit serum (1:100) or hybridoma medium with M75 antibody (1:10) in 1 % BSA-PBS. (c) Incubation for 1 h with biotinylated swine anti-rabbit IgG (Dakoplatts, Glostrup, Denmark) or goat anti-mouse IgG (Dakopatts) diluted 1:300 in 1 % BSA-PBS. (d) Incubation for 30 min with peroxidase-conjugated steptavidin (Dakoplatts) diluted 1:500 in PBS and (e) incubation for 2 min in DAB solution containing 9 mg 3,3'-diaminobenzidine tetrahydrochloride (Fluka, Buchs, Switzerland) in 15 ml PBS and 5 μl 30 % H_2O_2. The sections were washed 3 times for 10 min in PBS after incubation steps b and c, and 4 times for 5 min after step d. All the incubations and washings were carried out at room temperature. After the immunostaining, the tumor sections were counterstained with hematoxylin. The stained sections were examined and photographed with Zeiss Axioplan 2 microscope (Zeiss, Göttingen, Germany).

The immunohistochemical results were semiquantitative based on the percentage of the positive cells and on the intensity of the epithelial staining evaluated in a total field of a single section. The extent of staining (EXT) was scored by four investigators (M.L., J.S., T.J.K., and S.Par.) as 1 when 1-10 % of the cells stained, 2 when 11-50 % of the cells stained, and 3 when 51-100 % of the cells stained. A negative score (0) was given to tissue sections which had no evidence of specific immunostaining. The intensity of staining (INT) was scored on a scale of 0 to 3 as follows: 0, no reaction; 1, weak reaction; 2, moderate reaction; 3, strong reaction. In the normal and hyperplastic gastric mucosa, the scores were first counted in the luminal surface, proliferative zone and glands, and relative staining indices (on the scale 0-3) were calculated separately for each histological layer using the following formula: $\sqrt{(EXT \times INT)}$. In the adenomas and metaplasias, the EXT and INT scores were counted separately in the deep and superficial parts of the mucosa, and the relative staining indices were calculated accordingly for both regions. Finally, the staining indices obtained in each region were used to calculate the mean values for each normal sample or lesion. The principle of these calculations is shown in Figure 1.

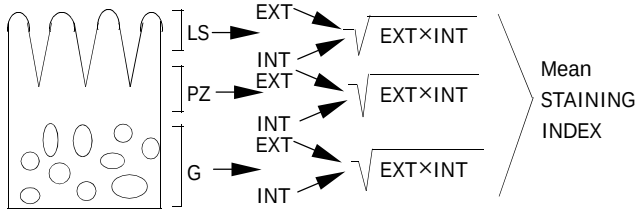

Figure 1 The principle for calculation of the relative staining index in one normal gastric sample (LS=luminal surface, PZ=proliferative zone, G=gastric glands).

Statistical analysis

Statistical analysis of the results was performed using SPSS for Windows software (SPSS Inc.). One-way analysis of variance was used to compare the staining for CA isozymes in different lesions. The pairwise comparisons between group means were performed using multiple comparison tests: Bonferroni, Tukey's honestly significant difference test, Sidak, Gabriel, Hochberg, and LSD (least significant difference).

RESULTS

Expression of CA IX

One intriguing finding of the present study was that the CA IX expression was sustained at relatively high level in many gastric tumors. Figure 2 shows some examples of CA IX immunostaining in the normal gastric mucosa (A) and different

gastric lesions (B-F). In the normal mucosa, CA IX was localized in all major cell types including parietal cells, chief cells, and mucus producing surface epithelial cells as described previously by Pastoreková *et al*.[8]. The positive staining covered all epithelial types of the gastric mucosa including glands, proliferative zone and the superficial epithelium of the mucosa. The staining was observed to be slightly weaker in the proliferative zone (data not shown) that contrasted with previous staining results in intestine where CA IX was mainly confined to the proliferative enterocytes[9]. Figure 2B demonstrates a typical distribution pattern of CA IX in intestinal metaplasia. It was notable that it was expressed in the crypts of metaplastic epithelium which was in line with its high expression in Lieberkühn crypts of the normal gut. Figure 3 demonstrates the mean staining indices for CA IX in the samples of normal gastric mucosa, hyperplasia, adenoma, adenocarcinoma, diffuse carcinoma, metastasis of gastric cancer, and metaplasia. The results demonstrated that the average staining reactions were quite similar in normal and hyperplastic gastric mucosa, while they became significantly weaker in dysplastic and malignant lesions. Figure 4 shows CA IX staining indices in gastric lesions grouped according to the stages of dysplasia and grades of malignancy. This analysis surprisingly revealed that adenomas and carcinomas formed two distinct entities based on the CA IX immunostaining. In adenomas, CA IX staining indices declined from 1.3-1.4 in lesions with slight or moderate dysplasia to 0.3 in those with severe dysplasia. In grade I adenocarcinomas, the staining index remained at the same level with normal and hyperplastic mucosa, while it again declined in carcinomas with higher malignancy grades.

Expression of CA XII

Figure 5 shows examples of CA XII immunostaining in the normal gastric mucosa and different lesions. Figures 6 and 7 show the staining indices for CA XII. In the non-neoplastic gastric mucosa, CA XII showed no or weak immunoreactions. The staining indices appeared to be significantly increased in hyperplastic and adenomatous lesions as well as in grades I and II adenocarcinomas and metastases, although they did not reach the values observed with CA IX. The indices were only very slightly increased in grade III adenocarcinomas and diffuse carcinomas, but the difference was not statistically significant.

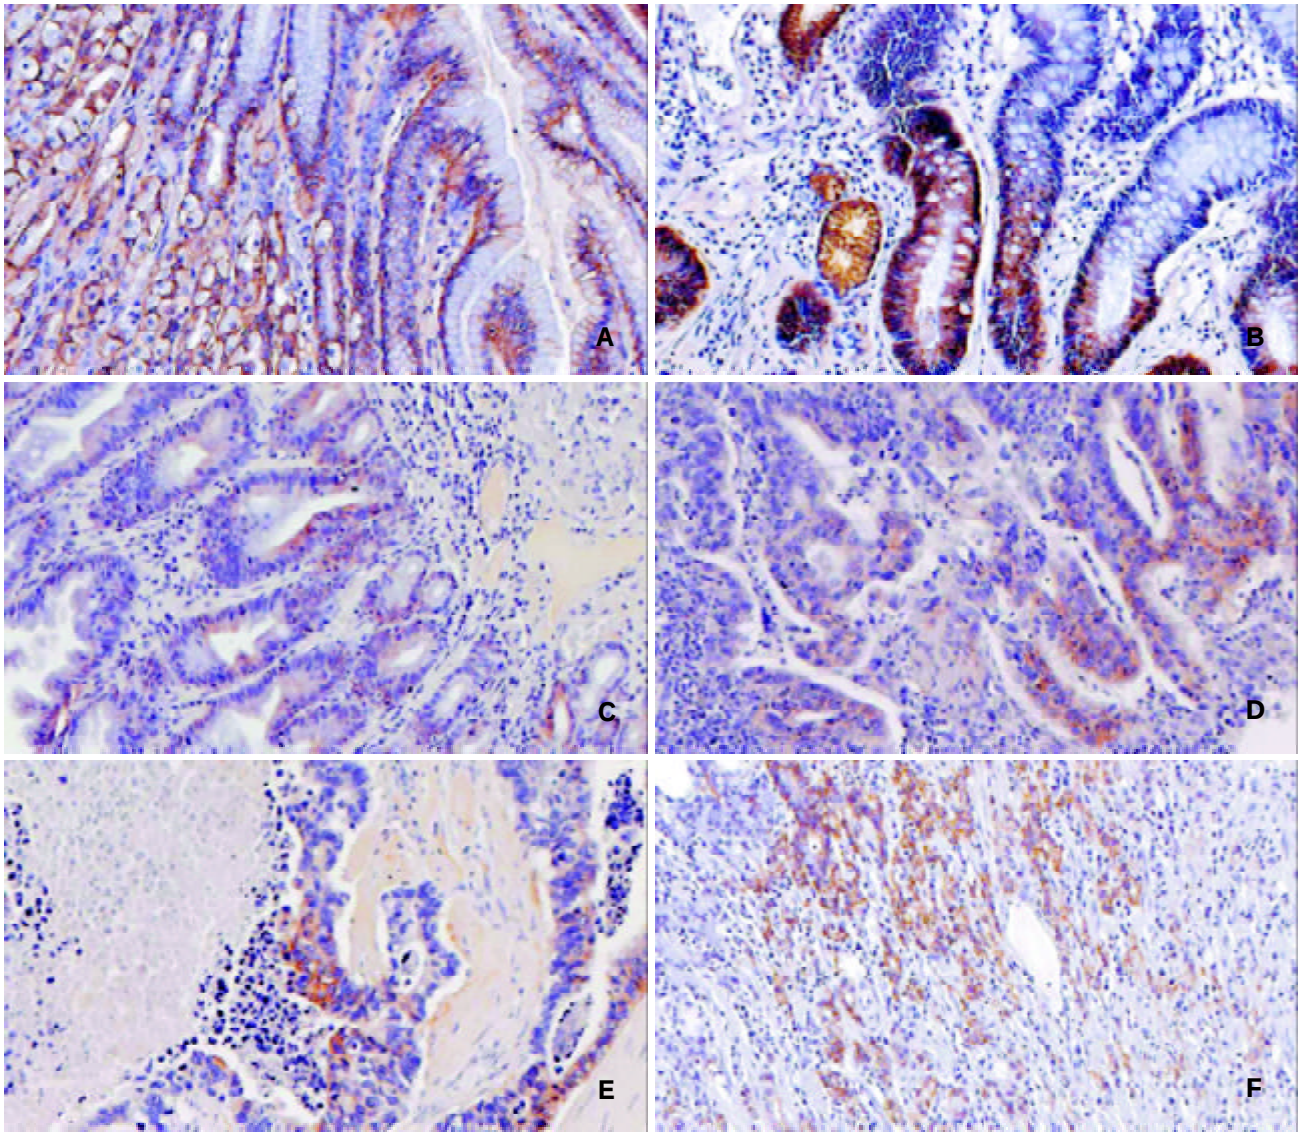

Figure 2 Immunohistochemical staining of CA IX in normal gastric mucosa (A), metaplasia (B), adenoma with moderate dysplasia (C), adenocarcinoma grade II (D), adenocarcinoma grade III (E), and diffuse carcinoma (F). In the normal mucosa, CA IX was expressed in all histological layers covering the luminal surface (LS), proliferative zone (PZ), and gastric glands (G). It was notable that CA IX was confined to deep crypts in metaplastic epithelium. The adenoma sample and all malignant lesions shown in this figure were positive for CA IX. (Original magnifications ×200).

Figure 3 The mean staining indices for CA IX in the normal gastric mucosa and different gastric lesions (P=0.002, normal *vs* dysplasia, adenocarcinoma, and metaplasia).

Figure 4 The mean staining indices for CA IX in the normal gastric mucosa and lesions grouped according to the stages of dysplasia and grades of malignancy (P<0.05, normal *vs* gd, gr. II and gr. III).

Figure 5 Immunohistochemical staining of CA XII in normal gastric mucosa (A), metaplasia (B), adenoma with moderate dysplasia (C), adenocarcinoma grade II (D), adenocarcinoma grade III (E), and diffuse carcinoma (F). From these samples, CA XII was

not expressed in the normal epithelium and showed weak expression in metaplastic epithelium and diffuse carcinoma. The signal was stronger in adenoma and adenocarcinoma samples.

Figure 6 The mean staining indices for CA XII in the normal gastric mucosa and different gastric lesions ($P<0.05$, normal *vs* adenocarcinoma).

Figure 7 The mean staining indices for CA XII in the normal gastric mucosa and lesions grouped according to the stages of dysplasia and grades of malignancy ($P=0.003$, normal *vs* gr. II).

DISCUSSION

CA IX is present in several types of human tumors, whereas it is usually absent in the normal tissues from which these tumors originate. For example, it is expressed in neoplasias of uterine cervix and renal cell carcinomas, but not in the normal cervix or kidney[12,13,15,35]. On the other hand, there are only a few non-cancerous tissues expressing MN/CA IX, including epithelia of stomach, intestine, and gallbladder[8]. The present study was focused on the tumors arising from the gastric mucosa, which is normally the predominant site of CA IX expression. One interesting finding of the present study was that CA IX expression was sustained in most cases of gastric neoplasias, even though the expression indices declined compared to the normal and hyperplastic gastric mucosa.

The exact molecular mechanisms of gastric tumorigenesis are still under discussion. Some investigators have postulated that differentiated adenocarcinoma may arise from pre-existing adenoma, following a similar adenoma-carcinoma sequential axis as described for colorectal tumors[36]. However, when gastric adenomas and adenocarcinomas were examined for loss of heterozygosity using microsatellite markers or *MUC* gene expression, the results suggested that the adenoma-carcinoma sequence was not a major pathway in gastric carcinogenesis[37-41]. Since CA IX expression levels seemed to be very low in adenomas with severe dysplasia and normal in grade I adenocarcinoma, the present findings could support the concept that these tumor types are usually distinct entities and do not represent progressive steps from one to the other. In this respect, CA XII did not show any prominent changes in different tumor categories, although its expression was slightly increased in all pathological lesions compared to the nonneoplastic gastric mucosa.

CA IX differs from the other CA isozymes in that it has a proposed dual function as an efficient enzyme[7] and as an adhesion molecule[42,43]. This dual function appears to be related to the structure of CA IX molecule that consists of an extracellularly exposed N-terminal proteoglycan-like region and a CA domain. The CA domain may contribute to the regulation of acid-base homeostasis on the basolateral surfaces of the gastrointestinal epithelial cells. In tumors, CA activity has been suggested to participate in acidification of an extracellular microenvironment facilitating tumor invasion[21]. On the other hand, the adhesion properties of CA IX may be involved in the maintenance of mucosal integrity contributing to proper intercellular contacts and communication[42,43]. Recent studies in *CA9* knockout mice have indicated that CA IX is, indeed, an important factor in gastric morphogenesis and homeostasis of the gastric epithelium possibly acting through the control of cell differentiation and proliferation[44]. The proposed involvement of CA IX in cell differentiation agrees with our observation that high expression of CA IX was associated with a differentiated phenotype of gastric epithelial cells. However, this fact is in contrast to data from other types of tumors, e.g. breast carcinomas, where CA IX expression is increased in tumors with less differentiation, while the opposite is true for CA XII[19].

Even though the present results indicated that CA IX and XII were not specific biomarkers for any categories of gastric tumors, and thus their clinical significance may be limited in this area, they have already revolutionized the field of the CA research in terms of the proposed functions. CA IX and XII are not only enzymatically active isoforms, but also play several important roles in biological processes such as malignant cell invasion[31], cell adhesion[42,43], and cell proliferation[9,10]. These "cancer-associated CAs" are also considered as potential targets in cancer therapy[21,35,45] and a number of promising anticancer therapeutic agents directed to inhibition of CA activity have already been developed and await further evaluation[32-34].

Abstract

AIM: To evaluate spiral computed tomography (CT) including virtual gastroscopy for diagnosis of gastric carcinoma in comparison with upper gastrointestinal series (UGI), fiberoptic gastroscopy (FG) and histopathology.

METHODS: Sixty patients with histologically proven gastric carcinoma (54 advanced and 6 early) were included in this study. The results of spiral CT were compared with those of UGI and FG. Two observers blindly evaluated images of spiral CT and UGI and video recording of FG with consensus in terms of diagnostic confidence with a five-point scale. Sensitivities of lesion detection, Borrmann's classification of spiral CT, UGI and FG, as well as the accuracy of TNM staging of spiral CT were determined by comparing them to surgical and histological findings.

RESULTS: The lesion detection rate was 98 % (59/60), 95 % (57/60) and 98 % (59/60) for spiral CT, UGI and FG, respectively. There were no statistical differences in the detection sensitivity among the three techniques ($P>0.05$). For the sensitivity in Borrmann's classification, spiral CT was higher than that of UGI ($P=0.025$) and similar to that of FG ($P>0.05$). The accuracy of spiral CT in staging the gastric carcinoma was 76.7 %. Six cases of early gastric carcinoma were all detected by spiral CT as well as FG.

CONCLUSION: Spiral CT is equivalent to UGI and FG in the detection of gastric carcinoma, and superior to UGI but similar to FG in the Borrmann's classification of advanced gastric carcinoma. Spiral CT is more valuable than FG in the staging of gastric carcinoma.

INTRODUCTION

Fiberoptic gastroscopy (FG) is generally regarded as a standard test for detection of gastric cancer. Upper gastrointestinal series (UGI), however, still represents a routine or survey examination for imaging gastric abnormalities although it has certain limitations in clinical use. Even though the application of conventional computed tomography (CT) in staging gastric carcinoma has been introduced, the results are unsatisfactory[1-3]. Recently, spiral CT, including various three-dimensional (3D) reconstructions such as virtual endoscopy and axial source images (2D) has been used in imaging the alimentary tract[2-16]. While most reports in literature laid emphasis on colon polyps[11-12, 14-15], there have been a few studies investigating gastric carcinoma with spiral CT[4-10]. In clinical practice, advanced gastric carcinoma is defined using Borrmann's classification, which is the pathological basis for UGI diagnosis, and the resectability of the tumor and prognosis of the patients are evaluated presurgically using TNM staging[17], which is one of the suggested applications of spiral CT.

In this study, 2D and 3D display techniques after spiral CT scan were cross-referenced. The role of this combined spiral CT technique was compared with that of UGI and FG in the detection and Borrmann's classification of gastric carcinoma, which, to our knowledge, has not been reported in literature. The staging of gastric carcinoma with spiral CT was also correlated with histopathology.

MATERIALS AND METHODS

Patients

During a 12-month period, 60 consecutive patients (36 males, 24 females) ranging from 27 to 79 years old (mean=62 a.), who were diagnosed of gastric carcinoma with FG and subsequent biopsy were recruited. Among the 60 gastric carcinoma patients, 43 were undertaken gastrectomy or subtotal gastrectomy, 17 were undertaken surgical exploration only because of severe adhesion between tumor and surrounding tissues. This study was approved by the administrative authority of the university hospital and fully informed consent was obtained from each patient. Within one week after FG procedure, UGI was performed prior to spiral CT scanning on each patient.

Imaging acquisition

Spiral CT was performed with a Hispeed CT/i scanner (General Electric Medical Systems, Milwaukee, WI). All patients were fasted for 12 hours. Before the CT scanning, 20 mg raceanisodamine hydrochloride was intramuscularly administered and two packs (6 g) of effervescent granules were taken orally. Usually patients were immediately placed on the scanning table in an oblique supine position. A scout projection was made to confirm the stomach to be distended by gas. If insufficient distention of stomach was found, half to one pack of effervescent granules was added and a scout projection was scanned again. Then, spiral CT was performed with a 3-mm collimation and a pitch of 1.2-1.5 mm during a single breath-hold of 22-33 seconds, which produced a 3D-volume

acquisition that included the entire stomach. Tube current was 200-280 mA, voltage was 120 kVp and scan time was 1 second per rotation.

Barium double contrast technique with standard projection was used for UGI studies by an experienced radiologist. Standard FG examination was performed by an experienced gastrologist and the biopsy samples were processed as a clinical routine of pathology department.

Image reconstruction

3D-postprocessing modes including CT virtual gastroscopy (CTVG), surface shaded display (SSD) and "Raysum" Display (virtual double contrast barium study) were performed by a built-in workstation (Advantage Window 2.0, General Electric Medical Systems, Milwaukee, WI) after raw data reconstruction with 1 mm interval. For intraluminal views of the stomach, a default level of -525 (Hounsfield unit, HU) provided by the Navigator (GE Company) was chosen. SSD and "Raysum" display were obtained with a threshold of -311HU.

Image analysis

Sixty sets of hard copy of grayscale spiral CT images (including axial source images, CTVG, SSD, and "Raysum" display) and UGI radiograms from 60 patients were obtained by one radiologist and were randomly reviewed and scored with consensus by two other experienced radiologists who were blinded to clinical data, pathology, and the information of other imaging techniques. Video recording of FG examinations was reviewed and scored with consensus by two experienced gastrologists.

The diagnostic confidence, appearance, location, and size of suspected lesions on images of spiral CT, UGI and FG were recorded. For spiral CT, the observers made the final judgments after referring to all 4 techniques including CTVG, SSD, "Raysum" and axial source images. The lesions were then classified as early and advanced gastric carcinoma according to Borrmann's classification[2]. Based on spiral CT, TNM staging[16] of gastric carcinoma of each case was also noted. Diagnostic confidence for detecting a lesion was rated as 1, definitely no lesion; 2, probably not a lesion; 3, possible lesion; 4, probable lesion; 5, definite lesion[18]. Any image artifacts that degraded diagnostic confidence were also noted.

All findings of lesions with spiral CT, UGI and FG were further verified with the results of surgical exploration, dissected specimen and histology, which were used as the gold standard for detection, Borrmann's classification and spiral CT staging of gastric carcinoma.

Statistical analysis

Data entry procedures and statistical analysis were performed with a statistical software package (SAS for windows, version 6.12, SAS Institute, Cary, NC). By using only those lesions allocated with confidence rate of 3 or higher, the sensitivity of detection and classification of gastric carcinomas of each technique was assessed[18] (Chi-square test). Significant differences were considered when the *P* value was less than or equal to 0.05.

RESULTS

The classification, size and location of the gastric cancer in this study are summarized in Table 1. A complete set of image data of a patient is exemplified in Figure 1.

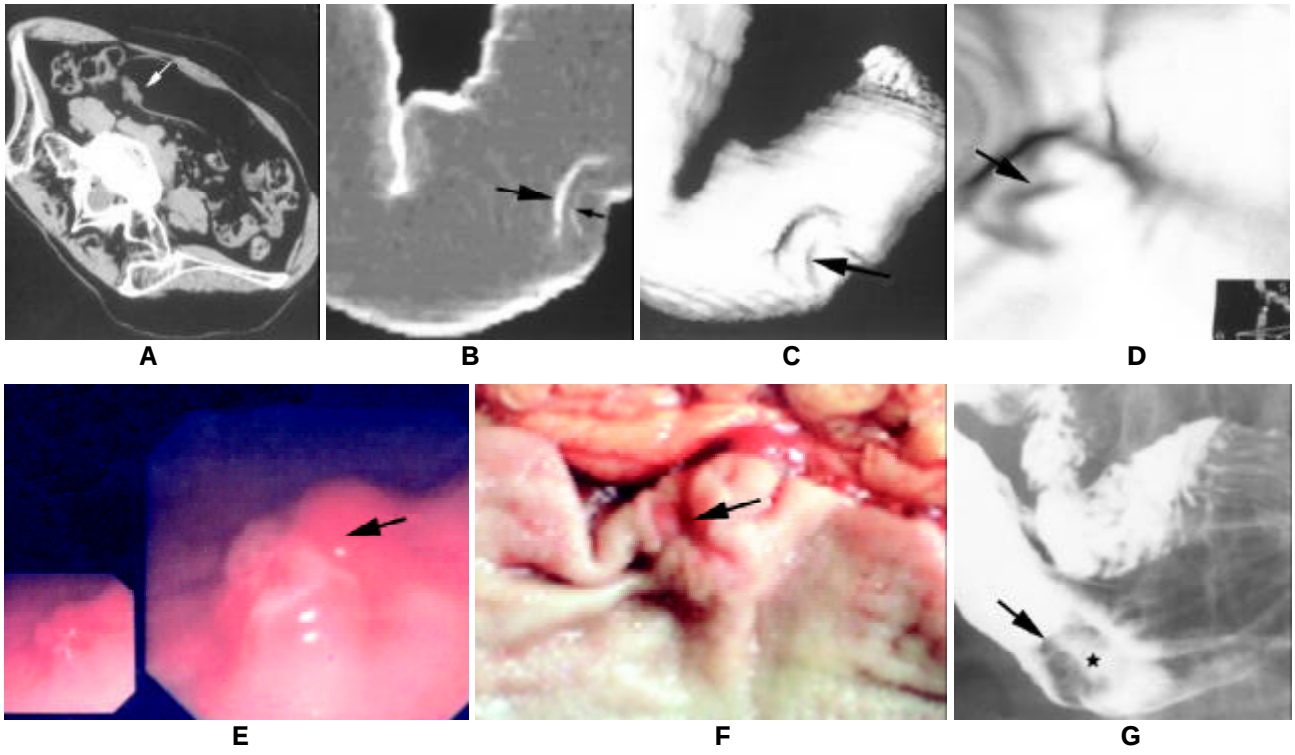

Figure 1 A complete set of image data of a patient. Spiral CT images (A-D), fiberoptic gastroscopy (E), surgical specimen (F) and corresponding barium study (G) from a patient (female, 48 a.) of Borrmann's type 2 and TNM stage 1 of advanced gastric carcinoma. (A), axial image (supine position with right side elevated) showed a focal irregular protruding (arrow) from the posterior wall of antrum. (B), "Raysum" display (virtual double contrast barium study) stressed double-margin changes at the greater curvature of antrum: tumor (large arrow) and ulcer (small arrow) margins. (C), SSD image showed depression at the antrum with a central ulcer (arrow). (D), CTVG image depicted an intraluminal irregular mass with a flat ulcer (arrow). The view angle was illustrated by the 2D image at lower right corner. (E), fiberoptic gastroscopic view showed a lobulated mass. (F), surgical specimen demon stratad a mass with a small central ulcer (arrow). (G), barium study revealed an intraluminal filling defect (arrows) with a flat ulcer (asterisk) at the greater curvature of antrum.

Table 1 Classification, size and location of gastric carcinoma (n=60)

Gastric cancer classification						Size of the tumor		
Early			Advanced*			<1 cm	1-3 cm	>3 cm
Type 2c	Type 3	Type 1	Type 2	Type 3	Type 4			
4 (6.7%)	2 (3.3%)	10(16.7%)	25 (41.7%)	14 (23.3%)	5 (8.3%)	6	24	30
Location of the tumor								
		Cardia area	Antrum	Great curv	Lesser curv	Antrum and body		
		29	18	5	5	3		

Notes: Numbers were patients. Curv.=curvature. *Borrmann's type of classification.

Lesion detection

In advanced gastric carcinoma, the lesion detection (with diagnostic confidence of 3 or higher) sensitivity of spiral CT was similar to that of UGI and FG (P>0.05). In early gastric carcinoma, it was higher than that of UGI (P=0.031) and similar to that of FG (Table 2). One false positive lesion (due to peristalsic wave at the lesser curvature) and one false negative lesion (with diagnostic confidence rate of 3 or lower) were noted in spiral CT. 3 and one false negative lesion was noted in UGI and FG, respectively (Table 3).

Table 2 Comparison of sensitivities on gastric carcinoma between different techniques

	Detection		Classification
	Early	Advanced	Advanced
SCT	100%	98%	77%
UGI	33%	95%	47%
FG	100%	98%	80%
	Chi-Square test		
SCT *vs* UGI	P=0.031	P>0.05	P=0.025
SCT *vs* FG	P>0.05	P>0.05	P>0.05

Notes: SCT=spiral CT, UGI=upper gastrointestinal series, FG=fiberoptic gastroscopy.

Table 3 Comparison of different techniques in erroneously interpreted lesions

	n	False positive	False negative	Bormann's classification	
				Can not be classified	Erroneously classified
SCT	60	1	1	2	12
UGI	60	0	3	9	23
FG	60	0	1	0	12

Notes: Data were the number of lesions. SCT=spiral CT, UGI=upper gastrointestinal series, FG=fiberoptic gastroscopy.

Borrmann's classification

The ability of spiral CT to correctly classify the lesions according to Borrmann's classification was statistically higher than that of UGI (P=0.025) and similar to that of FG (P>0.05) (Table 2).

For spiral CT, 12/60 lesions were erroneously classified and 2/60 could not be classified which were attributed to image artifacts of respiration movement and fluid retention in stomach. For UGI, 23/60 lesions were erroneously classified and 9/60 could not be classified. For FG, 12/60 lesions were erroneously classified (Table 3). So, a total of 47 lesions were erroneously classified from spiral CT, UGI and FG. The rates of erroneously classified lesions in Borrmann's types 1, 2, 3, and early gastric carcinoma were 6.4 % (3/47), 61.7 % (29/47), 25.5 % (12/47), and 6.4 % (3/47), respectively. The majority of erroneously classified lesions occurred in Borrmann's type 2 (61.7 %) and type 3 (25.5 %). No erroneously classified lesion was found in Borrmann's type 4.

TNM staging of spiral CT

43 of 60 patients were included in the TNM staging. Of the 43 cases, stage I was found in 12, 6 of which were early gastric carcinoma, stage II in 7, stage III in 19 and stage IV in 5. The accuracy of spiral CT in TNM staging was 76.7 % (33/43). 5 cases of overestimation and underestimation were noted respectively in spiral CT staging (Table 4).

Table 4 Comparison of TNM staging of gastric carcinoma between spiral CT and pathology

Pathological staging	Spiral CT staging				Total
	1	2	3	4	
1	10	2	0	0	12
2	0	4	3	0	7
3	0	7	12	0	19
4	0	0	2	3	5
Total	10	13	17	3	43

DISCUSSION

The evaluation of gastric carcinoma by conventional barium studies is hampered by the following limitations: (1) the impossibility to produce endoscopic views, (2) the projective nature of the technique, (3) the quality of barium coating and the examiner's technique and skills. The disadvantage of FG examination is that it cannot evaluate the tumor involvement of gastric wall and surrounding tissues and therefore it has inability of TNM staging. Spiral CT has brought about additional possibilities for the evaluation of gastric tumors. Since the assessment of endoluminal morphology of gastric tumors is limited when only source images are used, 3D visualization techniques have been advocated[4-10]. In a recently published paper, the SSD and virtual double contrast imaging were compared with conventional barium studies and CTVG was compared with gastroscopy in various types of gastric pathologies respectively[6]. The present report represents a comprehensive clinical study that covers all three different 3D techniques of spiral CT (CTVG, SSD and virtual double contrast), as well as axial source images in comparison with UGI and FG focusing on the detection, classification and staging of gastric carcinoma.

We used two reconstruction algorithms for the 3D visualization of the stomach. One was SSD display, which provided outside opaque images of inner surface of the gastric

wall generated with a thresholding technique and could be interpreted similarly as in single-contrast barium study[12]. The other was volume rendering technique including CTVG and virtual double contrast imaging as described elsewhere[12,13]. CTVG with perspective volume rendering technique produced intraluminal view similar to those obtained from fiberoptic gastroscopy. Virtual double contrast imaging displayed somewhat translucent images similar to those of double contrast barium study.

As different 3D techniques, the advantage of SSD and virtual double contrast display was to demonstrate the overall aspect and the contour changes of the stomach, but with poor mucosal information[6] (Figure1 B, C), and CTVG offered the overview of the intraluminal tumors but with indiscernible surface coloration and extraluminal tumor invading (Figure1D). Therefore, it is important to realize that information from 3D CT displays should be combined with that of source images in interpreting the gastric carcinoma clinically (Figure 1 A-D).

In our study, tumor detection sensitivities among spiral CT, UGI and FG were similar (P>0.05). However, the sensitivity was higher with spiral CT than that with UGI (P=0.031) and similar between SCG and FG (P>0.05) in early gastric carcinoma. Only a few studies on the detection of early gastric carcinoma with spiral CT were reported, the results so far have been controversial[10]. The detection rate of early gastric carcinoma was 93.5 % reported by Lee[10] with contrast enhanced SSD technique, and it was only 26 % by spiral CT according to Fukuya[19]. Moreover, it was even lower with 3D CT than that of UGI according to Ogata[6]. In our study, spiral CT correctly detected all 6 cases of early gastric carcinomas, the detection rate (100 %) was much higher than that of UGI (33.3 %). However, the very limited number of cases with early gastric carcinoma in this series did not allow any conclusion in this regard.

The distribution and prevalence rate of gastric tumor according to Borrmann' s classification in this study was slightly different from that reported, in which the most prevalent type was Borrmann' s 3 and the most common site of tumor was the posterior wall of the antrum[8]. In our investigation, the most prevalent type was Borrmann' s 2 and the most common site of tumor was the cardia and fundus. It has been reported that accurate classification of gastric tumor based on Borrmann' s classification is possible with 3D CT[7,8]. Our study indicated that Borrmann' s classification with spiral CT was better than that with UGI (P=0.025), and similar to that of FG (P>0.05). In this study, the majority of misclassification occurred in Borrmann' s types 2 and 3, in which UGI accounted for a highest proportion of the misclassification rate. The main reasons were most likely due to the following: (1) in the present study, cardia or fundus carcinoma was found in the highest percentage of the patients (48.3 %, 29/60), therefore Borrmann' s type 2 or 3 tumors at cardia tended to be misclassified as type 1, because of the poor visualization of some small and flat ulcers within the tumor. (2) The limited capability of UGI in visualizing the ulcer and the infiltrating nature of tumors at the cardia was also a reason for the difficult differentiation between Borrmann' s types 2 and 3. (3) On the contrary, Borrmann' s type 2 or 3 at the antrum tended to be erroneously classified as type 4, because these tumors were poorly visualized by spiral CT[8].

The rational work out of treatment scheme and accurate evaluation of gastric carcinoma are mainly dependent on TNM staging before surgery. Spiral CT is a practical approach in TNM staging because it can visualize the gastric wall, surrounding tissue and organs. Many studies on gastric carcinoma staging with conventional CT have been reported so far. The results in the literature were various due to the different CT scanner and materials and methods used[20]. Using a spiral CT technique of thin slice thickness (3 mm) and plain scanning, staging accuracy of gastric carcinoma in this study reached 76.7 %. This result was higher than that (72.0 %) obtained by conventional CT scanning with contrast enhancement[21], and was lower than that (81 %) obtained by triphase contrast enhancement of spiral CT[22]. Certainly, multiphase contrast enhanced spiral CT scan may further improve the staging of gastric carcinoma, the method we used, however, was simple, practical and more acceptable by the patients.

Some limitations of this study should be mentioned: (1) Since the size of more than half of the lesions in this group was large (>3 cm), the conclusions drawn from the results might not be applicable to small or flat gastric lesions. (2) Because all the CT examinations were performed in patients with known gastric carcinoma, the specificity of different imaging techniques was not investigated in our study.

In summary, the present clinical study demonstrates that spiral CT is equal to UGI and FG in the detection of gastric carcinoma. For Borrmann' s classification of gastric carcinoma, spiral CT scores better than UGI and similar to FG. Spiral CT is also of value in TNM staging of gastric carcinoma. It is suggested that spiral CT is an alternative to UGI and supplement to FG in gastric carcinoma diagnosis. However, further investigations on a larger scale are necessary to confirm the role of spiral CT in the evaluation of gastric carcinoma.

Abstract

AIM: To investigate the relationship between the expression of vascular cell adhesion molecule-1 (VCAM-1) and oncogenesis, tumor angiogenesis and metastasis in gastric carcinoma, and to evaluate the clinical significance of serum VCAM-1 levels in gastric cancer.

METHODS: Specimens from 41 patients with gastric cancer, 8 patients with benign gastric ulcer, and 10 healthy subjects were detected for the expression of VCAM-1 by immunohistochemistry. Microvessel density (MVD) was measured by counting the endothelial cells immunostained with the monoclonal antibody CD34 at x200 magnification. Serum VCAM-1 concentrations were measured by an enzyme linked immunosorbent assay in the 41 gastric cancer patients before surgery, and at 7 days after surgery as well as in 25 healthy controls. The association between preoperative serum VCAM-1 levels and clinicopathological features, and their changes following surgery was evaluated. In addition, serum carcinoembryonic antigen (CEA) was also examined.

RESULTS: Of the 41 gastric cancer tissues, 31 (75.6 %) were VCAM-1 positive. The VCAM-1 positive gastric cancers were more invasive and classified in the more advanced stage than the VCAM-1 negative ones. The VCAM-1 positive cancers were associated with more lymph node metastases than VCAM-1-negative ones ($P<0.05$). The expression of VCAM-1 was detected in tissues of two of the eight patients with gastric ulcer and two of the 10 healthy controls. The expression of VCAM-1 in gastric cancer patients was significantly more frequent than that in the healthy controls and ulcer group (both $P<0.05$). MVD in VCAM-1 expressing tissues was higher than that in VCAM-1 negative tissues ($t=2.13$,$P<0.05$). Serum VCAM-1 levels in gastric cancer patients were significantly higher than those in controls ($t=3.4$, $P<0.05$). There was a significant association between serum VCAM-1 levels and disease stage, as well as invasion depth of the tumor and the presence of distant metastases. The concentrations of serum CEA in gastric cancer were higher than normal controls. Both serum VCAM-1 and CEA levels decreased significantly after radical resection of the primary tumor ($P<0.05$). Furthermore, the serum levels of VCAM-1 were positively correlated with the expression of VCAM-1 in the tumor tissue ($r=0.85$, $P<0.05$).

CONCLUSION: The expression of VCAM-1 is closely related to oncogenesis, tumor angiogenesis and metastasis in gastric carcinoma. Serum VCAM-1 level in gastric cancer patients is significantly increased compared with normal controls, which decreases significantly after radical resection of the primary tumor. The serum concentration of VCAM-1 may be considered as an effective marker of tumor burden of gastric cancer. Moreover, overexpression of VCAM-1 in gastric cancer tissue is likely a major source of serum VCAM-1.

INTRODUCTION

Solid tumors are composed of two distinct but interdependent compartments, malignant cells themselves and the vascular and connective tissue stroma induced by malignant cells where malignant cells are dispersed. Stroma provides the vascular supply that tumors require for obtaining nutrients, gas exchange, and waste disposal. Thus, any increase in tumor mass, either primary or metastatic, must be accompanied by angiogenesis formation[1,2]. The mechanism by which tumors induce stroma has caused considerable attention in recent years. Emphasis is increasingly placed on tumor angiogenesis. Tumor angiogenesis has been linked to tumor progression and metastasis. Many reports have suggested that cell adhesion molecules (CAM) not only play key roles in various stages of tumor angiogenesis, but also are involved in tumor progression and metastasis[3-5].

CAMs are cell-surface glycoproteins which are critical for cell- to-cell interactions. Intercellular adhesion mediated by CAMs directly influences differentiation, and disruption of normal cell-cell contacts has been noted in neoplastic transformation and in metastasis. CAMs expressed on lymphocytes and vascular endothelial cells are thought to play an important role in lymphocyte trafficking for immune anti-infection response. There is evidence that vascular cell adhesion molecule-1 (VCAM-1) may be involved in tumor progression and metastasis[5,6].

VCAM-1 belongs to the immunoglobulin super family group of adhesion molecules, and is one of the most important adhesion molecules which plays a crucial role in this process. VCAM-1 is an 110 KDa glycoprotein that is constitutively expressed on tissue macrophage, dentric cells and epithelial cells, as well as on the surface of stimulated endothelial cells. Thus, VCAM-1 is a widely distributed protein. It is possible that VCAM-1 is a candidate for mediating tumor cell adhesion to vascular endothelial cells and promoting the metastatic process. Recent reports have shown that angiogenesis favors tumor growth and facilitates entry of cells into the circulation[7,8].

It has recently been reported that the microvessel density (MVD) in a tumor correlates with tumor progression, hematogenous metastasis and recurrence of gastric carcinoma.

MVD also reflects tumor angiogenesis[2-4,9]. In the present study, the expression of VCAM-1 and the density of microvessels were examined by immunohistochemistry in patients with gastric cancer. The association between the expression of VCAM-1 and oncogenesis, tumor angiogenesis and metastasis of gastric carcinoma was evaluated. Meanwhile we also detected the concentration of soluble forms of VCAM-1 and serum levels of carcinoembryonic antigen (CEA) in patients with gastric cancer and investigated its relation to clinical and pathological features.

MATERIALS AND METHODS

Patients

A total of 41 patients with histologically confirmed gastric cancer who had undergone curative gastrectomy at our department from March 1999 to March 2000 were included in this study. They consisted of 26 male and 15 female patients ranging in age from 35 to 74 years (mean, 58.4 years). The clinicopathologic findings were determined according to the principles set by the Japaneese Society Committee on Histologial Classifiation of Gastric Cancer. Of the 41 patients, 28 had lymph node metastasis. The patients had not received either chemotherapy or radiation therapy before operation. A tumor sample and a normal part of the stomach were obtained during surgical resection. The samples were each divided into two pieces, which were subjected to fixation in 10 % formalin for histological examination and immunohistological test. All patients had been performed distal partial gastrectomy, proximal partial gastrectomy, or total gastrectomy with regional lymph node dissection to group 1(D1), group 2(D2), group 3 (D3) with a curative intention. Gastric specimens from eight patients with gastric ulcer and 10 patients with normal gastric tissues were obtained by fiber gastroscope.

Both the expression of VCAM-1 and the density of microvessels were examined by immunohistochemical staining. Meanwhile, blood samples from the 41 gastric cancer patients were obtained before any treatment and at 7 days after surgery. There were no infections in all these patients. Additionally, blood samples were also obtained from 25 healthy subjects as controls. The mean age of these subjects was 39.1 years (age range 20-55 years), with a ratio of male to female of 12:8.

Immunohistochemistry

Specimens were fixed in a 40 g· L^{-1} formaldehyde solution and embedded in paraffin. Four-micrometer thick sections were cut and mounted on glass slides. Immunohistochemistry was performed using the avidin-biotin complex (ABC) method. Sections were dewaxed in xylene, dehydrated in ethanol, washed by phosphate-buffered saline solution (PBS, pH=7.4) and then heated in a microwave oven for 10 minutes to retrieve the antigens. Endogenous peroxidase activity was blocked by incubation of samples with 3 % hydrogen peroxide in methanol for 30 minutes. After being washed with PBS, 50 μl 10 % normal goat serum was added to glass slides for 10 minutes to reduce nonspecific antibody binding. Specimens were then incubated with a 1:250 dilution of anti-VCAM-1 antibody overnight at 4 ℃, followed by three washes with PBS. Sections were then incubated with biotinylated goat antimouse immunoglobulin G (Nanjing Sangon Biotechnology Co.) at a dilution of 1:50 for 2 hours followed by three washes. Slides were then treated with the complex of reagent A and reagent B (ABC kit, Nanjing Sangon Biotechnology Co.) for 2 hours at a dilution of 1:50 and were washed with PBS three times. Finally, slides were incubated in PBS containing diaminobenzidine and 300 mL· L^{-1} hydrogen peroxide for 10 minutes. Normal mouse immunoglobulin-G was substituted for primary antibody as the negative control. Immunoreactivity was graded as follows: +, more than 10 % of carcinoma cells were stained; -, no detectable expression or fewer than 10 % of carcinoma cells were stained.

Microvessel detection and counting

A detection procedure for microvessels was performed using anti-CD34 monoclonal antibody (Nanjing Sangon Biotechnology Co.). Envision-labeled polymer reagent was applied for immunoreaction. A single microvessel was defined as any brown immunostained endothelial cells, and other connective tissue elements. The stained sections were screened at ×100 magnification under a light microscope to identify the five regions of the section with the highest number of microvessels. The image was visualized on a computer display through a color video camera module and color image freezer. Microvessels were counted in this area at ×200 magnification, and the average number of microvessels in these five regions was recorded, and defined as MVD. The visualized area on the display was determined to be 0.075 mm^2.

Assay of soluble VCAM-1

For assay of soluble adhesion molecules venous blood samples. were collected into plain tubes, allowed to clot for up to 1 hour and centrifuged at 5 000 g for 5 min. The serum was removed, aliquoted and stored at -70 ℃ until assayed. Concenrations of soluble VCAM-1were measured with commercially available sandwich ELISA kits based on dual monoclonal antibodies. CEA test, a routine test in our department, was also performed.

Statistical analysis

The data were presented as $\bar{x}\pm s$. Differences in categorical variables between groups were determined by chi-square test, and differences in enumeration data between groups were determined by *t* test or by analysis of variance. Correlations between the levels of soluble adhesion molecules and the clinical and pathological variables were determined by Spearman rank correlation method.

RESULTS

Expression of VCAM-1 in gastric cancer, gastric ulcer and normal gastric tissue

VCAM-1 was positively stained in the cytoplasm or the membrane of vascular endothelial cells in brown or yellow in gastric cancer tissue. VCAM-1 was expressed not only in vascular endothelial cells, but also in the majority of gastric cancer cells. Generally, VCAM-1 expression was intense throughout the tumor, especially in keratin pearl of gastric cancer. VCAM-1positive vessels were preferentially found in vascular-rich tumor areas. VCAM-1 expression was present in 31 (75.6 %) out of 41gastric cancer tissues and in 5 (12.2 %) adjacent normal gastric tissue. The rate of expression of VCAM-1 in gastric caner tissue was significantly higher than that in adjacent normal gastric tissue (χ^2=52.1, P<0.05).

VCAM-1 expression was present in 25 % (2/8) of gastric ulcer tissue, and in 20 % (2/10) of healthy subjects (χ^2=0.1,P> 0.05). However, The rate of VCAM-1 expression in gastric cancer was remarkably higher than that in gastric ulcer and healthy subjects (both P<0.05).

CD34 was positively stained mainly in the cytoplasm of vascular endothelial cells as brown or yellow granules. MVD ranged from 21.5 to 71.2, with a mean value of 30.2 in gastric cancer tissues, and ranged from 2 to 14, with a mean value of

11.5 in normal gastric tissues. MVD in tumor tissue was significantly higher than that in normal tissues (t=3.1, P<0.05).

Association of the expressions of VCAM-1 and MVD with pathological features of gastric carcinoma

As shown in Table 1, VCAM-1 expression was present in 26 (92.9 %) of the 28 gastric cancer patients with lymph node metastasis, but in only 5 (34.5 %) of the 13 gastric cancer patients without lymph node metastasis. The rate of VCAM-1 in patients with lymph node metastasis was significantly higher than that in patients without lymph node metastasis (χ^2=11.4, P<0.05). Meanwhile VCAM-1 expression in the gastric cancer patients was also associated with clinicopathological stage and depth of infiltration (both P<0.05).

Furthermore, microvessel count in patients with gastric cancer was related to clinicopathological stage, depth of infiltration and lymph node metastasis (all P<0.05,). The rate of expression of VCAM-1 and MVD in gastric carcinoma tissue had no significant differences among the size, location, age and gender (data not shown).

Table 1 Association of expressions of VCAM-1 and MVD with pathological features of gastric carcinoma

Pathological chacteristics	*n*	Positive VCAM-1(%)	MVD($\bar{x}$+*s*)
Size of tumor			
<3 cm	10	6	37.1±12.1
3 cm	31	25	39.5±12.7
Location			
Lower third	10	7	39.4±7.3
Middle third	20	17	36.2±11.3
Upper third	11	7	41.4±13.3
Depth of invasion			
Mucosa and submucosa	11	5	28.4±8.1
Muscle and subserosa	12	9	36.9±10.7
Serosa	18	17[a]	49.6±15.1[b]
Clinicopathologic stage			
I	7	3	29.3±3.54
II	12	7	33.9±9.3
III	16	15	46.3±10.3
IV	6	6[c]	55.4±8.1[d]
Lymph node metastasis			
Present	28	26	45±9.8
Absent	13	5[e]	28.5±5.5[f]

MVD and expression of VCAM-1 had no significant difference in the size, location. The rate of positive VCAM-1 expression and MVD were positively correlated with depth of invasion ([a]P<0.05, [b]P<0.05 respectively). There was a significant difference between the rate of positive VCAM-1 expression, MVD and clinic pathological stage ([c]P<0.05, [d]P<0.05). The rate of positive VCAM-1 expression and MVD were significantly higher than that in those without lymph node metastasis ([e]P<0.05, [f]P<0.05 respectively).

Correlation between expression of VCAM-1 and MVD

MVD was 46.5±11.3 in VCAM-1 positive tissue in gastric cancer, while it was 31.2±8.4 in negative VCAM-1 tissue. MVD in VCAM-1-positive tumors was significantly higher than that in VCAM-1-negative tumors (t=2.13, P<0.05).

Association of soluble VCAM-1 with gastric cancer

In gastric cancer patients, soluble VCAM-1 was significantly elevated in comparison with that in healthy subjects (878±46 μg/lm *vs* 297±35 μg/ml, P<0.05, Table 2). The difference in serum concentration of soluble VCAM-1 was also significant between patients with stage I-II and those with stage III-IV gastric cancer, indicating that soluble VCAM-1 concentration correlated well with the staging of gastric cancer. No significant difference was found between ulcer group and controls (P>0.05). Concentrations of serum CEA in gastric cancer patients were higher than those in control group and ulcer group (both P<0.05). But no significant difference was found between stage I-II and stage III-IV gastric cancer.

Table 2 Soluble levels of VCAM-1, CEA in gastric cancer patients, ulcer patients and control group

	n	Soluble VCAM-1(μg / ml) ($\bar{x}$±*s*)	CEA
Gastric cancer	41	878±46[a]	4.7±0.43
I-II	17	764±24[b]	4.1±0.23
III-IV	24	1006±78[c]	4.9±0.31
Ulcer	8	301±21	4.5±0.41
Control	25	297±35	2.3±0.28

[a]P<0.05, [b]P<0.05, [c]P<0.05, (*vs* control group).

The concentration of soluble VCAM-1 was higher in the patients with lymph node metastasis than that in those without lymph node metastasis (P<0.05). Positive correlation was found between concentration of soluble VCAM-1 and depth of invasion of gastric cancer. In contrast, no significant association was found between concentration of soluble VCAM-1 and location, size, age and gender (data not shown).

Levels of postoperative soluble VCAM-1 in gastric cancer patients were reduced significantly compared to preoperative levels (578±39 μg/lm *vs* 878±46 μg/ml, P<0.05, Table 3). It was noteworthy that concentration of soluble VCAM-1 was positively correlated with expression of VCAM-1 in the tumor tissue (r=0.85, P<0.05). The level of serum CEA was also decreased significantly after radical resection of the primary tumor (P<0.05).

Table 3 Concentrations of soluble VCAM-1 and CEA at pre-operative and postoperative stages

	$\bar{x}$±*s* (ng / L)	*P*
sVCAM-1		
preoperative	878±46	
postoperative	578±39	0.0001
CEA		
preoperative	10.3±18.4	
postoperative	6.3±11.5	0.0031

Serum VCAM-1 and CEA levels decreased significantly after radical resection of the primary tumor (P<0.05).

DISCUSSION

Gastric carcinoma, as one of the most common human malignant tumors, ranks worldwide the first leading cause of gastrointestinal cancer-related mortality. In China, it now ranks the second among all malignant tumors. Recent important advance in oncology is the finding that tumor angiogenesis plays an important role in tumor genesis, growth and metastasis, and an increasing number of studies have proven that vascular targeting therapy is very effective[9-11]. Many factors are involved in tumor angiogenesis, one of the most important factors is VCAM-1, Which is capable of promoting and maintaining the establishment of tumor vascular system[12]. Thus it can directly stimulate tumor growth and metastasis. Generation of new blood vessels, or angiogenesis, plays a key role in the growth

of malignant disease and has drawn great interest in developing agents that inhibit angiogenesis. Angiogenesis is characterized by invasion, migration, and proliferation of endothelial cells, processes that depend on cell interactions with extracellular matrix components[12-14]. Our current study has shown VCAM-1 is a key player by providing a vasculature-specific target for antiangiogenic treatment strategies.

Expression of VCAM-1 may facilitate oncogenesis

Recent advances in molecular biology and genetic technology studies on adhesion molecules have demonstrated that cell-cell and cell-extracellular matrix interactions play an important role in cancer metastasis. In addition to activation of oncogenes and inactivation of tumor suppressor genes, alteration of adhesion molecules seems to be critical for the development of gastric cancer[15]. Tumour development is a multi-step process during which genetic and epigenetic events determine the transition from a normal to a malignant cellular state. In the past decade, extensive effort has been made not only to define the molecular mechanisms underlying progression to malignancy but also to predict the development of the disease and to identify possible molecular targets for therapy. Common to most tumours, several regulatory circuits are altered during multistage tumour progression of gastric cancer, which includes control of proliferation, balance between cell survival and programmed cell death (apoptosis), communication with neighbouring cells and extracellular matrix, induction of tumour neovascularization (angiogenesis) and tumour cell migration, invasion and metastatic dissemination. De-regulation of each of these processes represents a rate-limiting step for tumour development and, hence, has to be achieved by tumour cells in a highly selective manner during tumour progression. In this complex process, more attention has been placed on adhesion molecules, because adhesion molecules are necessary to mediate cell-matrix and cell-cell interactions, metabolism, and differentiation. Moreever, adhesive interactions between tumor cell surface receptors and endothelial cell adhesion molecules are thought to contribute to tumor cell arrest and extravasation during hematogenous metastasis[14-17]. Changes in expression and function of adhesion molecules are important characteristics in the development of gastrointestinal malignancies and might be used in future as prognostic factors or as new targets in diagnosis and therapy. VCAM-1, one of the adhesion molecules involved in malignant tumor, is found to be expressed mainly in activated endothelial cells, and dentric cells.

Maurer *et al*. confirmed that VCAM-1 protein was over-expressed in colorectal cancers at the mRNA level by Northern blotting, In comparison to normal controls, the expression of VCAM-1 mRNA was increased by 3.4 fold in colorectal cancers. Our study found that the expression of VCAM-1 in gastric tumor tissue was higher than that in adjacent-cancer tissue, and the ratio of positive VCAM-1 in gastric cancer tissue was higher than that in gastric ulcer and normal mucosa, suggesting that VCAM-1 may play a key role in the growth of gastric cancer.

However, we noteed that VCAM-1 expression was positive in one healthy subject, and in two patients with gastric ulcer, indicating that there are other factors involved in the expression of VCAM-1. Some studies believed that *Helicobacter pylori* infection of gastric mucosa was one of the causes responsible for VCAM-1 expression[18,19].

VCAM-1 expression stimulates tumor angiogenesis

Angiogenesis is of key importance in the process of tumour progression in a number of tumour types. Angiogenesis is a biological process by which new capillaries are formed from pre-existing vessels. It occurs in physiological conditions such as embryo development, and cyclically in wound repair of female genital system, and during pathological conditions, such as arthritis, diabetic retinopathy and tumors. In the both physiological conditions, angiogenesis is mediated accurately by feedback system. However, in solid tumor growth, a specific ally critical turning point is the transition from the vascular to the vascular phase. Having developed an intrinsic vascular network, the neoplastic mass is able to grow indefinitely (unlike other forms of cell growth, tumor angiogenesis is not limited in time) both *in situ* and at distant sites (metastasis). Thus, tumor angiogenesis cannot be controlled by feedback. Angiogenesis is capable of providing continuous nutrients, gas exchange, and waste disposal for tumors growth. Any increase in tumor mass, either primary or metastatic, must be accompanied by vascular formation. Therefore, tumor angiogenesis is a very complex process. At present, an increasing number of studies have shown that abnormal adhesion molecules contribute to tumor angiogenesis by stimulating neoplastic cells to produce growth factors specific for endothelial cells and able to stimulate growth of the host' s blood vessels[6,8,13,15]. Recent studies have demonstrated that VCAM-1 may contribute to tumor angiogenesis. MVD, a reliable index of tumor angiogenesis, has been confirmed to be linked to tumor progression, hematogenous metastasis, and tumor recurrence.

Our study indicated that MVD of gastric cancer tissues with VCAM-1 expression was significantly higher than that in tissues negative for VCAM-1, suggesting that VCAM-1 expression may be one of the factors mediating the activation of angiogenesis. Several reports have observed that gastric cancer cells are capable of activating vessel endothelial cells, which leads to expression of VCAM-1, and thus the induction of tumour neovascularization. Maeds *et al*. proposed that VCAM-1 binding to its ligand VLA4 not only results in activation of vessel endothelial cells, but also leads to shedding of tumor cells and invasion of adjacent tissue[20,21]. Byrne *et al*. suggested that VCAM-1 was expressed on endothelial cells as a result of stimulation by vascular endothelial growth factor (VEGF). In general, these findings suggest that VCAM-1 may be used for sustained angiogenesis and tissue invasion and metastasis via autocrine/paracrine manners[7].

Howerever, in some tumors, high MVD VCAM-1 expression was not detected, which suggests that other factors such as extracellular matrix, and metabolic and mechanical factors also contribute to tumor angiogenesis. Hence anti-angiogenesis therapy should utilize multiantiangiogenesis tactics[23,24].

MVD may be different according to the observer, and cut-off values are also different. In addition, it has been reported that different MVD could be obtained with different antibodies used in different studies. Therefore, MVD that was observed in this study may be different from those previously reported.

VCAM-1 favors lymph node metastasis of gastric cancer

It is generally accepted that the presence or absence of regional lymph node involvement is one of the important factors influencing survival in respectable gastric cancer. Lymph node metastasis occurs even in some patients with early gastric cancer. Recently, studies have confirmed that prognosis of gastric cancer patients with lymph node metastasis is very poor. Gastric caner patients with lymph node metastasis have been commonly reported to have poorly differentiated adenocarcinoma, and deeper invasion, in comparison with gastric cancer patients without lymph node metastasis. In our present study, we observed that VCAM-1 expression in 26 of 28 cases with lymph node metastasis, whereas in only 5 of 13 gastric cancer patients without lymph node metastasis. There

was a significant difference between the two groups ($P<0.05$), indicating that expression of VCAM-1 may be associated with lymph node metastasis of gastric cancer. VCAM-1 is predominantly expressed on gastric carcinoma cells, giving these tumor cells the ability to perform lymph-node metastasis. Meanwhile, expression of VCAM-1 significantly alters malignant transformation[11,20,21].

Tumor metastasis involves the release of cells from primary tumor due to a firmly formed cluster of tumor cells probably by detaching from the tumor nests with unstable adhesiveness, followed by their migration in extracellular matrix, adhesion to vessel walls, arrest in microcirculation of distant organs, and subsequent extravasation. Extravasation of metastatic tumor cells from bloodstream of the tissue space in a secondary organ is related specific binding to determinants on endothelial cell surface. Each step requires cell adhesive interactions involving specific adhesion molecules and receptors. Several families of adhesion molecules have now been identified, some of which are promising candidates for a role in neoplasia. So tumor metastasis is a very complex process, Colette *et al*. thought that VCAM-1 overexpression stimulated tumour neovascularization, and angiogenesis was necessary for tumor growth and metastasis, VCAM-1 expression was linked to lymph node metastasis[2,3,21-24].

We observed that VCAM-1 expression was present in 5 of the 13 cases without lymph node metastasis, which may be related to lymph node micrometastasis. It has been demonstrated that micrometastases consisting of one to a few cells in lymph nodes resected during gastrectomy are difficult to identify using conventional hematoxylin and eosin (H&E) stains[25,26].

Concentration of soluble VCAM-1 may be one of the important markers for gastric carcinoma

Our study demonstrated that serum concentration of VCAM-1 was elevated in patients with gastric cancer before treatment in comparison with the healthy group; hence, the concentration of soluble VCAM-1 may be of significance in diagnosis of gastric carcinoma. In addition, a positive correlation was observed between levels of soluble VCAM-1 and tumor stage, and invasion depth. More important was that the concentration of soluble VCAM-1 in patients with lymph node metastasis was significantly higher than that in patients without lymph node matastasis. These findings suggest that the levels of soluble VCAM-1 are linked to tumor growth and metastasis. Our results are consistent with the findings by Velikova *et al*, who also reported elevated serum levels of VCAM-1 in gastric cancer, and proposed that patients with elevated serum VCAM-1 have a poorer survival rate. Measurement of circulating VCAM-1 may bring additional prognostic information for patients with gastric cancer in relation to different stages and tumor pathology, and it should be included in future large multivariate analyses of prognostic factors should be performed whenever possible[27,28]. Animal experiments have confirmed that soluble VCAM-1 promotes angiogenesis in rat cornea, which is supported by our findings[29,30].

Additionally, It was first observed that postoperative concentrations of soluble VCAM-1 decreased significantly in patients with gastric cancer in comparison with preoperative concentrations ($P<0.05$). This finding suggests that measurement of circulating VCAM-1 may play a critical role in prognosis of gastric cancer patient. It is likely that tumor burden in patients with gastric cancer is decreased after operation, so the concentration of soluble VCAM-1 is reduced. If the levels of soluble VCAM-1 increase again after operation, we should pay great attention to tumor recurrence. Therefore, soluble VCAM-1 may be considered as a marker for tumor burden. Some investigators have reported a positive correlation between serum concentration of VCAM-1 and age of patients, but no such a correlation was found in healthy subjects. Our study did not confirm this although we noted that the median age in healthy group was lower than that of gastric cancer patients. Therefore, the effect of age on serum levels of VCAM-1 can not be excluded, and future studies should take it into account[31].

In our department, CEA is one of the routine tests in gastric cancer. It is well accepted that CEA is one of the most important marks of gastrointestinal carcinoma, and preoperative positivity for CEA is an independent risk factor for hematogenous recurrence of gastric carcinoma. Our finding on CEA is consistent with those previously reported[32,33].

Expression of VCAM-1 in tumor tissue is one of the sources of soluble VCAM-1 in gastric cancer

The source of soluble VCAM-1 is not yet known. VCAM-1 is known to be expressed predominantly on activated endothelial cells, dendritic cells and renal proximal tuble cells. We found that strong VCAM-1 expression occurred in gastric cancer cells and endothelial cells in tumor tissues, especially in vessel abundant regions. Some studies have reported that VCAM-1 has been found in malignant epithelial tissue, including metastasis gastric cancer cells, melanoma cell lines and hepatocellular cells. In our study, a strong correlation was found between expression of VCAM-1 in gastric cancer tissue and serum concentration of soluble VCAM-1 ($r=0.85$, $P<0.05$). Increased expression of VCAM-1 in gastric cancer cells and their shedding into circulation may be the factor accounting for the significantly elevated serum levels of VCAM-1. Other studies have reported that soluble VCAM-1 may be related to the white cell count. To eliminate this possibility, blood tests were performed, and gastric cancer patients with normal blood tests were included. We observed that expression of VCAM-1 in gastric carcinoma tissue was positively correlated with concentration of soluble VCAM-1, indicating that expression of VCAM-1 in gastric cancer tissue is a major source of soluble VCAM-1. VCAM-1 is expressed on endothelial cells as a result of vascular endothelial growth factor (VEGF) stimulation[4,6,19-21,34,35].

In conclusion, VCAM-1 may be involved in the progression of human gastric carcinoma, particularly via lymphangiogenesis. VCAM-1 expression at invading edge of gastric carcinoma may be a sensitive marker for metastasis to lymph nodes. Differentially expressed vascular molecules may influence the functional characteristics of extravasating leukocytes and represent new targets in anti-gastric cancer therapy. In general, an increasing number of studies on a variety of malignant diseases have suggested that VCAM-1 may play a role in the process of adhesion of tumor cells to endothelial cells and neovascularization. Expression of VCAM-1 is associated with oncogenesis, tumor angiogenesis and metastasis in gastric carcinoma. MVD in gastric carcinoma tissue is closely associated with lymph node metastasis, clinical stage and depth of invasion. Expression of VCAM-1 is closely related to MVD in gastric cancer, and thus VCAM-1 can act as an important index reflecting the biological behaviors of gastric carcinoma. VCAM-1 may be used as a metastasis marker and/or a target for antiangiogenic therapy. VCAM-1 has been shown to be a key player by providing a vasculature-specific target for antiangiogenic treatment strategies. Concentration of soluble VCAM-1 correlates well with tumor growth and metastasis. Expression of VCAM-1 in gastric cancer tissue is positively correlated with concentration of soluble VCAM-1. Elevated soluble VCAM-1 is decreased significantly in gastric caner patients after operation, and thus soluble VCAM-1 may be one of the markers for gastric carcinoma tumor burden, and

serum VCAM-1 may be considered as an effective diagnostic and prognostic factor.

Abstract

AIM: To study the role of Fas ligand (FasL) and Caspase-3 expression in carcinogenesis and progression of gastric cancer and molecular mechanisms of relevant immune escape.

METHODS: FasL and Caspase-3 expression was studied in adjacent epithelial cells, cancer cells and lymphocytes of primary foci, and cancer cells of metastatic foci from 113 cases of gastric cancer by streptavidin-biotin-peroxidase (S-P) immunohistochemistry. Expression of both proteins in cancer cells of primary foci was compared with clinicopathological features of gastric cancer. The relationship between FasL expression in cancer cells and Caspase-3 expression in cancer cells or infiltrating lymphocytes of primary foci was investigated.

RESULTS: Cancer cells of primary foci expressed FasL in 53.98 % (61/113) of gastric cancers, more than their adjacent epithelial cells (34.51 %, 39/113) (P=0.003, χ^2=8.681), while the expression of Caspase-3 in cancer cells of primary foci was detected in 32.74 % (37/113) of gastric cancers, less than in the adjacent epithelial cells (50.44 %, 57/113) (P=0.007, χ^2=7.286). Infiltrating lymphocytes of the primary foci showed positive immunoreactivity to Caspase-3 in 70.80 % (80/113) of gastric cancers, more than their corresponding adjacent epithelial cells (P=0.001, χ^2=10.635) or cancer cells of primary foci (P=0.000, χ^2=32.767). FasL was less expressed in cancer cells of metastases (51.16 %, 22/43) than in those of the corresponding primary foci (81.58 %, 31/38) (P=0.003, χ^2=9.907). Conversely, Caspase-3 was more expressed in cancer cells of metastases (58.14 %, 25/43) than in those of the corresponding primary foci (34.21 %, 13/38) (P=0.031, χ^2=4.638). FasL expression was significantly correlated with tumor size (P=0.035, rs=0.276), invasive depth (P=0.039, rs=0.195), metastasis (P=0.039, rs=0.195), differentiation (P=0.015, rs=0.228) and Lauren's classification (P=0.038, rs=0.196), but not with age or gender of patients, growth pattern or TNM staging of gastric cancer (P>0.05). In contrast, Caspase-3 expression showed no correlation with any clinicopathological parameters described above in cancer cells of the primary foci (P>0.05). Interestingly, FasL expression in primary gastric cancer cells paralleled to Caspase-3 expression in infiltrating lymphocytes of the primary foci (P=0.016, χ^2=5.825).

CONCLUSION: Up-regulated expression of FasL and down-regulated expression of Caspase-3 in cancer cells of primary foci play an important role in gastric carcinogenesis. As an effective marker to reveal the biological behaviors, FasL is implicated in differentiation, growth, invasion and metastasis of gastric cancer by inducing apoptosis of infiltrating lymphocytes. Chemical substances derived from the primary foci and metastatic microenvironment can inhibit the growth of metastatic cells by enhancing Caspase-3 expression and diminishing FasL expression.

INTRODUCTION

Gastric cancer is one of the commonest malignancies in China, and even in the world[1-7]. Although early diagnosis and treatment have somewhat improved the patients' outcome, gastric cancer still remains the major killer among Chinese[8,9]. The stepwise transitions during gastric carcinogenesis and progression show that growth-limited gastric epithelial cells become immortalized and in turn exhibit malignant phenotypes[10,11]. It is obvious that the intrinsic regulatory systems for normal cell survival and death are perturbed in these sequential changes of gastric carcinogenesis and progression, so a further understanding of aberrant apoptosis of gastric epithelial cells and cancer cell will be of great significance in the prevention, diagnosis and treatment of gastric cancer.

Fas ligand (FasL) is a family member of tumor necrosis factor (TNF) and nerve growth factor (NGF), which maps to human chromosome 1[12]. When membrane FasL (mFasL) crosslinks with membrane Fas (mFas), cellular apoptosis is induced. However, soluble Fas is released into tumor microenvironment to neutralize FasL on tumor infiltrating lymphocytes and consequently blocks their apoptotic induction, leading to tumor immune escape[13]. Some matrix metalloproteinases can hydrolyze the mFasL into impotent soluble FasL, which can resist apoptosis-induced effect by lymphocytes[14]. In Fas/FasL pathway, association of Fas with FasL can activate the Fas-associated death domain (FADD) and make mitochondrion release cytochrome C[15], which eventually initiates the key Caspase-3 in catalyzing the specific cleavage of many important cellular proteins during apoptosis[16,17].

Capase-3/CPP32 is a member of the interleukin-1β-converting enzyme (ICE) family, which specifically cleaves substrates at the C-terminal of aspartic acid residues. Capase-3 includes two types of CPP32α and CPP32β with cysteine protease activity, and shows a high homology to the pro-apoptotic ced-3 of C elegans[18,19]. Several members of the Caspase family have been implicated in apoptosis, among

which Caspase-3 is thought to act as a central mediator of programmed cell death (PCD) in mammalian cells[20]. Caspase-3 is synthesized as an inactive 32 kd proenzyme and processed during apoptosis into its active form that is composed of two subunits, p17-20 and p10-12. Activated Capase-3 is responsible for the cleavage of poly (ADP-ribose) polymerase (PARP), actin and sterol regulatory element binding protein (SREBP), which relate to apoptosis[19,21-23]. Inhibition of the CPP32-induced proteolytic breakdown of PARP has been demonstrated to result in the attenuation of apoptosis[15].

Previous study suggested that high expression of Fas and FasL was involved in gastrocarcinogenesis[24]. In the current study, we aimed to evaluate the expression of FasL and Caspase-3 in adjacent epithelial cells, cancer cells and lymphocytes of the primary foci, and cancer cells of the metastatic foci of gastric cancer and to find out if there is any relationship between their expressions in cancer cells of the primary foci and clinicopathological features of gastric cancer, as well as between FasL expression in cancer cells of the primary foci and Caspase-3 expression in cancer cells or its infiltrating lymphocytes of the primary foci in order to clarify the role of FasL and Caspase-3 expression in carcinogenesis and progression of gastric cancer and the molecular mechanism of relevant immune escape.

MATERIALS AND METHODS

Subjects

Surgical specimens of 113 gastric cancers were studied from the Second Affiliated Hospital of China Medical University from Sep. 1997 to Feb. 2001. None of the patients underwent radiotherapy or chemotherapy before operation. Adjacent mucosa and primary tumors of all the cases, as well as 43 metastases from 38 cases were fixed in 4 % formaldehyde solution, embedded in paraffin and cut into 4 μm sections.

Evaluation of clinicopathological features

Hematoxylin-and-eosin-stained sections were examined by two pathologists to confirm the histological diagnosis and other microscopic characteristics. These cancers were histologically classified into differentiated and undifferentiated cancers. Their growth pattern was classified into mass, nest, or diffuse types, as reported previously[6]. Penetration of gastric wall, lymph node and distal metastases were routinely described in each patient. Tumor staging was assessed according to TNM classification system.

Immunohistochemistry

The representative and consecutive sections from each adjacent mucosa, primary and secondary tumor were immunostained with streptavidin-peroxidase technique (S-P kit, Zhongshan Biotech.). Anti-FasL antibody (Boster Biotech.) and anti-Caspase-3 antibody (DAKO Biotech.) were diluted in phosphate-buffered saline (PBS, 0.01 mol/L, pH7.4) at the dilution ratio of 1:50 and 1:100 respectively. All procedures were implemented according to the product illustration. For negative controls, sections were processed as the above but with PBS instead of the primary antibodies.

Evaluation of FasL and Caspase-3 staining

The immunoreactivity to FasL or Caspase-3 was localized in the cytoplasm. From 5 randomly selected representative fields of each section, one hundred cells were counted by two independent observers, who did not know the clinicopathological features of these gastric cancers. According to proportion of positive cells, the degree of staining achieved with their antibodies was graded as follows: negative (-), $\leqslant$5 %; weakly positive (+), 5-25 %; moderately positive (++), 25-50 %; and strongly positive (+++), $\geqslant$50 %.

Statistical analysis

Statistical evaluation was performed using *chi*-square to differentiate the rates of different groups and using Spearman's test to analyze ranking correlation. $P<0.05$ was considered statistically significant. SPSS 10.0 software for Windows was employed to analyze all data.

RESULTS

FasL and Capase-3 expression in adjacent epithelial cells, cancer cells and lymphocytes of the primary foci, and cancer cells of the metastatic foci of gastric cancer

Cancer cells of the primary foci expressed FasL in 53.98 % (61/113) of gastric cancers, more than the adjacent epithelial cells (34.51 %, 39/113) (P=0.003, χ^2=8.681), while Caspase-3 in cancer cells of primary foci was expressed in 32.74 % (37/113) of gastric cancers, less than in the adjacent epithelial cells (50.44 %, 57/113) (P=0.007, χ^2=7.286). Infiltrating lymphocytes in the primary foci showed strong immunoreactivity to Caspase-3 in 70.80 % (80/113) of gastric cancers, more than that in the corresponding adjacent epithelium (P=0.001, χ^2=10.635) or cancer cells of the primary foci (P=0.000, χ^2=32.767). FasL was less expressed in cancer cells of metastases (51.16 %, 22/43) than in those of the corresponding primary foci (81.58 %, 31/38) (P=0.003, χ^2=9.907). Conversely, Caspase-3 was more positively expressed in cancer cells of metastases (58.14 %, 25/43) than in those of the corresponding primary foci (34.21 %, 13/38) (P=0.031,χ^2=4.638) (Table 1, Figures 1-4).

Relationship between FasL and Caspase-3 expression in cancer cells of the primary foci and the clinicopathological features of gastric cancer

FasL expression was significantly correlated with tumor size (P=0.035, rs=0.276), invasive depth (P=0.039, rs=0.195), metastasis (P=0.039, rs=0.195), histological classification (P=0.015, rs=0.228) and Lauren's classification (P=0.038,

rs=0.196) of gastric cancer in cancer cells of the primary foci, whereas not with growth pattern or TNM staging of gastric cancer, gender or age of patients (P>0.05). Comparatively, Caspase-3 expression showed no significant correlation with tumor size, invasive depth, metastasis, histological classification, TNM staging, age and gender of patients in cancer cells of the primary foci (P>0.05) (Table 2).

Relationship between FasL and Caspase-3 expression in gastric cancer

Interestingly, our results showed FasL expression in cancer cells of the primary foci was positively associated with Caspase-3 expression in their infiltrating lymphocytes (P=0.016, χ^2=5.825), not with Caspase-3 expression in cancer cells of the primary foci (P>0.05) (Table 3).

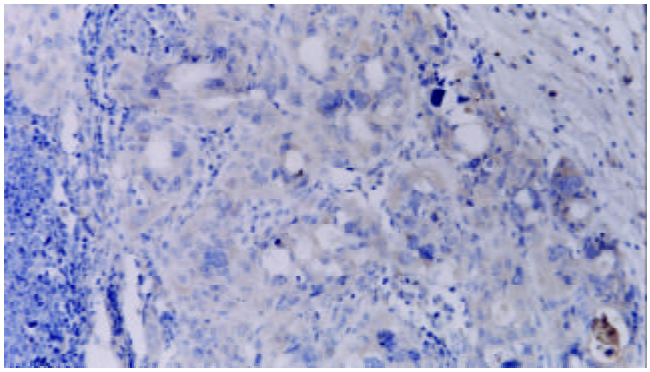

Figure 3 FasL was strongly expressed in gastric cancer cells of lymph node metastasis (+++). S-P×400.

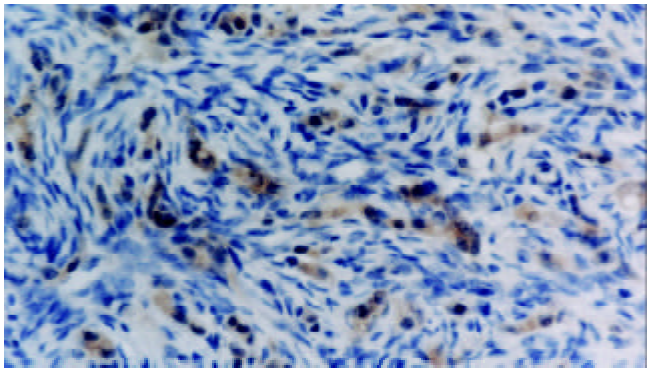

Figure 4 Caspase-3 was strongly expressed in gastric cancer cells of ovary metastasis (+++). S-P×400.

DISCUSSION

As a transmembrane type II protein, FasL initiates PCD through activating FADD when coupled with mFas, so FasL greatly contributes to apoptotic induction in most cells[25]. During the course, Caspase-3 will be activated by a series of cascade reactions, and eventually DNase (CAD, CPAN, or DEF40) is activated, which belongs to the Mg^{2+}-dependent endonuclease and acts as a killer in apoptosis. Some previous studies demonstrated that esophageal and colon cancers highly expressed FasL at the levels of mRNA and protein. Furthermore, increased FasL can bind to mFas in infiltrating lymphocytes, which is eliminated by inducing their apoptosis[26,27]. Therefore, cancer cells can form an immune escape.

In this study, we found that FasL and Caspase-3 were expressed in 34.51 % (39/113) and 50.44 % (57/113) of adjacent epithelial of gastric cancer respectively, most of which exhibited inflammation, regeneration, or intestinal metaplasia. Li *et al*.[24] detected FasL expression in normal gastric mucosa and atrophic gastritis. It was previously documented that most cells from human organs showed positive immunoreactivity to Caspase-3, including cryptal cells of gastric pit. These data indicate that FasL and Caspase-3 play an important role in regulating the balance of cellular proliferation and apoptosis in gastric mucosa by inducing apoptosis.

Moreover, FasL is more frequently expressed in cancer cells of primary foci than in their adjacent epithelial cells ($P<0.05$). Belluco *et al*.[28] found that FasL was overexpressed in adenoma-adenocarcinoma of colorectum and FasL expression paralleled to malignant degrees. These results suggest that up-regulated expression of FasL contributes to gastric carcinogenesis. On the other hand, Capase-3 expression was less frequently detected in cancer cells of the primary foci, than in the adjacent epithelial cells ($P<0.05$), as described previously[29]. Hoshi *et al*.[30] also found the positive rate of Caspase-3 expression was lower in gastric cancers than in their adjacent mucosa and gastric adenoma, and was correlated negatively with proliferative index of Ki-67, as well as positively with apoptotic index labeled by TUNEL. These studies reveal that down-regulated expression of Capase-3 is implicated in gastric carcinogenesis.

Additionally, our results also indicated that Caspase-3 expression in infiltrating lymphocytes was found in 70.80 % of gastric cancers, significantly more than in cancer cells and adjacent epithelial cells of their primary foci ($P<0.05$). So most of primary gastric cancers showed strong expression of Capase-3 in infiltrating lymphocytes, whereas weak or no expression of Caspase-3 in primary cancer cells. Interestingly, we found that FasL expression in primary cancer cells was closely correlated with Caspase-3 expression in filtrating lymphocytes of the primary cancer ($P<0.05$). Although FasL-positive gastric cancer expressed more Caspase-3 than FasL-negative one, the positive rates of Caspase-3 expression in FasL-positive and FasL-negative carcinomas were of no significant difference ($P>0.05$). The more FasL was expressed in cancer cells, the more Caspase-3 was expressed in lymphocytes in the primary foci. Some investigators found that FasL-positive cancer showed increased apoptosis in its infiltrating lymphocytes and decreased apoptosis in cancer cells[31]. Our study showed that more expression of Caspase-3 in infiltrating lymphocytes of gastric cancer demonstrated its critical contribution to Fas-mediated immune escape. However, FasL-positive gastric cancer also showed high expression of Caspase-3, suggesting there were other mechanisms that played an important role in Fas-Caspase apoptotic pathway of gastric cancer cells.

In our study, FasL expression in cancer cells of primary foci was not correlated with gender or age of patients with gastric cancer ($P>0.05$), suggesting that FasL expression in

the primary cancer cells genetically did not depend on the gender or age of patients, and they therefore had no effect on relationship between FasL expression and patho-biological behaviors of gastric cancer. Our results showed that FasL expression in cancer cells of primary foci was closely associated with tumor size, invasive depth, metastasis, histological differentiation and Lauren' s classification (P<0.05), but not with growth pattern or TNM staging of gastric cancer (P>0.05). Tsutsumi *et al*[32] found serum content of soluble FasL (sFasL) was correlated with invasive depth, lymph node and distal metastasis. These indicate that FasL is implicated in progression of gastric cancer by forming immune counterattack. Although FasL expression in primary cancer cells was not significantly associated with growth pattern of gastric cancer, higher expression of FasL in mass-type than in nest-type or diffuse-type gastric cancer revealed that increased FasL expression in cancer cells responsed to elevated infiltrating lymphocytes in gastric cancer with mass growth. Notably, FasL was expressed more in intestinal-type gastric cancers than in diffuse-type ones (P<0.05), indicating that both types of gastric cancer have different histogenetic pathways. Furthermore, this study showed no relationship between down-regulated expression of Caspase-3 and clinicopathological features of gastric cancer described above (P>0.05), suggesting that Caspase-3 expression is genetically independent of gender or age and is not implicated in progression.

FasL was significantly expressed in cancer cells of the primary foci than in corresponding metastatic foci (P<0.05), while Caspase-3 was less expressed in cancer cells of primary foci than in corresponding metastatic foci of gastric cancer (P<0.05), demonstrating that decreased ability of metastatic cancer cells to induce apoptosis of lymphocytes and increased apoptosis in metastatic cancer cells, might be influenced by tumor microenvironment. It was documented that metastases grew rapidly after the primary foci of tumor were removed, and a kind of substance from the primary foci could inhibit growth of metastases[33]. If so, another reason for this phenomenon might be that primary foci regulate the expression of Caspase-3 and FasL of metastatic cancer cells so as to suppress their ability to proliferate.

In conclusion, up-regulation of FasL expression and down-regulation of Caspase-3 expression in cancer cells of primary carcinoma are involved in gastric carcinogenesis. As an effective marker to reveal the patho-biological behaviors, FasL contributes to differentiation, growth, invasion and metastasis of gastric cancer by inducing apoptosis of infiltrating lymphocytes. Chemical substances from primary foci and metastatic microenvironment can induce apoptosis of metastatic cancer cells or weaken ability of metastatic cancer cells to counterattack adjacent lymphocytes by decreasing FasL expression and increasing Caspase-3 expression of metastastic cancer cells, eventually resulting in the inhibition of their growth.

Abstract

AIM: To investigate the role of cyclooxygenase-2(COX-2) and vascular endothelial growth factor (VEGF) in the development of gastric carcinoma and correlation between expression of COX-2 and VEGF and clinicopathologic features in tissues from patients with gastric carcinoma.

METHODS: 281 patients with gastric carcinoma who underwent surgical resection between 1990 and 1999 at the First Affiliated Hospital, Anhui Medical University, PRC, were followed up. Expression of COX-2 and VEGF was investigated retrospectively in 232 gastric carcinoma tissues and 60 noncancerous specimens by using immunohistochemistry.

RESULTS: The 5-year survival rates of early gastric carcinoma (EGC) and advanced gastric carcinoma (AGC) were 93.4 % and 59.0 %, respectively. Survival time was highly correlated with lymph node metastasis, vascular invasion, depth of invasion and treatment with chemotherapy. Compared with paired noncancerous tissues, expression of COX-2 and VEGF and microvessel density (MVD) value in carcinoma tissue were significantly higher. The MVD value was much higher in COX-2-positive group and VEGF-positive group than that in COX-2-negative group and VEGF-negative group. Expression of COX-2 and VEGF, as well as MVD value were highly correlated with lymph node metastasis and vascular invasion. The 5-year survival rate of patients with expression of COX-2 or VEGF was significantly lower than that of patients without COX-2 or VEGF expression. Multivariate analysis revealed that VEGF overexpression, lymph node metastasis, COX-2 overexpression, depth of invasion and vascular invasion were all independent prognostic factors of gastric carcinoma.

CONCLUSION: Overexpression of COX-2 and VEGF in patients with gastric carcinoma can enhance the possibility of invasion and metastasis, implicating a poor prognosis. They may serve as the fairly good prognostic factors to indicate biologic behaviors of gastric carcinoma.

INTRODUCTION

Gastric carcinoma is one of the most common malignancies worldwide. Carcinogenesis and progression of carcinoma are believed to be from multi-stage processes involving the activation of oncogenes and/or the loss of suppressor genes. Epidemiologic studies have shown that nonsteroidal anti-inflammatory drugs (NSAIDs) can reduce the incidence rate and mortality of digestive tract carcinomas, including esophageal, gastric, colon, and rectal lesions[1,2]. The prostaglandin synthetic enzyme cyclooxygenase (COX) is a target for NSAIDs therapy, and a key enzyme in the conversion of arachidonic acid to prostaglandins. Recent studies have confirmed the presence of two forms of COX, constitutively produced COX-1 and inducible COX-2[3]. COX-1 is a constitutively expressed gene in many tissues, and levels of this protein do not fluctuate in response to stimuli[4]. COX-2 is induced by pathologic stimuli, such as inflammation, various growth factors, and cytokines produced by tumor cells[5]. Human gastric mucosa, however, normally expresses barely detectable levels of COX-2 protein[6]. To date, whether COX-2 is involved in the growth of gastric carcinoma remains to be clarified, although COX-2 overexpression has recently been reported in human gastric adenocarcinoma[7].

Recently, many studies have reported on the relation between the malignant potential of neoplasms and tumor angiogenesis[8-10]. Vascular endothelial growth factor (VEGF) is one of these angiogenic factors, and is known to play a crucial role in the formation of neovasculature[11]. VEGF expression is correlated significantly with tumor vascularity and a marker for tumor angiogenesis[12,13]. In the current study, we examined COX-2 and VEGF expression in primary gastric carcinoma tissues at various stages to investigate the relations between COX-2 and VEGF expression and clinicopathologic features of these tumors. We also investigated the prognostic value of these two biologic factors in gastric carcinoma and compared them with the conventional clinicopathologic factors.

MATERIALS AND METHODS

Clinical materials

Totally 281 patients with gastric carcinoma who received gastrectomy without preoperative chemotherapy between 1990 and 1999 at our university hospital were followed up. Among the 281 patients, there were 110 patients with early gastric carcinoma (EGC) in which carcinoma invasion was confined to the mucosa or submucosa and 171 patients with advanced gastric carcinoma (AGC) that invaded beyond the submucosal layer (but not to serosa in our study) according to the criteria of the Japanese Research Society for Gastric Cancer[14]. The patients were comprised of 198 men and 83 women with an average age of 55.6 years (range, 22 to 80 years). Of these 281 patients, 66 had lymph node metastasis and 39 had vascular invasion. Patients who died of other disease were excluded from the study. 60 paired control samples (including 30 cases of chronic atrophic gastritis (CAG) and 30 cases of gastric epithelial dysplasia) were obtained from the antrum.

Immunohistochemical techniques

In brief, archival paraffin-embedded tissue specimens and controls were sectioned at a thickness of 4 μm, deparaffinized,

and rehydrated. The slides were incubated with 3 % hydrogen peroxide in methanol for 10 minutes to block endogenous peroxidase activity, and then washed in phosphate-buffered saline (PBS) and incubated in 10 % normal rabbit serum for 5 minutes to reduce nonspecific antibody binding. Rabbit polyclonal antibody specific for human COX-2 (H-62; Santa Cruz Biotechnology, Inc. Santa Cruz, CA) was applied as the primary antibody at a dilution of 1:100. Mouse monoclonal antibody against VEGF(A-20, Santa Cruz Biotechnology, Inc. Santa Cruz, CA) or Factor VIII related antigen (PC-10, Maxim Biotech, Inc.) was also applied as the primary antibody. These slides were incubated with primary antibody for 60 minutes at room temperature, followed by 3 washes with PBS. Sections then were incubated with biotinylated IgG for 20 minutes followed by 3 washes. Slides then were treated with streptoavidin-peroxidase reagent for 20 minutes and washed with PBS 3 times. Finally, slides were incubated in PBS containing diaminobenzidine and 1 % hydrogen peroxide for 5-10 minutes, counterstained with Mayer hematoxylin, and mounted. PBS was substituted for primary antibody as the negative control.

Staining analysis

COX-2 staining The expression of COX-2 was semiquantified. The degree of immunostaining for COX-2 was considered positive when unequivocal staining of the cytoplasm was observed in tumor cells[7].

VEGF staining Immunoreactivity was graded as follows[12]: Positive, unequivocal staining of the membrane or the cytoplasm was seen in more than 5 % of carcinoma cells, negative, no detectable expression or less than 5 % of tumor cells were stained.

Microvessel staining and counting Intratumoral microvessels were highlighted by immunostaining with anti-Factor VIII related antigen monoclonal antibody. Any single brownly-stained cell or cluster of endothelial cells that was clearly separated from adjacent microvessels, tumor cells, and other connective tissue elements were considered a vessel[12]. Branching structures were counted as a single vessel unless there was a discontinuity in the structure. The stained sections were screened at ×100 magnification under a light microscope to identify the 5 regions of the section with the highest vascular density. Vessels were counted in the 5 regions at ×200 magnification, and the average numbers of microvessels were recorded[12]. Two observers did the counting, and the mean value was used for the analysis.

Statistical analysis

Data were analyzed using the chi-square test for categoric variables and Student' s *t* test for continuous variables. Five-year survival was compared using the Kaplan-Meier method and analyzed by the log rank test. Factors affecting survival were analyzed by Cox proportional hazards model using the SPSS statistic package Version 10.0. Differences with *P* values <0.05 were considered statistically significant.

RESULTS

The detection rates of EGC between 1990 and 1999 fluctuated between 1.1 % and 6.6 %. The average detection rate was 4.3 % (110/2533). In patients with EGC, cardia gastric tumors more frequently occurred than corpus and antrum gastric carcinoma in 60-69 age group (50.0 % *vs* 28.9 %, 21.3 %, *P*<0.05).

Five-year survival rate

The follow-up rates of EGC and AGC were 88.2 % (97/110) and 84.8 % (145/171), respectively. The overall disease-specific 5-year survival rates for patients with EGC and AGC were 93.4 % and 59.0 %, respectively. The 5-year survival rates for patients with EGC with different tumor location were as follows: cardia, 90.9 %; corpus, 91.3 %; and antrum, 96.3 %. The 5-year survival rate for patients with EGC with different depth of invasion was 96.7 % for mucosa invasion and 90.3 % for submucosa invasion. The 5-year survival rates for patients with AGC with different tumor location were as follows: cardia, 45.0 %; corpus, 69.6 %; and antrum, 60.0 %.

Correlation between postoperative survival time and clinicopathologic factors

Table1 shows the clinicopathologic data of 106 patients who survived for ⩾5 years and 47 patients who died within 5 years. There were no differences with respect to gender, age, location of the tumor, or histology between patients with long and short survival time. But survival time was highly correlated with depth of invasion, lymph node metastasis, vascular invasion, and treatment with chemotherapy (*P*<0.05-0.01).

Immunohistochemical analysis

Correlation between expression of COX-2 and clinicopathologic factors Immunoreactivity for COX-2 protein was present in the cytoplasm of tumor cells, smooth muscle cells, and surrounding glands, but not in the surrounding stroma (Figure 1). Positive immunostaining for COX-2 was also seen in some CAG (23.3 %) and mucosal atypical hyperplasia (60.0 %) specimens (Figure 2). However, it was observed more frequently in tumor cells (Table 2), which showed that the expression of COX-2 was significantly higher in mucosal atypical hyperplasia than that in CAG (*P*<0.01).

Compared with paired noncancerous specimens, COX-2 levels in carcinoma tissue were significantly higher (P<0.05-0.01). There was no significant association between COX-2 expression and gender, age, location of the tumor, or depth of invasion. However, significant difference was noted with respect to histologic type, lymph node metastasis, and vascular invasion. The COX-2-positive rate was significantly higher in patients with lymph node metastasis or vascular invasion than that in those without such metastasis or invasion (P<0.05-0.01). Similar results were obtained in relationship between the histologic type and the COX-2-positive rate (P<0.01, Table 2).

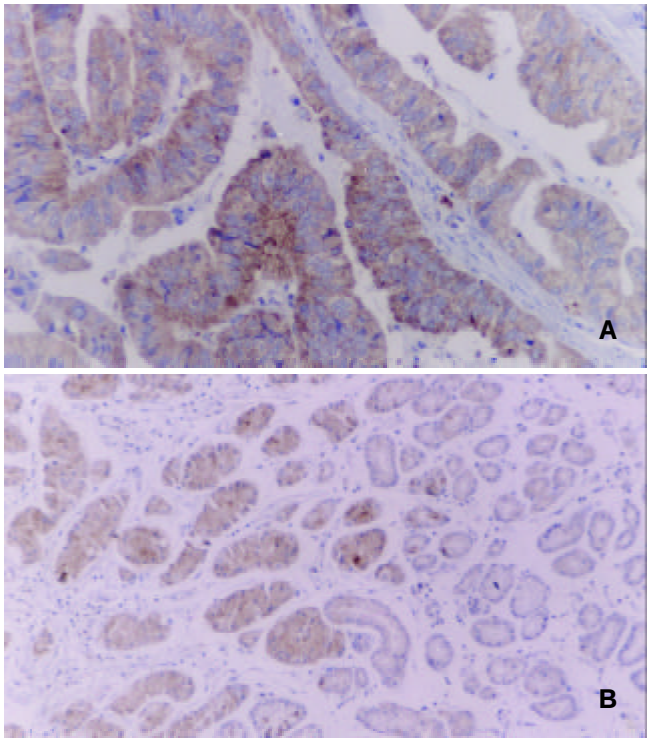

Figure 1 Immunohistochemical staining of COX-2 protein in gastric carcinoma. Immunoreactivity for COX-2 protein was present in the cytoplasm of tumor cells, smooth muscle cells (A, ×200), and surrounding glands (B, ×100).

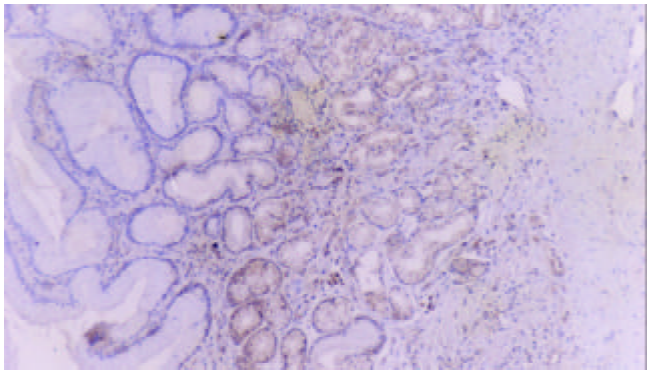

Figure 2 Positive immunostaining for COX-2 was observed in some CAG specimens (×100).

Correlations between expression of VEGF, microvessel counting and clinicopathologic factors VEGF was mainly localized in the cytoplasm or on the membrane of carcinoma cells (Figure 3). Tumor cells that were strongly immunopositive for VEGF were observed more often in the invasive front than that in the center of the tumors. Weakly positive VEGF staining was seen in some endothelial cells and noncancerous specimens. VEGF expression was detected in 122 (52.6 %) tumors and significantly higher (P<0.01) than that in noncancerous specimens (13.3 %). Correlations between VEGF expression, MVD and different clinicopathologic variables are shown in Table 3. VEGF-positive rate and MVD value were significantly correlated with depth of invasion, lymph node metastasis, and invasion of blood vessels (P<0.01). There was no significant association among VEGF expression, MVD value and histologic type. The microvessel count in COX-2-positive or VEGF-positive tumors (28.76±8.58 and 26.23±8.47, respectively) was significantly higher than that in COX-2-negative or VEGF-negative tumors (19.27±8.36 and 18.91±8.12, respectively), P<0.01.

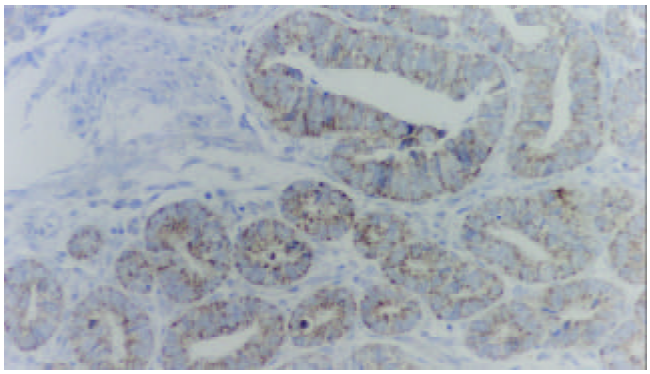

Figure 3 Immunohistochemical staining for VEGF in gastric carcinoma. VEGF was mainly localized on the membrane of the carcinoma cells or in the cytoplasm (×200).

Correlations between postoperative survival time and expression of COX-2 and VEGF COX-2 or VEGF positive rate was significantly higher in patients who died within 5 years (93.6 % and 78.7 %, respectively) than that in those survived ⩾5 years (69.8 % and 49.1 %, respectively, $P<0.01$). Expression of COX-2 or VEGF was highly correlated with postoperative survival time. The 5-year survival rate was 67.9 % in patients with COX-2-positive tumors and 91.4 % in patients with COX-2-negative tumors. Accordingly, the prognosis for patients with a COX-2-negative tumor was significantly better than that for patients with a COX-2-positive tumor (Figure 4, $P<0.01$). The survival curves subdivided according to VEGF expression are shown in Figure 5. The 5-year survival rate was 61.2 % in patients with VEGF-positive tumors, which was significantly lower than the rate in those patients with VEGF-negative tumors (91.5 %, $P<0.01$).

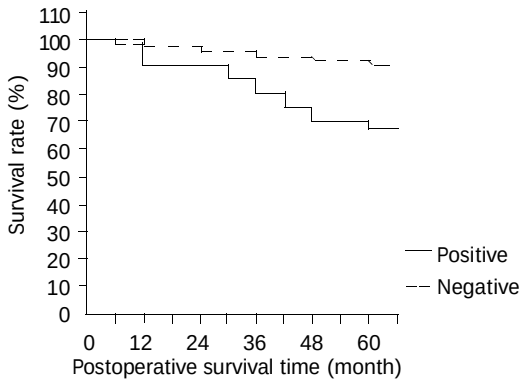

Figure 4 Kaplan-Meier survival curves of patients with gastric carcinoma with regard to COX-2 expression (positive and negative), $\chi^2=7.56$, $P<0.01$.

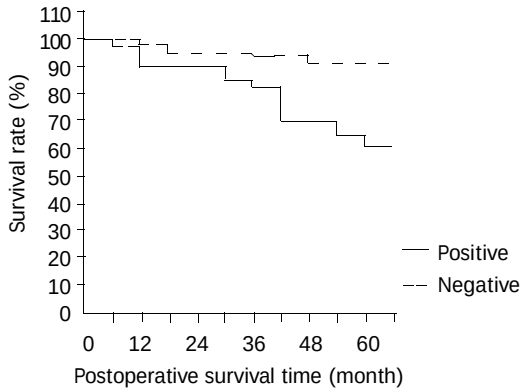

Figure 5 Kaplan-Meier survival curves of patients with gastric carcinoma with regard to VEGF expression (positive and negative), $\chi^2=16.51$, $P<0.01$.

Multivariate analysis

The effects of variables presumably associated with prognosis were studied by multivariate analysis using the Cox model. As a result, the depth of wall invasion, lymph node metastasis, vascular invasion, COX-2 expression, and VEGF expression emerged as independent prognostic factors (Table 4). Among these parameters, VEGF expression was the most important factor for predicting overall survival, followed by lymph node metastasis and COX-2 expression.

Table 4 Risk factors affecting survival determined by multivariate analysis using the Cox proportional hazards model

Variables	Regression coefficient	Standard error	Odds ratio (95% confidence interval)	*P* value
Histology (differentiated / undifferentiated)	0.564	0.337	1.758 (1.583-2.147)	NS
Depth of invasion (EGC / muscularis propria)	0.524	0.248	1.688 (1.638-1.714)	<0.05
Lymph node metastasis (present / absent)	0.796	0.1934	2.220 (1.518-3.239)	<0.01
Vascular invasion (present / absent)	0.413	0.213	2.003 (1.499-2.460)	<0.01
COX-2 expression (positive / negative)	0.776	0.194	2.173 (1.486-3.178)	<0.01
VEGF expression (positive / negative)	1.071	0.254	2.917 (1.774-4.796)	<0.01

Note: NS, not significant.

DISCUSSION

Recently, detection of gastric cancer at an early stage has been widely used in diagnostic procedures such radiography and endoscopy with targeted biopsy. In Japan, more than 50 % patients with gastric carcinoma were EGC[15]. However, in U.S., the proportion of EGC was approximately 20 %[16]. In the current study, our detection rate of EGC (4.3 %) was lower than that in above reports. This indicates the need to upgrade diagnostic efforts in the future. The incidence of adenocarcinoma of the gastric cardia has increased gradually in the West[17]. In our study, carcinoma of the gastric cardia accounted for 16.4 % of EGC and 30.4 % of AGC. The absolute number and the rates of cardia carcinoma have been increasing significantly and this increase may be derived from advances in endoscopic techniques and equipment. Our data also showed that carcinoma of the gastric cardia more frequently occurred in 60-69 age group than distal gastric cancer. Thus, we should pay attention to those patients who are older than 60 years in

the diagnosis of early carcinoma of the gastric cardia during an endoscopic examination.

The prognosis for EGC is universally excellent. Almost all Western and Japanese authors reported 5-year survival rates were over 90 % for EGC if relative survival or deaths from gastric carcinoma alone were considered. The results of the current study indicat that prognosis of patients with AGC was poorer than that with EGC and that prognosis of patients with submucosa invasion was poorer than that with mucosa invasion. The survival of patients with tumors in the upper third of the stomach was significantly worse compared with that of patients with tumors in the middle third and lower third of the stomach[16,18]. Our study disclosed that the 5-year survival rate of patients with tumors in the upper third of the stomach was lower than that of patients with tumors in the middle third and lower third of the stomach, especially in patients with AGC. However, there were no statistically significant differences among them (data not shown).

The depth of wall invasion, lymph node metastasis, and vascular invasion were reported to be the most important prognostic parameters in gastric carcinoma[19]. The current study demonstrated that long or short survival time was highly correlated not only with depth of invasion, lymph node metastasis, and vascular invasion, but also with adjuvant chemotherapy. The results were in agreement with other reports.

However, preoperative diagnosis of the extent of wall invasion or the presence of lymph node metastasis and vascular invasion is difficult in some cases. Therefore, not only conventional clinicopathologic factors but also biologic factors should be examined for the prediction of clinical outcome. Recently, some studies[20,21] found an increase in COX-2 protein levels in gastric carcinoma beyond the levels in paired normal gastric mucosa samples. The present study demonstrated that expression of COX-2 was significantly higher in mucosal atypical hyperplasia than that in CAG and that its expression was significantly higher in carcinoma tissue compared with noncancerous specimens. These indicate that COX-2 is involved in the growth of gastric carcinoma and that COX-2 promotes malignant transformation in human gastric carcinoma.

Recent studies have found that overexpression of COX-2 protein is associated significantly with lymph node metastasis[22,23] and depth of invasion[24,25] and that there is no correlation between the hisologic types of gastric carcinoma and the expression of COX-2 protein[24,26]. We found that COX-2 expression was associated with lymph node metastasis, vascular invasion, and the degree of tumor cell differentiation and did not connect to depth of invasion. The results suggest that COX-2 might enhance the metastatic potential as well as tumorigenicity and might be mainly involved in the progression of well-differentiated gastric carcinoma. The different conclusions of our study and above reports might have two explanations. First, differences in the methods employed (COX-2 mRNA level or protein immunoreactivity) and subjects may well influence the results of these studies. Second, there may have been discrepancies in the histologic type distribution among different areas.

Solid tumors need angiogenesis for growth and metastasis. Tumor angiogenesis may be regulated by angiogenic factors that are secreted by tumor cells, and VEGF is thought to be such a factor[27,28].VEGF is a selective mitogen for endothelial cells and may directly stimulate the growth of new blood vessels[27]. Numerous studies have demonstrated that the expression of VEGF is a significant predictor of an increased risk of metastatic disease and overall survival by stimulating angiogenesis in gastric carcinoma[9,28] and other carcinomas[29]. In this study, we found that VEGF expression and microvessel count were significantly associated with lymph node metastasis, depth of invasion, and vascular invasion. The finding that the microvessel count in VEGF-positive or COX-2-positive tumors was significantly higher than that in VEGF-negative or COX-2-negative tumors suggests that COX-2 as well as VEGF may faciliate tumor progression by promoting tumor angiogenesis[9,30].

With regard to prognosis, many studies have shownd that expression of VEGF is an independent prognostic indicator[12,31]. However, there have been few studies on the association of COX-2 expression and the postoperative survival rate of patients with gastric carcinoma[32]. The current study demonstrated that the 5-year survival rate in patients with COX-2-positive or VEGF-positive tumors was significantly lower than that in patients with COX-2-negative or VEGF-negative tumors. The results suggest that the presence of COX-2 or VEGF expression, as well as conventional clinicopathologic factors, are prognostic indicators in patients with gastric carcinoma. Multivariate analysis revealed five independent prognostic factors. Combination analysis of these pathologic and biologic features of gastric carcinoma will give aid to the improvement of the prognosis of some patients. If these assessments of COX-2 and VEGF expression are confirmed in long term follow-up of a larger group of patients, COX-2 and VEGF staining using endoscopically biopsied specimens prior to surgery could be used for the prediction of clinical outcome and in the preoperative selection of treatment for patients with gastric carcinoma. Accordingly, the inhibition of COX-2 activity may have an important therapeutic benefit in the control of gastric carcinoma[33].

Abstract

AIM: To study the preventive effect of hydrotalcite on gastric mucosal injury in rat induced by taurocholate, and to investigate the relationship between the protective mechanism of hydrotalcite and the expression of trefoil factor family 2 (TFF2) mRNA and c-fos protein.

METHODS: Forty five male Wistar rats were randomly divided into hydrotalcite group, ranitidine group and control group. Gastric mucosal injury was induced by introgastric acidified taurocholate. OD value of TFF2 mRNA expression in gastric mucous cells was determined by hybridization and computer image analysis system. OD value of c-fos protein expression in gastric mucous cells was measured by immunohistochemistry and computer image analysis system.

RESULTS: The gross mucosal injury index in hydrotalcite group was significantly lower than that in ranitidine group and control group (8.60±2.20 *vs* 16.32±4.27, 29.53±5.39; $P<0.05$, $P<0.01$). The expression level of TFF2 mRNA in hydrotalcite group was markedly higher than that in ranitidine group and control group (0.56±0.09 *vs* 0.30±0.05, 0.28±0.03, $P<0.05$). The OD value of c-fos protein in hydrotalcite group was higher than that in ranitidine group and control group (0.52±0.07 *vs* 0.31±0.04, 0.32±0.05, $P<0.05$).

CONCLUSION: Hydrotalcite can protect gastric mucosal injury in rats induced by taurocholate, which may be related to the increased expression of TFF2 and c-fos protein.

INTRODUCTION

Hydrotalcite is one kind of protective agents for gastric mucosal[1,2], it neutralizes the gastric acid[29], stimulates the synthesis of prostaglandin and the release of epidermal growth factor[3] from gastric mucosa[4]. Because hydrotalcite binds to cholalic acid in the stomach[5,6], it is effective on bile reflux gastritis. Trefoil factor family 2 (TFF2)[7-9] is one of the members in the trefoil peptide factor family[10-13] mainly produced by mucus-secreting cells in the gastrointestinal tract[1,14,15]. It involves restitution of epithelial lining after epithelial cell injury[16,17], mucosal defense[18,19] and healing of ulcer[20-23]. c-fos gene[24,25] is one of the earlier expressed genes after gastric mucosa injury. c-fos protein relates to mucosal repair after mucosal injury[26]. In the present study, we aimed to study the preventive effect of hydrotalcite on gastric mucosal injury in rat induced by taurocholate and the relationship between the protective mechanism of hydrotalcite and the expression of TFF2 mRNA and c-fos protein.

MATERIALS AND METHODS

Methods

Animals model Forty-five adult male Wistar rats weighing 200-250 g were divided into three groups randomly: hydrotalcite group, ranitidine group and control group, 15 rats in each group. The animals were housed at the Experimental Animal Center of Wuhan University. Taurocholate was dissolved in normal saline and HCl was added to a final concentration of 0.2 mol/L with pH value of 1.4[27]. The rats in hydrotalcite group were given 100 mg/kg hydrotalcite. The rats in control group were given 1.5 ml normal saline at the same time. The rats in ranitidine group were given 30 mg/kg ranitidine twice 12 hrs the day before. After one hour of hydrotalcite administration, gastric mucosal damage in three groups was induced by introgastric administration of 1.5 ml taurocholate[1] at 15 mmol/L. Two hours later, the animals were killed by cervical dislocation. The abdomen was opened, and the stomach was removed and incised along the greater curvature. The mucosal surface was gently washed with normal saline. Gastric lesions were scored by a previously described scoring system[28] as follows: one point, point erosion; two point, <1 mm of erosion; three point, 1-2 mm of erosion; four point, 3-4 mm of erosion; five point, >4 mm of erosion. The mucosa injury index was calculated on the totally accumulated points. After scored, the mucosa was obtained and prepared for histological examination and other tests.

TFF2 mRNA *in situ* hybridization Gastric mucosa tissue immersion-fixed in neutral buffered formaldehyde was dehydrated, oriented in cross section and embedded in wax. Four micrometer sections were cut, dewaxed, and rehydated to PBS. Sections were permeabilized with proteinase K, postfixed in 4 % paraformaldyhyde in PBS, and acetylated with acetic anhydrated in 0.1 mol/L triethanolamine. The tissues were then dehydrated for hybridization. Hybridization was performed according to the instructions of text kit (Sigma Co). Oligo-nucleo tides probe sequence was 5'-GTAGTGACAAATCTTCCACAGA. The optic density (OD) value of the hybridization signals was assessed by image analysis system.

Immunohistochemistry of c-fos protein Sections of gastric mucosa tissues were incubated with monoclonal antibody against human c-fos protein for four hours at 37 ℃. Immunostaining of c-fos protein was revealed using a commercially available peroxidase-based method (SP vectastain, Zhongshan Co.) according to the instructions of the manufacturer. The optic density of immunosignals was determined by image analysis system.

RESULTS

Gross inspection showed that there were obvious hyperemia, edema, sheet or strip of necrosis and spot hemorrhage in the gastric mucosa of control groups. There were milder lesions after hydrotalcite pretreatment, and microscopic examination confirmed marked protection against taurocholate-induced gastric injury. The degree of lesion in ranitidine group fell in-between the two groups. The gastric mucosa injury index was 8.60±2.20, 16.32±4.27, 29.53±5.39 in hydrotalcite, ranitidine and control groups, respectively. The gastric mucosa index in hydrotalcite group was significantly lower than that in ranitidine group ($P<0.05$) and control group ($P<0.01$).

In all three groups TFF2 mRNA was expressed in the atrium of stomach as revealed by *in situ* hybridization. TFF2 mRNA was mainly confined in gastric epithelial cells and gastric gland mucous neck cells, especially in the margin of the injury region (Figure 1-2).

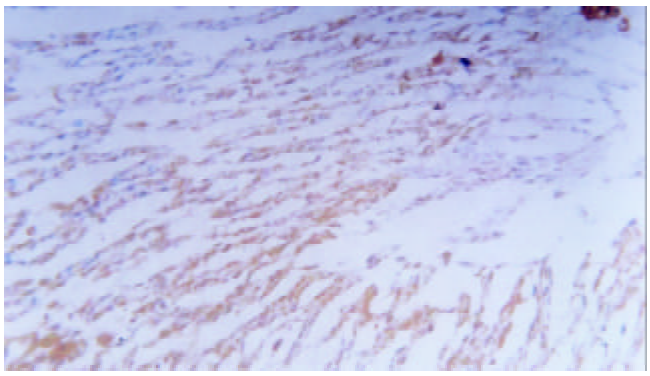

Figure 1 TFF2 mRNA in situ hybridization in hydrotalcite group Positive cells were stained brown-yellow ×200.

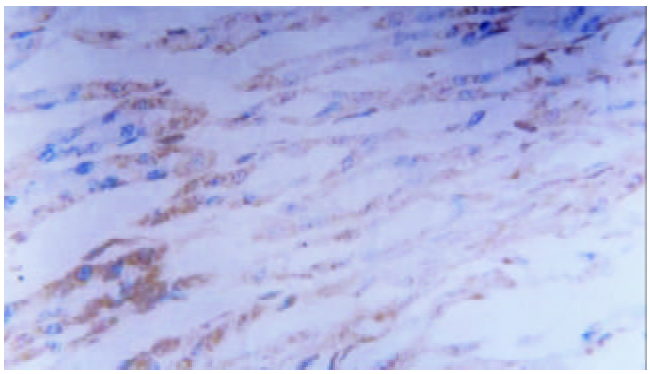

Figure 2 TFF2 mRNA in situ hybridization in hydrotalcite group Positive cells were stained brown-yellow ×400.

Immunochemistry showed that c-fos protein localized in nuclei of positively stained cells, which were mainly gastric gland mucous neck cells (Figure 3-4). The OD values of TFF2 mRNA and c-fos protein in the three groups are shown in Table 1.

Table 1 OD values of TFF2 mRNA staining and c-fos protein staining

Group	Animal number	TFF2 mRNA	c-fos protein
Hydrotalcite	15	0.56±0.09[a]	0.52±0.07[a]
Ranitidine	15	0.30±0.05[b]	0.31±0.04[b]
Control	15	0.28±0.03	0.32±0.05

[a]$P<0.05$ *vs* control, [b]$P>0.05$ *vs* control.

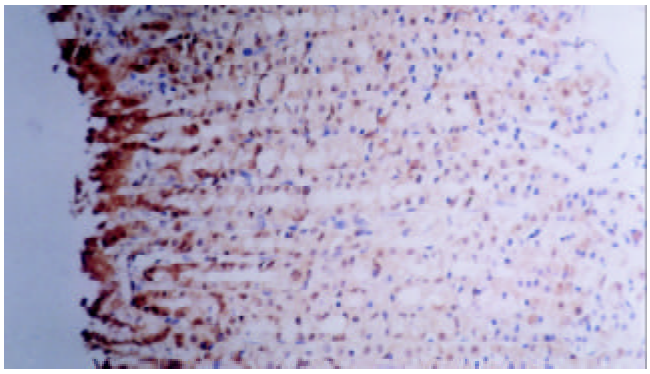

Figure 3 c-fos protein Immunostaining in hydrotalcite group Nuclei of positive cells were stained brown-yellow ×200.

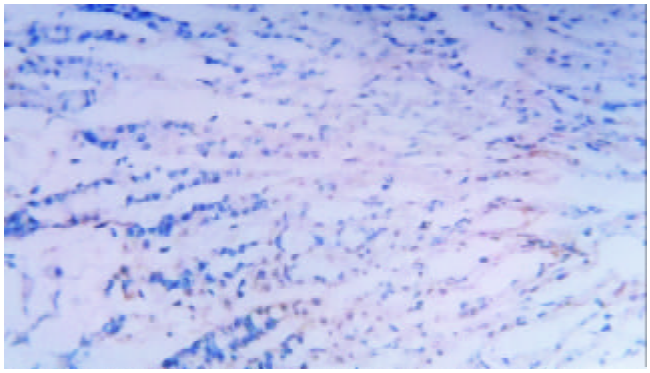

Figure 4 c-fos protein Immunostaining in ranitidine group Nuclei of positive cells w ere stained buff ×200.

DISCUSSION

Hydrotalcite is a complex comprised of aluminum hydroxide, magnesium hydroxide, carbonate and H_2O, which neutralizes gastric acid[29], binds pepsin[30,31] and choliac acid[5,31], *etc*. Our study showed that hydrotalcite could markedly protect gastric mucosa against taurocholate-induced lesions. The mucosal injury index in hydrotalcite group was significantly lower than that in ranitidine and control groups. Choliac acid has been thought to elicit gastric injury by degrading the difference of potential in gastric mucosa, increasing inversed diffusion of acid, and stimulating mast cell to release histamine. Recent researches indicated that transforming growth factor was related to the recovery of gastric mucosal injury induced by taurocholate[27,32,33]. Hydrotalcite has been shown to enhance the synthesis and release of prostaglandin and to increase the amount of epidermal growth factor in mucosal blood[4].

The mechanism of the protective and healing effect of TFF2 on gastric mucosa is still not fully elucidated. *In vitro* studies, TFF2 was shown to stimulate cell migration[34]. Recently hTFF was shown to decrease proton permeation through interacting with mucus in both *in vivo* and *in vitro* studies[35]. Orally-administrated TFF2 was found to bind to the mucus layer of the stomach[36,37], which accelerates the healing of gastric ulcer in the rat[38-41]. In this study, we have shown that hydrotalcite reduces gastric injury induced by taurocholate in rats, and it also increases expression of TFF2 mRNA in margin of the injury region, suggesting that the protective effect of hydrotalcite on gastric mucosa is related to the increase of TFF2 expression. The reason why hydrotalcite increases expression of TFF2 is not yet fully understood. Previous studies indicate that TFF expression and secretion are regulated by neuropeptides and acetylcholine[42], and hydrotalcite increases the amount of epidermal growth factor in gastric mucosa[4]. It is presumed

that hydrotalcite regulates TFF2 mRNA expression through the increase of epidermal growth factor.

C-fos gene is one of the immediate early genes which are involved in the control of cell proliferation in a variety of cell types[43-46]. Change of c-fos mRNA expression is found as early as two hours in the healing of gastric mucosal stress ulcer[26,47]. In this study, the expression of c-fos protein was found two hours later in gastric mucosal damage induced by taurocholate. The amount of c-fos protein in hydrotalcite was higher than that in ranitidine and control groups, suggesting that c-fos protein participates in the mechanism of the protective effect of hydrotalcite in gastric mucosa. It has been shown that EGF[48,49] stimulates the proliferation[50] of cells derived from gastric fundus and induces the expression of c-fos and c-myc, and hydrotalcite increases the amount of epidermal growth factor in gastric mucosa. It may be presumed that hydrotalcite increases c-fos protein through the increase of the amount of epidermal growth factor in gastric mucosa.

Abstract

AIM: To investigate the expression of NGF family and their receptors in gastric carcinoma and normal gastric mucosa, and to elucidate their effects on gastric carcinoma.

METHODS: RNA of gastric cancer tissues and normal gastric tissues was respectively isolated and mRNA was purified. Probes of both mRNA reverse transcription product cDNAs labled with α-^{33}P dATP were respectively hybridized with Atlas Array membrane where NGF and their family genes were spotted on. Hybridized signal images were scanned on phosphor screen with ImageQuant 5.1 software after hybridization. Normalized values on spots were analyzed with ArrayVersion 5.0 software. Differential expression of NGF family and their receptors mRNA was confirmed between hybridized Atlas Array membranes of gastric cancer tissues and normal gastric mucosa, then their effects on gastric carcinoma were investigated.

RESULTS: Hybridization signal images on Atlas Array membrane appeared in a lower level of nonspecific hybridization. Both of NGF family and their receptors Trk family mRNA were expressed in gastric cancer and normal gastric mucosa. But adversely up-regulated expression in other tissues and organs. NGF, BDGF, NT-3, NT-4/5, NT-6 and TrkA, B and C were down-regulated simultaneously in gastric carcinoma in comparison with normal gastric mucosa. Degrees of down-regulation in NGF family were greater than those in their receptors Trk family. Down-regulation of NT-3 and BDGF was the most significant, and TrkC down-regulation level was the lowest in receptors Trk family.

CONCLUSION: Down-regulated expression of NGF family and their receptors Trk family mRNA in gastric cancer is confirmed. NGF family and their receptors Trk family probably play a unique role in gastric cancer cell apoptosis by a novel Ras or Raf signal transduction pathway. Their synchronous effects are closely associated with occurrence and development of gastric carcinoma induced by reduction of signal transduction of programmed cell death.

INTRODUCTION

Recently, NGF family and their receptors family have been found in other non-neural tissues of the body, and more and more attentions are being paid to their effects on these tissues, especially on tumor tissues. Gene expression of NGF and Trk families in gastric tissue and gastric carcinoma has been seldom documented. Simultaneous detection of NGF family and their receptors family expression has become possible since cDNA microarray was developed[1]. As abnormal expression of many genes is involved in gastric carcinogenesis[2-11], it contributes to a better understanding of their roles in the occurrence and development of gastric cancer and helps reveal mRNA expression of the family genes in gastric tissue and gastric carcinoma.

MATERIALS AND METHODS

RNA extraction and mRNA purification

RNA of gastric cancer tissues and normal gastric mucosa was respectively isolated with Trizol (Gibco) in five cases of gastric cancer from Xijing Hospital, Fourth Military Medical University. To ensure good total RNA quality 28S/18S $\geqslant$1.5, samples were immediately placed into liquid nitrogen after being removed intraoperatively, and trituration of the samples was performed in liquid nitrogen. Then, mRNA was purified in Oligotex mRNA Kit (Qiagen). An equal mRNA mixture of gastric cancer tissues and normal gastric mucosa from five patients respectively constituted gastric cancer group and normal gastric mucosa group. At last, reverse transcription product (the first stranded cDNAs) of mRNA mixture was electrophoresed to evaluate its size and quality.

Probe labeling

One μg of mRNA mixture of gastric cancer tissue and normal gastric mucosa from five patients was respectively transcripted into cDNAs as a probe labeled with 3.5 μl α-^{33}P dATP (>2, 500 kCi· mol^{-1}, 10 Ci· L^{-1}, Dupont) and 1 μl CDS primer 1 (Clontech) in a mixture containing 1 μl MMLV, 1 μl 10× dNTP Mix (for dATP label), 0.5 μl DTT (100 mM), and 2 μl 5× reaction buffer in a final volume of 10 μl was incubated for 0.25 h at 50 ℃ using an unregulated heat block (Eppendorf). Labeled reaction was stopped by adding 1 μl 10×Termination Mix. To purify the labeled cDNA from unincorporated ^{33}P-labeled nucleotides and small (<0.1 kb) cDNA fragments, the above probe synthetic reactions were diluted to 200 μl total volume with Buffer NT2 included in Atlas cDNA Expression Arrays (Clontech), then transferred to a NucleoSpin Extraction Spin Column. 400 μl Buffer NT3 was added into the column after centrifugation at 14 000 rpm for 1 min and the flowthrough

was discarded. The procedure was repeated twice. To elute the labeled probe, 100NE was added into the column, centrifuged at 14 000 rpm for 1 min. The flowthrough was obtained as the labeled probe.

Prehybridization and hybridization

Prehybridization of Atlas Array membrane was carried out in 0.5 mg heat-denatured sheared salmon DNA, and 5 ml prewarmed ExpressHyb solution (Clontech) in a hybridization bottle was incubated for 0.5 h at 68 ℃. Then, heat-denatured cDNA probes were added into the above prehybridization bottle together with 5 μl heat-denatured C_0t-1 DNA. The hybridization reactions were performed at 68 ℃ overnight. The next day, the Atlas Array membrane was washed three times in prewarmed wash solution 1 (2×SSC, 1 % SDS) with continuous agitation at 68 ℃ for 0.5 h, and in prewarmed wash solution 2 (0.1×SSC, 0.5 % SDS) at 68 ℃ for 0.5 h. The damp Atlas Array membrane was wrapped in a plastic wrap after the last washing in 2×SSC at room temperature for 5 min.

Exposure of hybridization signals to phosphorimager and result analyses

Atlas Array hybridization membrane was exposed to phosphor screen at room temperature overnight. The hybridization signals were analyzed with ArrayVersion 5.0 software (MD) after the phosphor screen was scanned with ImageQuant 5.1 software (MD). Quantitative data of each hybridization signals were obtained.

RESULTS

Identification of mRNA quality

Good total RNA quality was confirmed by 28S/18S ⩾1.5. Size range of reverse transcription product cDNAs represented a smear from 0.2-4kb both in gastric cancer and normal gastric mucosa (Figure 1).

Image of scan on hybridization signals of phosphor screen

Hybridization signal images on Atlas Array membrane appeared in lower levels of nonspecific hybridization (Figure 2).

Expression of NGF family and their receptors Trk family mRNA

To quantify hybridization signals, signal intensity was detected after hybridized signal normalization of two hybridization Atlas Array membranes between gastric cancer and the normal mucosa. Signal intensity of NGF family and their receptors Trk family on Atlas Array membranes represented their mRNA expression level. NGF, BDGF, NT-3, NT-4/5, NT-6 and TrkA, B and C were down-regulated in gastric carcinoma in comparision with normal gastric mucosa. Degrees of down-regulation in NGF family were greater than those in their receptors Trk family. Down-regulation of NT-3 and BDGF was the most significant, and TrkC down-regulation level was the lowest in receptors Trk family (Table 1).

Table 1 Signal intensity of NGF family and their receptors Trk family

Dot	Gene	CAVOL	NORnVOL	NORnVOL/CAnVOL

DISCUSSION

Gene microarray has been rapidly and extensively used in detecting expression of genes, DNA sequence, novel genes and gene mutants, DNA polymorphism, and in screening drugs, diagnosing diseases and mapping gene library since Schena reported it in 1995[12-28]. Profiling of differentially expressed genes in human gastric carcinoma by cDNA expression array was also reported[29]. The study detected expression of NGF family and their receptors Trk family mRNA by using cDNA microarray. The Atlas Array membranes were provided by Clontech. A set of housekeeping genes was included on the Atlas Array membranes to normalize mRNA expression levels. Our good total RNA and mRNA quality, as well as successful synthesis and labeling of a cDNA probe with highly specific activity ensured the best possible results. ExpressHybTM hybridization solution was used in our hybridization experiments, a low-viscosity hybridization solution that significantly enhances the sensitivity of detection and reduces background.

NGF is composed of three subunit proteins (α, β and γ) among which β subunit represents an active form. NGF produced by targets of sympathetic neuron, sensory central neuron exerts an important effect on growth, development, differentiation of these neurons. Brain-derived nerve growth factor (BDNF), NT-3, NT-4/5 and NT-6 are members of the

NGF family, and NGF has 50 % of homology with BDNF. Difference between members of the family comes from the distribution of tissues, the early and/or later expression, and different receptors. NGF family receptors are subdivided into three types: Trk A, TrkB and TrkC. The structure of the three receptors consists of cellular external region, transcellular membrane region and cellular internal region. The receptors all are tyrosine kinase, and there is 66-68 % of homology between them. NGF binds TrkA, and BDNF, NT-3, NT-4/5 and NT-6 bind TrkB, in which binding of NT-3 is weaker and mainly with TrkC. As the functions of NGF family, TrkA, TrkB and TrkC can regulate growth, development and differentiation of corresponding neurons while receiving signals of NGF, BDNF, NT-3, NT-4/5 and NT-6. NT-3 and its receptor TrkC play a role in early growth, development and differentiation of neural systems.

Recently NGF family and their receptors family were found in other non-neural tissues of the body, and more and more attentions are being paid to their effects. It was reported that dermal pigment cells expressed NGF and Trk[30], hepatic cells expressed BDNF, NT-3, NT-4/5 as well as TrkA, which were related to liver pathophysiology. Hepatic stellate cells expressed BDNF, NT-3, NT-4/5, TrkB and TrkC that were involved in liver remodeling[31]. NT-3, NT-4/5, TrkB and TrkC expressed by microphages played a role in tissue inflammatory reaction and repair[32]. Cardiac myocytes expressed TrkC and NT-3, and early growth and development of the heart were retarded when blockage of TrkC was used[33]. Schneider *et al*[34] demonstrated TrkA and TrkC expression in pancreatic ducts and pancreatic islets, TrkB in apha-cells of islets, NGF in pancreatic ducts and pancreatic acinar cells, NT-3 and NT-4 respectively in capillary endothelia and ductule cells. Additionally, TrkB and TrkC were found in endocrine cells of gut epithelium and neural tissues in fish[35,36], and TrkA, TrkB and TrkC were all expressed in testis of rats. A current study also indicated NGF family and their receptors played an essential role in the development of tubulogenesis in embryonic kidney, spermatogenesis, hair follicle, heart and vascular differentiation and maintenance of blood and immune cells[37].

Similarly, more attentions are being paid to their effects on tumors. Antagonists of NGF family and their receptors are being applied to kill tumor cells experimentally. It was noted that NGF family and their receptors were not expressed in some normal tissues, but expressed in their corresponding tumors. For example, up-regulated expression of Trk was present in tumors originating from thyroid and ovary while absent in the normal tissues. When chromosomal translocation occurred, a fusion protein of Trk-T1 composed of carboxyl terminal tyrosine kinase domain of NTRK1 and amino terminal portion of TPR (translocated promoter region) was formed. Trk-T1 was oncogenic *in vivo* and contributed to the papillary neoplastic transformation of the thyroid[38]. These results suggest that NGF family and their receptors are involved in tumorigenicity. A recent study showed that pancreatic carcinoma cells could express NGF, TrkA and TrkC[34]. It is interesting that Trk was highly expressed in esophageal carcinoma, thyroid carcinoma and prostate carcinoma, and adversely Trk expression revealed significantly lower in gastric carcinoma and colon carcinoma[39,40]. Difference between NGF and Trk expression in various tumors suggests that NGF family and their receptors may play a different role or have directly reverse effects on various carcinoma originating from different tissues. Some studies verified the assumption that ocurrence of apoptosis could be inhibited and/or enhanced while cascade effect was brought out by intracellular signal transduction pathway blocking or inducing programmed cell death[41,42]. Its signal transduction pathways include Ras, the Cdc42/Rac/RhoG protein family, MAPK, PI3K and PLC-gamma. Adversely, other novel Ras and/or Raf pathways participate in signal transduction paths mediating programmed cell death. For example, prostate growth depends on autocrine NGF interaction with Trk expressed by itself, otherwise, apoptosis occurred in medulloblastoma when NGF was bound to Trk[43]. Therefore, inhibition or enhancement of apoptosis induced by Trk depended on cellular types and development periods of cells[44].

The study showed that expression of NGF family and their receptors were simultaneously down-regulated in gastric cancer tissues. NT-3 and BDGF down-regulation was the lowest in NGF family, Trk C down-regulation was the lowest in Trk family. The evidences support that NGF family and their receptors Trk family may play a unique apoptotic role in gastric cancer by a new Ras or Raf signal transduction pathway. These further substantiate that NGF family and Trk family have synchronous effects on the occurrence and development of gastric carcinoma induced by reduction in signal transduction of programmed cell death brought out by simultaneously down-regulated expression of NGF family and Trk family. It remains unclear that which cells in gastric mucosa secret NGF family, and whether NGF plays a role in the occurrence and development of gastric carcinoma in autocrine or paracrine way.

Abstract

AIM: To study the expression of survivin, an inhibitor of apoptosis protein, in human gastric carcinomas and gastric carcinoma models of rats.

METHODS: With the method of immunohistochemical staining, we studied the expression of survivin in 20 cases of chronic gastritis and 56 cases of gastric carcinomas. We used N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) and high dose sodium-chloride diet to induce rat gastric carcinomas. Survivin expression was studied in glandular stomachs of normal rats, adenocarcinomas and tissues adjacent to the tumor, as well as in rats during the induction period.

RESULTS: Survivin was expressed in 27 of 56 (48.2 %) cases of human gastric carcinoma tissues and 1 of 20 (5 %) cases of chronic gastritis. It was found that the expression of survivin had no relation with the elements of age, tumor depth, tumor size, and disease stage, but was significantly related to histological type. The positive rate of survivin expression in cases of intestinal type was significantly higher than that in cases of diffuse type ($P<0.05$). In animal experiments, survivin expression in glandular stomachs of normal rats, of rats in middle induction period, in adenocarcinomas and tissues adjacent to tumor were 0, 40.0 %, 78.3 % and 38.9 %, respectively. Compared with the survivin expression in normal rats, the differences were significant.

CONCLUSION: These data imply that survivin plays an important role in the onset of gastric carcinoma and that high survivin expression is an early event of gastric carcinoma.

INTRODUCTION

Survivin, a member of the inhibitors of apoptosis protein (IAP) family, is a mitotic spindle-associated protein involved in linking mitotic spindle function to the activation of apoptosis in mammalian cells. The structure of full-length human survivin determined by X-ray crystallography is 2.7 A°. The structure forms a very unusual bow tie-shaped dimer. The unusual shape and dimensions of survivin suggest that it serves as an adaptor through its alpha-helical extensions[1]. Just like other IAP members, survivin can suppress apoptosis through combination with Caspase3, Caspase7 by baculoviral IAP repeat (BIR)[2,3]. The common pathway of apoptosis is the activation of Caspase3, Caspase7 or Caspase 6, hence high expression of survivin may protect cells from many apoptosis signals and help cells survive[4,5]. Now, substantial data have shown that inhibition of apoptosis plays a great role in carcinogenesis[6-10], so survivin may be an important factor in the development of cancer. It has reported that survivin is undetectable in terminally differentiated adult tissues and becomes prominently expressed in transformed cell lines and in most common human cancers of lung, colon, pancreas, prostate and breast[2]. Some data indicate that high expression of survivin is correlated with poor prognosis and chemotherapy resistance[11-13]. In this study, we investigated the expression of survivin in human gastric carcinoma and its relationship with clinicopathological factors, as well as the expression of survivin in gastric carcinoma models of rats.

MATERIALS AND METHODS

Patients and samples

A total of fifty-six cases of gastric carcinoma were involved in this study including 46 males and 10 females. The age range was 26-79 years, mean age was 59.8 years. The patients with gastric carcinoma, having undergone potentially curative tumor resection at Huashan Hospital from 2000 to 2001, had received neither chemotherapy nor radiation therapy before surgery. The histological types of tumors were classified according to Lauren as intestinal type and diffuse type, and the disease stage was defined in accordance with the tumor-node-metastasis (TNM) classification[14]. There were 32 cases of intestinal type and 24 cases of diffuse type. Materials were composed of 19 cases of stage I, 8 cases of stage II, and 29 cases of stage III. The tissues containing principal tumor were selected and fixed with formalin, embedded in paraffin routinely. Serial sections of 4 μm were prepared for immunohistochemical examination and histopathological study. The expression of survivin was investigated in these 56 gastric carcinoma patients and 20 cases of chronic gastritis by immunohistochemical examination.

Animal experiment

Forty-six male 6-week-old Wistar rats were divided into 2 groups. Thirty rats in group A were fed with a diet supplemented with 8 % NaCl for 20 weeks and simultaneously given N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) in drinking water at a concentration of 100 ug/ml for the first 17 weeks. From week 18, these rats were given normal water. From week 21, these rats were fed with normal diet for 15 weeks. The other sixteen rats in group B were fed with normal diet for 35 weeks and served as the control. At week 20, 10 rats in group A were killed and all the rest animals were killed

at the end of week 35. The whole stomach and a part of duodenum were sampled and cut open along the greater curvature. The number of tumors with their locations and sizes were recorded in details. All the specimens were histopathologically investigated and the expression of survivin was examined with immunohistochemical analysis as they were done in human specimens.

Immunohistochemical staining for survivin and assessment of its expression

Anti-survivin polyclonal antibody was purchased from Santa Cruz Company. Immunohistochemical analysis was carried out with the standard streptavidin-biotin-peroxidase (SP) complex technique using the Ultra sensitive™ S-P kit (Maixin-Bio Company). One case of stage III gastric carcinoma intensively and reproducibly stained for survivin expression in more than 50 % of tumor cells served as positive control. Negative control slides were stained without primary antibody. To assess the expression of survivin in various samples examined, a 4-grade-method was established according to the mean percentage of positive tumor cells and their intensity. Moderately stained slides with a mean percentage of positive tumor cells no less than 30 % were scored as positive (+). Moderately or intensively stained slides with a mean percentage of positive tumor cells more than 70 % were scored as intensely positive (+++). Slightly or moderately stained slides with a mean percentage of positive tumor cells between 30 % and 70 % were scored as moderately positive (++). Slightly or moderately stained slides with a mean percentage of positive tumor cells less than 30 % were scored as negative (-).

Statistical analysis

Software Stata (version 6.0, STATA Corp, College Station) was applied to compare the rates.

RESULTS

Correlation between expression of survivin and clinicopathological factors in human gastric carcinomas

Positive staining for survivin was located in cytoplasm of tumor cells (Figure 1). A clinicopathological analysis of survivin-positive cases is shown in Table 1. The expression of survivin was positive in 27 of 56 (48.2 %) cases of gastric carcinoma tissues and 1 of 20 (5 %) cases of chronic gastritis. Expression of survivin had no relation with age, tumor depth, tumor size, and disease stage (P>0.05), but it was significantly related to histological type. The positive rate of survivin expression in cases of intestinal type was significantly higher than that in cases of diffuse type (P<0.05).

Table 1 Correlation between expression of survivin and clinicopathological factors in human gastric carcinomas

Variables	Cases	Survivin expression *n* (%)	*P*
Chronic gastritis	20	1(5%)	<0.001
Gastric carcinoma	56	27(48.2%)	
Age			
<55	18	11(61.1%)	0.184
>55	38	16(42.1%)	
Invasion size			
<12.3 cm^2	31	16(51.6%)	0.571
>12.3 cm^2	25	11(44.0%)	
Invasion depth			
Muscular layer unaffected	14	5(35.7%)	0.280
Muscular layer affected	42	22(52.4%)	
Lymph node metastasis			
Regional lymph Node unaffected	20	9(45.0%)	0.720
Regional lymph Node affected	36	18(50%)	
Histological type (Lauren) intestinal	32	20(62.5%)	0.013
Diffuse	24	7(29.2%)	
Disease stage(TMN)			
I	19	8(42.1%)	0.873
II	8	4(50.0%)	
III	29	15(51.7%)	

Notes: The disease stage of each tumor was defined in accordance with the tumor-node-metastasis (TNM) classification, the histological type was classified according to Lauren, and other pathological variables were defined in accordance with the Gastric Carcinoma[14].

The expression of survivin in gastric carcinoma models of rats

By the end of week 35, neoplastic foci were found in antral mucosa in 18 rats of group A which were histologically determined to be adenocarcinomas. Of these 18 rats, the total number of adenocarcinomas was 23, and 22 were very well differentiated, which could be classified as intestinal type according to Lauren classification. Just like human gastric carcinoma, positive staining for survivin was located in cytoplasm of tumor cells (Figure 2). No survivin expression was detected in antral mucosa of normal rats (group B). As shown in Table 2, in antral mucosa of those rats at week 20, survivin expression was positive in 4 of 10 rats. In adenocarcinomas and tissues adjacent to the tumor, the ratio was 78.3 % and 38.9 %, respectively. Compared to normal tissue, the difference was significant (Table 2).

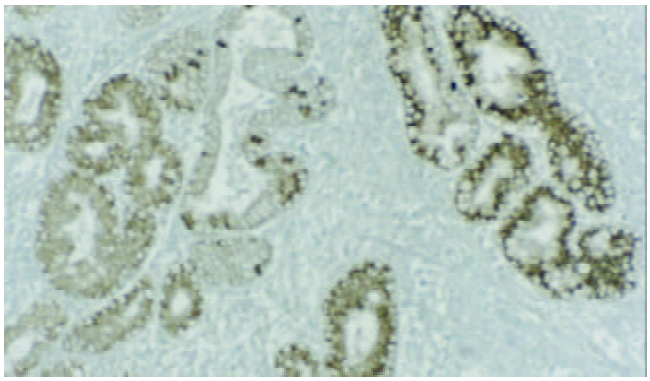

Figure 1 Immunohistochemical staining for the expression of survivin in human gastric carcinoma. Positive staining for survivin was located in cytoplasm (×50).

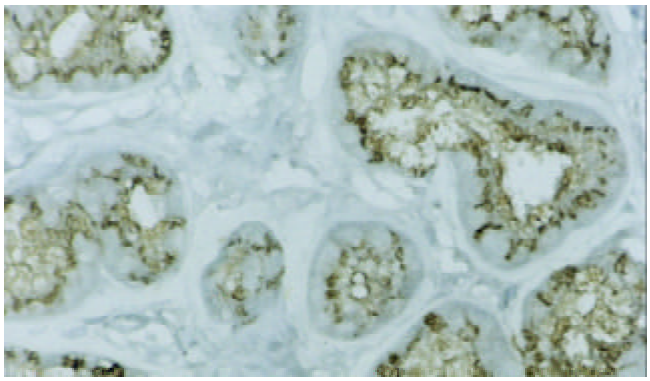

Figure 2 Immunohistochemical staining for the expression of survivin in gastric carcinoma of rat model. Positive staining for survivin was also located in cytoplasm. (×100).

Table 2 Survivin expression in experimental gastric carcinoma

	Cases	Survivin expression	Positive rate(%)
Control (group B)	16	0	0
Group A			
Antral mucosa of rats at week 20	10	4	40%[a]
Adenocarcinomas	23	18	78.3%[b]
Tissues adjacent to tumor	18	7	38.9%[c]

Ten rats of group A were killed at week 20, and the antral mucosa were examined. At week 35, all rats in both group A and B were killed and investigated. Tissues adjacent to tumor were defined as the tissues 5 mm away from the edge of tumor. [a]$P<0.05$ *vs* control group, [b]$P<0.001$ *vs* control group, [c]$P<0.01$ *vs* control group.

DISCUSSION

Survivin is expressed in a series of human cancers, and it has been widely accepted that survivin is highly related to the onset and development of cancer. In this study, we adopted human gastric carcinoma specimens and experimental gastric carcinoma models to discuss the effect of survivin on gastric cancer.

Survivin was expressed in 27 of 56 (48.2 %) cases of human gastric carcinoma tissues and only 1 of 20 (5 %) cases of chronic gastritis. In experimental gastric carcinoma, the positive rate rose to 78.3 %. These data suggest that high expression of survivin is a common phenomenon in gastric cancer and inhibition of apoptosis resulted from survivin expression may play an important role in carcinogenesis.

Our data on human gastric carcinoma proved that the expression of survivin in intestinal type cases is significantly higher than that in diffuse type cases and the expression of survivin is correlated with intestinal histological type. This result is consistent with Lu[15]. The Lauren histological classification has a specific epidemiological significance because the epidemiological study has determined that intestinal type cases are dominant in high risk areas while diffuse type cases are dominant in low risk areas. Substantial data suggest that intestinal type cases are highly related to circumstances and diffuse type cases are related to heredity. At present, Correa' s theory of an atrophy-metaplasia-dysplasia-carcinoma sequence in the development of intestinal type gastric carcinoma has been widely accepted[16-22]. The fact that the expression of survivin in intestinal type was higher than that in diffuse type suggests that survivin plays a more important role in the former and indicate that survivin may be an important factor contributing to the conversion from atrophy to carcinoma. Our animal experiment provided further evidences.

In our animal experiment, 95.7 % of the induced gastric carcinomas were intestinal type, and we did find atrophy and dysplasia lesions during the induction period. These data suggest that our rat model could simulate the development of human gastric carcinoma (intestinal type). We dynamically investigated the expression of survivivn during the induction period and found 4 cases were positive in 10 rats at week 20, and 78.3% was positive in gastric carcinoma. These data indicate a rising trend of survivin expression during the development of gastric cancer, and suggest an important role of survivin expression in tumor formation.

Some scholars concluded that survivin could only be found in tumor[15], but others thought it could be found in precancerous lesions[23,24]. Our results supported the latter. In our experiment, the expression of survivin was positive in some gastritis patients, and in some rats during the induction period, as well as in some tissues adjacent to tumor. Hence, we may conclude that survivin is not only expressed in cancer tissues but also in damaged tissues. The expression of survivin occurs before the formation of adenocarcinomas, and is an early event in carcinoma development.

Recently, some studies have partly explained why survivin was highly expressed in cancer. According to the study of Hoffman *et al*[25], the anti-apoptotic gene, survivin, is a p53-repressed gene. Chromatin immunoprecipitations indicate that wild type p53 binds survivin promoter *in vivo*, which results in transcriptional repression. Mirza *et al*[26] study implicated that wild-type p53 suppresses survivin expression at both mRNA and protein levels. It is widely accepted that mutated p53 loses its function as a tumor inhibitor and this may contribute to the loss of inhibition to survivin. Due to the high incidence of p53 mutation in gastric cancer, we put forward the hypothesis that long term effect of carcinogen should lead to p53 or other important gene damage, which results in survivin expression and apoptosis inhibition. Abnormal apoptosis leads to carcinogenesis.

According to our clinical data, age and prognostic factors such as different tumor size, tumor depth, lymph node metastasis or disease stage have no significant correlation with survivin expression, which indicates that survivin has little impact on tumor biological behavior.

Survivin plays an important role in gastric carcinoma and is a key molecule of cell cycle, mitosis and apoptosis[27]. Moreover, inhibition of survivin function will result in cell apoptosis[28-30]. The antisense oligonucleotide targeting survivin expression sensitizes lung cancer cells to chemotherapy[30]. All these data suggest that survivin may be an attractive target for gastric cancer therapy.

Abstract

AIM: To establish cDNA suppression subtraction library with a high subtraction efficiency by counterpart normal gastric mucosa mixture mRNA subtracting gastric cancer cells mixture mRNA for screening down-regulated genes in gastric carcinoma.

METHODS: RNA of gastric cancer tissues and counterpart normal gastric mucosa were respectively isolated in five patients with gastric cancer, and their mRNA was purified. cDNA suppression subtraction library was established by counterpart normal gastric mucosa mixture mRNA (tester) subtracting gastric cancer tissues mixture mRNA (driver) of five patients with gastric carcinoma. The library plasmids were transformed into competent bacteria DH5a after ligation of the library cDNA fragments with T vectors. Library plasmids were extracted after picking colonies and shaking bacteria overnight. Its subtraction efficiency was confirmed by PCR and reverse hybridization of a nylon filter onto which the colonies of bacteria were transfered with probes of reverse transcription products cDNA of gastric cancer tissues mRNA and counterpart normal gastric mucosa mRNA labeled with α-^{32}P dCTP.

RESULTS: mRNA purified from total RNA of gastric cancer tissues and counterpart normal gastric mucosa in five patients with gastric carcinoma revealed a good quality. cDNA suppression subtraction library constructed for screening down-regulated genes in gastric carcinoma represented a high subtraction efficiency. 86 % of differential expression in down-regulated genes between counterpart normal gastric mucosa and gastric carcinoma was confirmed.

CONCLUSION: cDNA suppression subtraction library with a high subtraction efficiency for screening down-regulated genes in gastric carcinoma is successfully established.

INTRODUCTION

High incidence of 50-80 % LOH (loss of hybridization) in gastric carcinoma cells reveals obvious chromosome fragments loss[1,2], e.g 8p, 18q12.2, 21q22, 1p35-pter of regions of LOH were currently found[2-8]. These suggest the novel tumor suppressor genes in the regions of LOH are involved in gastric tumorigenicity[9]. But these novel tumor suppressor gene candidates have not been cloned. To reach the targets, we screened down-regulated genes in a suppression subtraction cDNA library established by counterpart normal gastric mucous membrane mixture mRNA (tester) subtracting gastric cancer cells mixture mRNA (driver) of five patients with gastric cancer based on the suppression subtractive hybridization (SSH) technique[10]. These down-regulated genes obtained from the library probably are tumor suppressor gene candidates. Up to now, down-regulated genes in gastric cancer cloned from gastric tissues have been seldom documented except CA11, LDOC1[11-13].

MATERIALS AND METHODS

RNA extraction and mRNA purification

RNA of gastric cancer tissues and counterpart normal gastric mucosa was respectively isolated with Trizol (Gibco) in five patients with gastric cancer from Xijing Hospital, Fourth Military Medical University. To ensure good total RNA quality 28S/18S $\geqslant$1.5, samples were immediately placed into liquid nitrogen after being removed intraoperatively, and trituration of the samples must be performed in liquid nitrogen. Then, mRNA was purified in Oligotex mRNA Kit (Qiagen). An equal mRNA mixture of gastric cancer tissues and counterpart normal gastric mucosa in five patients with gastric cancer contributed to driver group (gastric cancer tissues) and tester group (counterpart normal gastric mucosa) respectively. At last, reverse transcription products (the first stranded cDNAs) of mRNA mixture were electrophoresed to evaluate their size range and quality.

Suppression substraction library construction

First-strand was synthesized with 1 μl cDNA synthesis primer (10 μmol· L^{-1}, Clontech) in a mixture containing 2 μg mRNA mixture, 20U AMV, 2 μl 5×first-strand buffer in a final volume of 10 μl at 42 ℃ for 1.5 h. Then, second-strand synthesis was carried out in 10 μl first strand react volume, 4.0 μl 20× second-strand enzyme cocktail, 48.4 μl of sterile H_2O, 1.6 μl dNTP Mix (10 mM· L^{-1}), 16.0 μl 5×second-strand buffer solution for 2 h at 16 ℃. Polymeric reaction was performed at 16 ℃ for 0.5 h after 2 μl (6 units) of T4 DNA polymerase was added into the above reaction volume. The second-strand synthesis was terminated by adding 4 μl of 20×EDTA/Glycogen Mix (Clontech). After phenol:chloroform: isoamyl alcohol (25:24:1) and chloroform: isoamyl alcohol (24:1) extraction twice respectively, and 4 M NH4OAc and 95 % ethanol precipitation of the second stranded cDNAs, the pellet was dissolved in 50 μl of sterile H_2O when precipitate was washed in 80 % ethanol and residual ethanol was evaporated after the supertant was removed.

The second double-stranded cDNA was digested with 15U RsaI in a final volume of 50 μl at 37 ℃ for 1.5 h. Enzyme digestion was terminated by adding 2.5 μl 20×EDTA/Glycogen Mix. After extraction and precipitation of digested second-strand cDNAs, the pellet was dissolved in 5.5 μl of sterile H_2O when precipitate was washed in 80 % ethanol and residual ethanol was evaporated after the supertant was removed.

One μl of digested first-strand cDNAs of normal gastric mucosa was diluted with 5 μl of sterile H_2O. Each 2 μl of the cDNA was acted as tester1-1 and tester1-2 that were respectively mixed with adaptor1 and adaptor 2, and 1 μl T4 DNA ligase (400 $kU \cdot L^{-1}$) in a final volume of 10 μl, while mixture of 2 μl of each tester1-1 and tester1-2 was taken as control (Tester C). Ligation to adaptors completed at 16 ℃ overnight.

Then, 1.5 μl of tester1-1 with adaptor 1 and tester1-2 with adaptor 2 was respectively hybridized with 1.5 μl digested first-stranded driver cDNA of gastric cancer in 1.0 μl 4×hybridization buffer solution at 68 ℃ for 10 h. Tester1-2 hybridization sample was drawn into the pipette tip. Afterwards, 1 μl denatured mixture from 1 μl digested second-stranded driver cDNA, 2 μl H_2O, 1 μl 4×hybridization buffer solution at 98 ℃ was drawn into the pipette tip with a slight air space below the droplet of the above tester1-2 hybridization sample. Sequentially, the entire mixture of pipette tip was transferred to a tube containing the above tester1-1 hybridization sample overnight at 68 ℃. After second hybridization, 200 μl dilution buffer was added into the tube. One μl of tester C was diluted with 1 000 μl of sterile H_2O. 1 μl of diluted tester C and the secondary hybridization sample were amplified with PCR primer 1 and 50×advantage cDNA polymerase mix in a final volume of 25 μl respectively after adaptors were extended at 75 ℃. 3 μl of primary PCR product was diluted with 27 μl of sterile H_2O. 1 μl of diluted primary PCR products was again amplified with nested PCR primer 1, 2R and 50×advantage cDNA polymerase mix in a final volume of 25 μl for 12 cycles.

Analyses of adaptor ligation efficiency and subtraction efficiency by PCR

One 1 μl of tester1-1 and tester1-2 with adaptors was diluted with 200 μl of sterile H_2O respectively. 1 μl of diluted tester1-1 and tester1-2 was repeatedly amplified respectively using G3PDH 3' primer, PCR primer 1 as well as G3PDH 3' primer, G3PDH 5' primer after adaptors were extended at 75 ℃. 1 μl of subtraction cDNA and secondary PCR product of tester C was diluted with 9 μl of sterile H_2O. 1 μl of diluted subtraction cDNA and secondary PCR product of tester C was respectively amplified with G3PDH 3' primer, G3PDH 5' primer. 5 μl of PCR products collected at 18, 23, 28, and 33 cycles was electrophoresed on 2 % agarose gel respectively.

Identification of suppression substraction library

Six μl of secondary PCR product of subtraction cDNA was ligated to T vectors in a mixture containing 2 μl T vectors, 1 μl T4DNA ligase in a final volume of 10 μl at 16 ℃ for 36 h. Then, 5 μl of ligated product was transformed into 100 μl of competent DH5a (stratgene) for electroporation. Competent DH5a transformed by ligated product was grown on LB medium plates. White colonies were placed into LB medium and shaken overnight at 37 ℃. In a large scale, fragments inserted into library plasmids were identified by PCR amplification with SP6 and T7 primers after library plasmids were extracted. Each colony of plasmids with inserted fragments was inoculated twice on a LB medium plate (100 colonies per plate, and one pair of positive and negative controls per plate) and grown until colony diameter reached to 3 mm. At time, colonies were transfered onto a nylon filter (NEN), then the nylon filter was cross-linked by using an UV stratalinker (CL-1000, Upland). Each 200 ng mRNA of the normal mucosa and gastric carcinoma was reverseiy transcripted with 1 μg Oligo $(dT)_{15}$ and super transcriptase II as a probe labeled with α-^{32}PdCTP, hybridized respectively with filters. The filters were exposed to phosphore screen and analyzed.

RESULTS

Identification of mRNA quality

Good total RNA quality was confirmed by 28S/18S ⩾1.5. Size range of reverse transcription product cDNAs was represented in a smear from 0.2-4kb both in gastric cancer and normal mucosa (Figure 1).

RsaI enzyme digestion

Size range of double-strand cDNA without digestion showed a normal size as expected. By comparison, RsaI enzyme digested double-strand cDNA on electrophoresis represented a smear from 0.2-2kb caused by complete digestion (Figure 2).

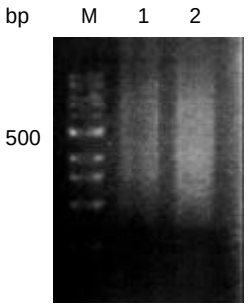

Figure 1 Size range of mRNA on 2 % agarose gel electrophorsis. Normal gastric mucosa mRNA (lane1) and gastric carcinoma mRNA (lane 2). 100 bp size marker (lane M).

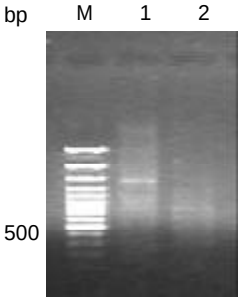

Figure 2 Digested and undigested double strands cDNA products. Undigested double strands cDNA products (lane 1) and RsaI digested double strands cDNA products (lane 2). 100bp size marker (lane M).

Detection of adaptor ligation efficiency and analyses of PCR products

A 0.75 kb band of tester1-1 and tester1-2 PCR product accorded with the theoretic size as expected when they were amplified with G3PDH3' primer and PCR1 primer respectively. The 0.75 kb band intensity of tester1-1 and tester1-2 PCR product also was as same as the band of tester1-1 and tester1-2 PCR product amplified with G3PDH3' and G3PDH5' primers (Figure 3). Secondary PCR product of subtraction sample exhibited a smear from 0.2-2 kb with some distinct bands that were greatly different from that appeared in unsubtraction samples (Figure 4).

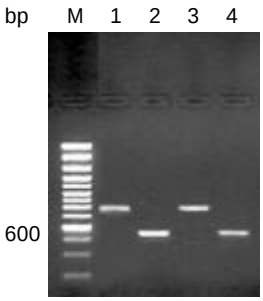

Figure 3 Detection of adaptors ligation efficiency. Tester1-1 was amplified with G3PDH3' primer, PCR primer1 (lane 1) and tester1-1 with G3PDH3', 5' primers (lane 2). Tester1-2 was amplified with G3PDH3' primer, PCR primer1 (lane 3) and tester1-2 with G3PDH3', 5' primers (lane 4). 100 bp size marker (lane M).

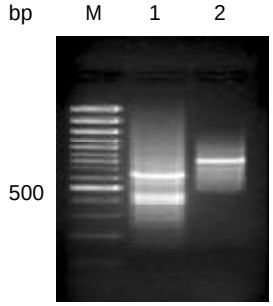

Figure 4 Analyses of PCR products. Secondary PCR products of subtraction samples (lane 1) and unsubtraction samples (lane 2). 100 bp size marker (lane M).

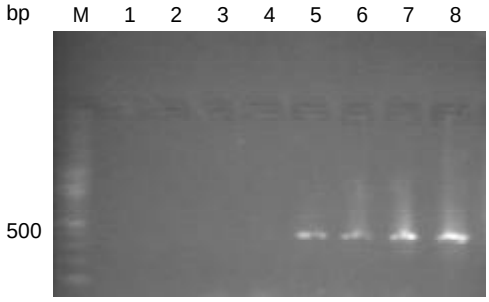

Figure 5 Identification of subtraction efficiency by PCR. G3PDH PCR products of subtracted samples at 18, 23, 28 and 33 cycles (lanes1, 2, 3 and 4) respectively and G3PDH PCR products of unsubtracted samples respectively at 18, 23, 28 and 33 cycles (lanes 5, 6, 7 and 8). 100 bp size marker (lane M).

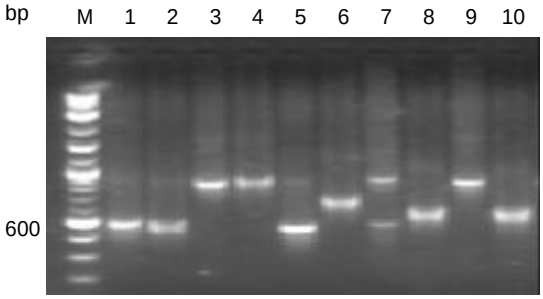

Figure 6 Identification of inserted fragments in plasmids of library by PCR. Inserted fragments in plasmids of library (lanes 1-10). 100 bp size marker (lane M).

Analyses of subtraction efficiency by PCR

G3PDH persistently was expressed at 18, 23, 28 and 33 cycles of PCR and the bands exhibited greater and greater intensity with increasing cycle numbers in unsubtraction control group, but not expressed in subtraction group (Figure 5).

Identification of inserted fragments in plasmids of library by PCR and positive clone by reverse hybridization

PCR products of library plasmids amplified with SP6 and T7 primers on a larger scale showed that each plasmid included one inserted fragment ranging from 300-700 bp (Figure 6). 86 % of down-regulated genes between normal gastric mucosa and gastric carcinoma were confirmed by hybridization of a transferred filter with probes of reverse transcription product cDNAs.

DISCUSSION

Many genes involves in gastric tumorigenicity and tumor metastasis[14-24]. Occurrence and development of gastric carcinoma are closely associated with loss or lower expression of suppressor genes[25,26]. It contributes to a better understanding of the molecular mechanism of gastric tumorigenicity, and the expression profiles of down-regulated genes in gastric carcinoma, as well as cloning of novel genes , especially human stomach-specific gene. The novel genes usually express in lower abundance, and play an important role in cell differentiation and development. We have successfully established the cDNA suppression subtraction library to screen down-regulated genes in gastric carcinoma.

It is an important step to guarantee mRNA quality in constructing cDNA suppression subtraction library with a high subtraction efficiency because it is directly relatd to subtraction efficiency. Good mRNA quality depends on total RNA quality except for mRNA purification. To ensure good total RNA quality of 28S/18S $\geqslant$1.5, samples must be immediately placed into liquid nitrogen after removed intraoperatively, and trituration of samples must be performed also in liquid nitrogen. At last, reverse transcription products (the first stranded cDNAs) of mRNA were electrophoresed to evaluate its size and quality. The mRNA size range should accord with its theoretic value.

Each step for establishing cDNA suppression subtraction library was verified by corresponding methods provided by Clontech to ensure suppression subtraction efficiency. Many reports have shown that the suppression subtractive technique has successfully constructed a lots of cDNA suppression subtraction library with high efficiency, and cloned many novel genes[27-45]. Our experiments were carried out strictly according to the rule. Identifications of experimental results step by step revealed complete enzyme cutting, and enzyme digested size of double-strand cDNA accorded with theoretic size range, enough ligation of the digested fragments of double-strand cDNA and adaptors. It demonstrated that, in cDNA suppression subtraction library with high subtractive efficiency, G3PDH was persistently expressed at 18, 23, 28 and 33 cycles of PCR and the bands exhibited greater and greater intensity with increasing cycles in unsubtraction control group, but not expressed in subtraction group.

After establishment of the cDNA suppression subtraction library with a high efficiency, maximum cloning of novel down-regulated genes in gastric cancer depends on highly efficient plasmid transformation method and competent bacteria cells. Lower abundance of gene fragments will be likely cloned if commercially availiable high concentration competent cells are used ($1\times10^{12}\cdot L^{-1}$) for transformation with a high transformation rate ($1\text{-}2\times10^{8}$/μg PUC19).Use of electroporation method can greatly enhance library plamids transformation rate by obtaining 10^{8}/μg PUC19. Additionally, it especially fits transformation of the small fragments produced in cDNA suppression subtraction library.

Several identified methods for cDNA suppression subtraction library were described below. The expression pattern of individual clones could be confirmed by Northern blot analysis. 10-20 clones were randomly picked from the subtracted library as probes on Northern blots. If less than two clones were confirmed as differentially expressed genes, the differential screening procedure should be performed to eliminate false positives. Dot or Southern blot analysis was performed. Secondary PCR products of the unsubtracted tester cDNA, the unsubtracted driver cDNA, and the subtracted cDNA were electrophoresed on a 1.5 % agarose gel, transferred onto nylon filters and hybridized respectively with differential expressing genes as probes labeled with α-^{32}PdCTP. But more background bands of unpredicted sizes often appeared. Nylon filters onto which the library colonies of bacteria were transferred and hybridized with reverse transcript product cDNA of gastric cancer tissues mRNA and normal gastric mucosa mRNA were used as probes labeled with α-^{32}PdCTP respectively. This method has been extensively used. The disadvantage is that only a high abundance of mRNA can be detected. Another approach can bypass the problem of losing a low-abundance of sequences. By this method, the subtracted library was hybridized with forward- and reversely-subtracted cDNA probes. To make reversely-subtracted probes, subtractive hybridization was performed with the original tester cDNA as a driver and the driver cDNA as a tester. Plasmids colonies that are truly differentially expressed will hybridize only with the forward-subtracted probe. Plasmids colonies that hybridize with the reversely-subtracted probe may be considered as the background. This approach requires one additional step: before it can be used as probes, the forward- and reversely-subtracted probes must undergo restriction enzyme digestion to remove the adaptor sequences. Despite their small size, these adaptors can cause a very high background when the subtracted probes are hybridized to the subtracted cDNA library.

Abstract

AIM: Now many countries have developed cancer therapy with heavy ions, especially in GSI (Gesellschaft für Schwerionenforschung mbH, Darmstadt, Germany), remarkable results have obtained, but due to the complexity of particle track structure, the basic theory still needs further researching. In this paper, the genotoxic effects of heavy ions irradiation on SMMC-7721 cells were measured using the single cell gel electrophoresis (comet assay). The information about the DNA damage made by other radiations such as X-ray, γ-ray, UV and fast neutron irradiation is very plentiful, while little work have been done on the heavy ions so far. Hereby we tried to detect the reaction of liver cancer cells to heavy ion using comet assay, meanwhile to establish a database for clinic therapy of cancer with the heavy ions.

METHODS: The human hepatoma cells were chosen as the test cell line irradiated by 80Mev/u $^{20}Ne^{10+}$ on HIRFL (China), the radiation-doses were 0, 0.5, 1, 2, 4 and 8 Gy, and then comet assay was used immediately to detect the DNA damages, 100-150 cells per dose-sample (30-50 cells were randomly observed at constant depth of the gel). The tail length and the quantity of the cells with the tail were put down. EXCEL was used for statistical analysis.

RESULTS: We obtained clear images by comet assay and found that SMMC-7721 cells were all damaged apparently from the dose 0.5Gy to 8Gy (*t*-test: $P<0.001$, *vs* control). The tail length and tail moment increased as the doses increased, and the number of cells with tails increased with increasing doses. When doses were higher than 2Gy, nearly 100 % cells were damaged. Furthermore, both tail length and tail moment, showed linear equation.

CONCLUSION: From the clear comet assay images, our experiment proves comet assay can be used to measure DNA damages by heavy ions. Meanwhile DNA damages have a positive correlation with the dose changes of heavy ions and SMMC-7721 cells have a great radiosensitivity to $^{20}Ne^{10+}$. Different reactions to the change of doses indicate that comet assay is a useful tool to detect DNA damage induced by heavy ions.

INTRODUCTION

During the past few decades, radiation research has developed into specialized sub-disciplines, from basic physics and chemistry to tumor biology and experimental radiation therapy[1]. Although the radiobiological effects are extensively investigated for X-ray and γ-ray, little work has been directed towards heavy ion beams. With the exploration of the outer space, the research of high linear energy transfer (LET) has attracted more and more attention. Since heavy ions were first applied in the mid-1970s to cure cancer at Bevalac of Lawrence Berkeley Laboratory (LBL), United States, promising results have been reported when compared with the conventional radiotherapy for soft tissue sarcoma, bone sarcoma and prostate cancer[2]. Now scientists in many countries (GSI in Germany, HIMAC in Japan[25,26], HIRFL in China) have designed accelerators to deliver beams of ions for the treatment and started basic researches of cancer therapy with heavy ions such as carbon, neon, oxygen and argon.

The aim of our present study was to investigate DNA damages induced by heavy ions by comet assay. The theoretical value was then compared to responses to external X-ray or γ-ray and other irradiations, so that we could establish the data base for clinical therapy.

Comet assay, the alkaline version in particular, has become a very popular method for the analysis of DNA damage caused by various chemical and physical agents because of its simplicity and rapidity[4-10]. DNA damages consisted of DNA strand breakage, alkali-labile sites and incomplete excision repair sites[11]. Although the direct DNA-breaking capacity can be estimated by alkaline elution, nick translation and alkaline single cell gel electrophoresis (SCGE), SCGE has been shown to be more sensitive than the former two. It had been proved that the sensitivity of SCGE is significantly higher than that of cytokinesis-blocked micronucleus (CBMN) test[12]. The most important point is that comet assay is an electrophoretic technique, which allows measurements of DNA damages as well as DNA repair rates on an individual cell. Therefore its contribution to DNA damages by irradiating cells with heavy ions at once or after a while can be reflected as initial damages or residual DNA damages, if time is allowed for enzymatic repairs of initial DNA strand break. In our lab, we focused on the radiobiological effects of heavyions on tumor cells. Previous experiments were mainly on cell survival measurements and could not explain the underlying radiosensitization mechanism at molecular level[2]. To verify the radiobiological effects of heavy ions on cellular DNA, SCGE also called comet assay was used to directly measure DNA damages in cells.

MATERIALS AND METHODS

Cells and cell culture

Human hepatoma cells SMMC-7721, purchased from Second Military Medical University in Shanghai, were cultivated in

RMIP-1640 medium (Gibco product) supplemented with 15 % calf serum in a standard incubator at 37 ℃. One passage of cells every 2-3 days and change of the medium everyday were performed, to ensure the cells growth in good conditions. Two days before the irradiation, the cells were shifted to Φ 35 mm petri-dishes, each had 2 ml cell suspension, and the density of the cells was 5×10^4 cells/ml. Each dose had 5 petri-dishes. Before irradiation, cells in each petri-dish were examined under the inverted light microscope to select materials good in growth and even in density, and medium 1640 in petri-dishes was removed, only Dulbecc' s phosphate -buffered saline medium (PBS) was left to keep the moisture of the cells when irradiated.

Selection of ion beams

Irradiation was performed using $^{20}Ne^{10+}$ with energy of 80 Mev/u and intensity of 0.00136nA (2.1×10^6p/s). The cells were irradiated at the doses of 0, 0.5, 1, 2, 4, 8Gy. The doses of cells were measured by an air ionization chamber.

Preparation of single cell suspension and comet assay

As soon as irradiation ended, the cells were washed and collected, the final concentration of cells was adjusted to $(5\text{-}10)\times10^6$ by adding Dulbecc' s phosphate -buffered saline medium (PBS) to the single cell suspension.

The alkaline version of comet assay was carried out based on the work of Ostling and Johansson with some minor modifications as followings: On the day of electrophoresis, an aliquot of 10 μl freshly prepared suspension of cells was mixed with 30 μl 0.5 % low- melting-agarose in Dulbecc' s PBS (pH 7.4). The mixture was layered on top of an ordinary microscope slide precoated with 0.5 % normal-melting -agorose, which was allowed to dry at room temperature protected from dust and other particles. After low-melting-agarose was solidified in a refrigerator for 10 minutes, the coverslip was carefully removed and the slide was gently immersed in a freshly prepared lysing solution (2.5MNaCl, 10mM Tris, 1 % sodium lauryl sarcosinate, 100mM Na_2EDTA, with 1 % Triton-100 and 10 % DMSO added just before use). From this moment until the end of neutralization, all steps needed to avoid the sunlight.

After lysis for 1-1.5 h, the microscopy slides were transferred to electrophoresis session, 18 microscopy slides from 6 samples (3 slides/each sample) were randomly placed in a electrophoretic unit.

After 20-30 minutes of DNA unwinding in electrophoresis buffer (1 mM EDTA-Na_2, 300 mM NaOH, pH>13), single cell gel electrophoresis was performed in the same buffer (20 min, 20 V, 300 nA). After electrophoresis the slides were neutralized with 0.4 M Tris buffer (pH7.5).

Evaluation of DNA damage

The microscopy slides were stained with ethidium bromide in water (40 μg/ml, 50 μl/slide). After application of a coverslip was removed, each slide was examined at 10×20 magnification in a fluorescence microscope (excitation filter: 400nm, barrier filter: 590nm). 100-150 cells per dose-sample (30-50 cell were randomly observed at constant depth of the gel, avoiding the edges of the gel on each of three replicate slides). The tail length and the quantity of the cells with the tail were put down, at the same time, photos were taken with 135# black and white film (ISO 400). Then analysis was done using EXCEL.

RESULTS AND DISCUSSION

Formation of comet assay images-DNA loops and alkaline unwinding

The comet assay is attractive for many reasons. Apart from being a quick, simple, sensitive, reliable and fairly inexpensive way of measuring, it also produces appealing images.

There are two explanations about what the comet tails consist of. One is that it is a fragment DNA, the other is that the length of such a fragment is about 1 mm, but the length of the tail of a comet is a few percentages of it[13-16], as to our experiment the longest mean length of tail was no more than 200 μm. Nuclear DNA is not a tangle of string, even after treatment with detergents and a strong salt solution, as in the SCGE procedure, the nuclear (or nucleoid) had a structure, the DNA was organized as loops, which retained the super coils that were contained in the nucleosome. Cook *et al*[17] deduced the presence of supercoiled loops and then they observed that, when DNA was broken by irradiation, supercoiling was relaxed and loops spilled out into a ' halo' around the nucleoid. By analogy, it is assumed that the Comet tail is made up of relaxed loops, and that the number of loops in the tail indicates the number of DNA breaks.

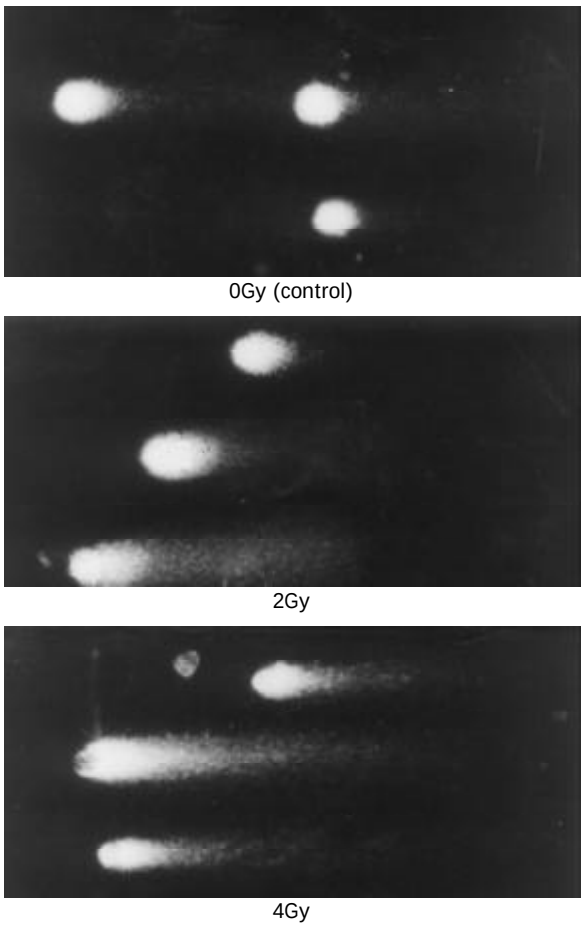

Figure 1 Comet assay image at different doses.

The alkaline comet assay can detect DNA breaks including single and double DNA strand breaks, and AP sites, which are alkali-labile and probably converted to breaks while DNA is in the electrophoretic solution at high pH[14-16]. The present comet assay is generally practiced including incubation of DNA at high pH before and during electrophoresis, different from the original work of Ostling and Johansson who employed near-neutral pH. Collins AR[13] proved that both the neutral and alkaline methods could detect low levels of DNA damage, however, the breaks by higher levels of damage were more clearly resolved from the head under alkaline conditions[18]. Thus in our experiment, the alkaline version was used.

Furthermore, breaks will be transiently present when cells repair lesions via base excision or nucleotide excision so that

a high level of breaks in the Comet assay may indicate either severe damage or efficient repair[13]. In fact, much useful information can be obtained by exploiting cellular repair to produce DNA breaks and thus to reveal or amplify the effect of radiation that otherwise may not show positive effects by the comet assay. This will be discussed in our later work on the repair effects of heavy ions.

DNA damage caused by heavy ions

The SCGE test or comet assay is a straightforward visual method for the detection of DNA damage of cells in interphase. This technique is especially sensitive in detecting DNA single-strand breaks, alkali-labile damage and excision repair sites in individual cells[13-16]. The Comet assay has been widely applied in the following fields: radiation biology[5-6,9-12,19], excisable DNA damage, DNA cross-links[20], oxidative damage[21,22], genetic toxicology and apoptosis[23,24].

Ionizing radiation is a ubiquitous environmental agent. Its physiochemical interaction with cellular DNA produces a variety of primary lesions, such as single-strand breaks (SSB), double-strand breaks (DSB), DNA-DNA and DNA-protein crosslinks, and damage to purine and pyrimidine bases. And using ionizing radiation may avoid complications of drug metabolism, intracellar distribution, membrane permeability and drug efflux. Although the technique of SCGE is very sensitive to ionizing radiation, information about DNA damage made by other radiations such as X-ray[10,12], γ-ray[8,9], UV[9] and fast neutron[19] irradiation is very plentiful, little work has been done on heavy ions so far.

Microdosimetric considerations suggest that, in a given type of radiation, the yield DNA damage must be proportional to dose, so that besides the influence of changing repair efficiency, the magnitude of the dose might not be expected to be critical in comparison of the results. Heavy ion is a kind of high LET (Linear Energy Transfer) irradiation, as emphasized long ago by Lea, high-LET radiation could, through the increased frequency of DSB in close proximity, cause interactive damages and misrepair[27-28]. We anticipated that heavy ions probably had strong effects on the cellular DNA, but we wonder if it can make the linear equation after irradiation by heavy ions.

In our experiment, the data for DNA damages induced by heavy ions at the doses of 0-8Gy are presented in Table 1. The dose-response curves for tail length and tail moment (the fraction of DNA in the tail multiplied by tail length) are shown in Figure 2. We could see tail length and tail moment showed linear equation. It proved that SMMC-7721 cells have high radiosensitivity to heavy ions and comet assay is very useful to detect DNA damages induced by heavy ions.

Figure 3 shows the change of tail DNA as the dose increased. It was found that almost 100 % cells were damaged when the dose reached at 2Gy. But the details were unknown about how badly DNA was damaged when the dose was higher than 2Gy. To completely evaluate DNA damages by different doses, comets of every dose-sample were sorted visually into classes 0-4, representing increasing amount of damage. Figure 4, result shows that with increase of the dose, slighter damage of DNA tail (class 0-2) converted to more severe change of DNA (DNA migrated from the head to form longer and longer tail).

We should pay more attention to the dose of 2Gy, which is the conventional choice of γ-ray radiotherapy. At the dose of 2 Gy, 100 % cells were damaged, with different grade of DNA damage (classes 1-4). Among them nearly 25 % cells were badly damaged. It is known that a central phenomenon in radiobiology is the efficiency of densely ionizing radiation for cellular effects. As in our experiment, chromosomal aberrations or cell killing occurred on these badly damaged cells[27-30, 33-35]. Additionally, we noticed that nearly 80 % cells were most severely damaged (class 4) at the dose of 8Gy. It showed that 8Gy might be or near the highest dose that the cells could withstand.

Table 1 Values of damages detected by Comet assay after 80Mev/u $^{20}Ne^{10+}$ irradiation

Dose Gy	Tail length mean ±S.E. μm	Tail DNA mean ±S.E %	Tail moment mean ±S.E.	*t*-test *P*
0	29.44±1.46	38.50±3.50	11.53±1.45	
0.5	54.18±11.74	59.21±9.21	33.02±11.80	2.06227E-07
1	90.16±6.66	85.54±2.21	76.96±3.44	8.7291E-21
2	115.09±3.26	100.00±0.00	115.09±3.25	6.97944E-31
4	134.17±8.18	98.86±1.07	134.17±8.10	4.48617E-68
8	194.08±15.58	100.00±0.00	194.08±15.58	6.4087E-104

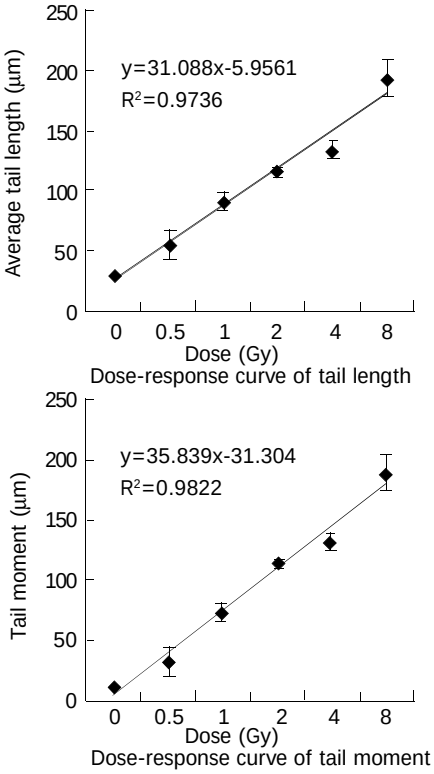

Figure 2 Curve of tail length and tail moment.

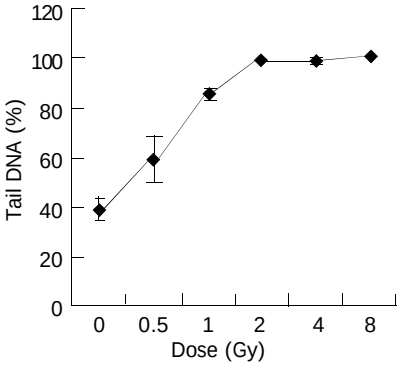

Figure 3 Dose-response curve of tail DNA.

One thing to be mentioned here is that the relative biological effectiveness (RBE) tends to increase with linear energy transfer (LET). For very heavy ions with LET in excess of about 100-200 kev/μm, a more complex dependence on particle track structure emerges[31,32]. Therefore, the study on particle track structure is very important for further research.

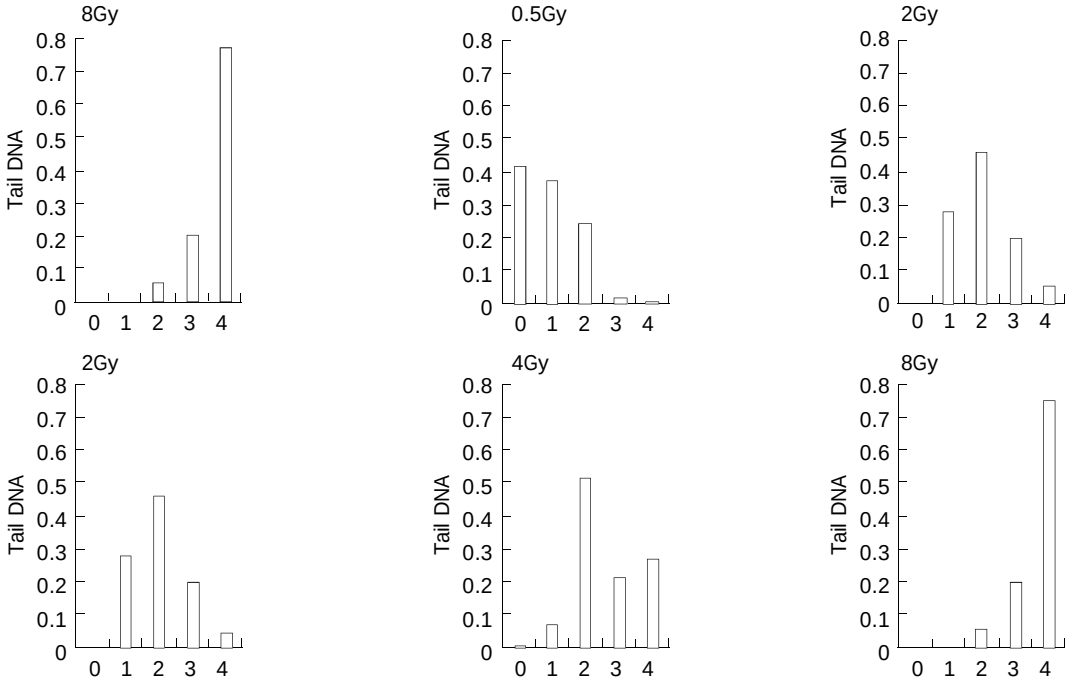

Figure 4 Comet class at the dose of 0-8Gy of heavy ions irradiation.

Abstract

AIM: To prepare and characterize polyclonal antibodies against aldose reductase-like (ARL-1) protein.

METHODS: ARL-1 gene was inserted into the *E. coli* expression vector pGEX-4T-1$(His)_6$C and vector pQE-30. Recombinant ARL-1 proteins named ARL-$(His)_6$ and ARL-GST were expressed. They were purified by affinity chromatography. Sera from domestic rabbits immunized with ARL-$(His)_6$ were purified by CNBr-activated sepharose 4B coupled ARL-GST. Polyclonal antibodies were detected by Western blotting.

RESULTS: Recombinant proteins of ARL-$(His)_6$ with molecular weight of 35.7 KD and ARL-GST with molecular weight of 60.8 KD were highly expressed. The expression levels of ARL-GST and ARL-$(His)_6$ were 15.1 % and 27.7 % among total bacteria proteins, respectively. They were soluble, predominantly in supernatant. After purification by non-denatured way, SDS-PAGE showed one band. In the course of polyclonal antibodies purification, only one elution peak could be seen. Western blotting showed positive signals in the two purified proteins and the bacteria transformed with pGEX-4T-1$(His)_6$C-ARL and pQE-30-ARL individually.

CONCLUSION: Polyclonal antibodies are purified and highly specific against ARL-1 protein. ARL-GST and ARL-$(His)_6$ are highly expressed and purified.

INTRODUCTION

Aldose reductase (AR) is a NADPH-dependent enzyme that is involved in diabetic complications[1-17]. Some reports showed that AR was induced in rat hepatoma, suggesting that it may be essential for detoxifying harmful metabolites produced by fast growing cancer cells[18-27]. Partial sequence determination of a protein induced in rat hepatoma called Spot 17 showed that it was highly homologous to the rat AR[28,29]. Cao *et al*.[22] found about 29 % of liver cancers over-expressed AR. Moreover, they identified a novel human protein that was highly homologous to AR, then submitted it to GenBank™ (HARL U37100). This protein, known as ARL-1, consists of 316 amino acids, the same size as AR, and its amino acid sequence is 71 % identical to that of AR. About 54 % of hepatocellular carcinoma (HCC) over-express ARL-1 gene. These suggest ARL-1 might be related to liver cancers.

ARL-1 is a novel gene, its function and exact relationship with liver cancers are unclear. In order to clarify the role of ARL-1 in HCC, two recombinant proteins of ARL-$(His)_6$ and ARL-GST were expressed, and highly specific polyclonal antibodies against ARL-1 protein were prepared.

MATERIALS AND METHODS

Restrictive endonuclease and T4 DNA polymerase enzymes were purchased from TaKaRa Biotech Corp. Glutathione sepharose 4B, CNBr-activated sepharose 4B and pGEX-4T-1 $(His)_6$C were obtained from Pharmacia Biotech. Rainbow markers and mid-range protein molecular weight markers were obtained from Amersham Pharmacia Biotech and Promega, respectively. PVDF membrane was from Schleicher & Schüll. T4 DNA ligase and GeneRuler™ 100 bp DNA ladder plus were products of MBI Fermentas. TALON^R metal affinity resin was obtained from Clontech. Freund' s adjuvant incomplete and Freund' s adjuvant complete were purchased from Sigma. *E.coli* strains were from Stratagene. Horseradish peroxidase (HRP)-conjugated anti-rabbit secondary antibody was from New England Biolabs Inc.

The following primers used in this study were made by HaoJia Corp: cg gaa ttc atg gcc acg ttt gtg gag c, cg ctc gag tca ata ttc tgc atc gaa ggg according to GenBank™ (accession number HARLU37100).

RT-PCR to subclone cDNA of ARL-1

According to the reference[22], cDNA of ARL-1 was obtained by RT-PCR (data not shown).

Expression of ARL-1 in E. coli

ARL-1 polymerase chain reaction-amplified products were inserted into the *E. coli* expression vector pGEX-4T-1$(His)_6$C, and their proteins would be translated in-frame from the vector' s start codon. The plasmid DNA was then transformed into bacteria host BL21. Induction of expression of ARL-1 inserts and purification of the recombinant proteins named ARL-GST were done according to the manufacturer' s manual. Briefly, bacteria growing to A_{600}=0.4 were induced by 0.05 mM isopropyl-1-thio-β-D-galactopyranoside at 30 ℃ overnight. Cells were harvested and lysed by sonication. After centrifugation to remove debris, the supernatant was mixed with a 50 % slurry of glutathione sepharose 4B, which bound to the glutathione S-transferase (GST) at the amino terminus of the recombinant protein. The slurry was then loaded onto a column and eluted with 5 bed volumes of elution buffer (10 mM reduced glutathione in 50 mM Tris-HCL, pH 8.0). Fractions of 500 μL were collected, and samples from the column were analyzed in 15 % SDS-polyacrylamide gel electrophoresis. Fractions containing the recombinant protein ARL-GST were stored at -20 ℃.

We subcloned ARL-1 gene into another *E. coli* expression vector pQE-30 (Qiagen), expressed another recombinant protein named ARL-$(His)_6$. According to the user manual, ARL-$(His)_6$ was purified with TALON^R metal affinity resin whose cobaltions bound to the 6-histidine residues at the amino terminus of the recombinant protein. Briefly, TALON^R metal affinity resin was saturated with a bacterial polyhistidine-tagged GFPuv lysate in extraction buffer (pH 8.0). The resin was then washed twice with 5 mL of wash buffer (pH 7.0). At last, bound protein was eluted by washing three times with 1 mL elution buffer (pH 7.0), a sample of each eluate was analyzed by electrophoresis on a 15 % SDS-polyacrylamide gel to verify the purity of elution protein. The purified ARL-$(His)_6$ was stored at -20 ℃.

Preparation of polyclonal antibodies against ARL-1 protein

Domestic rabbits were injected with 0.4 mg recombinant protein ARL-$(His)_6$ with Freund' s complete adjuvant. Three weeks later, they were injected with 0.16 mg ARL-$(His)_6$ with Freund' s incomplete adjuvant, which was repeated four times at 2-week intervals. After a little serum was collected from rabbit ear and proved positive by double agar diffusion test, rabbit sera were taken by carotid intubation and stored in 0.1 % sodium azide at -20 ℃.

According to the manufacturer' s manual, polyclonal antibodies against ARL-1 protein were purified with CNBr-activated sepharose 4B. Firstly, rabbit sera were filtered through a 0.22 μM filter and diluted one to four times with phosphate-buffered saline (PBS, pH 7.4). Secondly, the gel was prepared with 1mM HCL. The purified recombinant protein ARL-GST was then coupled with the prepared gel in coupling buffer (0.1M $NaHCO_3$, pH 8.3, containing 0.5M NaCL). Finally, the prepared rabbit sera were mixed with the sepharose coupled ARL-GST in a stopped vessel. The mixture was rotated end-over-end overnight at 4 ℃ and subsequently stood at room temperature for hours. The gel was washed with 1×PBS (pH 7.4), 2M NaCL in 1×PBS (pH 7.4) and 1×PBS (pH 4.5) till the OD_{280} of washed solution was zero, respectively. At last, it was eluted with 0.1M glycine (pH 2.8). The polyclonal antibodies were collected in 0.05 mM Tris-base (pH 9.5) and stored in 0.1 % sodium azide at -20 ℃.

Western blotting

All plasmids including pGEX-4T-1(His)$_6$C-ARL, pGEX, pQE-30-ARL and pET-CTF that encoded protein ARL-GST, GST, ARL-$(His)_6$ and CTF-$(His)_6$, were transformed to BL21, respectively. After bacteria grew to A_{600}=0.4, they were induced by 0.05 mM isopropyl-1-thio-β-D-galactopyranoside at 37 ℃ for 3 h. A 1/4 volume of SDS sample buffer containing Tris-HCl 0.33 mol· L^{-1}, 10 % SDS (w/v), 40 % glycerol (v/v), and 0.4 % bromophenol blue was added to cell lysates above and purified ARL-$(His)_6$ and ARL-GST. After being boiled for 5-10 min, 10 μg protein was electrophoresed on 15 % SDS-polyacrylamide gel. The protein was transferred to PVDF membrane, which was then blocked for 1 h at room temperature with 5 % BSA in TBST (100 mmol/L Tris-HCl and 0.9 % NaCl containing 0.05 % Tween-20). The blots were incubated with the primary polyclonal antibodies against ARL-1 protein (1:2 000 in TBST) and subsequently with HRP-labeled second antibody (1:5 000 in TBST) at room temperature for 1 h, respectively. At last, immunoreactive signals were visualized by DAB in 0.03% H_2O_2.

RESULTS

Construction of pGEX-4T-1(His)$_6$C-ARL and pQE-30-ARL

The recombinant plasmids were identified by restrictive endonuclease and/or polymerase chain reaction. All products of pGEX-4T-1(His)$_6$C-ARL amplified by polymerase chain reaction and digested by *EcoR*I only or *EcoR*I and *Xho*I in combination, underwent 1.5 % agarose electrophoresis. The expected 950 bp could be seen, which was ARL-1 gene (Figure 1). In the same way, pQE-30-ARL was identified by restrictive endonuclease. All fragments were expected including 4.5kb fragment of pQE-30-ARL which was digested by *HindIII* alone, 0.7kb and 3.8kb fragments of pQE-30-ARL digested by *BamH*I only, and 3.4kb, 0.7kb and 0. 3kb fragments of pQE-30-ARL digested by *BamH*I and *HindIII* in combination (Figure 2).

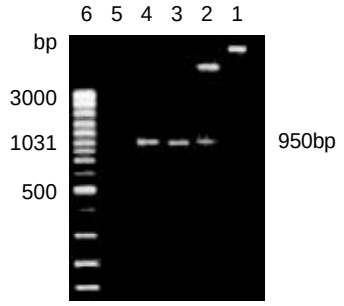

Figure 1 Recombinant plasmid pGEX-4T-1(His)$_6$C-ARL was identified by restrictive endonuclease and polymerase chain reaction (1.5 % agarose electrophoresis). Lane 1: The recombinant plasmid pGEX-4T-1(His)$_6$C-ARL digested by *EcoR*I only, about 5.9 kb fragment could be seen; Lane 2: The recombinant plasmid pGEX-4T-1(His)$_6$C-ARL digested by *EcoR*I and XhoI, two fragments of 5.0 kb and 950 bp could be seen; Lane 3: pGEX-4T-1(His)$_6$C-ARL being template, 950 bp was amplified by polymerase chain reaction; Lane 4: positive control of PCR; Lane 5: negative control of PCR; Lane 6: GeneRuler™ 100 bp DNA ladder plus.

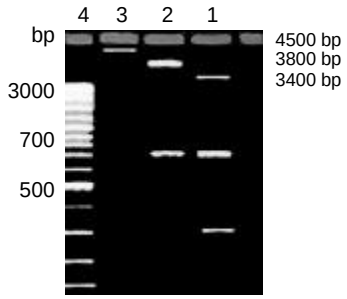

Figure 2 Recombinant plasmid pQE-30-ARL was identified by restrictive endonuclease (1.5 % agarose electrophoresis). Lane 1: 3.4 kb and 0.7 kb and 0.3 kb fragments of pQE-30-ARL digested by *BamH*I and *HindIII* together; Lane 2: 0.7 kb and 3.8 kb fragments of pQE-30-ARL digested by *BamH*I only; Lane 3: 4.5 kb fragment of pQE-30-ARL digested by *HindIII* alone; Lane 4: GeneRuler™ 100 bp DNA ladder plus.

Expression of recombinant proteins ARL-GST and ARL-$(His)_6$

The transformed pGEX-4T-1(His)$_6$C-ARL BL21 induced by 0.05 mM isopropyl-1-thio-β-D-galactopyranoside could express the protein with molecular weight of 60.8 KD, which was recombinant protein ARL-GST. Its expression level was 15.1 % of total bacteria proteins. Under the same conditions, the transformed pQE-30-ARL BL21 expressed recombinant protein ARL-$(His)_6$ with molecular weight of 35.7 KD. Among total bacteria proteins, ARL-$(His)_6$ expression level was 27.7 %. Two recombinant proteins were purified by non-denatured method because they were soluble, predominantly in supernatant. After purification, only one band could be seen,

indicating that ARL-GST and ARL-$(His)_6$ were highly purified (Figures 3 and 4).

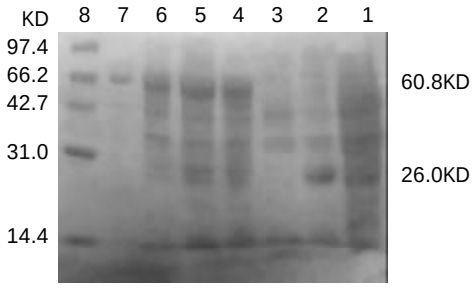

Figure 3 The transformed pGEX-4T-1$(His)_6$C-ARL BL21 induced by 0.05 mM isopropyl-1-thio-β-D-galactopyranoside. Lane 1: BL21 transformed with pGEX-4T-1$(His)_6$C, no IPTG induced; Lane 2: BL21 transformed with pGEX-4T-1$(His)_6$C, IPTG induced, GST (26KD) was expressed; Lane 3: BL21 transformed with pGEX-4T-1$(His)_6$C-ARL, no IPTG induced; Lane 4: BL21 transformed with pGEX-4T-1$(His)_6$ C-ARL, IPTG induced, recombinant protein ARL-GST (about 60.8 KD) was expressed; Lane 5: supernatant; Lane 6: pellet; Lane 7: purified ARL-GST; Lane 8: mid-range protein molecular weight markers.

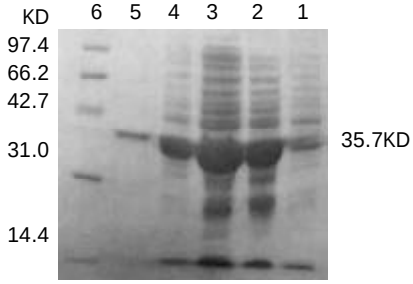

Figure 4 The transformed pQE-30-ARL BL21 induced by 0.05 mM isopropyl-1-thio-β-D-galactopyranoside. Lane 1: BL21 transformed with pQE-30-ARL, no IPTG induced; Lane 2: BL21 transformed with pQE-30-ARL, IPTG induced, ARL-$(His)_6$ (35.7KD) could express; Lane 3: supernatant; Lane 4: pellet; Lane 5: purified ARL-$(His)_6$; Lane 6: mid-range protein molecular weight markers.

Preparation of polyclonal antibodies against ARL-1 protein

Purification of polyclonal antibodies against ARL-1 protein: The rabbit sera immunized with ARL-$(His)_6$ were purified by CNBr-activated sepharose 4B coupled ARL-GST. After mixed with sera, washed with solution as described above, the gel was eluted with 0.1 M glycine (pH 2.8), only one elution peak could be seen in the elution curve (Figure 5), suggesting that polyclonal antibodies against ARL-1 protein were highly purified.

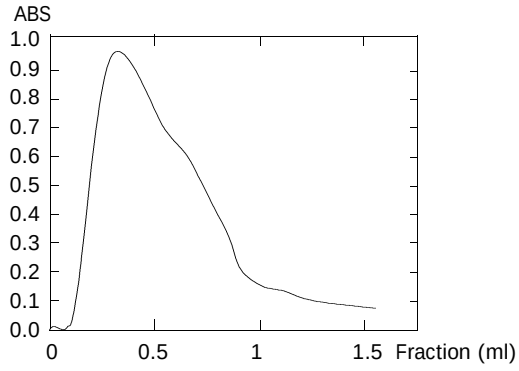

Figure 5 The gel eluted with 0.1 M glycine (pH 2.8).

Specification of polyclonal antibodies against ARL-1 protein: Proteins of all bacteria described were tested by Western blotting using polyclonal antibodies against ARL-1. Figure 6 displays that positive signals could be seen in the two purified proteins and the bacteria transformed with pGEX-4T-1$(His)_6$C-ARL and pQE-30-ARL individually.

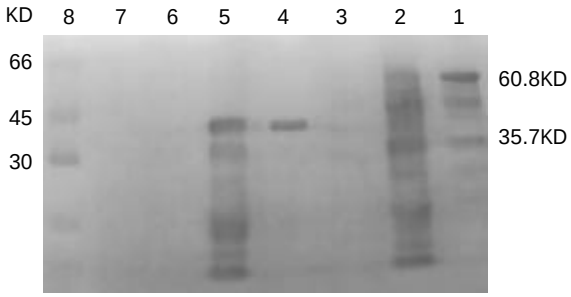

Figure 6 Proteins of all bacteria described were tested by Western blotting using polyclonal antibodies against ARL-1. Lane 1: purified ARL-GST; Lane 2: BL21 transformed with pGEX-4T-1$(His)_6$C-ARL; Lane 3: BL21 transformed with pGEX-4T-1$(His)_6$C; Lane 4: purified ARL-$(His)_6$; Lane 5: BL21 transformed with pQE-30-ARL; Lane 6: BL21 transformed with pET-CTF; Lane 7: BL21; Lane 8: Rainbow markers.

DISCUSSION

The cDNA of ARL-1 gene was cloned and identified by Cao *et al*. The amino acid sequence of this protein called ARL-1 was 71 % identical to that of AR. It is more homologous to a group of AR-like proteins. Its amino acid sequence was 80 %, 82 %, 83 %, and 94 % identical to that of the mouse vas deferens protein (MVDP), the mouse fibroblast growth factor-regulated protein (FR-1), the Chinese hamster ovary (CHO) reductase, and Spot 17 in rat hepatoma, respectively[22].

ARL-1 is a new member of AKR1B group of aldoketo reductases including AR, MVDP, FR-1, CHO reductase, Spot 17, etc. The gene expression spectrum is not the same. MVDP gene was primarily expressed in the vas deferens and the adrenal gland[30-37]. AR, was different. In adults, AR message was most abundant in the prostate, testis, skeletal muscle, and the heart. Substantial amounts were found in the ovary, small intestines, colon, thymus, spleen, kidney, and the placenta. Lower levels were found in the brain, lung, leukocytes, and the pancreas. Of the four fetal tissues tested, AR mRNA was most abundant in the kidneys, a substantial amount was found in the brain, and a low level in the lung and liver[38,39]. FR-1 was expressed quite strongly in the small intestines, and it was expressed in testis, ovary, brain, heart, liver, kidney, and muscle, but FR-1 expression has not been screened in urinary bladder and jejunum[40-44]. CHO reductase mRNA was quite abundant in the urinary bladder and the jejunum, this gene was also expressed in the testis and the ovary. However, CHO reductase mRNA was not detectable in brain, heart, liver, kidney, and muscle[45-47]. ARL-1 was not expressed in many tissues. Its message was most abundant in the small intestines and colon, and a low level of its mRNA was found in the liver, thymus, prostate, testis, and skeletal muscle. No ARL-1 mRNA was detected in the four fetal tissues tested including the kidney, brain, lung and liver. Moreover, ARL-1 mRNA was not present in human vas deferens. Although many functions of all these AR-like genes are not known, different expression spectrums indicate that their physiological functions are quite different[22].

Not only 71 % of ARL-1 amino acid sequence was identical to that of AR, but also all of the key amino acids being responsible for AR' s enzymatic activities were conserved in

this protein. They included Ser[159], Asn[160], Gln[183], and Lys[262] for cofactor NADPH binding, Tyr[48] and His[110] as potential hydrogen donors, and active site residues Lys[77], Tyr[209], and Cys[298]. The enzymatic activity of ARL-1 was similar to that of the well-characterized human AR. In terms of pH optimum, salt requirement, and kinetics in reducing some substrates, these two proteins were different. For example, the activity of ARL-1 was not affected by 0.3 M sulfate ion, which was the optimum concentration for stimulating AR activity[22]. In the present project, two recombinant ARL-1 proteins were expressed and highly purified, polyclonal antibodies against ARL-1 were prepared and characterized. Polyclonal antibodies prepared by us were only against ARL-1 protein, the yeast and fly tissues were detected by Western blotting using our antibodies, no signals were visualized (data not shown), suggesting that these polyclonal antibodies were highly specific. Other characters of ARL-1 protein should be studied, as well as the relation between ARL-1 and human diseases.

AR is thought to be involved in diabetic complications such as cataract, retinopathy, neuropathy, and nephropathy. It is not clear if ARL-1 also contributes to these diabetic complications. So two recombinant ARL-1 proteins and polyclonal antibodies against ARL-1 prepared in our research would help determine the relationship between ARL-1 and diabetes. AR and an AR-like protein called Spot 17 were induced in rat hepatomas, suggesting that these proteins may be needed to detoxify methylglyoxal or other metabolites generated by fast growing cancer cells. About 29 % of individual human HCCs over-expressed AR and 54 % of them over-expressed ARL-1. The deduced protein sequence of ARL-1 was 94 % identical to that of Spot 17, indicating that it is most likely the human homologue of that protein[22]. In our studies, ARL-1 protein was detected in 94.4 % (17/18) liver cancer tissues, but only in 82.4 % (14/17) surrounding nontumorous tissues. Moreover, in all normal liver tissues (5 cases), ARL-1 protein was negative, ARL-1 expression in all detected liver cancer tissues was up-regulated (data not shown). All these studies suggest that ARL-1 is closely related to liver cancers.

In conclusion, two recombinant ARL-1 proteins and polyclonal antibodies against ARL-1 protein were prepared. As a basic research, these would help us identify the function of ARL-1, the exact relationship between ARL-1 and liver cancers. The life expectancy of HCC patients is hard to predict because of the high possibility of postoperative recurrence. Many factors, such as patients' general conditions, macroscopic tumor morphology, as well as tumor histopathological features, have been proven of prognostic significance[48-58]. With the progress in ARL-1 studies, the early diagnosis rate and the therapy level of liver cancers might be elevated, which will improve the prognosis of patients with liver cancer in the future.

Abstract

AIM: To establish a luciferase reporter cell line that responds dioxin-like chemicals (DLCs) and on this basis to evaluate its characteristics and application in the determination of DLCs.

METHODS: A recombinant luciferase reporter plasmid was constructed by inserting dioxin-responsive element (DREs) and MMTV promoter segments into the pGL_3-promoter plasmid immediately upstream of the luciferase gene, which was structurally demonstrated by fragment mapping analysis in gel electrophoresis and transfected into the human hepatoma cell line $HepG_2$, both transiently and stably, to identify the inducible expression of luciferase by 2, 3, 7, 8-tetrachlorodibenzo-*p*-dioxin (TCDD). The time course, responsive period, sensitivity, structure-inducibility and dose-effect relationships of inducible luciferase expression to DLCs was dynamically observed in $HepG_2$ cells stably transfected by the recombinant vector ($HepG_2$-Luc) and compared with that assayed by ethoxyresorufin-*O*-deethylase (EROD) in non-transfected $HepG_2$ cells ($HepG_2$-wt).

RESULTS: The inducible luciferase expression of $HepG_2$-Luc cells was noted in a time-, dose-, and AhR-dependent manner, which peaked at 4 h and then decreased to a stable level at 14 h after TCDD treatment. The responsiveness of $HepG_2$-Luc cells to TCDD induction was decreased with culture time and became undetectable at 10th month of $HepG_2$-Luc cell formation. The fact that luciferase activity induced by 3, 3', 4, 4'-PCB in $HepG_2$-Luc cells was much less than that induced by TCDD suggests a structure-inducibility relationship existing among DLCs. Within the concentrations from 3.5×10^{-12} to 5×10^{-9} mol/L, significant correlations between TCDD doses and EROD activities were observed in both $HepG_2$-luc and $HepG_2$-wt cells. The correlation between TCDD doses from 1.1×10^{-13} to 1×10^{-8} mol/L and luciferase activities was also found to be significant in $HepG_2$-luc cells ($r=0.997$, $P<0.001$), but not in their $HepG_2$-wt counterparts. For the comparison of the enzyme responsiveness between cell lines to TCDD, the luciferase sensitivity and reproducibility in $HepG_2$-luc cells were both better than that of EROD in $HepG_2$-wt cells, the former was at 1.1×10^{-13} mol/L and 3.5×10^{-12} mol/L, and the coefficients of variation (CV) of the latter was 15-30 % and 22-38 %, respectively.

CONCLUSION: The luciferase expression of $HepG_2$-luc cells established in the present study could sensitively respond to the DLCs stimulation and might be a prospective tool for the determination of DLCs.

INTRODUCTION

It has been well known in recent years that dioxin-like chemicals (DLCs) such as 2,3,7,8- tetrachlorodibenzo-*p*-dioxin (TCDD) can produce a wide variety of species- and tissue-specific toxic and biological effects, such as epidermal lesion, wasting syndrome, birth defect, hepatotoxicity, lethality, alteration in endocrine homeostasis, tumor promotion, myelotoxicity, immunotoxicity and induction of numerous enzymes (e.g. cytochrome P4501A1)[1-4]. Many of these responses are mediated by the cytosolic aryl hydrocarbon receptor (AhR) and modulated by the interaction of DLCs: AhR complex with its DNA recognition sequence [the dioxin-responsive element (DRE)][5-9]. Generally, the combination of DLCs with cytoplasmic AhR is the initial step of DLCs-triggered cell signaling pathway. After that, two molecules of hsp90 dissociate from DLCs: AhR complex, and the latter enters the nucleus to form a new complex with AhR nuclear translocator protein (ARNT), which further binds to the DRE, leading to the transcriptional activation of adjacent genes and toxic effects[10,11]. Therefore, AhR and its related signal pathway have been usually taken as the useful targets to be investigated for the determination of DLCs in different situations. Till now, the DLCs-responsive receptor assays have been established in mammalian cell lines[12] and in mice[13].

However, not all of these assays have been considered to be satisfactory yet. For example, the ethoxyresorufin-*O*-deethylase (EROD) induced as a common and rapid response to DLCs under DREs control has been widely used to evaluate the relatively toxicological potency of a complex mixture containing DLCs[14-16] except that higher concentrations appear when the enzyme activity is inhibited. Some detecting methods are time-consuming, expensive and inadequate to be used for screening and diagnosing dioxin and dioxin-like compounds in large numbers of samples[17-19]. Even if the chemical-activated luciferase expression (CALUX) bioassay method based on the pGL_2 vector[20] is to a certain extent lack of sensitivity and needs to be improved.

We therefore conducted the present study in an attempt to establish a more effective luciferase reporter cell line that responds to the alteration of DLCs concentrations and to evaluate its characteristics and applications in measurement of DLCs.

MATERIALS AND METHODS

Materials

Plasmids pHAV and pMcat were generously provided by Dr. James P. Whitlock Jr., Stanford University. Restriction endonuclease and other reagents used for molecular cloning were from Huamei Ltd. (China, Shanghai) or Promega Corporation. 2,3,7,8-TCDD and 3',4,4' - polychlorinated biphenyl (PCB) were purchased from Accustanfards Inc. (New Haven, CT). Dimethylsulphoxide (DMSO) was from BIB Corporation. Luciferase assay reagents came from Promega Corporation.

Construction of inducible luciferase expression vector

Plasmid pHAV containing DREs was cleaved with *HindIII*. Following purification by agarose gel electrophoresis, the smaller *Hin*d*III* fragment was further digested by *BamHI* and *EcoRV* to produce a 630-bp segment containing DREs, which was then ligased with *BglII* linkers and cleaved with *BglII* to create cohesive ends. To get the MMTV promoter, plasmid pMCat was cleaved with *Hin*d*III* and the smaller *Hin*d*III* fragment was then cleaved with *BglII* to produce cohesive 5' *BglII* and 3' *Hin*d*III* termini. The two segments containing DREs and MMTV promoter were connected with T_4 DNA ligase to form a 1 020 bp fragment with cohesive 5' *BglII* and 3' *Hin*d*III* termini, which was further subcloned into the *Bgl*II-*Hin*d*III* site immediately upstream of the luciferase gene in the pGL_3-promoter plasmid (Promega). As such, the luciferase' s expression was under the control of DREs. The recombinant vector was identified structurally with restriction endonuclease analysis.

Inducible expression of recombinant vector

$HepG_2$ cells were seeded in a 60 mm culture dish at a density of 3×10^5 cells in 5 ml of RPMI1640 supplemented with 10 % heat-inactivated fetal calf serum at 37 ℃ with saturated humidity and a 5 % (v/v) CO_2 atmosphere[21]. After cultured for 24 h, the cells were transiently or stably transfected by 15 μg of recombinant vector with calcium phosphate mediated method[22]. For transient transfection, the cells were allowed to grow for 48 h, followed by adding 0.5 % DMSO or 0.1-1 nmol/L TCDD dissolved in DMSO. After cultivated for another 24 h[22], cells were harvested to determine luciferase expression.

For the establishment of stable transfection, $HepG_2$ cells were cotransfected with the selective plasmid PTK-Hyg and the recombinant vector simultaneously. Following 24 h of cultivation in nonselective medium, the transfected cells were transferred into a selective medium containing hygromycin and cultured for 4 weeks when TCDD-induced luciferase expression was conducted. The clone with the largest ratio of inducible to constitutive expression of luciferase was selected for further study[23]. To identify the time course of inducible luciferase expression, the stably transfected cells ($HepG_2$-Luc) were cultured with exposure to 0.5 % DMSO or 1 nmol/L TCDD and the induced luciferase activities were determined at every 2 h up to 28 h post-exposure. For determination of the responsive period of luciferase induction, the $HepG_2$-Luc cells were treated with the same kinds of inducers for 24 h and their luciferase activity was assayed, which was performed at every month up to 12 months. The structure-inducibility and dose-effect relationships of different inducers that might represent their ability to bind AhR were also analyzed in $HepG_2$-Luc cells with the indicated concentrations of 3, 3' , 4, 4' -PCB, another member of DLCs, and TCDD.

Luciferase assay was performed by the routine procedures. Briefly, after removal of the culture medium, the incubated cells were washed twice with phosphate buffered saline (PBS) and lysed using luciferase lysis reagent for 15 min at room temperature. Following centrifugation, 20 μl of supernatant was added into 100 μl luciferase assay reagent, the resulting bioluminescence was quantified immediately with Lumate LB 9570 luminometer over 3 s. The concentration of the sample protein was determined with Bio-Rad method[24]. The luciferase activity was finally expressed as relative light unit (RLU) per microgram protein[21, 25].

Comparative study with EROD determination

EROD activity was employed as a variable to evaluate the effectiveness of $HepG_2$-luc cells in response to TCDD and to compare with luciferase. $HepG_2$ ($HepG_2$-wt) and $HepG_2$-luc cells were seeded in 6-well dishes at a density of 2×10^5 cells in 3 ml of medium and cultivated for 24 h, then they were exposed to the indicated concentrations of TCDD in DMSO and further incubated for 72 h. Following removal of the culture medium, the cells were washed twice with PBS and stored at -80 ℃. EROD activity was assayed using fluorescent method. The concentrations of sample protein were determined with Bio-Rad method[24]. EROD activity was finally expressed as pmol resorufin production per microgram protein per minute[26, 27].

Statistical analysis

Data values in the present study were presented as the mean for each independent determination of four replicates. The detection limit was expressed as the average value plus three times of standard deviations (SD). Coefficients of variation (CV) were calculated by SD/mean ×100 %. Correlation coefficients (r) were obtained using least-squares linear regression analysis.

RESULTS

Identification of inducible expression of recombinant vector

Structurally, segment analysis by restriction endonuclease digestion confirmed that the inserted fragment sequences containing DREs and MMTV promoter in the constructed plasmids were completely consistent with that of the theoretical calculations as shown in Figure 1.

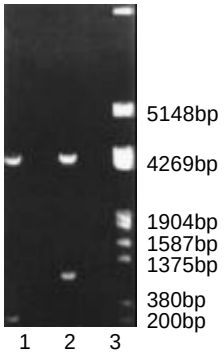

Figure 1 Fragment mapping analysis of recombinant plasmid digested with *Bgl*II and *Hin*dIII in gel electrophoresis. Lane 1: pGL_3 plasmid was cleaved into two fragments, which showed about 5 000 bp and 200 bp respectively. Lane 2: Recombinant plasmid was cut into a fragment of about 5 000 bp and the one of about 1 000 bp. Lane 3: DNA marker.

Inducible expression of luciferase by the recombinant plasmid was identified in transiently transfected $HepG_2$ cells, which produced a significantly higher induction of luciferase activity (80-fold, data not shown) compared with that of their non-transfected counterparts when exposed to TCDD. Dynamically, TCDD-induced luciferase activity in $HepG_2$-Luc cells peaked at 4 h and then decreased to a stable level at about

14 h after TCDD treatment (Figure 2). Responsiveness of $HepG_2$-Luc cells to the TCDD induction was decreased with culture time and became undetectable at 10th month of $HepG_2$-Luc cell formation (Figure 3), which indicats that the recombinant plasmid could not integrate stably with $HepG_2$ chromosome. The structure-inducibility relationship of different DLCs inducers was demonstrated by the fact that the luciferase activity induced by 3, 3', 4, 4' -PCB was much less than that induced by TCDD and a dose-dependent increase of luciferase activity was evoked by both of the DLCs inducers as shown in Figure 4.

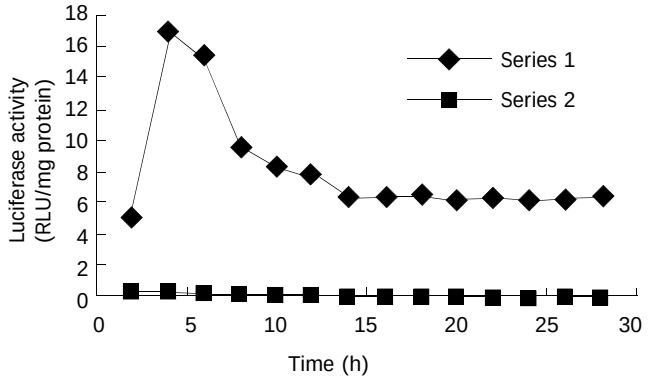

Figure 2 The time course of luciferase activities induced by TCDD and DMSO in stably transfected cells. The TCDD-induced luciferase activity in $HepG_2$-Luc cells peaked at about 4 h, and then decreased to a stable level at about 14 h after TCDD treatment.

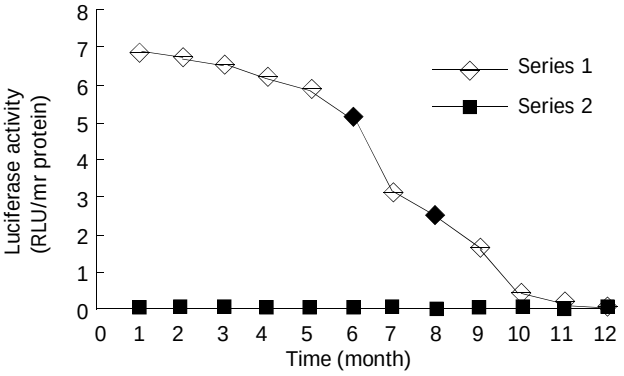

Figure 3 Responsive period of $HepG_2$-Luc cells to TCDD induction. The responsiveness of $HepG_2$-Luc cells to TCDD induction was decreased with culture time and became undetectable at about 10th month.

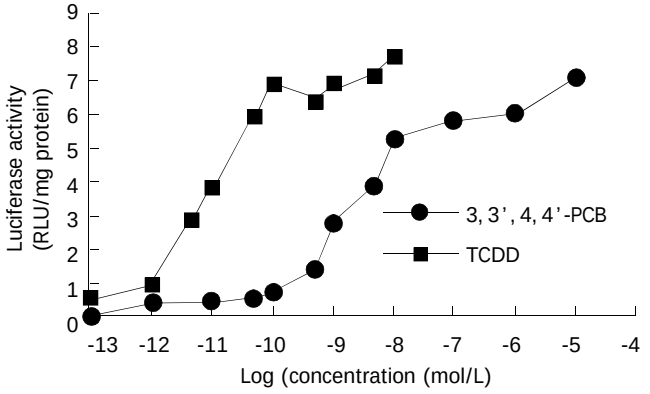

Figure 4 Comparison of luciferase activity induced by TCDD and 3, 3', 4, 4'-PCB in $HepG_2$-Luc cells. The luciferase activity induced by indicated concentrations of 3, 3', 4, 4'-PCB was much less than that induced by TCDD.

Comparative study

Within concentrations from 3.5×10^{-12} to 5×10^{-9} mol/L, significant correlations between TCDD doses and EROD activities were observed in both $HepG_2$-luc and $HepG_2$-wt cells. The correlation between TCDD doses from 1.1×10^{-13} to 1×10^{-8} mol/L and luciferase activities was also found to be significant in $HepG_2$-luc cells (r=0.997, P<0.001), but not in their $HepG_2$-wt counterparts. For comparison of the enzyme responsiveness between cell lines to TCDD, the luciferase sensitivity and reproducibility in $HepG_2$-luc cells were better than those of EROD in $HepG_2$-wt cells, which were 1.1×10^{-13} mol/L and 3.5×10^{-12} mol/L, whose CV was 15-30 % and 22-38 % (data not shown), respectively.

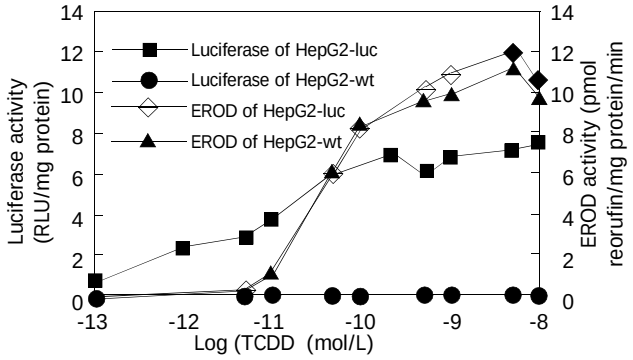

Figure 5 Comparison of EROD and luciferase responsiveness to the induction of TCDD in both $HepG_2$-luc and $HepG_2$-wt cells.

DISCUSSION

Few environmental compounds have generated much interest within the scientific community and in the lay public as polychlorinated dibenzo-p-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs). Their ubiquitous presence in the environment and the risk of accidental exposure have raised concern over a possible threat of PCDDs or PCDFs to human health. The most extensively studied potent isomer is TCDD or dioxin, which is known to induce a wide range of toxic and biochemical responses in laboratory animals and humans[8, 11]. Therefore, monitoring the levels of DLCs in environmental pollutants is important for assessing and maintaining the safety of food and the health of environment. Exploring new biodetectors such as bioassays, biomarkers, enzyme immunoassays (EIAs), or other bioanalytical tools has been a continuously growing area in recent years[15]; in which, however, establishing luciferase reporter cell lines for bioassays has been considered as the rapid, sensitive and inexpensive methods for the screening and diagnosis of dioxin and dioxin-like compounds[20, 28].

In the present study, we constructed a recombinant expression plasmid that contained the luciferase gene under TCDD-inducible control of several DREs and responded to DLCs with the induction of firefly luciferase, which has been identified by both transient and stable transfection of this vector into $HepG_2$ cells. Our results indicate that this established $HepG_2$-luc cell bioassay reporter system can respond sensitively to DLCs with the induction of luciferase in a time-, dose-, and AhR-dependent manner and harbors lots of better features. Firstly, it bears higher level of sensitivity and can detect TCDD within the linear range from 1.1×10^{-13} to 1×10^{-8} mol/L, which is 10-fold more sensitive than that of previously similar studies and 30-fold more sensitive than the EROD assay. This is partially because the vector plasmid employed in the study is pGL_3, whose expression efficiency of luciferase is 10-100 times more than that of pGL_2. In addition, no post- transcriptional procedures are needed to regulate the expression of prokaryotic

luciferase, thus its linear relationship is better than that of endogenous gene. Secondly, its pronounced accuracy has been demonstrated by the significant correlation between inducible luciferase activities and TCDD doses (r=0.997, P<0.001), and by the satisfactory reproducibility of TCDD determination with $HepG_2$-luc cells (CV=15-30 %). Finally, the simplicity and facility of $HepG_2$-luc cells in analytical methodology make it possible to perform a rapid screening and semi-quantitation of DLCs[29, 30] and to deal with lots of samples in a short period of time.

Besides the detection of DLCs described above, $HepG_2$-luc cells can also be applied to many other DLCs-related research fields. Since ARNT is required to exert biological effects by some TCDD and related ligands, interactions between AhR and hypoxia signaling pathways can be studied by using luciferase transfected cell line[31]. In accordance with the fact that the toxic factor of 3,3' ,4, 4' -PCB equivalent to TCDD is 0.01[32], our results showed that the ability of 3, 3' , 4, 4' -PCB to induce luciferase expression was much less than that of TCDD, suggesting that the structure-inducibility relationship existing in some DLCs could be reflected by $HepG_2$-luc cells, and the latter can be used alone or with chromatographer to evaluate the relative toxicity of DLCs[19, 33, 34]. In addition, this kind of recombinant cell lines can also be used for the detection and relative quantitation of AhR agonists/ antagonists in complex mixtures of environmental and biological samples, for identification and characterization of novel AhR agonists, and for examination of species differences in DLCs responsiveness[12].

One limitation of the present study is the relatively short duration of responsiveness to DLCs by established $HepG_2$-luc cells, although it is in accordance with that reported by most of the other studies. Up to the present, many established luciferase reporter cell lines such as MLE/BV, H4IIE, GPC16 and HGL1.1c3 responding to DLCs maintain their stable TCDD responsiveness for 6-12 months, except for Hepa1 which maintains its sensitivity for over 3 years[27]. Therefore, our further study has been designed aiming at improving and maintaining the sensitivity of $HepG_2$-luc cells to DLCs for a longer time.

ACKNOWLDGEMENTS

We thank Dr. James P. Whitlock Jr. (Stanford University) for his kind gift of plasmids pHAV and pMcat.

Abstract

AIM: To construct a recombined human AFP eukaryotic expression vector for the purpose of gene therapy and target therapy of hepatocellular carcinoma (HCC).

METHODS: The full length AFP-cDNA of prokaryotic vector was digested, and subcloned to the multi-clony sites of the eukaryotic vector. The constructed vector was confirmed by enzymes digestion and electrophoresis, and the product expressed was detected by electrochemiluminescence and immunofluorescence methods.

RESULTS: The full length AFP-cDNA successfully cloned to the eukaryotic vector through electrophoresis, 0.9723 IU/ml AFP antigen was detected in the supernatant of AFP-CHO by electrochemiluminescence method. Compared with the control groups, the differences were significant ($P<0.05$). AFP antigen molecule was observed in the plasma of AFP-CHO by immunofluorescence staining.

CONCLUSION: The recombined human AFP eukaryotic expression vector can express in CHO cell line. It provides experimental data for gene therapy and target therapy of hepatocellular carcinoma.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a very common malignancy in China[1-5], and it has a very poor prognosis[6-9]. Only a minority of patients are eligible for surgical therapies due to advanced tumors or extrahepatic diseases at primary diagnosis[10,11]. Therefore, it is urgent to find a novel strategy to prevent the proliferation of malignant cells. It is a hot spot at present to study prophylactic vaccination targeting the tumor-associated antigen (TAA) or tumor-specific antigen (TSA). This approach has been successful in mouse models, such as the tyrosinase-related protein (TRP)-2 in murine melanoma[12,13]. A colon cancer specific DNA vaccination directed against the carcinoembryonic antigen (CEA) is in phase I clinical trial[14].

The oncofetal alpha-fetoprotein (AFP) may be a possible target for an HCC-specific vaccination. It is a 70-ku to 80-ku secretory protein that is heterogeneously glycosylated. AFP is usually expressed at high concentrations in fetal liver, gastrointestinal tract, and the yolk sack. It is transcriptionally down-regulated after birth, and frequently re-expressed in HCC and therefore, used as a diagnostic marker for this tumor[15-21]. Serum AFP is useful not only for diagnosis, but also a prognostic indicator for HCC patients[22,23]. AFP mRNA has been proposed as a predictive marker of HCC cells disseminated into the circulation and for metastatic recurrence[24-27]. Some experiments *in vitro* have also demonstrated that AFP promotes cell proliferation of hepatoma cell lines[28,29].

AFP may be used as a target molecule for immunotherapy or prophylaxis against HCC. For this purpose, we constructed the recombined human AFP eukaryotic expression vector, and hope that it will provide experimental data for the treatment of HCC.

MATERIALS AND METHODS

Cell line and culture condition

CHO cell line was provided by the Department of Biochemistry, Fourth Military Medical University. Cells were maintained in RPMI 1640 medium, supplemented with 10 mL/L FCS, 1 mmol/L glutamine, and 100 kU/L penicillin.

Plasmids

The prokaryotic expression vector pRESTA-AFP containing human full-length AFP-cDNA was presented by Dr. Stephen M Festein, Hamiliton College, USA. The eukaryotic vector pCEFL was provided by Dr. Pan YL, Fourth Military Medical University.

Amplification of pRESTA-AFP

Transformation of competent bacterial DH5-α was carried out with pRESTA-AFP. The transformed cell DH5-α was transferred onto LB medium which was anti-aminobenzyl penicillin, cultured overnight in an incubator at 37 ℃. Four-five clones were selected and maintained in LB medium, and shaken overnight at 37 ℃.

Evaluation of pRESTA-AFP

Five mL bacterial medium was picked up, and the plasmid

DNA was extracted following the procedures of EZNA plasmid miniprep kit (Omega). The extracted DNA was digested by *Bam*H I and *Eco*R I (TaKaRa). The digested products were evaluated with 10 g/L agarose gel electrophoresis.

Construction of recombined human AFP eukaryotic expression vector

The human full-length AFP-cDNA was retrieved following the procedures of UNIQ-10 centrifugation column type gel retrieve kit (Sangon, Shanghai) and ligated to the multi-clony sites of pCEFL that was digested by *Bam*H I and *Eco*R I at a ratio of 10:1 with T4 DNA ligase (TaKaRa). Amplification, extraction, digestion and evaluation were performed according to the above-mentioned methods. It demonstrated that the full-length AFP-cDNA was inserted into pCEFL successfully, and named pCEFL-AFP.

Transfections of CHO cells

CHO cells were transiently transfected with pCEFL-AFP by liposome, Lipofectamine™ 2000 (Gibco). All the procedures were performed according to the guidance of the reagent. CHO cells were also transfected with pCEFL as control group, CHO cells not being transfected also served as control.

Detection of AFP expression by electrochemiluminescence

The supernatants of the cells from the three groups were collected, and detected by electrochemiluminescence method with Elecsys 1010 (Roche) and AFP electrochemiluminescence detection kit (Roche).

Detection of AFP expression by immunofluorescence

The transfected cells were stabilized with 10 g/L formaldehydum polymerisatum for 30 minutes at 4 ℃, and blocked with 100 g/L bovine serum albumin (BSA) for 1 hour at room temperature, then coated with rabbit anti-human AFP antibody (Dako) for 45 minutes at 37 ℃, followed by goat anti-rabbit IgG-FITC (Boster, Wuhan) for 30 minutes at 37 ℃. The antibody-coated cells were observed under fluorescence microscope (Optiphot XIF, Nicon, Japan) within 24 hours.

Statistical analysis

Student' s *t* test was used to compare the difference of AFP molecule in the supernatants between control groups and transfected pCEFL-AFP group. *P* value less than 0.05 was considered statistically significant.

RESULTS

Evaluation of pRESTA-AFP

pRESTA-AFP was digested by *Bam*H I and *Eco*R I and evaluated with electrophoresis. Figure 1 shows that pRESTA-AFP contained the full-length human AFP-cDNA.

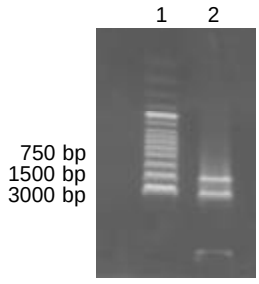

Figure 1 Electrophoresis of pRESTA-AFP. 1. Marker, 2. Full length AFP-cDNA in the upper, pRESTA in the lower.

Evaluation of pCEFL-AFP

To demonstrate that the full-length human AFP-cDNA was inserted into the multi-clony sites of pCEFL correctly, pCEFL-AFP was digested by *Bam*H I and *Eco*R I and evaluated with electrophoresis. Figure 2 shows that AFP-cDNA was inserted into pCEFL successfully.

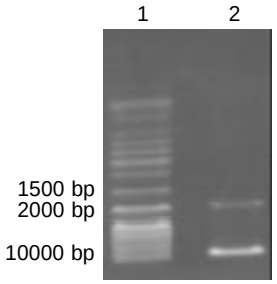

Figure 2 Electrophoresis of pCEFL-AFP. 1. Marker, 2. Full length AFP-cDNA in the upper, pCEFL in the lower.

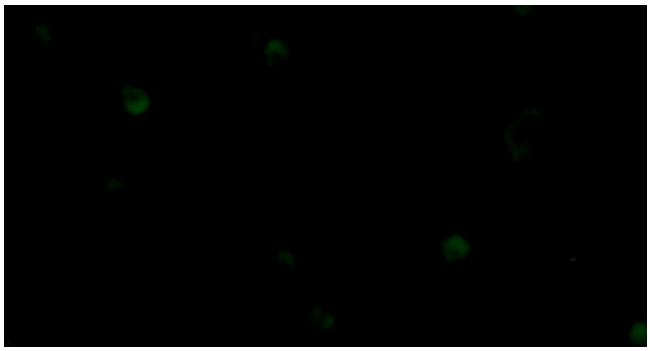

Figure 3 CHO transfected with pCEFL-AFP. The fluorescence staining in the cytoplasm was positive. ×400.

Figure 4 CHO transfected with pCEFL. The fluorescence staining in the cytoplasm was negative. ×400.

Figure 5 Non-transfected CHO. The fluorescence staining in the cytoplasm was negative. ×400.

AFP molecule expression in the supernatant

CHO cells were transfected with pCEFL-AFP. To demonstrate that the transfection was successful, the supernatant of CHO cells was detected by electrochemiluminescence method. The results showed that AFP molecule expression in the supernatant of CHO cells transfected with pCEFL-AFP was higher (972.3±69.9 IU/L) than that transfected with pCEFL (556.3±60.2 IU/L, $P<0.05$) and also higher than that not being transfected (582.3±58.0 IU/L, $P<0.05$). The differences were significant.

Immunofluorescence staining of transfected cells

The transfected cells were coated with AFP antibody and fluorescent antibody. Under fluorescence microscope, it could be observed that the fluorescence staining was positive in the cytoplasm of CHO cells transfected with pCEFL-AFP and negative in the controls (Figures 3-5).

DISCUSSION

In China, the incidence of HCC is very high, and surgical operation, chemotherapy, and interventional therapy are the common therapies. But only a few patients of earlier stage without extrahepatic malignancy are indicated for operation, and for the advanced cases, chemotherapy and interventional therapy usually cannot achieve a satisfactory effect. AFP is a TAA of HCC, which may be used as a target for treatment.

Vollmer *et al*[30] firstly showed a prophylactic effect of an AFP-specific DNA vaccination on the growth of AFP-positive tumor cells in C57BL/6 mice. In their experiments, only 7.4 % of mice were fully protected from tumor growth. In the remaining animals, a prolonged time until tumors reached diameters of 10 mm was observed. Wang *et al*[31] found that antisense S-ODNs targeting AFP gene treatment led to reduced AFP gene expression. Specific antisense S-ODNs, but not control S-ODNs, inhibited the growth of hepatoma cells *in vitro*. *In vitro*, only antisense S-ODNs exhibited obvious antitumor activities. Guo *et al*[32] found that the dendritic cells (DCs) based vaccine with HLA-A2 restricted peptide epitope derived from hAFP have marked cytotoxicity against AFP positive primary HCC. In their experiments, after stimulated by DCs loaded with CTL epitope based peptide derived from hAFP, lymphocytes showed good characteristics and the culture medium of activated lymphocytes contained a high level of Th1 type cytokines of IL-12 and TNF. Activated lymphocytes not only specifically lysed HLA-A2 (+) HepG2 line but also had the cytotoxicity against T2 target cells loaded with peptide of hAFP. Hanke *et al*[33] demonstrated that DNA vaccination with AFP-encoding plasmid DNA could prevent the growth of subcutaneous AFP-expressing tumors and not interfere with liver regeneration in mice. Grimm *et al*[34] achieved similar outcomes.

Since immunotherapy or gene therapy targeting TAA or TSA is a direction of tumor therapy, AFP as a TAA of HCC, has shown its profound effect on HCC treatment in animal models. In our experiment, we constructed the recombined human AFP eukaryotic expression vector successfully. This, we believe, provides experimental data for gene therapy and immunotherapy of HCC. It may be used as a treatment target of human HCC.

Abstract

AIM: To investigate the density of mast cells (MCs) in human hepatocellular carcinoma (HCC), and to determine whether the MCs density has any correlations with histopathological grading, staging or some baseline patient characteristics.

METHODS: Tissue sections of 22 primary HCCs were histochemically stained with toluidine blue, in order to be able to quantify the MCs in and around the neoplasm using a computer-assisted image analysis system. HCC was staged and graded by two independent pathologists. To identify the sinusoidal capillarisation of each specimen 3 μm thick sections were histochemically stained with sirius red, and semi-quantitatively evaluated by two independent observers. The data were statistically analysed using Spearman's correlation and Student's *t*-test when appropriate.

RESULTS: MCs density did not correlate with the age or sex of the patients, the serum alanine aminotransferase (ALT) or aspartate aminotransferase (AST) levels, or the stage or grade of the HCC. No significant differences were found between the MCs density of the patients with and without hepatitis C virus infection, but they were significantly higher in the specimens showing marked sinusoidal capillarisation.

CONCLUSION: The lack of any significant correlation between MCs density and the stage or grade of the neoplastic lesions suggests that there is no causal relationship between MCs recruitment and HCC. However, as capillarisation proceeds concurrently with arterial blood supply during hepatocarcinogenesis, MCs may be considered of primary importance in the transition from sinusoidal to capillary-type endothelial cells and the HCC growth.

INTRODUCTION

Mast cells (MCs) have fascinated the biomedical sciences ever since they were first recognised by Paul Ehrlich in the late 1800s' [1]. MCs originate from haematopoietic stem cells in bone marrow[2, 3]. MCs circulate in the blood only as progenitors, and it is not until they enter the tissues that they undergo their terminal differentiation into mature cells. MCs provide granule and membrane mediators as well as different cytokines during the course of many human and experimental diseases[4-8]. It has recently been shown that MCs play an important role in antigen presentation to T cells, and that there is a direct interaction between them and the B cells signalling immunoglobulin E (lgE) production. Although a number of studies have shown that MCs play different roles in human tumours[9-26], the exact nature of the relationship between them and HCC has still to be established. The aim of the present study was to investigate MCs density in HCC and compare it with stage and grade of the neoplasia, and some clinical and histopathological characteristics of the patients.

MATERIALS AND METHODS

Patient profiles and surgical specimens

The study was conducted in accordance with the guidelines of the Ethics Committee of the hospital treating the patients (Istituto Clinico Humanitas, Rozzano, Milan, Italy), all of whom were informed of the possible discomforts and risks of surgical treatment.

The study involved 22 primary HCC patients (15 men and 7 women, mean age: 68.22 years, range 48-80 years) who were surgically treated between 1997 and 2001 (Table 1). Tumours were independently graded and staged by two experienced histopathologists. The study was performed on surgical specimens fixed in formalin and embedded in paraffin.

Histochemical detection of MCs and capillarisation

Sections of 3 μm were cut, mounted on glass slides, de-waxed in xylene and re-hydrated using graded alcohol/water baths. They were then rinsed in distilled water for 5 minutes and incubated for 30 minutes at room temperature with a freshly made staining aqueous solution consisting of 0.1 % toluidine blue (Sigma Chem. Co., MO, USA) and 0.005 % acetic acid. The number of MCs detectable on the whole surface of the available liver sections at a magnification of 200× was quantified using a computer-assisted image analysis system consisting of an Axiophot light microscope (Zeiss, Germany), a 3-CCD camera (JVC KY-F55BE, Italy), a Pentium 600 computer (Hewlett-Packard, Italy) with an incorporated frame-grabber board (Imascan, USA), and Image-Pro Plus image analysis software (Immaginie Computer, Rho, Italy). The digitized image, which was composed of a variable number of fields tiled together to form a unique final image, represent all of the histological materials available for examination (>30 mm^2 for each slide). The Image Pro-Plus software automatically selected stained MCs as single objects on the basis of similarities in the color of adjacent pixels, the image intensity was the same throughout the study. MCs density (d) was automatically calculated using the formula: d=(number of

MCs)/(sample surface), where the sample surface was expressed in μm^2.

In order to evaluate the hepatic sinusoid capillarisation of each specimen, a 3 μm section was stained with Direct-red 80 (Sigma Chem. Co., MO, USA; 0.1 % in saturated picric acid). The sections were subsequently washed in running tap water for 30 minutes to remove excess staining, counter-stained in Mayer's hemallum solution, dehydrated, and mounted in Eukitt (Bio-Optica, Milan, Italy). Sinusoid capillarisation was independently scored as strong (+++), moderate (++), weak (+) or absent (0) by two experienced histopathologists.

Statistical analysis

Linear regression analysis was used to assess the statistical correlation between MCs density and the other histopathological and clinical data. The relationships were determined using Spearman's correlation and Student's *t*-test when appropriate. Statistical analysis was performed using Statistica software (StatSoft Inc., Tulsa, OK, USA). $P<0.05$ was considered statistically significant.

RESULTS

Table 1 shows the baseline characteristics of the 22 patients involved in the study. MCs were strongly identified in 18 cases (82 %). They were found in and around the neoplastic tissue. MCs density did not correlate with the patients' age ($r=0.1698$). It correlated non-significantly with disease stage (Figure 1A) and disease grade (Figure 1B), nor with serum alanine aminotransferase (ALT, $r=0.20765$) or aspartate aminotransferase (AST, $r=-0.0439$) (Figure 2). There was no significant difference in the density of MCs between the patients with and without chronic hepatitis C virus disease (Figure 3), but a semi-quantitative evaluation showed that MCs density did correlate significantly with the capillarisation process (Table 2). MCs were found abundantly in tissues showing a higher capillarisation phenomenon (Figure 4).

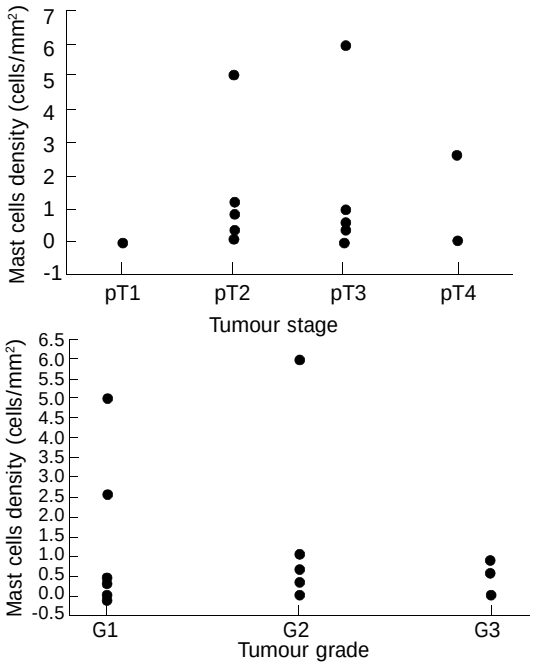

Figure 1 Relationship between MCs density and tumour stage (A) and tumour grade (B).

Table 2 Semi-quantitative evaluation of sinusoidal capillarisation related to MCs density (cells / mm^2)

MC density	Presence of capillarisation			
	Absent	Weak	Moderate	Strong
0-0.01	3	2	0	0
0.01-0.1	3	0	0	0
0.1-1	1	5	1	0
>1	0	0	2	3[a]

[a]$P<0.005$ *vs* the other categories.

(b) Sinusoidal capillarisation in HCC tissue (sirius red, objective magnification 20×).

DISCUSSION

MCs are a group of long-living cells of bone marrow origin that are commonly found in the skin and the gastrointestinal and respiratory systems. These cells produce, store and release a high number of bioactive mediators, such as TNF-α, IL-1, IL-4, IL-5, IL-6, IL-8, IL-13, NGF, β-FGF and TGF-β, histamine, and the serine proteases, tryptase and chymase[3, 4, 27].

MCs are known to be present in normal and pathological livers. In normal human livers, there are a few resident MCs located near the portal tracts which are more densely distributed around the biliary tree. Large amounts of MCs have been detected in the fibrotic septa and portal regions in cirrhotic human livers. A number of studies have indicated that MCs are associated with hepatic fibrosis as they promote fibroblast growth, collagen synthesis and may inhibit extracellular matrix degradation by means of inhibitors of metalloproteases (TIMPs)[6, 27-32]. MCs density is a valid index of acute liver inflammation[7, 8].

MCs were recognized in various human tumours[8, 26]. The accumulation of MCs around the neoplasia is a well-known phenomenon in basal cell carcinoma, melanoma, lung, prostate and breast cancer.

Although the functions of intra-tumour MCs are yet unclear (some MCs have been evidenced in close apposition to tumour cells, suggesting the existence of direct cell-to-cell interactions), two main hypotheses have been proposed: The first is that MCs may accelerate tumour growth, invasion and neovascularity. Contrarily, the second is that MCs have cytotoxic activity for some tumours (especially those sensitive to TNF-α), as a result of cytotoxic products or the enhancement of the cytotoxic activation of mainly peri-tumoural eosinophils and macrophages[33-36].

Experimental studies have shown that an increase in MCs density is stimulated by IL-3 and IL-4, thus suggesting that their defensive role against tumour growth may be particularly associated with T cells[37-39]. IL-4 is essential for the triggering of Th2 lymphocytes that they themselves produce to initiate inflammatory cell accumulation and B lymphocyte immunoglobulin class switching to IgE[40].

However, the well documented relationship between MCs and angiogenesis makes the first hypothesis more persuasive[23,27]. Secreting MCs are able to induce and enhance angiogenesis via multiple in part interacting pathways[27]. The supporting evidence includes: (a) The fact that tumour cells produce agents promoting MC chemotaxis. Moreover, most of the tumour-infiltrating MCs exhibit anaphylactic or piecemeal degranulation, indicating that the MCs are activated *in situ*. (b) MCs degranulation facilitates the endothelial cell invasion in connective tissue. (c) MC heparin stimulates the endothelial cell motility essential for the angiogenic process. (d) The *metachromasia* that is determined by the presence of highly sulphated proteoglycans in the secretory granules of MCs, is commonly found at the tumour periphery, suggesting the release of vasoactive substances around the tumour. (e) Histamine, VEGF, and certain lipid-derived mediators that induce microvascular hyperpermeability having pro-angiogenic effects.

In the present paper, we showed that HCC contained a higher density of toluidine blue stained MCs, thus suggesting that the recruitment of MCs increases during the development of HCC. However, the results obtained from 22 HCC patients

did not indicate any significant correlation between MCs density and disease stage. We hypothesize that the lower density observed in the most severe stage may be due to the massive degranulation of a large number of MCs.

Moreover, the obtained results allow the following conclusions to be drawn: (a) MCs density did not significantly correlate with disease grade, but there was a trend towards a decrease in MCs number as the grade increased. (b) There was no correlation between MCs density and some baseline characteristics of the patients, such as the sex or age of the patients, since the tumour evolves more slowly in older patients, we expected to find a higher density in younger cases. This hypothesis was partially substantiated by an albeit statistically non-significant negative correlation between MCs density and age. This behaviour was in line with theoretical models showing that a large number of biological events were age-dependent [7]. (c) MCs density did not correlate with serum ALT or AST levels. HCV, cirrhosis and HCC were associated with persistent or fluctuating elevations in ALT levels, but did not distinguish among these conditions. (d) There was no significant difference in the density of MCs between patients with and without HCV disease. As it is known that there is a close relationship between HCC and hepatitis C virus infection, it is not surprising that we had more HCV-positive than HCV-negative cases. Nevertheless, MCs density was similar in both groups, suggesting that HCV infection did not increase MC recruitment. (e) The close proximity of MCs and surrounding tumour cells suggested the existence of roles of MCs in the development of HCC, including tumour growth as well as host immunity and stromal reaction. (f) The density of MCs was higher in the specimens showing a greater capillarisation of sinusoidal endothelial cells.

A number of studies have indicated that the sinusoidal endothelial cells tend to show phenotypic changes in the early stage of hepatocarcinogenesis. In HCC, endothelial fenestrae are diminished and basement membrane become thick: due to the fact that as the arterial blood supply for HCC increases, the sinusoidal endothelial cells may form basement membranes, mainly consisting of type IV collagen and laminin, and take on the morphological appearance of capillaries[41-44].

Capillarisation of sinusoids has also constant features such as the appearance of new junctions between endothelial cells, deposition of fibrillary material in Disse' s spaces, and flattening of hepatocyte microvilli. Capillarisation of the sinusoid may also cause a disturbance in exchanges of many bioactive substances between the sinusoidal blood and liver cells across the Disse space. Capillarisation, resulting in impairment of microcirculation, subsequently, affecting the exchange of the oxygen and substance of the liver cell seriously, thus brings about or aggravates the damage of liver cell[45]. Capillarisation may contribute to the HCC metastatic process. The angiogenesis of liver metastases may progress stepwise as the metastases enlarge, and capillarisation of sinusoidal endothelium around the liver metastases may occur. A number of papers have suggested that (a) tumour vessels in metastatic liver cancers consist of endothelium, collagenic basement membrane and pericytes, (b) the sinusoids adjacent to tumours undergo capillarisation, and (c) VEGF, a well-demonstrated mediator secreted by MCs may contribute to angiogenesis in metastatic HCC.

It is well documented that heparin, combined to a range of heparin-binding factors such as b-FGF or TGF-β, or other potent factors, such as IL-8 and VEGF, are able to promote neovascularity, and that MC proteases cause loss of the extracellular matrix integrity[27].

All these comments suggest that MCs accumulation at the tumour site may lead to increased rates of tumour vascularity and, consequently, increased rates of tumour growth and metastasis.

In conclusion, since capillarisation proceeds concurrently with arterial blood supply during hepatocarcinogenesis, MCs may be considered as a key element in the process of transition from sinusoidal endothelial cells into capillary-type endothelial cells and concurrently in the development of collagen' s basement membrane. MCs mediated capillarisation may thus be of pathogenic significance in tumor growth.

ACKNOWLEDGMENTS

The authors are grateful to prof. Massimo Roncalli and Dr Piergiuseppe Colombo for supplying the HCC specimens, and for their grading and staging classification. They would also like to thank Giorgia Ceva-Grimaidi for her precious technical support.

Abstract

AIM: To study the antitumor and immunomodulatory activity of resveratrol on experimentally implanted tumor of H22 in Balb/c mice

METHODS: The cytotoxicity of peritoneal macrophages (M ϕ) against H22 cells was measured by the radioactivity of [^{3}H]TdR assay, mice with H22 tumor were injected with different concentrations of resveratrol, and the inhibitory rates were calculated and IgG contents were determined by single immunodiffusion method. the plaque forming cell (PFC) was measured by improved Cunningham method, the levels of serum tumor necrosis factor-α (TNF-α) were measured by cytotoxic assay against L929 cells.

RESULTS: Resveratrol 2.5 mg·L^{-1}, 5.0 mg·L^{-1}, 10.0 mg·L^{-1}, 20.0 mg·L^{-1} (E:T=10:1, 20:1) promoted the cytotoxicity of M ϕ against H22 cells. Resveratrol ip 500 mg·kg^{-1}, 1 000 mg·kg^{-1} and 1 500 mg·kg^{-1} could curb the growth of the implanted tumor of H22 in mice. The inhibitory rates were 31.5 %, 45.6 % and 48.7 %, respectively (P<0.05), which could raise the level of serum IgG and PFC response to sheep red blood cell. Resveratrol 1 000 mg·kg^{-1} and 1 500 mg·kg^{-1} and BCG 200 mg·kg^{-1} ip could increase the production of serum TNF-α in mice H22 tumor. However, the effect of resveratrol was insignificant (P >0.05).

CONCLUSION: Resveratrol could inhibit the growth of H22 tumor in Balb/c mice. The antitumor effect of resveratrol might be related to directly inhibiting the growth of H22 cells and indirectly inhibiting its potential effect on nonspecific host immunomodulatory activity.

INTRODUCTION

Recently, considerable attention has been focused on identifying naturally occurring chemopreventive substances capable of inhibiting, retarding, or reversing the multi-stage carcinogenesis. Resveratrol (3,5,4' -trihydroxy-trans-stilbene), a phytoalexin found in grapes and other dietary and medicinal plants, has been shown to have anti-inflammatory, antioxidant and antitumor activities[1-7]. Many of these beneficial effects of resveratrol require participation of the cells of the immune system. However, the effect of resveratrol on the development of immuological responses remains unknown.

In the present study, the antitumor activity and immunomodulatory actions of resveratrol, including M ϕ against H22 cells, serum IgG and the plaque forming cells and tumor necrosis factor (TNF-α) content in Balb/C mice with experimentally implanted tumor of H22 were investigated.

MATERIALS AND METHODS

Materials

Resveratrol, MTT, IPS and dimethylsulfoxide (DMSO) were purchased from SGMA Co. Mouse hepatocellular carcinoma cells H22, L929 and sheep red blood cell (SRBC) were kindly supplied by Cheng Wei (Center of Molecular Biology, First Affiliated Hospital, Xi' an Jiaotong University). Cells were subcultured in RPMI 1640 (Gibco) which was supplemented with 10 % fetal bovine serum, penicillin (100 IU·ml^{-1}) and streptomycin (100 mg·l^{-1}). Stock solution of resveratrol was made in dimethylsulfoxide (DMSO) at a concentration of 10 g·L^{-1}. Working dilutions were directly made in the tissue culture medium. [^{3}H]TdR was purchased from Shanghai Nuclear Research Institute. IL test kit and LPS were purchased from Gibco Co. Balb/C mice, 2.5 month old, weighing 20±2 g, were purchased from the Animal Center, Xi' an Jiaotong University.

Methods

Effect of resveratrol on cytotoxicity of peritoneal macrophages (M ϕ) against H22 cells M ϕ was collected from the peritoneal cavity of Balb/c mice 3 days after ip 10 % sheep red blood cells (SRBC,1 ml/mouse). The cells were washed twice and resuspended in RPMI 1640 culture medium. H22 cells were cultured for 12 h, and 100 μl M ϕ suspension and different concentrations of resveratrol were added to each well of 96-well plates at a ratio of effectors: target (E:T) cell 10:1 or 25:1. After cultured for 24 h, each well was added with [^{3}H]TdR (9. 3 kBq/well), and then was incubated for another 6 h. Cells were placed onto the glass fiber filter and [^{3}H]TdR incorporation was determined by liquid scintillation. The cytotoxicity was calculated with the following formula: the cytotoxicity of M ϕ =(control-treatment)/control×100 % (dpm).
Anti-tumor activity of resveratrol and its effect on serum antibody IgG, plaque forming cells (PFC) in Balb/C mice with implanted tumor of H22 Mouse ascites (including 2×10^5 cells) were injected into the right axilla of 40 Balb/c mice. On the second day, 40 Balb/c mice were divided into 4 groups randomly, and then were injected with resveratrol at a dose of 500 mg·kg^{-1},1000 mg·kg^{-1}, 1 500 mg·kg^{-1} and normal saline for 10 d. Mice were sensitized to ip SRBC (3×10^7 cells). After 4 d, the mice were bled to obtain serum for IgG investigation. At the same time, spleens were excised for PFC counting. IgG contents were determined by single immunodiffusion method. PFC was measured by modified Cunningham method.
Effect of resveratrol on serum tumor necrosis factor alpha

(TNF-α) production induced by LPS in Balb/c mice Ascites cells of 2×10^5 were injected into the Balb/c mice. Resveratrol at a dose a 500 mg· kg^{-1}, 1 000 mg· kg^{-1} and 1 500 mg· kg^{-1} was injected for 10 d, and BCG of 200 mg· kg^{-1} as a positive control agent was injected ip on d 1.On d 11, 90 minutes after ip LPS of 0.1 mg· kg^{-1}, the mice were exsanguinated. Blood was centrifuged (400×g,10 min). The levels of serum TNF-α were measured by cytotoxic assay against L929 cells as described previously. The TNF-α activity was calculated with the following formula: cytotoxicity=$(A_{control}-A_{test})/A_{control}\times100$ %.

RESULTS

Effect of resveratrol on cytotoxicity of peritoneal macrophages (M φ) against H22 cells

Resveratrol at 2.5 mg· l^{-1} could decrease the cytotoxicity of M φ against H22 cells (P>0.05). Resveratrol at l2.5 mg· l^{-1}, 5.0 mg· l^{-1}, 10.0 mg· l^{-1} could enhance insignificantly the cytotoxicity of M φ against H22 cells (P>0.05) concentration-dependently, However, resveratrol at 20.0 mg· l^{-1} could raise significantly the cytotoxicity of M φ against H22 cells (P<0.05) (Table 1).

Table 1 Effect of resveratrol on cytotoxicity of peritoneal macrophages (M φ) against H22 cells *in vitro* (n=3)

Resveratrol (mg·l^{-1})	Cytotoxicity of M φ: H22 (10:1)	φ(%) M φ: H22 (25:1)
Control	12.6±7.9	15.6±6.0
1.25	10.9±2.9[a]	10.6±5.4[a]
2.50	12.5±3.2[a]	16.4±1.8[a]
5.0	13.4±2.8[a]	27.6±2.6[a]
10.0	14.6±3.7[a]	18.3±4.2[a]
20.0	16.7±4.7[b]	20.2±3.1[b]

[a]P>0.05, [b]P<0.05 *vs* control.

Anti-tumor activity of resveratrol and its effect on serum antibody IgG, plaque forming cells(PFC) in Balb/c mice with implanted tumor of H22

Resveratrol ip at a dose 500 mg· kg^{-1}, 1 000 mg· kg^{-1} and 1 500 mg· kg^{-1} could significantly curb the growth of implanted tumor of H22 in mice. The inhibitory rates were 31.5 %, 45.6 % and 48.7 %,respectively (P<0.05, Table 2).

Table 2 Inhibitory rates of resveratrol on H22 in mice *in vivo*

Group	Dose mg.kg^{-1}	Route	Mice begin/end	Tumor weight (x±s) (g)	Inhibitory rate (%)	P value
Control		ip	10/9[b]	1.81±0.62		
Resveratrol 1	500	ip	10/8[b]	1.24±0.40	31.5	<0.05[a]
Resveratrol 2	1000	ip	10/9[b]	0.99±0.35	45.6	<0.05[a]
Resveratrol 3	1500	ip	10/10	0.93±0.25	48.7	<0.05[a]

[a]P<0.05 *vs* control; [b]killed by other mice.

The result also showed that the immunity of mice with tumor could be more significantly inhibited than that of normal mice, and resveratrol ip could raise the level of serum LgG and number of PFC in Balb/c mice with implanted tumor of H22 *in vivo*. Resveratrol, however, could insignificantly increase the immunity of mice with tumor (P>0.05, Table 3).

Effect of resveratrol on serum tumor necrosis factor alpha (TNF-α) production induced by LPS in Balb/c mice

The ability of TNF-α production of mice with H22 tumor was significantly stronger than that of normal mice. Furthermore, the group of control and BCG at 200 mg· kg^{-1} ip had an increase in the at production of serum TNF-α in mice with H22 tumor (P<0.05), but resveratrol at a dose of 500 mg· kg^{-1}, 1 000 mg· kg^{-1} and 1 500 mg· kg^{-1} had less effect on mice with H22 tumor (P>0.05, Table 4).

Table 3 Effects of resveratrol on serum antibody IgG, plaque forming cells (PFC) in Balb/c mice with implanted tumor of H22 *in vivo*

Group	Dose mg.kg^{-1}	Route	IgG/g·L^{-1}	PFC/10^6 cells
Normal mice	NS	ip	27±8	441±32
Control	NS	ip	19±6[a]	297±57[a]
Resveratrol 1	500	ip	20±8[a]	305±53[a]
Resveratrol 2	1000	ip	23±6[a]	328±49[a]
Resveratrol 3	1500	ip	24±5[a]	348±46[a]

[a]P>0.05 *vs* normal mice or control.

Table 4 Effect of resveratrol on TNF-α production induced by LPS in Balb/c mice

Group	Dose (mg· kg^{-1})	Route	TNF-α activity specific lysis
Normal mice	NS	ip	7.1±3.2
Control	NS	ip	16.3±2.3[a]
Resveratrol 1	500	ip	15.8±2.0[ab]
Resveratrol 2	1000	ip	17.7±2.9[ab]

Control+BCG	200	ip	29.8±3.7[ab]

[a]P<0.05 *vs* normal mice; [b]P>0.05 *vs* control.

DISCUSSION

Resveratrol is a phytopolyphenol isolated from the seeds and skin of grapes. Recent studies have indicated that resveratrol can block the process of multistage carcinogenesis, namely, tumor initiation, promotion and progression. Resveratrol can also reduce the risk of cardiovascular diseases in man. These activities have been identified by some authors[8-13]. Roberto *et al*[14] have shown that PBMC exposure to resveratrol produced a biphasic effect on the anti-CD3/anti-CD28-induced development of both IFN-y-IL-2 and IL4-producing CD8+ and CD4$^+$T cells, with stimulation at low resveratrol concentrations and suppression at high concentrations. Similarly, the compound was found to induce a significant enhancement at low concentrations and suppression at high concentrations of both CTL and NK cell cytotoxic activity. Gao *et al*[15] found that mitogen-, IL-2- or alloantigen-induced proliferation of splenic lymphocytes, induction of cytotoxic T lymphocytes (CTLs) and lymphokine activated killer (LAK) cells, and production of the cytokine interferon (IFN)-y, interleukin (IL)-2, tumor necrosis factor(TNF)-α were significantly suppressed at 25-50 μM resveratrol, but in some cases mitogen/IL-2-induced production and CTL generation were enhanced following pretreatment of cells with resveratrol. The effects of resveratrol on immune function of mice *in vivo* have not been reported yet.

Our results indicate that resveratrol of 2.5 mg· l^{-1} could decrease the cytotoxicity of M φ against H22 cells (P>0.05). Resveratrol of 2.5 mg· l^{-1}, 5.0 mg· l^{-1} and 10.0 mg· l^{-1} could insignificantly enhance the cytotoxicity of M φ against H22 cells concentration-dependently (P>0.05). However, resveratrol of 20.0 mg· l^{-1} could raise significantly the cytotoxicity of M φ against H22 cells (P<0.05). So, resveratrol could alone affect the [^{3}H]TDR uptake by H22 cells *in vitro*,

suggesting that the antitumor action of resveratrol had a direct cytotoxic effect. This result is coincident with the previous studies[16-18]. Resveratrol ip could insignificantly increase the host nonspecific immunological defense of mice with H22 tumor, by raising the level of serum IgG and TNF-α and the number of PFC (P>0.05). *In vivo* resveratrol could also augment the cytotoxicity of peritoneal macrophages against H22 cells, and there was an insignificant difference compared with the control group (P>0.05). Therefore, resveratrol could inhibit the growth of H22 cells *in vivo*, but it could not significantly enhance the host immune defense against tumor. Based on the results of the present study, it can be suggested that the antitumor activity of resveratrol might be due to direct cytotoxic/antiproliferative activity against tumor cells, but not to the augmentation of immune response against tumors. It has demonstrated that resveratrol inhibits cell proliferation, cell-mediated cytotoxicity, and cytokine production, at least in part through the inhibition of NF-kappa B activation. But the molecular mechanism by which resveratrol imparts cancer chemopreventive effects has not been clearly defined and further studies are needed.

Abstract

AIM: To assess the feasibility and efficacy of laparoscopic total mesorectal excision (LTME) of low rectal cancer with preservation of anal sphincter.

METHODS: From June 2001 to June 2003, 82 patients with low rectal cancer underwent laparoscopic total mesorectal excision with preservation of anal sphincter. The lowest edge of tumors was below peritoneal reflection and 1.5-7 cm from the dentate line (1.5-5 cm in 48 cases, 5-7 cm in 34 cases).

RESULTS: LTME with anal sphincter preservation was performed on 82 randomized patients with low rectal cancer, and 100 % sphincter preservation rate was achieved. There were 30 patients with laparoscopic low anterior resection (LLAR) at the level of the anastomosis below peritoneal reflection and 2 cm above from the dentate line; 27 patients with laparoscopic ultralow anterior resection (LULAR) at the level of anastomoses 2 cm below from the dentate line; and 25 patients with laparoscopic coloanal anastomoses (LCAA) at the level of the anastomoses at or below the dentate line. No defunctioning ileostomy was created in any case. The mean operating time was 120 minutes (ranged from 110-220 min), and the mean operative blood loss was 20 mL (ranged from 5-120 mL). Bowel function was restored and diet was resumed on day 1 or 2 after operation. The mean hospital stay was 8 days (ranged from 5-14). Postoperative analgesics were used in 45 patients. After surgery, 2 patients had urinary retention, one had anastomotic leakage, and another 2 patients had local recurrence one year later. No interoperative complication was observed.

CONCLUSION: LTME with preservation of anal sphincter is a feasible, safe and minimally invasive technique with less postoperative pain and rapid recovery, and importantly, it has preserved the function of the sphincter.

INTRODUCTION

The optimal operation for rectal cancer still remains controversial. Surgical management of rectal cancer has undergone a significant change during the past two decades, a new concept of total mesorectal excision (TME) was introduced[1], and its feasibility and efficacy had been confirmed by a series of clinical trials[2-5]. Compared with conventional procedure, TME markedly improved both oncological and functional outcomes of rectal cancer[6-9], therefore, this procedure has been used as a golden standard for rectal cancer.

Laparoscopic approach has been employed in colorectal surgery for ten years, and its feasibility has been shown in a variety of colorectal operations[10-14]. However, for inadequate operative vision and limitation of the narrow pelvis, total laparoscopic TME with construction of colo-anal anastomosis for low rectal cancer has been regarded as being difficult and time-consuming, and mainly used for upper rectal cancer for a long time[15,16]. Few cases about laparoscopic TME with anal sphincter preservation (SP) for low rectal cancer were reported[17]. The current study was performed to assess the feasibility and efficacy of laparoscopic total mesorectal excision (LTME) for low rectal cancer with preservation of anal sphincter.

MATERIALS AND METHODS

Patients

Between June 2001 and June 2003, randomized 82 patients with low rectal cancer underwent laparoscopic total mesorectal excision with anal sphincter preservation at Department of General Surgery of West China Hospital. The lowest edges of tumors were below peritoneal reflection and 1.5-7 cm from the dentate line (1.5-5 cm in 46 cases, and 5-7 cm in 36 cases). Patients with previous abdominal surgery, obese body, and other surgical benign diseases were not excluded from the laparoscopic procedure. Clinical and demographic data including age, sex, tumor diameter, distances of tumor from the dentate line, concomitant diseases are shown in Table 1.

Table 1 Clinical and demographic data

Parameters	Data
Age, mean (years)	26-85, 44
Sex (No. of patients)	
Male	46
Female	36
Tumor diameter, mean (cm)	1.5-13, 5.6
Distance of the tumor from the dentate line (cm)	1.5-7
1.5-5 cm from lowest edge of tumors to the dentate line (No. of patients)	48
5-7 cm from lowest edge of tumors to the dentate line (No. of patients)	34
Concomitant diseases (No. of patients)	
Chronic cholecystitis, cholecystolithiasis, torsion of ovarian cyst and diabetes	2
Chronic cholecystitis and cholecystolithiasis	6
Previous lower abdominal operation	7

Preoperative examinations including flexible endoscopes, biopsy, ultrasonography, CT scan, radiography of the chest were performed routinely. All patients underwent preoperative bowel preparation (1L 10 % mannite electrolyte solution). Prophylactic antibiotics (ciprofloxacin and metronidazole) were given three days before operation routinely. A urinary catheter and a nasogastric tube were used.

Operative techniques

Under general anesthesia, 82 patients were operated in lithotomic position with 15° head-down tilt by the same surgeon (ZZ ZHOU) with two assistants (YY. YU and Y. SHU). Pneumoperitoneum was introduced through subumbilical incision to maintain pressure at 12-14 mmHg (1 mmHg=0.133 Kpa). A camera port was created in subumbilical zone with trocar, then an operative port in the right midclavicular line at the level of umbilicus, and an other two operative ports in the left and right McBurney point were created.

Laparoscope was inserted at 25° or 30° into abdominal cavity via the camera port. Routine intra-abdominal exploration was performed. All sharp dissections and divisions on peritoneum, fascia, and connective tissue in retroperitoneal space were performed with a harmonic scalpel. Left lateral peritoneal was divided first, and then sigmoid and descending colon were mobilized completely to ensure the subsequent colo-anal anastomosis free of tension. Then the bowel and its mesentery by a cotton tape at the level 8-10 cm above the upper margin of the tumor were tied, lymph nodes around inferior mesenteric vessels were dissected, and inferior mesenteric vessels were ligated at the high level.

With the operation proceeding of total mesorectal excision, division was moved downward into the pelvis along the anatomic space between visceral and parietal endopelvic fascia. Lateral ligaments of the rectum containing the middle rectal artery or its branches (Figure 1) were gradually divided with the harmonic scalpel from the inner limit of the inferior hypogastric nerve fibers (Figure 2). The pelvic splanchnic nerves were preserved intact as far as possible. Anteriorly, Denonvilliers' fascia was dissected and the seminal vesicles and prostate or the posterior wall of the vagina were exposed (Figure 3). At posterior, the rectosacral ligament, anococcygeal ligament, and pubococcygeus muscle were divided, and S_2, S_3, and S_4 sacral splanchnic nerves were identified and protected carefully. The mesorectum, especially the distal mesorectum (DMR), was excised completely till levator ani. Thus, longitudinal muscle layer of the distal precutting rectum and levator ani could be clearly visualized under laparoscopic view, so-called ' denudation' and ' muscularization' . For low bulky tumor, the ' denudation' should be performed under intra-anal finger-guidance to avoid inadvertent damage of adjacent structures. The rectal cross clamping was performed 1.5-3.5 cm below the tumor with endo-cutter (Figure 4).

To extract the bowel loop of the tumor, the port incision was extended at the left McBurney' s point to about 3.5 cm long, and isolated the tumor routinely by inserting in a sheath-shaped plastic bag through the incision. The tumor and the proximal colon was extracted through the bag, and then transected the bowel at the level of 10-15 cm above upper margin of the tumor. After inserting the anvil of 29 or 30 mm-sized circular stapler into the end of proximal bowel and securing with 2/0 prolene purse-string suture, the proximal bowel was internalized and the extended incision was closed. Pneumoperitoneum was induced again. Laparoscopic colo-anal or colo-rectal anastomosis was done with CDH 29 circular stapler. After the circular stapler was inserted into the anus, its puncturing cone was pricked through the midpoint of the distal occluding line of the rectum (Figure 5), and fitted into the anvil of the stapler in the pelvic cavity. The stapler was then closed slowly with extreme cautions to avoid inadvertent stapling of adjacent important structures. In this way, the low/ultralow/ colo-anal anastomoses were accomplished smoothly. A 10 mm-sized latex tube was routinely put into pelvic cavity through the port at the right McBurney point. No defunctioning ileostomy was created in any case. Distal clearance measurements were taken in an unfixed and unpinned status of surgical specimen in the operating room. The specimen was routinely checked if the visceral endopelvic fascia was dissected completely, and then sent for pathologic examination (Figure 6).

Laparoscopic cholecystectomy and ovariectomy could be performed simultaneously for patients with cholecystolithiasis, chronic cholecystitis, ovarian cyst, and torsion of the ovary.

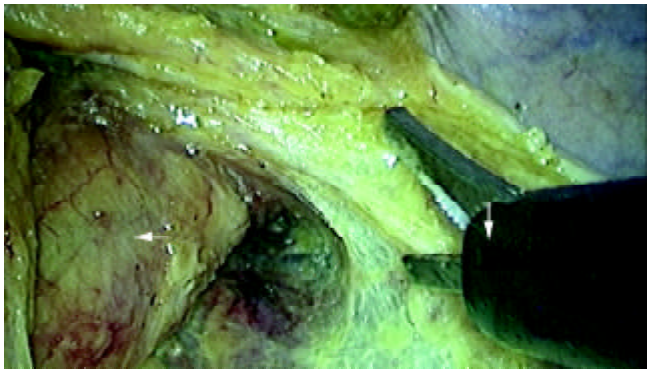

Figure 1 The "lateral ligaments" (→) of rectum containing middle rectal artery or its branches, and mesorectum (←) were dissected completely with a harmonic scalpel (↓).

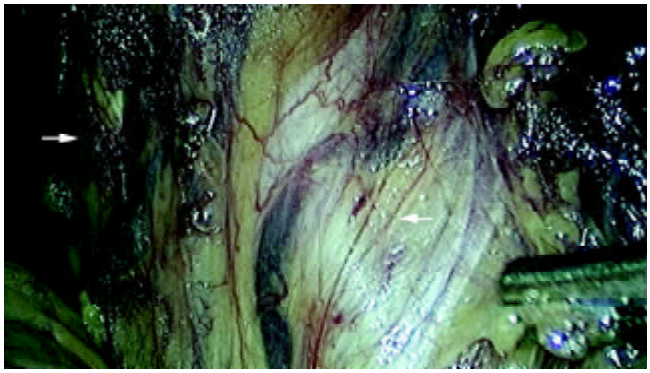

Figure 2 The left pelvic splanchnic nerves were preserved intact as far as possible. Inset shows the inferior hypogastric nerve nerve fibers (←) and the ureter (→).

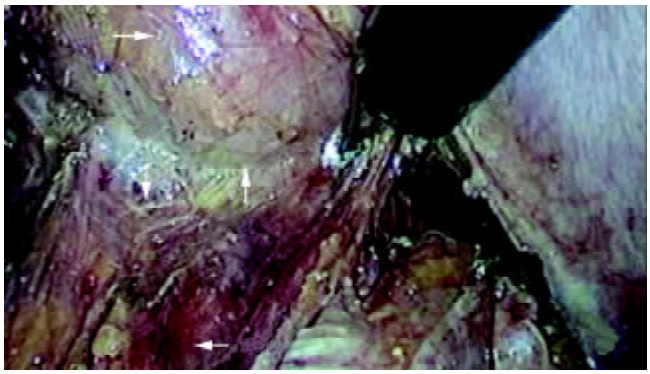

Figure 3 Denonvilliers' fascia (↓)was dissected along the space (↑) between the posterior wall of vagina (→) and the rectum (¡ û).

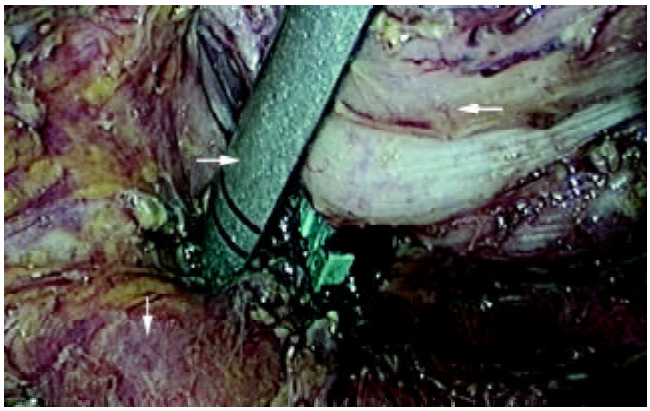

Figure 4 The cross clamping of the rectum (←) was performed 1.5~3.5cm below the tumor with endo-cutter (→). Pelvic floor 'muscularization' was shown (↓).

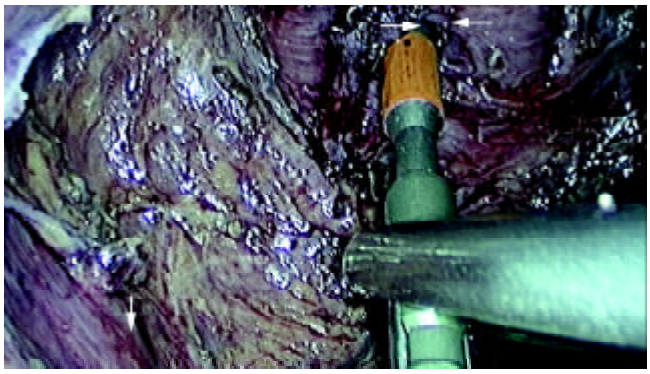

Figure 5 The puncturing cone (→) of the circular stapler pricked through the midpoint of occluding line of the distal rectum(←). Levator ani muscles were exposed (↓).

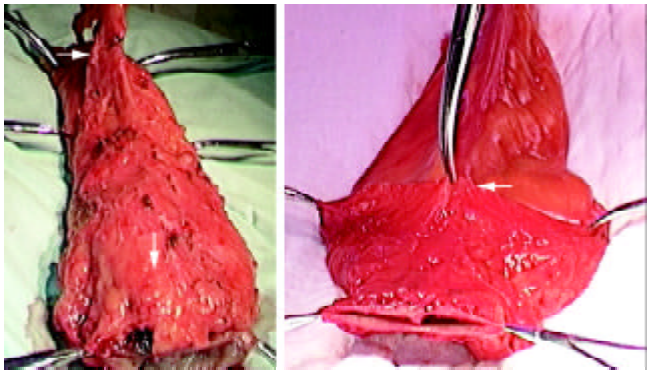

Figure 6 The dorsal mesorectum (→) and distal mesorectum (↓) of the rectal specimen were shown (6a). The anterior side of the specimen and distal margin (←) were shown (6b).

RESULTS

TME with anal sphincter preservation was accomplished with laparoscope in 82 randomized patients with low rectal cancer, and 100 % sphincter preservation rate was achieved. There were 30 patients by laparoscopic low anterior resection (LLAR) at the level of the anastomosis below peritoneal reflection and 2 cm above the dentate line; 27 patients by laparoscopic ultralow anterior resection (LULAR) at the level of the anastomosis 2 cm below the dentate line; and 25 patients by laparoscopic coloanal anastomoses (LCAA) at the level of the anastomosis at/below the dentate line (Figure 7). No defunctioning ileostomy was created in any case. The mean operating time was 120 minutes (ranged from 110-220 min), and the mean operative blood loss was 20 mL (ranged from 5-120 mL). Both bowel function recovery and diet resumption occurred within 1-2 days after surgery, and the mean hospital stay were 8 days (ranged from 5-14). Postoperative analgesics were used in 45 patients. One patient was converted to open surgery due to dysfunction of coagulation. After operation, 2 patients had urinary retention, one had anastomotic leakage, 2 patients had local recurrence one year later, and no interoperative complication was observed. Clinical and surgical details in this study including tumor and anastomotic levels from anal verge, stage of disease, duration of surgery, length of specimen removed, duration of parenteral analgesia, time to passage of flatus, time to resumption of liquids and solids, and length of post-operative stay are shown in Tables 2,3 and 4.

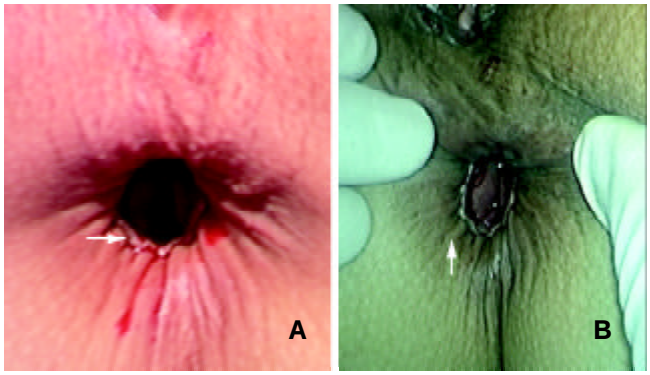

Figure 7 The anastomotic ring (→) could be shown easily in the patient receiving colo-anal anastomosis (a). Satisfactory contractive function of the saved anus (↑) was achieved in the patients receiving laparoscopic TME with anal sphincter preservation at the first day after operation (b).

Table 2 Clinical parameters for patients with LTME and SP

Parameters	Data
Dukes stage (No. of patients)	
A	5
B	10
C1	33
C2	30
D	4
Pathologic types (No. of patients)	
High differentiated adenocarcinoma	24
Moderately differentiated adenocarcinoma	37
Low differentiated adenocarcinoma	21
Multiple primary carcinomas on the bowel wall	3
Distance of the tumor from the section edge (cm)	1.5-4
Cancer cell found in the cut margins (No. of patients)	1
Colo-rectal / anal anastomotic height (cm) (No. of patients)	
LLAR, below peritoneal reflection and 2 cm above the dentate line	30
LULAR, 2 cm below the dentate line	27
LCAA, at / below the dentate line	25

Table 3 Early results for laparoscopic TME and SP

Parameters	Data
Operation time (min)	120(110-220)
Operative bleeding (ml)	20(5-120)
Time for bowel function recovery (d)	1-2
Time to resume normal diet (d)	1-2
Post-operative analgesic requirement (No. Of patients)	45
Total hospital stay (d)	8 (5-14)
Sphincter preservation rate (%)	100 %
Mortality (%)	0

Table 4 Complications of laparoscopic TME and SP

Complications	No. of patients
Total number of patients	82
Perforation of rectum	0
Urethra damage	0
Intra-abdominal bleeding	0
Pelvic abscess	0
Urinary retention	2
Anastomotic Leakage	1
Local recurrence	2

The patients were mobilized two days after operation. Oral intake was gradually increased with the recovery of intestinal function. Most of the patients with low anastomosis as well as about 1/2 of the patients with ultralow or colo-anal anastomosis experienced a quick recovery in anal sphincter' s function and controlling of defecation, while 50 % of patients with ultralow anastomosis or colo-anal anastomosis suffered from urgent defecation about 5-10 times per day, and their defecation was controlled gradually by proper medication and functional exercise of anal sphincter and levator ani around half a year.

There were no portal site recurrence and mortality observed during follow-up, which ranged from 1 to 24 months.

DISCUSSION

Study on the management of rectal cancer has progressed greatly in both clinical practice[18-23] and basic research[24-27] in recent years. Multiple clinical studies have demonstrated the correlation of high pelvic recurrence with the degree of mesorectal excision[28]. Residual mesorectum, especially inadequate excision of distal mesorectum (DMR), contributed to poor oncologic outcomes. Regarding DMR, histopathological evidence revealed a high metastasis rate in this region, and it was also found that patients with metastasis in this region would experience a poor prognosis. This is why the principle of TME should be followed in the treatment of rectal cancer[29-31]. Since clinical application of TME, the local recurrence rate of the cancer has decreased dramatically to 5-7.1 %[7,32,33], while that of conventional operative procedure remains 18.5 %.

Up to now, there are only a few reports on laparoscopic procedure for low rectal cancer in the literatures, which was mainly due to inadequate surgical vision and limitation of the narrow pelvis. The area 5-8 cm from anal verge and below peritoneal reflection has ever been considered as a blind zone and that within 5 cm from anal verge as a forbidden zone. The current study revealed that the so-called blind and forbidden zones could be broken through, and minimally invasive TME with anal sphincter preservation could be performed safely for patients with rectal cancer based on our success of the large number of open TME and low/ultralow/colo-anal anastomosis and proficient laparoscopic skill. This study is concerned with our experience in colorectal surgery and deals with special laparoscopic colorectal techniques including LLAR, LULAR and LCAA.

Based on our clinical experiences, laparoscopic TME and SP have the following advantages: (1) it helps surgeons identify accurately the interspace of loose connective tissue between visceral and parietal pelvic fascia, and select operative access by amplifying inner image on the monitors. (2) 25° or 30° laparoscope, the third eye of the surgeon, can reach the narrow lesser pelvis and magnify the local vision; (3) it is more definite to identify and protect the pelvic autonomic nerve fiber and plexus due to its magnifying function. (4) hemostatic benefit was owed to minimally invasive sharp dissection with minimal blood loss under laparoscopic view.

However, the laparoscopic technique has its disadvantages, such as long operative time, short of direct hand feeling, technical constraints of the narrow pelvis, difficulty in assessing adequate surgical margins and in ultralow rectal cross clamping, and a long learning course for surgeons.

Good experience with laparoscopic surgery leads to shorter operating time and encouraging results. A bulky tumor or a thickening mesentery usually occupies the most space of narrow pelvic cavity and often influence the operation. To avoid this impact, the camera operator should try his best to adjust laparoscope constantly by 25-30°, which keeps the operator at a correct position. Crack sight and smog are other troublesome problems. Crack sight often occurs after the operation moving into lesser pelvis and it can be solved by adjusting the angle of laparoscope properly. Smog results from the operation of using the harmonic scalpel or cautery, which often distracts operator' s vision, even breaks the operative process. The camera operator should withdraw the laparoscope and disperse the smog in time when smog is too heavy or obscures the lens of laparoscope. Therefore, the role of the camera operator is so important that his skill can directly influence the operative processes and results.

The anastomosis is a critical step for the success of this minimally invasive technique with anal sphincter preservation[28]. Double stapling technique (DST) is the remarkable progress in the anastomosis for the operation of low rectal cancer in recent years. Research showed that local recurrence rate was much lower in patients treated with DST than those treated with conventional anastomosis[34]. Low/ultralow/colo-anal anastomoses in all cases of laparoscopic procedure were achieved with DST at this hospital. Based on our experience, there are two special points regarding the anastomosis with DST: (1) denudation of the distal rectal tube, and (2) selection of the pricking point on the occluding line. By denuding the pre-cutting part of the rectal tube, the fat and lymphatic tissue within the mesorectum of distal rectum could be thoroughly excised, the denuded rectal longitudinal muscle could be visualized, and the distal rectum could easily be divided and occluded with endo-stapler. The pricking point of the cone on the stapler should locate at midpoint of the occluding line, because too much displacement of the pricking point may result in ischemia and leakage of the anastomosis, or stapling of adjacent important structures. These two steps can effectively prevent rectal wall from damage and dehiscence of the anastomosis, reduce the use of endo-staplers, and decrease local recurrence.

Special training on TME technique is necessary for surgeons to have enough experience of TME and SP[35]. Proficient skills of laparoscopic operation in pelvis and plentiful experience of open TME are important factors for the success of LTME and SP.

Abstract

AIM: To study changes in characteristics of colorectal carcinoma during the metastatic process and to investigate the correlation between cell proliferation activity and metastatic ability of patients with Dukes' stage C or D.

METHODS: Formalin fixed and paraffin embedded materials of primary tumors and corresponding lymph node metastases resected from 56 patients with Dukes' stage C or D of colorectal carcinoma were stained immunohistochemically with proliferating cell nuclear antigen (PCNA) and CD44 variant exon 6 (CD44v6).

RESULTS: Thirty-one of 56 patients (55.4 %) expressed PCNA in the primary sites and 36 of 56 patients (64.3 %) expressed PCNA in the metastatic lymph nodes. A significant relation in PCNA expression was observed between the primary site and the metastatic lymph node ($0.010<P<0.025$). Forty-one of 56 patients (73.2 %) expressed CD44v6 in the primary site and 39 of 56 patients (69.6 %) expressed CD44v6 in the metastatic lymph node. There was also an significant relationship of CD44v6 between the primary site and the metastatic lymph node ($0.005<P<0.010$). No difference was observed between expression of CD44v6 and PCNA in the primary site ($0.250<P<0.500$).

CONCLUSION: This study partially demonstrates that tumor cells in metastatic lymph node of colorectal carcinoma still possess cell proliferation activity and metastatic ability of tumor cells in primary site. There may be no association between cell proliferation activity and metastatic ability in colorectal carcinoma.

INTRODUCTION

Colorectal carcinoma appears to be increasing in Chinese populations and is characterised by an aggressive course and frequent metastases resulting in death. To reduce morbidity and mortality, identification of those patients with a high propensity to develop distant metastases is of great importance, since they might benefit from adjuvant chemotherapy and/or radiotherapy[1,2]. Although Dukes' classification is still considered as the most accurate predictor of prognosis after resection, even within a group of tumors of a specified stage, tumor behaviour and prognosis of the disease is not uniform[3-5]. For this reason, additional markers that predict tumor metastatic behaviour are needed[6-9]. At present, PCNA has been described as a significant factor in the prognosis of colorectal carcinoma in several studies[10-12]. On the other hand, many studies demonstrated that expression of CD44v6 correlated with poor survival and was an independent prognosticator in patients who underwent radical surgery[13-17]. However, to our knowledge questions concerning metastases, characteristic changes that occur during the metastatic process, and the correlation between tumor characteristics have to be clarified in detail[18-20]. To our knowledge, there has been neither any study regarding patients with Dukes' stage C or D analyzing both primary sites and corresponding metastatic lymph nodes genetically or immunohistologically nor a study assessing their relationship.

We examined the expression of these two factors in both primary sites and metastatic lymph nodes to elucidate the characteristic changes of the tumor during metastases and to evaluate the correlation between cell proliferation activity and metastatic ability of the tumor in patients with Dukes' stage C or D of colorectal carcinoma.

MATERIALS AND METHODS

Materials

175 consecutive patients with colorectal carcinoma admitted to our department underwent resection between 1989 and 1996. The total rate of lymph node metastasis was 33.7 %, 77.2 %, of which lymph node metastasis next to the colorectum was, 17.9 % and 4.9 % mesentery and mesenteric artery ligation point respectively. Of these 175 patients, 62 (35.8 %) were diagnosed with Dukes' stage C or D. Among these 62 patients, 56 whose primary site and metastatic node tissues were immunohistochemically evaluable were enrolled in the study. They were comprised of 30 males and 26 females with a mean age of 51.3±14.2 years. Forty nine patients with Dukes' stage C underwent a complete tumor resection with lymph node dissectioned and 7 patients with Dukes' stage D underwent a palliative tumor resection with lymph node dissectioned in the Department of Gastroenterology, Shannxi Provincial Cancer Hospital in Xi' an, China. The patients had not been treated before. Their respective clinical data were collected through the review of their medical records. Histologic typing revealed 12 papillary adenocarcinomas, 27 tubular adenocarcinomas, 10 mucinous adenocarcinomas, 5 signet-ring cell carcinomas

and 2 undifferentiated carcinomas. Of these patients, there were 49 patients with Dukes' stage C, whose average number of metastatic lymph nodes was 5.3±2.1 and 7 patients with Dukes' stage D, whose average number of metastatic sites including lymph node, liver, greater omentum and peritoneum was 8.7±2.6. The paraffin-embedded blocks and histological slides were taken from the Department of Pathology, Shaanxi Provincial Cancer Hospital (Table 1).

Table 1 Characteristics of patients with Dukes' stage C or D colorectal carcinoma

Gender	Male	30
	Female	26
Age(yrs) (mean±SD)	51.3±14.2	
Histology	Papillary adenocarcinoma	12
	Tubular adenocarcinoma	27
	Mucinous adenocarcinoma	10
	Signet-ring cell carcinoma	5
	Undifferentiated carcinoma	2
Dukes' classification	Stage C	49
	Stage D	7

Methods

Formalin fixed, paraffin embedded sections of samples were stained immunohistochemically with labeled streptavidin-biotin (LSAB) using a LSAB Kit (Doctor Biotechnology Company, Wuhan, Hubei Province, China). The samples were thinly sectioned (4 μm thick). After deparaffinization, the sections were hydrolyzed with ethanol and endogenous peroxidase activity was inhibited with 0.3 % hydrogen peroxide-containing methanol at room temperature for 15 minutes. For antigen retrieval, the sections were mounted in 300 mL 0.01 M sodium citrate buffer (pH 6.0) in a container and microwaved for 15 minutes at maximum power in a Sharp microwave oven (850 W). Nonspecific binding sites were blocked with 10 % nonimmune goat serum. For PCNA, PC10 (Zymed Laboratories, California) whose optimal dilution was 1:150 was used for the first antibody and allowed to react at 4 ℃ for 12 hours. For CD44v6, CD44 variant exon 6 (VFF-18; Bender Co.) whose optimal dilution was 1:100 was used for the first antibody and allowed to react at 4 ℃ for 12 hours. After the second antibody was made to react, peroxidase-labeled streptoavidin was finally allowed to react as an enzyme reagent. Diaminobenzidine was used for coloring. Sections of human tonsils and submucosal lymphoid follicles were used as positive control for PCNA. Positive control of CD44v6 was normal human stratified squamous epithelium which could be strongly stained by anti-CD44v6 antibodies[15]. Sections stained by omitting the primary antibody were used as their negative controls. At least 5 visual fields of the immunohistochemically stained sample were observed at random at ×100 or ×400 magnification. More than 1000 tumor cells were counted by two investigators who were blinded to the clinical outcome. The number of positive cells was counted and expressed as percentage. For PCNA, when the percentage of positive cells was ≤50 %, the specimen was diagnosed as negative, and when >50 %, the specimen was diagnosed as positive. We also determined the percentage of cells positively stained for CD44v6, as well as the intensity of this staining. Negative, ≤ 10 % of cells were positively stained, and positive, >10 % cells were positively stained[21]. The data were analyzed using χ^2 text and a P value <0.05 was considered significant.

RESULTS

Immunohistochemical staining with PCNA showed a selective nuclear pattern (Figures 1,2). Thirty-one of 56 patients (55.4 %) expressed PCNA in the primary site and 36 of 56 patients (64.3 %) expressed PCNA in the metastatic lymph node. Among these 56 patients, twenty-four expressed PCNA in both the primary site and metastatic lymph node, seven patients expressed PCNA in the primary site but did not express it in the metastatic lymph node, whereas twelve patients did not express PCNA in the primary site but expressed it in the metastatic lymph node, thirteen patients expressed PCNA in neither the primary site nor metastatic lymph node (Table 2). For expression of PCNA in these 56 patients, a significant relation was observed between the primary site and the metastatic lymph node ($0.010< P<0.025$).

To evaluate the correlation between cell proliferation activity and metastatic ability, we studied expression of PCNA and CD44v6 in the primary site. Among these 56 patients, twenty-one expressed both PCNA and CD44v6 and 5 expressed neither PCNA nor CD44v6 in the primary site, twenty expressed CD44v6 but did not express PCNA, whereas ten did not express CD44v6 but expressed PCNA in the primary site (Table 4).

No difference was observed between expression of CD44v6 and PCNA in the primary site($0.250< P<0.500$).

Cell morphology

Immunohistochemical staining with PCNA showed a selective nuclear pattern (Figures 1,2). Intensely positive staining with CD44v6 mainly occurred on the cell membrane surface of tumor cells (Figure 3). Expression of CD44v6 in corresponding metastatic lymph node showed that tumor cells were invading lymph node from periphery (Figure 4).

DISCUSSION

One of the first steps in multistage colonic carcinogenesis is increased cell proliferation. PCNA, which is a nonhistone nuclear protein of 36 kilodaltons, also is known as cyclin and an auxiliary factor in DNA polymerase, plays a very important role in DNA replication[22]. Because of this direct relation with cell proliferation, PCNA is considered to be an important factor in prognosis. In fact, it has been described as a significant factor in the prognosis of colorectal carcinoma in several studies[10-12]. CD44, a glycoprotein of the membrane penetration type, functions as an extracellular matrix glycan receptor and a hyaluronate receptor[23]. As a consequence of studies in rats showed that CD44v6 could confer metastatic potential to rat pancreatic carcinoma cell lines[24], studies addressing the prognostic and biological significance of CD44 variant expression in human cancer have largely been focused on CD44v6. Overexpression of CD44v6 has been demonstrated in colorectal neoplasia by immunohistochemistry, RT-PCR and *in situ* hybridization. Their expression was found to correlate with tumor stage[13-17]. As for prognosis, it was shown that expression of CD44v6 correlate with poor survival rate and was an independent prognosticator in patients who underwent radical surgery. Hence, it identifies individuals with a high propensity to develop metastases. These patients might benefit from adjuvant therapy[16].

Despite intensive research in recent years, very little is known about the characteristic changes of malignant colorectal tumor cells during the process of metastases. We examined expression of these two factors in both primary site and metastatic lymph node. Among these 56 patients, twenty-four expressed PCNA in both the primary site and metastatic lymph node and thirteen expressed PCNA in neither the primary site nor metastatic lymph node. The concordence rate of PCNA expression in the primary site and in the metastatic lymph node was 66.1 % ($0.010< P<0.025$). That is to say, compared with primary site, PCNA expression in metastatic lymph node had no significant change. This suggests that cell proliferation activity revealed by PCNA still exists in the tumor cells of metastatic lymph nodes. Similarly, the concordence rate of CD44v6 expression in the primary site and in the metastatic lymph node was 75.0 % ($0.005<P<0.010$). This also means that metaststic ability revealed by CD44v6 still exists in the tumor cells of metastatic lymph nodes.

Although cell proliferation and metastasis are a very complicated problem involving many molecular mechanisms and biologic factors, our study partially showed that tumor cells in metastatic lymph node of colorectal carcinoma still possessed cell proliferation activity and metastatic ability of tumor cells in primary site. However, Kimball *et al*[25] isolated a cellular subpopulation from a human colonic carcinoma cell line and Brattain *et al*[26] reported that malignant cells from a human colonic carcinoma possessed heterogeneity. A question rises: do tumor cells of colorectal carcinoma not possess heterogeneity between the primary site and the metastatic lymph node? It is well known that cancer cell population, either as a solid tumor mass *in vivo* or as a continuous cell line *in vitro*, is an ever-changing entity due to their genetic instability and selective environmental pressure. A tumor mass consists of different cell clones, a phenomenon known as tumor

heterogeneity[27,28]. Based on this phenomenon, tumor cell clones with different biological properties have been isolated from a number of human and animal tumor cell lines. The differences included a variety of biological characteristics such as tumor cell morphology, karyotypes, *in vitro* and *in vivo* growth patterns[29,30], DNA ploidy[31] tumorigenicity, metastatic patterns and metastatic potentials[32]. Cancer metastasis is the ultimate display of complex interactions between the malignant cells and the host defense mechanism. The process of metastasis consists of selection and sequential steps that include angiogenesis, detachment,motility, invasion of the extracellular matrix, intravasation, circulation, adhesion, extravasation into the organ parenchyma and growth[28]. The ability of cancer cells to form metastasis depends on a set of unique biological properties that enable the malignant cells to complete all those steps of metastatic cascade. But this basically biological theory is not in contradiction with our present study, because our results are a clinicopathologic outcome depending upon experiment.

Our study showed that there was no significant association between expression of CD44v6 and PCNA in the primary site ($0.250< P<0.500$). This result partially indicated that there existed no absolute association between cell proliferation activity and metastatic ability in colorectal carcinoma. At present, whether tumor cell growth rate is directly related to metastasis is not clear yet. Yasoshima *et at*[33] using metastatic gastric cancer cell line, and Samiei *et al*[34] using metastatic mammary clones found that metastasis was independent of tumor cell growth, while other works[35-37] showed a close association between tumor cell growth rate and metastasis. Further study of the correlation between cell proliferation activity and metastatic ability in colorectal carcinoma is therefore needed.

In conclusion, we have partially demonstrated in the present study that tumor cells in metastatic lymph node of colorectal carcinoma still possess cell proliferation activity and metastatic ability in primary site. There may be no association between cell proliferation activity and metastatic ability in colorectal carcinoma.

Abstract

AIM: To explore the prevalence of autoimmune gastritis in chronic hepatitis C virus (HCV) patients and the influence of α-interferon (IFN) treatment on autoimmune gastritis.

METHODS: We performed a prospective study on 189 patients with positive anti-HCV and viral RNA enrolled in a 12-month IFN protocol. We evaluated: a) the baseline prevalence of autoimmune gastritis, b) the impact of IFN treatment on development of biochemical signs of autoimmune gastritis (at 3, 6 and 12 months), c) the evolution after IFN withdrawal (12 months) in terms of anti-gastric-parietal-cell antibodies (APCA), gastrin, anti-thyroid, and anti-non-organ-specific antibodies.

RESULTS: APCA positivity and 3-fold gastrin levels were detected in 3 (1.6 %) and 9 (5 %) patients, respectively, at baseline, in 25 (13 %) and 31 (16 %) patients at the end of treatment (both $P<0.001$, *vs* baseline), and in 7 (4 %) and 14 (7 %) patients 12 months after withdrawal ($P=0.002$ and $P=0.01$ respectively, *vs* baseline; P=not significant *vs* end of treatment). The development of autoimmune gastritis was strictly associated with the presence of autoimmune thyroiditis ($P=0.0001$), no relationship was found with other markers of autoimmunity.

CONCLUSION: In HCV patients, IFN frequently precipitates latent autoimmune gastritis, particularly in females. Following our 12-month protocol, the phenomenon generally regressed. Since APCA positivity and high gastrin levels are associated with the presence of antithyroid antibodies, development of autoimmune thyroiditis during IFN treatment may provide a surrogate preliminary indicator of possible autoimmune gastritis to limit the need for invasive examinations.

INTRODUCTION

Chronic hepatitis C virus (HCV) infection can lead to the development of chronic liver disease, cirrhosis and hepatocellular carcinoma (HCC)[1]. Chronic HCV patients frequently have a broad spectrum of autoantibodies and/or concurrent autoimmune disease[2-4], apparently not closely associated with the HCV genotype[5] or to the severity of liver disease[6]. Several studies have indicated that immunological abnormalities are sometimes unmasked by interferon-α (IFN) therapy[7-12]. Although autoimmune thyroiditis is one of the most common immunological side effects of IFN treatment, with very close monitoring, its presence is not an absolute contraindication for the therapy. A close association has been reported between autoimmune thyroiditis and autoimmune (i. e. type A) gastritis[13]. Autoimmune gastritis involves the fundus and the body of the stomach while sparing the antrum. It is associated with pernicious anemia, autoantibodies to gastric parietal cells, achlorhydria, low serum pepsinogen I with normal serum pepsinogen II concentrations[14] and high serum gastrin concentration, the latter is resulted from hyperplasia of gastrin-producing cells. It is thought that *Helicobacter pylori* (*H.pylori*) could be implicated in the development of autoimmune gastritis[15,16], since it induces antigenic mimicry[17] and antibodies against *H. pylori* can cross-react with both antral mucosal and gastrin-producing cells.

The frequencies of thyroiditis manifestations during IFN treatment of chronic hepatitis C infection are well documented[7,9,10]. However, the impact of IFN therapy on the development of autoimmune and other types of gastric disease is unknown. To address this issue, we designed a prospective study on 189 chronic HCV patients treated with IFN. In particular, we investigated: a) the baseline prevalence of autoimmune gastritis, b) the impact of IFN on the development of biochemical signs of autoimmune gastritis, c) the outcome of twelve months after withdrawal of IFN. We also examined the presence of antithyroid, antigastric parietal-cell and anti-non-organ-specific (anti-NOS) antibodies. Finally, we investigated whether the presence of *H. pylori* affected the development of autoimmune gastritis.

MATERIALS AND METHODS

Patients and study design

We prospectively studied a group of 189 consecutive IFN-treated chronic hepatitis C patients (95 males, 94 females, mean age 58±18 years) who entered an IFN therapeutic program at our institution from September 1996 to July 1998 (Table 1). Criteria for the diagnosis of chronic HCV infection were: 1) presence of anti-HCV antibodies and polymerase chain reaction (PCR) positivity for HCV-RNA, 2) histological confirmation of chronic hepatitis C, 3) exclusion of other causes of chronic liver diseases (alcoholism, Wilson's disease, drugs, hemochromatosis, a1 antitrypsin deficiency, autoimmune hepatitis, PBC). Criteria for inclusion in the IFN treatment program were the generally recognized ones (transaminase levels over two times the upper limit, age between 18 and 70

years, absence of pregnancy and psychiatric history or other chronic severely invalidating conditions). None of the patients had received immunosuppressive or immunostimulatory therapy before entry into the study. All the patients were negative for human immunodeficiency virus (HIV) antibodies and hepatitis B surface antigen (HBsAg). Disease activity and stage were evaluated according to Scheuer' s histological score. None of the patients were receiving proton pump inhibitors or anti-H_2 antagonist drugs. Informed consent was obtained from each patient and approval for the study protocol was granted by the Ethical Committee of our institution.

Table 1 Baseline characteristics of patients

Patients (*n*)	189	
Age (*year*) ± SD	58±18	
Sex (M / F)	95 / 94	
ALT (U / L) ± SE	142±8	
AST (U / L) ± SE	103±7	
Genotype 1-4 *vs* others	115 *vs* 74	61 *vs* 39%
Anti-*Hp* positive antibody	60	31.8%
Gastrin (pg / ml)(median±SE)	52.0±10.4	
TSH (UI / ml)	2.2±0.15	
ANA positive (*n*)	34	18%
AMA positive (*n*)	-	
ASMA positive (*n*)	57	30%
LKM positive (*n*)	1	0.5%
APCA positive (*n*)	3	1.6%
ATM positive (*n*)	15	7.8 %
Liver histology (*n*)		
CAH without cirrhosis (*n*)	138	73 %
CAH with cirrhosis (*n*)	51	27 %

All the patients received 6 MU of recombinant IFN daily for the first month, followed by 6 MU each alternate day for 5 months and then 3 MU each alternate day for a further 6 months. In the event of side-effects, the dosage was decreased. If side effects were severe or sustained, IFN treatment was suspended.

Serum samples were analyzed in all the patients for presence of gastric parietal cell autoantibodies and gastrin at the following time points: baseline, after 3 and 6 months of treatment, the end of IFN treatment (i.e. at 12 months, or at the time of suspension, if earlier), 12 months after suspension of IFN. Multiple endoscopic gastric biopsies were always performed when positive anti-gastric parietal cell autoantibodies and/or serum levels of gastrin were found to be over 3 times the normal upper limit, presence of gastrinoma was excluded by the secretin stimulation test. In all patients, *Helicobacter pylori* status was serologically tested before the start of treatment. Criteria for diagnosis of autoimmune gastritis were according to Sidney classification system[18,19].

Biochemical and virological assays

Serum samples were analyzed for routine biochemical liver function tests with a multichannel autoanalyzer. HBsAg and anti-HBs and anti-hepatitis B core (HBc) antibodies were tested using a commercial solid-phase radioimmunoassay (Abbott Laboratories, North Chicago, IL). HIV determination was done according to a standard enzyme-linked immunosorbent assay (ELISA) procedure (HIV ELISA, Abbott Laboratories, North Chicago, IL). Anti-HCV antibodies were tested using a second-generation ELISA procedure (ELISA-2, Ortho Diagnostic Test Systems, Raritan, NJ). HCV RNA was detected by nested PCR analysis using primers from the highly conserved 5' non-coding region of the HCV genome (Shindo *et al*, 1991). HCV genotype was determined by InnoLipa.

Immunoserological evaluation

Anti-nuclear, anti-mitochondrial, smooth-muscle and liver-kidney microsome-1 auto-antibodies (ANA, AMA, SMA and LKM-1) were determined using indirect immunofluorescence assays on unfixed cryostat frozen sections of mouse liver, kidney and stomach. Sera were screened for anti-parietal cell autoantibodies (APCA) by immunofluorescence reactivity with paraffin-embedded sections of mouse stomach and for H^+/K^+-ATPase autoantibodies by ELISA. A positive result required a titer of at least 1/40. Basal serum gastrin and thyroid serum hormone (TSH) concentration were measured by radioimmunological assay (RIA), which detects sulfated and non-sulfated human heptadecapeptide (hG-17), as well as human big gastrin (hG-34). Gastrin results were expressed as pg/ml. Thyroid microsomal and thyroglobulin autoantibodies (TMA and TGA) were analyzed using hemagglutination tests (Ames, Elkhart, IN, USA). The cut-off points for both TMA and TGA were 1:100.

H. pylori investigation

Serum immunoglobulin G (IgG) response to *H. pylori* purified antigens was measured by ELISA, the cut-off value used was an optical density ratio >1.0. The presence or absence of *H. pylori* was also defined by histological examination of multiple gastric biopsy specimens from the antrum, fundus, or cardia in all the patients with positive APCA and/or elevated levels of gastrin. All biopsy specimens were fixed in Hollande' s fixative and stained with H&E and Giemsa.

Statistical analysis

Intent-to-treat analysis was adopted. To analyze associations among groups the Fisher' s exact test and the χ^2 test with Yates' correction were used. A two-tailed *P* value less than 0.05 was considered significant.

RESULTS

Treatment outcome

The entire 12-month treatment schedule was completed by 168/189 (89 %) of patients. In 21 patients, the IFN dose was reduced due to the severity of side effects (severe thrombocytopenia and/or severe leukopenia with neutrophil count <800/mm^3, continuous fever unresponsive to paracetamol, or severe myalgia). At least three months of treatment were completed by all but two of the patients (one suspended due to severe depression and suicidal tendency, the other due to side effects coupled with lack of motivation). None of the patients who discontinued therapy was positive for APCA.

Abdominal symptoms

In 164/189 (87 %) patients, no abdominal symptoms were reported. The most frequently reported symptoms were epigastric pain and/or abdominal discomfort. Presence of abdominal symptoms was not affected by positivity/negativity for *H. pylori*.

APCA and hypergastrinemia outcome (Tables 2, 3)

At the start of treatment, APCA positivity was detected in 3 (1.6 %) patients, and hypergastrinemia (i.e. serum gastrin levels over three times the normal upper limit) was found in a further 9 (5 %). At the end of treatment, these incidences rose to 25 (13 %) and 31 (16 %) patients, respectively (both $P<0.001$ *vs* baseline values). Thus, 22 patients developed both APCA and hypergastrinemia, mostly by the third month of therapy. Twelve

months after suspension of IFN, APCA and hypergastrinemia were still present in 7 (4 %) and 14 (7 %) patients, respectively (P=0.002 and P=0.01, respectively, *vs* end of IFN treatment; both P=not significant *vs* baseline). During IFN treatment, females were more prone to have increased APCA (P=0.017) or increased serum gastrin levels (P=0.011) than males.

Serum gastrin levels (defined as median ± Standard Error) increased during administration of IFN (from 52±10.4 pg/ml to 57±17.2 pg/ml, P=0.001). Twelve months after withdrawal of therapy, serum gastrin levels (56±12.6 pg/ml) were still higher than those at baseline (P=0.001), although they were significantly lower than those at the end of treatment (P=0.001). Serum TSH levels increased during administration of IFN (from 2.6±0.13 MCU/ml to 3.2±0.17 MCU/ml, P=0.02), and subsequently remained higher than the baseline values at 12 months from withdrawal of therapy (3.2±0.3 MCU/ml, P=0.02 *vs* baseline, P =not significant *vs* withdrawal). As can be seen from Tables 2 and 3, the behavior of the antithyroid autoantibodies TPO was very similar to that of APCA. By contrast, IFN did not affect the non-organ-specific antibodies ANA, SMA and AMA.

Table 2 Variations of APCA positivity and hypergastrinemia in IFN treated patients

	Before IFN *n* (%)	IFN withdrawal *n* (%)	12 months after withdrawal *n* (%)
APCA positivity	3 (1.6%)	25 (13%)[a]	7 (4%)[b,d]
Hypergastrinemia	9 (5%)	31(16%)[a]	14 (7%)[c,d]

[a]P<0.001 *vs* before IFN; [b]P<0.002 *vs* IFN withdrawal; [c]P<0.01 *vs* IFN withdrawal; [d]P=not significant *vs* before IFN.

Table 3 Organ-specific and non-organ-specific autoantibodies

	Before IFN + (%)	IFN withdrawal + (%)	12 months after withdrawal+(%)
Organ-specific antibodies			
TPO	14 (8.0%)	39 (20.6%)[a]	23 (12.2%)
Non-organ-specific antibodies			
ANA	34 (18.0%)	45 (24.0%)	41 (22.0%)
SMA	56 (30.0%)	62 (33.0%)	60 (31.0%)
AMA	-	1 (0.5%)	1 (0.5%)
LMK 1	1 (0.5%)	3 (1.6%)	2 (1.1%)

[a]P<0.001 *vs* before IFN; P=0.036 *vs* 12 months after IFN withdrawal.

H. pylori status

At baseline, 61/189 (32.3 %) patients had a positive serum IgG response to *H. pylori* whole-cell antigen. These included 3 of the 9 (33.3 %) patients with autoimmune gastritis and 12 of the 31 (38.7 %) who developed biochemical signs of autoimmune gastritis during treatment.

Histology

Multiple endoscopic gastric biopsies were performed when positive APCA and/or serum levels of gastrin were found to be over 3 times the normal upper limit. At biopsy, all the patients with either baseline APCA positivity (n=3) or hypergastrinemia (n=9) showed a histological picture consistent with autoimmune gastritis. Among the 22 patients who developed both APCA positivity and hypergastrinemia during IFN therapy, the histology of the fundus was consistent with autoimmune gastric atrophy in 13 (59 %). Four other patients who were persistently consistent with presence of gastric atrophy maintained histological lesions at 12 months from IFN withdrawal.

Outcome of HCV infection

At baseline, 115/189 (61.0 %) patients were found to be infected with HCV genotype 1 or 4, while the remaining 74 (39.0 %) were infected with more IFN-responsive strains. Overall, 37/189 (19.5 %) patients showed a long-term virological response to IFN (at 12 months from withdrawal). In particular, long-term response was observed in 8/109 (7.3 %) patients with genotype 1, 21/39 (35 %) with genotype 2, 7/14 (50 %) with genotype 3, and 1/6 (16 %) with genotype 4, respectively. No difference in responsive rate was observed among the patients who developed hypothyroidism and/or hypergastrinemia and those who did not. No relationships were observed between HCV genotype and the development of autoimmune gastritis.

DISCUSSION

The prevalence of autoimmune gastritis in chronic HCV patients is currently unknown. Autoimmune gastritis can be associated with thyroid autoimmune abnormalities. The hypothesis that IFN therapy encourages the development of autoimmune gastritis in these patients has never been tested.

In this prospective study, we investigated the occurrence of autoimmune gastritis in 189 chronic HCV patients treated with IFN. The baseline prevalence of biochemical signs and histological features of autoimmune gastritis was similar to that found in the general population. However, the number of patients who displayed biochemical and/or histological signs of autoimmune gastritis significantly increased during IFN treatment. By 12 months after interruption of IFN, the number of patients showing these signs had partially regressed, although it still remained higher than the baseline value. Seven more patients continued to have elevated APCA and gastrinemia, all with histological evidence of autoimmune gastritis. These findings are in line with the hypothesis that IFN can unmask patients with latent autoimmune gastritis and sometimes may even induce permanent alterations consistent with autoimmune gastritis. Our findings also support the concept that these abnormalities are more frequent in females.

Patients with autoimmune gastritis have a 3-fold increased risk of gastric carcinoma and a 13-fold higher risk of gastric carcinoid tumours[20]. However, it is not known whether hypergastrinemia or mucosal damage plays a dominant etiologic role[21]. Evidence exists that endogenous hypergastrinemia is associated with stimulation of rectal[21] and liver cell proliferation[22,23], as also occurs in conditions that are known to raise the risk of colon cancer and HCC. HCV patients are at increased risk of developing HCC anyway[1] but IFN treatment seems to prevent or delay its onset[24]. Hence, the implications of the occurrence of hypergastrinemia followed by autoimmune gastritis during IFN treatment of HCV infection require careful consideration.

Although 13/22 of our patients developed histological signs of autoimmune gastritis during the 12-month period of therapy, in the majority of cases, these signs regressed in the following year. Persistent histological and biochemical hallmarks of autoimmune gastritis were only eventually found in 4 % (7 of 189) of our patients. The relatively short duration of immunostimulation by IFN may explain why the autoimmune gastritis regressed in most cases. Therefore, our findings may only be applicable to the effects of short-term treatment.

The presence of antithyroid antibodies does not absolutely contraindicate the use of IFN[25], even though it has to be remembered that IFN leads to permanent thyroid alterations in more than one-fifth patients[26,27]. Likewise, although the presence of autoimmune gastritis does not contraindicate IFN treatment, it has to be considered that some patients may develop permanent gastric alterations.

In the present study, we also investigated the possibility that *H. pylori* infection might play a pathogenetic role in the onset of autoimmune gastritis in IFN-treated chronic HCV patients[15,16]. Our data provided no support for this hypothesis. Indeed, in our series of patients, there was no observable difference in the frequencies of autoimmune gastritis between chronic HCV patients with and without *H. pylori* infection, either before, during or after IFN treatment.

Furthermore, we were unable to find any association between the presence of non-organ specific antibodies and that of antithyroid antibodies or APCA. This finding is of clinical interest because positivity for antithyroid antibodies or APCA reveals autoimmune thyroid or gastric disease, whereas the presence of anti-NOS antibodies may only refer to an autoimmune epiphenomenon. This underlines the importance of testing antithyroid antibodies and APCA as well as the anti-NOS ones.

In conclusion, IFN treatment for chronic hepatitis C does appear to be associated with frequent occurrence of autoimmune gastritis, particularly in female patients. In the majority of cases, autoimmune gastritis in the wake of our protocol appeared to be a transient phenomenon. However, this may depend on the limited (12 month) duration of treatment, and this point requires further investigation, especially in regard to the effects of long-term treatment. Autoimmune gastritis is an asymptomatic disease, but in the long run increases the risk for developing a variety of tumors especially in the stomach. Our experience underlines the importance of measuring APCA and/or gastrin levels in chronic HCV patients treated with IFN, and especially those who develop thyroid dysfunction. Development of autoimmune thyroiditis during IFN treatment might provide a surrogate indicator of possible autoimmune gastritis, limiting the need for invasive gastric procedures.

Abstract

AIM: To investigate the safety and efficacy of long-term combination therapy with alpha interferon and lamivudine in non-responsive patients with anti-HBe-positive chronic hepatitis B.

METHODS: 34 patients received combination treatment (1 month lamivudine, 12 month lamivudine+interferon, 6 month lamivudine), 24 received lamivudine (12 months), 24 received interferon (12 months). Interferon was administered at 6 MU tiw and lamivudine at 100 mg orally once daily. Patients were followed up for 6 months after treatment.

RESULTS: At the end of treatment, HBV DNA negativity rates were 88 % with lamivudine+interferon, 99 % with lamivudine and 55 % with interferon, (P=0.004, combination therapy *vs.* interferon, and P=0.001 lamivudine *vs.* interferon), and serum transaminase normalization rates were 84 %, 91 % and 53 % (P=0.01 combination therapy *vs.* interferon, and P=0.012 lamivudine *vs.* interferon). Six months later, HBV DNA negativity rates were 44 % with lamivudine+interferon, 33 % with lamivudine and 25 % with interferon, and serum transaminase normalization rates were 61 %, 42 % and 45 %, respectively, without statistical significance. No YMDD variants were observed with lamivudine+interferon (*vs.* 12 % with lamivudine). The combination therapy appeared to be safe.

CONCLUSION: Although viral clearance and transaminase normalization are slower with long-term lamivudine+interferon than that with lamivudine alone, the combination regimen seems to provide more lasting benefits and to protect against the appearance of YMDD variants. Studies with other regimens regarding sequence and duration are needed.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection remains a major worldwide public health problem. Over 300 million people are affected by the disease[1], which is associated with high mortality and morbidity due to the associated risk of cirrhosis and hepatocellular carcinoma[2]. In addition, HBV infection is becoming an increasingly relevant problem for transplanted and immunodeficient patients, who are prone to develop more severe, accelerated liver disease[3].

Until recently, interferon-α (IFN) was the only drug approved throughout the world for chronic HBV infection[4,5]. Unfortunately, relapse with return of viremia and hepatitis occurs in up to 50 % of cases[6]. The hepatitis B s antigen (HBsAg) may become negative in months to years after the end of treatment, suggesting total viral clearance[7]. IFN is less effective in the presence of HBeAg negativity[8], or in patients who have already developed cirrhosis or have had recurrence of HBV after a hepatic allograft.

Lamivudine (3TC) is the first potentially non-cytotoxic[9,10] oral nucleoside analogue approved for the treatment of chronic hepatitis B. It suppresses viral DNA replication by means of chain termination, and competitively inhibits viral polymerase, but does not act on supercoiled DNA. For these reasons, lamivudine rapidly reduces serum HBV DNA, enhances transaminase normalization, and improves the histological picture[11-13]. But only 16 % achieve full HBeAg seroconversion, and after suspension of therapy serum HBV DNA levels and transaminases generally return to pretreatment values[14]. Furthermore, after clearance of HBV DNA, mutations in the sequence of the YMDD locus of the HBV RNA-dependent DNA polymerase appear in 15 % of cases after one year of therapy, leading to recurrence of viremia[15]. Onset of resistance generally occurs after six months to several years of lamivudine therapy[16].

Combination therapy with IFN and lamivudine is being investigated in order to take advantage of the drugs' different mechanisms of action[17-21]. However, the results of short-term treatment studies have been not altogether encouraging[18]. The aim of the present study was to investigate whether long-term combination therapy was safe and well tolerated, and whether it could provide additional therapeutic benefits with respect to either of the single drug regimens. In particular, we set out to evaluate efficacy in terms of primary and sustained viremia and transaminase responses. We also assessed histological response, incidence of YMDD-variant HBV, and safety.

MATERIALS AND METHODS

Patients

This open trial concerned 82 adult Italian patients with chronic anti-HBe positive hepatitis B (68 males, 14 females) enrolled between February 1997 and February 1999 who had either not responded to or had relapsed after previous interferon treatment. The experimental protocol was carried out in accordance with the Helsinki Declaration, and was approved by the Ethics Review Committee, and all patients gave written informed consent to participate in a trial involving long-term treatment either with interferon plus lamivudine or with lamivudine or interferon alone.

Inclusion criteria for the study were: age between 18 and 70 years, detectable hepatitis B surface antigen (HBsAg) in serum at the time of screening and for at least six months before the start of the study, serum HBV DNA levels of at least 5 pg/ml at screening, raised alanine transaminase values within three months before the start of therapy. Exclusion criteria were: presence of co-infection with hepatitis C and D virus or HIV, signs of hepatic decompensation or hepatocellular carcinoma, other possible causes of chronic liver damage (i.e. alcohol abuse, hemochromatosis, Wilson' s disease, a1-antitrypsin deficiency, autoimmune diseases, drug-induced hepatotoxicity and congestive heart failure), assumption of immunosuppressive or antiviral therapy within six months before the study. Needle biopsy performed in all cases within 2 years of the study, showed that 33 patients had a Scheuer score for fibrosis >3.

The patients were divided into three groups: group A (n=34) for combination treatment, group B (n=24) for treatment with lamivudine alone, group C (n=24) for treatment with interferon alone.

Treatment protocols and study design

Patients in group A received 100 mg/day of lamivudine (Glaxo-Wellcome Inc, Research Triangle Park, NC, USA) orally for one month, followed by lamivudine (100 mg/day) in association with six million units three times per week of natural interferon (Wellferon, Glaxo-Wellcome Inc, Research Triangle Park, NC, USA) for twelve months, and then lamivudine (100 mg/day) alone for six months. Patients in group B received lamivudine (100 mg/day) orally for twelve months. Patients in group C received six million units three times per week of natural interferon for twelve months. Interferon was administered subcutaneously by the patients after adequate training. Patients were followed up after the end treatment for twenty-four weeks. All patients had a liver biopsy within 2 years of entering the study, and were requested to have another at the end of treatment. Hepatitis flare up was defined as an increase in serum ALT during therapy and classified as mild, moderate or severe (>1.5, 5, 10 times respectively) according to the preceding ALT value.

The main end point of the study was to evaluate the end-of-treatment and sustained response, defined as HBV DNA loss and serum ALT normalization at the end of therapy and follow-up, respectively. Secondary variables included histological response, incidence of YMDD-variant HBV, and safety.

Laboratory methods

Blood samples were obtained immediately before therapy, after 15 days, and then every month during treatment and follow-up. Routine biochemical tests and blood cell counts were performed. HBsAg, HBeAg, and anti-HBs and anti-HBe antibodies were determined by enzyme immunoassay. Serum HBV DNA was measured quantitatively by a solution-hybridization assay (Abbott, Chicago, USA) with a lower limit of 3.0 pg/ml of serum.

Presence of the YMDD variant was evaluated by a restriction fragment length polymorphism assay in all ends of treatment samples and in cases where initial loss of HBV DNA was followed by a return to positivity, regardless of transaminase values. The biopsy specimens were scored according to the Scheuer histological activity index[22].

Statistical analysis

Baseline characteristics of the patients were presented as mean values ± standard error (SE). Statistical evaluations were conducted according to the intention-to-treat procedure. The Chi-square test or the Fisher' s exact test was used to compare differences in proportion between treatment groups. Continuous data were analyzed using Kruskall-Wallis test and Mann-Whitney test. A two-tailed P value of less than 0.05 was considered to be statistically significant.

RESULTS

Study population

All treatment arms were well matched with regard to baseline characteristics (Table 1). Of the 82 patients, 79 completed the treatment schedule, while the remaining 3 dropped out of the study: one group A patient withdrew, one group B patient and one group C patient experienced depression.

Table 1 Baseline characteristics of patients

Characteristics	Lamivudine+ interferon (n=34)	Lamivudine alone (n=24)	Interferon alone (n=24)
Age (year)	44.0±2.0	48.7±2.4	44.4±2.5
Sex (m / f)	30 / 4	18 / 6	20 / 4
ALT (U / l)	151±21	160±39	130±17
AST (U / l)	81±10	111±37	66±10
GT (U / l)	48±3	57±6	47±3
Albumin (gr / dl)	3.94±0.04	3.97±0.04	4.01±0.03
HBV DNA (pg / ml)	60±25	85±43	73±36
Histology:			
Cirrhosis	13 (38%)	10 (42%)	10 (42%)
Severe activity	10 (29%)	7 (29%)	9 (37%)

P value was not significant for all comparisons.

Virological response (Figure 1)

End-of-treatment response HBV DNA negativity was observed at the end of treatment in 30 (88 %) patients who received combination therapy (i.e. group A), 23 (99 %) who had lamivudine alone (i.e. group B), and 13 (55 %) who had interferon alone (i.e. group C). HBV DNA negativity was achieved in week 12, 4 and 32, respectively, in the three groups. Two differences in primary response among the three groups were highly significant [combination *vs.* interferon: *OR* 6.34 (95 % CI: 1.7-23 %), P=0.004; lamivudine *vs.* interferon: *OR* 19.46 (95 % CI: 3.3-113 %), P=0.001].

Sustained response A total of 15 (44 %) patients in group A, 8 (33 %) in group B and 6 (25 %) in group C were HBV DNA negative at the end of the follow-up. None of the differences in sustained virological response among the three groups reached statistical significance.

Biochemical response (Figure 2)

End-of-treatment response Serum transaminases became normal at the end of treatment in 29 (84 %) patients in group A, 21 (91 %) in group B and 13 (53 %) in group C [combination *vs.* interferon: *OR* 4.9 (95 % CI: 1.4-17 %), P=0.01; lamivudine *vs.* interferon: *OR* 5.92 (95 % CI: 1.28-25.3 %), P=0.012]. Normalization was achieved in week 20, 8 and 38, respectively,

in the three groups. A mild flare-up without bilirubin alteration was observed only in 8 group A patients. In all cases, serum transaminase normalization was preceded by a rise of HBV DNA at 2-8 months of therapy. The flare-up was always followed 1-2 months later by serum HBV DNA negativization and transaminase normalization. None of these patients had a YMDD variant.

Sustained response Sustained serum transaminase normalization was observed in 21 (61 %) patients in group A, 10 (42 %) in group B and 11 (45 %) in group C. None of the differences in sustained transaminase response among the three groups had statistical significance. Only 4 of the 8 patients who experienced a flare-up during combined therapy mantained their primary response.

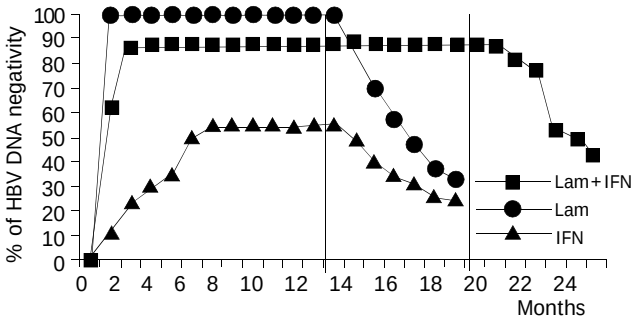

Figure 1 Virological response. Percentages of patients with HBV DNA negativity related either to the treatment or to the follow-up times. The vertical lines were drawn at the end of each treatment (19 months for interferon and lamivudine in combination, and 12 months for lamivudine and interferon monotherapy).

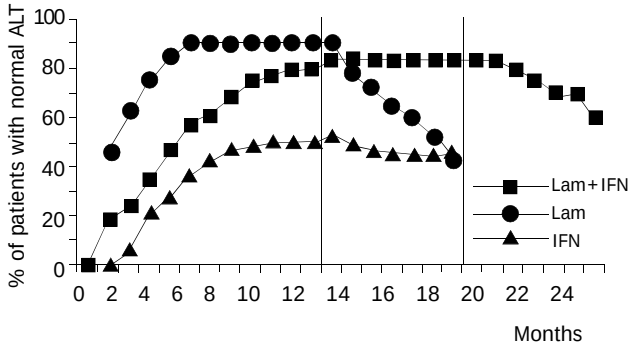

Figure 2 Biochemical response. Percentages of patients with normal ALT levels related either to the treatment or to the follow-up times. The vertical lines were drawn at the end of each treatment (19 months for interferon and lamivudine in combination, and 12 months for lamivudine and interferon monotherapy).

Secondary criteria of efficacy

Histological findings Paired pre- and post-treatment liver biopsies were available for 22 (65 %), 15 (62 %) and 14 (58 %) patients in groups A, B and C, respectively. None of the post-treatment biopsies showed a worsening or unchanged histological picture. Significant improvements in necro-inflammatory activity in parenchyma ($P<0.01$) and portal space ($P<0.01$) were observed in each group. Significant improvements in fibrosis were found in groups A and B ($P<0.05$), but not in group C.

Incidence of YMDD variant HBV YMDD variants of HBV were not detected in any of the patients who received combination or IFN therapy. 3 of the 24 (12 %) patients treated with lamivudine alone had a YMDD variant after 6-9 months of therapy. In particular, two had a YVDD variant and the other had a YIDD variant. They continued lamivudine therapy and were monitored weekly. After a progressive rise of serum HBV DNA, two of the patients showed 5 times of elevation of transaminases (with respect to the upper limit) and another showed 1.5 times of elevation. However, after the emergence of the variant, the HBV DNA and transaminase levels always remained lower than the baseline.

Safety

The whole treatment program was completed by 33 (98 %), 23 (96 %) and 23 (94 %) patients in groups A, B and C, respectively. No patient received reduced dosage but we directly stopped treatment. The side effects of the combination regimen were generally similar to those of interferon treatment. In addition, among the 34 patients in group A, symptomatic and reversible rises in serum levels of amylase, lipase and creatinine phosphokinase were recorded in 9 (28 %), 2 (5 %) and 1 (3 %) cases, respectively. Worsening of pre-existing hypertriglyceridemia was recorded in 2 (7 %) cases. By comparison, among the 24 patients in group B, lamivudine therapy was associated with an asymptomatic and reversible rise in amylase, lipase or creatinine phosphokinase in 6 (25 %), 1 (4 %) and 1 (4 %), respectively. No case of hepatocellular carcinoma, liver decompensation or death was recorded, and no patient requested orthotopic liver transplantation (Table 2).

Table 2 Adverse events documented during treatment

Adverse events	Lamivudine+ interferon (n=34), n (%)	Lamivudine alone (n =24), n (%)	Interferon alone (n =24), n (%)
Influenza-like symptoms	24 (70%)	none	19 (79%)
Hair loss	8 (23%)	none	9 (38%)
Weight loss	5 (16%)	none	4 (15%)
Depression	none	1 (4%)	1 (6%)
Low white-cell count	19 (56%)	none	14 (59%)
Low platelet count	14 (42%)	none	10 (44%)
Amylase rise	9 (28%)	6 (25%)	none
Lipase rise	2 (5%)	1 (4%)	none
CPK rise	1 (3%)	1 (4%)	none
Hypertriglyceridemia	2 (7%)	none	none

DISCUSSION

The development of effective treatment strategies for patients with HBV remains a major clinical challenge. We investigated the possible benefits of a long-term interferon/lamivudine combination treatment regimen in a cohort of patients who had already received unsuccessful treatment with interferon alone. The effects of this long-term combination regimen were compared with single-agent treatment with either interferon or lamivudine in three similar groups of patients. In regard to virological response, we found that at the end of therapy, HBV DNA had become undetectable in 88 % of the patients receiving combination treatment, as compared with 99 % and 55 % of those who had single-line therapy with lamivudine or interferon, respectively. These differences in end-of-treatment response were statistically significant in comparison of the combination therapy and lamivudine monotherapy with interferon monotherapy. The analysis of sustained response showed that 44 % patients in the combination therapy group maintained DNA clearance as compared with only 33 % in the lamivudine group and 25 % in the interferon group. Although these differences did not have statistical significance, there was a trend in favor of the combination regimen. Similarly, although the end-of-treatment transaminase normalization rate was significantly higher in the combination

treatment (84 %) group and in the lamivudine group of patients (91 %) than that in interferon (53 %) group, the sustained response showed a non-significant trend in favor of the combination regimen (61 % in the combination group *vs.* 42 % and 45 % with lamivudine or interferon alone, respectively).

As has been reported for short-term treatment[23], during our long-term combination therapy regimen there was a progressive viral decline, whereas with single-line lamivudine therapy the HBV DNA levels leveled off. Our data are in keeping with the concept that lamivudine therapy is more rapid and effective on virological and biochemical response than interferon alone or even in combination with lamivudine. However, after discontinuation of therapy, virological and biochemical relapses were considerably more common with lamivudine alone than those with the combination regimen (even though this difference did not actually reach statistical significance). Moreover, there was a trend suggesting that combination therapy delays relapse. The non-significant status of these trends could be due to the relatively small cohort sizes.

Among the two monotherapy options, interferon appeared less effective than lamivudine. In our study, interferon provided less end-of-treatment responses than lamivudine, and no advantages in terms of sustained response. The relatively poor capacity of interferon monotherapy to promote viral clearance may be explained by an inability to induce an efficient immune response.

After about 5 months of combination therapy, we observed a mild flare-up in 8 patients following a rise in serum HBV DNA. The flare-up was always followed, after a further one to two months of therapy by a return to serum HBV DNA negativity and normalization of transaminases. They may have been caused by enhanced immune responses prompted by increased mutant viral replication other than YMDD, which however were unable to permanently eradicate the virus.

As regards the secondary criteria of response, all the patients who underwent a post-treatment biopsy derived histological benefit in terms of necro-inflammatory activity in parenchyma and in portal space, regardless of their serological response. However, in keeping with other reports[24], interferon monotherapy provided no improvement in fibrosis.

YMDD HBV variants were not detected in any of the patients who received combination therapy or interferon alone. After 6-9 months of lamivudine monotherapy, 3 (12 %) patients had YMDD, a rate similar to that reported in Asian patients. Interferon therapy seemed to exert a protective effect against the emergence of variants, probably because it lowers viral replication and enhances immunological response. In any case, in the three affected patients, the serum HBV DNA levels did not return completely to pretreatment levels. Thus, the mutant strains of HBV DNA that break through during prolonged therapy with lamivudine may not be as replicative-efficient or as pathogenic as wild-type strains. As in other reports[25], we found that 3 to 4 months after lamivudine treatment was stopped, there was disappearance of this HBV mutant and re-emergence of the wild type virus. Honkoop *et al.*[26] observed acute exacerbation of chronic HBV infection after withdrawal of lamivudine therapy and concluded that the relationship between the development of "lamivudine-withdrawal hepatitis" and the lamivudine-resistant mutant virus was currently unclear, since both the emergence of a lamivudine resistant viral mutant and the resurgence of wild-type virus after withdrawal of therapy were able to induce severe hepatitis exacerbations. Studies of rechallenge with lamivudine have yet to be reported, and the significance of YMDD variant is being evaluated in the ongoing follow-up clinical trials.

As regards safety, the combination therapy was well tolerated and no serious side effects were observed. The side effects observed during the course of the long-term combination regimen were those that were commonly associated with the two drugs. As expected, in the two monotherapy groups, the incidence of drug-related adverse events was much lower with lamivudine than that with interferon.

In conclusion, these results suggest that for patients who have already been unsuccessfully treated with interferon, long-term combination therapy may have some advantages over single-line treatment with lamivudine or interferon[27]. Other studies with other regimens regarding dose, sequence and duration of interferon and lamivudine are needed. Finally, correct staging of patients according to the particular phases in the natural history of chronic hepatitis B appears to be important to personalise patients' management. It is possible that combinations of two[28,29] or more nucleoside analogs may reduce the development of viral resistance, increase overall response rates, decrease adverse events. In general, multi-drug therapies[30] that take advantage of different modes of action concurrently may provide a more appropriate approach for particular subgroups of patients.

Abstract

AIM: To analyze the molecular evolution of different viral genomic regions of HCV in an acute HCV infected patient chronically infected with HIV through a 42-month follow-up.

METHODS: Serum samples of a chronically HIV infected patient that seroconverted to anti HCV antibodies were sequenced, from the event of superinfection through a period of 17 months and in a late sample (42nd month). Hypervariable genomic regions of HIV (V3 loop of the gp120) and HCV (HVR-1 on the E2 glycoprotein gene) were studied. In order to analyze genomic regions involved in different biological functions and with the cellular immune response, HCV core and NS5A were also chosen to be sequenced. Amplification of the different regions was done by RT-PCR and directly sequenced. Confirmation of sequences was done on reamplified material. Nucleotide sequences of the different time points were aligned with CLUSTAL W 1.5, and the corresponding amino acid ones were deduced.

RESULTS: Hypervariable genomic regions of both viruses (HVR1 and gp120 V3 loop) presented several nonsynonymous changes but, while in the gp120 V3 loop mutations were detected in the sample obtained right after HCV superinfection and maintained throughout, they occurred following a sequential and cumulative pattern in the HVR1. In the NS5A region of HCV, two amino acid changes were detected during the follow-up period, whereas the core region presented several amino acid replacements, once the HCV chronic infection had been established.

CONCLUSION: During the HIV-HCV superinfection, each genomic region analyzed shows a different evolutionary pattern. Most of the nucleotide substitutions observed are non-synonymous and clustered in previously described epitopes, thus suggesting an immune-driven evolutionary process.

INTRODUCTION

It has been proven that patients with HIV infection are frequently coinfected with other viruses, including that of HCV. Both HIV and HCV share the same route of transmission, and thus, coinfection with these two viruses is rather common among intravenous drug users or transfused patients[1, 2]. HCV infection is considered as an HIV opportunistic disease[3].

The clinical impact of HIV-HCV coinfection has been widely studied[4]. However, the viral molecular interaction during the establishment of HCV superinfection is not yet well understood as the acute phase is frequently a subclinical event.

HCV, an RNA virus, shows a marked variability but nucleotide substitutions are unevenly distributed along the entire genome[5]. HCV diversity is the greatest in the envelope proteins E1 and E2, especially in a 27 amino-acid segment at the N-terminus of E2 designated hypervariable region 1 (HVR1). The variation of this region is thought to be related to the maintenance of persistent infection by emerging escape variants[6] and it is considered as the main target for humoral immunity as well as an immunologic decoy[7].

A similar degree of heterogeneity is found within the gp120 V3 loop region of HIV, an RNA virus that also causes persistent infections in the host. This region has been found to elicit neutralizing antibodies as well as cytotoxic and Th-cell responses, properties that are also ascribed to the HVR1[8].

NS5A is an HCV nonstructural protein that is associated with several functions such as being an *in vitro* transcriptional repressor[9] and tightly associated via the "interferon sensitivity determining region" (ISDR), with the subversion of the IFN activity. ISDR inhibits the cellular double-stranded RNA-activated protein kinase R[10], an effector of the IFN antiviral activity. There is also evidence that the C-terminal domain of NS5A including the ISDR contains transcriptional activity[11], suggesting that NS5A might function as a viral transactivator. The core gene is located in the 5' end of the HCV genome and its primary function is to form the viral nucleocapsid. The core protein has many effects on host-cell signalling pathways that includes the host-cell gene expression[12], apoptosis by interaction with the cytoplasmic tail of the lymphotoxin receptor and with TNF receptor[13, 14], transforming activity[15], modulation of lipid metabolism[16, 17]. Several studies have shown that the region contains multiple and highly immunogenic humoral[18, 19] and cellular [19, 20] epitopes.

In a previous report we described the *in vivo* down regulation of HIV replication in an HIV-infected patient after HCV superinfection[21]. Herein we presented a further study of this patient through the analysis of hypervariable regions of both viruses, and the less variable core and NS5A regions of HCV.

MATERIALS AND METHODS

Patient

A 16 year-old HIV patient was referred to the Liver Unit because of an acute hepatitis-like illness with the manifestations of jaundice, nausea, abdominal pain, fever, diarrhea, itching and elevated ALT and AST levels. She was in the 30th week of gestation and her prenatal course had been uneventful until this episode. Diagnosis of acute hepatitis C was established by

seroconversion of HCV antibodies by an EIA test (HCV EIA 2.0; Ortho Diagnostics) and confirmed with a strip immunoblot assay (RIBA HCV 2.0; Chiron Corporation). HIV and HCV were thought to be acquired by intravenous drug use. Serum HCV and HIV RNAs were detected by RT-PCR using primers for the 5NC and the gag regions, respectively[21] (Table 1).

Thereafter, the patient was followed up for 42 months and serum samples were taken monthly during the first 17 months of the analyzed period and in the 42nd month as a late specimen. Serum samples before HCV superinfection were also available. Liver function tests (AST, ALT, γ-glutamyl-transferase, alkaline phosphatase, albumin, gamma globulin, bilirubin and prothrombin time) were routinely performed using automatic standard procedures.

A liver biopsy was obtained at the 15th month of follow-up showing a histological picture of chronic hepatitis (Knodell score 5) without fibrosis.

No antiviral therapy was implemented during the study period because of the patient's refusal. This study followed the ethical standards of the World Medical Association Helsinki Declaration adopted in 1964 and amended in 1996 and was approved by the local Ethics Committee. At all times, written consents were obtained from the woman.

Methods

RNA extraction RNA was recovered from 150 µl aliquots as described by Chomczynski and Sacchi[22] using components from a commercially available RNA extraction kit (Trizol®, Life Technologies) and resuspended in 20 µl dH_2O.

cDNA synthesis and PCRs RNA was used as templates in randomly primed reverse transcription reactions to produce cDNA in the following conditions: 50 mM TrisHCl (pH 8.3), 25 mM KCl, 3 mM $MgCl_2$, 0.1 mM DTT, 1.0 mM dNTPs, 18 U RNasin ribonuclease inhibitor (Promega) and 100 U Moloney murine leukemia virus RT (Life Technologies). The reactions were performed for 90 min at 37 ℃. After heat inactivation at 95 ℃ for 5 min and chilling on ice, the cDNA was amplified.

Different genomic viral regions -gp120 V3 loop region of HIV and the HVR1, core and NS5A regions of HCV- were amplified and directly sequenced. The PCR reaction (50 µl) contained 20 mM TrisHCl, 50 mM KCl, 50 pmol of each primer and 1.25 U *Taq* DNA polymerase (Promega). Nested PCR was performed with 2 µl PCR product as a template, using internal primers under the same conditions as the first round. The first and second round primers and cycling parameters for each region are shown in Table 1 and were made according to Kwok and Higuchi's recommendations[23].

Nucleotide sequencing Each DNA was purified and directly sequenced with a Thermo Sequenase radiolabeled-terminator-cycle sequencing kit (U.S. Biochemical Corporation) using the same cycling parameters of the second PCR round. Confirmatory sequencing was performed on reamplified DNA.

RESULTS

The genomic regions of HCV: HVR1, core and NS5A and the gp120 V3 loop of HIV were sequenced during a 42 month follow-up of a chronically HIV patient acutely infected with HCV. Phylogenetic analysis of core and NS5A grouped the HCV sequences into genotype 1a (data not shown).

After alignment and comparison of genomic sequences obtained before and after HCV superinfection, the nucleotide sequence of HIV gp120 V3 loop showed three nonsynonymous mutations (I309L, T317A and E320D) that appeared in the sample obtained 2 months after HCV superinfection and

Figure 1 (A) Biochemical profile of the HIV / HCV superinfected patient during the first 17 months of follow-up. Amino acid sequences of consecutive samples corresponding to V3 loop (B) and HVR1 (C). V3 loop sequence was obtained in the initial sample (0) and after 2, 17 and 42 months of follow-up. HVR1 sequences in samples were obtained from 0 to the 17th month of follow-up and in the 42th month of follow-up. The number at the left of each sequence corresponded to the month of the follow-up when the samples were sequenced. Nucleotide sequences at the different time points were aligned with CLUSTAL W 1.5, and the corresponding amino acid ones were deduced.

Figure 2 Amino acid sequences of consecutive samples corresponding to HCV NS5A (A) and core (B). The number at the left of each one corresponded to the month of the follow-up when the sequences were done. The black bar indicated the ISDR. Amino acid positions were according to the HCV-1 (M62321).

maintained thereafter for the rest of the period (Figure 1).

As far as HCV sequences were concerned, in the HVR1 three nonsynonymous mutations were observed (F399L, G393S and A397S) in the acute phase of the infection, conversely, the mutation dynamics followed a sequential and cumulative pattern, occurring at the 6th, 8th and 12th follow-up months. Each mutation was associated with an ALT flare-up (Figure 1). In the last sample, 42 months after HCV superinfection, two more amino acid changes were selected (G398A and L399F).

Different patterns of substitutions were observed in the HCV core and NS5A regions. In the core, three nonsynonymous substitutions (Q63P, H69R and R74G) appeared at the 17th month of the follow-up (Figure 2), once chronic hepatitis was fully established. Late on the follow-up, four mutations were selected: P63Q, A68V, G74R and G152A. The amino acids that were resulted from the modifications in positions 63 and 74 were the same as that which was present in the earliest samples.

In the portion of NS5A sequenced (nt 6632-7077), one amino acid substitution was observed in the acute phase (E2227Q) and remained thereafter, and another one was selected at the end of the follow-up (V2251I).

The sequences were submitted to GenBank and assigned accession numbers: AF361170 through AF361176 and AF359345 through AF359354.

DISCUSSION

In this study, we analyzed the evolution of different viral genomic regions during HCV superinfection of a chronically HIV infected patient.

Most of the nucleotide substitutions fixed during the HCV superinfection process were nonsynonymous and located at described epitopes, suggesting a positive immune selection mechanism driving their molecular evolution.

We found that hypervariable regions of both HCV and HIV had several amino acid modifications during the acute phase of superinfection. However, these changes occurred simultaneously on the gp120 V3 loop whereas they were sequentially selected and showed a cumulative pattern in the HVR1.

The selection of an HIV viral population with three amino acid modifications in the V3 loop region right after HCV superinfection maybe resulted from the overgrowth of markedly different but minor HIV quasispecies from the initial sample.

In contrast, the HVR1 evolved showed a cumulative pattern of mutations during the 17 month period. Each time of sequential incorporation of a nonsynonymous mutation was associated with an ALT flare up and resulted from the selection process, also exerted by the evolving host immune response[24].

It has been proposed that the evolution of hypervariable regions may be caused by the successive accumulation of point substitutions as we have seen in the HVR1-HCV or, alternatively from the selection of a pre-existing minor subpopulations, which was different from the previous one, as observed in V3 loop of HIV[25].

Once the chronic infection was established, two extra amino acid mutations were observed in the HVR1, the first one was at position 398 (G→A), and the second one was at position 399 (L→F). F or L occupied the last position alternatively in most of the HVR sequences published elsewhere[26] and may be considered as a return to a previous state of the quasispecies equilibrium.

The timing of the substitutions observed in the core region, which were late (after 17 months and 42 months of infection), implied its involvement in the infection once persistence had been established. Non-synonymous changes clustered in HCV epitopes that stimulated the humoral and cellular response and were previously described[18, 20, 27], suggesting an active participation of these epitopes in the persistence of HCV infection. Moreover, the sample at the end of the follow-up showed two modifications (aa 63 and 74 of the core protein) that recovered the early amino acid sequences. As far as the HVR sequences concerned, this effect that might be due to the return to a quasispecies equilibrium state favored the outgrowth of the fittest quasispecies for that particular host conditions, as a consequence from the interplaying of virus populations in every situation.

Two substitutions were selected in the NS5A region. One of them occurred at the early phase of the infection whereas the second appeared at the end of the follow-up. The first mutation selected (E2227Q) was located in the ISDR, described as related to the IFN resistance of some HCV genotypes by means of its interactions with the cellular PKR and in a cellular epitope, as previously described[19].

In conclusion, during the HCV superinfection process, each genomic region analyzed presents a different pattern of evolution, and is probably related to their functions in the viral life cycle. The localization of mutations at described epitopes suggests the participation of the host immune system drives the balance of the viral subpopulations towards escape and better fitness ones. In order to study this hypothesis, a quasispecies analysis is worth to be done to address the changes showed during the coinfection by means of the population equilibriums.

Abstract

AIM: To investigate the effect of hepatitis B virus (HBV) specific immunoglobin (HBIG) and lamivudine on HBV intrauterine transmission in HBsAg positive pregnant women.

METHODS: Each subject in the HBIG group (56 cases) was given 200 IU HBIG intramuscularly (im.) every 4 weeks from 28-week (wk) of gestation, while each subject in the lamivudine group (43 cases) received 100 mg lamivudine orally (po.) every day from 28-wk of gestation until the 30th day after labor. Subjects in the control group (52 cases) received no specific treatment. Blood specimens were tested for HBsAg, HBeAg, and HBV-DNA in all maternities at 28-wk of gestation, before delivery, and in their newborns 24 hours before the administration of immune prophylaxis.

RESULTS: Reductions of HBV DNA in both treatments were significant ($P<0.05$). The rate of neonatal intrauterine HBV infection was significantly lower in HBIG group (16.1 %) and lamivudine group (16.3 %) compared with control group (32.7 %) ($P<0.05$), but there was no significant difference between HBIG group and lamivudine group ($P>0.05$). No side effects were found in all the pregnant women or their newborns.

CONCLUSION: The risk of HBV intrauterine infection can be effectively reduced by administration of HBIG or Lamivudine in the 3rd trimester of HBsAg positive pregnant women.

INTRODUCTION

It is of vital importance to interrupt the transmission of viral hepatitis B from mother to fetus in control of its prevalence[1-3], including HBV intrauterine infection[4-7]. This study investigated the effect of administration of HBIG (im.) and lamivudine (po.) on the interruption of HBV intrauterine infection from the 3rd trimester of gestation.

MATERIALS AND METHODS

Subjects

One hundred and fifty one pairs of women and their newborns who followed the antepartum care were selected and admitted for labor in our hospital from January of 1999 to December of 2001. These pregnant women were HBsAg positive, with normal liver and kidney function. Serial tests were negative for HAV, HCV, HDV and HEV in these women and no other severe complications were found and no other drugs, including the ones that were studied, anti-virus, cytotoxic, steroid hormones, or immune regulating drugs were administrated. The patients were randomly allocated into 3 groups. There were 56 patients in the HBIG group (22 were both HBsAg and HBeAg positive) and 43 in the lamivudine group (33 were both HBsAg and HBeAg positive). There were 52 patients in the control group (17 were both HBsAg and HBeAg positive). No significant differences were found in age, race, time of gestation and parturition, gestational age, way of delivery, and incidence of threatened abortion, threatened labor or pregnancy-induced hypertension syndrome (PIH). The 151 pregnant women delivered 151 newborns.

Methods

Patients in the HBIG group were administered HBIG 200IU intramuscularly (im.) from 28-wk of gestation, once every 4 weeks till labor. Patients in the lamivudine group were administered 100 mg (po.) lamivudine orally daily till the 30th day after labor. Patients in the control group were given no specific treatment. Blood specimens were tested for HBsAg, HBeAg, and HBV-DNA in all the subjects at 28-wk and before delivery, and their newborns (blood from the femoral vein) 24 hours before administration of immune prophylaxis.

HBsAg and HBeAg were assessed by ELISA, the assay kits were produced by Zhongshan Biological and Engineering Co. Ltd. HBV-DNA was assessed by fluorogenic quantitative polymerase chain reaction (FQ-PCR), and the assay kits were produced by Da'an Gene Diagnosis Center, Sun Yat-Sen University.

Before the administration of positive and/or active prophylaxis at 24 hours after delivery, intrauterine HBV infection would be considered if HBsAg and/or HBeAg were tested positive in neonatal peripheral blood.

Statistics

The *t*-test and χ^2 test were used to analyze our data using Excel software. Statistical significance was set at $P<0.05$. HBV DNA values were expressed as $\bar{x}\pm s$, and neonatal intrauterine HBV infection rates were expressed as percentage of total cases in each group.

RESULTS

Changes of HBsAg, HBeAg and HBV DNA

HBsAg turned negative in 1 case of the HBIG group, but HBeAg turned negative in no case. HBsAg and HBeAg turned negative in 1 case of the lamivudine group. No cases turned negative of HBsAg or HBeAg in the control group.

Before administration of agents, there was no significant difference in the values of HBV DNA among 3 groups

(P>0.05). But there was significant difference between the values of HBV DNA in HBIG group and lamivudine group after administration of either reagent respectively (both values reduced, P<0.05). The reduction of value before and after administration of the reagents was significantly different between the administered groups and control group (P<0.05). (Table 1).

Table 1 Comparison of HBV DNA values before and after administration of the reagents

Group	*n*	Log10 HBV DNA before administration of drugs (copies / ml)	Log10 HBV DNA before labor (copies / ml)	Minus value of log10 HBV DNA before and after administration of agents (copies / ml)
HBIG	56	7.38±1.17[a]	5.28±2.77[bd]	2.09±2.28[b]
Lamivudine	43	7.49±0.54[a]	5.33±1.34[bd]	2.16±1.27[b]
Conrol	52	7.05±1.29[a]	6.23±3.66[c]	0.82±2.73[c]

[a]P>0.05 *vs* other groups; [b]P>0.05 between HBIG group and lamivudine group; [c]P<0.05 *vs* HBIG group or lamivudine group; [d]P<0.05 (before *vs* after administration).

Incidence of HBV intrauterine infection

Three newborns were HBsAg positive, and 7 cases were HBeAg positive, one of them was doubly positive for HBsAg and HBeAg in HBIG group. Corresponding cases in lamivudine group and control group were 1, 7, and 1, or 8, 11, and 2 respectively. The infection rates of HBIG, lamivudine, and control groups were 16.1 %, 16.3 %, and 32.7 %, respectively. There were significant differences between the incidence of HBV intrauterine infection in either reagent administrated group and control group (P<0.05), while there was no significant difference between HBIG group and lamivudine group (P>0.05). (Table 2).

Table 2 Incidence of neonatal intrauterine infection in 3 groups

Group	*n*	HBsAg(+) *n*	HBeAg(+) *n*	Intrauterine infection	
				n	%
HBIG	56	3	7	9	16.1[a]
Lamivudine	43	1	7	7	16.3[a]
Control	52	8	11	17	32.7[b]

[a]P>0.05 between HBIG group and lamivudine group; [b]P<0.05 *vs* HBIG group or lamivudine group.

Safety

There were no incidences of fever, rigor, rash, or other complaints and dysfunction of the liver and kidney in subjects throughout administration and follow-ups. There were no significant differences in gestational age, severity of postpartum hemorrhage, rate of cesarean section, neonatal weight, neonatal height, circumference of neonatal head and Apgar score (P>0.05).

DISCUSSION

There are several thoughts about the mechanisms of HBV intrauterine transmission, including placental infection[8], placental exudation and transudation[9-11], peripheral blood monocyte (PBMC)[12] infection, fraternal transmission, etc. Infection through placenta is the most active pathway in maternity-fetus transmission. It is suggested that infection mainly occurs in the 3rd trimester. This might be resulted from the fact that the layer of trophoblastic cells becomes thinner and turns into chorion-vessel membrane, which makes it easier for HBV to pass the placental barrier[13]. The organs of fetus during this period have already developed, therefore, it is safe for the administration of reagents. So we chose this period to begin the interruption of infection. Lamivudine (po.) or HBIG (im.) was administered from 28-wk of gestation.

Barrier-destroying factors, such as threatened abortion, threatened premature labor and TORCH (toxoplasmosis, others, rubella, cytomegalovirus, herpes) infection, were the highly risk factors for HBV intrauterine infection[14]. It is generally considered that intrauterine infection might be the general effect of maternity and virus. In this study, there were no significant differences among the 3 groups in the highly risk factors (threatened abortion, threatened premature labor) or age, time of gestation and delivery, pregnant complication, medical or surgical complication, gestational age at labor or way of delivery.

It has been clinically accepted to administer joint immune reagents (HBIG together with HBV vaccine) to neonates with high risks, but the immune failure rate is still about 10-20 %[15,16], the main reason is intrauterine infection. So, it is important to study the mechanism of HBV intrauterine infection, and we further investigated the intrauterine prevention and interruption of HBV infection.

HBIG is a highly effective immune globulin[17], which is purified from highly effective plasma or serum taken from healthy individuals after the use of HBV vaccine. HBs antibody can bind HBsAg, activate the complimentary system at the same time and strengthen humoral immune, clear HBV, and reduce the number of virus in the maternal blood. It can prevent and decrease the incidence of normal cell infection and might reduce HBV copy in the body. Placenta has the function of transmitting antibody in the form of IgG to the fetus. It is suggested that after maternal administration of HBIG (im.), HBsAb can be transmitted to fetus, which makes it possible for the fetus to obtain the protection of intrauterine passive immunization and to prevent intrauterine infection[18]. The results of this study suggest that regular administration of HBIG (im.) to HBV positive pregnant women might reduce the amount of HBV DNA in blood, and neonatal intrauterine infection rate also reduced significantly when compared with control group. DNA polymerase of HBV has many functions in the process of virus replication. After infection of liver cells by HBV, the incomplete double strand DNA integrates into a complete one, enters the nuclei, forming super helix covalent closed circular DNA (cccDNA). cccDNA is extremely stable, and is the resource of viral DNA and directs the formation of viral protein. The whole mRNA replicated from cccDNA model can form a single strand minus-DNA by reverse-transcription of the HBV DNA polymerase. This DNA can form incomplete double strand DNA through DNA polymerase. The latter can also integrate with antigen proteins in the endoplast, forming new, contagious mature viral particles and be released into blood, or migrate into the nuclei to supply cccDNA there. The multiple functions of HBV polymerase enable it to become one of the most prosperous anti-virus targets.

Lamivudine is a potent anti-virus nucleotide analogue to HBV and HIV. Through competitive inhibition of HBV DNA polymerase and formation of new HBV DNA strand, it can terminate the synthesis of new strand[19,20]. After several days of the administration of lamivudine, the level of HBV DNA drops dramatically, and throughout the treatment, HBV DNA will be suppressed continuously. It can reduce the necrosis and inflammation of the liver and bring ALT level to normal without significant side effects or malformation-causing effects[21-31]. We found the amount of HBV DNA in blood and the rate of neonatal intrauterine infection after administration of lamivudine in the 3rd trimester were significantly lower than that in control group. This suggests that administration of lamivudine of HBV positive pregnant women in the 3rd trimester can effectively decrease the rate of intrauterine HBV infection.

As a passive antibody, the main effect of HBIG is to neutralize HBV in the body, prevent and decrease infection of normal cells[32]; while lamivudine is a potent anti-virus agent, which can suppress the replication of HBV actively, decrease HBV level during pregnancy. Our data showed that the neonatal infection rates, after these two reagents were used in the 3rd trimester to interrupt intrauterine HBV infection, were 16.1 % and 16.3 %, respectively, with no significant difference between these 2 groups (P>0.05). But compared with control group, the infection rates of both groups were significantly lower. These data indicate that both of them are safe and effective in the interruption of intrauterine HBV infection.

We found in our previous studies that HBV DNA level in maternal serum was an important factor for intrauterine infection[1]. Especially when HBV DNA is $\geqslant 10^8$ copies/ml, it has significant correlation with neonatal HBV infection[33]. Administration of HBIG in combination with lamivudine in these patients might decrease the neonatal HBV infection rate more effectively. Further studies are required to improve our understanding about this problem.

Abstract

AIM: To construct human eosinophil-derived neurotoxin (hEDN) and HBV core protein (HBVc) eukaryotic fusion expression vector with a linker $(Gly_4Ser)_3$ between them to optimize the molecule folding, which will be used to inhibit HBV replication *in vitro*.

METHODS: Previously constructed pcDNA3.1(-)/TR was used as a template. Linker sequence was synthesized and annealed to form dslinker, and cloned into pcDNA3.1(-)/TR to produce plasmid pcDNA3.1(-)/HBc-linker. Then the hEDN fragment was PCR amplified and inserted into pcDNA3.1(-)/HBc-linker to form pcDNA3.1(-)/TNL in which the effector molecule and the target molecule were separated by a linker sequence. pcDNA3.1(-)/TNL expression was identified by indirect immunofluorescence staining. Radioimmunoassay was used to analyse anti-HBV activity of pcDNA3.1(-)/TNL. Meanwhile, metabolism of cells was evaluated by MTT colorimetry.

RESULTS: hEDN and HBVc eukaryotic fusion expression vector with a linker $(Gly_4Ser)_3$ between them was successfully constructed. pcDNA3.1(-)/TNL was expressed in HepG2.2.15 cells efficiently. A significant decrease of HBsAg concentration from pcDNA3.1(-)/TNL transfectant was observed compared to pcDNA3.1(-)/TR (P=0.036, P<0.05). MTT assay suggested that there were no significant differences between groups (P=0.08, P>0.05).

CONCLUSION: Linker introduction enhances the inhibitory effect of HBV targeted ribonuclease significantly.

INTRODUCTION

Hepatitis B virus (HBV) remains a major public health problem worldwide[1-6] and causes transient and chronic infection of liver[7-9]. Transient infection may produce serious illness, and chronic infection may also have serious consequences: nearly 25 % of chronic HBV infected patients terminate in untreatable liver cancer of 350 million chronic HBV infected patients. The available treatments are of limited efficacy, such as interferon-α (INF-α)[10-12], nucleoside analogues[13-15] and gene therapy strategy[16,17]. Alternative approaches to inhibit HBV replication are urged. Capsid-targeted viral inactivation (CTVI, also called virion-targeted viral inactivation) was established by Natsoulis and Boeke in 1991, in which a viral capsid protein or other virion associated protein as a carrier guides a degradative enzyme into virus particles specifically to inhibit virus replication or kill it[18]. CTVI has been thoroughly investigated in experimental treatment for retrovirus, such as Moloney murine leukemia virus (MMLV) and HIV, showing a promising prospect as an antiviral treatment[19,20]. Previously we fused HBV core protein (HBVc) to human eosinophil-derived neurotoxin (hEDN), and after transfection of the fusion protein encoding plasmid into HepG2.2.15 cells HBV replication was inhibited, due to the fact that HBV pregenome RNA (pgRNA) was degraded by the effector molecule, hEDN, *via* the guiding of the target molecule, HBVc[21,22]. Here we reported the further enhancement of the degradative effect by introduction of a linker sequence $(Gly_4Ser)_3$ to separate the effector molecule and the target one.

MATERIALS AND METHODS

Reagents and equipments

pcDNA3.1(-)/TR was constructed in our laboratory[21]. HepG2.2.15 cells were kindly provided by Dr. Hao (Tangdu Hospital, Fourth Military Medical University). Restriction enzymes, alkaline dephosphoratase, *TaKaRa Ex Taq*™, DNA marker-DL2000 and T_4 DNA ligase (*TaKaRa* Biotechnology Co., Ltd., Dalian), Plasmid Miniprep Kit, Agarose Gel Extraction kit (Watson Biotechnology, Shanghai), LipofectinMine2000 (GIBCO), mouse anti-HA and rabbit anti-mouse IgG labeled with FITC (Sino-American Biotechnology Company), Radioimmunoassay Kit (Beijing Bei Mian Dongya Biotech Institute), GeneAmp PCR System 9600 (Perkin Elmer).

Linker and primers

All the oligomers were synthesized by Sangon (Shanghai).
LinkerF 5' -gcg cgg atc cgg tgg cgg tgg ctc ggg cgg tgg tgg gtc ggg tgg cgg cgg atc tga tga gct cgc gc- 3' (*Bam*HI, *Sac*I)

P2: 5' - gcg agatct gat gat tct atc cag gtg aa- 3' (*Bgl*II)

Cell culture

HepG2.2.15 cells integrated full-length HBV genome were cultured in DMEM medium containing 150 mL/L fetal bovine serum at 37 ℃, in 50 mL/L CO_2. G418 was added to screen cells at the final concentration of 100 g/L. The media were freshed once every two days and the cells were passaged every six days.

Introduction of linker

To prepare double stranded linker, linkerF and linkerR were annealed by heating at 100 ℃ for 5 min and then slowly cooling to room temperature, and dissolved at a concentration of 0.1 g/L.

Dslinker bearing *Bam*HI and *Sac*I restriction sites was digested and cloned into pcDNA3.1(-)/TR digested by the same restrictions, to produce plasmid pcDNA3.1(-)/HBc-linker.

hEDN fragment acquired from pcDNA3.1(-)/TR was PCR amplified by using primers and taking pcDNA3.1(-)/TR as a template. The PCR products digested by *Bam*HI/*Bgl*II were inserted into pcDNA3.1(-)/HBc-linker which was restricted by *Bam*HI and dephosphorated, and the direction of hEDN was identified by enzyme restriction. The constructed plasmid was called pcDNA3.1(-)/TNL in which the effector molecule and the target molecule were separated by a linker sequence. The linker sequence and the PCR products were confirmed by sequencing by gencore (Shanghai).

Transfection and indirect immunofluorescence

Transfections were performed as described by the provider of LipofectinMine2000 and the transfecting condition had already been optimized by our laboratory[21]. The cell density of 4×10^8 /L was added by 500 μL/well in 24-well plate in which the cover glasses were put in advance. Transfecting work was performed when cells were adhered, usually after 24 hours[18]. The experiment was divided into 3 groups: test group in which pcDNA3.1(-)/TNL was used, and two control groups in which blank vector pcDNA3.1(-) was used in the second group and the third was taken for mock transfection. Tri-wells were contained in each group. 48 hours post-transfection cells were quickly washed with 1mL sterile PBS (pH8.0) for 5 minutes, fixed in 1 g/L TritonX-100 diluted with 20 g/L paraformaldehyde and put on ice for 30 minutes. The fixed cells were washed three times with cold PBS, incubated with mouse anti-HA (1:100) for 15 minutes at 4 ℃, and then washed three times in cold PBS, followed by incubation in rabbit anti-mouse IgG labeled with FITC (1:100) for 10 minutes at 4 ℃. After rinsed with PBS for 1 hour, the slides were mounted with cover ships by using 500 g/L glycerol/PBS. The results were observed by fluoroscopy and pictures were taken.

Analysis of anti-HBV activity for pcDNA3.1(-)/TNL

24 hours before transfection, HepG2.2.15 cells were plated into a 96 well-plate with of 4×10^4 cells per well. Transfections were performed as described above. To determine HBsAg concentration, transfection experiment was divided into 7 groups, they were pcDNA3.1(-)/TNL, pcDNA3.1(-)/TR, pcDNA3.1(-)/hEDN$_{mut}$-HBVc, pcDNA3.1(-)/HBVc, pcDNA3.1(-)/hEDN, pcDNA3.1(-) and mock transfection, named as A to G respectively. Each transfection was performed in triplicate. After 48 hours of transfection the cell suspension was taken and HBsAg concentration was determined by RIA kit (completed by Nuclear Medicine Department of Xijing Hospital). Meanwhile the transfected cells were used to analyze the metabolic activity in order to analyze the effect of expressing protein on host cells. The data obtained were analyzed by SPSS software.

MTT assay

Metabolism of cells was evaluated by MTT colorimetry. 48 hours following transfections, 20 μL of MTT solution (5 g/L) was added into each well and incubated at 37 ℃ for another 4 h. 150 μL DMSO was added and surged for 10 min to dissolve the crystal completely. Absorbance values were identified at 490 nm wavelength by ELISA reader.

RESULTS

Linker introduction

To separate HBc and hEDN, a linker was introduced. Both the linker sequence cloned into plasmid pcDNA3.1(-)/HBc-linker and hEDN fragment from PCR products, were subsequently inserted into pcDNA3.1(-)/TNL, and confirmed by sequencing. plasmid pcDNA3.1(-)/TNL was identified by restrictions of *BamH*I/*Sac*I and *Sac*I/*Hind*III, the results suggested the construction was successful (Figure 1).

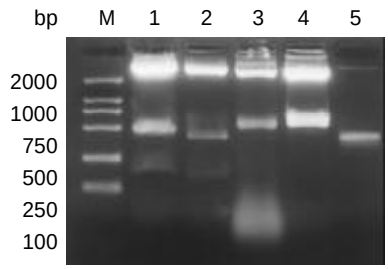

Figure 1 Identifications of plasmids in construction of pcDNA3.1(-)/TNL. 1: pcDNA3.1(-)/TNL digested by *Sac*I/*Hind*III; 2: pcDNA3.1(-)/TR by *Bam*HI/*Sac*I; 3: pcDNA3.1(-)/TR by *Sac*I/*Hind*III; 4: pcDNA3.1(-)/TNL by *Bam*HI/*Sac*I; 5: PCR products of hEDN.

Indirect immunofluorescence

To observe the expression of linker-separated fusion protein of pcDNA3.1(-)/TNL, indirect immunofluorescence was performed after 48 h of transfection (Figure 2).

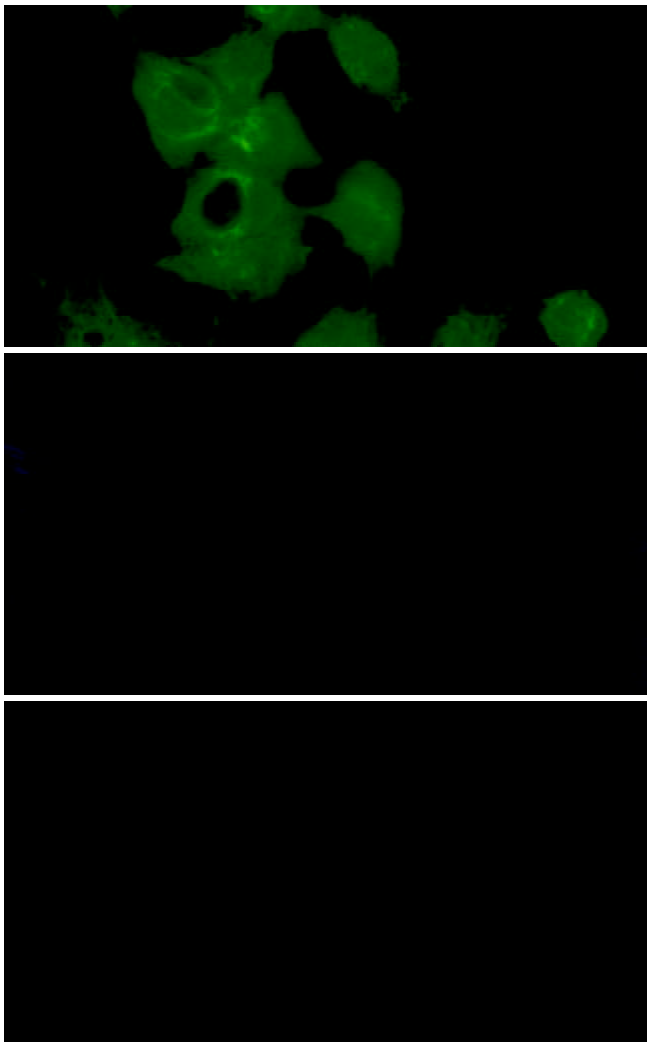

Figure 2 Detection of fusion protein by indirect immunofluorescence. 1: Green fluorescence in cells transfected by pcDNA3.1(-)/TNL; 2, 3: No fluorescence was observed in pcDNA3.1(-) transfectant and mock transfection.

Linker effect

To analyze the digestion effect of hEDN separated by a linker with HBVc. HBsAg concentration was determined by RIA after transfection. The significant decrease of HBsAg concentration in pcDNA3.1(-)/TNL transfectant, compared to pcDNA3.1(-)/TR(P=0.036, P<0.05, Figure 3), suggested that linker introduction enhanced hEDN digestion effect, which may be due to optimization of the folding of both hEDN and HBVc molecules. Also there were significant differences between groups A, B and groups C, D, E, F, G (P=0.0054, P<0.01), and no significant difference was found between groups C, D, E, F and group G (P=0.085, P>0.05).

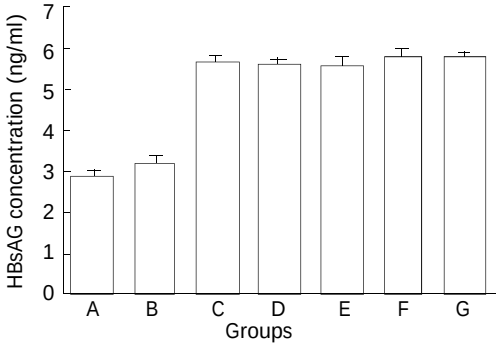

Figure 3 Comparision of HBsAg concentration in transfection groups.

Cell toxicity effect

48 hours post-transfection cell growth was observed and cell toxic effect of linker-separated fusion protein on host hepatocytes was detected by MTT assay. The A_{490} value of HepG2.2.15 cells transfected with pcDNA3.1(-)/TNL, pcDNA3.1(-)/TR, pcDNA3.1(-)/hEDN$_{mut}$-HBVc, pcDNA3.1(-)/HBVc, pcDNA3.1(-)/hEDN, pcDNA3.1(-) and mock transfection was 0.62±0.16, 0.69±0.10, 0.70±0.05, 0.64±0.04, 0.75±0.08, 0.78±0.04, 0.54±0.16, respectively ($\bar{x}$±s, n=3). The results suggested that there were no significant differences between groups (P=0.08, P>0.05).

DISCUSSION

HBV infection is an important health problem worldwide. Int-erferons and nucleosides analogues are effective drugs for chronic HBV infection, but only 20-30 % of treated patients maintain a long-lasting response to anti-viral drugs[23]. The expense of prolonged treatment makes these therapies poorly suitable for people in developing countries, where the prevalence of chronic HBV infection is often high. Therefore, new therapy strategy for HBV infection is urgent.

A new strategy called CTVI was established to guide effector molecule to target molecule and inhibit virus replication[18]. Previously we fused HBVc to hEDN, and after transfection of the fusion protein encoding plasmid into HepG2.2.15 cells, HBV replication was inhibited due to the fact that HBV pregenome RNA (pgRNA) was degraded by the effector molecule, hEDN, by guiding the target molecule, HBVc[21,22]. To further enhance the degradative effect of targeted ribonuclease, the classic linker $(Gly_4Ser)_3$ was introduced to separate the effector molecule and the target one. In our investigation, HBsAg concentration decreased significantly in pcDNA3.1(-)/TNL transfectant compared to pcDNA3.1(-)/TR transfectant due to linker introduction which may augment the digestion effect of hEDN significantly (P=0.036, P<0.05) via optimizing the protein folding.

Linker introduction, one of the gene fusion techniques, has become an increasingly useful tool in a variety of biomedical researches[24]. Many naturally occurring enzymes are composed of two or more distinct modules that are joined into a single macromole by stretches of amino acids referred to as linkers[25]. In structural biology, construction of recombinant fusion proteins has been used as a means to increase the expression of soluble proteins and to facilitate protein purification[26-28]. In recent years, a wide range of applications of gene fusion techniques has been reported in the fields of biotechnology. These applications include selection and prodution of antibodies and proteins with specialized functions, such as proteins that target specific genes[29-31]. Recent studies have provided examples of linkers that are important in establishing the structural and functional assembly of multi-domain proteins[32]. These interdomain linkers are relatively long and probably flexible in order to allow the two modules to perform independent functions. Recombinant production of chimeric enzymes requires stable linkers to join fusion partners without interfering with their function. The use of long linkers may result in low yield of active fusion protein since unprotected and flexible regions are often susceptible to proteolytic cleavage during recombinant protein production. A shorter linker might overcome problems associated with protease degradation. On the other hand, there is a risk that a shorter linker brings the modules too close to each other, resulting in a loss of function[25]. In many studies functional single-chain antibodies (scFvs) were engineered by linking immunoglobulin heavy and light chain variable domains (V_H and V_L) *via* $(G1y_4Ser)_3$, which satisfies the needs above. Further enhancement of hEDN digestion and inhibitory effect may be completed by further linker design and screening, and the work involved in this field is in progress in our lab.

Abstract

AIM: To establish a rapid, sensitive and specific immunogold assay for detection of hepatitis A virus infection.

METHODS: Rabbit monoclonal antibodies to anti-human IgM and IgG (Dako) were dotted on a nitrocellulose membrane (NCM) respectively to capture the human sera IgM and IgG. Then the captured antibodies would conjugate to HAV antigen, which was revealed by mouse anti-HAV IgG conjugated to gold particles. Final results were assessed by blind method.

RESULTS: Sera from 96 patients with acute hepatitis were used for our study. Compared with well-recognized standard (Abbott Laboratory, USA), the sensitivity and specificity of IgM-DIGFA (self-made) were 91.3 % (42/46) and 96.0 % (48/50), and those of IgM-ELISA (Kehua, Shanghai) were 97.8 % (45/46) and 100.0 % (50/50). The identical results were produced from the study with reagents at different conditions, and the study was repeated in 15 negative sera and 10 positive sera. The serum anti-HAV IgG was tested with DIGFA at the same time. In comparison with ELISA, the sensitivity and specificity of DIGFA for IgG anti-HAV were 87.2 % (41/47) and 91.8 % (45/49), respectively.

CONCLUSION: This assay can detect anti-HAV IgM and IgG simultaneously, and be done within 3 minutes. The simplicity, rapidity and specificity of the assay were useful for screening and epidemiological study.

INTRODUCTION

Hepatitis A is a self-limiting disease and often a subclinical disorder[1,2]. Since symptomatic hepatitis A infection can be clinically undistinguished from hepatitis B, C or E, serological testing is an important tool in its diagnosis[3-6]. Diagnosis of HAV infection depends mainly on the detection of specific antibody[3,4]. Although enzyme linked immunosorbent assay (ELISA) and RT-PCR are currently used for the detection of HAV infection and meet most of the clinical requirements[7-11], the two methods provide little information on prevention of diseases[12-15]. Dot immunogold filtration assay for the detection of anti-HAV IgM was established[16,17]. In our study a dot immunogold filtration assay was established to detect both anti-HAV IgM and IgG simultaneously.

MATERIALS AND METHODS

Sera

Blood samples were continuously collected from acute hepatitis inpatients in Xi' an Infectious Disease Hospital from March to October 2000 with permission of both the hospital and patients. Five milliliters of blood were drawn from each patient and the specimen was centrifuged at 3 000 r/min for 15 minutes to separate the serum. Ninety-six sera specimens were collected by the end of study. Anti-HAV IgM was detected as positive in 46, anti-HBc IgM in 31, anti-hepatitis C in 15, transmission-transmitted virus (TTV) in 3 by RT-PCR[18]. No hepatitis virus markers were found in 6 specimens, and positive anti-HAV and HBV were detected simultaneously in 2 sera.

Preparation of probe

Colloidal gold was produced by citromalic acid trisodium recovery method. The colloidal gold solution was scanned between 400 nm and 700 nm by using a spectrophotometer. The batch with λmax between 519 and 520 was used subsequently for conjugating with mouse anti-HAV IgG (CAPM). The pH was adjusted to 8.0 with 0.2 mol/L K_2CO_3. Then mouse anti-HAV IgG (1 μg per milliliter) was added into the colloidal gold solution and mixed for 30 minutes, then stored at 4 ℃ overnight. The pellet was collected by centrifugation at 15 000 r/min for 60 minutes, and the absorbance (A) was regulated by 0.02 mol/L PBS to the value of 1.5.

ELISA test for anti-HAV IgM and IgG

ELISA test was performed strictly according to instructions of the kit (anti-IgM kit from Kehua Biotech Co. and anti-IgG kit from Huaguang Biotech Co). Diluted sera (1:1 000) were incubated at 37 ℃ for one hour in a reactive well, and after washed, HAV Ag and anti-HAV peroxidase conjugates were added and incubated at 37 ℃ for 10 minutes, and followed by washing. Then the substrate was added, and the reaction was stopped by diluted sulfuric acid 10 minutes later. The absorbance was measured at 540 nm. An absorbance of 2.1 times the negative control value was considered as positive. The detecting procedures for HAV IgG were the same as for IgM except for serum dilution (1:50).

AXSYM HAVAB-M (Abbott Laboratory) was based on microparticle enzyme immunoassay technology[19-21]. Samples and all AXSYM HAVAb-M reagents required for one test were pipetted with the sampling probe into wells in reactive vessel in the sampling center. The reaction vessel was immediately

transferred into the processing center. Further pipetting was done in the processing center by the processing probe. All steps were completed automatically and the diagnostic results were reported immediately.

DIGFA

There were 4 components in the kit: solid phase reaction board (SPRD, self-made), HAV Ag, color-developing reagents and lotion. Anti-human IgM and IgG antibodies (Dako, USA) were blotted onto small round nitrocellulose membranes (Hyclone, USA) separately, air-dried at room temperature, and then incubated in 20 g/L bovine serum albumin (BSA) overnight, and finally washed and air dried. These nitrocellulose membranes prepared were fitted in SPRD with coated side facing exteriorly. Then SPRD was filled with water-absorbed stuff. One drop of lotion (PBS-T, pH8.0 containing 05 g/L Tween20 and 20 g/L BSA) was added to prepare SPRD. 100 μL of serum with dilution of 1:100 was added to each reaction well, and then washed with one drop of lotion. Then one drop of HAV Ag was added, and then was washed. Finally two drops of anti-HAV IgG colloidal gold conjugates were added, and then washed with one drop of lotion. A reddish dot with sharp margin was considered as positive.

Statistical analysis

The following definitions and formulae were used in this study. A true positive (a) sample was both reactive by DIGFA/ELISA and ABBOTT. A true negative (d) sample was nonreactive by both DIGFA/ELISA and ABBOTT. A false positive (b) sample was reactive by DIGFA/ELISA but negative by ABBOTT and a false negative (c) sample was negative by DIGFA/ELISA but positive by ABBOTT. The sensitivity of DIGFA was defined as the probability that a sample containing anti-HAV antibodies would be positive in DIGFA/ELISA. The specificity of DIGFA/ELISA was defined as the probability that a sample without anti-HAV antibodies would be negative in DIGFA/ELISA. Chi-square test was used.

RESULTS

Preparation of probe

Transmission electron microscopic studies revealed that the average diameter of the gold particle was 15 nm (15±0.7 nm). The maximum absorbing wavelength was 519 nm, indicating that the colloid gold met the experimental requirements. After purification of labeling anti-HAV IgG to gold particle, one drop of probe was added to SPRD coated by goat anti-mouse IgG and a pink dot appeared 30 seconds later, indicating effectiveness of the probe.

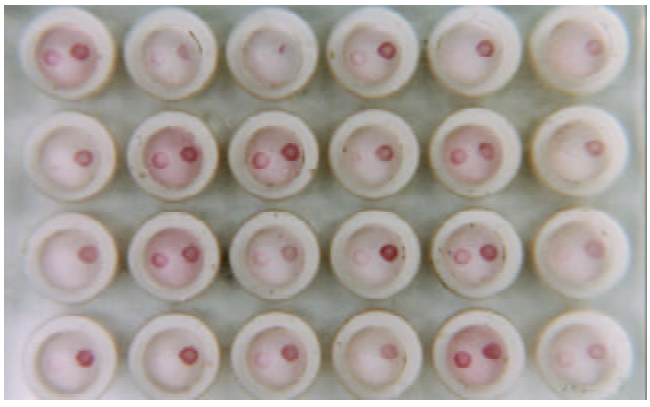

Figure 1 Detection of 24 sera from acute hepatitis inpatients by DIGFA. Red dot: positive; Left: anti-human IgG; Right: anti-human IgM.

Comparison of three diagnostic methods (Tables 1, 2 and 3)

Abbott kit has been widely recognized in the world, but its usage was limited in China due to the relatively high cost. The comparative analysis of 96 serum specimens showed that the sensitivity and specificity of IgM-ELISA were higher than those of IgM-DIGFA (Table 1). Statistical analysis (two tailed binomial probability test) showed no significant differences in sensitivity and specificity (Figure 1). Cross-reaction was found in DIGFA for anti-HAV IgM in a serum specimen, which was diagnosed as anti-HBV positive by ELISA.

Table 1 Comparison of DIGFA, ELISA and AXSYM HAVAb-M

IgM		HAVAB-M (Abbott laboratory)		Total
		+	-	
DIGFA	+	42	2	44
	-	4	48	52
ELISA	+	45	0	45
	-	1	50	51

Sensitivity of IgM-DIGFA was 91.3 % (42/46) and specificity was 96.0 % (48/50). Sensitivity of IgM-ELISA was 97.8 % (45/46) and specificity was 100.0 % (50/50). There were no significant differences in sensitivity (P=0.36) and specificity (P=0.49).

Anti-HAV IgG and IgM were detected in all sera. ELISA kit was purchased from Huaguang Biotech Co, Xi' an, China. Forty-one of 96 sera specimens were detected as positive with both methods and 86 were diagnosed coincidentally. The sensitivity and specificity were 87.2 % (41/47) and 91.8 % (45/49), respectively (Table 2).

Table 2 Comparison of IgG-DIGFA with IgG-ELISA

IgG-DIGFA	IgG-ELISA		Total
	+	-	
+	41	4	45
-	6	45	51
Total	47	49	96

In this study, twenty-three sera specimens were detected as positive for IgG, and 30 as negative for both IgM and IgG, which indicated that some individuals in general population were possibly susceptible to HAV infection (Table 3).

Table 3 Analysis of anti-HAV IgG and IgM by DIGFA method

Anti-HAV IgG	Anti-HAV IgM		Total
	+	-	
+	23	22	45
-	21	30	51
Total	44	52	96

Repeatability and stability

All reagents could be stored effectively at 4 ℃ for 3 months, at room temperature for 15 days and at 48 ℃ for 2 days. Fifteen negative and ten positive sera samples were selected randomly and detected with reliable results.

DISCUSSION

Detection of antibody against hepatitis A virus

DIGFA is a new technique of solid phase labeled immunoassay,

in which NCM is used as a support and colloidal gold as the label, and the principle of filtration is adapted for the rapid reaction of antigen and antibody[22,23]. The use of visible gold-conjugated monoclonal antibody instead of enzyme in ELISA makes the test simple[24]. The sensitivity of DIGFA is lower than that of ELISA. This method can detect two kinds of anti-HAV antibodies simultaneously that are similar to protein biochip, but the cost is much lower than that of biochip[25]. It is very suitable for screening and vaccination program[26-29]. IgM antibody persists for 3 to 6 months afterwards, and is seldom found after vaccination. Patients with asymptomatic hepatitis A may have detectable anti-HAV IgM for a shorter period than patients with symptomatic diseases[30]. Although anti-HAV IgG may be present at early stage of infection, it is always accompanied by anti-HAV IgM at the onset of illness. Anti-HAV IgG alone indicates a past infection and persists for decades after acute HAV infection, reflecting recovery and resistance to reinfection[31,32]. However, detection of anti-HAV IgG is often ignored due to its limited clinical value, but it can show whether a person is susceptible to HAV and offer a good instruction to health workers. Twenty-two sera were detected as negative for both anti-HAV IgM and IgG, which indicated that these people need to be vaccinated.

Comparison with ELISA

The sensitivity and specificity of IgM-DIGFA for HAV in these sera were lower than those of IgM-ELISA. However, there was no significant difference in specificity of both assays. IgM-DIGFA can be used as an eligible assay to screen HAV infection for its rapidity and specificity. It takes a few minutes to complete the whole process by DIGFA, and the detection of 30 sera specimens can be done within 30 minutes. Shortened reaction time gives a proper explanation to the lower sensitivity of IgM-DIGFA. A cost-analysis of DIGFA and ELISA was done, and found that pure reagents cost of DIGFA was 0.75 Yuan (RMB) and that of anti-HAV IgM ELISA was 1.20 Yuan (RMB). It was not as expensive as expected and two kinds of antibodies were detected at one time[33]. All the reagents leaked through NCM and took a full reaction with antibodies attached to NCM. This was due to the effect of immunoconcentration [34]. It is easy to tell the results without the help of extra apparatus. Therefore, it can be widely used in an epidemiological survey.

Abstract

AIM: Cytotoxic T lymphocytes (CTLs) play an important role in resolving HBV infection. In the present study, we attempted to evaluate the efficiency of bone marrow-derived dendritic cells (DCs) transduced with recombinant retroviral vector bearing hepatitis B virus (HBV) core gene and the capability of generating CTLs against HBcAg by genetically modified DCs *in vivo*.

METHODS: A retroviral vector containing HBV core gene was constructed. Replicating DC progenitor of C57BL/6 mice was transduced by retroviral vector and continually cultured in the presence of recombinant mouse granulocyte-macrophage colony-stimulating factor (rmGM-CSF) and interleukin-4(IL-4) for 6 days. LPS was added and cultured for additional two days. The efficiency of gene transfer was determined by PCR, Western blot and FACS. Transduced DCs immunized C57BL/6 mice subcutaneously 2 times at an one-week interval. Intracellular IFN-γ and IL-4 of immunized mice lymphocytes were analyzed. Generation of CTLs in lymphocytes stimulated with mitomycin C-treated EL4-C cell which stably expresses HBcAg was determined by LDH release assays.

RESULTS: Recombinant retroviral expression vector (pLCSN) was positively detected by PCR as well as enzyme digestion with *EcoR*I and *BamH* I. Retroviruses were generated by pLCSN transfection packing cell and the virus titer was 3×10^5 CFU/ml. Indirect immunofluorescence and FACS showed that HBV core gene was expressed in murine fibroblasts. Transduced bone marrow cells had capability of differentiating into DCs *in vitro* in the presence of rmGM-CSF and rmIL-4. The result of PCR showed that HBV core gene was integrated into the genome of transduced DCs. Western blot analysis showed that HBV core gene was expressed in DCs. The transduction rate was 28 % determined by FACS. Retroviral transduction had no influence on DCs expressions of CD80 and MHC class II. HBcAg specific CTLs and Th1 type immune responses could be generated in the mice by using transduced DCs as antigen presenting cells (APCs).

CONCLUSION: Retroviral transduction of myeloid DCs progenitors expresses efficiently HBcAg, and genetically modified DCs evoke a higher CTLs response than HBcAg *in vivo*.

INTRODUCTION

Individuals with chronic hepatitis B virus(HBV) infection have a high risk of developing liver cirrhosis and primary hepatocellular carcinoma. Current treatments for chronic HBV infection are poorly efficacious[1-3].

Cytotoxic T lymphocytes (CTLs) are thought to contribute to HBV clearance by killing infected hepatocytes and secreting antiviral cytokines. Acutely infected patients characteristically produce a vigorous, polyclonal, and multispecific CTLs response that is usually sufficient to clear the infection, while persistently infected patients produce a weak or undetectable HBV-specific CTLs response. The cumulated data suggest that CTLs activity may play an important role in resolving HBV infection[4-13]. Based on these observations, therapeutic enhancement of T cell responsiveness to HBV has the potential to terminate chronic HBV infection.

Dendritic cells (DCs) are highly specialized antigen presenting cells (APCs) that possess unique immunostimulatory properties and function as the principal activators of naï ve T cells[14,15]. DCs are distributed throughout the body and can be expanded with granulocyte-macrophage CSF (GM-CSF) and IL-4. When DCs are pulsed with antigen protein or peptide, they can induce specific antibody and CTLs responses both *in vitro* and *in vivo*. Since activated DCs express a high level of costimulatory molecules and secrete inflammatory cytokines, they have the potential to activate anergic T cells.

In the present study, we attempted to induce CTLs response using retrovirally transduced DCs. The results demonstrated that administration of retrovirally transduced DCs could evoke HBcAg-specific CTLs responses in mice.

MATERIALS AND METHODS

Generating expression vector

The full-length HBV core gene was generated by PCR amplification from pADR(kindly provided by Prof. Zheng-Hong Yuan) which contains complement nucleotide sequence of HBV subtype adr with a pair of primers (5'-TGTGAATTCTGGCTTTGGGGCATGGACATTG-3', corresponding to the nucleotide sequence 1891-1912 of HBV genome with an additional *EcoR*I restriction site, and 5'-GCTGGATCCAGTTTCCCACCTTATGAGTCCA-3', corresponding to the nucleotide sequence 2462- 2483 of HBV genome with an additional *BamH*I restriction site). After digestion with *EcoR*I and *BamH* I, PCR products were inserted downstream of LTR of retroviral vector pLXSN (Clontech,USA) to obtain a recombinant retroviral expression vector pLCSN.

Virus production

To produce retroviral virus, packing cell (PT67, Clontech, USA) was cultured in a 24 well culture plate with D-MEM containing 10 % heat-inactivated FBS and transfected with 1 μg of retroviral vector plasmid pLCSN by lipofectAMINE2000 (GIBCO,USA). Colonies were isolated by neomycin selectin (G418, Amresco, USA) and expanded. Supernatants of cloned packing cells were harvested, filtered (0.45 μm pore size), and tested for the presence of virus. Viral titration was performed on NIH3T3 according to the instructions of the manufacturer yielding a titer of 3×10^5 infectious particles/ml.

DC culture, transduction and immunization

Bone marrow cells were collected from femurs of C57BL/6 mouse and depleted of red cells with ammonium chloride. After extensively washed with RPMI1640, cells (5×10^5 cells/ml) in RPMI1640 supplemented with 10 % FBS, 500 U/ml rmGM-CSF and 250 U/ml rmIL-4 were plated in a 24 well culture plate, incubated at 37 ℃ in 5 % CO_2-atmosphere. After 24-h incubation, the cells were transducted with retroviral supernatants and polybrene (Sigma,USA) at a final concentration of 8 μg/ml. The cells were incubated at 37 ℃, in 5 % CO_2 atmosphere for 2-3 h. The supernatant was replaced with RPMI1640 supplemented with 10 % FBS, 500 U/ml rmGM-CSF and 250 U/ml rmIL-4 overnight. The transduction procedure was repeated 3 times. After 6 days, LPS (1 μg/ml) was added and mature DC was obtained after additional culture for 2 days. The cells were washed three times, and 5×10^5 DCs suspended in 0.5 ml of PBS were injected subcutaneously. The immunization was repeated after 7 days.

Polymerase chain reaction

DNA from retrovirally transduced and untransduced DCs was isolated according to the manufacturer' s protocol (Boehringer, Germany). DNA was isolated from the G418 resistant PT67 cell line as positive control. Primers used for amplification of HBcAg were mentioned above. PCR was performed for 1 min at 94 ℃, for 1 min at 54 ℃, and for 1 min at 72 ℃ for 30 cycles, followed by a final extension time of 6 min at 72 ℃. The PCR product was resolved on a 1.5 % agarose gel.

Western blot analysis of HBcAg

Cell lysates were made from retrovirally transduced and untransduced DCs. Protein samples were separated by SDS-PAGE and transferred to nitrocellulose. HBcAg protein was identified using the anti-HBc positive serum as primary Ab and goat anti-human IgG peroxidase-conjugate (1:500, volume ratio) as secondary Ab. The blots were developed using substrate solution containing DAB and H_2O_2.

Intracellular cytokine analysis

Spleen lymphocytes were stimulated with Con A at 20 μg/ml, and 1 μl GolgiPlugTM was added for every 1 ml of cell culture to inhibit cytokine secretion. Lymphocytes were incubated for 6 hours, then harvested and washed with staining buffer. Cells were thoroughly resuspended and 100 μl of cytofix/cytoperm solution was added into each well for 20 min at 4 ℃. Cells were washed and stained with FITC-labled anti-mouse IFN-γ and PE-labled anti-mouse IL-4, incubated at 4 ℃ for 30 min in the dark, then washed twice and analyzed with a flow cytometer.

CTL_S assay

The tumor cell line EL4 ($H\text{-}2^b$) was transduced with recombinant retrovirus and then selected in the presence of 400 ug/ml G418. The G418-resistant clones (EL4-C) were screened for HBcAg expression by PCR and indirect immunofluorescence. Spleen cells obtained from individual mice were stimulated with EL4-C treated by 25 μg/ml mitomycin C at effector:stimulator ratio of 20. The specific CTLs were expanded by adding 50 IU/ml of IL-2 for 7 days. The CTLs activity in the cultures was measured in triplicate in a standard four-hour LDH release assay using EL4-C cells as target cells according to the manufacturer' s instructions(Roche, Switzerland).

RESULTS

Generation of retroviral expression vector and retrovirus

The HBV core gene fragment generated by PCR amplification and digested with *EcoR*I and *BamH* I was successfully cloned into downstream of LTR of pLXSN to obtain recombinant retroviral expression vector pLCSN (Figure 1). Recombinant retroviral vector was positively detected by PCR as well as enzyme digestion with *EcoR*I and *BamH*I. To produce retroviral virus, packing cells were transfected with retroviral expression vector pLCSN. Colonies were isolated by neomycin selectin and expanded. Supernatants of G418 resistant cells were harvested. The virus titer was 3×10^5 infectious particles/ml. It was found that retroviruses could infect a number of eukaryotic cells, such as NIH3T3, EL4, and SP2/0(data not shown).

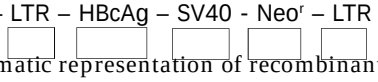

Figure 1 Schematic representation of recombinant retroviral vector pLCSN.

Retroviral transduction of bone marrow cells and differentiation into DCs

To assess the expression of HBcAg in DCs, we transduced bone marrow cells from C57BL/6 mice in packing cell supernatants. The transduced cells were then cultured in the presence of rmGM-CSF, rmIL-4 and LPS for the purpose of differentiation into mature DCs. After cultured for 8 days, the majority of cells displayed distinct DC morphology with many fine dendrites. Retroviral transduction had no influence on DCs expressions of CD80 and class II molecule of MHC (72.94 % *versus* 73.43 %, 86.54 % *versus* 91.75 %, respectively). T-cell stimulatory activity of DCs in MLR was expressed as stimulation index (SI) value, at a T cell:DC ratio of 80:1, 40:1, 20:1 and 10:1. The SI values were 3.16, 7.26, 23.99, 31.70, respectively. The HBV core gene in transduced DCs was demonstrated by PCR (Figure 2). Approximately 28 % of the bone marrow derived cells could express HBcAg determined by flow cytometric analysis. Finally, Western blot analysis demonstrated that HBcAg was expressed in transduced DCs (Figure 3).

Induction of CTLs responses in vivo

Next we evaluated the capability of retrovirally transduced DCs to induce CTLs responses *in vivo*. C56BL/6 mice were immunized subcutaneously with 5×10^5 DCs transduced with HBcAg. The immunization was repeated after one week. 7 days after the last immunization, the mice were sacrificed and splenocytes were collected. Splenocytes were restimulated *in vitro* for 7 days in the presence of mitomycin C-treated EL4-C cell and IL-2, and then cocultivated with different target cells at varied E:T ratios to measure target cell lysis with LDH release cytotoxic assay. As shown in Figure 4, splenocytes from mice immunized with transduced DCs demonstrated significantly higher cytotoxicity than those from controlled mice. To determine the type of Th responses, we measured the lymphocyte which could secret IFN-γ or IL-4 with intracellular cytokine analysis. After immunization of retrovirally transduced DCs in mice, lymphocyte producing IFN-γ was significantly higher than that from mice injected

only with untransduced DCs (1.15 % *versus* 0.28 %). At the same time, lymphocyte producing IL-4 in both mice with injections of transduced and untransduced DCs was similar (0.74 % *versus* 0.47 %).

DISCUSSION

Chronic HBV infection has a significant association with liver cirrhosis and hepatocellular carcinoma. Studies on immunological mechanisms have demonstrated that CTLs play a critical role in the control and termination of HBV infection. CTLs are thought to contribute to HBV clearance by killing infected hepatocytes and secreting antiviral cytokines. Acutely infected patients characteristically produce a vigorous, polyclonal, and multispecific CTLs response that is usually sufficient to clear the infection, while persistently infected patients produce weak or undetectable HBV-specific CTLs responses[4-13]. Based on these observations, therapeutic enhancement of T cell responsiveness to HBV has the potential to terminate chronic HBV infection.

A number of experimental reports showed that CTLs responses could be induced. Vaccination with HBsAg-anti-HBs immune complex could affect HBeAg seroconversion and clearance of serum HBV DNA in patients[16]. Sallberg *et al*[17] observed a marked decrease of HBV DNA level and seroconversion of HBeAg to anti-HBe in sera of experimental chimpanzees after immunization of HBV core gene using retrovirus. Plasmid DNA immunization has been shown to induce specific antibody and CTLs responses in normal mice and rhesus monkeys[18-20]. ISCOMS-based hepatitis B polypeptide vaccine could also induce a higher CTLs response *in vivo*[21].

DCs play a central role in humoral and cellular immunity because they can take up and process antigen in peripheral tissues and present the antigen to T cells in secondary lymphoid tissues, such as lymph nodes. The mature DCs screen for passing antigen-specific naï ve T cell, and induce primary T cell-mediated immune response. Mature DCs are thought to be functionally competent and have been used in clinical studies to induce antigen-specific T cells[14,15,22,23]. In this study, we used DCs as an attractive approach for immunotherapy of chronic HBV infection. In developing strategies to optimize the use of DCs in immunotherapy, viral transduction of DCs with antigen genes may offer more advantages over peptide-pulsed DCs. The efficacy of peptide-pulsed DCs might be limited *in vivo*, because peptides pulsed onto DCs stay bound to MHC molecules only transiently. Additionally, use of peptide-pulsed DCs is dependent on the knowledge of the HLA haplotype of patients. Transduction of DCs by viral vectors can produce a high level of antigen expression, and endogenous protein synthesis may allow presentation of antigens by class I molecules of MHC, resulting in induction of $CD8^+$ CTLs responses. Several viruses have the potential for use in immunotherapy, such as vaccina virus, adenovirus, and retrovirus[24]. Retroviral transduction of DCs may allow constitutive expression of protein leading to prolonged antigen presentation *in vivo*, and presentation of multiple or unidentified antigen epitopes in the context of class I and II molecules of MHC. But as nonreplicating, mature DCs are poor candidates for retroviral gene modification. However, dividing bone marrow progenitor cells can be efficiently transduced with retroviral vectors[25-29]. In this study, rapidly dividing bone marrow progenitor cells were used as targets for retroviral transduction and cultured in the presence of GM-CSF and IL-4 plus LPS. Our results showed that retrovirally transduced progenitor cells could differentiate into mature DCs *in vitro*, transduced or untransduced dendritic cells expressed comparable levels of CD80 and class II of MHC, the transduction efficiency was about 28%. Retrovirally transduced DCs could be used to induce strong CTLs responses in C57BL/6 mice *in vivo*.

Previous studies showed that Th1 type response was beneficial for the clearance of chronically infected viruses[30,31]. The profiles of cytokine production were indicators of helper T cell responses. IFN-γ and IL-4 were observed in the present experiment as Th1 and Th2 type cytokines, respectively. After immunization of retroviral transduced DCs, lymphocyte producing IFN-γ was significantly higher than that from mice injected only with untransduced DCs, indicating Th1 type immune responses occurred in mice immunized with retroviral transduced DCs.

These results together with other studies support the ongoing efforts to develop genetically modified DCs for immunotherapy of chronic HBV infection. Further study is underway to determine whether this genetically modified DCs can break the immune tolerance in the HBV transgenic mouse model.

Abstract

AIM: HBsAg is the most important serological marker for acute or chronic hepatitis B. Nevertheless, there were reports of HBsAg-negative infection caused by hepatitis B virus in recent years. We had a patient with crytogenic cirrhosis who was negative for HBsAg, positive for anti-HBs and HBeAg. This paper was to explore the pathogenic and molecular basis of the unusual serological pattern.

METHODS: HBV serologic markers were qualitatively and quantitatively determined. HBV DNA in serum was qualitatively tested using routine Polymerase chain reaction (PCR), and the viral level was determined with real-time fluorescence quantitative PCR. HBsAg gene was amplified and cloned. Four clones were sequenced. The new genomic sequences were compared with GenBank on the DNA level as well as the protein level.

RESULTS: The qualitative results of serological markers were HBsAg(-), anti-HBs(+), HBeAg(+), anti-HBe(-) and anti-HBc(+). The quantitative results of serological marker were HBsAg (S/N): 0.77 (cut off of S/N: $\geqslant$2.00), HBeAg (S/N): 56.43 (cut off S/N: $\geqslant$2.10), anti-HBc (S/C_O): 2.03 (cut off of S/C_O: $\leqslant$1.00). The viral level was as high as 1.54×10^9 copies/ml. Sequencing of the HBsAg gene clones revealed a unique point mutation at nucleotide 336 (C to A), which resulted in a novel stop codon at aa 61. The novel HBsAg gene stop mutation had not been described.

CONCLUSION: The lack of detection of HBsAg in the presence of high viral levels of replication may be caused by the existence of viral genomes harboring point mutations which resulted in stop codon upstream of the "a" determinant in HBsAg gene.

INTRODUCTION

Hepatitis B virus (HBV) is a small DNA-containing virus with 4 overlapping open reading frames. The four genes are core, surface, X and polymerase. The surface antigen open reading frame is divided into three regions, pre-S1, pre-S2 and S, which encode three envelope proteins respectively termed large, middle and major protein. All the three envelope proteins contain the major protein, HBsAg, which consists of 226 amino acids and is the predominant protein of the 20 nm small spherical particles representing circulation excess surface protein[1,2].

Serological evidence for acute or chronic hepatitis B is provided most commonly by assays detecting the HBsAg. Its detection is believed to prove the presence of hepatitis B virus in the liver and the peripheral blood. Both the clearance of HBsAg from serum and the appearance of antibodies to HBsAg (anti-HBs) are associated with a resolution of hepatitis in acute or chronic hepatitis B infection[3]. However, the development of polymerase chain reaction (PCR) technique has permitted the detection of very low levels of HBV in patients. There are a number of reports of HBsAg-negative virus carriers[4,5]. Moreover, even cases of anti-HBs-positive carriers have been described although antibodies against the viral envelope usually neutralize the virus and confer protection from infection[6]. China is a highly endemic area for HBV infection, some studies suggested that 30 % to 40 % of HBsAg-negative patients with cryptogenic cirrhosis, chronic active hepatitis, or chronic persistent hepatitis had HBV-DNA in serum or liver tissue[7]. A well-characterized explanation for the latter pattern is surface mutation. Over the past decade many kinds of surface mutations have been described. We present here a patient with cirrhosis and active viral replication in the presence of anti-HBs. Sequencing of the HBV DNA from the patient revealed a point mutation at nucleotide 336 (C to A) in HBs-gene. This mutation led to a stop codon at 61 amino acids of HBsAg and a premature translation stop, which has not been described elsewhere up to now.

MATERIALS AND METHODS

Case report

The patient was a 56-year-old man. He was positive for HBsAg but asymptomatic in 1988. In 1990 his alanine aminotransferase (ALT) level was slightly elevated. In 1992 he developed a very severe disease which was diagnosed as severe type hepatitis B. He recovered 3 months later. He felt well from 1992 to 1998, no data about HBV serology and liver function were available during that period. However, he began to feel fatigue, weakness, abdominal distension from the beginning of 1999. His WBC and platelet were markedly decreased, but negative for HBsAg, and positive for anti-HBs. Abdominal ultrasound examination showed splenomegaly. Cryptogenic cirrhosis was diagnosed. Cirrhosis caused by HCV, alcohol, drugs, Wilson' s diease and schistosomiasis was excluded. In order to find the cause of the cirrhosis, he came to our hospital in August 2000. Serum was collected at the time and stored at -70 ℃ until analysis.

HBV serological markers detection

HBsAg, anti-HBs, HBeAg, anti-Hbe, anti-HBc-IgG and anti-HBc-IgM were tested using commercially available standard enzyme immunoassay kit (Kehua Bio-Engineering Co. LTD, Shanghai, China). HBsAg, HbeAg and anti-HBc-IgG were

quantitatively determined using Abbott reagent with IMX automatic immunoassay analyzer (Abbott Laboratories, North Chicago, IL), according to the manufacturer' s instructions.

Serum HBV DNA detection

HBV DNA detection was carried out using commercially available PCR kit (Liver Research Institute, Beijing Medical University, Beijing, China), according to the manufacturer' s instructions. Serum samples (200 μl) were digested with 1 g/L proteinase K and 0.5 % sodium dodecyl sulfate (at 37 ℃ **for** 2 hours), followed by phenol-chloroform extractions and ethanol precipitation. After centrifugation, the pellet was dissolved in 10 μl distilled water. Five μl elute was used for PCR. Thermal cycling conditions were as follows: 35 cycles of amplification were performed at 94 ℃ for 30 s and at 60℃ for 45 s. The PCR products were investigated by staining with ethidium bromide on ultraviolet transilluminatior after electrophoresis in 1.5 % agarose gel.

HBV DNA quantification

HBV DNA in serum was quantified using a commercially available real-time fluorescence quantitative PCR (FQ-PCR) kit (Da An Gene Diagnostic Center, Sun Yet-Sen Medical University, Guangzhou, China), in accordance with the manufacturer' s instructions. Briefly, 40 μl of serum was mixed with 40 μl of DNA-extracting solution (provided by the kit). The mixture was vortexed and placed in a 100 ℃ heating block for 10 min, then overnight at 4 ℃. The mixture was centrifuged for 5 min at 10 000 rpm. Two μl of supernatant was added to the tube containing FQ-PCR core reagent (provided by the kit). FQ-PCR was performed using a GeneAmp 5700 sequence detection system (Perkin Elmer, Foster City, CA). Thermal cycling conditions were as follows: at 93 ℃ for 2 min for initial denaturation, followed by 40 cycles of at 93 ℃ for 30 s, at 55 ℃ for 60 s. Analysis of raw data was done with the GeneAmp 5700 SDS Software (PE Biosystems). Data were collected at the annealing step of each cycle, and the threshold cycle (C_T) for each sample was calculated by determining the point at which the fluorescence exceeded the threshold limit. The standard curve was calculated automatically by plotting the C_T value against each standard of known concentration and calculation of the linear regression line of this curve. Calculation of the correlation coefficient was done for each run, and the minimal value was 0. 98. Sample copy numbers were calculated by interpolation of the experimentally determined standard curve.

Amplification of HBsAg gene

The primers were designed by ourselves according to the sequences published[8,10], which could amplify whole HBsAg gene (from nt 155 to 833). The procedures for HBV DNA extraction were the same as routine PCR described above. The reaction conditions were: the total volume was 30 μl, containing 50 mmol/L KCl , 10 mmol/L tris-HCl (pH9.0), 0.1 % triton 100, 0.2 mmol/L dNT, 1.5 mmol/L $MgCl_2$, 15 pmol primer 1 and primer 2, TaqDNA polymerase 2.5U, a drip of paraffin oil was added on the top of the solution. PCR conditions were as follows: at 94 ℃ for 5 min for initial denaturation, followed by 30 cycles at 94 ℃ for 1 min, at 56 ℃ for 50 s, at 72 ℃ for 10 s, at 72 ℃ for 10 min for extension. The PCR products were investigated by staining with ethidium bromide on ultraviolet transilluminatior after electrophoresis in 1.5 % agarose gel or used for HBsAg gene cloning.

Forward primer: 5' GGGAAGCTTATGGAGAACATCACATCAGGATTC3'

Reverse primer: 5' CGCGGATCCTTAAATGTATACCCAGAGACAAAA3' .

Cloning and sequencing of HBsAg gene

The amplified products of HBsAg gene were cloned using pGEM-T easy vectors system kit (Promega Co., Madison, WI.), according to the manufacture' s instructions. To detect the vectors containing the PCR products, white/blue colony selection was used. The inserted products were analyzed by electrophoresis in 1 % agarose gel after EcoR 1 digestion and PCR (as amplification of HBsAg gene described above). Four clones were sequenced. The sequence of the complete HBsAg gene was obtained by forward and reverse reading of overlapping fragments using ABI PRISM BigDye terminator cycle sequencing ready reaction kit (Perkin Elemer, Foster City, CA). To identify mutations, the new genomic sequences were compared with GenBank on the DNA level as well as the protein level.

RESULTS

All HBV serologic markers were tested repeatedly. HBsAg, HBeAg and anti HBc were tested again using Abbott reagent. The results confirmed that the patient was HBsAg-negative, anti-HBs-positive and HBeAg-positive. It was estimated that the patient had cirrhosis caused by HBV. To confirm the diagnosis, the presence of HBV DNA in serum of the patient was tested using routine PCR and HBV DNA was detected. The quantity of HBV DNA in serum was determined using real-time fluorescent quantitative PCR, which was unexpectedly as high as 1.54×109/ml (Tables 1 and 2).

Table 1 Viral and clinical examination results of the patient

Item	Jan. 1999	Apr. 1999	Oct. 1999	Aug. 2000	Nov. 2000	Mar. 2001
HBsAg	-	-	-	-	-	-
Anti-HBs	+	+	+	+	+	+
HbeAg	+	+	+	+	+	+
Anti-Hbe	-	-	-	-	-	-

WBC (10^9/L)	Nd	Nd	Nd	2.1	2.8	2.6
Platelet (10^9/L)	Nd	Nd	Nd	26	58	40

Nd, not determiined; +, positive; -, negative. ALT, alanine aminotransferase; WBC, white blood cell.

Table 2 HBsAg, HBeAg and anti-HBc level determined using Abbott reagent

Item	Results	Cut off
HBsAg	0.77	≥2.00(S/N)
HbeAg	56.433	≥2.10(S/N)
Anti-HBc	2.033	≤1.0(S/Co)

Due to the massive production of viral particles in the absence of HBsAg and presence of anti-HBs, HBsAg gene mutation, possibly in the "a" determinant, was suspected. Therefore, HBV DNA was extracted from the serum of the patient, HBsAg gene was amplified. After electrophoresis of the PCR products corresponding to the complete HBsAg gene amplified from serum and ethidium bromide staining of the gel, a PCR fragment about 700 bp was detected (the figure was not shown). Then the PCR products of HBsAg gene were cloned, 4 clones were sequenced. The complete sequence of

the HBsAg gene was obtained by forward and reverse reading of overlapping fragments (Table 3). All of the 4 clones had the same sequence. The nucleotide and amino acid sequences of the HBsAg gene were compared with GenBank. There were no nucleotide insertions or deletions in the HBsAg gene. Surprisingly, sequencing of the HBsAg gene clones revealed a unique point mutation at nucleotide 336 (C to A), which resulted in a novel stop codon at aa 61. Thus, only a truncated version of HBsAg containing 21 amino acids could be synthesized from this gene, which lacked the entire "a" determinant. The novel HBsAg gene stop codon caused by a point substitution mutation upstream of the "a" determinant of HBsAg gene has not been described up to now.

The isolate belonged to subtype adw2 according to the amino acid sequence deduced from the nucleotide sequence of the HBsAg gene. The patient's nucleotide sequence and amino acid sequence were compared with a published sequence of the same subtype reported by Ono *et al*[9] and a Chinese consensus sequence of the same subtype (China J Microbiol Immunol, 1999; 19: 197-200). A two by two analysis of the three nucleotide and amino acid sequences demonstrated a relatively high degree of homogeneity. The nucleotide and amino acid difference was 5.28 % and 8.37 % between the patient's and Ono's sequences, and was 4.84 % and 7.92 % between the patient's and the Chinese consensus sequences, respectively. The "a" determinant of the patient's sequence differed from the Ono's sequence by only 2 amino acids and differed from the Chinese consensus sequence by another 2 amino acids, which might reflect the genetic heterogeneity of the same subtype and could not be the mutation (Table 4).

DISCUSSION

Hepatitis B virus replicates via an RNA intermediate, using a reverse transcriptase that appears to lack a proofreading function. Therefore, HBV exhibits a mutation rate more than 10-fold higher than other DNA virus[10-12]. Mutations in all 4 genes have been described. Surface gene mutation were initially noted as vaccine escape mutants, detected in 2-3 % of children in HBV endemic regions receiving HBV immunoprophylaxis at birth, and also observed in liver transplanted HBV carriers who received hepatitis B immunoglobulin to prevent re-infection of the graft[13-17]. Similar mutations could also arise in the natural course of HBV infection. The prevalence and clinical significance of naturally occurring mutations in full-length surface and overlapping polymerase genes of hepatitis B virus were analyzed in 42 patients with chronic hepatitis, mutations were observed in 10 patients (24 %) in the "a" determinant region[18,19].

The surface gene of HBV contains a dominant neutralizing epitope termed "a" determinant located between aa 121-149 of HBsAg, The production of antibodies to the "a" determinant after vaccination usually protects against HBV infection. The surface protein variants noted in most studies were clustered within the "a" determinant, especially the substitution of glycine for arginine at aa 145, which makes this epitope unlikely to bind to antibodies generated to wild-type HBsAg. However, other kinds of mutation outside of the "a" determinant have been described in recent years, including deleting and inserting mutations in the surface gene of HBV[20-22].

In contrast to the mutations mentioned above, an uncommon point mutation at nucleotide 336 (C to A) of HBsAg-gene occurred in our isolates, which resulted in a novel stop codon at aa 61. This finding could not be a laboratory error, because all sequences of four clones were the same. Because of this new stop codon introduction, only truncated molecules of surface antigen could be expressed, which contained only 60 amino acid residues and was lack of the "a" determinant. This unique mutation could well explain the patient' s unusual serologic pattern: HBsAg-negative, but HBeAg-positive, anti-HBs-positive and HBV DNA-positive. The novel HBsAg gene stop codon caused by a point substitution mutation upstream of the "a" determinant has not been described up to now. Our finding is very similar to the deletion mutation of HBsAg gene described by Weinberger *et al*. The deletion mutation located at the nucleotide 31 of the HBsAg gene, which led to a frame-shift and introduced a stop-codon after 21amino acids of HBsAg[23].

To initiate infection, a virus must attach to a host cell receptor via one of its surface proteins. Hepatitis B virus has three related surface proteins, small S, middle S, and large S. It is not clear which of these three proteins serves as the HBV attachment protein. It has been thought that the pre-S region or S region determines viral binding[24,25]. However, due to the lack of a susceptible cell line that could be used to test specific blocking reagents, which protein is involved in the initial stage of HBV infection is difficult to determine. The HBV DNA level in our patient was as high as 10^9/ml in serum, indicating that isolates that bear such truncated molecules on their surface (the mutant HBsAg was only equal to one-fourth of HBsAg from wild type) can well finish their life cycle including viral binding and entry. Our finding presented here provides the evidence that sequences in the pre-S region determine viral binding.

However, our finding raises a theoretical question: Cells infected with hepatitis B virus produce both virions and 20nm subviral (surface antigen) particles. Although hepatitis B virus encodes three envelope proteins, all of the information required to produce 20 nm HBsAg particles resides within the S protein[26]. The nucleotide sequence of the HBsAg gene predicts the existence of three hydrophobic domains, located at residues 4 to 28 (signal I), 80 to 100 (signal II) and 164 to 221 (signal III). Studies on certain artificial deletion mutants suggested that deletion of signal II completely destabilized the chain, and deletion of the signal III resulted in a nonsecreted chain[27]. How such a drastically shortened HBsAg which is lack of signal IIand signal III, can be able to form morphologically correct viral and subviral particles? Because when co-expressed with wild type S protein, the mutant polypeptide can be incorporated into particles and secreted, therefore, it is assumed that the presence of a minor population of intact genomes helps in replication and formation of intact virions. All virus isolates consist of a mixture of viral strains. Multiple variants have been found in a single host. Advances in molecular biology technique have revealed significant diversities in sequence of of HBV isolates. Sequencing results suggest that there were HBV quasispecies groups in chronically infected patients[28-31]. Actually, electron microscopy of serum samples containing mutated DNA from the patient reported by Weiinberger *et al*. revealed typical subviral particles with an average diameter of 17-20 nm, but did not reveal a single filamentous particle[23]. Our results show that lack of detection of HBsAg in the presence of high viral levels of replication may be caused by the existence of viral genomes harboring point mutation which results in stop codon upstream of the "a" determinant of HBsAg gene.

Abstract

AIM: To investigate whether the formation of aggregated HBx has a potential linking with its cellular responses.

METHODS: Recombinant HBx was expressed in Escherichia *coli* and purified by Ni-NTA metal-affinity chromatography. Anti-HBx monoclonal antibody was developed for immunocytochemical detection. Bicistronic expression vector harboring full-length DNA of HBx was employed for transfection of human HepG2 cells. Immunocytochemical staining was used to examine the intracellular HBx aggregates in cells. The effects of HBx aggregation on cell cycle and apoptosis were assessed by flow cytometry.

RESULTS: Immunocytochemical staining revealed most of the HBx was formed intracellular aggregate in cytoplasm and frequently accumulated in large granules. Flow cytometry analysis showed that HepG2 cells transfected with vector harboring HBx significantly increased apoptosis and largely accumulated in the G0-G1 phase by maintenance in serum medium for 36 hours. Control cells without HBx aggregates in the presence of serum entered S phase and proliferated more rapidly at the same time. EGFP fluorescence in HBx expression cells was significantly decreased.

CONCLUSION: Our observations show that cells with HBx aggregate undergo growth arrest and apoptosis, whereas control cells without HBx remain in growth and progression into S phase. Our data may provide helpful information to understand the biological effects of HBx aggregates on cells.

INTRODUCTION

Hepatitis B virus (HBV) causes transient and chronic infections of the liver. Transient infections may produce serious illness, and approximately 0.5 % terminates with fatal, fulminant hepatitis. Chronic infections may also have serious consequences: nearly 25 % terminate in untreatable liver cancer. Worldwide deaths from liver cancer caused by HBV infection probably exceed one million per year. X gene is a unique fourth open reading frame of HBV. X gene codes for a 16.5-kDa protein (X protein, HBx) and is well conserved among the mammalian hepadnaviruses[1]. HBx is a multifunctional viral regulator that modulates transcription, cell responses to genotoxic stress, protein degradation, and signaling pathways[2]. The ability of HBx to modulate cell survival is potentially relevant to viral pathogenicity in acute and chronic HBV infection as well as to the late development of hepatocellular carcinoma[3]. HBx activates signal-transduction cascades such as the Ras/Raf mitogen-activated protein kinase, Src kinase, c-Jun NH2-terminal kinase and Janus family tyrosine kinases/signal transducer and activators of transcription[4,5]. HBx targets mitochondrial calcium and activates cytosolic calcium-dependent proline-rich tyrosine kinase-2[6,7]. HBx may directly interact with transcription factors[8]. HBx is also known to play an important role in alterating gene expression, sensitizing cells to apoptosis and affect cell cycle checkpoints[2]. The fate of infected cells expressing HBx is likely to be determined by the balance between apoptotic and anti-apoptotic signals of viral, cellular, and environmental origin.

HBx expression in different cells results in distinct and opposing cellular function responses of cell cycle and apoptosis[9,10]. Most of the investigations described the effects of HBx through cellular signal-transduction pathways. Some reports suggested that HBx could induce cell death when it was expressed at high levels[11-13]. The nine residues of cysteine among 154 amino acids of HBX might involve in disulfide bridge formation and be in favor of aggregate formation[14]. Protein aggregation leads to cell cycle arrest and initiates cell death[15]. We propose that intracellular deposition of aggregated HBx may have a potential linking to its cellular responses. In this study, we reported the cytoplasmic aggregates of HBx and its effect on cell cycle and apoptosis.

MATERIALS AND METHODS

Biological and chemical materials

Restriction enzymes and T4 DNA ligase were obtained from TaKaRa Biotech (Japan). QIA express Kit including pQE-60 Vector, *E. coli* strain M15 [pREP4] and Ni-NTA Superflow was purchased from QIAGEN (USA). GeneJammer transfection reagent was from Stratagene (USA). The plasmid pSPX46, a gift of Dr. Curtis C. Harris (National Institutes of Health, USA), encodes full-length HBx of the adr subtype. The bicistronic expression vector pIRES-EGFP-HBx harboring X gene (subtype ayw) was kindly provided by Drs. Jingyu Diao and Christopher D. Richardson (University of Toronto, Canada). SABC immunocytochemical detection kit was from Wuhan Boster Biological Technology Co. (China). Other chemicals of analytical grade were from Sigma.

Construction of HBx expression vector

The coding DNA fragment was amplified by polymerase chain reaction (PCR) using the pSPX46 as a template and the 5' -PCR primer (5' -TTT CCA TGG CTG CTC GGG TGT GC-3') carrying the NcoI site before and the 3' -PCR primer (5' GCGAGATCTGGCAGAGGTGAAAAAGTTG-3') carrying the Bgl II site after the X reading frame. The PCR product was digested with NcoI and *Bgl* II and ligated into pQE-60. According to the cloning strategy, recombinant construct based on the pQE-60 vector was produced by placing the 6xHis tag at the carboxy-terminus of HBx with the protein beginning with its natural ATG start codon. pQE-60X was obtained as an expression system for biosynthesis of HBx.

Expression and purification of HBx

Recombinant pQE-60X was transformed into E. coli strain M15 [pREP4]. The culture was induced with 1 mM isopropyl β-D-thiogalactopyranoside for 4.5 hours at 37 ℃. The bacteria were harvested and lysed in a buffer containing 6 mol/L guanidine hydrochloride. The purification procedure of QIAexpress Kit was optimized. Elution with 250 mmol/L imidazole could effectively separate HBx from nickel-nitrilotriacetic acid (Ni-NTA) resins. Recombinant HBx was analysed by sodium dodecyl sulfate -polyacrylamide gel electrophoresis (SDS-PAGE). Electrophoresis was performed on 15 % polyacrylamide gel. After electrophoresis, gels were fixed in 30 % ethanol, 10 % acetic acid, and stained with Coomassie brilliant blue.

Preparation of monoclonal antibody against HBx

Balb/c mice were immunized repeatedly. Spleen cells from the most responding mouse were fused with myeloma cells (Sp-2/0) according to the routine method described by Yang *et al*[16]. Positive hybrids were selected on hypoxanthine, aminopterin and thymidine containing medium.

Cell culture and transfections

Human hepatoma cell line HepG2 was grown on coverslips or 60-mm dish and maintained in Dulbecco' s modified Eagle minimal medium containing penicillin (100 IU/ml) and streptomycin (100 mg/ml) and supplemented with 10 % fetal calf serum. Bicistronic expression vector pIRES-EGFP-HBx derived from pIRES-EGFP by adding the DNA fragments of HBx[17]. Cells at 70 % confluence were respectively transfected with pIRES-EGFP-HBx and pIRES-EGFP using GeneJammer transfection reagent. DNA transfections were performed according to the protocols supplied with the reagents.

Immunocytochemical assay

After transfection for 36 hours, HepG2 cells were washed in phosphate-buffered saline (PBS) and fixed with 90 % ethanol. SABC detection kit was used for immunocytochemical analysis. Cells were incubated with HBx monoclonal antibody for 1 hour at 37 ℃. After washed three times with PBS, cells were incubated with anti-mouse biotinylated secondary antibody. Following extensive washes with PBS, color development was demonstrated with diaminobenzidine tetrahydrochloride chromagen. Finally, the slides were counterstained with hematoxylin. Stained cells were examined using light microscopy and photographed.

Flow cytometric analysis

To assess the effect of HBx aggregation on cell cycle, apoptosis and fluorescence of enhanced green fluorescent protein (EGFP), we analyzed the transfected cells by flow cytometry for GFP fluorescence and DNA content[18]. The efficiency of transfection was verified by fluorescent signal. Cells were released by trypsinization, resuspended in PBS at a density of 2×10^6 cells/ml, and analyzed on a Becton Dickinson flow cytometer using CellQuest software.

RESULTS

Vector construction for encoding HBx

In order to develop an HBx: anti-HBx antibody system for immunocytochemical purposes, an efficient E. *coli* expression system to produce HBx in large quantity was established. HBx was expressed in E. *coli* cells harboring pQE-60X as HBx carboxy-terminally fused to six histidine residues. pQE-60X was confirmed by PCR, restriction enzymes analysis and DNA sequencing.

HBx antigen and anti-HBx monoclonal antibody

Recombinant HBx was expressed in Escherichia *coli*. Because of the high stability of HBx aggregates, the purification procedure was optimized. E. *coli* cells were lysed in a buffer containing 6 mol/L guanidine hydrochloride. Six consecutive histidine residues that placed at the carboxy-terminus of HBx facilitated Ni-NTA metal-affinity chromatography. Elution with 250 mmol/L imidazole could effectively separate HBx from Ni-NTA resins. HBx was eluted as a pure protein (Figure 1). Starting with 1L of culture, only one milligram of recombinant HBx was attained under our experimental conditions. An anti-HBx monoclonal antibody was established following the conventional approach. The anti-HBx monoclonal antibody recognized the recombinant antigen as proved by high optical density measured in a simple binding enzyme-linked immunosorbent assay. Monoclonal antibody secreted by hybridoma clone was alike optimal for immunocytochemistry.

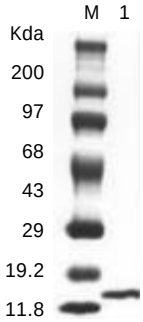

Figure 1 SDS-PAGE analyses of the purified HBx. SDS-PAGE showed a single band at the expected molecular weights (lane 1).

Immunohistochemical detection of HBx aggregates

HBx aggregate and its distribution were verified by immunocytochemistry. HBx-bearing cells exhibited positively staining by anti-HBx monoclonal antibody. Cytoplasmic HBx characteristically accumulated in large granules or strongly stained aggregates (Figure 2A, arrows). No immunoreactivity could be detected in a negative control stained by the same antibody under the same conditions (Figure 2B).

Flow cytometric analysis of HepG2 cells

A transient expression plasmid, pHBx-IRES-EGFP was used in this experiment. The vector contained HBx and EGFP reporter genes under control of a cytomegalovirus promoter and the element of internal ribosome entry site (IRES), respectively[17]. More than 80 % of human HepG2 cells could be transfected with pIRES-EGFP-HBx and pIRES-EGFP respectively as shown by fluorescence flow cytometry. A representative flow cytometric profile at the 36th is shown in Figure 3A and 3B. Results were expressed as percentage of HepG2 cells in G0-G1, G2-M and S phases of the cell cycle

(Figure 3C). Apoptosis was also monitored by flow cytometry (Figure 3C). Each value corresponded to the mean ± standard deviation of two independent experiments. Using Student's *t*-test, statistical analysis was performed. HepG2 cells transfected with vector harboring HBx were accumulated largely in the G0-G1 phase after maintenance in serum medium for 36 hours. Control cells that could not synthesize HBx protein in the presence of serum proliferated more rapidly and entered S phase at the same time.

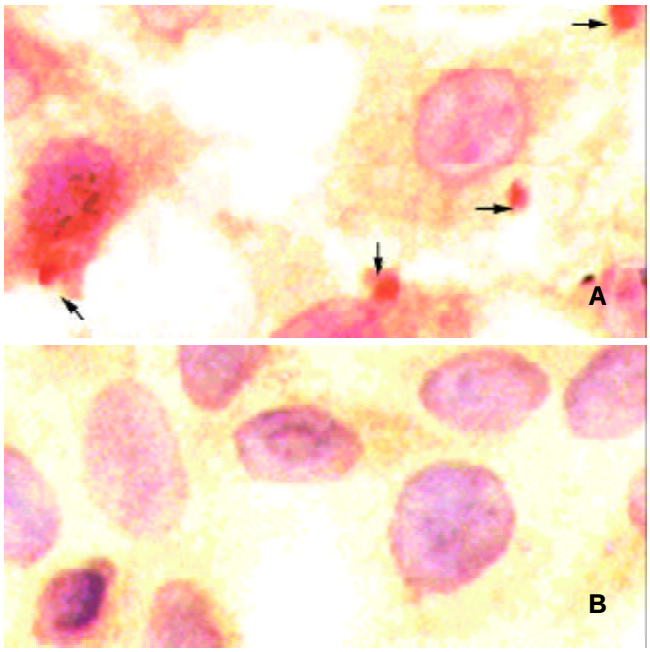

Figure 2 Immunocytochemical detection of HBx aggregates within HepG2 cells (magnification, ×400). HBx aggregates were clearly visible as granules within the cytoplasm (A). HBx could not be detected within control cells transfected with pIRES-EGFP (B).

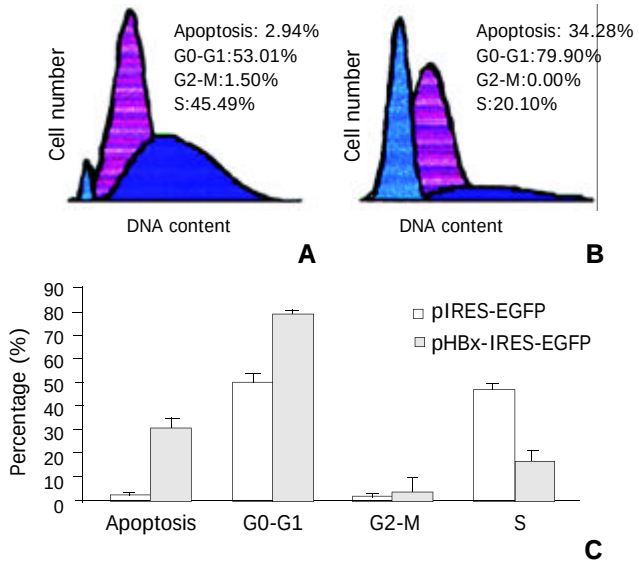

Figure 3 Flow cytometric analysis of apoptosis and cell cycle phases of HepG2 cells. (A) Control cells transfected with vector alone did not contain HBx. (B) Cells transiently transfected with the HBx expression plasmid. Apoptosis was significantly increased in HepG2 cells compared with control cells without HBx (C, $P<0.02$). Cells displayed a marked decrease in S phase ($P<0.02$) and demonstrated an evident increase in G0-G1 fraction ($P<0.01$) with control expression vector that lacked the HBx gene (C).

EGFP fluorescence was decreased in HBx transfected cells

The mean fluorescence of 10^4 EGFP positive cells was measured by fluorescence cytometer. The EGFP fluorescence value was 4.43±0.58 and 3.45±0.15 of experiments in triplicate for HepG2 cells transfected with pIRES-EGFP and pIRES-EGFP-HBx, respectively. EGFP fluorescence in HBx expression cells was significantly decreased as compared with control pIRES-EGFP ($P<0.05$).

DISCUSSION

The X open reading frame of HBV is highly conserved among all mammalian hepadnaviruses. HBx might regulate the expression of certain viral and cellular genes which are important for the creation of an environment suitable for viral propagation. HBx inhibits clonal outgrowth of cells and induces apoptosis by a p53-independent pathway. HBx expression can induce a late G1 cell cycle block prior to their counterselection by apoptosis. Furthermore, mutations in the HBx-gene evolving in hepatocellular carcinoma can abolish both HBx-induced growth arrest and apoptosis. Abrogation of the anti-proliferative and apoptotic effects of HBx by naturally occurring mutations might render the hepatocytes susceptible to uncontrolled growth and contribute to multistep hepatocarcinogenesis associated with HBV infection[18]. HBx has been shown to be able to regulate cell cycle. HBx can activate the cyclin A promoter, induce cyclin A-cyclin-dependent kinase 2 complexes, and promote cycling of growth-arrested cells into G1 through a pathway involving activation of Src tyrosine kinases[5]. HBx stimulation of Src kinases and cyclin gene expression was found to force growth-arrested cells to transit through G1 but to stall at the junction with S phase, which may be important for viral replication.

The structure feature of HBx may affect its biophysical properties including solubility, tendency toward aggregation with itself and with other proteins. Gupta *et al*.[19] purified HBx from E. *coli*, subjected the protein to air oxidation, and analyzed intramolecular disulfide bonds. They found that eight of the nine cysteines were disulphide linked in a sequential manner. The disulphide linkages were between Cys7 and Cys78, Cys17 and Cys115, Cys61 and Cys137, Cys69 and Cys143 while Cys148 was free. The disulphide arrangement in HBx followed a pattern where each cysteine was joined to the fourth cysteine. HBx is able to form intramolecular disulfide bonds even under the reducing conditions of the cytosol. With analysis of purified HBx from eukaryotic sources by using electrospray ionization mass spectrometry, Urban *et al*.[14] uncovered some components: the unmodified, monomeric, fully oxidized form with five intramolecular disulfide bridges, and its N-acetylated modification. It is not very clear whether the disulfide bridge formation is a prerequisite of HBx function, but a point mutation of Cys-69 to Ala abolishes its transactivation activity[20]. Intracellular deposition of aggregated proteins is a prominent cytopathological feature of most neurodegenerative diseases[21]. Protein aggregation is a central event in the initiation of cell death[6]. Protein aggregation directly impaires the function of the ubiquitin-proteasome system and leads to cell cycle arrest and cell death.

In view of the investigations, we proposed apoptotic effects of HBx be related to its aggregate formation. Immunohistochemical examination revealed that only a minor immunological signal of HBx was detectable in a soluble form, whereas most of the protein formed intracellular aggregates in cytoplasm. HBx frequently accumulated in large granules. Our observation could suggest that HBx transfected cells underwent growth arrest and apoptosis, whereas control cells without HBx remained in growth and progression into S phase. In addition, we used the reporter molecule EGFP to reflect the situation of

HBx expression indirectly. By counting equal number of EGFP positive cells, pIRES-EGFP-HBx transfected cells showed a weak fluorescence as compared with pIRES-EGFP transfected cells. Diao *et al.*[17] also reported that human primary hepatocytes transfected with pIRES-EGFP-HBx showed less intense fluorescent signal. HBx aggregates may affect the fluorescence intensity of EGFP in the same cell.

HBx were detected in aggregated structures and it was further showed that HBx aggregates mediated growth arrest and cell death. Our data may provide helpful information on the biological effects of HBx aggregates. The precise mechanism by which HBx aggregates could affect cell cycle and apoptosis remains to be established.

Abstract

AIM: To prepare and purify TAT-HBV targeted ribonuclease fusion protein, evaluate its transduction activity and investigate its effect on HBV replication in 2.2.15 cells.

METHODS: The prokaryotic expression vector pTAT containing TR gene was used in transforming *E.coli* BL21 (DE3) LysS and TR was expressed with the induction of IPTG. The TAT-TR fusion protein was purified using Ni-NTA-agrose and PD-10 desalting columns, and analyzed by SDS-PAGE. Transduction efficiency of TAT-TR was detected with immunofluorescence assay and the concentration of HBeAg in the supernatant of the 2.2.15 cells was determined via solid-phase radioimmunoassay (spRIA). MTT assay was used to detect the cytotoxicity of TAT-TR.

RESULTS: The SDS-PAGE showed that the TAT-TR fusion protein was purified successfully, and the purity of TAT-TR was 90 %. The visualization of TAT-TR by immunofluorescence assay indicated its high efficiency in transducing 2.2.15 cells. RIA result suggests that TAT-TR could inhibit the replication of HBV effectively, it didn't affect cell growth and had no cytotoxicity.

CONCLUSION: TAT-TR possesses a significant anti-HBV activity and the preparation of TAT-TR fusion protein has laid the foundation for the use of TR in the therapeutic trial of HBV infection.

INTRODUCTION

The introduction of proteins into mammalian cells has been achieved by transfection of expression vectors, microinjection, or infectious virus, *etc*. Although these approaches have been somewhat successful, the classical manipulation methods are not easily regulated and can be laborious. One approach to resolve these problems is the use of PTD-mediated protein transduction[1, 2]. Linked covalently to proteins, peptides, nucleic acids, or as in-frame fusions with full-length proteins, PTD would let them enter any cell type in a receptor and transporter independent fashion[3]. HIV-TAT is a member of protein transduction domains and appears to possess high level of protein-transduction efficiency[4,5]. TAT fusion proteins were shown to transduce into all cells and tissues present in mice[6], including those present across the blood-brain barrier[7,8]. And many, if not most, proteins may be transduced into cells by using this technology. Therefore, TAT PTD may let us address new questions in preclinical research work and even help in the treatment of human disease.

Hepatitis B is a major world-wide health problem[9-13]. Chronic infection is associated with high risk of liver cirrhosis and primary liver carcinoma[14-22]. Currently available therapies are of limited efficiency[23-35]. HBV targeted ribonuclease (TR) gene, a fusion gene of HBVc and hEDN, was constructed by Liu *et al* in our lab[36], according to the theory of capsid-targeted viral inactivation (CTVI) which is a promising strategy in anti-virus research. HBVc was used as the target molecule, which was the structure protein of HBV and was indispensable during the packaging of HBV particle. The effector molecule was hEDN, a kind of human ribonuclease that can degrade pgRNA of HBV. Transfection of 2.2.15 cells with the eukaryotic expression vector bearing TR gene suggested that TR inhibited the replication of HBV significantly[37]. Therefore, linking HIV-TAT to TR would provide us a more efficient approach to deliver TR into hepatocytes, and greatly help us to utilize TR in the treatment of HBV infection. Reported here are the purification of TAT-TR fusion protein, the identification of its transduction and the anti-HBV effect on the 2.2.15 cells. To confirm its anti-HBV mechanism, we also prepared and purified TAT-TRmut, TAT-hEDN and TAT-HBVc proteins for use as negative controls.

MATERIALS AND METHODS

Materials

Ni-NTA-agrose was purchased from Qiagen Company. PD-10 desalting columns were purchased from Amersham Pharmacia Biotech. Anti-his mAb was from Santa Cruz Company. Protein molecular mass markers, IPTG and G418, imidazole and MTT were all from Sino-American Biotech. RIA HBVeAg assay kit was purchased from Beimian Dongya Biotechnology Institute. 2.2.15 cells was a kind gift of Prof. Cheng, 302 Hospital of Chinese PLA. hEDN was purified by Li *et al*[36]. pTAT-HA/TR, TAT-HA/TRmut, pTAT-HA/hEDN and pTAT-HA/HBVc were all prepared in our Lab[38]. PET-30a/TR, PET-30a/TRmut, PET-30a/HBVc and *E.coli* BL21 (DE3) LysS were maintained in our Lab.

Methods

Expression and purification of TAT fusion proteins pTAT-HA/TR, TAT-HA/TRmut, pTAT-HA/hEDN, pTAT-HA/HBVc and pTAT-HA were employed to transform *E.coli* BL21 (DE3) LysS by using $CaCl_2$ perforation. The transformants were separately cultured in 3 mL TB amp (100 μg/L) at 37 ℃ overnight. 100 μL culture was inoculated into 10 mL fresh TB amp, and incubated for up to 4 hours at 37 ℃. Then IPTG was added to each tube to a final concentration of 100 μmol/L, and the culture was incubated for an additional 4 hours. The induced cells were harvested by centrifugation, and cell lysates were analyzed by 120 g/L SDS-PAGE. The his-tagged fusion

proteins were purified by using Ni-NTA-agrose and PD-10 desalting columns according to the manufacturer's recommendations (Qiagen and Amersham Pharmacia). The purified proteins were analyzed by 120 g/L SDS-PAGE.

Expression and purification of proteins without TAT PTD PET-30a/TR, pET-30a/TRmut, and pET-30a/HBVc transformed *E.coli* BL21 (DE3) LysS. After the analysis of expression levels, the three proteins were purified in the same way as for TAT fusion proteins.

Culture of 2.2.15 cells Cells were cultured in DMEM containing 150 mL/L fetal bovine serum at 37 ℃ in 50 mL/L CO_2 and 100 mg/L G418.

Identification of TAT fusion protein transduction 2.2.15 cells (2×10^8/L) were plated into 6-well plates with coverships, and allowed to adhere for 24 hours. TAT-TR, TAT-TRmut, TAT-hEDN, TAT-HBVc, TR, TRmut, hEDN and HBVc were added into the wells, respectively, at the final concentration of 100 nmol/L. Incubated for 30 min at 37 ℃, all cells were immediately washed with sterile PBS (pH8.0), fixed in 20 g/L paraformaldehyde and 1 g/L TritonX-100 diluted in PBS and put on ice for 30 min. Cells were washed three times with cold PBS. Non-specific epitopes were blocked by using 10 g/L BSA for 10 min at 42 ℃. Cells were washed three times with cold PBS, and then incubated with mouse anti-His mAb (1:500) for 15 min at 42 ℃. After washing three times in cold PBS, the rabbit anti-mouse IgG labeled with FITC (1:1 000) was added to each well and incubated for 10 min at 42 ℃. Rinsed with PBS for 1 hour and the coverships were mounted on slides by using 500 mL/L glycerol. The cells were observed by fluorescence microscopy.

Determination of anti-HBV effect of TAT-TR 2.2.15 cells were plated at the density of 2×10^8/L into 12-well plates. TAT-TR, TAT-TRmut, TAT-hEDN and TAT-HBVc were added into the wells, respectively, at the final concentration of 100 nmol/L. 20 μL DMEM was added into wells as mock group. Four parallels were set up for each group. 24 hours later, HBVeAg in the supernatant was determined by using spRIA kit as described by the manufacturer.

MTT assay 2.2.15 cells were plated at the density of 2×10^8/L into 96-well plates. After 24 hours, TAT-TR, TAT-TRmut, TAT-HEDN, TAT-HBVc were added into (A), (B), (C), (D) groups at the final concentration of 100 nmol/L. 20 μL DMEM was added into well (E). 72 hours later, the morphology of cells was observed through inverted microscopy and MTT was applied in each well at the final concentration of 5 g/L. After another 4 hours' culturing, 150 μL DMSO was added into all wells and the light absorbance at A_{490} was detected.

Statistical analysis

All data obtained were processed by SPSS software. $P<0.05$ was considered statistically significant.

RESULTS

Expression and purification of TAT fusion proteins

In order to obtain the fusion proteins, pTAT-HA/TR, pTAT-HA/TRmut, pTAT-HA/hEDN and pTAT-HA/HBVc were used to transform *E.coli* BL21 (DE3) LysS and expressed with the induction of IPTG. The same strain transformed by pTAT-HA was used as negative control. The expression levels were determined by 120 g/L SDS-PAGE. Four predicted new bands could be detected in the lysates of TAT fusion transformants, but not in the control. Then the proteins were purified by using Ni-NTA affinity columns and PD-10 desalting columns (Figure 1). The degrees of purity of the fusion proteins were 90 %, 88 %, 80 % and 85 % respectively.

Expression and purification of proteins without TAT PTD

In a similar fashion, pET-30a/TR, pET-30a/TRmut and pET-30a/HBVc were induced to express proteins without TAT PTD by IPTG in BL21 (DE3) LysS, and they produced proteins with predicted molecular masses (Figure 2). Then the proteins were purified by using Ni-NTA affinity columns and PD-10 desalting columns. The degrees of purity of the fusion proteins were 88 %, 76 % and 81 % respectively.

Purified TAT-HBVc.

Identification of protein transduction

To evaluate the fusion proteins' transduction ability in crossing the membrane of 2.2.15 cells. TAT-TR, TAT-TR mut, TAT-hEDN and TAT-HBVc were added in the culture media at the final concentration of 100 nmol/L. TR, TRmut, hEDN and HBVc without TAT PTD were used as negative controls. Under the fluorescence microscope, abundant fluorescence could be seen in cytoplasm of the cells transduced with TAT fusion proteins, but no fluorescence could be found in the control cells (Figure 3). This result clearly suggests that TAT fusion proteins could cross the membrane of 2.2.15 cells with high efficiency.

Analysis of anti-HBV activity for TAT-TR

Statistical analysis with SPSS software showed that the mean HBeAg concentration of the TAT-TR group decreased significantly as compared with control groups (The mean difference is significant at the 0.05 level). In addition, there is no significant difference among the mean concentration of control groups (P>0.05). The HBeAg concentration of TAT-TR group decreased by 60.3 % (Figure 4).

MTT assay

After 72 hours culture, the morphology of cells was observed under inverted microscope and it was found that there was no discernable difference among the four experiment groups and the DMEM control. MTT assay showed no significant difference among the five groups. Their A_{490} absorbance values ($\bar{x}\pm s$, n=4) were 0.4875±0.018, 0.4675±0.022, 0.4690±0.028, 0.4800±0.029 and 0.4855±0.050, respectively, (P>0.05).

DISCUSSION

The transduction of proteins into cells was first described in 1988 independently by Green *et al*[39] and Frankel *et al*[40]. In 1994, Faweell *et al*[5] expanded these observations by demonstrating that heterologous proteins chemically cross-linked to a 36 amino acid domain of TAT were able to transduce into cells. Subsequent to the TAT discovery, other transduction domains were identified that resided in the Antennapedia (Antp) protein from Drosophila[41] and HSV VP22 protein from HSV[42]. Although the exact mechanism of protein transduction across the cellular membrane remains unclear, PTD's widespread application has been realized. TAT-mediated transduction provides several advantages over DNA transfection, the current standard method of intracellular protein expression. Importantly, all eukaryotic cell types tested to date are susceptible to transduction, even osteoclasts, primary cells and peripheral-blood mononuclear cells, which are impervious to DNA transfection and retroviral infection, can be effectively transduced[43,44]. Additionally, as transduction occurs so rapidly (15 min rather than 12 h in serum-free media for transfection), issues of timing can be addressed. The exact intracellular concentration can also be controlled precisely just by varying the amount added to the culture medium. Furthermore, every cell in the population appears to contain a near-identical intracellular protein level[3]. Another dominant advantage of the system allows denatured fusion protein be directly applied without the laborious renature course, and thus it also provides much convenience for protein purification. Once transduced inside the cells, the denatured proteins can be correctly refolded by chaperones[45], and are capable of binding their cognate intracellular targets and performing biochemical functions.

To explore the feasibility of using PTD in the anti-HBV research work and provide an alternative strategy for treatment of hepatitis B in this study, we prepared and purified the TAT-TR fusion protein, and also other control proteins. Transduction of TAT-fusion proteins was detected by immunofluorescence assay. Strong fluorescence appeared in the cytoplasm of the cells applied with four TAT fusion proteins, but not in the control groups. These results showed the high transduction efficiency of TAT fusion proteins. We also investigated TAT-TR's anti-HBV activity by radioimmunoassay and got an exciting result. As compared with the mock group, concentration of HBeAg in TAT-TR group decreased by 60.3 %, which indicated that the purified TAT-TR possessed a potent anti-HBV activity. There was no significant difference between any other group and the mock group, suggesting HBVc or hEDN alone had no effect on HBV replication, and TRmut, a fusion molecule of HBVc with an inactivated mutant hEDN, also had no inhibitory effect. These further confirmed the anti-HBV mechanism of the HBV targeted ribonuclease. While TR was transduced into 2.2.15 cells, it could be packaged into the HBV core particles by HBVc, and then hEDN, as a ribonuclease, could degrade the pgRNA packed in the core particles, thus inhibiting the replication of HBV. We performed MTT assay to reveal whether the TAT fusion proteins were harmful to 2.2.15 cells, and the results indicate that they did not affect the growth of 2.2.15 cells and the purified TAT-TR may be applied *in vivo*. Therefore, we conclude that the TAT-HBV targeted ribonuclease fusion protein obtained in this study has laid the foundation for using TR in the therapy of HBV infection.

Abstract

AIM: To clone hpaA gene from a clinical strain of *Helicobacter pylori* and to construct the expression vector of the gene and to identify immunity of the fusion protein.

METHODS: The hpaA gene from a clinical isolate Y06 of *H. pylori* was amplified by high fidelity PCR. The nucleotide sequence of the target DNA amplification fragment was sequenced after T-A cloning. The recombinant expression vector inserted with hpaA gene was constructed. The expression of HpaA fusion protein in *E.coli* BL21DE3 induced by IPTG at different dosages was examined by SDS-PAGE. Western blot with commercial antibody against whole cell of *H.pylori* as well as immunodiffusion assay with self-prepared rabbit antiserum against HpaA fusion protein were applied to determine immunity of the fusion protein. ELISA was used to detect the antibody against HpaA in sera of 125 patients infected with *H.pylori* and to examine HpaA expression of 109 clinical isolates of *H.pylori*.

RESULTS: In comparison with the reported corresponding sequences, the homologies of nucleotide and putative amino acid sequences of the cloned hpaA gene were from 94.25-97.32 % and 95.38-98.46 %, respectively. The output of HpaA fusion protein in its expression system of pET32a-hpaA-BL21DE3 was approximately 40 % of the total bacterial proteins. HpaA fusion protein was able to combine with the commercial antibody against whole cell of *H.pylori* and to induce rabbit producing specific antiserum with 1:4 immunodiffusion titer after the animal was immunized with the fusion protein. 81.6 % of the serum samples from 125 patients infected with *H.pylori* (102/125) were positive for HpaA antibody and all of the tested isolates of *H.pylori* (109/109) were detectable for HpaA.

CONCLUSION: A prokaryotic expression system with high efficiency of *H.pylori* hpaA gene was successfully established. The HpaA expressing fusion protein showed satisfactory immunoreactivity and antigenicity. High frequencies of HpaA expression in different *H.pylori* clinical strains and specific antibody production in *H.pylori* infected patients indicate that HpaA is an excellent and ideal antigen for developing *H.pylori* vaccine.

INTRODUCTION

In China, chronic gastritis and peptic ulcer are the most prevalent gastric diseases and gastric cancer is one of the malignant tumors with high morbidities[1-34]. *Helicobacter pylori*, a microaerophilic, spiral and gram-negative bacillus, is recognized as a human-specific gastric pathogen that colonizes the stomaches of at least half of the world's populations[35]. Most infected individuals are asymptomatic. However, in some subjects, the infection causes acute, chronic gastritis or peptic ulceration, and plays an important role in the development of peptic ulcer and gastric adenocarcinoma, mucosa-associated lymphoid tissue (MALT) lymphoma and primary gastric non-Hodgkin's lymphoma[36-43]. This organism is categorized as a class I carcinogen pronounced by the World Health Organization[44], and direct evidence of carcinogenesis was recently demonstrated in an animal model[45,46]. Immunization against the bacterium represents a cost-effective strategy to prevent *H.pylori*-associated peptic ulcer diseases and to reduce the incidence of global gastric cancers[47]. The selection of antigenic targets is critical in the design of *H.pylori* vaccine. To date, this field is scarcely touched upon. The majority of studies focused on urease enzyme, heat shock protein, vacuolating cytotoxin, and so on[35,48-50], but rarely on *H. pylori* adhesin (HpaA) which is a flagellar sheath protein with approximately 29KDa located in the bacterial outer membrane[51]. So, in this study, a recombinant plasmid inserted with the gene (hpaA) responsible for encoding HpaA was constructed and the immunogenicity and immunoreactivity of its expression product were examined. Furthermore, the fusion protein of HpaA and its rabbit antiserum were also used to detect serum samples from *H.pylori* infected patients and *H. pylori* isolates, respectively. The results of this study will be helpful for determining whether the recombinant HpaA (rHpaA) becomes one of the good candidates as an antigen in *H.pylori* vaccine.

MATERIALS AND METHODS

Materials

A well-characterized clinical strain of *H.pylori*, provisionally named Y06, was provided by the Department of Medical Microbiology and Parasitology, College of Medical Sciences, Zhejing University. Plasmid pET32a (Promega) and *E.coli* BL21 DE3 (Promega) were used as expression vector and host cell, respectively. The primers for amplification were synthesized by BioAsia (Shanghai, China). EX Taq high fidelity PCR kit and restriction endonucleases were purchased from TaKaRa (Dalian, China). T-A cloning kit and sequencing service were offered by BBST (Shanghai, China). Rabbit antibody against the whole cell of *H.pylori* and HRP-labeling sheep antibodies against rabbit IgG and human IgG were

purchased from DACO and Jackson ImmunoResearch, respectively. The agents used in isolation and identification of *H.pylori* were purchased from Sigma and bioMérieux, etc. 126 biopsy specimens from patients with positive *H.pylori* (86 males and 40 females; age range: 6-78 years; mean age: 40.5 years) for gastroduodenoscopy in four different hospitals in Hangzhou were collected during the period of the end of 2001 to the midyear of 2002. Each of the patients consented to be enrolled in this study and all of them agreed to offer their biopsy samples. Among the 126 patients, 68 suffered from chronic gastritis (CG) in cluding 48 with chronic superficial gastritis, 10 with chronic active gastritis and 10 with chronic atrophic gastritis, and 58 patients suffered from peptic ulcer (PU) in cluding 12 with gastric ulcer, 40 with duodenal ulcer and 6 with gastric and duodenal ulcer. None of the patients had received nonsteroidal anti-inflammatory drugs or antacid drugs and antibiotics within the previous two weeks before the study. At the same time, 126 serum specimens from these patients were also collected.

Methods

Isolation and identification of clinical *H.pylori* strains Each of the biopsy specimens was homogenized with a tissue grinder and then inoculated onto Columbia agar plates supplemented with 8.0 % (V/V) sheep blood, 0.2 % (W/V) cyclodextrin, 5 mg/L trimethoprim, 10 mg/L vancomycin, 2.5 mg/L amphotericin B and 2 500 U/L polymyxin B. The plates were incubated at 37 ℃ under microaerobic conditions (5 % O_2, 10 % CO_2 and 85 % N_2) for 3 to 5 days. Isolates were identified as *H.pylori* according to typical Gram stain morphology, positive biochemical tests for urease and oxidase, and agglutination with commercial rabbit antibody against whole cell of the microbe. All of *H.pylori* isolates were stored at -70 ℃ for ELISA.

Preparation of DNA template Genomic DNA of *H.pylori* strain Y06 was extracted by routine phenol-chloroform method, DNase-free RNase digestion and phenol-chloroform extraction. The DNA template was solved in TE buffer, and its concentration and purity were determined by ultraviolet spectrophotometry[52].

Polymerase chain reaction Oligonucleotide primers were designed to amplify the whole sequence of hpaA gene from *H.pylori* strain Y06 based on the published corresponding genome sequence[51,53]. The sequence of sense primer with an endonuclease site of *BamH* I was: 5' -CCGGGATCCATGA GAGCAAATAATC-3' . The sequence of antisense primer with an endonuclease site of *EcoR* I was: 5' -CCGGAATTCTTCT TATGCGTTATTTG-3' . The total volume of PCR reaction mixture was 100 μL containing 2.5 mol· L^{-1} each dNTP, 250 nmol· L^{-1} each primer, 15 mol· L^{-1} $MgCl_2$, 3.0 U EX Taq polymerase, 200 ng DNA template and 1×PCR buffer (pH8.3). The parameters for PCR were as follows: at 94 ℃ for 5 min, one cycle; at 94 ℃ for 30 sec, at 50 ℃ for 30 sec, at 72 ℃ for 60 sec, 10 cycle; at 94 ℃ for 30 sec, at 50 ℃ for 30 sec, at 72 ℃ for 70 sec (additional 10 sec for each of the following cycles), 20 cycle, at 72 ℃ for 10 min, 1 cycle. The results of PCR were observed under UV light after electrophoresis in 15 g· L^{-1} agarose pre-stained with ethidium bromide. The expected size of target amplification fragment was 802 bp.

Cloning and sequencing The target amplification DNA fragment of hpaA gene was cloned into pUCm-T vector (pUCm-T-hpaA) by using the T-A cloning kit according to the manufacturer' s instructions. The recombinant plasmid was amplified in *E.coli* strain DH5α and then extracted by Sambrook' s method[52]. A professional company (BBST) was responsible for nucleotide sequence analysis of the inserted fragments. Two different strains of *E.coli* DH5α containing pUCm-T-hpaA and expression vector pET32a were amplified respectively and the two plasmids were extracted[52]. The plasmids were digested with *BamH* I and *EcoR* I. The target fragments of hpaA and pET32a were recovered and then ligased. The recombinant expression vector pET32a-hpaA was transformed into *E.coli* BL21DE3. pET32a-hpaA was prepared for sequencing again after the amplification in its host cell.

Expression and identification of the fusion protein The hpaA prokaryotic expression system pET32a-hpaA-BL21DE3 was rotationally cultured in LB medium at 37 ℃ under induction of isopropylthio-β-D-galactoside (IPTG) at different dosages of 1, 0.5 and 0.1 mmol· L^{-1}. The supernatant and precipitate were isolated by centrifugation after the engineering bacterium pellet was ultrasonically broken (300V, 5sec once for three times). The molecular weight, output and location of HpaA fusion protein were examined by SDS-PAGE. HpaA fusion protein was collected by Ni-NTA affinity chromatography. The immunoreactivity of HpaA fusion protein was determined by Western blot with commercial rabbit antibody against whole cell of *H.pylori* and HRP-labeling sheep antibody against rabbit IgG, respectively. Rabbits were immunized with HpaA fusion protein to obtain the antiserum. Immunodiffusion assay was applied to determine antigenicity of the fusion protein.

ELISA The antibodies against HpaA in sera of the patients infected with *H.pylori* were detected by ELISA with HpaA fusion protein at the concentration of 20 μg/mL as coated antigen, the patients' sera (1:200 dilution) as the first antibody, HRP-labeling sheep antibody against human IgG (1:4 000 dilution) as the second antibody and ortho-phenylene diamine as a substrate. The result of ELISA for a patient' s serum sample was considered as positive if its OD_{490} value was over the mean plus 3 SD of 6 cases of negative serum samples[54]. HpaA expression of clinical isolates of *H.pylori* was detected by ELISA using ultrasonic supernatant at the protein concentration of 50 μg/mL of each *H.pylori* isolate as coated antigen, the self-prepared rabbit antiserum against HpaA fusion protein (1:2 000 dilution) as the first antibody, HRP-labeling sheep antibody against rabbit IgG (1:3 000 dilution) as the second antibody and ortho-phenylene diamine as a substrate. The result of ELISA for an *H.pylori* ultrasonic supernatant was considered as positive if its OD_{490} value was over the mean plus 3 SD of 6 cases of ultrasonic supernatant at the same protein concentration of *E.coli* ATCC 25922 played as negative control[54].

Data analysis The nucleotide sequences of the cloned hpaA gene inserted in the two recombinant plasmid vectors were compared for homologies with 6 published hpaA gene sequences (X92502, NC000915, X61574, NC000921, AF479028 and U35455)[51,53,55-58] with a special molecular biological analysis soft ware.

RESULTS

PCR

Target fragment with expected size amplified from DNA template of *H.pylori* strain Y06 is shown in Figure 1.

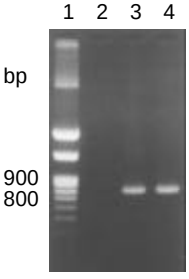

Figure 1 The target fragment of hpaA gene amplified from *H.pylori* strain Y06 (1: 100 bp DNA marker; 2: blank control; 3 and 4: the target fragment amplified from *H.pylori* strain Y06 DNA).

Nucleotide sequence analysis

The hpaA gene nucleotide sequences in the recombinant plasmid vectors of pUCm-T-hpaA and pET32a-hpaA were completely the same. The homologies of the nucleotide and putative amino acid sequences in the pUCm-T-hpaA and pET32a-hpaA compared with the published hpaA gene sequences[51,53,55-58] were from 94.25-97.32 % and 95.38-98.46 %, respectively (Figures 2, 3).

Figure 3 Homology comparison of the putative amino acid sequences of hpaA gene ([1]-[6]: the reported sequence from GenBank (No. X92502, strain 11637; No. NC000915, strain 26695; No. X61574, strain 8826; No. NC_000921, strain J99; No. AF479028, strain CH-CTX1; No. U35455, strain CCUG 17874); [7]: the sequencing result of Hp strain Y06 hpaA gene).

Expression of target fusion protein

1, 0.5 and 0.1 mmol· L^{-1} of IPTG were able to efficiently induce the expression of HpaA fusion protein in pET32a-hpaA-BL21DE3 system. The product of HpaA fusion protein was mainly presented in ultrasonic precipitate and the output was approximately 40 % of the total bacterial proteins (Figure 4).

Immunoreactivity and antigenicity of HpaA fusion protein

The commercial rabbit antibody against the whole cell of *H.pylori* could combine with HpaA fusion protein confirmed by Western blot (Figure 5) and the titer demonstrated by immunodiffusion assay between HpaA fusion protein and rabbit antiserum against the fusion protein was 1:4.

ELISA

The mean ±SD at OD_{490} of the negative serum samples was 0.11±0.03 and the positive reference value was 0.20. The mean ±SD at OD_{490} of the negative bacterial control was 0.04±0.04 and the positive reference value was 0.16. According to the reference values, 81.6 % (102/125, another serum sample was

contaminated) of the tested patients' serum samples were positive for antibodies against HpaA fusion protein with a range of 0.54-1.84 and 100 % (109/109, other 17 isolates could not be revived from -70 ℃) of the tested *H.pylori* isolates were detectable for HpaA with a range of 0.52-1.47.

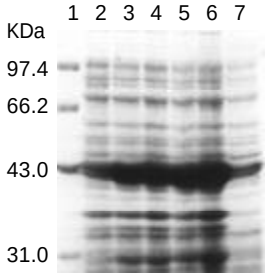

Figure 4 Expression of HpaA gene in pET32a-hpaA-BL21DE3 induced by IPTG with different dosages shown in SDS-PAGE (1: protein marker; 2: non-induced; 3-5: induced with 0.1, 0.5, 1 mmol·L^{-1} of IPTG, respectively; 6: the bacterial precipitate induced with 1 mmol·L^{-1} of IPTG; 7: the bacterial supernatant induced with 1 mmol·L^{-1} of IPTG).

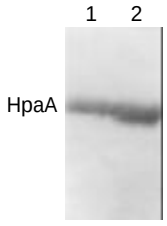

Figure 5 Western blot result of commercial rabbit antibody against whole cell of *H.pylori* and HpaA fusion protein (1 and 2: 20 μl and 40 μl of expressed HpaA product induced with 0.1 mmol·L^{-1} of IPTG, respectively).

DISCUSSION

The outer membrane is a continuous structure on the surface of gram-negative bacteria. For outer membrane proteins in the outer monolayer of bacterial membrane, they have bilateral particular significance as a potential target for protective immunity and bacterial pathogens. Outer membrane vaccines have been used with considerable success to induce protection against a number of organisms, including heat shock protein, vacuolating cytotoxin, ureases A, B of *H.pylori* and so on[59-65]. HpaA is one of the major structural outer membrane proteins of *H.pylori* and plays an important role in adhesion of the microbe[51,53]. HpaA gene is located in genome DNA of *H.pylori* and considerably conservative for its nucleotide and amino acid sequences[55,56]. Furthermore, antibody against HpaA could be found in approximately 86 % of *H.pylori* infected patients' sera and this proportion was obviously higher than that of heat shock protein (68 %) and vacuolating cytotoxin (68 %)[57] and was similar to that of urease B[64]. Therefore, HpaA is an ideal antigen candidate for *H.pylori* vaccine.

In this study, the homologies of the nucleotide and putative amino acid sequences in the cloned HpaA gene from *H.pylori* strain Y06 compared with the 6 published hpaA gene sequences[51, 53, 55-58] were as high as 94.25-97.32 % and 95.38-98.46 %, respectively, whereas the nucleotide and putative amino acid homologies among the 6 HpaA gene sequences were 93.72-98.21 % and 95.00-98.78 %. These data indicate that the mutation level of the HpaA gene of *H.pylori* strain Y06 is within the range reported by the literatures.

The results of SDS-PAGE demonstrated that the constructed expression system pET32a-hpaA-BL21DE3 was able to efficiently produce the target fusion protein presented with the form of inclusion body even if induced by IPTG at lower concentration of 0.1 mmol· L^{-1} and the output was approximately 40 % of the total bacterial proteins.

The rabbit antibody against the whole cell of *H.pylori* could recognize and combine with HpaA fusion protein confirmed by Western blot, indicating that the fusion protein has an active and satisfactory immunoreactivity. The immunodiffusion assay performed in this study demonstrated that HpaA fusion protein could efficiently induce rabbit to produce specific antibody with a higher titer against the fusion protein, which indicates that HpaA fusion protein has favorable antigenicity. The results of ELISA showed that all of the tested clinical isolates of *H.pylori* would express HpaA and the majority of *H.pylori* infected patients' sera (81.6 %) were present for the specific antibody against the microbe.

All the evidences mentioned above suggest that HpaA is an excellent and ideal antigen for developing *H.pylori* vaccine and an HpaA expression system with high efficiency was successfully constructed in this study.

Abstract

AIM: To evaluate the association of pre-treatment *Helicobacter pylori* (*H. pylori*) density with bacterial eradication and ulcer healing rates in patients with active duodenal ulcer.

METHODS: One hundred and four consecutive duodenal ulcer outpatients with *H. pylori* infection ascertained by gastric histopathology and ^{13}C-urea breath test (UBT) were enrolled in this study. *H. pylori* density was graded histologically according to the Sydney system (normal, mild, moderate, and marked). In each patient, lansoprazole (30 mg b.i.d.), clarithromycin (500 mg b.i.d.) and amoxicillin (1 g b.i.d.) were used for 1 week, then 30 mg lansoprazole once daily was continued for an additional 3 weeks. Follow-up endoscopy was performed at 4 weeks after completion of the therapy, and UBT was done at 4 and 8 weeks after completion of the therapy.

RESULTS: The *H. pylori* eradication rates were 88.9 %/100.0 %, 94.3 %/100.0 %, and 69.7 %/85.2 %; and the ulcer healing rates were 88.9 %/100.0 %, 94.3 %/100.0 %, and 63.6 %/77.8 % (intention-to-treat/per protocol analysis) in the mild, moderate, and marked *H. pylori* density groups, respectively. The association of pretreatment *H. pylori* density with the eradication rate and ulcer healing rate was both statistically significant (P=0.013/0.006 and 0.002/<0.001, respectively; using results of intention-to-treat/per protocol analysis).

CONCLUSION: Intragastric bacterial load may affect both the outcome of eradication treatment and ulcer healing in patients with active duodenal ulcer disease.

INTRODUCTION

Helicobacter pylori (H. pylori) has been considered as the main cause of chronic gastritis and peptic ulcer[1]. It has been identified in 90-95 % of patients with duodenal ulcer and 60-80 % of patients with gastric ulcer[2]. Strong evidence has also shown an association between the eradication of *H. pylori* infection and the cure of peptic ulcer diseases[3-5].

Recommendations and guidelines for *H. pylori* eradication therapy have been developed rapidly during recent years. The global trend of eradication therapy has now shifted to proton pump inhibitor (PPI)-based triple therapy (a PPI and two different anti-microbials)[6], which can assure rapid symptom relief, improve ulcer healing, and reduce ulcer recurrence[7,8]. However, some cases failed to heal with this advanced PPI-based triple therapy. Patient compliance and antibiotic resistance are currently regarded as the major causes of eradication failure[9]. Several researchers have also revealed that high antral density of *H. pylori* may increase the rate of ulcer recurrence and be related with low eradication rate after triple therapy[10-12]. Intragastric bacterial load might be another factor affecting the success of eradication therapy[12]. Therefore, we conducted this study to investigate the association of *H. pylori* density in the stomach with the efficacy of eradication therapy and ulcer healing in patients with active duodenal ulcers.

MATERIALS AND METHODS

Patients

From January 2000 to June 2002, consecutive outpatients with endoscopically verified active duodenal ulcers (5 mm in diameter or larger) at Cathay General Hospital were enrolled in this study. All panendoscopic examinations were performed and interpreted by the same group of experienced endoscopists. We only enrolled patients with positive diagnosis of *H. pylori* infection proven by both histological examinations and ^{13}C-urea breath tests (UBT). To avoid interference in evaluating the status of *H. pylori*, the following patients were initially excluded before endoscopy: those who had ingested bismuth, antibiotics, anti-secretory medication, or PPI during the 4 weeks prior to the beginning of the study; those who used non-steroidal anti-inflammatory drugs; those who were pregnant or immuno-compromised, and those who had a history of gastric surgery or a previous attempt to eradicate *H. pylori*. The patients with coexisting gastric ulcers or gastric cancer were also excluded. All procedures were performed after obtaining informed consent from the patients.

The patients enrolled were treated with the same regimen of 30 mg lansoprazole b.i.d. plus 500 mg clarithromycin b.i.d. and 1 g amoxicillin b.i.d. for 7 days. After 1 week of anti-*H. pylori* therapy, 30 mg lansoprazole once daily was continued for an additional 3 weeks. From then on, either PPI or anti-secretory H_2-blocker was avoided; only oral antacids were taken for symptomatic relief when necessary. The second endoscopic examination was performed 4 weeks after completion of the therapy.

Histology

During the first endoscopic examination, three biopsies were taken from the gastric antrum (one near the incisura and the

other two on the greater and lesser curvature, 2 cm within the pyloric ring)[13]. On the follow-up endoscopic examination, two additional specimens were taken from the greater curvature of the gastric body due to the possibility of patchy distribution of *H. pylori* after eradication therapy. An "Olympus GIF-XQ 200' endoscope was used, the biopsy forceps were the "FB 25-K" type. The specimens were stained with hematoxylin-eosin and with a modified Giemsa stain. Then they were examined by experienced histopathologist who was unaware of the clinical diagnosis for the existence of *H. pylori* of the patients. The version of the visual analogue scale in the updated Sydney system was used to grade the density of *H. pylori* (4 grades: normal, no bacteria; mild, focal few bacteria; moderate, more bacteria in several areas; and marked, abundance of bacteria in most glands)[14]. If the density varied, the highest grade of density in the specimens was selected.

Urea breath test

UBTs were performed before the start of therapy and on two separate occasions, at 4 and 8 weeks after the cessation of therapy, respectively. The ^{13}C-urea used was 100 mg 99 % ^{13}C-labelled urea produced by the Institute of Nuclear Energy Research, Taiwan. Patients drank 100 ml of fresh milk as the test meal. The procedure was modified from the European standard protocol for the detection of *H. pylori*[15,16]. We chose 3 per mil for the cut-off level of the rise in the delta value of $^{13}CO_2$ at 15 min after the ingestion of ^{13}C-urea. UBT was defined as positive when the excess $\delta^{13}CO_2$ was above this value. By using this cut-off, the sensitivity and specificity of UBT were 97 % and 95 %, respectively[16].

Eradication of *H. pylori* infection was defined as negative results on UBT and histology tests at 4 weeks after the cessation of therapy or negative results on two UBTs at both 4 and 8 weeks after the cessation of therapy[17]. Healing of ulcers was defined as complete disappearance of the ulcer and non-healing as persistence of ulcers, even if the size had decreased[18].

To be included in the intention-to-treat analysis, the infection of *H. pylori* had to be confirmed using both UBT and histological examination results. When protocol violations which were likely to influence the response variable or its assessment occurred, patients were excluded from the per protocol analysis.

Statistical analysis

Chi-square or Fisher' s exact test was used to evaluate the qualitative data. ANOVA test was applied for the quantitative data. The eradication rates of *H. pylori* and healing rates of duodenal ulcers in the three groups of different *H. pylori* densities were compared using chi-square test or Fisher' s exact test and assessed on the basis of both intention-to-treat and per protocol analysis. The 95 % confidence intervals (95 % CI) were calculated. The relationship between *H. pylori* eradication and duodenal ulcer healing was evaluated by Fisher' s exact test. *P* value less than 0.05 was considered significant.

RESULTS

Patients

One hundred and ten patients were initially included in the study, but 6 patients were later excluded due to their negative results of *H. pylori*. We enrolled 104 patients who fulfilled the inclusion criteria. Table 1 shows the demographic and other baseline characteristics of the patients divided by the grade of *H. pylori* density. None of differences in variables was statistically significant. Among them, 12 patients did not complete the study because of poor compliance of taking medications (3 cases) or refusal to receive the second endoscopy (9 cases). Because we wanted to observe the results of both the eradication therapy and the ulcer healing, the patients who refused the second endoscopy were excluded. Therefore, 92 patients were included for per protocol analysis.

Table 1 Clinical characteristics of patients

	H. pylori density		
	Mild (*n*=36)	Moderate (*n*=35)	Marked (*n*=33)
Sex (male / female)	23 / 13	25 / 10	23 / 10
Age (years, Mean ±S.D.)	45.6±10.3	44.1±12.7	47.2±13.4
Smoking(yes / no)	18 / 18	20 / 15	18 / 15
Ulcer size			
< 1 cm	32	32	30
1-2 cm	4	2	3
>2 cm	0	1	0
Ulcer number			
One	34	32	30
Two	2	3	3
Drop outs	4	2	6

Eradication rate and the density of H. pylori

The overall eradication rates were 84.6 % (95 % CI: 75.9-90.7 %) in the intention-to-treat analysis set and 95.7 % (95 % CI: 88.6-98.6 %) in the per protocol set. The eradication rates of the three grades of bacterial densities had a downward trend as the bacterial load became denser (Table 2). The association was statistically significant (*P*=0.013 and 0.006, by intention-to-treat and per protocol analysis).

Table 2 Eradication rates and the density of *H. pylori*

	Eradication rates	95% CI	*P* value
Intention-to-treat			
H. pylori density			
Mild	32 / 36 (88.9%)	73.0 – 96.4 %	
Moderate	33 / 35 (94.3%)	79.5 – 99.0 %	
Marked	23 / 33 (69.7%)	51.1 – 83.8 %	
Total	88 / 104 (84.6%)	75.9 – 90.7 %	0.013[a]
Per protocol			
H. pylori density			
Mild	32 / 32 (100.0%)	86.7 – 100.0 %	
Moderate	33 / 33 (100.0%)	87.2 – 100.0 %	
Marked	23 / 27 (85.2%)	65.4 – 95.2 %	
Total	88 / 92 (95.7%)	88.6 – 98.6 %	0.006[b]

Notes: [a]Based on Chi-square test; [b]Based on Fisher' s exact test.

Healing rates of duodenal ulcer and the density of H. pylori

The healing rates of active duodenal ulcer are shown in Table 3. According to both of the intention-to-treat and per protocol analysis, the differences in the ulcer healing rates of the three grades of *H. pylori* densities were statistically significant (*P*=0.002 and <0.001, respectively). As the bacterial density increased in the stomach, the healing rate of duodenal ulcer decreased.

Relationship between H. pylori eradication and duodenal ulcer healing

Table 4 shows the positive impact of *H. pylori* eradication on duodenal ulcer healing. The association was statistically significant (*P*<0.001). Active ulcers of 97.7 % of the patients with successful *H. pylori* eradication had healed at the time of

the second endoscopic examination.

Table 3 Healing rates of duodenal ulcer and the density of *H. pylori*

	Healing rates	95% CI	*P* value
Intention-to-treat			
H. pylori density			
Mild	32 / 36 (88.9%)	73.0 – 96.4 %	
Moderate	33 / 35 (94.3%)	79.5 – 99.0 %	
Marked	21 / 33 (63.6%)	45.1 – 79.0 %	
Total	86 / 104 (82.7%)	73.8 – 89.2 %	0.002[a]
Per Protocol			
H. pylori density			
Mild	32 / 32 (100.0%)	86.7 – 100.0 %	
Moderate	33 / 33 (100.0%)	87.2 – 100.0 %	
Marked	21 / 27 (77.8%)	57.3 – 90.6 %	
Total	86 / 92 (93.5%)	85.8 – 97.3 %	<0.001[b]

Notes: [a]Based on Chi-square test; [b]Based on Fisher's exact test.

Table 4 Relationship between *H. pylori* eradication and duodenal ulcer healing

	H. pylori	
	Eradicated (*n*=88)	Not eradicated (*n*=4)
Duodenal ulcer		
Healed	86 (97.7%)[a]	0 (0.0%)
Not healed	2 (2.3%)	4 (100.0%)

[a]*P*<0.001 *vs* not eradicated group, based on Fisher's exact test.

DISCUSSION

H. pylori is an important factor in the pathogenesis of duodenal ulcer. Researchers have shown the eradication of *H. pylori* not only prevents ulcer recurrence but also aids ulcer healing[19]. Eradication of *H. pylori* has changed the natural history of duodenal ulcer and has become a standard therapy for duodenal ulcer patients[3, 4, 10].

At present, short-term (7-day) triple therapies including a PPI and two antibiotics (clarithromycin, and amoxycillin or a nitroimidazole compound) are considered as the first line in anti-*H. pylori* regimens[12]. However, despite of the high efficacy of different anti-*H. pylori* treatment schemes, a proportion of patients, varying from 10 % to 25 %, fails the first attempt to eradicate *H. pylori*[9]. Patient compliance and antibiotic resistance are currently regarded as the key factors affecting the outcome of treatment[9,12]. The evidence for other possible factors associated with lower eradication rates is somewhat sparse and equivocal. Nevertheless, several reports revealed that the patients with higher intragastric *H. pylori* load had reduced eradication rates. This association was found in both bismuth and PPI-based triple therapies[9-12]. Therefore, pre-treatment bacterial density was used by some authors to predict the success of *H. pylori* eradication in patients with chronic duodenal ulcer[10,11].

Our working hypothesis was that "the higher the intragastric *H. pylori* colonization, the less effective the short-term triple therapy". In our study, an inverse relationship between successful eradication and intragastric bacterial load was found, which is compatible with the results of other studies[9-12]. Increased bacterial density of *H. pylori* was associated with a significant reduction in the eradication rate after anti-*H. pylori* treatment. This correlation provides additional support for the importance of bacterial density as a factor in *H. pylori* eradication.

With more *H. pylori* inhabiting the antrum, the gastric mucosa will suffer greater damage by this bacteria[20, 21]. The denser infection of *H. pylori* associated with greater antral inflammation may cause lower somatostatin expression, leading to higher levels of gastrin and acid production, which may therefore predispose the duodenum to ulceration[22]. Alam *et al*[21] have shown that the prevalence of duodenal ulcer increased with increasing *H. pylori* density, and a greater likelihood of ulceration was noted among patients with high concentrations of *H. pylori*. Effective *H. pylori* eradication was found to induce good responses in peptic ulcer healing[18]. Treiber *et al* [23] reported successful *H. pyl*ori eradication therapy accelerated peptic ulcer healing even without concomitant acid suppression. In several trials, *H. pylori* eradication not only did result in greater duodenal ulcer healing, but also dramatically decreased ulcer recurrence rate 12 months following treatment[24]. The cure rates of *H. pylori* infection could be expected more than 90 % using standard triple therapy according to the Maastricht consensus guidelines, and the effective *H. pylori* eradication therapy could achieve rapid peptic ulcer healing in more than 90 % of subjects[23,25].

In our study, 86/88 cases (97.7 %) in the *H. pylori* eradication group had complete healing of ulcers, which were proven by the results of follow-up endoscopy. The association between *H. pylori* eradication and ulcer healing was statistically significant. Therefore, a positive impact of *H. pylori* eradication on peptic ulcer healing is concluded.

Intragastric bacterial load can affect the success of *H. pylori* eradication therapy, and *H. pylori* eradication can influence the healing of duodenal ulcer. Thus, the healing of duodenal ulcer might be associated with the *H. pylori* density in the stomach. According to our results, *H. pylori* density was revealed to be inversely related to ulcer healing. We asked every patient enrolled to receive follow-up endoscopic examinations so that we could observe the healing process of duodenal ulcer directly. Although some patients refused the second endoscopic examination, our results were still able to confirm the assumed association mentioned above.

Identification of pre-treatment predictors of eradication therapy is important in clinical practice. Therapeutic regimens may be tailored to individual patients according to their particular conditions. Despite the fact that high *H. pylori* density might adversely influence the efficacy of eradication therapy, patients with high intragastric bacterial loads were found to benefit from an extension of eradication regimen from 1 to 2 weeks[9]. Prolonging duration of the standard triple therapy was proposed as a way to overcome the unfavorable effects caused by high *H. pylori* density and proved to be effective[9,12].

Most patients (101/104 cases, 97.1 %) included in this study had good drug compliance. Bacterial culture and drug sensitivity test to assess the effect of antibiotic resistance were not performed. Therefore, we could not demonstrate the influence of drug resistance on eradication therapy by our results. Although some authors mentioned the resistance to antimicrobials could be considered as a statistical event and estimated as a certain proportion of the *H. pylori* population in the stomach[26], the relationship between antibiotic resistance and bacterial load of *H. pylori* has not been studied. Further investigation is warranted to elucidate this issue. The culture and susceptibility testing of *H. pylori* are time-consuming and expensive, and they are rarely performed in most developing countries[27]. In Taiwan, they are not routinely performed either. Our study may thus provide a practical option to identify the pre-treatment predictors of eradication therapy and ulcer healing when information on drug sensitivity is not available.

In conclusion, our findings reveal that pre-treatment high bacterial density of *H. pylori* in the stomach adversely affects

the success of eradication therapy and influences the healing of ulcers in patients with active duodenal ulcers, and effective *H. pylori* eradication is also shown to be significantly associated with duodenal ulcer healing. Identifying patients with high bacterial loads before treatment and making adjustments of therapeutic regimens accordingly may further improve the efficacy of eradication therapy.

Abstract

AIM: To study the significance of polymorphism of MHC class I chain-related gene A (MICA) gene in patients with cholelithiasis.

METHODS: Subjects included 170 unrelated adults (83 males) with cholelithiasis and 245 randomly selected unrelated adults (130 males) as controls. DNA was extracted from peripheral leukocytes and analyzed for polymorphism of 5 alleles (A4, A5, A5.1, A6 and A9) of the MICA gene.

RESULTS: There was no significant difference in phenotype, allele, and genotype frequencies of any of the 5 alleles between cholelithiasis patients and controls.

CONCLUSION: This study demonstrates that MICA alleles studied bear no relation to cholelithiasis.

INTRODUCTION

Molecular genetics has a substantial impact on our understanding of inherited susceptibility to many diseases. There is an increased familial frequency of cholelithiasis[1], which is a prevalent disorder in Taiwan[2]. HLA gene is associated with many human diseases. It is reasonable to speculate on whether there is a correlation between cholelithiasis and HLA gene.

MICA gene is located near HLA-B on chromosome 6, and is by far the most divergent mammalian MHC class I gene known[3]. It lies 46.4 kb centromeric to HLA-B gene, and they are oriented head-to-head. It has a triplet repeat microsatellite polymorphism $(GCT)_n$ in the transmembrane region. This polymorphism consists of five alleles, with 4, 5, 6, and 9 repetitions of GCT or 5 repetitions of GCT with 1 additional nucleotide insertion (G), designated as A4, A5, A6, A9, and A5.1, respectively[4]. The alleles vary among individuals, and hence this microsatellite can be used as an informative polymorphic marker for genetic mapping and for analysis of disease susceptibility.

To date, there have been no reports investigating an association between MICA gene and cholelithiasis. We designed this study to compare MICA polymorphism among Chinese with cholelithiasis, their family members, and unaffected controls.

MATERIALS AND METHODS

Patients with cholelithiasis and controls

One hundred and seventy unrelated adult patients (83 males) with cholelithiasis were enrolled. The average age at diagnosis was 50.5±3.1 years. Cholelithiasis was documented ultrasonographically and/or after operation (75 patients underwent cholecystectomy). The ultrasonographic criterion for diagnosis of cholelithiasis was echogenic material with a postural shift and/or casting an acoustic shadow in the gallbladder. According to their number and size, ultrasonographic patterns of gallbladder stones were divided into 3 types: single, particle (multiple, larger size) and sandy (multiple, sand-like appearance). Control subjects consisted of 245 unrelated subjects (130 males) from the same area where the patients resided. They came to the hospital for physical checkups, minor operations or injuries, or evaluation of fever or abdominal pain. Those with autoimmune disorders, liver diseases, or blood diseases were excluded from the study. In addition, a total of 144 family members of 75 patients with cholelithiasis were included for further comparison. Blood was drawn from all the subjects to extract genomic DNA. All the subjects were Chinese, and they all gave written consent. The study was approved by the local ethics committee.

DNA extraction

Genomic DNA was extracted from fresh or frozen peripheral blood leukocytes by standard techniques[5, 6].

Determination of the polymorphism of $(GCT)_n$ microsatellite

Primers for analysis of microsatellite polymorphism in the transmembrane region of MICA gene, PCR primers flanking the transmembrane region (MICA5F, 5'-CCTTTTTTTCAGGGAAAGTGC-3'; MICA5R, 5'-CCTTACCATCTCCAGAAACTGC-3') were designed according to the reported sequences[3, 4]. The MICA5F primer corresponded to the intron 4 and exon 5 boundary region and MICA5R was located in intron 5[4]. MICA5R was 5' end-labelled with fluorescent dye (Applied Biosystems)[7, 8].

Polymerase chain reaction (PCR) The amplification reaction mixture (15 μl) contained 50 ng genomic DNA, 10 mM Tris-HCl (pH 9.0), 50 mM KCl, 1.5 mM $MgCl_2$, 0.01 % gelatin, 0.1 % Triton X-100, 0.2 mM of each dNTP, 0.5 mM of each primer and 0.5 unit Pro Taq DNA polymerase (Protech Technology Enterprise). PCR amplification was carried out in a GeneAmp PCR system (Applied Biosystems). The mixture

was subjected to denaturation at 95 ℃ for 5 min, followed by 10 cycles at 94 ℃ for 15 sec, at 55 ℃ for 15 sec, at 72 ℃ for 30 sec, then by an additional 20 cycles at 89 ℃ for 15 sec, at 55 ℃ for 15 sec, at 72 ℃ for 30 sec, and by a final extension at 72 ℃ for 10 min.

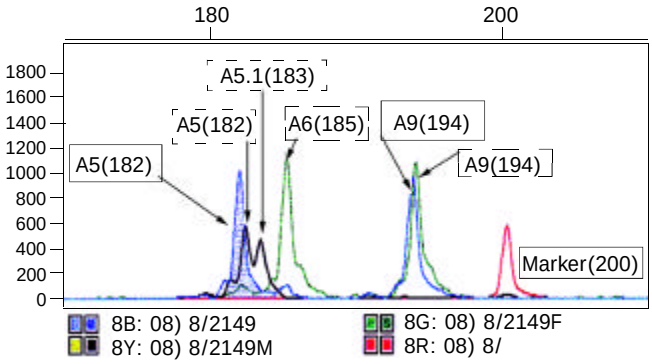
Analysis of triplet repeat polymorphism The amplified products were denatured at 100 ℃ for 5 min, mixed with formamide-containing stop buffer, and subjected to electrophoresis on 4 % polyacrylamide gels containing 8-M urea in an automated DNA sequencer (ABI Prism 377-18 DNA sequencer, Applied Biosystems). The number of microsatellite repeats was estimated automatically with Genescan 672 software (Applied Biosystems) by means of the local Southern method with a size standard marker of GS-350 TAMRA (Applied Biosystems)[8]. Alleles were designated according to Mizuki *et al.*[4] and Perez-Rodriguez *et al.*[9], with amplified sizes of 179 bp (A4), 182 bp (A5), 183 bp (A5.1), 185 bp (A6), 194 bp (A9), and 197 bp (A10).

Statistical analysis

Evaluation of the Hardy-Weinberg equilibrium was performed by comparing observed and expected heterozygotes and homozygotes, as well as observed and expected genotypes, using the χ^2 test[10]. Phenotype, allele, or genotype frequencies of patients and controls were compared by the χ^2 test with Yates' correction where appropriate (one expected number <5). Patients and controls positive for a factor were compared using a free statistical program on the internet[11]. *P* values were corrected using the Bonferonni inequality method for the number of comparisons[12]. Statistical significance was defined as $P<0.05$.

RESULTS

Figure 1 shows the electrophoretograms of the PCR products of 3 subjects. We did not detect A10 in any of the patients or controls. The distribution of MICA genotypes in the two groups was in Hardy-Weinberg equilibrium, i.e. observed and expected figures did not differ. No significant difference was found between patients with cholelithiasis and controls in phenotype, allele, or genotype frequencies. There were also no differences between male and female patients or between patients with different sonographic stone types. Age at diagnosis was also not correlated with allele frequency (Tables 1, 2 3). As the difference between patients and controls was not remarkable, it was not meaningful to compare the results between patients and their family members (data not shown).



Genotypes of a subject (2149), his father (2149F), and mother (2149M)

Subject	Line	Genotype
2149	solid	A5 / A9
2149F	dash	A6 / A9
2149M	dot	A5 / A5.1

Figure 1 Electrophoretograms of the PCR products for three subjects. Amplified sizes of the alleles were 182 bp (A5), 183 bp (A5.1), 185 bp (A6), and 194 bp (A9).

DISCUSSION

Cholelithiasis is quite prevalent in Taiwan[2] and is easily detected by ultrasonography, which has become a commonly used screening tool for health maintenance exams. There is as yet no well documented method to prevent cholelithiasis formation. However, it is now well known that detecting genetic defects may lead to better surveillance or even avoidance of certain diseases. Thus it seems worthwhile to search for gene disorders in a common disease like cholelithiasis.

MHC class I genes (HLA-A, -B and -C) encode single polypeptides organized into three domains: α_1, α_2, and α_3. Their surface expression on most nucleated cells of the body depends on the noncovalent association with a fourth domain, the non-MHC-encoded polypeptide β_2-microglobulin[13]. MHC class I molecules are important in the efferent limb of immunity, which is designed to destroy cells bearing foreign antigens. Foreign peptides presented within the cell are deposited in the binding groove of MHC class I molecules and expressed on the cell surface. Cytotoxic T cells recognize them and destroy the cell[14]. Certain MHC class I molecules have been found to be associated with various diseases, including type 1 diabetes and cholelithiasis[15-18]. An even stronger association has been found with MHC class II molecules[18, 19]. The initial explanation of HLA class I associations is linkage disequilibrium between certain subtypes of MHC class I and class II molecules[19, 20]. However, other studies have suggested that there may be other loci in the MHC gene complex that also play a role[21, 22]. Further investigation of such loci nearby or within MHC class I genes, such as MICA gene, is necessary to clarify these discrepancies.

MICA gene has recently been found to be more significantly associated with disease susceptibility that had been previously reported to be associated with the HLA-B locus (HLA-B7, -B8, -B15, -B18 in Caucasians; -Bw22, and -Bw54 in Chinese; -B5, -Bw52, and -Bw54 in Japanese are reportedly associated with various diseases)[4, 7, 8, 15, 16, 23-28]. This suggests that susceptibility associated with the HLA-B locus might be due to different genotypes of MICA gene.

MICA is specifically expressed by fibroblasts, epithelial cells, keratinocytes, endothelial cells, and monocytes[3, 29]. The molecule is similar to MHC class I antigens. Thus MICA is thought to represent a second lineage of MHC antigens and possibly to play a specialized or modified role in the immune response[3]. The recruitment of γδ T cells in skin and intestinal mucosa mirrors the pattern of expression of MICA and is consistent with the hypothesis that these molecules may play a role in inflammation and in the response to stress or damage in certain tissues[29]. MICA expression is regulated by promoter heat shock elements similar to those of HSP70 genes[30]. The high levels of MICA expression in epithelial cell lines together with the upregulation of MICA after heat shock may represent a molecular mechanism for exposing stressed epithelial cells to the immune system[31]. Thus MICA may function as an indicator of cell stress and may be recognized by γδ T cells in an unusual interaction. It is possible, therefore, that MICA regulates the immune response when cells are stressed and might be involved in the development of cholelithiasis.

However, our study showed that the polymorphic MICA alleles were not significantly associated with cholelithiasis, nor were there any differences when we looked at subgroups of patients, stratified according to sex, types of gallstone, or age. The latter factor is of interest in considering the contribution of heredity *vs.* environment. These results are perhaps not surprising, since the pathogenesis of cholelithiasis in Taiwan is multifactorial[32]. Nevertheless, our demonstration of the absence of an association between MICA gene and cholelithiasis is useful in pointing future research in other directions. The fact of the increased familial frequency of cholelithiasis[1] thus remains to be explained, perhaps by studying other loci on the human chromosome.

Abstract

AIM: To investigate the protective effects of early enteral feeding (EEF) on postburn impairments of renal function and their possible mechanisms.

METHODS: Wistar rats with 30 % of total body surface area (TBSA) full-thickness burn were adopted as the experimental model. The effects of EEF on the postburn changes of gastric intramucosal pH (pHi), endotoxin levels in portal vein, water contents of renal tissue, and blood concentrations of tumor necrosis factor (TNF-α), urea nitrogen (BUN), creatinine (Cr), as well as the changes of clearance of creatinine (CCr) were dynamically observed within 48 h postburn.

RESULTS: EEF could significantly improve gastric mucosal acidosis, reduce portal vein endotoxin levels and water contents of renal tissue, as well as blood concentrations of TNF-α after severe burns ($P<0.01$). The postburn elevations of BUN and BCr were not found to be recovered by EEF. However, the CCr in EEF group was greatly increased by 4.67-fold compared with that of the non-feeding burned control (16.43±2.90 *vs*. 3.52±0.79, $P<0.01$).

CONCLUSION: EEF has beneficial effects on the improvement of renal function in severely burned rats, which may be related to its increase of splanchnic blood flow, decrease of the translocation of gut-origin endotoxin and the release of inflammatory mediators.

INTRODUCTION

Acute renal failure (ARF) is one of the well-known complications after severe burns with an extremely high incidence of death[1-4]. In most circumstances, it manifests as a part of multiorgan dysfunction syndrome[5, 6] and the kidney-oriented supportive therapy so far has not achieved satisfactory results[6, 7]. In recent years, abundant researches have suggested that the translocation of gut-origin endotoxin in certain pathological conditions may lead to remote organ injury[8, 9], which may also be the major contributor to renal dysfunction[10-13]. Meanwhile, it has become increasingly apparent that early enteral feeding (EEF) in various groups of patients could produce multiple beneficial effects, including increase of blood flow to the splanchnic organs, maintenance of gut mucosal integrity, prevention of intramucosal acidosis and permeability disturbances, and alleviation of the translocation of gut-origin bacteria and endotxin[14-19]. We therefore presume that EEF might be possible to improve renal function injured by severe burns, which up to now has been seldom documented. Thus, the present study was designed to demonstrate this hypothesis, in attempt to seek ways to improve the treatment of severely injured patients, which would be no doubt of both theoretical and practical importance.

MATERIALS AND METHODS

Animals

Healthy adult Wistar rats of both sexes, weighing 220±30 g, were employed in the study. They were housed in individual metabolic cages in a temperature conditioned room (22-24 ℃) with a 12 h light-dark circle, allowed access to standard rat chow (provided by experimental animal center, Third Military Medical University) and water ad libium, and acclimatized to the surroundings for 7 days prior to the experiments.

Operative procedure

All animals were weighed and anesthetized with 1 % pentobarbitale sodium (30 mg/kg, ip). After laparotomy, a polyethylene catheter (1.5 mm in diameter) was inserted into duodenum on the anterior wall 1.5 cm from pylorus via a puncture hole made by a metal needle for enteral feeding. The catheter was appropriately fixed, tunneled under the skin and exited through the nape skin. The animals were housed and fed as described above after operation.

Burn injury and resuscitation

After a recovery period of 24 h, the animals inserted with a feeding tube were anesthetized, having their dorsal hair shaved and placed in a wooden template designed to expose 30 % of the total body surface area (TBSA), and then immersed in water at 92 ℃ for 20 seconds, which resulted in a clearly demarcated full-thickness burn. One hour after burn injury, the animals were resuscitated with 10 ml of warm 0.9 % NaCl (normal saline solution, 37 ℃) given by intraperitoneal injection. Control animals were similarly anesthetized, shaved, resuscitated but not burned.

Feeding and experimental protocol

Nutrient feeding liquid was prepared as one with a caloric of 2.1 KJ/ml before use by mixing nutritional powder (ENSURE, USA) with an appropriate amount of warm boiled water. According to different feeding regimens, the animals were randomly divided into three groups: (1) EEF group. Enteral

feeding was initiated 1 h postburn in burned animals via a feeding tube with a total caloric of 202 KJ· Kg^{-1}· 24 h^{-1}. The feeding nutrient liquid required for 24 hours was administered evenly at 6 time points. (2) Burn group. The animals were treated exactly the same as EEF group, except that the nutrient feeding liquid was substituted for the same amount of saline. (3) Control group. Only the feeding tube was inserted, whereas no tube feeding and burn were conducted. The animals in this group were allowed access to standard rat chow, nutrition liquid and water ad libium. Time points for different measurements and assays in all groups were made at 3, 6, 12, 24 and 48 h postburn, except for the determination of renal tissue water content, which was performed at 12 h after thermal injury. 24-hr urine was collected for the detection of urea nitrogen and creatinine that were used to calculate CCr. For plasma assays, rats were sacrificed by decapitation at each time point and heparinised blood was collected in a separator tube spun at 3 000 g for 10 min, decanted and frozen at -20 ℃ until analysis.

Measurements

The gastric intramucosal pH was determined with an indirect method as previously described[20] with minor modifications. Briefly, the animals were anesthetized and injected cimetidine (15 mg) intraperitoneally 1 h prior to each time point, a polyethylene catheter was inserted into gastric lumen through pylorus via a puncture hole on the anterior wall of duodenum made by a metal needle after a midline laparotomy. A 2.5-ml of normal saline was injected into gastric lumen though the catheter and removed in order to get rid of intragastric residues, then 1.5-ml of normal saline was injected and retained in the gastric lumen. After an equilibration interval of 60 min, 1 ml of saline solution was aspirated and PCO_2 was determined using the blood gas analyzer. A simultaneously obtained arterial blood sample was used to determine the [HCO_3^-]. pHi was then calculated as:

$$pHi=6.1+\log([HCO_3^-] / [PCO_2\times 0.03])$$

The multifunction-biochemical analyzer Beckman Synchron CX-7 was employed to detect urea nitrogen and creatinine in both blood and urine.

Portal plasma endotoxin levels were assayed with the limulus-amoebocyte-lysate test (LAL)[21]. Briefly, plasma samples were diluted tenfold with pyrogen-free water and heated to 75 ℃ for 5 min to overcome assay inhibition by plasma. The samples were incubated with LAL for 33 min at 37 ℃. Then the chromogenic substrate was added and the samples was incubated for another 3 min. After the reaction was stopped with acetic acid, sample optical density was read at 545 nm and the endotoxin concentration was finally expressed as Eu/ml.

Radioimmunoassay of TNF-α levels in systemic circulation was conducted according to the instructions with kits from Dong-Ya Research Institute of Immunotechnology.

Renal tissue water contents were determined with a method as reported in a previous study[22] with minor modifications. Eight renal tissue samples for each group were harvested at 12 h postburn, weighed and put in an oven at 90 ℃ for 24 h, then weighed again. The renal tissue water contents were calculated as: Renal tissue water contents=(wet weight - dry weight / wet weight)×100 %

Statistical analysis

Experimental results were analyzed by analysis of variance and *t*-tests for multiple comparisons. Data were expressed as mean ± standard error of the mean. Statistical significance was determined at $P<0.05$.

RESULTS

BUN and BCr in both EEF and Burn groups were significantly increased postburn with the peak value at 6 h. Though gradually decreased thereafter, they were still significantly higher than those of the control at 24 and 48 h time points ($P<0.01$). The beneficial effects of EEF on the renal function manifested as the improvement of CCr, in which a 4.67-fold increase was observed in EEF group as compared with burn group and the CCr value in EEF group tended to be close to that in the control (Table 1).

Gastric mucosal acidosis was significantly improved in EEF group as indicated by the elevation of gastric pHi at most of the postburn time points, however, gastric pHi in burn group was sustained in lower levels until 48 h postburn (Table 2).

Table 3 displays the changes in portal endotoxin levels after severe burns. Three hours postburn, endotoxin concentration was significantly increased in burn group and peaked at 6 h, another increase appeared at 24 h and persisted until 48 h postburn. However, the portal endotoxin levels in animals that received EEF markedly decreased at almost all time points as compared with that of the burn group.

The data for plasma TNF-α levels are shown in Table 4. In accordance with other observations, EEF could also significantly reduce TNF-α levels in systemic circulation at most postburn time points as compared with that of burnt animals.

For EEF, burn and control groups of animals, the renal tissue water contents reached 75.36±0.99 %, 78.94±1.56 % and 76.26±1.25 % respectively (Figure 1). It was evident that a significant decrease of renal tissue water content was seen in EEF group compared with that in burn group at 12 h postburn ($P<0.01$).

DISCUSSION

Nutritional support plays an important role in the management of critically ill patients to prevent and treat multiple organ dysfunction syndrome (MODS)[23]. Numerous clinical and animal studies have demonstrated that early enteral feeding could preserve the gut barrier function, diminish hypermetabolic response, maintain caloric intake, reduce the chance of gut origin infection and significantly shorten hospital stay following injury[14-19]. Unfortunately, the protective effects of EEF on the splanchnic function after severe traumas were relatively neglected in most of these investigations.

In a previous study, Roberts and his associates[24] observed that acute impairment of renal function inflicted by rhabdomyolysis was improved with EEF. Through 72 h dynamic observation, they found both BUN and BCr in EEF rats decreased by 65.7 % and 60 % respectively and the mortality reduced by 43 % compared with that of the animals fed with water. In contrast, in present animal model of severely thermal injury, BUN and BCr in both EEF and burn groups were significantly elevated, and no effect of EEF on the postburn changes of these variables was noted. We conjecture the phenomenon might be attributed to the more severity of the injury, difference in feeding components and blood condensation postburn. It has been reported that CCr could correlate well with the inulin clearance and exhibit renal function more accurately in the presence of acute renal failure[25]. In a animal study on renal dysfunction caused by ischemia, Mouser and his colleagues[25] demonstrated that the percentage of CCr increment in enterally fed animals was 2.5-fold higher than that in animals fed intravenously, whereas no significant changes of BUN and BCr were observed, showing that the improvement of renal function would not be always in accordance with BUN and BCr changes. In the present study, CCr in EEF animals increased by 4.67-fold compared with that in burn group, indicating that EEF could exert protective effects on the postburn renal impairment, and that aborative

attention should be paid to the selection of proper variables to perform such investigations.

The mechanisms of EEF to improve posttrauma renal function so far have not been clarified yet. It was once considered that the enhanced feeding of certain nutrients such as proteins or amino acids might increase the glomerular filtration rate (GFR). However, Mouser *et al*.[25] have shown that even with the same kind of nutrients, CCr in intravenously fed animals with renal ischemia was significantly lower than that in enterally fed animals, suggesting that the enteric factors beyond nutrients play a role in the improvement of impaired renal function. In fact, in severe traumas including burn, loss of large amount body fluids and release of stress hormones caused a sharp reduce of blood flow to many organs, especially the gastrointestinal tract and the kidney. Reduced intestinal blood flow then led to translocation of bacteria and/or their toxic products through the gut mucosa. Subsequent bacteria- and/or toxin-induced persistent and excessive release of cytokines (i.e. tumor necrosis factor, interleukins) and complement activation initiated progressive multiple organ failure and even caused death[26, 27]. In accordance with this theory, numerous studies have proposed that the renal ischemia and endotoxemia occurred in various pathological conditions be the major contributors to the renal dysfunction[10-13, 28-30].

Postprandial gut hyperemia is a locally mediated vascular response to the presence of foodstuff in the lumen, an important physiological phenomenon for food digestion and absorption. Even though in some pathological conditions, this phenomenon still exists. In burned guinea pigs, Inoue *et al*[31] using radiolabeled microspheres demonstrated that blood flow to the jejunum and cecum was higher in the diet group than in the control during initial 24 h of enteral feeding. In a dog model of splanchnic ischemia induced with endotoxin, Eleftheriadis *et al*.[32] reported that portal vein, hepatic and superior mesenteric artery blood flow, hepatic and intestinal microcirculation, hepatic tissue PO_2 and energy charge, and intestinal intramucosal pH were significantly increased after early enteral feeding, which were all reduced in the early septic condition. In the present study, we showed that postburn EEF could effectively restore reduced gastric intramucosal pH, decrease endotoxin concentrations in portal vein and TNF-α levels in systemic circulation, as well as alleviate renal tissue edema compared with burn controls. All the above indicate that in addition to provision of nutritional substrates, posttrauma EEF is most likely via a mechanism of postprandial hyperemia, to improve gut low flow and splanchnic ischemic status, to maintain gut mucosal integrity, and to block the vicious circle of mutual activation between the translocation of gut origin bacteria and their toxic products, and the release of inflammatory mediators[33], thereby reducing hypoxic and inflammatory tissue damage. However, detailed mechanisms are needed to be further studied.

The facts that EEF could improve postburn renal function are of both theoretical and practical importance. The present study revealed that EEF should not be taken merely as a method or a route for nutritional support. Its clinical value has exceeded the range of nutrition and is not limited to the locally enteric benefits as well. Although the results from the animal study can not be extrapolated directly to humans, a better understanding of the postburn EEF might lead to new ways for the further improvement in prevention and treatment of MODS posttrauma.

Abstract

AIM: To modify the hamster-to-rat liver xenotransplant technique to prevent postoperative complications, and to study the inhibiting effect of multiglycosides tripterygium wilfordii (T_{II}) on immune rejection.

METHODS: Female golden hamsters and inbred male Wistar rats were used as donors and recipients, respectively. One hundred and twelve orthotopic liver xenotransplants were performed by Kamada's cuff technique with modifications. Over 72 hour survival of the animal after operation was considered as a successful operation. When the established surgical model became stable, 30 of the latest 42 cases were divided into untreated control group (n=15) and T_{II} group (n=15) at random. Survival of recipients was observed. Liver specimens were collected at 2 and 72 h from the operated animals and postmortem, respectively, for histological study.

RESULTS: The successfully operative rate of the 30 operations was 80 %, and the survival of the control and T_{II} group was 7.1±0.35 was days and 7.2±0.52 days, respectively (t=0.087,P=0.931). The rate of conjunctival hyperemia in control group (100 %) differed significantly from that (31 %) in T_{II} group (P=0.001). Rejection did not occur in both groups within 2 h postoperatively, but became obvious in control group at 72 h after surgery and mild in T_{II} group. Although rejections were obvious in both groups at death of recipients, it was less severe in T_{II} group than in control group.

CONCLUSION: This modified Kamada's technique can be used to establish a stable hamster-to-rat liver xenotransplant model. Monotherapy with multiglycosides tripteryguiumwilfordii (30 mg· kg^{-1}· d^{-1}) suppresses the rejection mildly, but fails to prolong survival of recipients.

INTRODUCTION

The hamster-to-rat liver transplant model is useful to study immunology and physiology of liver xenotransplantation (XT)[1-11], especially for the extended host response to long-surviving xenografts[12]. As it is very difficult to establish this surgical model[13], we summarized our surgical experience in producing for performing this model.

The model could serve as a tool to evaluate immunosuppressive drugs[14,15]. Tripterygium wilfordii hook F (TWHF) has been used for more than two thousand years as a traditional Chinese herb. T_{II} is extracted and refined from the root of TWHF. In recent years, T_{II} and other extracts of TWHF have been applied to allotransplantation and cardiac XT as immunosuppressive drugs with successful results[16-27]. However, the effects of T_{II} in liver XT are unknown and deserve study.

MATERIALS AND METHODS

Animals and liver xenotransplantation

Female golden hamsters (weighing 80-130 g) and inbred male Wistar rats (weighing 130-180 g) were used as donors and recipients, respectively. One hundred and twelve orthotopic liver xenotransplants were performed by Kamada's cuff technique[28] with modifications, which were outlined as follows.

Donor operation Ligaments and vessels around the liver were partially dissected while the liver was protected by wrapping film. The common bile duct was entered from anterior wall and a Teflon catheter was inserted into the lumen proximally. The proper hepatic artery was dissected but not ligated. The infrahepatic vena cava (VC) was clamped at the level of left renal vein. The liver was perfused through the abdominal aorta with 10-20 ml of cold (4 ℃) lactated Ringer's solution containing 5 U/ml of heparin. Meanwhile the thoracic cavity was opened with the thoracic aorta clamped, and the thoracic inferior VC was opened to release the perfusate. Then, the infrahepatic VC was transected at the upper part of the clamp. So the perfusate could escape from the two ends of VC. Deep ligaments around the liver were dissected while perfusing and the right suprarenal vein was ligated. At the end of perfusion, the proper hepatic artery and portal vein (PV) at the level of splenic vein were ligated and transected. The free liver was stored in lactated Ringer's solution at 0-4 ℃.

Preparation of donor liver Preparation of the donor liver was done in lactated Ringer's solution at 0-4 ℃. Two cuffs with different diameters were mounted on the PV and infrahepatic VC, respectively. The cystic duct near the common bile duct was ligated and followed by removal of the gallbladder. The suprahepatic VC was trimmed and a stitch was left on each side for suture.

Recipient operation Vessels, the common bile duct and ligaments around the recipient liver were divided, respectively. The right suprarenal vein behind the papilla lobe was ligated, the recipient liver was removed and covered with fresh film orthotopically. The suprahepatic VC was sutured, the PV was anastomosed with cuff method. The infrahepatic VC was anastomosed as the method for suprahepatic VC. Finally, the distal part of Teflon catheter in donor bile duct was inserted into the recipient bile duct and secured by a silk suture. The greater omentum was wrapped around the bile duct. The abdominal incision was closed with continuous suture.

Treatment of the animal with T_{II}

When the model became stable, 30 recipients of the latest 42 cases were divided into untreated controls (n=15) and treatment group with T_{II} 30 mg· kg^{-1}· d^{-1} (n=15) at random by gavages three days prior to operation till the end of experiment.

Liver specimens were collected at 2 and 72 h after operation or at death of the recipients, respectively, fixed in 10 % formalin, embedded in paraffin, sectioned and stained with hematoxylin and eosin for light microscopy to determine the grade of rejection.

Statistical methods

The results were analyzed by t test and Fisher' s exact test, respectively. Statistical significance was defined as a P value less than 0.05.

RESULTS

Liver xenotransplantation

One hundred and twelve operations were performed from October 2000 to March 2001. The successful rate of the latest 30 operations was 80 % (24/30). The causes of death were anesthesia accident in one case, chronic hemorrhage from the surface of donor liver in 3 cases, thrombosis in infrahepatic VC in one case and suppurate peritonitis in one case. The 6 recipients died within 72 h after operation were excluded from the experiment[14]. The average survival of 24 cases was 7.2±0.44 days.

Effects of T_{II} on survival of recipients

The average survival of the untreated controls and T_{II} group was 7.1±0.35 days and 7.2±0.52 days, respectively (t=0.087, P=0.931). Four cases in controls and 2 in T_{II} group died within 72 h after operation were eliminated from statistic study.

Effects of T_{II} on conjunctival hyperemia of recipients

The morbidity of conjunctival hyperemia was 100 % (11/11) in controls and 31 % (4/13) in T_{II} group (P=0.001). The commence time of conjunctival hyperemia in controls and T_{II} group were 4.73±0.47 days and 5.75±0.5 days, respectively (t=3.688, P=0.003).

Pus in conjunctiva was obvious in controls with conjunctival hyperemia, and three cases had ablepsia. However, no pus and ablepsia were observed in T_{II} group.

Figure 5 Histological changes of the liver in controls (HE,×100).
Figure 6 Histological changes of the liver in T_{II} group (HE,×200).

Histopathology

Two hours after operation The structures of hepatic lobule were normal and no inflammatory cells in portal area in both groups were observed (Figures 1 and 2).

Seventy-two hours after operation In controls, hepatic lobules were normal, numerous inflammatory cells consisting mainly of mononuclear cells and neutrophilic granulocytes infiltrated in portal area, edema could be seen in the tunica intima of interlobular veins and inflammatory cells infiltrated into subintima. However, epithelia of interlobular bile ducts were not injured (Figure 3).

In T_{II} group, the structures of hepatic lobules and interlobular veins were normal, moderate amounts of inflammatory cells were found in portal area, and epithelium of interlobular bile ducts was intact (Figure 4).

Postmortem specimens on day 7 postoperation In controls, hepatic lobules were damaged severely, inflammatory cells consisting mainly of mononuclear cells and neutrophilic granulocytes in portal area as well as massive hemorrhage were observed, interlobular vessels were disappeared and damaged epithelia of interlobular bile ducts were observed (Figure 5).

In T_{II} group, many mixed cells could also be seen in portal area, but most of the interlobular vessels and bile ducts were existed with inflammatory intima, and variable injured epithelia, hepatocytes around portal area were swollen, degenerated and partially necrotic and some liver plates were destroyed (Figure 6).

DISCUSSION

Sun *et al.*[29] firstly advocated that perfusate should enter the liver via dual vascular systems of the hepatic artery and the PV, then the liver and its structures around were divided. The authors performed 300 liver transplantations in rats, and the successful rate of operation and survival rate in one week were 92.7 % and 88.4 %, respectively. So we adopted this dual perfusion except for perfusion by PV in initial trials of 20 cases. We found that perfusion by PV could often result in incomplete perfusion in some small areas and undesirable pressure. Incomplete perfusion did not occur with dual perfusion, and due to the invariant pressure of intestinal circulation, the liver was not mechanically injured by fluctuant pressure and warm ischemia and mechancial injuries were avoided. If the donor liver was dissected at the end of complete perfusion, the vessels became pale and were difficult to be identified and were easily injured accidentally. After modification of the technique, the quality of the liver in donor was excellent in the trials and the survival time of recipient animals was similar to that in the literature[14,30,31].

We used to ligate the cystic duct, and then to remove the gallbladder and electrocauterize the bed of the gallbladder. However, it usually rendered slow hemorrhage in the bed of the gallbladder and the recipients died in hours after transplantation. So we modified the method as follows: ligating cystic duct near the common bile duct, then ligating cervix of the gallbladder and cutting gallbladder at the distal side of the ligation. No postoperative hemorrhage was observed after the modifications.

For the sake of exposing and ligating suprahepatic VC of the donor and the recipient, papilla lobe and right lobe of the liver were turned over frequently and thus were injured easily, and the recipient could die from mild hemorrhage from the surface of the graft. Sometimes, ligation of the infra-branch of suprarenal vein was mistaken for main stem with left supra-branch unligated, which rendered hemorrhage at recipient liver' s cutting and posttransplantation. Therefore, we ligated the right suprarenal vein at the end of perfusion, the structures around the donor liver were divided completely and the right suprarenal vein was exposed easily, so that liver injury and false ligation were reduced. Loop-ligation behind papilla lobe method was used to ligate the suprarenal vein of the recipient. The right suprarenal vein and part of ligaments behind the recipient liver were ligated with 5-0 silk sutures behind the papilla lobe and near the infrahepatic VC. This ligation was reliable, simple, and shortened the anhepatic phase directly.

Hamster' s liver is more fragile than that of rat. Slight press or attrition on its surface could result in contuse and chronic hemorrhage. Moreover, it has poor coagulating mechanism. Thus, fresh film has been used to protect the donor liver in operation, and the pressure on donor liver could be dispersed, the accident stab to the donor liver by instruments could be relieved to some extent and the donor liver could be kept from drying and crisping. Moreover, careful and delicate operation should not be ignored. Nevertheless, in our 30 trials, 3 of 6 failed cases died due to chronic hemorrhage on the surface of the donor liver.

We found that T_{II} at a dosage of 30 $mg\cdot kg^{-1}\cdot d^{-1}$ could not prolong the survival of the operated animal. But the rejection in T_{II} group was less severe in comparison with that of controls. We speculated that this dosage of T_{II} had certain limited immunosuppressive effect. Li *et al.*[32] found that the extracts of TWHF could inhibit human peripheral blood mononuclear cells (PBMC) in a concentration-dependent manner and the best inhibitory rate could be achieved at 72 h. Another research suggested that T_{II} at a dosage of 30 $mg\cdot kg^{-1}\cdot d^{-1}$ had no effects on the liver, kidney, heart and the total number of WBC in rat, but could inhibit the transforming of spleen lymphocytes significantly. T_{II} at this dosage could prolong the survival time of renal allotransplantation in Wistar-to-SD combination significantly. When it was combined with CsA, the survival time could be further prolonged[19]. Nevertheless, in other organ transplantations such as small intestine transplantation, whose rejection was relatively strong, and the monotherapy with T_{II} was demonstrated to have limited effects[21]. Wang *et al.*[16] applied PG27 (extract of TWHF) combined with a low dosage of CsA to hamster-to-rat cardiac xenotransplantation and all xenografts survived more than 100 days. However, they found that either PG27 or CsA had no such effects. Therefore, although a high dosage of T_{II} was given to the recipient 3 days before operation in our trials as monotherapy, the survival time of the recipient was not prolonged due to the strong rejection in this model.

In this study, conjunctival hyperemia occurred in all untreated control recipients on day 4-5 after operation, and deteriorated rapidly, even resulted in ablepsia. However, in the recipients treated with T_{II}, the sign occurred only in 31 % rats (on day 5-6 after transplantation) and ablepsia did not occur. The differences between the two groups were highly significant and the similar report has not been found in literature. We speculated that conjunctival hyperemia could be a local representation of rejection in this model. Relieving the sign with T_{II} treatment supported the hypothesis, but the exact mechanism of the sign needs to be further studied.

Abstract

AIM: Rodent testes are generally more susceptible to cadmium (Cd)-induced toxicity than liver. To clarify the molecular mechanism of Cd-induced toxicity in testes, we compared metallothionein (MT) gene expression, MT protein accumulation, and Cd retention at different time in freshly isolated testicular interstitial cells and liver of rats treated with Cd.

METHODS: Adult male Sprague-Dawley rats weighing 250-280 g received a s.c injection of 4.0 μmol Cd/kg and were euthanized by CO_2 asphyxiation 1 h, 3 h, 6 h, or 24 h later. Tissue was sampled and testicular interstitial cells were isolated. There were three replicates per treatment and 3 animals per replicate for RNA analyses, others, three replicates per treatment and one animal per replicate. MT1 and MT2 mRNA levels were determined by semi-quantitative RT-PCR analysis followed by densitometry scanning, and MT was estimated by the enzyme-linked immunosorbent assay (ELISA) method. Cadmium content was determined by atomic absorption spectrophotometry. The same parametersd were also analyzed in the liver, since this tissue unquestionably accumulate MT.

RESULTS: The rat testis expressed MT1 and MT2, the major isoforms. We also found that untreated animals contained relatively high basal levels of both isoform mRNA, which were increased after Cd treatment in liver and peaked at 3 h, followed by a decline. In contrast, the mRNA levels in interstitial cells peaked at 6 h. Interestingly, the induction of MT1 mRNA was lower than MT2 mRNA in liver of rat treated with Cd, but it was opposite to interstitial cells. Cd exposure substantially increased hepatic MT (3.9-fold increase), but did not increase MT translation in interstitial cells.

CONCLUSION: Cd-induced expression of MT isoforms is not only tissue dependent but also time-dependent. The inability to induce the metal-detoxicating MT-protein in response to Cd, may account for a higher susceptibility of testes to Cd toxicity and carcinogenesis compared to liver.

INTRODUCTION

Metallothionein (MT) gene expression appears to be not only tissue specific but also cell specific[1,2]. In rodents, the testes and ventral prostate have been shown to have a higher sensitivity to cadmium (Cd)-induced carcinogenesis than many other tissues[3]. These tissues have also been shown to have either no induction or a reduced expression of MT gene when animals were exposed to Cd or some other MT inducer agents[4,5]. It has been reported that testicular Cd is bound to a protein different from MT. The testicular Cd-binding protein contains less cysteine and more glutamate than MT[6]. However, some other studies have shown that MT is constitutively expressed in the whole testes or specific testicular cells at levels higher than that in some other organs, e.g. the liver, and that *in vivo* or *in vitro* Cd exposure increases MT gene expression in the testes[7-9].

Therefore, the published data are inconclusive as to whether MT exists in the testes under physiological conditions and whether this protein plays an important role in the detoxification of testicular Cd. Some of the controversies may derive from analyzing the whole testicular tissue instead of individual cell types, since MT gene expression appears to be not only tissue specific but also cell specific[1,2]. On the other hand, MT might affect testicular Cd accumulation toxicokinetically by sequestering the metal in the liver, thus diverting it from target tissues, such as the testes. It has been well established that Cd significantly enhances hepatic MT gene expression and MT synthesis. Such enhancement of liver MT might lead to lower testicular Cd uptake and toxicity.

In rodents testicular Cd appears to be localized in the interstitial tissue and a high incidence of interstitial cell (Leydig cell) tumors can occur following Cd exposure. However, testicular lesions as a result of Cd exposure have not been reported in men[10]. A single s.c. dose $\geqslant$5 μmol Cd/kg could result in a high incidence of testicular interstitial cell tumors. An elevated incidence of testicular tumors in rats was also found after chronic oral exposure to Cd. Within the interstitial tissue, Leydig cells appeared to be highly sensitive to Cd cytotoxicity[11]. However, most of the studies on MT gene expression and synthesis have been focused on the whole testes, which might mask the results on MT activity in these specific cells, since they only contributed to 11 % of parenchymal volume. Some authors investigated Cd-induction of MT expression in cultured Leydig cell lines established from Leydig cell tumors[12], but their findings gave little insight into MT synthesis in normal testicular interstitial cells or purified Leydig cells isolated from animals exposured to Cd.

Furthermore, MT gene expression is time-dependent. It was reported that both MT isoform mRNA levels in rat livers were substantially increased 4-6 h after Cd treatment, followed by a reduction and chromatography demonstrated a significant time-related increase in MT protein level. *In vitro* studies showed that MT induction was dose- and time-dependent in both Leydig and Sertoli cells[13]. Therefore some of the controversies may derive from the different study time.

In general, the studies on Cd-induced MT gene expression and MT synthesis in the testis, have been carried out under acute exposure to toxic Cd levels. It is also conceivable that

the biochemical changes occurring in the testes under such conditions of Cd toxicity might mask the molecular processes of MT gene expression at a lower Cd exposure dose.

Although there is a wealth of published information regarding MT gene expression and MT synthesis following induction by Cd[14-16], little systematic information is available on MT gene expression at different time in testes, particularly in testicular interstitial cells. The aim of this study therefore was to clone MT gene and to investigate MT gene expression, MT accumulation, and Cd retention at different time in testicular interstitial cells isolated by collagenase dispersion and density gradient centrifugation from rats treated with a non-toxic Cd dose. The same parameters in the liver were also analyzed, since this tissue unquestionably accumulated MT.

MATERIALS AND METHODS

Animals and treatments

Adult male Sprague-Dawley rats weighing 250-280 g were obtained from the Animal Center of Second Military Medical University. Rats received a single s.c. injection of 4 μmol Cd/kg and were euthanized by CO_2 asphyxiation 1 h, 3 h, 6 h, or 24 h later for RNA, total Cd, and MT analyses in interstitial cells and liver. Untreated rats (0 h) were also treated as described above. There were three replicates per treatment and 3 animals per replicate for RNA analyses, others, three replicates per treatment and one animal per replicate. Testes and liver were weighed and processed as described below.

Preparation and purification of testicular interstitial cells

Immediately after the testes were removed, these cells were decapsulated, deveined and incubated in a solution of 2 mg/ml collagenase (334 μ/mg, Type IA, Worthington Biochemical Co.) with minimum essential medium (MEM) (6 ml/2 testes) at 37 ℃ in a shaking water bath at 90 oscillations/min for 15 min. DNase (Sigma Chemical Co.) was added as needed (5-10 drops of 0.1 %) to reduce the clumping of cells to the DNA released from damaged cells. After collagenase dispersion, the digestion media were diluted with 12 ml prewarmed MEM and the tubules were allowed to settle. The resultant supernatant was centrifuged at 80×g for 10 min at 4 ℃. Crude interstitial cells from 2 testes were resuspended in ≤3 ml cold MEM and layered on the top of a linear (0-50 %) Percoll density gradient. The gradient was prepared in a LKB gradient mixer with 4 ml of a solution containing 50 % Percoll, 0.15 M NaCl, and 0.07 % bovine serum albumin (BSA) in the diluting chamber and 4 ml of an aqueous solution with 0.15 M NaCl, and 0.07 % BSA in the mixing chamber. Crude interstitial cells were then separated from other cell types by centrifugation at 800×g for 20 min in tubes (8×1.5 cm, 3 tubes for one type of cells from one sample) at 4 ℃. Purified interstitial cells formed a distinct band at 41-42 mm from the gradient bottom. Cell band was aspirated, diluted three times its volume with cold MEM to remove Percoll and centrifuged at 80×g for 10 min. Testicular interstitial cells were then suspended in a minimal volume of MEM and processed for RNA, total Cd, or MT protein analysis after aliquots was taken for cell count. Morphological observations by light microscopy showed that the purity ranged from 80 % to 85 %.

Cadmium content

Interstitial cells and liver tissue were wet-ashed in HNO_3 (u. p.)-H_2O_2 and Cd was determined by atomic absorption spectrophotometry (detection limit: 0.001ppm). Precautions were taken to avoid Cd contamination by acid-washing all glasswares and blanks were run along with the samples.

RNA extraction

Total ribonucleic acids were extracted from freshly isolated interstitial cells and liver tissue using RNAzol (GibcoBRL). Total RNA was determined by UV absorbance at 260 nm and its purity was estimated by the absorbance ratio A_{260}/A_{280} nm. In addition, RNA integrity was confirmed by ethidium bromide staining of ribosomal RNA following gel electrophoresis.

Polymerase chain reaction(PCR) primers

Oligonucleotide primers were synthesized using a DNA synthesizer (Worthington Biochemical Co.). The sequences of sense and antisense primers for rat MT-1 were 5'-ACTGCCTTCTTGTCGCTTA-3' and 5'-TGGAGGTGTA-CGGCAAGACT-3' respectively. They spanned a 310bp fragment. The sequences of sense and antisense primers for rat MT-2 were 5'-CCAACTGCCGCCTCCATTCG-3' and 5'-GAAAAAAGTGTGGAGAACCG-3' respectively, spanning a 300bp fragment. The sequences of sense and antisense primers for β-actin were 5'-CCCATTGAACACGG-CATTG-3' and 5'-GGTACGACCAGAGGCATACA-3' respectively, spanning a 236bp fragment.

Reverse transcription-PCR (RT-PCR) and products analysis

First-strand cDNA was synthesized with 1 μg total RNA, 50 pmol oligo (dT)18, 10U avian myloblastosis virus (AMV) reverse transciptase and 20U RNase inhibitor in a final 20 μl reaction mixture containing 1× reverse transcriptase buffer, 8 mM $MgCl_2$, 0.5 mM of each dNTP. The reaction mixture was incubated at 42 ℃ for 60 min. The cDNA products were stored at -20 ℃ until use.

PCR was carried out in a 25 μl reaction mixture containing 0.2 mM of each dNTP, 1 pmol of each sense and antisense primer and 0.625 unit of Taq DNA polymerase (TaKaRa), including 4 μl of cDNA products. After an initial denaturation at 95 ℃ for 5 min, amplification was carried out for approximately 27 cycles comprising 1 min at 95 ℃ for denaturation, 1 min at 55 ℃ for annealing, 1 min at 72 ℃ for extension with a final entension step at 72 ℃ for 5 min. The PCR products were applied to electrophoresis using a 2.0 % (w/v) agarose gel, which was stained with ethidium bromide and visualized under UV light. In order to confirm that there was no significant contamination in the total RNA preparation, we synthesized the first-strand DNA and performed control reactions in the absence of reverse transcriptase, and did not find any band on further PCR. In order to guarantee amplification in phase of exponential increase, we minimize the cycles of PCR in condition that the strap of gel electrophoresis could be detected. MT1 and MT2 mRNA levels were determined by RT-PCR analysis followed by densitometry scanning. All MT1 and MT2 RT-PCR products were normalized to the corresponding β-actin RT-PCR results that served as an internal control to ensure an approximate ratio of MTs mRNA.

Cloning of PCR products

PCR products were cloned using pUCm-T vector, The constructed plasmids were transfected into JM109, positive colonies were selected and the DNA sequence was analysed using a DNA sequencer (Worthington Biochemical Co.).

MT content analysis

Testicular interstitial cells were suspended in 500 μl of 10 mM Tris-HCL, pH 7.4, and lysed by sonication (3×10 s) on ice. Cytosol was then obtained by centrifugation at 18 000×g for 20 min at 4 ℃. Liver tissue was homogenated in 10 mM Tris-HCL, pH 7.4, with a glass homogenizer and a Teflon pestle. MT content analysis was performed by the enzyme-linked

immunosorbent assay (ELISA) method. The test procedure was similar to that described by Ruitenberg *et al*[17] and affinity-purified sheep anti-(rat MT) IgG was provided by Environmental Health Sciences Division, National Institute for Environmental Studies, Japan.

Statistical analysis

Data were represented as means ±S.E. of three replicates per Cd treatment or untreatment. Differences between Cd-treated (1 h, 3 h, 6 h, 24 h) and untreated rats were evaluated by Student' s *t*-test with $P<0.05$ as the limit of significance.

RESULTS

DNA sequences of RT-PCR products

After cloning the RT-PCR products described above into a pUCm-T vector, we examined their DNA sequences (Figure 1) and compared with rat liver MT1 and MT2 cDNAs. These data clearly indicate that the MT1 and MT2 genes are constitutively expressed in the rat testis.

Cadmium content

Cadmium accumulated in the liver rapidly after its administration, but then leveled off. 24 h after Cd content in the liver increased about 10 000-fold whereas interstitial cell Cd was not detected (Figure 2). This indicated that the Cd content in interstitial cells might be below atomic absorption spectrophotometry detection limit (<1 ng/10^7 cells).

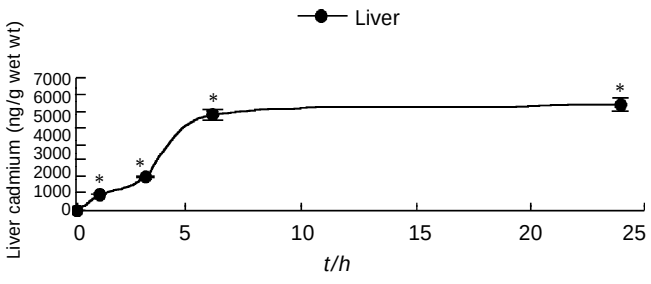

Figure 2 Time course of Cd accumulation in liver after a single subcutaneous injection of 4 μmol Cd / kg. The values were the mean ± S.E. (n=3). An asterisk indicated a significant difference (*P<0.05 *vs* control) from the untreated.

Effects of cadmium on transcription of MTs in interstitial and cells liver

To assess gene expression of both MT1 and MT2 genes, semi-quantitative RT-PCR was used. Results from the semi-quantitative RT-PCR (Figure 3) showed that untreated animals contained relatively high basal levels of both isoform mRNA, which were substantially increased after Cd treatment in the liver and peaked at 3 h, followed by a decline. In contrast, the mRNA levels in interstitial cells peaked at 6 h (Figure 3). Interestingly, the induction of MT1 mRNA was lower than MT2 mRNA in the liver of rats treated with Cd, but it was opposite to interstitial cells.

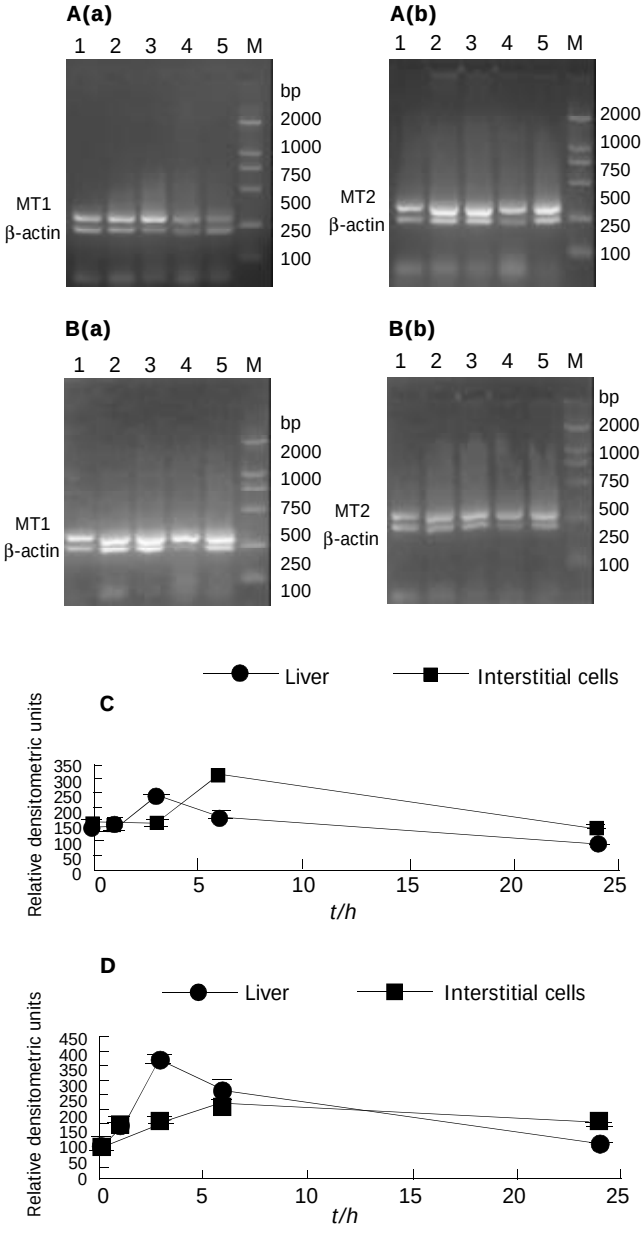

Figure 3 Effect of cadmium treatment on MT1(a) and MT2(b) mRNA levels in testicular interstitial cells (B) and the liver (A) of untreated rats (0h) and Cd-treated rats after 1 h, 3 h, 6 h, or 24 h (lanes 1-5). Values were obtained by RT-PCR analysis followed by densitometry scanning and expressed as MT1(C) or MT2(D) mRNA RT-PCR products to β-actin mRNA RT-PCR products ratio. Data represented the mean ± SE (n=9, three treatment replicates with three analyses per replicate).

Effects of cadmium on translation of MT in testicular interstitial cells and liver

In parallel to the elevation of liver Cd, the level of hepatic MT

increased significantly (3.9 hold increase) 24 h after Cd injection (Figure 4). In sharp contrast to the 3.9-fold elevation of hepatic MT, the MT in testicular interstitial cells of rats treated with Cd slightly declined as compared to untreated animals.

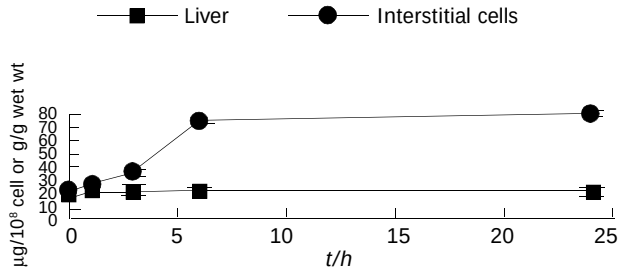

Figure 4 Metallothionein protein in testicular interstitial cells and liver of untreated and Cd-treated rats. Experimental conditions are shown in Figure 3. The values were the mean ± S.E. (n= 3).

DISCUSSION

MTs exist not only in tissues from various animal species, but also in bacteria and plants, and are thought to play essential, but as yet unknown roles in cellular processes[18-22]. MTs are known to detoxify heavy metals. However, male genital organs, particularly testis, are extremely susceptible to Cd. Thus, it has been a long-standing issue as to whether MTs are present in male genital organs or not. We have previously summarized the major points of dispute arising from earlier studies that advocated either the presence or the absence of MTs in the testis, since these earlier studies utilized indirect experimental methods to characterize testicular Cd-binding proteins. Therefore,we considered it essential to analyse directly the cDNA sequence. It has been demonstrated by RT-PCR analysis and DNA sequence analysis of the cloned PCR products that MT1 and MT2 genes are transcripted as their respective mRNA in the rat testis. The present results have clearly shown that the rat testis contains MT1 and MT2, the major isoforms of MT, thus supporting the results of earlier studies, not only in turns of the amounts of MT(-like) proteins estimated by the Cd-binding method in the rat testis, but also in regard to the localization of MT in male genital tissues.

Our observations demonstrated that MT1 and MT2 mRNAs were expressed in interstitial cells under normal physiological conditions, which confirmed the results of others in the whole testes of rats and mice. Furthermore, our results showed that both MT1 and MT2 mRNA increased, but did not translate into any higher protein in interstitial cells in response to Cd treatment. Cd-inducibility of MT1 and MT2 mRNA that we observed in freshly isolated intertitial cells, corroborated the findings of others using cultured mouse interstitial tumor cell lines exposed to Cd *in vitro*. In contrast, other reports indicated decrease, no changes, or little increases of MTs mRNA levels in the whole testes of Cd-treated rats and mice[16,23]. The discrepancy in the results among the various studies might be due to analysis of whole testicular tissue rather than isolated interstitial cells, or species and strain differences in Cd-induced MT. MT expression in male reproductive tissue might also depend on doses, time course between Cd administration and tissue sampling, age and reproductive states of the animals[24]. The present data showed that untreated animals contained relatively high basal levels of both isoforms of mRNA, which were substantially increased after Cd treatment in the liver and peaked at 3 h, followed by a decline. In contrast, the mRNA levels in interstitial cells peaked at 6 h (Figure 3). Interestingly, the induction of MT1 mRNA was lower than MT2 mRNA in the liver of rats treated with Cd, but it was opposite to interstitial cells. This indicates that Cd-induced transcription of MT gene is not only tissue-dependent, but also time-dependent. Therefore, the time selected to analyse mRNA levels might be another source of discrepancy. Furthermore, both isoforms were different from Cd-induction in different tissues or cells. The cause is unclear, and might be related to methylation status of the MT gene, since DNA methylation controls MT gene expression in murine lymphoid cells.

We also found that interstitial cells isolated from unteated animals contained relatively high basal levels of MT protein, thus supporting the results of earlier studies that MT were constitutively present in the testes at levels higher than that in many other tissues, such as the liver and kidney[25].

MT might not have any significant role in the detoxification of Cd in the testes, since 20 μmol Cd/kg destroyed the testicular endothelium of both normal mice and mice with inactivated MT1 and MT2 genes. Furthermore, mouse strain differences in Cd-induced testicular toxicity have not been reported to be correlated with testicular MT levels. In fact, resistance to Cd-induced testicular necrosis is linked to the cdm gene, which is located in a different chromosome from the genes for MT1 and MT2.

One hypothesis, which may explain why Cd-induced MT mRNA in interstitial cells was not accompanied by an increase of MT synthesis, is that MT mRNA increases were not translated into the corresponding protein. The existence of nonfunctional MT translations in interstitial cells could explain the higher susceptibility of testes than the liver to Cd toxicity. On the other hand, the absence of an increase in the MT gene translation product in interstitial cells accompanied by a significant increase in the liver of Cd-treated animals, could also be due to kinetic differences between interstitial cells and liver on the rate at which MT mRNA molecules were translated into MT or the rate of MT degradation[1]. The discrepancy between MT mRNA and MT protein in interstitial cells suggested that MT synthesis was regulated at the level of post-transcription[26], since an increase of mRNA should not result in decreased protein if regulation was only through transcription. While it is well known that MT gene expression is specifically induced by metals through metal response elements and the heavy metal induction of MT is mediated through the transcription factor MTF-1[27-29]. We not determine whether the effect of these metals on MT mRNA translation and/or protein degradation was specific to MT. Therefore it is possible that the metals have a more widespread effect on translation of genes[30-32]. However, it is clear that metals do not have a widespread effect on gene transcription through stress or nonspecific events. For example, housekeeping genes, such as β-actin or dihydrofolate reductase, in the liver and kidney of CD-1 mice were unaffected when treated with 0.6 mg cadmium/kg.

In summary, our observations clearly demonstrate that both MT mRNA and MT are constitutively expressed in isolated interstitial cells and Cd-induced expression of MT isoforms are not only tissue dependent but also time-dependent. Our findings of Cd-induced MT mRNA without increases in MT protein in interstitial cells deserve further investigation. The inability to induce metal-detoxicating MT-protein, in response to Cd, might account for the higher susceptibility of testes to Cd toxicity and carcinogenesis compared to the liver.

ACKNOWLEGEMENTS

We thank for Prof. Chiharu Tohyama for kindly providing affinity-purified sheep anti-(rat MT) IgG and Dr. Xu Qin-Hua for invaluable assistance with analysis of cadmium content.

Abstract

AIM: To explore the anti-fibrotic effect of a traditional Chinese medicine, compound rhodiola sachalinensis A Bor on CCl_4-induced liver fibrosis in rats and its probable molecular mechanisms.

METHODS: Ninety healthy male SD rats were randomly divided into three groups: normal group (n=10), treatment group of compound rhodiola sachalinensis A Bor (n=40) and CCl_4-induced model group (n=40). The liver fibrosis was induced by CCl_4 subcutaneous injection. Treatment group was administered with compound rhodiola sachalinensis A Bor (0. 5 g/kg) once a day at the same time. Then the activities of several serum fibrosis-associated enzymes: alanine aminotransferase (ALT), aspartate aminotransferase (AST), N-acetyl-beta-D-glucosaminidase (β-NAG) and the levels of serum procollagen III (PCIII), collagen IV (CIV), hyaluronic acid (HA) were assayed. The histopathological changes were observed with HE, VG and Masson stain. The expression of TGF-β1 mRNA,α1 (I) mRNA and Na^+/Ca^{2+} exchanger (NCX) mRNA was detected by reverse transcription polymerase chain reaction (RT-PCR) *in situ*.

RESULTS: Compound rhodiola sachalinensis A Bor significantly reduced serum activities of ALT, AST, β-NAG and decreased the levels of PCIII, CIV, HA, improved the liver histopathological changes, inhibited the expression of TGF-β1 mRNA, α(I) mRNA and Na^+/Ca^{2+} exchanger mRNA in rats.

CONCLUSION: Compound rhodiola sachalinensis A Bor can intervene in CCl_4-induced liver fibrosis in rats, in which potential mechanisms may be decreasing the production of TGF-β1, reducing the production of collagen, preventing the activation of hepatic stellate cell (HSC) and inhibiting the expression of TGF-β1 mRNA, α1(I) mRNA and Na^+/Ca^{2+} exchanger mRNA.

INTRODUCTION

Transforming growth factor beta 1 (TGF-β 1) is the most potent profibrogenic mediator in liver fibrosis and cirrhosis as shown in animal models and human chronic hepatic injury[1-4]. It plays critical roles in the activation of hepatic stellate cell (HSC) and the regulation of the production, degradation, and accumulation of extracellular matrix (ECM) proteins[5-7]. Recent studies have identified that TGF-beta 1 mRNA transcription is significantly increased during chronic liver injury. Thus the TGF-beta signal transduction pathway has become a new effective target for the prevention or treatment of liver fibrosis[8-11]. Several traditional Chinese herbs have been shown to have the ability of intervention in liver fibrosis[12-20], however, most of them were limited in morphological and serum studies, lacking of deep research in their molecular biological mechanisms. Our previous study has shown another Chinese medicine, compound rhodiola sachalinensis A Bor, can effectively prevent CCl_4-induced liver fibrosis in rats[21-23]. In this study, the probable biological mechanism of it, especially in the expression of TGF-beta 1 mRNA, α1(I) mRNA and Na^+/Ca^{2+} exchanger mRNA was explored.

MATERIALS AND METHODS

Animals

Male SD rats (weighing 140-160 g) were obtained from the Experimental Animal Center of Sichuan University (Chengdu, Sichuan Province, China). The rats were housed in a room with controlled temperature (15-20 ℃) and lighting (10 h light, 14 h dark). Free access to water and food was allowed during the experimental period. All the rats were randomly divided into three groups: normal group (n=10), treatment group (n=40) and model group (n=40). For model group, 300 mL/L CCl_4 in liquid paraffin was injected subcutaneously at a dose of 3 mL/kg twice weekly. The treatment group, apart from the administration of CCl_4, was fed with compound rhodiola sachalinensis A Bor 0.5 g/kg once per day. The model group was given normal food and water, received injection of liquid paraffin with the same dosage and duration as CCl_4.

At the end of the 15-week experimental period, all the rats were anesthetized with intramuscular injection of sodium pentobarbital (30 mg/kg) before sacrificed. Blood was collected from the heart and the serum obtained through centrifugation. The liver was removed rapidly, part of it was conserved in 100 mL/L neutral formalin, and the rest was frozen in a refrigerator at -20 ℃.

Serum parameters of hepatic fibrosis

Parameters of hepatic fibrosis were determined by levels of type III procollagen (PCIII), type IV collagen (CIV) and hyaluronic acid (HA),using radioimmunoassay (commercial kit obtained from Shanghai Navy Medical Institute, China). Serum activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were assayed by a automatic analyzer. Another serum enzyme N-acetyl-beta-D-glucosaminidase (β-NAG) was assayed with spectrophotometric method.

[a]$P<0.01$ *vs* model group.

Histopathological grading

Liver samples from each rat were embedded in paraffin, stained with hematoxylin-eosin (HE), Van Gieson (VG) and Masson trichrome collagen stain, and then examined under an optical microscope. Fibrosis-degree of liver sections was graded numerically based on the criteria described below: 0, no fibrosis; +, slight fibrosis, fibrosis located in the central liver lobule; +2, moderate fibrosis, widen central fibrosis; +3, severe fibrosis, fibrosis extended to the edge of liver lobule; +4, liver cirrhosis.

Molecular biological detection: RT-PCR in situ

Each liver sample embedded in paraffin was sectioned and fixed onto a poly-L-lysine covered glass. The expression of α1(I) mRNA, TGF-β1 mRNA and Na^+/Ca^{2+} exchanger (NCX) mRNA was detected with RT-PCR *in situ*. (primers obtained from Shanghai Sangon Biotechnology Co. Ltd.) (Table 1).

Statistical analysis

Data were analyzed using *t*-test and Microsoft Excel 2000.

RESULTS

Changes of serum fibrosis-associated markers

In model group, the serum activities of ALT, AST and β-NAG were significantly increased ($P<0.01$), the serum levels of PCIII, CIV and HA were also elevated ($P<0.01$). With administration of compound Rhodiola Sachalinensis A Bor (RSC), serum activities of ALT, AST, β-NAG and levels of PCIII, CIV, HA were decreased obviously ($P<0.01$), although they were still higher than those in normal group ($P<0.05$) (Table 2).

Histopathological changes of the liver

The control livers showed a normal lobular architecture with central veins and radiating hepatic cords. The staging score was 0. Subcutaneous injection of CCl_4 caused severe liver pathological damages such as: inflammation, necrosis and excessive collagen deposition. The semiquantitative staging score of hepatic fibrosis was raised to 3.53±0.68 in model group. The livers in treatment group showed less inflammation, necrosis, collagen deposition and a significantly decreased staging score of 2.43±0.47 ($P<0.05$) (Table 3, Figures 1, 2).

Molecular biological changes

Scoring method: according to the number of positive cells within one visual field on average. (-), no positive cells, scoring 0; (+), positive cells <1/3, scoring 1; (++), positive cells <2/3, scoring 2; (+++), positive cells >2/3, scoring 3. There were less positive signals of α1(I) mRNA, TGF-β1 mRNA and Na^+/Ca^{2+} exchanger mRNA detected with RT-PCR *in situ* in normal group, in which scores were 1.11, 0.75, 0.10 and the ratio of positive samples was 77.8 %, 62.5 %, 10.0 % respectively (Tables 4-6). In model group, the positive signals of RT-PCR *in situ* for α1(I) mRNA, TGF-β1 mRNA and Na^+/Ca^{2+} exchanger mRNA were significantly enhanced. The semiquantitative scores of them were increased to 2.80, 2.40, 2.30 and the ratio of positive samples rised to 100.0 %, 90.0 %, 100.0 % respectively ($P<0.01$). Treatment with RSC made the scores reduced to 1.63, 1.20, 1.50, and positive ratio lowered to 87.5 %, 80.0 %, 80.0 % respectively in comparison with model group ($P<0.05$) (Tables 4-6, Figures 3-6).

DISCUSSION

Liver fibrosis is generally preceded by chronic liver injury despite of its primary causes, including alcohol, hepatic virus, oxidant stress and other persistent damages. The activation of hepatic stellate cells (HSC) is considered to be of great importance during the long period of liver fibrosis, which is induced by some critical cytokines and then becomes the main source of most collagen proteins[24]. Among the cytokine mediating factors, transforming growth factor beta 1 (TGF-β1) has been considered as the essential profibrogenesis factor and the main target of treatment[25-31]. Additionally, Na^+/Ca^{2+} exchanger was a newly noticed factor whose expression increased along with the activation of HSC, and its real role in liver fibrosis has not been interpreted[32]. Thus, detection of the expression of TGF-β1 and Na^+/Ca^{2+} exchanger mRNA is useful in exploring the probable mechanisms of anti-fibrotic drugs.

Several drugs, including cytokines, antioxidant, chemical drugs, soluble type II receptor of TGF-β1[9, 33], antibody of TGF-β1 have been used to block liver fibrosis. But their effects are not as prosperous as we expected[1]. Besides, some traditional Chinese drugs have been found to be effective on preventing fibrogenesis and other chronic liver injury, which develop a more hopeful future in controlling liver fibrosis and cirrhosis. The present study aimed at exploring the effects of a traditional Chinese herb, compound rhodiola sachalinensis A Bor, which consists of rhodiola sachalinensis A Bor, sophora flavescens Ait and other herbs, on the prevention of CCl_4-induced liver fibrosis in rats. The potential mechanisms of RSC was explained at the same time.

In this study, chronic administration of CCl_4 caused liver fibrosis and cirrhosis as indicated by the changes of serum markers, histopathological changes, and molecular biological changes. The activities of serum fibrosis-associated enzymes, namely ALT, AST, β-NAG and contents of extracellular matrix (ECM) components (PCIII, CIV, HA) were significantly

increased along with increased expression of α1(I) mRNA, TGF-β1 mRNA and Na^+/Ca^{2+} exchanger mRNA. Under the light microscope, the liver fibrosis/cirrhosis was verified by the typical liver structure: inflammation, necrosis and excessive collagen deposition, some of the samples even had pseudolobules. With the therapy of compound rhodiola sachalinensis A Bor, serum parameters of liver fibrosis (ALT, AST, β-NAG, PCIII, CIV, HA) were significantly decreased ($P<0.01$). HE, VG and Masson stained histopathological sections showed mild inflammation, necrosis and fewer collagen deposition. The semiquantitative fibrosis staging scores were also decreased obviously ($P<0.01$). The expression of α1(I) mRNA, TGF-β1 mRNA and Na^+/Ca^{2+} exchanger mRNA was significantly inhibited using RT-PCR *in situ* ($P<0.01$). These results suggest that compound rhodiola sachalinensis A Bor may prevent experimental liver fibrosis by modulating the synthesis and releasing of critical cytokines, such as TGF-β1, thus inhibiting the activation of HSC and its production of collagen proteins. The inhibition of Na^+/Ca^{2+} exchanger mRNA may partly relate to its anti-fibrotic effects. In conclusion, traditional Chinese medicine compound rhodiola sachalinensis A Bor has significant anti-fibrogenesis effects on CCl_4-induced liver fibrosis in rats. The probable molecular mechanisms may include blocking the synthesis of TGF-β1, interfering with the activation of HSC, preventing production and deposition of collagen, and inhibiting the expression of Na^+/Ca^{2+} exchanger mRNA. The exact molecular mechanisms remain to be explored.

Abstract

AIM: To investigate the effect of tetramethylpyrazine on hepatic/renal ischemia and reperfusion injury in rats.

METHODS: Hepatic/renal function, histopathological changes, and hepatic/renal P-selectin expression were studied with biochemical measurement and immunohistochemistry in hepatic/renal ischemia and reperfusion injury in rat models.

RESULTS: Hepatic/renal insufficiency and histopathological damage were much less in the tetramethylpyrazine-treated group than those in the saline-treated groups. Hepatic/renal P-selectin expression was down regulated in the tetramethylpyrazine-treated group.

CONCLUSION: P-selectin might mediate neutrophil infiltration and contribute to hepatic/renal ischemia and reperfusion injury. Tetramethylpyrazine might prevent hepatic/renal damage induced by ischemia and reperfusion injury through inhibition of P-selectin.

INTRODUCTION

Hepatic/renal ischemia-reperfusion injury is common clinically. Up to now, there has been no effective treatment for this pathological injury. Cell adhesion molecules have been found to play an important role in hepatic/renal ischemia-reperfusion injury by mediating interactions of polymorphonuclear neutrophils with endothelium. P-seletin monoclonal antibody has been demonstrated to prevent effectively reperfusion-induced hepatic/renal tissue damage[1-23]. Tetramethylpyrazine (TMP), a traditional Chinese herb, has been widely used especially in the treatment of patients with cerebral and cardiac ischemic diseases in China. Experimental study has found that TMP could protect vascular endothelial cells, and inhibit respiratory explosion and free radicals of polymorphonuclear neutrophils[24-28]. In the present study, we investigated the effect of TMP and P-selectin on hepatic ischemia and reperfusion injury in rats.

MATERIALS AND METHODS

Animal model

Ninety male Wistar rats (Shanghai Experimental Animal Center of Chinese Academy of Sciences), weighing 200±10 g, were given free access to food and water for three days before the experiments. The rats were anesthetized with 2.5 % sodium pentobarbital intraperitoneally, and randomly divided into 2 groups. In one group of rats, the ligament linking liver, diaphragm and abdominal wall were separated, the portal vein and liver artery that drain blood to left hepatic lobe were freed by blunt dissection and then blocked with a microvascular clamp for 60 minutes, then the clamp was removed, and reperfusion was performed. While in the other group, the left renal artery was freed, and blocked with a microvascular clamp for 60 minutes, then the clamp was removed and reperfusion was performed, simultaneously, the right kidney was cut off. The two groups of rats were randomly divided into TMP-treated group (n=20) and non-treated group (n=20). They were divided into subgroups according to the indicated time 1,3,6,24 hours after reperfusion. TMP or saline was intravenously injected five minutes before the reperfusion. A sham-operated group (n=5, anesthesia and opening celiac cavity, no blocking of hepatic or renal blood flow) served as control.

Collection and measurement methods of specimens

Blood and hepatic and renal tissues were harvested at the indicated time. Serum levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and blood urea nitrogen (BUN) and creatinine (Cr) were measured with a 747 automatic analyzor (Hitachi Boehringer Mannhein, Mannhein, Germany). Hepatic and renal tissue samples were fixed in 10 % formalin and embedded in paraffin. 5 μm thick sections were cut into and stained with hematoxylin and eosin for light microscope examination. Expression of P-selectin in hepatic/renal tissue was detected by immunohistochemistry method with a labeled streptavidin biotin (LSAB) kit (Fujian Maixin Biotechnology Co., products of Biotechnology Co. CA, USA).

Statistical analysis

Data were presented as $\bar{x}\pm s$, and Student' s t test was used to determine changes between different groups. $P<0.05$ was considered significant.

RESULTS

Histopathologic evaluation

One hour after reperfusion, visual observation revealed that the left hepatic lobe was more swollen than the right lobe, and was dark in color. Under the light microscope, interstitial congestion and infiltration of inflammatory cells were

observed. One hour after reperfusion, the renal cortex was macroscopically pale, the renal medulla displayed blood stagnation and was dark in color. Under the light microscope, edema, denaturation with different extent and necrosis of renal tubular epithelial cells were observed. Simultaneously, interstitial congestion, edema and infiltration of inflammatory cells were also observed. However, in the TMP-treated group, the outward appearance of the liver and kidney was similar to that of normal. Hepatic cells and tubular cells showed less swelling and no denaturation or necrosis, and interstitial changes were not obvious.

Hepatic and renal function evaluation

Twenty four hours after hepatic reperfusion, the serum levels of ALT (628±91 u/L) and AST (1 608±199 u/L) in the saline-treated group were much higher than those in the sham-operated group (52±11 u/L and 80±17 u/L respectively, $P<0.01$). The TMP-treated group revealed significantly lower levels of ALT (190±21 u/L) and AST (386±62 u/L) than those in the saline-treated group ($P<0.01$).

Twenty four hours after renal reperfusion, the serum levels of BUN (14.54±0.67 mmol/L) and Cr (102.2±4.67 μmol/L) were much higher in the TMP-treated group than those in the sham-operated group (7.88±0.57 mmol/L and 39.00±4.47 μmol/L, respectively, $P<0.01$). The TMP-treated group presented with significantly lower levels of BUN (11.21±0. 56 mmol/L) and Cr (70.61±4.95 μmol/L) than those in the saline-treated group ($P<0.01$).

P-selectin expression in hepatic and renal tissues

P-selectin was expressed widely within hepatic and renal tissues 1 hour after reperfusion, which was mainly distributed on small vessels of left hepatic lobe and kidney. In addition, it was also expressed on part of hepatic cellular membrane, glomerulomesangium, capillary loops, and interstitium. After treatment with TMP, there were no obvious yellow-brown positive granules in the hepatic and renal tissues, suggesting that P-selectin expression was not displayed.

DISCUSSION

Recently, the role of cell adhesion molecules and neutrophils in ischemia and reperfusion injury has aroused attention[29-50]. Ischemia reperfusion liver injury is characterized by microvascular leukocyte accumulation and massive infiltration of postischemic tissues. Primary leukocyte endothelial cell interaction(rolling) is mediated by selectins, whereas firm adherence and transendothelial migration involve immunoglobulin superfamily(intercellular adhesion molecule-1, ICAM-1) with leukocyte β_2-integrins (CD11/CD18)[51]. As a potential member of the selectin family, P-selectin has been found in both Weibel-Palade body of epithelial cells of middle and small blood vessels and α-granule of platelets. It is expressed rapidly on the surface of these cells in seconds after their activation. Furthermore, P-selectin can be up-regulated by *de novo* synthesis in the ischemia-reperfusion injury in hours. P-selectin plays an important role in inflammation by initiating neutrophil rolling, adhesion and recruitment to injured tissue[15]. Blockade of P-selectin expression or interaction with its ligands can attenuate leukocyte adherence and infiltration during ischemia and reperfusion injury. And P-selectin monoclonal antibody has been found to have protective effects on the injury[21].

Tetramethylpyrazine (TMP) is an active ingredient of Ligustium Wallich Franch. It has been shown in animal models and clinical investigations that TMP is effective on ischemic diseases such as heart, brain and lung. TMP could block the calcium channel, reduce the bioactivity of platelets and platelet aggregation, and inhibit free radicals, and has inhibitory roles in platelets and arterial thrombus formation in dogs[52]. However, the roles and mechanisms of TMP in treatment of digestive diseases have not been extensively studied.

The effect of TMP on ischemia and reperfusion injury was observed in this study based on the established rat model of hepatic/renal ischemia-reperfusion.

Hepatic and renal tissues displayed significantly histopathologic damages after hepatic/renal ischemia-reperfusion while the serum levels of ALT and AST as well as BUN and Cr were increased. It was showed that hepatic/renal injury induced by ischemia-reperfusion was remarkably attenuated when TMP was given 5 minutes before reperfusion as shown by improved hepatic/renal function and less pathologic damage. The results suggest that TMP has a protective effect on hepatic/renal reperfusion injury by inhibiting the interaction of neutrophils and endothelium.

After ischemia and reperfusion, P-selectin expression was up-regulated in hepatic and renal tissues, suggesting that P-selectin is related to hepatic/renal reperfusion injury. It was found that leukocyte rolling and recruitment were delayed when deficient mice are infected, suggesting that P-selectin is involved in the early events of inflammation mediated by leukocytes[53]. Results from this study showed that P-selectin expression in hepatic and renal tissues was inhibited in TMP-treated group. This is consistent with down-regulated expression of sialyl Lewis X, a ligand for P-selectin located mainly in neutrophils, as with anti-P-selectin therapy (unpublished data). These suggest that P-selectin might mediate neutrophil infiltration within the liver and kidney in the early stage of hepatic/renal reperfusion injury. Furthermore, blockade of P-selectin can attenuate inflammatory cell infiltration and pathological damage. Wu found that TMP could reduce significantly the number of α-granule membrane protein (GMP140) of platelets and had inhibitory effects on platelets and arterial thrombus formation in dogs. TMP can play a protective role in hepatic and renal injury caused by ischemia-reperfusion by inhibiting the adhesion and activation of neutrophils mediated by P-selectin.

In an animal model of thioacetamide (TAA) induced acute hepatotoxicity, increase of serum SGOT and SGPT produced by TAA was decreased by TMP, and increase of malondialdehyde (MDA) produced by TAA was also prevented by *in vitro* addition of TMP to liver homogenates. A rise of serum interleukin-2 was similarly prevented. The results suggest that part of hepatocellular injury induced by TAA is mediated by oxidative stress caused by the action of cytokines through lipid peroxidation, TMP may act by preventing lipid peroxidation[54]. Another study showed that the hepatoprotective effect of TMP might be in part due to its inhibitory ability on membrane lipid peroxidation and free radical formation and its free radical scavenging ability[55]. Therefore, TMP might be effective on the treatment of on reperfusion injury.

Abstract

AIM: To assess the putative involvement of NF-κB and pro-inflammatory cytokines in the pathogenesis of cancer cachexia and the therapeutic efficacy of indomethacin (IND) on cachexia.

METHODS: Thirty young male BABL/c mice were divided randomly into five groups: (a) control, (b) tumor-bearing plus saline, (c) tumor-bearing plus IND (0.25 mg·kg^{-1}), (d) tumor-bearing plus IND (0.5 mg·kg^{-1}), and (e) tumor-bearing plus IND (2 mg·kg^{-1}). Colon 26 adenocarcinoma cells of murine were inoculated subcutaneously to induce cachexia. Saline and IND were given intraperitoneally daily for 7 days from the onset of cachexia to sacrifice. Food intake and body composition were documented, serum levels of TNF-α and IL-6 and activity of NF-κB in the spleen were investigated in all animals.

RESULTS: Weight loss was observed in all tumor-bearing mice. By day 16, body weights of non-tumor mice were about 72 % of healthy controls (P<0.01), and the weight of gastrocnemius was decreased by 28.7 % (P<0.01). No difference was found between groups in food intake (P>0.05). Gastrocnemius weight was increased markedly (P<0.01) after treatment of IND (0.5 mg·kg^{-1}), while the non-tumor body weights were not significantly elevated. Tumor-bearing caused a 2-3 fold increase in serum levels of both TNF-α and IL-6 (P<0.01). The concentration of TNF-α (P<0.05) and IL-6 (P<0.01) in tumor-bearing mice was reduced after administration of 0.5 mg·kg^{-1} IND for 7 days. But the level of IL-6 was slightly elevated following treatment of IND 2.0 mg·kg^{-1}. NF-κB activation in the spleen was increased in tumor-bearing mice in comparison with controls in electrophoretic mobility shift assay (EMSA). NF-κB activity was reduced in mice treated with 0.5 mg·kg^{-1} of IND, whereas a higher NF-κB activity was observed in mice treated with 2.0 mg·kg^{-1} of IND.

CONCLUSION: Colon 26 adenocarcinoma cells can induce severe cancer cachexia experimentally, and the mechanism may be partially due to the enhanced TNF-α and IL-6 in tumor-bearing animals, which is controlled by NF-κB. Low dose of indomethacin alleviates the cachexia, decreases the activation of NF-κB and the serum levels of TNF-α and IL-6, and prevents body weight loss and muscle atrophy, while no further effect is gained by a higher dosage.

INTRODUCTION

Cancer cachexia is characterized by significant weight loss even at an early course of malignancy, and reduces the quality of life of patients as well as responsiveness to chemotherapy. It is the most debilitating and life-threatening aspect of cancer and is associated with psychological distress and a lower quality of life. Thus, it is necessary to clarify the cellular and molecular biological mechanisms of cancer cachexia for the improvement of cancer treatment.

It has been well established that pro-inflammatory cytokines are important in inducing and promoting the development of experimental cancer cachexia. Most research efforts have focused on the role of cytokines of tumor necrosis factor α (TNF-α), interleukin 6 (IL-6) and interleukin 1 (IL-1)[1-4]. Many of these cytokines are responsible for weight loss, an acute phase of protein response, fat and skeletal muscle protein breakdown and elevated energy expenditure in animals and patients[5]. The nuclear factor-kappaB proteins are ubiquitous transcription factors that mediate cellular responses to a diverse array of stimuli, including lipopolysaccharide, reactive oxygen species (ROS) and several cytokines. Over the past decade, significant advances have been made in elucidation of the molecular signals leading to NF-κB activation, as well as in identification of gene regulation by NF-κB. The role of NF-κB proteins in regulating genes associated with immune system and inflammation has been extensively studied. Activation of NF-κB in immune cells upregulates the expression of cytokines, and growth factors that are essential to immune response contribute to inflammation. An autoregulatory feedback loop has been generated with production of cytokines TNF-α and IL-1. NF-κB represents an upstream element of a common pathway that produces catabolic cytokines[6-8]. Such a pathway has an obvious clinical importance in providing potential targets for therapeutic intervention to inhibit or reverse cancer cachexia.

In the present study, a cachectic model was established in mouse bearing colon 26 adenocarcinoma cells for studying the mechanism and therapies of cancer cachexia. As with human cachexia, there was a significant loss of body weight in this model, and the animals had substantial hypoglycemia and an increase of circulating pro-inflammatory cytokines that were thought to be correlative to the onset of cancer cachexia[9-12]. Early researches showed that indomethacin (IND) could prolong the mean survival time of patients with advanced solid cancer[13]. In this study, we chose IND as an anti-inflammatory agent to study its effect on peripheral blood cytokine levels and NF-κB activation in spleen. The purpose of this study was to assess the relationship of NF-κB and cancer cachexia and the role of IND in the treatment of cachexia.

MATERIALS AND METHODS

Animals and tumor implantation

BABL/c male mice aged 6-8 weeks (weighing 19-22 g) were

purchased from the Animal Center of Chinese Academy of Sciences, Shanghai, China. They had free access to standard laboratory chow and tap water, and were maintained in a temperature-controlled room (22±1 ℃) on a 12-h light-dark cycle. Thirty animals were evenly divided into five groups randomly: (a) control, (b) tumor-bearing plus saline, (c) tumor-bearing plus IND (0.25 mg· kg^{-1}, ICN, Biomedicals Inc. Ohio, USA), (d) tumor-bearing plus IND (0.5 mg· kg^{-1}), and (e) tumor-bearing plus IND (2 mg· kg^{-1}). The mice were allowed to adjust to new environment and diet for at least 1 week before experiment.

Colon 26 adenocarcinoma is appropriate for investigating cancer cachexia. This murine tumor is responsible for inducing weakness, abnormal carbohydrate metabolism, hypercorticism, and elevated levels of pro-inflammatory cytokines. Colon 26 adenocarcinoma cells were kindly supplied by Institute Materia Medica, Chinese Academy of Medical Sciences. Stock cells were passed on the BABL/c mice. Mice of passages three or four were used in the study. On day 0, a homogenate of murine colon 26 adenocarcinoma (50 mg of solid tumor tissue in 0.1 ml of sterile 0.9 % NaCl) was injected s.c. into armpits of the tumor-bearing groups. All procedures in the study were approved by the Institutional Animal Care Committee.

Experimental procedures

After inoculation of tumor cells, physical activity, fur condition, and other signs of general well being of the animals were registered. The tumor inoculation site and the tumor size were inspected. The tumor volume was estimated by using the equation $ab^2/2$, where a and b are length and width (cm) of the tumor. Body weight was monitored and food intake was measured at 10 a.m. everyday.

Significant loss of body weight was observed in tumor-bearing groups beginning on day 9 to day 16, 0.1 ml saline and variable dosages of indomethacin were given intraperitoneally to groups *b*, *c*, *d* and *e* daily for 7 days, respectively. On day 16, carcass weight was measured after removing the entire tumor. Blood samples were collected from orbital veins by removal of one side eyeballs of the animals and stored at -20 ℃ for determination of TNF-α and IL-6 by ELISA kit (Bender Medsystems, Vienna, Austria). Weight of the gastrocnemius of left hind leg was measured. The spleens were frozen in liquid nitrogen, and stored at -70 ℃ for nuclear protein extraction and electrophoretic mobility shift assay.

Nuclear protein extraction and electrophoretic mobility shift assay (EMSA)

Nuclear extracts of spleen tissues were prepared by hypotonic lyses followed by high salt extraction as references[14,15]. EMSA was performed using a commercial kit (Gel Shift Assay System; Promega, Madison, WI) as previously described. The NF-κB oligonucleotide probe, (5' -AGTTGAGGGGACTTTCCCAGGC-3'), was end-labeled with [γ-^{32}P] ATP (Free Biotech, Beijing, China) with T4-polynucleotide kinase. Nuclear protein (20 μl) was preincubated in 9 μl of a binding buffer, consisting of 10 mM Tris -Cl, pH 7.5, 1 mM $MgCl_2$, 50 mM NaCl, 0.5 mM EDTA, 0.5 mM DTT, 4 % glycerol, and 0.05 g· L^{-1} of poly-(deoxyinosinic deoxycytidylic acid) for 15 min at room temperature. After addition of 1 μl ^{32}P-labeled oligonuleotide probe, the incubation was continued for 30 min at room temperature. Reaction was stopped by adding 1 μl of gel loading buffer, and the mixture was subjected to non-denaturing 4 % polyacrylamide gel electrophoresis in 0.5×TBE buffer. The gel was vacuum-dried and exposed to X-ray film (Fuji Hyperfilm) at -70 ℃ with an intensifying screen. NF-κB was quantitated with densitometry.

Statistical analysis

Data were expressed as means ±SE. Statistical significance was determined by one-way ANOVA using SPSS 10.0. $P<0.05$ was considered statistically significant.

RESULTS

Tumors were palpable in mice initially on day 5 after inoculation of tumor cells, symptoms of cachexia began 3-4 days later. Weight loss began once a tumor grew to 1 cm^3 and a rapid loss of body weight occurred. Initial body weights of mice before experiment had no difference. By day 16, non-tumor body weights of tumor-bearing mice were about 72 % of healthy controls ($P<0.01$), and the weights of gastrocnemius were lowered by 28.7 % ($P<0.01$), though the final whole body weights were elevated because of tumor growth. Food intake between groups was not different ($P>0.05$, Table 1).

After administration of indomethacin for 1 week, the non-tumor body weights of tumor-bearing mice were increased, but had no significant difference from that in group b. The gastrocnemius weights in animals treated with 0.5 mg· kg^{-1} of IND increased significantly ($P<0.01$). But no weight gain of gastrocnemius in animals treated with IND 2.0 mg· kg^{-1} was observed. On the contrary, the tumor weight of this group was increased compared with that in saline group ($P<0.01$, data not shown). There was no evidence that IND had additional effects on appetite because quantity of food intake of mice treated with IND did not increase.

Table 1 Clinical features of tumor-bearing and non-tumor-bearing mice

Group	Initial body wt (g)	Final body wt (g)	Nontumor body wt (g)	Gastrocnemius muscle wt (mg)	Dry food intake (g· day^{-1})
Control	20.93±1.40	25.50±1.71	25.50±1.71	136.8±6.11	6.65±0.24
Tumor + saline	20.91±1.29	25.95±1.61	20.92±1.52[a]	97.5±8.32[a]	6.53±0.31
Tumor +IND(0.25 mg· kg^{-1})	20.98±1.42	27.75±2.20	21.75±1.64	95.65±13.5	6.56±0.27
Tumor +IND(0.5 mg· kg^{-1})	20.92±1.14	27.83±1.88	22.48±1.57	115.82±9.63[b]	6.70±0.32
Tumor +IND(2.0 mg· kg^{-1})	21.38±1.00	28.00±1.24	21.90±1.38	93.15±10.83	6.53±0.19

[a]$P<0.01$, *vs* control; [b]$P<0.01$, *vs* tumor + saline.

Table 2 Serum levels of TNF-α and IL-6 in mice

Parameter	Control	Tumor + saline	Tumor+IND (0.25mg· kg^{-1})	Tumor + IND (0.5mg· kg^{-1})	Tumor +IND (2.0mg· kg^{-1})
TNF-α(pg / ml)	43.24±13.37	113.83±16.91[a]	89.9±4.5	71.68±16.70[b]	110.96±20.93
IL-6 (pg / ml)	1445.82±244.20	2646.05±93.39[a]	2527.78±266.43	1983.07±219.19[c]	2733.33±201.84

[a]$P<0.01$, *vs* control; [b]$P<0.05$, *vs* tumor + saline; [c]$P<0.01$, *vs* tumor + saline.

Tumor-bearing caused a 2-3 fold increase in serum levels of both TNF-α and IL-6 (P<0.01). Administration of IND 0.5 mg· kg^{-1} for 7 days reduced the concentrations of TNF-α (P<0.05) and IL-6 (P<0.01) in tumor-bearing mice (Table 2). But level of IL-6 slightly increased after administration of 2.0 mg· kg^{-1} of IND.

EMSA experiments were performed to examine the effect of indomethacin on the activation of NF-κB induced by tumor bearing. As shown in Figure 1, NF-κB activation in spleen was increased in tumor-bearing mice, compared to controls. The tumor-bearing mice treated with 0.5 mg· kg^{-1} of indomethacin had a lower level of NF-κB than the cachectic mice without treatment. No dose-dependent response of NF-κB activity to different dose of IND treatment was observed. Instead, a higher NF-κB activity was found in the mice treated with IND 2.0 mg· kg^{-1}.

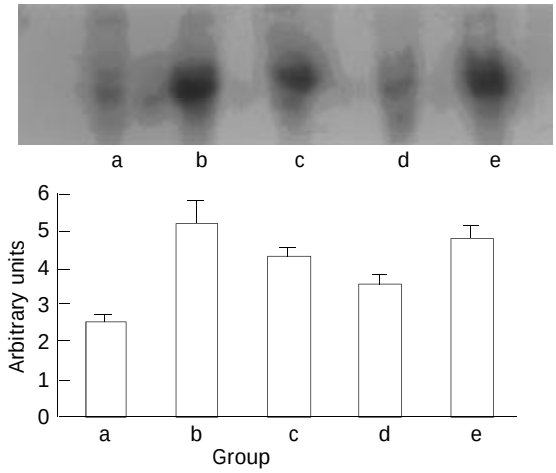

Figure 1 Activation of NF-κB in spleen. Lane a represents the control group, Lane b, c, d, e represents the group of tumor-bearing plus saline, indomethacin 0.25 mg·kg^{-1}, 0.5 mg·kg^{-1}, 2 mg·kg^{-1}, respectively.

DISCUSSION

The syndrome of cancer cachexia including progressive weight loss, particularly in skeletal muscle and adipose tissue, weakness, anemia, and often accompanied by anorexia is an important problem in the management of cancer patients. Nearly all cancer patients have significant weight loss by the time of death. Progressive wasting is an acknowledged clinical problem, it contributes to cancer mortality and may reduce the ability of patients to tolerate aggressive chemotherapy and radiotherapy. Although cachexia is frequently accompanied by anorexia, the decrease of food intake alone may be insufficient to account for cachexia because the body composition change in cachexia differs from that of starvation. Loss of skeletal muscle is more prominent in cachectic patients, leading to weakness and immobility of cancer patients eventually to death due to dysfunction of respiratory muscle. The fact that calories provided by total parenteral nutrition cannot maintain body weight of cancer patients suggests that weight loss is resulted from complex metabolic events rather than simple nutrition insufficiency[16].

Some possible mechanisms can be considered for the wasting in cachexia. It has been reported that weight loss is associated with anorexia in some tumor cachexia model[17]. But it is unlikely that the cachexia in our model was due to anorexia, because food intake was not significantly reduced while the mice were losing weight. Several cytokines are suggested to be involved in the development of cancer cachexia. The last decade has witnessed the discovery of multiple actions of cytokines on the regulation of metabolism in normal and pathophysiological conditions. Some of them are clearly involved in the wasting process that is often accompanied by chronic infection or cancer. We found that TNF-α and IL-6 levels in peripheral blood of animals were elevated while body and muscle weight decreased, which suggested the two cytokines were involved in our cachectic model. TNF-α levels were detectable in serum of pancreatic cancer patients, particularly in those with advanced disease, and these levels correlated with poor nutritional status[18]. Muscle wasting during tumor growth may be associated with the activation of non-lysosomal ubiquitin-dependent proteases associated with enhanced skeletal muscle proteolysis. This activation seems to be mediated by these cytokines, especially TNF-α, IL-6 and some other catabolic factors produced by tumors and hosts[19-22]. It was previously reported that TNF-α was partially mediated DNA fragmentation in skeletal muscle, suggesting an apoptotic phenomenon during experimental cancer-associated cachexia[23]. Production of pro-inflammatory cytokines also induces production of corresponding anti-inflammatory cytokines such as IL-15, IL-1 and IL-6 receptor antagonist, which may significantly reduce the severity of key parameters of cachexia[24-26]. Clearly the balance between pro-inflammatory and anti-inflammatory mediators may be crucial in determining the net clinical effects.

Several experiments suggested that cytokines (IL-1, IL-6, and TNF-α) induced anorexia in tumor-bearing and infected animals, and the appetite was improved in indomethacin-treated animals[17]. However, tumor-bearing mice in our experiments had no significant appetite change, and indomethacin had no obvious effect on diet consumption. So, the wasting condition in this model may have no relation with food consumption, but may be attributed to metabolic disorders. The present study confirmed previous reports demonstrating that a low dose of NASID, particularly indomethacin could inhibit cancer cachexia, whereas a high dose might be toxic[17, 27,28]. We found a low dose of indomethacin treatment could decrease TNF-α and IL-6 productions which were very important in the process of immune regulation and inflammation in this experimental model. Indomethacin also protected the host from deterioration in body composition, particularly lean body mass. It is likely that the inhibition was confined to host cell, since indomethacin caused no growth inhibition of tumors. However, contrary evidence also exists. Other reports suggested that IND appeared to suppress the growth of colon 26 as long as the tumor burden was small, whereas it facilitated the tumor growth when the tumor burden was large[29].

NF-κB is normally sequestered in the cytoplasm of nonstimulated cells and must translocate into nuclei to regulate effector gene expression. A family of inhibitory proteins, IκBs, binds to NF-κB and masks its nuclear localization signal domain and therefore controls the translocation of NF-κB. Exposure of cells to extracellular stimuli that perturb redox balance results in rapid phosphorylation, ubiquitination, and proteolytic degradation of IκBs. This process frees NF-κB from the NF-κB/IκBs complexes and enables NF-κB to translocate to the nuclei where they regulate gene transcription. Many effector genes such as those encoding cytokines and adhesion molecules are in turn regulated by NF-κB[6]. Some anti-inflammatory agents (e.g. salicylates, dexamethasone) can inhibit NF-κB, which also indicates that NF-κB is an important molecular target for modulation of inflammatory disease[30-33]. However, the identity of NF-κB, and its role in cancer cachexia still remain to be investigated. In the present study, a low baseline activity of spleen NF-κB was observed in controls, while tumor bearing increased NF-κB activities markedly. A low dose of indomethacin decreased NF-κB activities variably.

In summary, colon 26 adenocarcinoma cells could produce severe cancer cachexia, including loss of non-tumor whole

body and gastrocnemius muscle weight. The wasting condition may be partially due to the enhanced TNF-α and IL-6 production in the tumor-bearing animals, which is controlled by NF-κB. A low dose of indomethacin alleviates the wasting, decreases the activation of NF-κB, and serum level of TNF-α and IL-6, delays body weight loss and muscle atrophy. These results suggest that activation of NF-κB may play a critical role in inflammatory response of cancer cachexia. However, other possible mechanisms cannot be excluded. Indomethacin can suppress activation of NF-κB, and can be used as a reagent to improve the catabolic status in cancer cachexia. Although the present study could not clarify the definite mode of the anticachectic action of IND, the ability of IND to reverse cachexia should be considered as one of the various actions of this drug. Further studies are required to evaluate its clinical effects and mechanism in patients with cancer cachexia.

Abstract

AIM: To evaluate the specific inhibition of maxizyme directing against mutant-type p53 gene (mtp53) at codon 249 in exon 7 (AGG→AGT) *in vitro.*

METHODS: Two different monomers of anti-mtp53 maxizyme (maxizyme right MzR, maxizyme left MzL) and control mutant maxizyme ($G^5 \rightarrow A^5$) were designed by computer and cloned into vector pBSKU6 (pBSKU6MzR, pBSKU6MzL). After being sequenced, the restrictive endonuclease site in pBSKU6MzR was changed by PCR and then U6MzR was inserted into pBSKU6MzL, the recombinant vector was named pU6Mz and pU6asMz (mutant maxizyme). Mtp53 and wild-type p53 (wtp53) gene fragments were cloned into pGEM-T vector under the T7 promoter control. The ^{32}p-labeled mtp53 transcript was the target mRNA. Cold maxizyme transcripts were incubated with ^{32}p-labeled target RNA *in vitro* and radioautographed after denaturing polyacrylamide gel electrophoresis.

RESULTS: In cell-free systems, pU6Mz showed a specific cleavage activity against target mRNA at 37 ℃ and 25 mM $MgCL_2$. The cleavage efficiency of pU6Mz was 42 %, while pU6asMz had no inhibitory effect. Wtp53 was not cleaved by pU6Mz either.

CONCLUSION: pU6Mz had a specific catalytic activity against mtp53 in cell-free system. These lay a good fundation for studying the effects of anti-mtp53 maxizyme in HCC cell lines. The results suggest that maxizyme may be a promising alternative approach for treating hepatocellular carcinoma containing mtp53.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the major causes of mortality worldwide[1,2]. Several risk factors are associated with the development of HCC including chronic infection with hepatitis B virus (HBV) and hepatitis C virus (HCV), exposure to genotoxic environmental agents such as aflatoxins. The high incidence of HCC has been observed in areas such as sub-saharan Africa, Thailand and the Southern region of China (Qidong) where concomitant infection occurs with HBV and high intake of aflatoxins[3-5]. Mutational inactivation of tumor suppressor gene p53 is very common in hepatocellular carcinoma. Indeed, p53 gene mutations, deletions or loss is a very important step during carcinogenesis and might participate in all stages of HCC development[6-9]. AGG to AGT transversion in codon 249 (the third base of codon 249) of exon 7 of p53 gene occurs in over 50 % of HCC from endemic regions, where both chronic infection with HBV and exposure to carcinogens such as aflatoxin B1(AFB1) prevail[10-13]. The p53 tumor suppressor gene product plays a crucial physiological role as a "cellular gatekeeper" by exerting a variety of effects following DNA damage[14,15]. Study of p53 as a tumor suppressor gene has attracted a large number of top scientists worldwide. But mutant p53 has drawn much less attention. Mutant p53 may not be an inactivated tumor suppressor gene, it appears to be one of the most prominent members of a new family of oncogenes[16,17]. Inactivation of p53 contributes not only to tumor progression but also to resistance of cancer cells to chemotherapy. Mutant p53 protein may possess transforming ability and can cooperate with other oncogenes in the transformation of normal cells. Mutant p53 protein has a prolonged halflife of 2 to 12 hours, resulting in higher intracellular concentrations than the wild-type protein[18,19]. Loss of ability to suppress transformation and gain of transforming potential and tumorigenicity are the properties of mutant p53 gene product.

Ribozyme is a kind of catalytic RNA which can catalyze the cleavage of sequence-specific RNA[20]. Among different types of ribozymes discovered, hammerhead ribozyme has been studied extensively for the treatment of disorders ranging from cancer to infectious disease[21-29]. However, because the limited number of cleavable sequences on target RNA, in some cases conventional ribozyme does not have precise cleavage specificity. This shortcoming may greatly limit the utility of hammerhead ribozyme[30,31]. A minizyme (minimised ribozyme) is a hammerhead ribozyme with short oligonucleotide linker instead of stem II. It has lower cleavage activity compared with that of wild-type parental hammerhead ribozyme[32,33]. Two minizymes could form an active dimeric structure. The dimmers can be homodimeric (with two identical binding sequences) or heterodimer (with two different binding sequences). In order to distinguish monomeric forms of conventional minizymes that have extremely low activity from novel heterodimer with high-level activity, the latter was designated as "maxizyme"[34-36]. Maxizyme stands for minimized, active, heterodimeric, and intelligent ribozyme. Some study showed that maxizyme could cleave chimeric genes, such as BCR-ABL mRNA, which cauases chonric myelogenous leukemia (CML)[37]. In this study, we designed maxizyme targeting mtp53 mRNA by computer and examined its cleavage activity *in vitro*.

MATERIALS AND METHODS

Materials

In vitro transcription kit and pGEM-T vector were purchased from Promega Company. Restriction endonucleases, T4 DNA ligase, RNase inhibition and DNA marker were purchased from TaKaRa Company. [α-^{32}p] dUTP was purchased from Beijing Yahui Company. *E.coli* DH5α was maintained in our laboratory. pBSKU6 vector was a generous gift from Dr.You-Xin Jin. pCMV-mtp53 (or wtp53) plasmid was kindly provided by Pro.Bert Vogelstein (Howard Hughs Medical Institute). Materials used were of analytical purity.

Maxizyme design

Maxizyme targeting mutant-type p53 (249 codon) was designed. Only after binding mutant-type p53 in codon 249 (the third base of 249 codon, AGG→AGT) can the maxizyme cleave mtp53 in 201bp site. The oligonucleotide sequences included Xba I and BamH I linker sites and were as follows: *MzL*: 5' CTA GAG AGG ATG GCT GAT GAG CGA AAG GTC TGG 3' ; 5' GAT CCC AGA CCT TTC GCT CAT CAG CCA TCC TCT3' . *MzR*: 5' CTA GAA GTT TCC ACT GAT GAG CGA AAC TCC GGG 3' ; 5' GAT CCC CGG AGT TTC GCT CAT CAG TGG AAA CTT 3' . A mutant maxizyme was designed with a sequence almost identical to that of the maxizyme except for G^5 to A^5 mutation within the catalytic core. This mutant maxizyme was expected to have no cleavage activity. They were chemically synthesized in Beckman Oligo 1000-DNA synthesizer. The structure of maxizyme against mtp53 is shown in Figure 1.

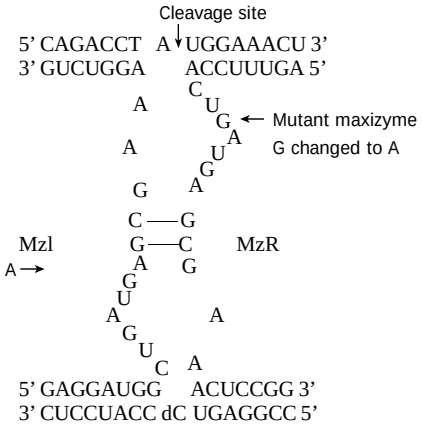

Figure 1 Structure of maxizyme against mtp53.

Methods

Construction of cell-free transcription plasmid for target RNA Mtp53 and wtp53 gene containing a cDNA fragment with 986 bases was amplified by PCR from pCMV-p53mt249 and pCMV-wtp53 vector. The PCR products were analyzed and purified by 2 % agarose gel and cloned into the transcription vector pGEM-T downstream of the T7 bacteriophage RNA promoter. The reconstructed plasmids were named as pmtp53 and pwtp53. The primers used were: upstream primer 5' GAT TCT CTT CCT CTG TGC 3' and downstream primer 5' CTT TCC ACG ACG GTG ACA 3' .

Construction of cell-free transcription plasmid for maxizyme Maxizyme targeting mtp53 was designed according to the computer software from professor Chen Nong-An (Shanghai Institute of Biochemistry of Chinese Academy of Sciences). The homologous possibility with the gene of humanbeing was excluded by consulting with RNA sequences of human cell from NCBI Genebank. The *in vitro* transcription vector pBSKU6 was digested with *Xba* I and *BamH* I restriction enzymes. The linearlized vector pBSKU6 was purified by 1 % agarose gel electrophoresis. After annealed, oligonucleotides of MzL and MzR were cloned into pBSKU6. The reconstructed plasmids were named as pBSKU6MzL and pBSKU6MzR. After being sequenced, the restrictive endonuclease site in pBSKU6MzR was changed by PCR and then U6MzR was inserted into pBSKU6MzL, the recombinant was named as pU6Mz. pBSKU6 vector contained the T7 RNA polymerase promoter for driving transcription of Mz *in vitro*. The steps of pU6Mz construction was shown in Figure 2.

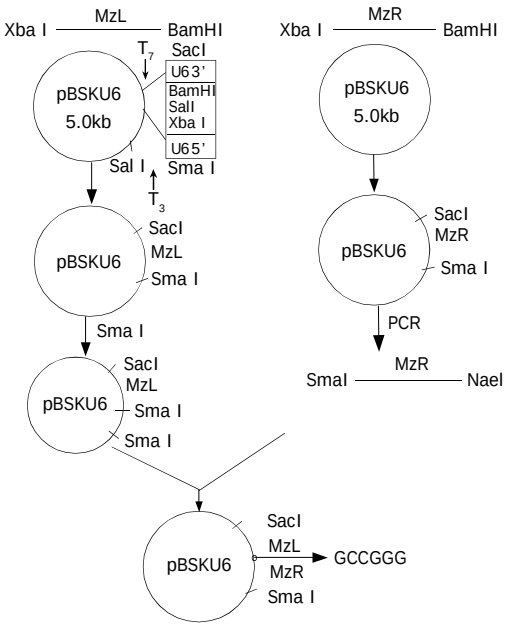

Figure 2 Steps of pU6Mz construction.

***In vitro* transcription of target RNA and maxizyme** Templates pmtp53 and pwtp53 were linearlized with Sal, while pU6Mz was linearlized with Sma I. The linearlized templates were transcribed in the presence of [α-^{32}p]dUTP (10 μl) using T7 RNA polymerase according to the manufacturer's protocol. Transcription was performed for three hours at 37 ℃ in a 50 μl final volume. The samples were purified by cutting off the autoradiograph bands after running on 8 % polyacrylamide (8 mol/l urea) gel and soaking in NES (0.5 M NH_4Ac, 0.1M EDTA, 0.1 % SDS pH 5.4) at 42 ℃ overnight. The products were precipitated by ethanol, washed once by 70 % ethanol, dissolved in DEPC-treated water and kept at -20 ℃.

***In vitro* cleavage reaction** The products of maxizyme and target RNA were quantified by measuring their radioactive cpm in 1 ul solution. The cleavage reaction was performed for 90 minutes at 37 ℃ in 25 mmol/l Tris-Cl (pH7.5) and 25 mmol/l $MgCl_2$ with cold maxizyme to [α-^{32}p] dUTP-labeled substrate ratio of 4:1 and stopped by adding 1 ul RNA loading buffer (0.25 % bromophenol blue, 0.25 % xylene cyanol FF, 20 mmol/l EDTA and saturated urea) and heated for 3 minutes at 95 ℃. The cleaved products were separated by 8 % polyacrylamide gel electrophoresis(PAGE) with 8M urea. The cleavage efficiency was calculated from cpm values of the bands of substrates (S) and products (P): cleavage efficiency=[P/(S+P)]×100 %.

RESULTS

Construction of cloning vector pU6Mz

Mz gene was successfully cloned into the vector pBSKU6. The gene complex was treated with restriction endonuclease *Sma* I and *Sac* I and analyzed by 2 % agarose gel (Figure 3). The DNA sequence analysis showed that chimeric U6 maxizyme was correct.

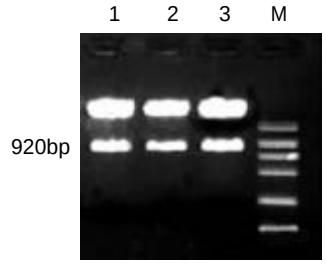

Figure 3 Restrictive enzyme analysis of recombinant plasmid pU6Mz by Sma I and Sac I. M was DNA Marker (DL2000). 1, 2, 3 were selected clones.

Identification of transcripts of pU6Mz and target RNA

The lengths of RNA transcribed from Sal I-linearlized templates of pmtp53 and pwtp53 shoud be 1002nt (Figure 4A). The transcription of pU6Mz from Sma I-linearlized templates including U6 and Mz bases shoud be 910nt (Figure 4B). The results showed that our design was correct.

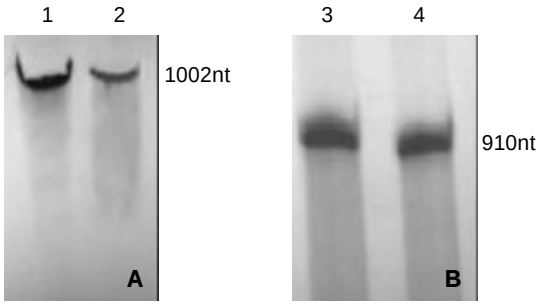

Figure 4 *In vitro* transcripts. (A) *In vitro* transcripts of wtp53 and mtp53 (1002nt). (B) *In vitro* transcripts of maxizyme and control maxizyme (910nt). lane 1: mtp53; lane 2: wtp53; lane 3: maxizyme; lane 4: control maxizyme.

In vitro cleavage reaction of Mz

Target RNA was ^{32}p-labeled. The cleavage results showed that the designed maxizyme had correct structure, it cleaved mtp53 mRNA efficiently, giving cleavage products with the expected size of 874nt and 128nt under conditions at 37 ℃ and high Mg concentration (25 mM), the cleavage efficiency was 42 %. More encouraging was that no cleavage was found with mutant maxizyme under the same conditions, and wtp53 was not cleaved by maxizyme (Figure 5).

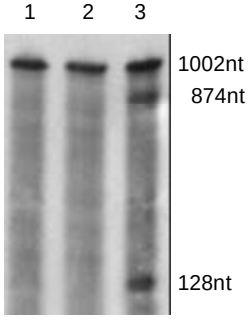

Figure 5 *In vitro* cleavage reaction. lane 1: cleavage of wtp53 by cold maxizyme; lane 2: cleavage of mtp53 by inactive cold maxizyme; lane 3: cleavage of mtp53 by cold maxizyme.

DISCUSSION

Ribozyme is a class of small catalytic RNA molecules that recognize specific substrate RNA by their complementary nucleotide sequence, and cleave the substrate RNA as an endoribonuclease at enzymatic rate. It has been demonstrated that potential utility in attenuating eukaryotic gene expression was studied in preclinical gene therapy models. Among different types of ribozymes discovered, the hammerhead ribozyme has received a great deal of attention in recent years because of its application in treatment of malignant and infectious diseases[38,39]. Many different hammerhead ribozymes targeting oncogene and HIV, HBV have been developed. The hammerhead ribozyme could cleave almost any RNA molecules containing the 3 base target recognition sequence NUX (N=any base, X is any nucleotide except G). The basic structure of a hammerhead ribozyme is composed of a catalytic core of 24 conserved bases containing helix II and two self-associating helices, I and III which are antisense to the substrate and position of ribozyme to catalyze cleavage. However, because the limited number of cleavable sequences on target RNA, in some cases conventional hammerhead ribozyme does not have precise cleavage specificity. Some scientists found that the stem II (loop II) region of hammerhead ribozyme did not appear to be directly involved in catalysis. For development of chemically systhesized ribozyme as potential therapeutic agent, it would certainly be advantageous to remove surplus nucleotides. This consideration led to the production of minizymes, which are conventional hammerhead ribozyme with a deleted stem II region. But the activities of minizyme are two or three orders of magnitude lower than those of the parental hammerhead ribozyme, suggesting that minizymes might not be suitable as gene inactivating reagents. But Kinetic and NMR analysis indicated that the minizyme was essentially inactive as a monomer but exhibited strong catalytic activity as a dimer. This dimeric structure is called maxizyme[40-42]. The maxizyme is also a metalloenzyme, its activity depends on the presence or absence of the correct formation of Mg ion-binding pocket. The maxizyme could bind to two different substrate-binding sites, one substrate-binding site functions as the "eye" that identifies the specific mRNA, wheareas the other serves as the "scissors" and cleaves the target mRNA. Some studies showed that only after binding to the target gene can the maxizyme form a cavity that captures the Mg ions.

As a novel class of ribozyme, maxizyme that targets different chimeric genes has been studied[43,45]. The chimeric gene is generated as a result of reciprocal chromosomal translocation. A well known chimeric gene is BCR-ABL gene which causes chronic myelogenous leukemia(CML). In the design of ribozyme that might cleave chimeric mRNA, it is necessary to avoid the cleavage of normal mRNA. There have been many attempts to specifically cleave chimeric BCR-ABL gene using ribozymes, but it is very difficult to cleave only chimeric gene without affecting the normal genes, such as BCR or ABL gene. Kuwabara *et al*[44] designed a maxizyme directly against BCR-ABL mRNA. The results showed that the maxizyme had extremely high specificity and high level activity not only *in vitro* but also in cultured cells. p53 mutation in 249 codon was observed in 50 % of hepatocellular carcinoma. Some studies have suggested that p53 has a gain of transforming function after mutation in addition to loss of tumor suppressor activity. Several groups have attempted to develop gene therapy methods to treat HCC via introduction of wild-type p53 cDNA into cancer cells. Unfortunately, these approaches did not result in regulated expression of p53 gene and did not reduce the expression of mutant p53 that was overexpressed in HCC cells. These shortcomings may greatly limit the utility of this gene replacement approach.

We designed a maxizyme directing against mutant-type p53 (249 codon). The cleavage results showed that the maxizyme cleaved mtp53 target mRNA efficiently. More encouraging

was that no cleavage was found in wild-type p53 under the same conditions. The activity of maxizyme must have originated from the formation of active heterodimers. So control of inactive maxizyme was also made by the mutation of a functionally indispensable ($G^5 \rightarrow A^5$) in the catalytic core. The *in vitro* cleavage reaction showed that the inactive maxizyme had no effects on target mRNA. This suggests that the cleavage effects of active maxizyme are clearly originated from the chemical cleavage. For the application of maxizyme to gene therapy, they must be expressed *in vivo* under the control of a strong promoter. Development of an efficient system for the expression of a small piece of RNA in the cell, such as antisense RNA and ribozyme, is a major challenge in nonviral gene therapy. Recently, U6 RNA has been explored to drive the expression of antisense RNA and oligonucleotide. It is much efficient than the CMV promoter which is used often[46,47]. In our study, the U6 expression system was explored for the construction of maxizyme plasmid. These lay a good fundation for the study in HCC cell lines.

In conclusion, the results of the present study showed that chimeric U6 maxizyme could cleave mtp53 mRNA *in vitro* with high efficiency. Anti-mtp53 maxizyme may be a promising tool for the treatment of hepatocellular carcinoma with an oncogenic mutation in codon 249 of p53 gene.

ACKNOWLEDGEMENTS

We would like to thank Dr Bert Vogelstein for his generous gift of plasmid p53.We also thank Mr.F Xu, Mr.XL Chen and Miss W Li for their kind help.

Abstract

AIM: To study whether patients with excess deoxycholic acid (DCA) differ from those with normal percentage of DCA with respect to biliary lipid composition and cholesterol saturation of gallbladder bile.

METHODS: Bile was collected during operation through puncturing into the gallbladder from 122 cholesterol gallstone patients and 46 gallstone-free subjects undergoing cholecystectomy. Clinical data, biliary lipids, bile acid composition, presence of crystals and nucleation time were analyzed.

RESULTS: A subgroup of gallstone patients displayed a higher proportion of DCA in bile than gallstone free subjects. By choosing a cut-off level of the 90th percentile, a group of 13 gallstone patients with high DCA levels (mean 50 percent of total bile acids) and a large group of 109 patients with normal DCA levels (mean 21 percent of total bile acids) were obtained. The mean age of the patients with high DCA levels was higher than that of the group with normal levels (mean age: 62 years *vs* 45 years) and so was the mean BMI (28.3 *vs.* 24.7). Plasma levels of cholesterol and triglycerides were slightly higher in the DCA excess groups compared with those in the normal DCA group. There was no difference in biliary lipid composition, cholesterol saturation, nucleation time or occurrence of cholesterol crystals in bile between patients with high and normal levels of DCA.

CONCLUSION: Gallstone patients with excess DCA were of older age and had higher BMI than patients with normal DCA. The two groups of patients did not differ with respect to biliary lipid composition, cholesterol saturation, nucleation time or occurrence of cholesterol crystals. It is concluded that DCA in bile does not seem to contribute to gallstone formation in cholesterol gallstone patients.

INTRODUCTION

The two major primary bile acids formed in human liver are cholic acid (CA) and chenodeoxycholic acid (CDCA). During the enterohepatic circulation, CA and CDCA are partly 7a-dehydroxylated by microbial enzymes, yielding deoxycholic acid (DCA) and lithocholic acid, respectively[1]. Only a small amount of lithocholic acid is absorbed from the intestine, whereas DCA is efficiently reabsorbed mainly via active transport in the distal part of ileum but also by passive diffusion along the small intestine and probably also from the proximal part of colon. DCA constitutes usually 10-35 % of bile acids in the bile. However, individuals may vary widely in the proportion of DCA in bile from 0 to more than 50 % of biliary bile acids. These wide inter-individual variations in DCA probably reflect the difference in colonic flora.

According to some previous studies, the proportion of DCA in bile of patients with cholesterol gallstone is higher than that of stone-free subjects and it has been suggested that DCA may play a role in cholesterol gallstone formation[2-8]. Other authors have found a normal percentage of DCA in patients with cholesterol gallstones[9-13]. An increased proportion of DCA in the bile acid pool of gallstone patients has been associated with higher levels of 7a-dehydroxylating faecal bacteria[6,14]. In a recent study, Thomas *et al*[8] found an increased 7a-hydroxylating activity in the caecal aspirates of patients with cholesterol gallstones, which was associated with slower colonic transit time and increased percentage of DCA in fasting serum. Berr *et al*[6] have reported about a subgroup of cholesterol gallstone patients with DCA excess and increased 7a-dehydroxylating activity and levels of faecal 7a-dehydroxylating bacteria which may trigger cholesterol gallstone disease.

In a recent study including large series of gallstone patients and gallstone free subjects, we could not find a significantly higher proportion of biliary DCA in cholesterol gall-stone patients compared to pigment stone patients or gallstone-free subjects[13]. No correlation was found between the percentage of DCA and cholesterol saturation in gallbladder bile. However, a subgroup of the patients with cholesterol gallstones had a high percentage of DCA.

The purpose of this study was to study whether patients with excess DCA differed from patients with a normal percentage of DCA with respect to biliary lipid composition, cholesterol saturation, nucleation time and occurrence of cholesterol crystals in gallbladder bile.

MATERIALS AND METHODS

Patients

The patients in the present study were included in a recent report from our group dealing with lipid composition of gallbladder bile in large series of patients with cholesterol gallstones and pigment stones and gallstone free subjects undergoing elective cholecystectomy[13]. In this study, only cholesterol gallstone patients (n=122) and gallstone-free subjects (n=46) in which data on biliary bile acid composition were available were included. Data on the patients are shown in Table 1. None of the patients had clinical or laboratory evidence of diabetes mellitus, alcohol abuse or other diseases that affect the function of the kidney or the liver. The patients

Gallstone free	46	38 / 18 (83)	45 (20-71)	23.2±0.5^c (45)	5.8±0.2 (36)	1.4±0.1 (36)

Notes: Mean values ± Standard Error of the Mean. *n*=number. $^aP<0.05$ *vs* Low DCA, $^bP<0.005$ *vs* Low DCA, $^cP<0.01$ *vs* Total gallstone.

were not on any medications known to affect lipid metabolism. None of the patients received or had been treated with antibiotics prior to or during cholecystectomy. The gallstone-free patients were cholecystectomized either because of polyps, cholesterolosis or adenomyomatosis or because of frequent, recurrent right upper biliary colic and other symptoms suggestive of gallbladder dysfunction.

Informed consent was obtained from each patient before operation. The ethical aspects of the study were approved by the Ethical Committée at Karolinska Institutet, Stockholm.

Experimental procedure

All patients were hospitalized in the surgical ward. The operations were done after an overnight fasting. After opening the abdomen or in the case of a laparoscopic procedure following application of pneumoperitoneum and establishing four laparoscopic ports, the gall bladder was completely emptied of bile with a sterile needle and syringe to avoid possible stratification of bile[15]. Indicative of a functioning gallbladder was the presence of dark concentrated bile in the gallbladder and no evidence of impacted stones in the neck of the cystic duct at operation. The gall bladder was then removed. The gallstones were classified as cholesterol stones by visual inspection and when necessary by analysis in the laboratory[16,17]. All gall bladders were routinely examined by a pathologist.

Analysis of biliary lipids and calculation of cholesterol saturation

Gallbladder bile was extracted with chloroform-methanol (2/1, w/w) for measurement of cholesterol and phospholipids. Cholesterol was measured by an enzymatic method[18] and phospholipids by the method of Rouser *et al*[19]. The total bile acid concentration in one aliquot of the bile sample was measured using a 3-alpha-hydroxysteroid dehydrogenase assay[20]. Cholesterol saturation was calculated as a percentage of the predicted cholesterol solubility at the respective biliary lipid concentration and composition as described by Carey[21].

Measurement of bile acid composition

Aliquots of bile were hydrolyzed in 1 mol/L potassium hydroxide at 110 ℃ for 12 h. The conjugated bile acids were extracted with diethyl ether after acidification to pH 1 with hydrochloric acid. After preparation of trimethylsilyl ethers, the bile acids were analyzed by gas-liquid chromatography using 1 % Hi-Eff BP 8 as the stationary phase. A Pye Unicam gas chromatograph (Pye Unicam Ltd, Cambridge, UK) equipped with a 1.5 m×4 mm column was used[22].

Analysis of cholesterol crystals and nucleation time

Bile samples were examined for typical rhomboid monohydrate cholesterol crystals by polarising light microscopy on pre-warmed slides. Nucleation time (NT) was determined by the method of Holan *et al*[23] with minor modifications[24].

Statistical analysis

Data were presented as mean ± SEM. The statistical significance of differences was evaluated with Student' s *t*-test. Nucleation time was evaluated by Wilcoxon' s sum of rank test.

RESULTS

Age, body mass index and plasma lipids

As can be seen in Figure 1, a subgroup of gallstone patients displayed a higher proportion of DCA in bile than gallstone-free subjects. Choosing a cut-off level of the 90th percentile, a group of 13 gallstone patients with high DCA-levels was obtained. The proportion of DCA in the high DCA-group averaged 50 % compared with 21 % in the normal DCA-group.

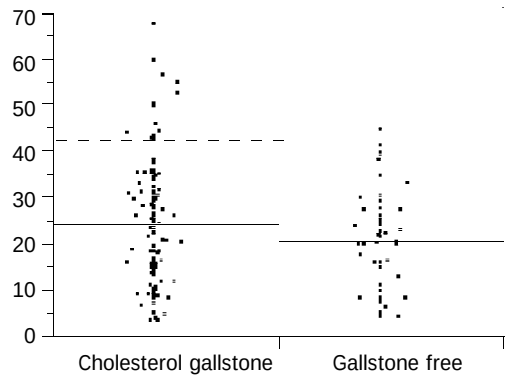

Figure 1 Deoxycholic acid levels in 122 gallstone patients and 46 gallstone free patients (Dotted line represented the 90th percentile in the gallstone patients).

The mean age of the patients with high DCA-levels was significantly higher than that of the patients with normal DCA-levels (mean ages: 62 years *vs* 45 years, Table 1). The mean body mass index (BMI) was also higher in the high DCA-group, 28.3, compared to 24.7 in the normal DCA-group ($P<0.005$). Plasma levels of cholesterol and triglycerides were slightly higher in the high DCA-group.

Lipid composition, cholesterol saturation, nucleation time and occurrence of crystals in gallbladder bile

The results are summarized in Table 2. There was no difference in biliary lipid composition, total lipid concentration or cholesterol saturation of bile between patients with high and normal levels of DCA.The molar percentage of cholesterol in cholesterol gallstone patients was significantly higher (7.8 mol %), compared to gallstone-free subjects (5.8 mol %). The total biliary lipid concentration was significantly lower in cholesterol gallstone patients compared to gallstone-free patients. Also the mean cholesterol saturation was significantly higher in gallstone patients (112 %) compared to gallstone-free subjects (79 %), ($P<0.0001$).

Table 3 Bile acid composition in patients with cholesterol gallstones and gallstone free subjects

Group	*n*	Cholic acid %	Deoxycholic acid %	Chenodeoxy-cholic acid %	Lithocholic acid %	Ursodeoxy-cholic acid %
Total gallstone	122	38.9±1.0	24.2±1.2	34.5±0.9	1.0±0.1	1.3±0.2
High DCA	13	22.7±1.7	50.0±2.1	24.5±1.7	1.4±0.4	1.3±0.9
Low DCA	109	40.8±1.0	21.1±0.9	35.7±0.9	0.9±0.1	1.3±0.2
Gallstone free	46	46.1±1.6[b]	20.7±1.6	30.6±1.0[a]	0.6±1.6	1.7±0.4

Notes: Mean values ± Standard Error of the Mean. *n*=Number of observations, [a]*P*<0.05 *vs* Total gallstone, [b]*P*<0.001 *vs* Total gallstone.

There was a tendency to shorter nucleation time in patients with normal DCA-levels compared to those with high DCA-levels, but the difference did not reach statistical significance. The proportion of patients with crystals in their bile was the same between patients with high and normal levels of DCA. Nucleation time was significantly shorter in cholesterol gallstone patients compared to that in gallstone-free patients, 6 days *vs.* 17 days (*P*<0.0001). The proportion of patients with bile positive for cholesterol crystals was significantly higher among gallstone patients (79 %) compared to gallstone-free subjects (11 %), (*P*<0.0001).

Bile acid composition

The bile acid composition is summarized in Table 3. The proportion of cholic acid was significantly lower and that of chenodeoxycholic acid was higher in the gallstone patients compared to the gallstone-free patients. There was no significant difference in the proportion of deoxycholic acid, lithocholic acid or ursodeoxycholic acid between gallstone patients and gallstone-free subjects.

DISCUSSION

In the present study, a subgroup of cholesterol gallstone patients with a high proportion of DCA in the gallbladder bile, mean 50 %, was compared to gallstone patients with a normal proportion of DCA, mean 21 %. The high DCA-level was not associated with either higher cholesterol content or cholesterol saturation of bile. The proportion of patients with cholesterol crystals in the bile did not differ between patients with high and normal levels of DCA. Nor was the nucleation time shortened in patients with high DCA content. If anything, there was a tendency to longer nucleation time in patients with high DCA-levels although the difference was not significant. These results were in agreement with some previous studies, showing that a high proportion of DCA in human gallbladder bile was not associated with a higher risk for formation of cholesterol gallstones[9-13].

The gallstone patients with a high level of DCA were of older age than those with a normal level of DCA. The reason why old age is associated with a high percentage of DCA in bile is not quite apparent. Slow colonic transit has been reported to lead to high biliary proportions of DCA, probably by increasing the intestinal residence time of bile salts[2]. Recently, Thomas *et al*[8] reported that slow colonic transit in combination with increased number of colonic gram-positive anaerobes and greater 7a-dehydroxylating activity favours enhanced DCA-formation in gallstone patients. Berr *et al*[6] also found that a group of gallstone patients with DCA-excess had higher 7a-dehydroxylating activity and increased counts of 7a-dehydroxylating bacteria in feces compared with a group of patients with normal DCA, but this difference was not due to a slow intestinal transit time. In agreement with that, van der Werf *et al*[25] have previously shown that elderly persons (55-75 years old) have a higher fractional turnover of cholic acid and a higher deoxycholic acid input rate from the large bowel than young adults (20-30 years old) and this is not due to any difference in gut transit time.

Another finding of this study was that high level of DCA was also associated with high BMI. This could indicate a potential role of BMI as a confounder when analysing biliary DCA levels in studies on cholesterol gallstone patients.

To conclude, gallstone patients with excess DCA are of older age and have higher BMI than patients with normal DCA. The two groups of patients do not differ with respect to biliary lipid composition, cholesterol saturation, nucleation time or occurrence of cholesterol crystals. These findings further underline that DCA in bile does not significantly contribute to cholesterol gallstone formation.

Abstract

AIM: The mostly known genotypic virulence features, of *H. pylori* are cytotoxin associated gene A (*cagA*) and Vacuolating cytotoxin gene A (*VacA*). We investigated the association of these major virulence factors with ulcer and non-ulcer dyspepsia in our region.

METHODS: One hundred and forty two dyspeptic patients were studied (average age 44.8±15.9 years, range 15-87 years, 64 males and 78 females). Antral and corpus biopsies were taken for detecting and genotyping of *H. pylori*. 107 patients who were *H. pylori* positive by histological assessment were divided into three groups according to endoscopic findings: Duodenal ulcer (DU), gastric ulcer (GU) and non-ulcer dyspepsia (NUD). The polymerase chain reaction (PCR) was used to detect *CagA* and *VacA* genes of *H. pylori* using specific primers.

RESULTS: *H. pylori* was isolated from 75.4 % (107/142) of the patients. Of the 107 patients, 66 (61.7 %) were *cagA*-positive and 82 (76.6 %) were *VacA*-positive. *CagA* gene was positively associated with DU and GU ($P<0.01$, $P<0.02$), but not with NUD ($P>0.05$). Although *VacA* positivity in ulcer patients was higher than that in NUD group, the difference was not statistically significant ($P>0.05$).

CONCLUSION: There is a significantly positive association between *CagA* genes and DU and GU. The presence of *VacA* is not a predictive marker for DU, GU, and NUD in our patients.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a gram-negative, spiral shaped microaerophilic bacterium that colonizes in the gastric mucosa in humans[1]. In the majority of individuals, infection causes asymptomatic histological chronic gastritis. A significant minority subsequently develop peptic ulcer disease (PUD), and infection with *H. pylori* is a significant risk factor for gastric carcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma[2-4]. The process by which different disease patterns develop has not been fully elucidated. But two putative virulence determinants of *H. pylori* have been identified as markers of ulcerogenic strains, the cytotoxin associated gene A (*CagA*) and the vacuolating cytotoxin gene A (*VacA*) (Phenotype 1, ulcerogenic; *CagA* & *VacA*-positive, phenotype 2, non-ulcerogenic; *CagA* & *VacA*-negative). The *CagA* gene encodes a 120-140 kDa protein of unknown function in about 60-70 % of *H. pylori* strains. This gene is part of the cag pathogenicity island (PAI), a 40-kbp segment with several genes involved in cytokine production[5, 6]. Strains that do not produce the *CagA* protein generally lack the entire cag PAI. *H. pylori* strains produced by *CagA* have been detected in patients with PUD more frequently than in patients with chronic gastritis alone[7- 9]. Another virulence factor that injures epithelial cells is encoded by *VacA*. *VacA* is present nearly in all *H. pylori* strains and contains at least two variable parts[10,12]. The s-region (encoding the signal peptide) exists as s1 or s2 allelic types. Among type s1 strains, subtypes s1a, s1b, and s1c have been identified. The m-region (middle) occurs as m1 or m2 allelic types. Among type m2, two subtypes have been identified, and designated as m2a and m2b[11]. Production of the vacuolating cytotoxin is related to the mosaic structure of *VacA*. The *VacA* signal sequence type s1, but not type s2 is closely associated with *in vitro* cytotoxin activitiy, PUD, and the presence of *CagA* gene[9, 10, 12]. The m1 allele is associated with higher levels of toxin activitiy and more severe gastric epithelial damage than the m2 allele[10, 12].

MATERIALS AND METHODS

Materials

Patients and classification of endoscopic findings One hundred forty two dyspeptic patients (excluding those taking proton pump inhibitors [PPIs] and/or NSAIDs in the past month, and/or had previous *H. pylori* eradication) were studied (average age 44.8±15.9 years, range 15-87 years, 64 males and 78 females) and referred for routine endoscopy at the Department of Gastroenterology in the Turgut Özal Medical Center, Malatya, Turkey. Endoscopic findings were recorded and according to endoscopic findings, *H. pylori* positive patients were divided into three groups: Group 1: Patients with duodenal ulcer (DU); Group 2: Patients with gastric ulcer (GU); Group 3: Patients with non-ulcer dyspepsia (NUD). All the patients gave informed consent to participate in the study.

Methods

Endoscopy and detection of *H. pylori* by histological assessment During each endoscopic procedure (by Olympus

GIF XQ 240 videoendoscope), two antral and two corpus mucosal biopsy specimens were obtained by using biopsy forceps (FB-25 k; Olympus, Japan) which were cleaned with a detergent and disinfected after each examination. Two biopsy samples were transported to pathology laboratory and fixed in 10 % formalin overnight. Tissue processing was undertaken with graded ethanol solutions and clearing was made with xylene. Paraffin tissue blocks were cut into 4-5 μm sections with a rotary microtome. The sections were stained with hematoxylin-eosin and tissue Giemsa and assessed for the presence of *H.pylori* microorganisms. 107 (75.4 %) patients (average age 45.8±15.7 years, range 17-87 years, 50 males and 57 females) were found to be *H. pylori* positive and the other two biopsy specimens of those patients were transported to the microbiology laboratory for PCR examination to determine *CagA* and *VacA* status.

PCR examination Biopsy samples obtained from 107 patients with positive *H. pylori* were put into 20 % dextrose solution and stored at -20 ℃ until a sufficient number was reached for PCR assay. The transport media contained the tissue samples were discarded and the tissue samples were resuspended with 100-200 μg/ml of lysis buffer (10 mM Tris-HCL, 0.1 M EDTA, 5 % SDS, 100-200 μg/ml proteinase K). The mixture was incubated at 52 ℃ for 2 hours in a thermal cycler. 100 μl phenol-chloroform-isoamyl alcohol (25:24:1) was added into the mixture. The mixture was then vortexed and centrifuged at 5 000×g for 5 minutes. The supernatant was discarded and isoamyl alcohol (24:1) was added as much as the taken volume. The mixture was vortexed and centrifuged as described above. The supernatant was discarded and 2.5 volume of cold ethanol (70 %) was added and stored at -20 ℃ overnight. On the following day, the mixture was centrifuged at 13 000×g for 13 minutes. The supernatant was discarded and the pellet was resuspended with TE buffer and used for PCR assay. The reaction mixture (50 μl) was prepared for *CagA* as described below. 2 μl dNTP mix (200 μM/ μl of each deoxynucleotide), 1 μl primer 1(0.5 μM/1 μl of each oligonucleotide), 1 μl primer II, 1 μl taq polymerase (2.5U/ μl), 4.5 μl 10×PCR buffer, 0.5 μl $MgCl_2$ (5 μM/ μl), 35 μl distilled water, 5 μl sample DNA. PCR reaction was performed in the thermal cycler (M.J. research) with the following incubation steps: at 94 ℃ **for** 4 min (Pre-heating), 35 cycles at 94 ℃ **for** 1 min (denaturation), at 57 ℃ 1.30 min (annealing) and at 74 ℃ **for** 2 min (elongation), 1 cycle at 74 ℃ **for** 5 min post elongation. *Cag A* primers: 5' -GAT AAC AGG CAA GCT TTT GAG G-3', 5' - CTG CAA AAG ATT ATT TGG CAA GA-3' targeting 349 bp fragment. The reaction mixture was prepared for *VacA* as described below. 2 μl dNTP mix, 1 μl primer 1, 1 μl primer II, 1 μl taq polymerase, 4.5 μl 10×PCR buffer, 0.5 μl $MgCl_2$, 35 μl distilled water, 5 μl sample DNA. Then at 94 ℃ **for** 1 min (denaturation), at 63 ℃ **for** 1.30 min (annealing), at 72 ℃ **for** 1 min (elongation), 30 cycles, and at 74 ℃ **for** 5 min 1 cycle for post elongation. *VacA* primers: 5' - CCG AAG AAG CCA ATA AAA CCC CAG-3', 5' - CAA AGT CAA AAC CGT AGA GCT GGC- 3' targeting 467 bp fragment. The PCR products were analysed by 2 % agarose gel with 0.5 % ethidium bromide via electrophoresis.

Statistical analysis

Normal χ^2 analysis and Fisher' s exact χ^2 method were used for statistical evaluation of data derived from the results of the procedures mentioned above.

RESULTS

Prevalence of H. pylori infection

H. pylori infection was found in 107 of 142 patients (75.4 %).

Endoscopic findings

35 of the 107 patients had DU (32.7 %), 24 (22.4 %) GU and 48 NUD (44.9 %).

Prevalence of CagA and VacA among H. pylori positive patients

While 66 of 107 *H. pylori* strains were *CagA* positive (61.7 %), 82 of the patients were *VacA* positive (76.6 %), and 62 of the patients were both *CagA* and *VacA* positive (57.9 %).

Relation between CagA-VacA status and DU, GU, and NUD

28 of 35 patients with DU (80 %), 20 of 24 patients with gastric ulcers (83.3 %) and 18 of 48 patients with NUD (37.5 %) were *CagA* positive. The presence of *CagA* in the patients with DU and GU was significantly higher than that in the patients with NUD, respectively (P=0.007, P=0.013). *CagA* positivity was statistically lower in patients with NUD (P<0.001). 29 of 35 patients with DU (82.9 %), 21 of 24 patients with gastric ulcer (87.5 %), and 32 of 48 patients with NUD (66.7 %) were *VacA* positive. *VacA* positivity was both higher in the patients with DU and GU than that in the patients with NUD, but this difference between the groups was not statistically significant (P>0.05). We detected phenotype 1 *H. pylori*, characterized by the expression of both *CagA* and *VacA*, in 57.9 % (62 of 107) of the patients (71.4 % DU, 79.2 % GU, 37.5 % NUD patients). The prevalence of phenotype 1 was significantly higher in patients with duodenal or gastric ulcer, than that in the patients with NUD (P<0.0004, P<0.0002). Phenotype 2 *H. pylori* characterized by a lack of expression of either *CagA* or *VacA*, was found in 19.6 % of the patients (21 of 107) in our study (8.6 % DU, 8.3 % GU, 33.3 % NUD). The prevalence of phenotype 2 in the patients with NUD was significantly higher than that in patients with duodenal or gastric ulcer (P<0.01, P<0.04). The remaining 22.4 % of the total number of patients studied (24 of 107) had an intermediate phenotype, which expressed either *CagA* independent of the presence of *VacA* (CagA-positive and *VacA*-negative, 3.7 %) or vice versa (CagA-negative and *VacA* positive, 18.7 %). There was not any significant difference between the groups according to intermediate phenotypes (P>0.05) (Table 1).

DISCUSSION

The most common interaction between *H. pylori* and human is asymptomatic bacterial colonisation in the gastric mucosa, which can be continued lifelong. However, the presence of this bacterium in an individual increases the risk of serious

Table 1 Distribution of endoscopic findings according to *CagA* and *VacA* status

gastroduodenal diseases such as gastritis, GU, DU, gastric cancer and MALT lymphoma[3, 4, 13, 14]. It has been suggested that *H. pylori* may induce more or less severe gastroduodenal diseases according to the strain virulence. Two major markers of virulence, *CagA* and *VacA*, have been described in *H. pylori*. The association between putative virulence markers with ulcer and NUD was investigated in a Turkish population.

In our study, the presence of *CagA*, and both *CagA* and *VacA* was significantly more prevelent in patients with DU and GU, than those in patients with NUD ($P<0.05$). The positivity of *VacA* was higher in the patients with DU and GU than that in the patients with NUD, but difference was not statistically significant ($P>0.05$). Previous studies from different countries showed that CagA-positive strains were more common in patients with ulcer disease. CagA-positive strains were found in 79 % to 100 % of DU patients[7,8,15,18-31], 71 % to 100 % of GU patients [7-9,19,20,27,28], as compared with 37 % to 89.7 % of NUD patients[8,18-24,26-31]. In the present study, we found a significantly higher prevalence of CagA-positive strains in DU and GU than that in NUD patients (80 %, 83.3 %, and 37.5 %, respectively). It was reported from different centers that in patients with duodenal ulcer, the positivity rates of cagA, *VacA*, and both *Cag A* and *VacA* were 79-100 %, 47.5-92 %, 37-75 %, respectively[7,8,15,18-31]. The positivity rates of *Cag A*, *VacA*, and both *CagA* and *VacA* in the patients with gastric ulcer, have been reported to be 71-100 %, 40.8-75 %, and 38.8-56.6 %, respectively[7-9,19-30]. In all of these studies, the positivity of *CagA* and *VacA* was higher in the patients with DU or GU, however some was statistically significant[7-10,12,15-18,24-26,28-31] and some not[19-21,23,32,33,35- 37,39,42,43] when it was compared to patients without ulcer.

In patients with NUD, the positivity rates of *CagA* and *VacA* were reported to be 37-89.7 %[8,18,19,21-24,26,28,29] and 33.3-73 %[8,19,21-23,28-30], respectively. Nearly in all of these studies, *CagA* and *VacA* positivity rate in the patients with NUD was found to be low compared to that in the patients with ulcer, however, this difference was statistically significant in some studies[7-9, 15-18, 24-26, 28-30], but not in some others[19-21,23,27,33,35-38,41,42]. In our study, the *CagA* positivity in the patients with NUD was significantly lower than that in the ulcer patients ($P<0.01$). This supported the results of DU and GU mentioned above. Although *VacA* positivity was higher in the patients with ulcer than that in the patients with NUD, this was not statistically significant and did not seem to be an important risk factor for the development of ulcer in our patients. However, determination the *VacA* genotypes and the presence of *CagA* gene together may contribute to potential clinic determination of patients who have different levels of risk. It has been shown that *VacA* type s1/m1 strains produce more cytotoxins than type s1/m2, and that type s2/m2 strains do not produce active cytotoxins[10]. Many studies have confirmed these findings[9,12,24,25,31,38]. In this study, we couldn' t detect the *VacA* subtypes for not having their primers. Also, we had no information on the *in vitro* cytotoxin production of our strains, so we could not compare our results directly with those from other studies. If we could have determined these factors, perhaps we would find an association between *VacA* and ulcer disease. It was reported that the presence of *CagA* and *VacA* genes in *H. pylori* isolates increased the risk of gastric cancer[22,40] but some studies refused this[37,41,42]. In two studies, no statisticallly significant difference between the presence of *CagA* or *VacA* in patients with MALT lymphoma and NUD was found[8]. In another study which interrogated the importance of the presence of *CagA* for developing resistance to metronidazole, which was used in eradication therapies of *H. pylori*, an association between resistance and the presence of *CagA* was not shown. It was investigated that if the patients could be selected for gastroscopy adequately only by looking for anti *H. pylori* and anti-*CagA* serologically, and it was observed that the method was not adequate for screening, since many serious pathology and malignancy could not have been noticed by just a selection of this method[43].

Gastroduodenal lesions developed in the patients infected with *H. pylori* isolates that had *CagA* and *VacA* gene and showed differences according to regions, countries and ethnic groups. In the literature, it has been controversial that *CagA* and *VacA* positive isolates cause more serious gastroduodenal lesions[7-42]. In our study, it was seen that gastric and duodenal ulcer incidence increased in the patiens with *CagA*, and both *CagA* and *VacA* positive. Recently, it was reported similar results for *CagA* in ulcer patients from Turkey abtained by using an ELISA method[46]. Many risk factors have been determined for *H. pylori* infection (CagA, *VacA*, *IceA* etc.), but none of them is specific for disease. It has been put forward that *CagA* plays a partial role in increased mucosal inflammation, increased density of *H. pylori* in antrum, and causes more profound inhibition of mucin synthesis, DU, GU and gastric cancer[7-9,39,44], and has a protective role in Barret' s esophagitis[16,17]. However direct association was found only with IL-8 induction[32,34,45]. The *IceA* gene, considered as a virulence factor for *H. pylori* infection recently, has no disease specific features, and there is no biologic and epidemiologic evidences that *IceA* gene is a virulence factor associated with *H. pylori*[33,34]. The opinion that *VacA* genotyping may be useful clinically (for example, predicting the presence of DU) is controversial from now on[19,32, 34].

As a result, the association between, the virulence factors in *H.pylori* positive patients, clinical course and gastroduodenal lesions that develop subsequently has not been understood yet. For determining these interactions, it needs great scale and multicenter studies which examine the structural features of *H. pylori* (virulence factors), host features and environmental features together. To have definite results, study must be large enough and include different diseases and ethnic groups. Also, in our country, multicenter and large scale studies would reveal the virulence differences between different regions.

Abstract

AIM: To investigate the expression of local renin and angiotensinogen mRNA in cirrhotic portal hypertensive patients.

METHODS: The expression of local renin and angiotensinogen mRNA in the liver, splenic artery and vein of PH patients was detected by RT-PCR analysis.

RESULTS: Expression of local renin mRNA in the liver of control group was (0.19±0.11), significantly lower than that in splenic artery(0.45±0.17)or splenic vein(0.39±0.12) respectively, (P<0.05). Expression of local angiotensinogen mRNA in the liver was (0.64±0.21), significantly higher than that in splenic artery(0.41±0.15) or in splenic vein (0.35±0.18) respectively, (P<0.05). Expression of local renin mRNA in the liver, splenic artery and vein of PH group was (0.78±0.28), (0.86±0.35) and (0.81±0.22) respectively, significantly higher than that in the control group, (P<0.05). Expression of local angiotensinogen mRNA in the liver, splenic artery and vein of PH group was (0.96±0.25), (0.83±0.18) and (0.79±0.23) respectively, significantly higher than that in the control group, (P<0.05). There was no significant difference between the liver, splenic artery and vein in the expression of local renin or local angiotensinogen mRNA in PH group, (P<0.05).

CONCLUSION: In normal subjects the expression of local renin and angiotensinogen mRNA was organ specific, but with increase of the expression of LRAS, the organ-specificity became lost in cirrhotic patients. LRAS may contribute to increased resistance of portal vein with liver and formation of splanchnic vasculopathy.

INTRODUCTION

The initial clues to the presence of an extrarenal or tissue RAS were suggested in the studies of hypertension. Biochemical and histologic evidences have been established for the existence of a tissue-based RAS within a variety of tissues such as blood vessels, liver, kidney, spleen. Many researchers documented that this RAS system was functionally independent of the endocrine system[1-3] and called tissue or local RAS (LRAS). Its activition includes both short and long-term regulatory roles in cardiovascular homeostasis and secondary structural changes, instead of short-term regulatory profile for endocrine RAS. Locally generated AngII plays a significant role not only in controlling the growth of vascular smooth muscle cells (VSMC), hepatocytes and hepatic satellite cells (HSC was one of the most important cells in liver fibrosis[4-6]), but also in regulating local vascular tone including hepatic microcirculation. Hyperdynamic circulation and splanchnic vasculopathy were the common pathological process and changes in cirrhotic portal hypertension[7-9], vascular and hepatic RAS may have great contribution to it. Through detection of expression of the two components of LRAS, the relationship between local renin and angiotensinogen and cirrhotic portal hypertensions was investigated.

MATERIALS AND METHODS

Materials

The liver tissues and a section of splenic artery and vein were obtained during the operation of esophagogastric devascularization and splenectomy in 20 cirrhotic portal hypertensive patients. The same samples were obtained during splenectomy and partial hepatectomy in 24 controls.

13 male and 7 female patients were included in this study with mean age of 49±21, mild or severe gastroesophageal varices and splenomagely were found in all patients.

16 male and 8 female subjects with mean age of 39±17 served as control, 12 of them underwent partial hepatectomy for hepatic trauma and 12 underwent splenectomy for splenic injury. Those with hepatitis or hypertension were excluded.

A portion of the resected tissues was routinely fixed with 10 % formalin and embedded in paraffin and cut into sections, another portion of tissues was stored in liquid nitrogens at -80 ℃ for use.

Methods

Immunohistochemical analysis To investigate splanchnic vascular changes in these patients, we took the splenic veins by using monoclonal anti-vascular smooth muscle cell α-cm-actin antibody, PCNA, and the splenic veins were stained with HE. Immunohistochemical analysis was performed according to routine methods as suggested by the manufacturer.

Preparation of specimens for electron microscopic observation Fresh vascular tissues were made into cubes of 1 mm^3 and prefixed for 2 h in 2.5 % glutaraldehyde, and then postfixed at 4 ℃ for 2 h in 1 % osmic acid. Alcohol of increasing concentrations and acetone were used for dehydration. The specimens were then embedded in epoxy resin EPON 812 and cut into ultrathin sections. Plumbum-double-staining was used to prepare the samples for ultrastructural observation under transmission electron

microscope (Opton EM 10C Model).

Reverse-transcription polymerse chain reaction (RT-PCR) Messenger RNA (mRNA) levels of local renin and angiotensinogen were assessed by RT-PCR analysis using β-actin as the house keeping gene. Total RNA was prepared from frozen tissues of the liver, splenic artery and vein. Diluted complementary DNA was cloned in a total volume of 50 μl containing DEPC 31.5 μl, buffer solution 5 μl, dNTP 4 μl, 2.5 mmol/l $mgcl_2$ 3 μl, primers 20 μmol*4 μl, cDNA 2.5 μl, and TAG 0.25 μl. The PCR conditions were at 94 ℃ for 4 min followed by 35 cycles at 90 ℃ for 30 sec, at 54 ℃ for 30 sec, and at 72 ℃ for 1 min. Total RNA was also analyzed for β-actin transcript expression and PCR for 28 cycles for β-actin.

Table 1 Primer sequences

MRNA		Sequence	Size of products
Renin	sense	5'-TCT CAG CCA GGA CAT CAT CA-3'	288bp
	antisense	5'-AGT GGA AAT TCC CTT CGT AA-3'	
Angiotensinogen			256bp
	sense	5'- TGT TGC TGC TGA GAA GAT TG-3'	
	antisense	5'-CCG AGA AGT TGT CCT GGA TG –3'	

RT-PCR products were visualized under ultraviolet and analyzed by computer which provided the data for analysis. Study values were normalized as a ratio to the β-actin signal in each sample, and each value was analyzed as a transcriptional index (transcript of the interest mRNA expression in samples of interest/β-actin mRNA expression in samples of interest).

Statistical analysis

P value <0.05 was considered statistically significant, and all variable data were summarized in terms of mean ±SD and analyzed by Student *t* test using SAS software.

RESULTS

Immunohistochemical staining

In these patients, such typical cirrhotic changes as hepatocyte degeneration, necrosis, pseudolobule formation and fibrosis were seen, and splenic vein wall was thickened and VSMC in media tunica was disorderly arranged (Figures 1,2). With α-cm-actin antibody staining method, VSMC could be seen in the intima of splenic vein, suggesting migration of VSMC from media to intima. Hyperplasia of VSMC could be seen in both splenic artery and vein by PCNA staining (Figures 3,4), there wes no obviously positive staining in the control group.

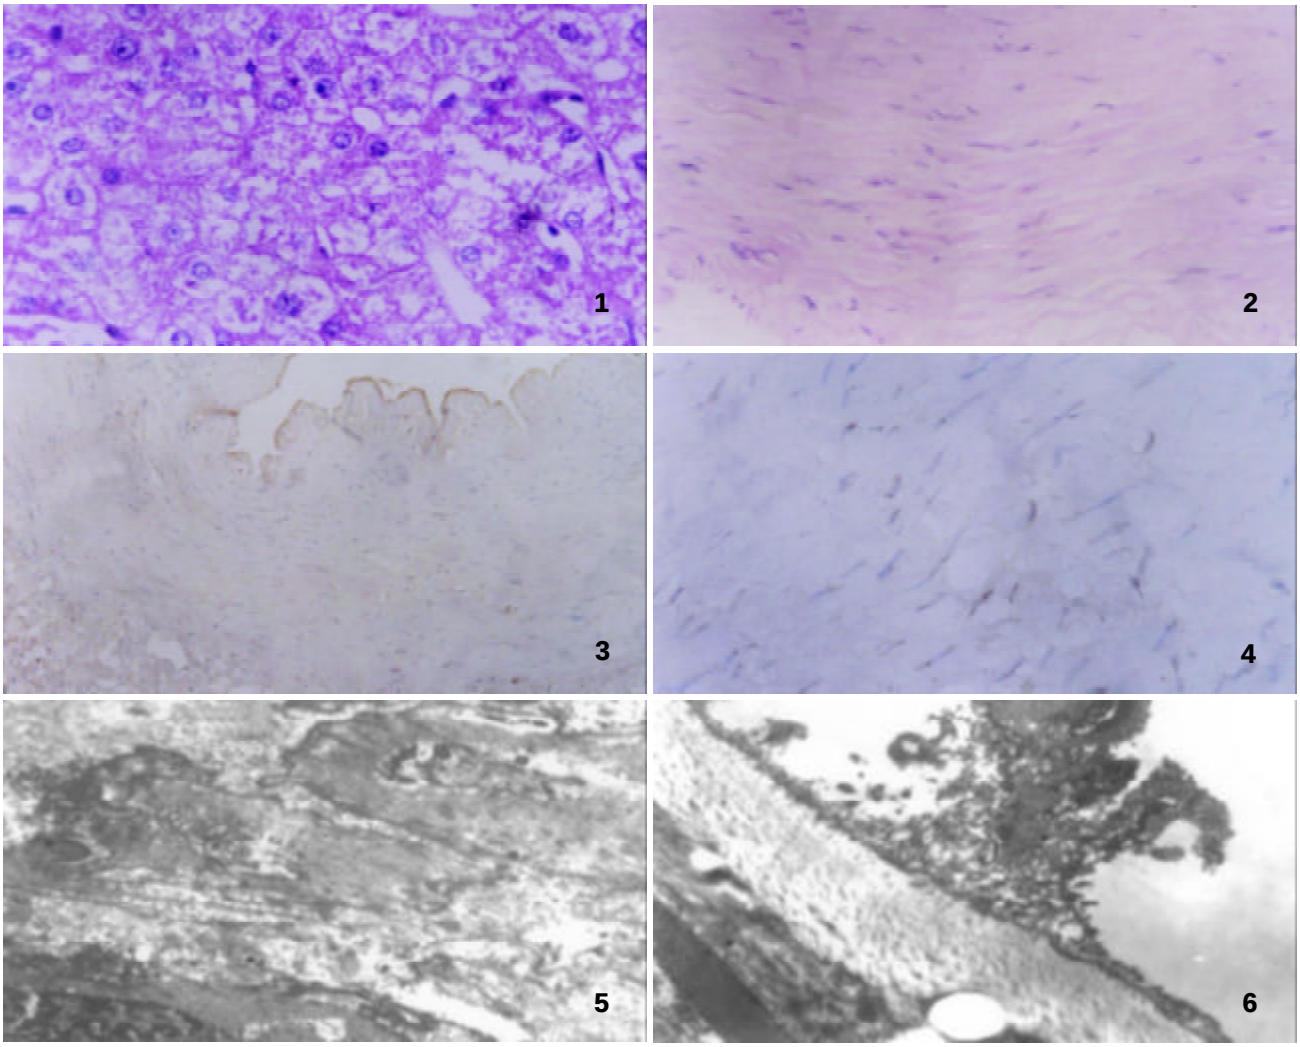

Figure 1 The liver tissue in portal hypertensive patients with HE staining × (400).
Figure 2 Splenic vein in portal hypertensive patients with HE staining method (×400).
Figure 3 Splenic vein in portal hypertensive patients by immunohistochemical staining with α-cm-actin antibody (×400).
Figure 4 Splenic vein in portal hypertensive patients by immunohistochemical staining with PCNA (×400).
Figure 5 Splenic vein of portal hypertensive patients under transmission electron microscope (×4000).
Figure 6 Splenic vein of portal hypertensive patients under transmission electron microscope (×6000).

Electron microscopic observation

In the splenic vein of these patients, endothelium was damaged with adhered thrombus, VSMC of media migrated into the subintima under transmission electron microscopy (Figures 5,6).

RT-PCR analysis

In the control group, the expression of local renin mRNA in the liver was significantly lower than that in the splenic artery or vein, $P<0.05$. Expression of local angiotensinogen mRNA in the liver was significantly higher than that in the splenic artery and vein, $P<0.05$. There was no significant difference in the expression of local renin or angiotensinogen mRNA between splenic artery and vein. ($P>0.05$, Figures 7,8,9).

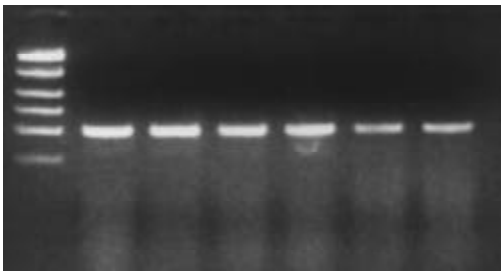

Figure 7 Expression of human β-actin mRNA (Note: from left to right there was PCR marker and lanes 1-6, figures 8,9 were the same).

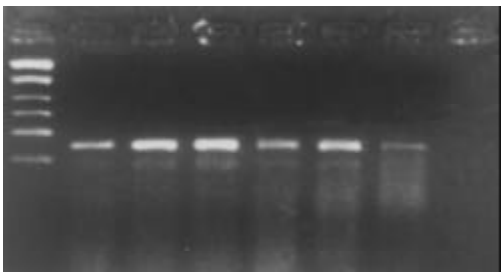

Figure 8 Expression of local renin mRNA in the liver, splenic artery and vein from the controls and cirrhotic portal hypertensive patients. Lanes 1,3,5 were splenic vein, artery and liver from controls, Lanes 2,4,6 were from patients.

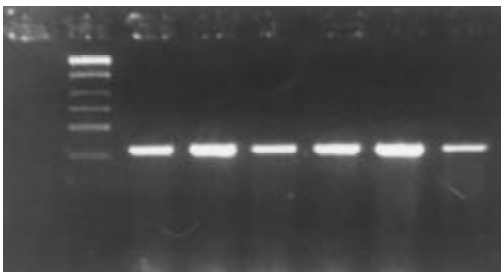

Figure 9 Expression of local angiotensinogen mRNA in the liver, splenic artery and vein from controls and portal hypertensive patients. Lanes 1,2,3 were splenic vein, artery and liver from controls, Lanes 4,5,6 were from portal hypertensive patients.

In cirrhotic portal hypertensive patient group, expression of local renin and angiotensinogen in liver, splenic artery and vein were all significantly higher than those in the controls respectively, $P<0.05$. Expression of local renin and angiotensinogen mRNA in the liver was not significantly different from those in the splenic artery or vein in PH group, $P>0.05$. The concrete data are listed in Table 2.

Table 2 Expression of local renin (Lr) and angiotensinogen (Lan) mRNA in the patient and control groups

	Control group (n=12)			Patient group (n=20)		
	Liver	Splenic artery	Splenic vein	Liver	Splenic artery	Splenic vein
Lr	0.19±0.11[a]	0.45±0.17	0.39±0.12	0.78±0.28[b]	0.86±0.35[b]	0.81±0.22[b]
Lan	0.64±0.21[a]	0.41±0.15	0.35±0.18	0.96±0.25[b]	0.83±0.18[b]	0.79±0.23[b]

The data were expressed as mean ±SD. Lr and Lan mRNA in the patient group versus those in the control group, [b]$P<0.05$. Within the same group, Lr and Lan mRNA in the liver versus those in splenic artery or vein respectively, [a]$P<0.05$.

DISCUSSION

The results demonstrated that expression of hepatic renin and angiotensinogen mRNA in cirrhotic portal hypertensive patients was significantly higher than that of the controls. Therefore the end product of LRAS, the synthesized local AngII increased and exerted a strong effect on hepatic microcirculation via its paracrine pathway.

Firstly, local AngII constricted blood vessels as well as sinusoids leading to increase of intrahepatic portal venous pressure through an increase in intracellular calcium in VSMC. Although VSMC was absent in the hepatic sinusoid, hepatic stellate cells (HSCs) expressed receptors for AngII, could also contract and increase the intrahepatic resistance[10-12].

Secondly, AngII has been shown to induce cell proliferation in various cell types, including hepatocytes and HSCs and was considered as a mediator of hepatic fibrogenesis[3,13]. Local angiotensinogen also induced increase of TGF-β mRNA expression which was an important growth promoting factor for HSC[14,15]. It was demonstrated that AngII could be a mitogenic factor for activated human HSCs through MAPK-dependent pathway[3,16]. Significant relationship was seen between high TGF-β and AngII production and the development of progressive hepatic fibrosis caused by hepatitis C virus[17,18]. AngII was also involved in the development of fibrosis in the heart and kidney through enhancement of TGF-β production[19]. *In vitro* study found that AngII could increase mRNA levels for collagen types I and III, procollagen α (I) and fibronectin in cardiac fibrosis[20]. Therefore it is possible that hepatic RAS plays an important role in the collagen synthesis, hepatic fibrosis and cirrhosis. In this study, the cirrhotic portal hypertension induced hepatic RAS activity which increased and accelerated the cirrhotic process and portal hypertension. By interrupting the vicious cycle, it was possible for medical treatment to prevent further progression of the disease. It has already been confirmed that catoprill could reduce the expression of procollagenI significantly and prevent liver fibrogenesis in a rat model of hepatic fibrosis[21-23].

The experimental data illustrated that expression of local renin and angiotensinogen mRNA in the splenic artery and vein of cirrhotic portal hypertensive patients was significantly higher than that of the controls and suggested that portal hypertension led to activation of LRAS of splenic vessels. The mechanism probably might be as follows: (1) Endothelial injury was caused by splanchnic hyperdynamic circulation and high blood flow shear, and the endothelial cells were the key site of LRAS metabolism[2]. (2) The splenic vessel wall was stretched by the increment of splanchnic blood flow. (3) Influence of other vasoactive substance.

When the expression of LRAS increased in splenic vessel, it could participate in many pathologic processes. Firstly, vascular RAS induced VSMC proliferation and enhanced progression of vascular remodeling. AngII induced hypertrophy, proliferation and migration of VSMC[24-26] with

modulation of expression of C-fos[22], C-jun, C-myc and synthesis of cytokines such as PDGF, b-FGf [23] etc. In this study, changes of VSMC in splenic vein of PH patients could be seen by HE stain, immunohistochemistry and electron microscopy. These suggested that vascular RAS was closely related with the structural alterations of the splenic vein. Response of VSMC to hypertension and injury of blood flow shear included: hypertrophy, proliferation and remodeling. As a result, the vascular RAS played an even more important role than endocrine RAS[27-30]. In addition, the matrix modulation was another key event in remodeling and vasculopathy[7,8]. Other studies reported that vascular RAS modulated the synthesis of vessel matrix via its effect on expression of PDGF and TGF-β etc[31,32]. Therefore, LRAS plays an important role in vascular remodeling and vasculopathy in portal hypertension.

Secondly, LRAS has vasoconstrictive functions. The response of splanchnic blood vessel to AngII decreased in advanced portal hypertension[33], it was due to decrease of AngII receptor on the blood vessel wall or due to the existence of post receptor dysfunction[34,35]. Furthermore, glucagon and other vasoactive substances could influence the effect of AngII on splanchnic vessel[36,37].

Thirdly, the imbalance of vasoconstrictors and vasodilators was existed in portal hypertension. Studies on vasculature showed that vascular RAS could change the response of blood vessel to other vasoactive substances[29] and *vice versa*[38]. For example, in the rabbit model of portal hypertension, the response degree of splanchnic vessel to AngII was improved by CO[33], the presence of ET could induce the local renin activity and increase sythesis of AngIIin rat mesentery artery[39], and LRAS could decrease the degradation of endogenous bradykin[30]. All the changes mentioned above could result in imbalance of vasodilators and vasoconstrictors. In this study, local renin and angiotensinogen mRNA expression in the liver was not significantly different from that in the splenic artery and vein in portal hypertensive patients, suggesting that the loss of expression of organ- specificity of LRAS components might be due to disordered metabolism of vasoactive substances.

In conclusion, increased LRAS activity in the hepatic and splenic vessels is due to cirrhotic portal hypertension, and the synthesis of local AngII increases, which contract the hepatic sinusoid, stimulate hyperplasia of HSC and proliferation of VSMC, and also interfere with the metabolism of other vasoactive substances. All these enhance the degree of cirrhosis and portal hypertension. By interruption of this vicious cycle, medical treatment may be able to improve the hemodynamic disturbance and ameliorate the splanchnic vasculopathy and to offer a new way for preventing the complications of portal hypertension[40].

Abstract

AIM: To prospectively explore the role of carcinoembryonic antigen (CEA) in gallbladder bile in patients with colorectal carcinoma and the morphological and clinical features of neoplasia and the occurrence of hepatic metastases.

METHODS: CEA levels in the gallbladder and peripheral blood were studied in 44 patients with colorectal carcinoma and 10 patients with uncomplicated cholelithiasis. CEA samples were collected from the gallbladder bile and peripheral blood during the operation, immediately before extirpating the colorectal neoplasia or cholecystectomy. Values of up to 5 ng/ml were considered normal for bile and serum CEA.

RESULTS: In the 44 patients with colorectal carcinoma who underwent operation with curative intent, the average level of serum CEA was 8.5 ng/ml (range: 0.1 to 111.0 ng/ml) and for bile CEA it was 74.5 ng/ml (range: 0.2 to 571.0 ng/ml). In the patients with uncomplicated cholelithiasis who underwent cholecystectomy, the average level of serum CEA was 1.9 ng/ml (range: 1.0 to 3.5 ng/ml) and for bile CEA it was 1.2 ng/ml (range: 0.3 to 2.9 ng/ml). The average duration of follow-up time was 16.5 months (range: 6 to 48 months). Four patients who underwent extirpation of the colorectal carcinoma without evidence of hepatic metastasis and with an average bile CEA value of 213.2 ng/ml presented hepatic metastases between three and seventeen months after removal of the primary colorectal neoplasia. Three of them successfully underwent extirpation of the hepatic lesions.

CONCLUSION: High CEA levels in gallbladders of patients undergoing curative operation for colorectal carcinoma may indicate the presence of hepatic metastases. Such patients must be followed up with special attention to the diagnosis of such lesions.

INTRODUCTION

Colorectal carcinoma is the second most common cancer type in the Western world and the liver is the organ most affected by its distant metastases[1,2]. At the time when primary tumor is extirpated, hepatic metastases are encountered in 20 to 25 % of the patients. Approximately half of the patients who have had colorectal lesions extirpated in an apparently curative manner will develop hepatic metastases postoperatively[1,3,4].

The majority of relapse monitoring programs for operated colorectal carcinoma include determinations at regular intervals of the serum concentration of carcinoembryonic antigen (CEA) and hepatic imaging via abdominal ultrasonography, tomography and/or magnetic resonance[3,5]. Nonetheless, even with such investigations, around 10 to 30 % of hepatic metastases will remain undiagnosed[4]. When lesions are present in the liver, extirpation is the treatment of choice. However, this is only possible in 20 % of such patients and only 25 % of these will achieve survival of more than 5 years[1,3,4].

In 1965, Gold and Freedman[6] described the presence of CEA in extracts from malignant tumors and fetal intestinal tissue. Today, assaying of blood CEA is utilized preoperatively and postoperatively among colorectal carcinoma patients for the detection of disease relapse[7-10].

In 1989, Yeatman *et al*[11] suggested that CEA concentration in bile could constitute a marker for detecting hepatic metastases at an earlier stage. Their hypothesis was based on the observation that CEA derived from hepatic metastases could be excreted both in bile and in blood. Since the bile volume is less than the plasma volume, rises in the detectable CEA concentration occur earlier in the gallbladder than in peripheral blood[11-13]. Yeatman and Paul *et al*[11-14] found elevated CEA concentrations in bile among patients with colorectal carcinoma and proven hepatic metastases and among patients who underwent curative extirpation without any hepatic involvement could be detected via imaging methods.

The role of CEA level in gallbladder bile remains controversial with regard to its contribution towards early detection of hepatic metastases in patients undergoing curative operation for colorectal carcinoma[15-23].

The aim of this study was to prospectively analyze the results of CEA determinations in peripheral blood and gallbladder bile among a series of patients treated by curative operation for colorectal carcinoma, relating them to morphological features of the neoplasia and hepatic relapse.

MATERIALS AND METHODS

Patients

Between 1998 and 2001, 44 patients experienced extirpation of colorectal carcinoma with curative intent. The term curative was utilized to designate an absence of macroscopic disease at the termination of the surgical procedure, verified in the report on the anatomopathological examination of the extirpated neoplastic lesions and associated structures. Samples of gallbladder bile and peripheral blood were collected during the operation, immediately before the start of excision of the neoplasia, for all patients.

This investigation was made in accordance with the ethical standards accepted by the Helsinki Declaration of the World Medical Association, adopted in 1964 and amended in 1996. The patients were aware of the study protocol and signed a statement of free and informed consent upon entering the present study.

The following were considered to be inclusion criteria: achievement of curative operation, absence of distant metastases and presence of adenocarcinoma of the large intestine confirmed by means of histopathological study of the extirpated lesion. Patients submitted to operations that were evaluated as non-curative were not included in this sample.

The clinical and morphological data were obtained by consulting the hospital records of the patients included in the study, or by interviewing the patients or their relatives at return outpatient visits.

Thirty-nine patients (88.6 %) were white, three were oriental (6.8 %) and two were black (4.5 %). Twenty-one patients (47.7 %) were male and 23 (52.3 %) were female. The average age was 63±14.7 years (range: 29 to 90 years). All patients had their preoperative diagnosis of colorectal carcinoma confirmed by biopsy specimens obtained via colonoscopy. For this, the thin sections were stained using the hematoxylin-eosin (HE) method and analyzed by a pathologist.

Neoplasia was considered to be Dukes A when it did not reach the external muscle tunica of the intestinal wall, Dukes B when it extended throughout the wall and also reached the adventitious adipose tissue, and Dukes C when lymph nodes were compromised, independent of the depth of parietal invasion.

Preoperative investigation of the presence of an extra-intestinal lesion was made via abdominal ultrasonography, abdominal tomography and chest radiography, and did not reveal metastases in any of these patients.

In ten patients with uncomplicated cholecystolithiasis who underwent elective cholecystectomy via laparotomy, blood and gallbladder bile samples were collected under the same conditions as for the patients with colorectal carcinoma. These served to furnish CEA levels in gallbladder bile for comparison purposes. All these patients were white, of whom seven (70 %) were female and three (30 %) were male. The average age was 50.8±20.1 years (range: 23 to 74 years old).

Sample collection

Blood and bile sample collection was performed during the operation. After making an inventory of the abdominal cavity, 5 ml samples of gallbladder bile were obtained via puncture of the fundic region of the gallbladder using a caliber 23 needle coupled to a plastic syringe of capacity 10 ml. Then, using another syringe of capacity 20 ml, the remainder gallbladder bile was evacuated, followed by occlusion of the location of the puncture by a pouch suture using thin atraumatic absorbable thread made of polyglycolic acid. At the start of the operation, prior to removing the colorectal neoplasia, 5 ml blood samples was collected via peripheral venous puncture in the non-dominant upper limb, divested of intravenous infusion of any solution, using a caliber 37 needle coupled to a plastic syringe of capacity 10 ml.

CEA assay

The serum and bile samples were stored in a freezer at -70 ℃ until the CEA analyses were done. A solid-phase fluoroimmunometric assay system was utilized (Delfia CEA Kit, Pharmacia, Turkü, Finland) for assaying the serum and bile CEA. The precision of the method was estimated via the coefficient of variation (c.v.), with intra-assay c.v. of 3.4 % and 2.4 % for low and high values, respectively, and inter-assay c.v. of 4.6 % and 2.8 % for the same parameters. The sensitivity of this CEA assay was 0.2 ng/ml and the upper limit on the recognition curve was 500 ng/ml. Whenever this value was exceeded, dilutions were needed for adjustment of the reactions.

The limit of normality adopted for bile CEA was 5 ng/ml which was based on the analysis of the values obtained in the group of patients who underwent cholecystectomy.

Statistical analysis

Considering the nature of the samples, non-parametric statistical tests were utilized in the evaluation of the results. Quantitative variables were represented by absolute frequency (*n*) and relative frequency (%). The statistical models utilized were arithmetic mean, standard deviation, Mann-Whitney test, Wilcoxon test and Kruskal-Wallis test. The normality of the data were tested using the Kolmogorov-Smirnov test and the homogeneity of the variance was verified using the Levene test.

In all tests, the level for the rejection of the null hypothesis was set at 0.05 % (significance level of 95 %), in accordance with the current standards in biological studies.

RESULTS

In the group of patients with colorectal carcinoma, there was a single lesion in 43 patients (97.7 %) and multiple lesions in one of them (2.3 %). The neoplasia was located in the rectum in 24 patients (54.5 %), in the cecum-ascending colon in 6 (13.7 %), in the transverse colon in 6 (13.6 %), in the sigmoid in 4 (9.1 %), in the descending colon in 2 (4.5 %), in the left flexure in 1 (2.3 %), and the lesion involved the cecum and rectum simultaneously in 1 patient (2.3 %). With regard to the degree of histopathological differentiation of the neoplasia, all the lesions were considered to be moderately differentiated. All the patients operated for colorectal carcinoma evolved without notable intercurrences and were discharged from hospital. The average duration of follow-up for the patients was 16.5 months (range: 6 to 48 months).

Concerning the Dukes classification, 2 patients (4.6 %) were classified as class A, 21 (47.7 %) as class B, and 21 (47.7 %) as class C.

Thirteen patients (29.5 %) classified as Dukes C were submitted to adjuvant chemotherapy using intravenous 5-fluorouracil over seven sessions.

In the patients with colorectal carcinoma, the average value was 8.5±18.7 ng/ml (range: 0.1 to 111.0 ng/ml) for serum CEA, and was 74.5±130.3 ng/ml for bile CEA (0.2 to 571 ng/ml) (Table 1).

In the group of patients with uncomplicated cholelithiasis, the average value was 1.94±0.8 ng/ml (range: 1.0 to 3.5 ng/ml) for serum CEA, and was 1.24±0.9 ng/ml for bile CEA (range: 0.3 to 2.9 ng/ml) (Table 2). The patients in this group were discharged from hospital with uneventful recovery.

Seventeen patients (38.6 %) presented a serum CEA value of more than 5.0 ng/ml, while 27 patients (61.4 %) exhibited a blood CEA level less than or equal to 5.0 ng/ml. With regard to bile CEA, 29 patients (65.9 %) exhibited values of more than 5.0 ng/ml, whereas 15 patients (34.1 %) had determinations of less than or equal to 5.0 ng/ml. In 35 patients (79.5 %), the bile CEA level was greater than the serum CEA level, and in nine patients (20.5 %), the serum CEA level was higher than the bile CEA level. Thirteen patients (29.5 %) simultaneously presented serum CEA and bile CEA values of more than 5 ng/ml. In 11 patients (25.0 %), the determinations obtained for serum CEA and bile CEA were less than or equal to 5.0 ng/ml.

The bile CEA values in the patients operated for colorectal carcinoma were significantly greater than those determined in the blood ($P<0.0001$) (Table 1). On the other hand, in the group of patients who underwent cholecystectomy, the bile CEA

values were significantly less than those of serum CEA (P=0.46) (Table 2). The bile CEA levels in patients with colorectal carcinoma were significantly greater (P<0.0001) than those that underwent cholecystectomy. Comparison of the bile CEA/serum CEA ratios for the colorectal carcinoma and cholecystectomy patients showed significantly greater values in the group with neoplasia of the large intestine than in those with cholecystectomy (P<0.0001) (Table 3).

Table 1 Average values for serum and bile CEA obtained from patients operated for colorectal carcinoma

Variables	Average (ng/ml)	S.D.	Minimum (ng/ml)	Maximum (ng/ml)	*n*
Serum CEA	8.5	18.7	0.1	111.0	44
Bile CEA	74.5	130.26	0.2	571.0	44

Wilcoxon (Z)=-4.614, P<0.0001 (Serum CEA *vs* Bile CEA), Notes: S.D.=standard deviation.

Table 2 Average values for serum and bile CEA obtained from patients operated for uncomplicated cholelithiasis

Variables	Average (ng/ml)	S.D.	Minimum (ng/ml)	Maximum (ng/ml)	*n*
Serum CEA	1.9	0.8	1.0 ng/ml	3.5 ng/ml	10
Bile CEA	1.2	0.9	0.3 ng/ml	2.9 ng/ml	10

Wilcoxon (Z)=-1.992, P<0.46 (Serum CEA *vs* Bile CEA), Notes: S.D.=standard deviation.

Table 3 Average values of the bile CEA/serum CEA ratio obtained from patients operated for colorectal carcinoma and cholelithiasis

Group	Variables	Average	S.D.	Minimum	Maximum	*n*
Colorectal carcinoma	Bile CEA/serum CEA	22.1	48.5	0.02	287.0	44
Cholelithiasis	Bile CEA/serum CEA	0.6	0.3	0.3	1.9	10

Mann-Whitney (U)=63.5, P<0.0001 (colorectal carcinoma group *vs* cholelithiasis group), Notes: S.D.=standard deviation.

In this study, there was no significant relationship between Dukes classification and serum CEA values (P=0.60) or bile CEA values (P=0.78). Besides, the bile and serum CEA values showed a non-significant relationship with the localization of the neoplastic lesions in the right colon, left colon or rectum (P=0.93 and P=0.53, respectively).

Four patients (9.1 %) with colorectal carcinoma showing elevated bile CEA levels who were operated on with curative intent presented evolution to hepatic metastases. They were initially diagnosed due to a rise in postoperative serum CEA levels, with an average of 8.6 ng/ml (range: 0.3 to 22.8 ng/ml). Only two of them presented increased serum CEA levels at the time of operation, although all four presented elevated bile CEA levels, with an average of 228.4 ng/ml (range: 6.6 to 571 ng/ml). They corresponded to 13.8 % of the 29 patients with elevated bile CEA. In these four patients, hepatic metastases developed on average around 9.7 months (range: 3 to 17 months) after removal of the primary colorectal lesion. Three of them were staged as Dukes C and one as Dukes B (Table 4). With the exception of the single Dukes B patient, who presented disease relapse with hepatic metastases disseminated in both lobes, the other three patients were submitted to hepatectomy for the removal of their metastases. Two of them died after removal of the hepatic lesions: one around nine months afterwards and the other 21 months afterwards. Although no necropsy was performed on these patients, there was no evidence of neoplasia recurrence up to the time of death. The third of these patients is still alive, without active disease, around eight months after extirpation of the hepatic metastases. The remaining 40 patients are alive, without signs of disease relapse, six to 48 months after removal of the primary colorectal lesion.

Table 4 Location of the lesion, Dukes staging and serum and bile CEA values, obtained from the patients operated for colorectal carcinoma with hepatic metastases during the follow-up

Case	Location	Dukes	Serum CEA (ng/ml)	Bile CEA (ng/ml)
1	Transverse colon	B	22.8	510.0
2	Rectum	C	2.1	292.0
3	Rectum	C	9.4	44.1
4	Sigmoid	C	6.6	6.6
Average			10.2	213.2

DISCUSSION

An ability to predict the appearance of hepatic metastases in patients operated on for colorectal carcinoma with curative intent could influence the use of adjuvant chemotherapy and intensify the follow-up of patients with indications for surgical treatment for lesions that could be extirpated[18,20,24-26].

Determination of bile CEA levels may be a potentially sensitive method for diagnosing hepatic metastases of colorectal carcinoma, since hepatic lesions smaller than 1 cm^3 are able to produce elevations of CEA concentrations in bile[11,16,22,26].

Huang and Tang[17] studied serum and bile CEA obtained by drainage using a preoperative duodenal tube in patients with benign affections and colorectal carcinoma, with and without hepatic metastases. These authors verified that the difference between bile CEA values in patients operated upon for colorectal carcinoma with and without hepatic metastases was significant, thus showing that the bile CEA level assisted in confirming the existence of hepatic lesions. Novell and Moura *et al*[19, 22] studied the levels of serum and bile CEA in patients with colorectal carcinoma and suggested that a determination of the bile CEA level might be useful in diagnosing concealed hepatic metastases. In the four patients of the present study who evolved with hepatic metastases, and in 29 other patients (65.9 %) who did not present metastases, the bile CEA values were also significantly greater than those for serum CEA. The average follow-up duration of 16.5 months was not yet sufficient for a conclusive evaluation of bile CEA determination as a predictive parameter for the appearance of hepatic metastases in these patients. An average follow-up for at least 60 months would increase the possibility of finding hepatic relapse of the disease and would furnish more consistent support for an assessment of the usefulness of bile CEA.

In patients with hepatic metastases of colorectal carcinoma, the concentrating capacity of the gallbladder has been singled out as the mechanism responsible for the elevated bile CEA levels in comparison with serum CEA levels[18,27-29]. The finding of elevated bile CEA values in the absence of hepatic metastases may also be credited to the fact that bile CEA is derived not only from the hepatic metastases but also from the primary tumor[29]. This situation is thought to contribute to the existence of a direct relationship between serum and bile CEA levels[13]. That is, when serum CEA levels are significantly elevated, bile CEA levels will also be, and consequently the serum CEA levels produced by the primary tumor may elevate the bile levels, even in the absence of hepatic metastases. These events could justify the findings in the present sample, in which 25 patients (86.2 %) with elevated bile CEA levels had not

presented hepatic metastases at the time of last follow-up consultation. Nonetheless, other studies[13,14,17,30] have suggested that increased CEA levels in bile in the presence of hepatic metastases are exclusively produced by neoformation in the liver, without originating in the portal circulation, indicating that patients with elevated bile CEA have silent hepatic metastatic disease. Paul *et al*[14] suggested that the bile CEA predicted hepatic disease only when collected after the removal of the primary tumor, which would avoid any significant contribution of serum CEA to bile CEA levels. It remains to be proven whether the finding of elevated serum and bile CEA levels during the extirpation of colorectal carcinoma, as occurred in 27 patients (61.4 %) of this study would constitute a selecting criterion for monitoring bile CEA levels after operation.

Yeatman *et al*[11] found elevated bile CEA levels in 70 % of their patients with colorectal carcinoma extirpated in a curative manner that had normal intraoperative hepatic ultrasonography. Over the average follow-up of 30 months for this group of patients, 13 % of them presented hepatic metastases. The result was close to that found in the present study, which observed that 9.1 % of patients had hepatic metastases over an average follow-up of 16.5 months. Li Destri *et al*[23] found a diagnostic accuracy for bile CEA of 91 % among patients operated for colorectal carcinoma with or without hepatic metastases, and 89.5 % among patients who evolved with hepatic metastases. Ishida *et al*[21] analyzed the relationship of CEA values in gallbladder bile collected during operation and in peripheral blood, with the appearance of metachronic hepatic metastases of colorectal carcinoma. In 49 patients without evidence of hepatic metastases at the time of operation, the elevated levels of bile CEA were predictive of the appearance of metachronic hepatic metastases with a 75 % sensitivity rate, 85 % specificity and 84 % accuracy. In another study, Ishida *et al*[15] showed that patients with elevated bile CEA or elevated bile CEA / serum CEA ratio could be candidates for hepatic relapse.

In the present study, four patients (9.1 %) operated for colorectal carcinoma with curative intent developed hepatic metastases after removal of the neoplastic lesion. Since the average follow-up duration for the patients was 16.5 months, it was possible that the number of patients affected by hepatic metastases and elevated bile CEA increased with the prolongation of the follow-up. This could make the determination of bile CEA levels a predictive parameter for the development of hepatic lesions.

However, other studies did not share the idea that bile CEA had a predictive value in relation to the development of hepatic metastases. Dorrance *et al*[20] determined serum and bile CEA levels in 26 patients submitted to curative surgery and followed up for an average of 63.5 months. Twelve patients (46.1 %) survived without relapse and 14 (53.8 %) died because of recurrence of neoplasia. The average value of serum CEA in the group free of disease was significantly greater than that in the group with relapse. The accuracy of serum CEA as a predictive indicator for concealed hepatic metastases was 77 %, in comparison with 72 % for bile CEA, without significant difference. The authors concluded that determination of intraoperative bile CEA levels was not more accurate than serum CEA as a predictive indicator for the occurrence of metastases among patients undergoing potentially curative surgery for colorectal carcinoma. Panaguzzi *et al*[16] studied the follow-up of patients operated for colorectal carcinoma without hepatic metastases although with elevated bile CEA levels. They concluded that, although the bile CEA levels were elevated in patients with hepatic metastases, these levels did not represent a predictive parameter for their presence in colorectal carcinoma. Garcia *et al*[18] determined the concentration of bile CEA in 24 patients with colorectal carcinoma, all of them exhibited elevated bile CEA, of whom 21 did not present evidence of hepatic metastases, while three had such lesions in the liver. These authors followed up their patients for an average of 32.3 months. Three of them developed hepatic metastases. The authors stressed that there was no clear relationship between the bile CEA values and the appearance of hepatic metastases, although they recognized that their sample was not large enough for definitive conclusions.

In our sample, nine patients (20.5 %) presented bile CEA values less than the respective values for serum CEA. One possible explanation for this fact is that the liver purification mechanisms for CEA produced by primary colorectal neoplasia might not be saturated and consequently the levels excreted into the bile would be less than into blood.

Bile CEA has apparently emerged as a promising tool for identifying patients with undiagnosed hepatic metastases. In patients with verified recurrence of neoplasia, the sensitivity of CEA determination in bile is greater than that for values found in the blood. Consequently, there could be a broadening of the indication for hepatectomy or radiofrequence ablation[31] due to hepatic metastases. Local or systemic chemotherapy procedures[32] could be introduced earlier, as could radioimmunoguided surgery or also treatments using anti-CEA monoclonal antibodies. To prove the real value of bile CEA for detecting hepatic relapses at an earlier stage, prospective studies with an adequate length of follow-up time, and standardized intervals between extirpation of colorectal neoplastic lesion and withdrawal of the bile samples, are needed.

Abstract

AIM: To study the effects of carbon dioxide on the metastatic capability of cancer cells, and to compare them with that of nitrogen.

METHODS: The colon cancer cell CCL-228 was treated with 100 % carbon dioxide or nitrogen at different time points and then cultured under normal condition. Twelve hours after the treatment, the survival rates of suspension cells and the expressions of e-cadherin and VEGF were examined.

RESULTS: After 60 min of carbon dioxide and longer time of nitrogen treatment, the suspended cells increased and the expression of e-cadherin decreased while the expression of VEGF was enhanced significantly. And the effects of nitrogen were similar to, but weaker than, those of carbon dioxide.

CONCLUSION: Carbon dioxide may improve the metastatic capability of cancer cells and its effects are significantly stronger than that of nitrogen. A sequential use of carbon dioxide and nitrogen in pneumoperitoneum may take the advantage of both gases.

INTRODUCTION

The indications for laparoscopic surgery have expanded significantly thanks to the improved expertise and equipment. The main method to expose the operative field is carbon dioxide pneumoperitoneum. A large number of laparoscopic surgeries for gastroenteric malignant diseases, especially rectum or colon resections, have been performed. But there is a dispute on whether laparoscopic surgery is suitable for malignant diseases[1-6]. To investigate if carbon dioxide influences the metastatic capability of gastroenteric cancer cells, we studied the effects of carbon dioxide on the adhesive growth and the expression of cadherin and VEGF of a colon cancer cell line CCL-228 propagated *in vitro*. And the effects of carbon dioxide were compared with those of nitrogen. We found that, the metastatic ability of CCL-228 cells might elevate after carbon dioxide treatment and the influence of nitrogen was significantly milder than that of carbon dioxide. Based on these results, we proposed a sequential pneumoperitoneum method to reduce the side-effect but remain the safe-guard ness of carbon dioxide, *i.e.*, to establish the pneumoperitoneum with carbon dioxide and to maintain it with nitrogen, and before the end of the surgery, insufflating carbon dioxide to remove the unabsorbable nitrogen. In the present study, we evaluated the influence of the sequential gas treatment on the expression of E-cadherin and VEGF in CCL-228 cells.

MATERIALS AND METHODS

Cell culture

Human colon cancer cell line CCL-228, supplied by the Type Culture Collection Center, Wuhan University, was maintained in RPMI 1640 medium supplemented with 10 % fetal bovine serum. The cell cultures were maintained as monolayer in a plastic flask and incubated in 5 % CO_2, 95 % air at 37 ℃. The cultures were free of mycoplasma.

Carbon dioxide or nitrogen treatment

The CCL-228 cells were seeded onto 6-well plates (1×10^6 cells per well). When the button was 80 % covered, the cells were divided into two groups. Three parallel wells of cells in each group were incubated either in 100 % CO_2 (CO_2 group) or in 95 % N_2+5 % CO_2 (N_2 group) for 30, 60, 120, 180 min, respectively. To evaluate the effect of sequential pneumoperitoneum on the metastatic ability of colon cancer cells, 3 wells of CCL-228 cells were treated with CO_2 for 15 min, with nitrogen for 90 min or 150 min, and then with CO_2 again for 15 min. After the gas treatment, all cells were incubated again in 5 % CO_2, 95 % air for 12 h.

Histology

The supernate was collected and stained with typan blue, and the survival rate of the supernatant cells was estimated.

Immunohistochemistry

The adhesive growth cells were collected and stained for immunohistochemical studies on the expressions of VEGF and E-cadherin. The cell smear was fixed with cold acetone for 10 min at room temperature and rinsed with phosphate-buffered saline (PBS). The endogenous peroxidase was blocked using 3 % hydrogen peroxide for 10 min and the unspecific combined site was blocked with normal goat serum. Excessive blocking serum was drained and the samples were incubated at 40 ℃ for 18 h with the appropriate dilution of monoclonal mouse anti-human

VEGF or E-cadherin (Santa Cluz). Each sample was then rinsed with PBS and incubated for 10 min at room temperature with 50 μl of biotin-labeled goat anti-mouse IgG. The samples were then rinsed with PBS and incubated for 10 min at room temperature with 50 μl peroxidase conjugated avidin. The smears were rinsed with PBS and incubated for 5 min with diaminobenzidine. They were then washed with water and counterstained with Mayer' s hematoxylin and fixed with neutral resin. The smears were examined under microscope and positive reaction was indicated by brownish precipitate in cytoplasm.

Analysis of results

The smears were analyzed with MPZAS-500 multimedia color pathological graph analyzing system. The average integral light density (ILD) of positive staining in each sample was obtained and presented as $\bar{x}\pm s$. Results were then analyzed with Student' s *t* test.

RESULTS

Effects of CO_2 and N_2 on adhesive growth of CCL-228

Sixty min of CO_2 treatment or 120 min of N_2 treatment was sufficient to increase the rate of suspending growth cells very significantly (Table 1). The difference of rates of alive suspending cells between CO_2 and N_2 treatments was very significant after 60 min of treatment ($P<0.01$).

Table 1 Counts and survival rate of suspension CCl-228 cells after CO_2 or N_2 treatment

Duration	Counts of suspension cells (×1000 / ml)		Survival rate of suspension cells	
	CO_2 group	N_2 group	CO_2 group	N_2 group
0 min	4.2±0.1		0.884±0.011	
30 min	7.5±2.9	4.9±2.5	0.912±0.018	0.852±0.022
60 min	16.7±5.4[ab]	5.2±0.7	0.914±0.041	0.897±0.021
120 min	23.2±10.7[ac]	8.5±1.4[d]	0.904±0.034	0.912±0.023
180 min	32.1±5.5[ac]	9.7±3.3[d]	0.845±0.028	0.912±0.032

[a]$P<0.01$, *vs* the 0 min in same group; [b]$P<0.05$, *vs* N_2 group at same time; [c]$P<0.01$, *vs* N_2 group at same time; [d]$P<0.05$, *vs* 0 min in same group.

Effects of CO_2 and N_2 on expression of E-cadherin in CCL-228 cell

Both CO_2 and N_2 treatment depressed the expression of E-cadherin in CCL-228 cell (Figure 1). The expression of E-cadherin after 60 min or longer time of CO_2 treatment was significantly different from that after the same time periods of N_2 treatment. Comparing with the expression of E-cadherin before any gas treatment, 120 min or longer time of CO_2 treatment produced a very significant depression ($P<0.01$) and the same periods of N_2 treatment caused a significant depression ($P<0.05$).

Effects of CO_2 and N_2 on expression of VEGF in CCL-228 cell

Both CO_2 and N_2 treatment improved the expression of VEGF in CCL-228 cell (Figure 2). Thirty min to 120 min of CO_2 treatment caused significantly higher expression of VEGF comparing with the normal control and the same periods of N_2 treatment ($P<0.05$). CO_2 treatment for 180 min resulted in a VEGF expression significantly lower than CO_2 treatment for 120 min, but still significantly higher than normal control. As for N_2, 30 min to 180 min of treatment resulted in a continuous increase of VEGF expression.

Effects of sequential treatment with CO_2 and N_2 on expression of E-cadherin and VEGF in CCL-228 cell

The effects of sequential gas treatment for 120 min or 180 min on expression of E-cadherin and VEGF in CCL-228 cell were not significantly different from those of continuous nitrogen treatment but significantly milder than those of continuous carbon dioxide treatment (Figures 1 and 2).

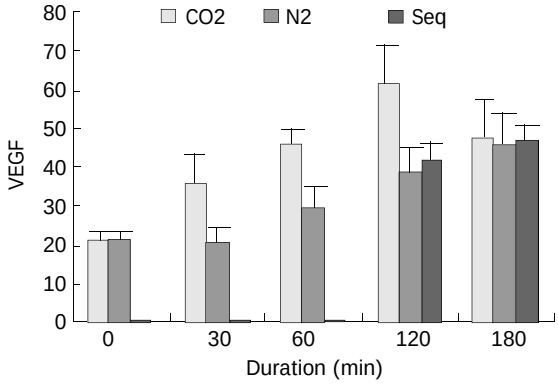

Figure 2 The expression of VEGF in CCL-228 cells after gas treatment.

DISCUSSION

It has been verified that laparoscopic surgery has many virtues such as minimal injury, less pain, sooner rehabilitation and less intervention in the immune function[7-11]. Now many gastroenteric surgeries including cancer resection could be fulfilled under laparoscope. Clinical trials have proved that laparoscopic surgery is feasible for gastroenteric malignant diseases. However, cancer metastasis in trocar site has been reported and has aroused a debate about whether laparoscopic surgery is suitable for malignant diseases. There is no consensus on if the incidence of metastasis in trocar site was accurately higher than that in the wound after open surgery[6], because the cases were few in each paper and there has been a decline in incidence of trocar site metastasis in recent reports, due to more attention paid to the wound protection during extraction of the specimen. Moreover, open surgery has been reported to increase cancer metastasis[12-15], and had more intervention in immunity. Therefore, whether laparoscopic surgery is suitable to early malignant diseases needs to be clarified by more clinical trials and further laboratory studies. In the present experiment, we studied the effect of carbon dioxide on the adhesive ness of colon cancer cells to the culture plate and the expressions of E-cadherin and VEGF. It should be noted that, the duration of carbon dioxide treatment was much longer than others because a laparoscopic surgery for gastroenteric cancer resection often lasts 2-3 hours.

We found that both carbon dioxide and nitrogen influenced the adhesive growth of CCL-228 cells. The cells in supernate increased after CO_2 or N_2 treatment. The rate of living cells in

supernate had no significant change confirmed by typan blue staining. Therefore, increase of cells in the supernate was a result of detachment of cells from the culture plate, but not the result of apoptosis or necrosis after gas treatment. It is suggested that CO_2 or N_2 could influence the adhesive ness of CCL-228 to matrix, resulting in easier metastasis by improving the detachment of cancer cells from the original lesion. We found that 30 min of CO_2 treatment caused an obvious increase of suspensive growth but the increase was not statistically significant, while 60 min and longer time produced very significant results. There were several laboratory reports on the effect of CO_2 on liver metastasis of intestinal cancer but the conclusions were controversial. We suppose that the controversy might result from a relatively short duration of pneumoperitoneum. Considering that laparoscopic surgery for malignant diseases usually needs several hours, the pneumoperitoneum time in experiments should be long enough to produce a practical result.

E-cadherin is one of the key adhesive molecules to mediate intercellular adhesion. It has been proved that, E-cadherin expression is depressed in metastatic tissues, which is helpful for the detachment of cancer cells from original lesions[16-20]. We examined the expression of E-cadherin in CCL-228 to explore if it plays a role in the influence of carbon dioxide on the adhesive growth of CCL-228. The results showed that, carbon dioxide treatment depressed E-cadherin expression and the effect was positively related to the duration of carbon dioxide treatment. Because cancer metastasis course includes the detachment of cells from the original lesion and also the settlement in the new environment, depression of adhesion has a two-edged effect on the metastasis of cancer. It is helpful for cancer cell dissemination but unfavorable to the settlement of circulating cancer cells.

The expression of VEGF is essential for cancer metastasis because it is a vital factor in tumor angiogenesis. A great deal of researches have indicated that cancer cells with higher VEGF expression results in much more persistently growing metastatic lesions, and inhibition of VEGF expression or function could interrupt the metastasis[21-25]. Therefore, we studied further the effect of carbon dioxide on VEGF expression in CCL-228 and found that it promoted VEGF expression. The promotion of VEGF expression suggests that decrease of E-cadherin expression in CCL-228 cells was not due to a general inhibition of protein synthesis by carbon dioxide, and the results implicate that carbon dioxide pneumoperitoneum was favorable for not only the detachment of cancer cells from the primary lesion but also for the growth of micrometastatic cells and their aggregation into a mass.

Many factors are supposed to be associated with the favorable effect on cancer growth and metastasis by carbon dioxide. The topical acidosis might be the main reason, and the less absorbable gases such as nitrogen and helium have less influence on metastasis[1,26,27]. In this experiment, we found that, comparing with carbon dioxide, nitrogen had a similar but much more mild effects on cancer cells. Since carbon dioxide had a significant duration-effect relationship with the expression of E-cadherin and VEGF, reduced carbon dioxide insufflation duration might be less harmful to patients with malignant diseases. Here we propose a sequential pneumoperitoneum, namely, establishing the pneumoperitoneum with carbon dioxide and maintaining it with nitrogen, and then, before the end of surgery, insufflating carbon dioxide to remove the unabsorbable nitrogen. We found that, during the 120 min or 180 min of gas treatment, when carbon dioxide was applied in the first and last 15 min but replaced with nitrogen in the time between E-cadherin and VEGF expressions were significantly different from that by persistent carbon dioxide treatment. Therefore, we think that in laparoscopic surgery for malignant diseases, the sequential pneumoperitoneum method may take the advantages of both nitrogen and carbon dioxide, as the effect of carbon dioxide on metastasis is reduced by nitrogen replacement during the operation, and the safe guard ness of carbon dioxide to prevent from gas embolism, usually happening during the establishment of pneumoperitoneum, is remained. And the remaining gas in abdomen after surgery is also carbon dioxide, which is ready to be absorbed.

Abstract

AIM: To study the risk factors for colorectal cancer in China.

METHODS: A meta-analysis of the risk factors of colorectal cancer was conducted for 14 case-control studies, and reviewed 14 reports within 13 years which included 5034 cases and 5205 controls. Dersimonian and Laird random effective models were used to process the results.

RESULTS: Meta analysis of the 14 studies demonstrated that proper physical activites and dietary fibers were protective factors (pooled OR<0.8), while fecal mucohemorrhage, chronic diarrhea and polyposis were highly associated with colorectal cancer (all pooled OR>4). The stratified results showed that different OR values of some factors were due to geographic factors or different resourses.

CONCLUSION: Risks of colorectal cancer are significantly associated with the histories of intestinal diseases or relative symptoms, high lipid diet, emotional trauma and family history of cancers. The suitable physical activities and dietary fibers are protective factors.

INTRODUCTION

Meta-analysis named by Glass, is generally defined as a quantitative summary of studies in a particular area, which has addressed the same research question, and an overall summary obtained by statistically aggregating the results of the reviewed studies. It is used to improve the statistical efficiency, to evaluate the disadvantages of formulated researches, and hypothesis and to reach reliable conclusions from the mixed assortment of the potentially relevant studies to determine the most promising directions for future researches. It has been gradually applied in medicine since it was adopted in 1970s.

Colorectal cancer is one of the most malignant cancers in China and has been steadily increasing in frequency in large or middle cities[1]. Thus, in order to provide the overall information on colorectal cancer risk factors, we performed a meta analysis of the results of 14 case-control studies in China.

MATERIALS AND METHODS

Materials

The published Chinese literatures of case-control studies related to colorectal cancer risk factors from 1988 to 2000 were collected by bibliographic searches through Index of Chinese Science and Technology Data. The selection criteria of literature were as follows: The independent case-control studies were published in Chinese magazines from 1988 to 2000, each study should have the synthetic statistical index: odds ratio (*OR*), the similar research goal with the identical study method. The overall results of literature should be presented with the corresponding statistical index, the latest articles were chosen among several ones with the same sample size. Duplicated, poor quality reports or those with little information on colon cancer were discarded. Thus, 14 papers were chosen by screening, and 5 034 cases and 5 205 controls were accumulated.

Methods

Different stratified studies were performed, including studies on prevalence/death cases (CD) versus incidence cases (ND) according to different cases, studies on general population (PB) and on patients in hospital (HB). The studies were classified in rural or urban areas in the north (NOR) and those in the south (SOU) separated by the Yangtze River as the boundary. Studies were divided into colon cancer (Jca) and rectal cancer (Zca) according to the sites of cancer.

Statistical treatment

Test of equal variance was conducted before statistical analysis, and the index odds ratio (OR) was performed using the model established by Dersimonian and Laird. The fundamental principle was as follows: $y_i=lnOR_i$, with its variance: $S_i=[P_{1\,i}(1-P_{1\,i})/y_in_{1i}]+[P_{2i}(1-P_{2i})/n_{2i}]$, ($P_{1i}$ and n_{1i} are the exposing rate of the case group and the sample size, respectively; P_{2i} and n_{2i} are the corresponding parameters in control group). OR could be calculated with the confidence limit, standard error or Chi-squared value in some way if the basic data could not be acquired. If the total comprehensive effect was $\bar{y}^*$, then $\bar{y}^*=\sum(W_i^*\cdot y_i)/\sum W_i^*$, with 95 % confidence interval $\bar{y}^*\pm1.96\cdot SE(\bar{y}^*)$.

$$SE(\bar{y}^*)=1/\sum W_i^*$$
$$W_i^*=(W_i^{-1}+\Delta^2)^{-1}$$
$$W_i=S_i^{-1}$$
$$\Delta^2=max\{0,Q-(k-1)/\sum W_i-(\sum W_i^2/\sum W_i)\}$$
$$Q=\sum[W_i(y_i-\bar{y})^2]$$
$$\bar{y}=\sum(W_i\cdot y_i)/\sum W_i$$

RESULTS

The papers used in the studies are shown in Table 1. The number of literature in Zhejiang accounted for a half of the total in this country since Zhejiang had a high incidence of colorectal cancer.

Meta analysis showed that all the risk factors of colorectal cancer except alcohol drinking were significant (P<0.05), (Table 2), while proper physical activities and dietary fibers were protective factors (pooled OR was 0.6-0.8). Histories of fecal mucohemorrhage and bowel polyps were more

significantly associated with colorectal cancer (pooled OR>4) than other ones (pooled OR was 1-4).

Results of the stratified meta analysis including index cases, study area, location of cancer and origins of the controls are shown in Table 3. The pooled OR of family history of cancers differed significantly between prevalence/death cases (CD) and incidence cases (ND), which in the latter (pooled OR=3.73 [95 % confidence interval (CI) 3.14-4.44]) was one-fold more than that in the former (1.76 [1.71-1.81]). History of chronic diarrhea was more frequently significant among rectum cancers (pooled OR=4.02, $P<0.05$). However, no significant association was observed with colon cancer ($P>0.05$).

[a]: No mutual involvement of OR by correspondent two ranges of 95 % CI was found. [b]: At least one 95 % CI of pooled OR was found including 1.00.

DISCUSSION

Environmental factors are the predominant contributors to colorectal cancer, and genetic factors show significant effects[1,3-5]. Meta analysis indicated that a variety of factors could contribute to colorectal cancer as follows.

1. **Intestinal disorders and colorectal cancer** Precancerous syndromes or diseases based on the review of Chinese literature included chronic diarrhea, fecal mucohemorrhage, polyposis, constipation, etc. Therefore, colorectal cancer should be suspected if chronic diarrhea, fecal mucohemorrhage or constipation of unknown cause occur in patients with a history of bowel polyps[2]. In addition, whether appendicitis is a risk factor of colorectal cancer remains plausible. However, it is considered as one of the risk factors since its pooled OR was 1.98 ($P<0.05$) demonstrated in this study. Because appendicitis weakens the immunological function of appendix and thus causes colorectal cancer.

2. **Diet** High fat diet was the highest risk factor of colon cancer ($OR=3.16$), followed by fish fry-cooked with soybean sauce ($OR=2.99$) and pickled vegetables ($OR=1.86$). In contrast, dietary fibers played a protective role in colorectal cancer (pooled $OR=0.79$, $P<0.05$). Fried fish with soybean sauce may generate mutagenic heterocyclic amines as red meats[6,7]. The dietary fiber may shorten the transporting time of excrement in intestines, decrease the time of carcinogens affecting intestinal mucus and reduce the growth of bacterial strains that produce carcinogens in the colonic lumen. However, no evidence was reported to suggest that high dietary fiber could reduce the incidence or recurrence of adenomatous polyps during a two to four year period[8]. In addition, many experimental findings indicated an association between diet with high calcium and vitamin D and low risk for colorectal cancer, which deserve further study[9].

3. **Physical activity, cigarette smoking and alcohol** The relationship between physical activities and colorectal cancer has been noticed recently. Studies showed that people with proper physical activities had low incidence of colorectal cancer since appropriate physical activities could decrease the random segmentation without propulsion of the intestine, and increase effective vermiculation, thus shortening the transit time of excrement in the intestine and reducing the contact between intestinal mucosa and carcinogen. No significant association was found between alcohol and colorectal cancer in meta analysis, though other studies reported that significantly lower levels of serum cholesterol and triglycerides were found in daily alcohol drinkers with colorectal adenomas[10], while cigarette smoking was regarded as a risk factor since its OR exceeded 1($P<0.05$) although it is plausible whether smoking causes colorectal cancer.

Moreover, it was suggested that long-term emotional trauma and family history of cancers were related to the increased risk of colorectal cancer. However, further work is needed to clarify the mechanism.

Bias and confounding factors can also be found in meta analysis, and so we conducted the stratified analysis as follows: (1) Since studies on the prevalence or death cases could lead to bias due to selection and exposure misclassification, stratified analysis for the index cases was performed, which showed that there was a difference between studies on the prevalence or death cases and those on the incidence cases (Table 3). (2) The results of different strata suggested that studies on incidence cases based on the population should be conducted strictly in the future. (3) Risk factors of colorectal cancer in south and in the north may be different. (4) The cause of colon cancer may not be completely the same as that of cancer in the rectum. In this study, chronic diarrhea and fecal mucohemorrhage were more frequent in cancers of rectum, while complaint of constipation, fish fry-cooked with soybean sauce and emotional trauma were more frequently seen in colon cancer.

Meta means "more comprehensive, transcending"[11]. Meta analysis has extended quickly from social sciences to medical sciences. Incidence of colorectal cancer has increased over the last decade in China, and it is necessary to study its causes. Thus, synthetic analysis was performed on the etiology of colorectal cancer in China in 12 years with meta analysis. However, the potential confounding factors may not be well controlled due to the limited literature and therefore the result may be affected. Thus, further study is required.

Abstract

AIM: To characterize the expression of p53, p21^{WAF-1} and proliferation-cell-nuclear-antigen (PCNA) in fetal esophageal epithelia and to determine the role of these genes in proliferation of fetal and adult esophageal epithelial cells.

METHODS: Immunohistochemical avdin-biotin peroxidase complex (ABC) method was applied to 31 cases of fetal esophageal specimens and 194 cases of adult esophageal specimens to detect the expression of p53, p21^{WAF-1} and PCNA in fetal and adult esophageal epithelia.

RESULTS: Both the PCNA positive immunostaining cell number and PCNA positive immunostaining rate in fetal esophageal epithelia (506±239) were significantly higher than those in adults, including normal epithelia (200±113) and epithelia with basal cell hyperplasia (BCH) (286±150) (P<0.05, t test). However, the number of PCNA positive immunostaining cells in adult esophageal dysplasia (719±389) and squamous cell carcinoma (SCC) (1261±545) was apparently higher than that in fetal esophageal epithelia (506±239) (P<0.05, t test). The positive immunostaining rate of P53 was 10 % (3/31) in fetal esophageal epithelia, which was significantly lower than that in adult normal esophageal epithelia (50 %), adult epithelia with basal cell hyperplasia (62 %), dysplasia (73 %) and squamous cell carcinoma (86 %) (P<0.05, Fisher's exact test). No p21^{WAF-1} positive immunostaining cells were observed in fetal esophageal epithelia. However, p21^{WAF-1} positive immunostaining cells were observed in adult esophagus with 39 % (11/28) in normal, 38 % (14/37) in BCH, 27 % (3/11) in DYS and 14 % (1/7) in SCC.

CONCLUSION: PCNA could act as an indicator accurately reflecting the high proliferation status of fetal esophageal epithelium. p53 may play an important role in growth and differentiation of fetal esophageal epithelium. p21^{WAF-1} may have no physiological function in development of fetal esophageal epithelium.

INTRODUCTION

Fetal esophageal epithelium is characterized by cellular hyperproliferation. Tumor suppressor genes have been known to suppress malignant cell proliferation through encoding corresponding proteins that inhibit cell cycle. But it is still not clear whether this inhibition effect of tumor suppressor genes is also involved in the proliferative activity of fetal epithelium.

Tumor suppressor proteins p53 and p21^{WAF-1} play important roles in regulating G1 phase progression, which is the key modulation point in the cell cycle[1-8]. Proliferating cell nuclear antigen (PCNA) acts as a good marker for cell proliferation and can reflect the status of epithelium growth[9,10]. To detect the expression of these proteins would help to explore fetal esophageal epithelium proliferation status and characteristics, and to further understand the role of tumor suppressor genes in fetal esophageal epithelium growth control.

Most previous studies about fetal esophagus development focused on the influences of certain chemical factors, such as nitrosamine[11,12], and biological factors, such as alternariol[13]. There are, however, few reports about the proliferation characteristics and control of cell cycle in growth of fetal esophageal epithelium.

In this study, immunohistochemical avdin-biotin peroxidase complex (ABC) method was applied to investigate the expression of PCNA, p53 and p21^{WAF-1} in fetal esophageal epithelium and adult esophageal epithelium with different histopathological subtypes. Comparison between the expression of the above proteins in fetal and adult esophageal epithelium would provide important evidences for characteristics of fetal esophageal epithelium proliferation and the mechanisms of its cell cycle control.

MATERIALS AND METHODS

Tissue collection and processing

Thirty-one cases of fetal esophageal specimens were collected from Runan County, Taikang County, Lankao County and Zhengzhou City. The ages of the fetuses ranged from 4 months to 10 months (Table 1). No history of drug using and family history of tumor were found among all the parents of these fetuses. 194 cases of adult esophageal specimens were collected in the same areas for control of PCNA expression, among which 83 adult esophageal specimens were used for the control of p53 and p21^{WAF-1} expression. All specimens were fixed in 85 % ethanol, embedded with paraffin and serially sectioned at

5 μm. The sections were mounted onto the histostick-coated slides. Four or five adjacent ribbons were collected for histopathological diagnosis (hematoxylin and eosin stain) and immunohistochemical staining.

Table 1 Distribution of fetus sex and age

Sex	Age (months)						Mean age (months)
	4	5	6	7	8	>9	
Male	0	2	4	3	0	0	6.11±0.78
Female	2	5	4	7	3	1	6.36±1.47[a]
Total	2	7	8	10	3	1	6.29±1.30

[a]P>0.05, t-test, no significant difference was detected in the distribution of age between male and female fetuses.

Histopathologic diagnosis

Histopathological diagnosis and categorization for esophageal epithelium were based on the changes in cellular morphology and tissue architecture in reference to previous reports[14-17], and the adult esophageal epithelium was correspondingly classified as normal, basal cell hyperplasia (BCH), dysplasia (DYS) and squamous cell carcinoma (SCC).

Immunohistochemical staining (IHC)

Anti-p53 antibody is a monoclonal mouse anti-serum against p53 of human origin, and recognizes both wild and mutant type p53 (Ab-6, Oncogene Science, Manhasset, NY). Anti-PCNA antibody is a monoclonal mouse anti-serum against PCNA of human origin (Mab, DAKO, Carpinteria, CA). Anti-$p21^{WAF-1}$ antibody is a monoclonal mouse anti-serum against $p21^{WAF-1}$ of human origin, and recognizes both wild and mutant type p21 (Ab-6, Oncogene Science, Manhasset, NY). The avidin-biotin-peroxidase complex method was used for the immunostaining of p53, PCNA and $p21^{WAF-1}$ as previously reported. In brief, after dewaxing, inactivating endogenous peroxidase activity and blocking cross-reactivity with normal serum (Vectastain Elite Kit; Vector, Burlingame, CA), the sections were incubated overnight at 4 ℃ with a diluted solution of the primary antibodies (1:500 for p53, 1:200 for PCNA and 1:20 for $p21^{WAF-1}$). Location of the primary antibodies was achieved by subsequent application of a biotinylated anti-primary antibody, an avidin-biotin complex conjugated to horseradish peroxidase, and diaminobenzidine (Vectastain Elite Kit, Vector, Burlingame, CA). The slides were counter-stained by hematoxylin. Negative controls were established by replacing the primary antibody with PBS and normal mouse serum. Known immunostaining-positive slides were used as positive controls.

The criteria of positive staining for p53 and $p21^{WAF-1}$ were as previously reported[6-8, 14-16]. Quatitative analysis of PCNA immunostaining results was recorded as the number of positive staining cells per mm^2 of the tissue section[17,18]. All the immunostaining slides were observed by two pathologists independently and the final concordant results were adopted.

Statistic analysis

Fisher' s exact χ^2 test and t-test were applied for the statistical analysis and two-sided P value of less than 0.05 was considered statistically significant.

RESULTS

Histopathological results

Among the cases of fetal esophageal epithelium, the number of basal cell layers ranged from 2 to 6. Five cases contained more than 10 basal cell layers and showed a high proliferation activity. As for the cases of adult esophageal epithelium, the results of histopathological diagnosis were 31 normal cases, 106 cases with BCH, 31 cases with DYS and 26 cases with SCC.

Comparison of PCNA protein expression between fetal and subtypes of adult esophageal epithelium

PCNA positive immunostaining cells were located mainly in the basal cell layer. And the positive immunoreaction occurred mainly in the nucleolus in dark brown. The mean number of PCNA positive immunostaining cells was 506±239 per mm^2 in fetal esophageal epithelia, which was significantly higher than that in adult esophageal epithelia of normal and BCH (P<0.05, t-test), but significantly lower than that in adult esophageal epithelia with DYS and SCC (P<0.05, t-test) (Table 2).

Table 2 Quantitative comparison of PCNA expression between fetal and subtypes of adult esophageal epithelia

Histopathological subtypes	Case (n)	Number of immunostaining positive cells / mm^2
Adult normal	31	200±113
Adult BCH	106	286±150
Fetal	31	506±239[a]
Adult DYS	31	719±389
Adult SCC	26	1261±545

[a]P<0.05 *vs* t-test.

Comparison of P53 protein expression between fetal and subtypes of adult esophageal epithelia

p53 positive immunostaining cells were located mainly in the basal cell layer and the positive immunoreaction occurred mainly in the nucleoli in brown.

The positive immunostaining rate of p53 was 10 % (3/31) in fetal esophageal epithelia, which was significantly lower than that of adult normal esophageal epithelia (50 %, 14/28), adult epithelia with BCH (62 %, 23/37), DYS (73 %, 8/11) and SCC (86 %, 6/7) (P<0.05, Fisher' s exact test) (Table 3).

Table 3 Comparison of p53 expression between fetal and subtypes of adult esophageal epithelia

Histopathological subtypes	Case (n)	Positive immunostaining	
		Number	Percentage (%)
Fetal	31	3	10[a]
Adult normal	28	14	50
Adult BCH	37	23	62
Adult DYS	11	8	73
Adult SCC	7	6	86

[a]P<0.05 *vs* Fisher' s exact test.

Expression of $p21^{WAF-1}$ protein in fetal esophageal epithelia

No positive immunoreaction of $p21^{WAF-1}$ was detected in all the fetal esophageal epithelia. However, $p21^{WAF-1}$ positive immunostaining cells were observed in adult esophagus with 39 % (11/28) in normal, 38 % (14/37) in BCH, 27 % (3/11) in DYS and 14 % (1/7) in SCC.

DISCUSSION

To our knowledge, this is the first report about the role of PCNA as an indicator of proliferation status of fetal esophageal epithelium. In our study, we observed that most PCNA immunostaining positive cells were located in the basal layer

of fetal esophageal epithelium. PCNA is an important index of cell proliferation kinetics. Qian *et al*[18] found that according to the proliferation status, most cell nuclei were in the G1 phase to S phase of cell cycle in the cell clones with high proliferative activity. And the positive rate of PCNA expression increased gradually in cell nuclei with the progress of G1 phase and reached a peak when entering S phase. Our research found that all fetal esophageal epithelia showed a positive immunoreaction of PCNA and possessed high level of positive immunostaining cells per mm^2, which was much higher than that in normal adult esophageal epithelium and BCH. This result is concordant with previous theory and suggests that PCNA may act as a good marker for fetal esophageal epithelium proliferation status.

In our study, we also observed that malignant adult esophageal epithelia possessed much more PCNA positive immunostaining cells than fetal esophageal epithelia. This phenomenon is plausible. It was reported that PCNA played a role in DNA damage repair (DDR). With the presence of nucleotide excision, PCNA binds replication protein A (RPA) and constitutes a subunit of DNA polymerase δ[19,20]. Kieczkowaske *et al*[21] also supposed that PCNA could combine with hMSH6 and hMSH3, the subunits of hMutSalpha and hMutSbeta that acted as cofactors in DNA mismatch repair system. Malignant tissue was characterized by high frequencies of DNA mismatch, breakages and mutations, which would in turn induce more expression of PCNA for its repair function. As for fetal esophageal epithelia, there were few opportunities of contacting external environmental carcinogens and incurring much DNA damages and mutations. As a result, adult malignant esophageal epithelia had much more PCNA positive immunostaining cells, which implied that PCNA could potentially act as an indicator of malignant proliferation.

For the expression of p53, the positive immunostaining rate was 10 % in fetal esophageal epithelia, which was much lower than that in adult esophageal epithelia of each histopathological subtype. These differences were due to lack of induced p53 expression by external environmental factors in fetal esophageal epithelia. But in our study, there were some cases that were observed with expression of p53. Guo *et al*[11] reported that no expression of p53 was detected in fetal esophageal epithelia that had been cultured by NMBzA for up to 3 weeks. p53 supervised cell cycle through G1 phase checkpoint[21]. Then we supposed that stable expression of p53 might be required for normal cell cycle in the highly proliferative fetal esophageal epithelia. Lowe *et al*[21] found that disfigurement was not detected during development of rat fetus, which showed strong p53 expression. It was suggested that p53 possessed a protective function in fetal tissue development. Although this mechanism should be studied further, our study confirmed its existence in fetal esophageal epithelium development and maybe this function of p53 worked in a special stage of fetal esophageal epithelium proliferation and differentiation.

No positive expression of p21^{WAF-1} was observed in fetal esophageal epithelia. This protein has been reported to be trans-activated by p53 and could repair genomic DNA damages[7, 8]. Fetal esophageal epithelium encountered few outer carcinogens and few DNA damages occurred in this tissue. We hypothesize that there may not be a large number of p21^{WAF-1} required for DNA damage repair in development of fetal esophageal epithelium.

In conclusion, PCNA can reflect the proliferation status of fetal esophageal epithelium, and p53 may contribute to its development. But p21^{WAF-1} may not play a role in the process of its development. Further studies to explore the molecular mechanisms of these proteins in esophageal development should be performed to provide more pronounced evidences.

Abstract

AIM: To observe the relationship between the expression of vascular endothelial growth factor (VEGF), microvascular density (MVD) and the pathological characteristics of esophageal and gastric carcinomas.

METHODS: S-P immunohistochemical staining was used to investigate the expression of VEGF in all the specimens. The antibody against factor VIII-related antigen was used to display vascular endothelial cells, and MVD was examined by counting the factor VIII-positive vascular endothelial cells.

RESULTS: The positive rates of VEGF expression in esophageal carcinoma and gastric carcinoma were 81.36 % and 67.5 % respectively, and the MVD averaged 41.81±8. 44 and 34.36±9.67 respectively, which were higher than those in benign diseases. The expression of VEGF and MVD were closely correlated with the degree of differentiation, lymphatic metastasis, but not related to depth of cancer invasion. In early stage gastric carcinoma, the rate of expression of VEGF and MVD was lower than that in progressive gastric carcinomas.

CONCLUSION: The expression of VEGF is correlated with tumor angiogenesis, and VEGF plays an important role in new blood vessels formation, the expression of VEGF and MVD play an important role in tumor growth and metastasis. MVD and the expression of VEGF may be two important indexes for patients' prognosis.

INTRODUCTION

The growth and metastasis of solid tumor, a complex biological event, are affected by many factors. Recent research found that the growth and metastasis of tumors needed constant angiogenesis, which could provide a way for tumor metastasis through vessels, and could affect the prognosis of patients[1]. Angiogenesis is not an active process by itself, and it is controlled by some angiogenic factors and some angiogenic inhibitors[2]. Of all the angiogenic factors, vascular endothelial growth factor (VEGF) is a potent, multifunctional cytokine that exerts several important and possibly independent actions on vascular endothelium. That is its property and capacity to induce angiogenesis, which has excited the greatest interest in VEGF[3].

In this study, we used immunohistochemical method to detect VEGF expression and MVD in 59 cases of esophageal carcinoma and 80 cases of gastric carcinoma. We studied the relationship between VEGF expression and MVD and pathological features, which will help to understand the role of VEGF and angiogenesis in the growth of esophageal and gastric cancers.

MATERIALS AND METHODS

Materials

The resected specimens from 59 cases of esophageal cancer and 80 cases of gastric cancer were obtained from our hospital from January 2000 to June 2002. Of 59 cases of esophageal carcinoma, 57 were male and 2 were female, with a mean age of 57 (38 to 79). Of 80 cases of gastric carcinoma, 55 were male, 25 were female, with a mean age of 59 (35 to 69). All these specimens were clearly classified by experienced pathologists based on the depth of invasion, metastasis of lymph nodes and degree of differentiation. We collected specimens of 20 normal esophageal tissues and 20 gastric tissues as control. All of them had not received any radiotherapy or chemotherapy.

Reagents and methods

Rabbit anti-human VEGF polyclonal antibodies (RAB-0243), rabbit anti-human VIII polyclonal antibodies (RAB-0070) and ready-to-use SP immunohistochemical reagent box were purchased from FuJian Maxin Co. Ltd. Formalin-fixed, paraffin-embedded specimens were available and sectioned sequentially with a thickness of 4 μm. The sections carrying the detected antigen were stained with SP immunohistochemical method.

In this study we used lung cancer specimen that was known as positive of VEGF expression to be positive control, and with the first antibody substituted by PBS as negative control.

Results

Criteria of positive staining VEGF According to the criteria proposed by Volms *et al*[4], brown granules in the cytoplasm of tumor cells or vascular endothelial cells were identified to be positive VEGF. The sections were graded respectively according to the density (1) and the percentage (2) of positively stained tumor cells into score 0, 1, 2 and 3. If the sum of two scores (1) and (2) were 0-2, the section was considered as negative, whereas 3-6 was considered as positive VEGF.

MVD According to the criteria proposed by Weidners *et al*[5], when the cytoplasm of vascular endothelial cells was stained brown or brownish yellow, it was positive. The microvessels were counted according to the number of single endothelial cell or endothelial cell cluster showing brownish yellow granules in the cytoplasm. The sections were observed first under the low power (×40), then the most dense area of microvessel sections was selected under the high power (×200, the surface area of every vision field being 0.785 mm^2). The number of microvessel in three vision fields were counted and averaged as MVD of this specimen.

Statistical methods

Statistic analysis was performed by using the χ^2 test to dispose the expression of VEGF and the pathological features. *t* test was used to detect the relationships between the expression of VEGF and MVD, and between MVD and pathological characteristics.

RESULTS

The relationship between the expression of VEGF and pathological features of esophageal carcinoma

Of 59 cases of esophageal carcinoma, 11 cases were negative and 48 cases were positive, and the positive rate was 81.36 % (48/59). Of 20 normal esophageal tissues, 4 cases were positive, and the positive rate was 20 %. The rate of expression of VEGF in esophageal carcinoma was higher than that in normal esophageal tissue (χ^2=24.99, P<0.001). The expression of VEGF was closely related to pathological grade, that is, the poorer differentiation of the tumor, the higher expression of VEGF (χ^2=7.08, P<0.05). The cases having lymph node metastasis had significantly higher VEGF expression than those having no lymph node metastasis (χ^2=5.59, P<0.05). The VEGF expression was not related to invasion depth of tumor (Table 1).

Table 1 Relationship between expression of VEGF and MVD and pathological features of esophageal carcinoma

Pathological characteristics	*n*	VEGF				MVD	
		-	+-++	x^2	*P*	$\bar{x}\pm s$	*P*(*t*)
Degree of differentiation							
Well differentiated	27	9	18	7.08	<0.05	38.52±9.22	<0.05
Poorly differentiated	32	2	30			43.43±7.61	(*t*=2.07)
Depth of invasion							
Invading musclaris	37	7	30	0.01	>0.05	40.38±8.31	>0.05
Invading serosa	22	4	18			42.53±9.24	(*t*=0.88)
LN metastasis							
-	35	10	25	5.59	<0.05	38.22±8.54	<0.05
+	24	1	24			45.5±7.04	(*t*=3.23)

The relationship between the expression of VEGF and pathological features of gastric carcinoma

Of 80 cases of gastric carcinomas, 26 cases were negative and 54 cases were positive, and the positive rate was 67.5 % (54/80). There was no positive stain in 20 cases of gastric tissues. The expression of VEGF was closely related to degree of differentiation (χ^2=11.31, P<0.01) and lymph node metastasis (χ^2=9.32, P<0.01). As in esophageal carcinoma, the expression of VEGF had no significant difference between the different depths of invasion (χ^2=0.40, P<0.05). The expression of VEGF in early stage carcinoma was significantly lower than that in progressive stage cancer (χ^2=19.67, P<0.001) (Table 2).

The relationship between MVD and pathological features in esophageal carcinoma and gastric carcinoma

In the two carcinomas, MVD was higher than that in normal tissue, and MVD was closely related to differentiation degree of tumor and metastasis of lymph nodes, but not related to depth of invasion. In gastric carcinoma, MVD was significantly different between the different stages of carcinoma. (Table 1 and Table 2).

The relationship between VEGF expression and MVD in the two cancers

In this study, MVD was closely related to the expression of VEGF in gastric carcinoma and esophageal carcinoma, that is, the stronger the expression of VEGF, the higher the MVD. This suggested that VEGF be related to MVD and angiogenesis. VEGF and MVD were closely related to tumor growth (Table 3).

Table 2 Relationship between expression of VEGF and MVD and pathological features of gastric carcinoma

DISCUSSION

The importance of tumor angiogenesis in the growth and infiltration of tumor has been well known since J Folkman first proposed the hypothesis "Growth of solid tumor and the formation of metastasis are dependent on the formation of new blood vessels" in 1971. Growth of solid tumors is dependent on the induction of new blood vessels[6]. In order to maintain the unlimited growth of tumor, tumor tissue must depend on the constant and wide formation of new blood vessels, which is essential for tumors to grow beyond minimal size, providing oxygenation and nutrient perfusion as well as removal of waste products[7]. In normal organism, angiogenesis is strictly controlled, but in tumors, angiogenesis is uncontrolled and immature[8]. Controlled by angiogenic factors and angiogenic inhibitors, tumor cells, endothelial cells and other cells can produce and release VEGF protein if the local microenvironment is changed by hypoxia, *etc*[9]. Some researches proved that in tumors with foci of relative hypoxia, VEGF mRNA may be expressed not only by malignant cells but also by stromal cells[10,11]. Different tumor needs different angiogenesis factors, such as bFGF, which is a very important angiogenesis factor in fibrosarcoma. In gastroenteric tumors VEGF proved to play a key role.

VEGF, also known as VPF (vascular permeability factor), is secreted by some tumor cells. It combines with its receptors on endothelial cells. It can render venules and small veins hyperpermeable to circulatory macromolecules, and induce angiogenesis, which can induce tumor growth[12].

The human VEGF gene has been assigned to chromosome 6p21.3. Its coding region spans approximately 14kb. Native VEGF is a basic, heparin-binding homodimeric glycoprotein[13,14]. VEGF target cell is endothelial cell. On the one hand it renders microvascular hyperpermeable, so that plasma proteins and fibrinogen leak, can stimulate angiogenesis and new stroma formation. On the other hand, VEGF stimulates the endothelial cell of microvessels to proliferate, migrate and alters their pattern of gene expression[15].

More and more researches proved the important role of VEGF in tumor growth. Recently, Meada *et al*[16] found that VEGF expression was consistent with MVD, that is, MVD of gastric carcinoma with positive expression of VEGF was higher than that with negative expression of VEGF, and MVD was higher in the area where VEGF expression was positive. Toi *et al*[17] found that the positive expression of VEGF and factor VIII were detected in the samples of breast carcinoma which were poorly differentiated, with inrasive growth and lymph node metastasis. So strong expression of VEGF and factor VIII may indicate a poor prognosis.

In our study, a strong correlation was found between VEGF expression and increased tumor microvasculature, malignancy and metastasis in esophageal carcinoma and gastric carcinoma. These results indicate that VEGF and angiogenesis promoted by VEGF play important roles in cancer growth, infiltration and metastasis in esophageal and gastric carcinoma. It also implied that VEGF expression and MVD have prognostic significance. We also found that there was an obvious heterogeneity in VEGF expression and new vessel formation in cancer tissue. New tumor vessels were deficienct in constant basement membrane. This proved that the new vessels were hyperpermeable. This may facilitate the tumor cells to penetrate through the blood vessels and metastasis. VEGF expression manifested that positive cells located at the center of tumor or at the edge of the necrosis area, this may be explained by the hypoxia, which can stimulate VEGF expression and its biological activity.

In the study of the correlation of VEGF expression and MVD, we proved that VEGF was closely related with MVD in the cancer tissues of both esophageal and gastric carcinoma, this result proved VEGF could induce formation of new blood vessels. Thus VEGF expression and MVD may play important roles in tumor biological behaviors, progression and prognosis.

In conclusion, VEGF overexpression and active angiogenesis exist in esophageal carcinoma and gastric carcinoma. VEGF and MVD are closely relevant to lymph node metastasis, tumor differentiation and clinical stage. VEGF and MVD may act as two valuable indexes of tumor prognosis. These conclusions may provide an important theoretical evidence for cancer therapy through antiangiogenesis.

Abstract

AIM: To investigate the effect of cell adhesion molecule P-selectin monoclonal antibody (Mab) on metastasis and immune function of mice orthototopically implanted with human gastric cancer tissue.

METHODS: SCID mice were implanted orthotopically with SGC-7901 human gastric carcinoma tissue. Starting from day 3 after operation, animals were given intravenously PBS or P-selectin Mab (100 μg/injection) (for both normal mice and tumor-implanted mice with tumors), twice weekly for 3 weeks. Two animals in each group were sacrificed randomly at the 1st, 2nd, 4th week and 6th week. While T cell and B cell transformation indices were determined with the ^{3}H TdR infiltration method, the NK cell activity was detected by the LDH release method.

RESULTS: The metastatic rate in the P-selectin Mab treated group was lower than that in the PBS treated group (with tumors). The NK activity of normal mice increased over time. The immune functions (T, B cell function, NK activity) of the tumor group in the 6th week were significantly lower than those in the 4th week, but the change was attenuated by P-selectin Mab.

CONCLUSION: P-selectin Mab could suppress the metastasis of gastric cancer with no adverse effect on host immune function.

INTRODUCTION

Gastric carcinoma is one of the most frequent tumors in China. Tumor metastasis is very common clinically. Cell adhesion molecules have been implicated to be crucial elements in the process of metastasis[1-28]. P-selectin is an adhesion molecules that mediates the cell to cell interaction of platelets and endothelial cells with neutrophils and monocytes as well as tumor cells[29]. Our previous study indicates that P-selectin expression is related to aggressive behavior, dissemination and poor prognosis of human gastric carcinomas, and P-selectin monoclonal artibody can inhibit gastric carcinoma metastasis[30-32]. The present study was performed to investigate effects of P-selectin monoclonal antibody on metastasis and immune function in SCID mouse metastaic models of human gastric cancer constructed by orthotopic implantation of histologically intact tumor tissue.

MATERIALS AND METHODS

Animal model

Forty-eight male SCID mice obtained from Shanghai Cancer Institute were 7-8 weeks old with weight of 20-25 g. Human gastric cancer SGC-7901, a poorly-differentiated adenocarcinoma line, was originally derived from a primary tumor and maintained by passage in nude mice subcutaneously.

SCID mice were randomly divided into experimental group (n=24) and normal group (n=24). Animal models in experimental group were made using orthotopic implantation of histologically intact tissue of human gastric carcinoma[33]. Tumors were resected aseptically. Necrotic tumor tissues were removed and the remaining non-necrotic tumor tissues were minced into pieces about 5-7 mm in diameter in Hank's balanced salt solution. Each of the tumor pieces was weighed and adjusted to be 150 mg with scissors. Mice were anesthetized with 4.3 % trichloraldehyde hydrate and an incision was made through the left upper abdominal pararectal line and peritoneal cavity was carefully exposed and a part of the serosal membrane in the middle of the greater curvature of the glandular stomach was mechanically injured by using scissors. A tumor piece of 150 mg was fixed on each injured site of the serosal surface. The stomach was then returned to the peritoneal cavity, and the abdominal wall and skin were closed. 3 d later, all animals implanted with intact tumor tissues received i.v. injection of PBS (group3, n=12) or P-selectin antibody (Suzhou Medical College; 100 μg/injectiom; group4, n=12) twice weekly for 3 weeks. Animals in normal group received i.v. injections of PBS (group1, n=12) or P-selectin antibody (100 μg/injection; group2, n=12).

Sample collection and pathological examination

Two mice in each group were sacrificed randomly on weeks 1, 2,and 4. The remaining animals were sacrificed at 6th week and the tumors growing on the stomach wall were removed and examined histologically. Tissues from all organs were examined for metastasis after careful macroscopic examination. The spleen of mice was harvested for detection of immune function.

Lymphocyte transformation test

Using ^{3}H TdR infiltration method, T cell transformation function was detected with Con A (5 μg/ml, Sigma), B cell function with LPS (50 μg/ml, Sigma). The spleen was made

into suspension and mononuclear cells were acquired with lymphocyte-separating fluid. The cell suspension was adjusted to 2×10^6/ml with RPMI 1640 liquid containing 10 % calf serum (GIBCO). Then 200 μl of the cell suspension was put into each well in 96-well plates. One plate was for Con A group, and another plate for LPS group. There were negative control group and experimental group for Con A or LPS group respectively, and each test had 5 repetitive wells and was cultivated under 5 % CO_2 at 37 ℃. The cell suspension in Con A group was cultivated for 3 d, while it was done for 5 d in Con A group. All wells were added up ^{3}H TdR 16 h before the end of cultivation. They were collected in filtration paper, and given 0.5 ml of scintillating liquid to detect cpm value with β-scintillator, which was presented with SI. SI amounts to cpm of experimental group/cpm of empty group.

NK activity

NK activity was detected by the 4 h LDH release method. NK cell activity (%)=

$$\frac{\text{Experimental group' s OD-Natural release group' s OD}}{\text{Max release group' s OD-Natural release group' s OD}}$$

Statistical methods

Comparisons among groups were performed by the student' s test and χ^2 test. A value of $P<0.05$ was considered significant.

RESULTS

Effects of P-selectin antibody on metastasis

All animals in each group were sacrificed randomly at the 1st, 2nd, 4th week and 6th week. Tumors grew in the implanted site. Under microscopy, the tumors demonstrated lower differentiated adenocarcinoma invadeing mucosal layer, submucosal layer and muscle layer. Tumor metastasis was observed most frequently in the regional lymph nodes and liver. It could be seen in lung, spleen and other organs.

In tumor group (Group 3), no metastasis was found at the 1st and 2nd week, but metastasis was found in 1 of 2 cases at the 4th week, in 5 of 6 cases at 6th week. However, in P-selectin antibody treated tumor group (Group 4), tumor metastasis was remarkably inhibited. No metastasis was found at 1st, 2nd, and 4th week, while it was found only in 1 of 6 mice at 6th week.

Table 1 Immune functions of mice in various groups ($\bar{x}\pm s$)

Effect of P-selectin antibody on immune function

The NK activity of normal mice increased over time, but no significant difference of the immune functions of T cell and B cell was found in all the groups. Over time, the immune functions (T, B cell function, NK activity) of SCID mice orthotopically implanted with tumor tissue were significantly lower in the 6th week than those in the 4th week, but the change was attenuated by P-selectin antibody ($P<0.05$) (Table 1).

DISCUSSION

Research on cell adhesion molecules and metastasis has aroused a lot of attention recently[34-50]. P-selectin (GMP140, CD62, or PADGEM) is located in alpha granules of platelets and Weibel-Palade bodies of endothelial cells. Once platelet or endothelial cell is activated by mediators such as thrombin, alpha granule and weibel-palade body membranes fuse rapidly with the plasma membrane, leading to the expression of P-selectin on the cell surface[29]. P-selectin contributes to interaction of tumor cell to cell adhesion by mediating endothelial cells and platelets with tumor cells.

We have immunohistochemically studied P-selectin expression in 60 cases of human gastric carcinomas. The study showed that P-selectin was expressed in human gastric cancer, which was detected not only on intratumoral endothelium but also on cancer cells. P-selectin expression was found higher in patients with lymph node metastasis than those without metastasis. The survival time and five-year survival rate were lower in P-selectin positive cases than those in negative cases[30-32]. Recently, our study indicated that P-selectin mRNA expression is related to tumor metastasis, and the metastasis may be inhibited by the monoclonal antibody. This finding is in accordance with Stone' s results[22]. These results suggest that selectins play an important role in metastasis by mediating the interaction of endothelial cells and platelets with cancer cells, and the metastasis can be inhibited by the monoclonal antibody.

Recently, study on anti-adhesion therapy with adhesion molecule monoclonal antibodies exhibits good clinical prospective[51-53]. However, there existed some problems. Antibody against intercellular adhesion molecule-1 (ICAM-1) might block inflammation while it inhibits the immune function of the body so that it increases the risk for infection[54,55]. The present study investigated the effects of P-selectin monoclonal antibody on tumor metastasis and immune function of SCID mice orthotopically implanted with gastric cancer tissue to lay foundation for clinical application of anti-adhesion therapy. The result indicated that P-selectin antibody could inhibit the metastasis. This is consistent with our previous study.

Results obtained in this study showed that NK activity of normal mice got higher with the passage of time. It was higher at 6th week than between 1st week and 4th week. But there had no significant change in both T cell and B cell function. The experiment suggested that mice used for metastasis models should not be too old, otherwise the metastasis rate of the mice implanted with tumor would be low. Our experiment discovered that the immune functions (T, B cell function, NK activity) of the tumor group were significantly lower in the 6th week than in the 4th week, but the change was remarkably attenuated by P-selectin antibody. No difference of the immune functions between the two groups at 1st, 2nd, 4th week was found. This result suggested that the immune functions of mice was suppressed with the development of tumor metastasis. On the other hand, the metastatic rates of tumor group were 50 % (1/2) at 4th week and 83.3 % (5/6) at 6th week, whereas it was 16.7 % (1/6) at 6th week in P-selectin antibody treated tumor group. Therefore, the improved immune function in the

antibody treated tumor group might result from the inhibition of metastasis by the P-selectin monoclonal antibody. Sharar discovered that P-selectin could not inhibit functions of neutrophils. The results suggest that P-selectin monoclonal antibody could inhibit the metastatic tendency with no harmful effect on host immune function.

Abstract

AIM: To evaluate the effects of heparin on liver fibrosis in patients with chronic hepatitis B.

METHODS: Fifty-two cases under study were divided into two groups, group A and group B. The two groups were given regular treatment and heparin/low molecular weight heparin (LMWH) treatment respectively. Hepatic functions, serum hyaluronic acid (HA) and type IV collagen levels were measured before and after the treatment, and six cases were taken liver biopsy twice.

RESULTS: After treatment, hepatic functions became significantly better in both groups. Serum HA and type IV collagen levels in group B compared with group A, decreased significantly after treatment. Collagen proliferation also decreased in group B after treatment.

CONCLUSION: Heparin/LMWH can inhibit collagen proliferation in liver tissues with hepatitis B.

INTRODUCTION

The treatment of liver cirrhosis is always a problem in the clinical practice. To control and stop liver fibrosis towards liver cirrhosis is of utmost importance. A recent trial indicated that heparin could inhibit the growth of Ito cells effectively *in vitro*[1], which suggested that heparin might act as an antifibrosis drug. In this study, we aimed to seek a safe and effective antifibrosis drug in 52 patients with chronic hepatitis B.

MATERIALS AND METHODS

Materials

Fifty-two patients were treated in Shandong Provincial Hospital from 1999 to 2002. There were 39 males and 13 females, age ranged from 14 to 70 years, diagnosis was made by clinical manifestations and serum hepatitis B viral markers.

Experimental design

These 52 cases were divided into two groups randomly. The treatment regime of each group is listed in Table 1.

Table 1 Treatment regimes in group A and B

Group	*n*	Treatment regime
A	18	regular treatment(GIK,diamnonium glycyrrhizinate injection,potassium magnesium aspartate,et al)
B	34	regular treatment and heparin(25mg,iv,bid) or low molecular weight heparin(6400IU,iH,qd)

Note: In group B, 18 cases were treated with heparin and 16 with low molecular weight heparin (LMWH). The LMWH was FLUX manufactured by ALFA WASSERMANN S.P.A (Italy).

All cases were treated for a course of 3 weeks. Serum alanine transaminase (ALT), prothrombin time (PT), total bilirubin (TBIL), hyaluronic acid (HA) and type IV collagen (IV-C) were measured before and after treatment. The liver tissue specimens were obtained by percutaneous needle biopsy. Ten cases in group A and sixteen in group B had liver biopsies before treatment. Six cases in group B had a second biopsy at 30-60 days after treatment.

Determination of serum HA and IV-C level

Serum HA and IV-C level was determined with radioimmunoassay. The procedures were strictly in accordance with the instructions.

Light microscopic examination

Part of the liver tissues were fixed in 10 % formalin, embedded in paraffin, and then cut into slices. The sections were stained with hematoxylin and eosin for histological study and Masson trichrome for collagen stained green.

Electron microscopic examination

Small liver blocks were fixed in 2.5 % glutaraldehyde, postfixed in 1 % OsO_4, dehydrated with ethanol, and embedded in epoxy resin. Ultrathin sections were stained with uranyl acetate and lead citrate and examined with H-800 transmitted electron microscope (Tokyo, Japan).

RESULTS

Changes of serum/plasma indexes before and after treatment

As shown in Table 2, the levels of ALT and TBIL decreased significantly after treatment, while the level of PT changed slightly only. The level of HA and IV-C in group B decreased markedly, while those in group A were elevated.

Table 2 Changes of the serum / plasma indexes before and after treatment in group A and B ($\bar{x}\pm s$)

	A		B	
	Before	After	Before	After
ALT	136.45±103.46	69.88±43.58[a]	185.58±138.54	84.93±57.14[a]
PT	17.84±3.22	15.98±2.67	18.45±4.25	18.62±3.67
TBIL	64.65±21.35	38.42±14.38[a]	69.54±26.53	31.25±17.84[a]
HA	254.43±116.37	309.48±214.03	579.59±191.45	286.45±136.54[a]
IV-C	237.5±104.44	259.3±137.65	349.56±112.43	189.8±79.63[a]

[a]$P<0.05$, *vs* before treatment.

Histologic changes before and after treatment with heparin/ LMWH

Hematoxylin and eosin staining Hepatocytes swelled and appeared balloon-like before treatment. Inflammatory cells penetrated into the interstitium. Red blood cells congregated in the sinusoids. After treatment with heparin/LMWH, the swollen hepatocytes alleviated , and the sinusoids became clearly seen (Figure 1,2).

Masson trichrome staining Collagens could be seen evidently before treatment. Some sinusoids had been compressed by collagens. After treatment with heparin/LMWH, the collagen fibers decreased significantly (Figure 3,4).

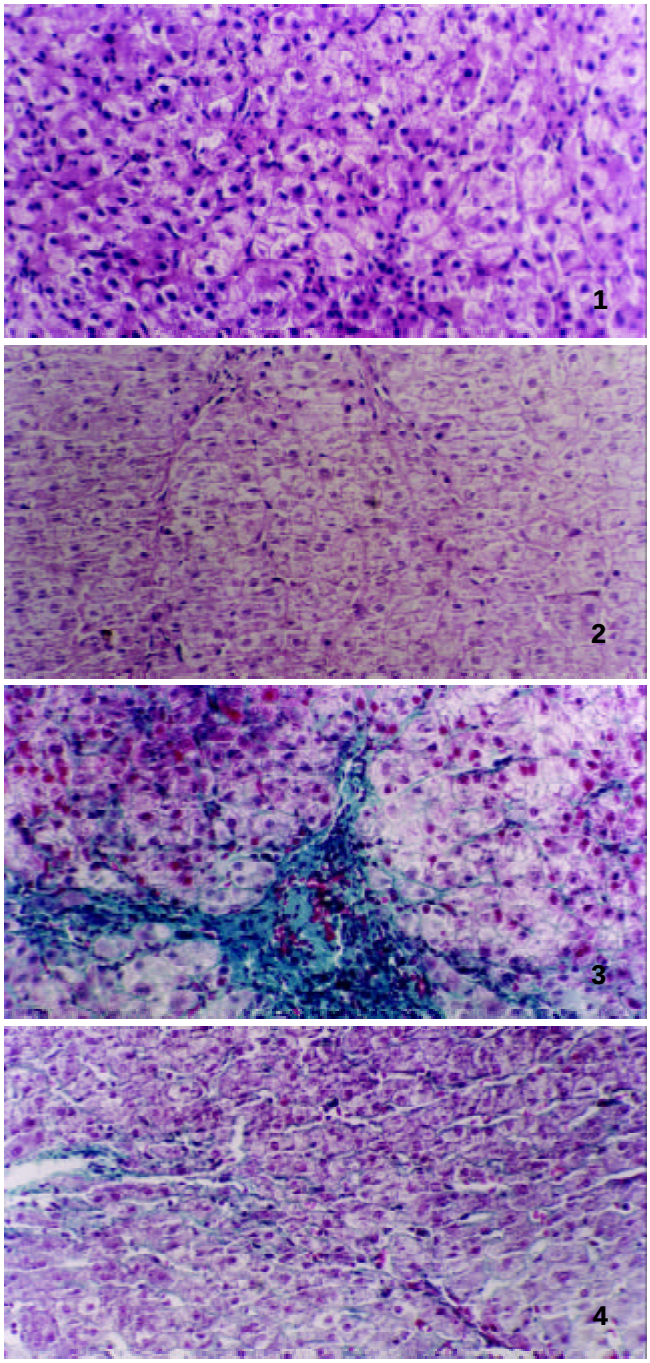

Figure 1 The liver tissue before treatment with heparin. H&E staining. ×200.
Figure 2 The liver tissue after treatment with heparin. H&E staining. ×200.
Figure 3 The liver tissue before treatment with heparin. Masson staining. ×200.
Figure 4 The liver tissue after treatment with heparin. Masson staining. ×200.

Electron microscopic observation Before treatment, hepatocytes were enlarged and cytoplasm appeared dissolved with swollen mitochondria. Base membrane was seen under the hepatic sinusoidal endothelial cells with collagen deposited in the Disse' s space. The Ito cells simulated fibroblasts. The edge of membrane looked uneven, saw-like in severe cases. The number of fat drops decreased markedly. There was microfilament-like structure in the cytoplasm, fibrils were seen around the Ito cells. After treatment, the swollen hepatocytes decreased , so did the base membrane and the depositioning collagen in the Disse' s space. The edge of Ito cells turned smooth. Several fat drops could be seen in the cytoplasm of Ito cells (Figure 5-8).

DISCUSSION

Liver fibrosis is caused by the deposition of extracellular matrix (ECM)[2-3]. All cells in the liver can synthesize and secrete ECM, which regulates the proliferation, differentiation and metabolism of liver cells. The abnormal metabolism and deposition of ECM lead to liver fibrosis. It has been recognized that Ito cells have intimate relationships with liver fibrosis[4], which have been postulated to play critical roles in the development of fibrosis of the liver from viral infection, alcohol and many drugs[5,6].Ito cells are relatively inactive fibroblasts in the liver lobules. During liver fibrogenesis, cytokines such as TGF-β_1, PDGF can activate Ito cells[7-9] to acquire a myofibroblast-like phenotype characterized by increased proliferation and synthesis of ECM component[10-27].

It has been proved in animal studies that heparin can inhibit the growth of Ito cells and the expression of α-actin, types I and IV procollagen *in vitro*[1]. Our studies showed that heparin/LMWH could decrease serum HA and IV-C levels in patients with chronic hepatitis B. After treatment, the collagen fibrils in the liver tissues decreased significantly and Ito cells turned oval and fatty drops reappeared in the cytoplasm. The above results indicate that heparin/LMWH act on Ito cells.

The liver functions were improved in both group A and B after treatment. HA and IV-C levels decreased significantly in group B, in contrast, they were elevated in group A. These results suggest that the routine liver function tests could not reflect the fibrosis completely. Kopke-Aguiar *et al*[28] also proved that serum hyaluronic acid was a good marker for hepatic fibrosis at the initial phase.

Wanless *et al*[29] have studied hepatic veins of medium size (0.2 to 3 mm in diameter) in 61 cirrhotic livers. Intimal fibrosis with at least 10 % luminal narrowing was found in 70 % of cirrhotic livers. They considered that multiple layers of intimal fibrosis in some livers suggested the presence of recurrent thrombosis. In other words, thrombosis was related to intimal fibrosis and even caused obstruction of the veins. Our previous studies[30] also showed that as an anticoagulant agent, heparin could improve hepatic microcirculation significantly and lessen sinusoidal capillarization. IV-C is considered an important marker of the development of hepatic sinusoidal capillarization and may appear basal-like membrane[31,32]. Therefore, decrease of the IV-C concentration can not only reflect the improvement of hepatic microcirculation, but also inhibit the fibrosis. It can be used as antifibrosis drug together with antiviral drugs.

Heparin is cheap and safe. LMWH has a weaker effect on thrombin than heparin, but has stronger effect on Xa. 90 % of LMWH can be absorbed hypodermically and its anti-Xa effect can last for 24 hours and therefore, LMWH can be used once a day. One needs not measure the activated coagulation time (ACT) during the procedure[33]. As to the mechanisms of its antifibrosis effect ,further studies are necessary.

Abstract

AIM: To appraise the effect of sea buckthorn (Hippophae rhamnoides) on cirrhotic patients.

METHODS: Fifty cirrhotic patients of Child-Pugh grade A and B were randomly divided into two groups: Group A as the treated group (n=30), taking orally the sea buckthorn extract, 15 g 3 times a day for 6 months. Group B as the control group (n=18), taking vitamin B complex one tablet, 3 times a day for 6 months. The following tests were performed before and after the treatment in both groups to determine LN, HA, collagens types III and IV, cytokines IL-6 and TNFα, liver serum albumin, total bile acid, ALT, AST and prothrombin time.

RESULTS: The serum levels of TNFα, IL-6, laminin and type IV collagen in group A were significantly higher than those in the control group. After a course of sea buckthorn treatment, the serum levels of LN, HA, collagen types III and IV, total bile acid (TBA) decreased significantly as compared with those before and after treatment in the control group. The sea buckthorn notably shortened the duration for normalization of aminotransferases.

CONCLUSION: Sea buckthorn may be a hopeful drug for prevention and treatment of liver fibrosis.

INTRODUCTION

Liver cirrhosis is a common chronic hepatic injury caused by chronic hepatitis B, ethanol consumption and metabolic disorders, etc. The patients often die of hepatic failure due to portal hypertension, bleeding of esophageal and gastric varices. Recent studies have shown that fat storing cells now called hepatic stellate cells (HSCs) are the main collagen producing cells in fibrotic liver. Under the influence of inflammatory cytokines, vitamin A- rich cells are activated, proliferating and transforming into myofibroblasts, producing extracellular matrix(ECM)[1,2]. Retinoic acid droplets and retinoic acid receptors (RAR) diminish. Recent studies have also shown that when retinyl esters and RAR contents are restored in HSC, HSCs would remain in the inactivated state. Hence HSCs are regarded as the therapeutic targets for prevention and treatment of hepatic fibrosis[3]. In this study, sea buckthorn (Hippophae rhamnoides,) was used in cirrhotic patients to determine its effect on the changes of fibrotic parameters, improvement of liver function and whether it could be used as a therapeutic antifibrotic agent.

MATERIALS AND METHODS

Subjects

Fifty patients aged 20-70 years were enrolled in this study with at least an elevation of two items of the following parameters, e,g, serum collagen types III and IV, laminin (LN), hyaluronic acid (HA). These patients were divided into treated group (group A, n=30, 25 hepatitis B cirrhosis and 5 alcoholic) and control group (group B n=20, 17 hepatitis B cirrhosis and 3 alcoholic). These two groups had similar demographic characteristics. All these patients had not taken any antifibrotic drug or immunomodulator or antiviral herbs in the past 6 months. Group A received sea buckthorn extract in fine granules (manufactured by Sichuan Pharmaceutical Co.LTD, China), 15 g, three times a day for 6 months. Group B received vitamin-B complex, 2 tablets once, 3 times a day for 6 months.

Measurement of cytokines, parameters of liver fibrosis and liver function tests

Cytokine: IL6 and TNFα were measured by enzyme-linked immunosorbent assay (ELISA). LN, HA, collagen types III and IV were measured by radioimmunoassay (RIA). Serum albumin (Alb), total bilirubin, aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), conjugates, total bile acid (TBA), prothrombin time (PT) were measured by a biochemical autoanalyzer.

Statistical analysis

All data were analyzed with SAS software. The results were expressed as mean ± standard deviation, the rate of normalization of AST, ALT was analyzed by Chi-square test. LN, HA, Alb, TBA, PT, collagen types III and IV were analyzed by signed rank test (both pre-and posttreatment in the same group) and Wilcoxon rank test (between the two groups, pre-and post treatment for comparison). P value <0.05 was considered statistically significant.

RESULTS

Determination of TNFα, IL-6, LN, HA

The levels of TNFα, IL-6, LN, collagen type IV in the 50 cirrhotic patients were significantly higher than those in the controls (P<0.05). There were positive correlations between TNFα, IL-6 and LN, collagen type IV (Table 1).

Table 1 Measurements of TNFα, IL-6, LN, type IV collagen ($\bar{x}\pm s$)

ECM parameters and liver function tests

Remarkable changes were found in AST and ALT after sea buckthorn treatment. The rate of normalization was 80 % in the treated group and 56 % in the control group (P<0.05). No difference was found in serum albumin and prothrombin time. In group A, serum LN, HA, total bile acid (TBA), collagen types III and IV were decreased after treatment as compared with group B. There was a significant difference between the two groups (P<0.05). (Tables 2-4).

DISCUSSION

Sea buckthorn is a plant growing in severely cold region of South-west China, its fruit juice has been taken as a tonic by the local Mongolians and Tibetans. It contains a great deal of vitamins, amino acids and trace elements, which are beneficial to human health[4]. Recent studies have shown that sea buckthorn contains lots of vitamin A precursors including β carotene and unsaturated fatty acids. Zhao *et al*[5] reported that sea buckthorn could protect the liver from damage by CCl_4. A combination of an antiviral drug and sea buckthorn in treating patients with chronic hepatitis B could shorten the duration for the normalization of serum ALT. The rate of turning negative of HBeAg and HBsAg was 52.16 % and 16.67 %, respectively[6].

In the normal liver, HSCs are mainly involved in the storage of vitamin A. In addition, they synthesize extracellular matrix components, matrix degrading metalloproteinases, cytokines, and growth factors[7,8]. Following acute or chronic liver injury, HSCs are activated and undergo a process of transdifferentiation, leading to a myofibroblastic phenotype. The activated HSCs are characterized by a loss of vitamin A droplets, increase of proliferation, release of proinflammatory, profibrogenic, and promitogenic cytokines and migration to the sites of injury with increased production of extracellular matrix components and alterations in matrix protease activity and provision for the fundamental needs of tissue repair[9]. In acute or self-limited liver damage, these changes are transient, whereas in case of persistent injury, they lead to chronic inflammation with an accumulation of extracellular matrix, resulting in liver fibrosis and ultimately cirrhosis. Several growth factors and cytokines are involved in HSCs activation and proliferation, of which transforming growth factor β (TGFβ), platelet derived growth factor (PDGF), TNFα and IL-6 are probably the most important ones[10].

TNFα is not only an anticancer factor, but also participates in the process of immunologic reaction and inflammation. The synthesis of collagen and some extracellular matrices were elevated 3 fold and 2.6 fold, respectively when rat HSCs were incubated with TNFα (5.0 nmol/l) for 24 hours[11]. IL-6 is a cytokine which has many biologic functions, such as promoting cell proliferation and differentiation, regulating immune

function. Wang *et al*[12,13] reported IL-6 increased in the peripheral blood of an early animal model of liver fibrosis, and the peripheral blood level of IL-6 in cirrhotic patients was remarkably higher than that in those without[14].

HSCs represent 5-8 % of all human liver cells. They have long cytoplasmic processes which run parallel to the sinusoidal endothelial wall. The second order branches sprout out from the processes, and embrace the sinusoids. Some HSCs are in close contact with nerve endings, some of which contain neuropeptides such as substance P, neuropeptide Y, somatostatin, and calcitonin gene-related peptide[15,16].

Our previous study showed[17] that retinoic acid receptor (RAR) and cAMP of primarily cultured HSCs were reduced, as compared with those in freshly isolated HSCs. The contents of RAR and cAMP of cultured HSCs were increased after treated with all-transretinoic acid (10^{-5} Mol/L).

Based on the recent articles and our results, we may deduce that the resting HSCs are activated by TNFα and IL-6 released by Kupffer cells during the process of acute or chronic inflammation, then TNFα and IL-6 in turn stimulate Kupffer cells to release TGFβ and PDGF. Eventually, HSCs proliferation and synthesis of ECM, along with the loss of vitamin A droplets, will transform themselves into myofibroblast producing liver fibrosis[18,19].

The present study showed that sea buckthorn could reduce the serum levels of laminin, hyaluronic acid, TBA, collagen types III and IV in patients with liver cirrhosis, indicating that it may restrain the synthesis of collagen and other components of ECM. We are attempting to restore vitamin A and RAR contents of HSCs, so as to keep HSCs in a quiescent status and to prevent progression of liver fibrosis. Sea buckthorn may be a hopeful drug for prevention and treatment of liver fibrosis, but further well controlled clinical trials are required.

Abstract

AIM: To investigate the relationship between breast cancer and fatty liver in Chinese patients.

METHODS: The study group consisted of 217 patients with newly diagnosed breast cancers and the control group of 182 subjects undergoing routine health examination in the same hospital. All subjects were female and the groups were matched for date of study. Ultrasound scanning was performed by the same operator using a 3.5 mHz transducer. Steatosis of the liver was diagnosed based on the criteria of Saverymuttu *et al*. Clinical variables were statistically analyzed.

RESULTS: Fatty liver was diagnosed in 98 patients of the study group and 37 patients of the control group, a significant difference was found in incidence (98/217, 45.2 % and 37/182, 20.3 %; $P<0.0001$). On univariate analysis, fatty liver in breast cancer patients was associated with overweight, hyperlipidemia, and hepatitis. On multivariate analysis in the same patients, obesity and hyperlipidemia were significantly associated with fatty liver.

CONCLUSION: The cause of fatty liver in women with breast cancer may be multifactorial. The present study confirms its link with overweight and hyperlipidemia.

INTRODUCTION

Breast cancer is a common cancer in the developed countries such as Western Europe and North America where women tend to be well-nourished. In 1973, the reported crude annual incidence rate of new breast cancer was 71.5 per 100 000 in Canada[1]. This contrasts with the incidence in Taiwanese women of 6.11 per 100 000 published in 1971[2]. However, more recent epidemiological studies revealed an increasing incidence of breast cancer with 12.46 per 100 000 in Taiwan[3]. The development of breast cancer is multifactorial. Genetic, dietary, environmental, menstrual, endocrine and ethnic factors all influence it[4]. In the course of using ultrasonography to assess liver metastases from breast cancer, we have noted a fair number of women with breast cancer who also have fatty liver. The aim of this study was to investigate the incidence and clinicopathological factors associated with fatty liver in patients with breast carcinoma.

MATERIALS AND METHODS

A hospital-based prospective study was conducted to investigate the relationship between fatty liver and breast cancer. From May 1994 to August 1997, 217 consecutive, newly diagnosed women with breast cancer were enrolled as the study group. 182 subjects presenting to the same hospital for routine health examination was served as the control group of the same period. All subjects underwent abdominal ultrasonography performed by the same operator using a 3.5 mHz transducer (Toshiba SSA-340A). Fatty liver was diagnosed in the presence of at least two of the following sonographic features: (1) increase in liver echoes, (2) loss of echoes from the wall of the portal veins, (3) exaggeration of liver and kidney echo discrepancy, and (4) ultrasonic attenuation of the liver parenchyma. Overweight was defined as a BMI >25 [body mass index = weight (kg)/height (m^2)]. Subjects were excluded if they were pregnant, on a weight reduction diet in the 6 months preceding the study, or taking cholesterol-lowering therapy or steroids. Data collected included age, the presence of hepatitis C virus antibodies with elevation of alanine aminotransferase (GPT) and aspartate aminotransferase (GOT), BMI, a history of diabetes or hyperlipidemia, drug use (contraceptives, steroids, tamoxifen, alcohol), and chemotherapy.

Statistical analysis

The chi-square test was used for univariate analysis of these factors. Statistically significant variables on univariate analysis were subsequently subjected to multivariate analysis with logistic regression. A P value less than 0.05 was considered to be statistically significant.

RESULTS

The mean age of the breast cancer patients was slightly higher than that of the controls (48.6±10.5 *vs* 46.8±12.0; $P=0.029$). None of the subjects in either group drank alcohol. Fatty liver was found in 98/217 (45.2 %) of the study group and in 37/182 (20.3 %) of the control group, with a statistically significant difference ($P<0.0001$). The breast cancer subjects were also significantly more likely to be obese than controls (124/217, 57.1 % *vs*. 45/182, 24.7 %, $P<0.0001$). There were no significant differences in the presence of hyperlipidemia or hepatitis C (Table 1).

On univariate analysis, fatty liver in subjects with breast cancer was significantly associated with overweight, hyperlipidemia, and hepatitis C but not with diabetes mellitus, tamoxifen, contraceptives, or chemotherapy (Table 2). Using logistic regression, the odds of fatty liver were increased in the breast cancer subjects in the presence of overweight (OR 1.406, $P<0.0001$) and hyperlipidemia (OR 1.206, $P=0.0473$) (Table 3).

DISCUSSION

Fatty liver is associated with alcohol abuse, obesity, malnutrition, diabetes mellitus, toxic agents, corticosteroids and endocrine imbalance. However, there had been little investigation of this disorder in relation to malignancy until Lanza reported in 1968 that a fair number of patients with known cancer had steatosis on percutaneous liver biopsy[5]. The diagnostic criteria and high accuracy of ultrasound in the detection of fatty liver were documented by Foster and Saverymuttu *et al*[6,7]. In a similar manner, an unusually high proportion of fatty liver in patients with carcinoma of breast was observed in the present study (Table 1). In this study, fatty liver was observed in 37 out of 182 (20.3 %) asymptomatic control subjects, significantly less than the 45.2 % of breast cancer subjects. Fatty liver was related to BMI, dietary fat intake, and ethnic differences. The actual incidence in the general population was varied.

The results of numerous epidemiological studies have demonstrated that the risk for breast cancer is related to a variety of factors, including age at menarche and at first childbirth, parity, level of education, previous benign breast tumor, family history of breast cancer, young age at menopause, environmental factors, ethnicity, BMI, dietary fat intake, and high central adiposity[2,8-10]. A significantly higher proportion of the breast cancer subjects were obese compared with controls (57.1 % *vs.* 15.4 %). With increasing weight, long chain fatty acid synthesis also increases, which in turn leads to lipid accumulation in the liver. It is likely that the higher incidence of fatty liver in our breast cancer subjects is related at least in part to their higher BMI.

The excess estrogen and insulin-like growth factor (IGF-1) produced by obese women have been suggested to be the key factor in promoting proliferation of mammary epithelial cells[11-14]. Furthermore, obesity may lead to delay in diagnosis, and it appears to be a poor prognostic factor[15,16].

Tamoxifen is an anti-estrogenic drug utilized in adjuvant therapy for breast cancer. Ogawa and colleagues suggested in 1998 that tamoxifen induced fatty liver in patients with breast cancer[17]. Nguyen published a study in 2001 demonstrating an increase in fatty liver and accumulation of visceral adipose tissue in breast cancer patients receiving tamoxifen[18]. Fatty liver can occur because of increased delivery of free fatty acids to the liver, increased synthesis of fatty acids in the liver, decreased β-oxidation of free fatty acids, and decreased synthesis or secretion of very low density lipoprotein[19]. Tamoxifen must therefore disarrange some of the steps in lipid metabolism[20].

There are a few reports of tamoxifen-associated steatohepatitis and multi-focal fatty infiltration of the liver[21,22]. Generally speaking, patients with fatty liver are usually symptom-free, but severe steatohepatitis may lead to liver cirrhosis in some cases. Therefore, careful attention should be paid to functional and morphological changes of the liver during tamoxifen treatment[21]. We have not yet found a significant relationship between tamoxifen and fatty liver in our subjects. This may be resulted from the insufficient length of tamoxifen treatment. Our subjects who took tamoxifen did for a mean of 12 months (range: 2-38 months), compared with a mean of 30 months (range: 4-84 months) in Nguyen' s series[18].

The clinical appearance of hepatic fatty changes may be diffuse, focal, multi-focal, the latter findings possibly mimic or harbor either primary or metastatic cancer[17,22]. Because of the possibility of liver metastases as well as the possibility of fatty liver (including the chance of progression to steatohepatitis or cirrhosis) with or without tamoxifen, it would be wise to monitor liver function and imaging in patients with breast cancer.

Abstract

AIM: To explore the characteristics of diarrhea caused by acaroid mites.

METHODS: Acaroid mites in fresh stools of 241 patients with diarrhea were separated by flotation in saturated saline. Meanwhile, skin prick test, total IgE and mite-specific IgE were detected in all patients.

RESULTS: The total positive rate of mites in stool samples of the patients was 17.01 % (41/241), the positive rates of mites in male and female patients were 15.86 % (23/145) and 18.75 % (18/96), respectively, without significant difference ($P>0.05$). The percentage of skin prick test as "+++", "++", "+", "±" and "-" was 9.13 % (22/241), 7.47 % (18/241), 5.81 % (14/241), 4.98 % (12/241) and 72.61 % (175/241), respectively. The serum levels of total IgE, mite-specific IgE in patients with and without mites in stool samples were (165.72±78.55) IU/ml, (132.44±26.80) IU/ml and (145.22±82.47) IU/ml, (67.35±45.28) IU/ml, respectively, with significant difference ($P<0.01$). The positive rate of mites in stool samples in staffs working in traditional Chinese medicine storehouses or rice storehouses (experimental group) was 26.74 % (23/86), which was significantly higher than that (11.61 %, 18/155) in people engaged in other professions ($\chi^2=8.97$, $P<0.01$).

CONCLUSION: Acaroid mites cause diarrhea and increase serum levels of total IgE and mite-specific IgE of patients, and the prevalence of diarrhea caused by acaroid mites is associated with occupations rather than the gender of patients.

INTRODUCTION

Grain or flour mite is a serious and widespread pest of stored foodstuffs, particularly grain and grain products[1-10]. Further studies have shown that some mites with strong vitality not only live freely, feeding on a wide variety of food, but also exist in animals or human intestines. After ingesting contaminated food by mites, like grain and grain products, individuals might have diarrhea, abdominal pain, burning sensation around anus and other symptoms of gastrointestinal tract[11]. The characteristics of diarrhea caused by acaroid mites were investigated in 241 patients with diarrhea in this study.

MATERIALS AND METHODS

Patients

Two hundred and forty-one patients with diarrhea (male 145 and female 96, aged from 6 to 58 years) were divided into experimental group (n=86) including staffs working in traditional Chinese medicine storehouses (n=47) and staffs working in rice storehouses or mills (n=39), and control group (n=155) including miners (n=36), staffs of railway system (n=34), pupils (n=62) and others (n=23).

Reagents

Horse anti-human IgE and standard working solution for IgE (17 000 IU/ml) were provided by Beijing Institute of Biological Products, and horse anti-human horseradish peroxidase-IgE was provided by Third Affiliated Hospital, Shanghai Second Medical University.

Methods

History-taking, separation of mites from stool samples, skin prick test and detection of total IgE and mite-specific IgE were carried out in all 241 subjects.

History-taking Detailed information of each subject was collected via telephone and personal interview, including age, gender, present history, anamnesis, symptoms (i.e. abdominal pain, cramps, diarrhea, urodynia, cloudy urine, and urination frequency), onset and duration of symptoms, personal hygienic habits, living conditions and the date of stool samples collected.

Stool examination The stool samples were collected, the mites were separated by flotation in saturated saline and identified under microscope. Stool examination was performed three times for each person, positive specimens were labeled once either adult or larval mite, egg, or hypopus was found.

Skin prick test Skin prick test was performed with the concentration of 1:100 (W/V). After skin was disinfected, a little of extract (about 0.01 ml) was dripped on skin of the right forearm flexor, then a sterile needle was pricked into the skin through the drop of the extract for about 0.5-1 mm in depth without bloodshed. About 5 cm distal and proximal of the prick site, normal saline and histamine were used as negative and positive control, respectively. The mean diameter of the wheals or areolae was measured 15~20 min after the test. The reactions of skin prick test with the mean diameter ≧1.5 mm, ≧2 mm, ≧3 mm, ≧5 mm and ≧10 mm were regarded as ±, +, ++, +++ and ++++, respectively. Otherwise, the reaction was judged as negative[12,13].

The test extract was prepared according to WHO approved document NIBSC 82/518 in 1984. The purified fraction was prepared as follows: the mites cultured in initial medium for several months were frozen and thawed several times. A 48-h maceration in borate buffer at pH 8.5 was centrifuged. The supernatant was neutralized and submitted to acetone precipitation at gradually increasing concentrations. The fraction precipitated in 80 % acetone was isolated, washed and dried. The purified extract was lyophilized or stocked in

50 % glycerol and 5 % phenol[14-16].

Detection of total IgE and mite-specific IgE To investigate humoral immune function in individuals with diarrhea caused by acaroid mites, the levels of total IgE and mite-specific IgE in peripheral blood of mite-positive individuals were tested with ELISA. Peripheral venous blood of the subjects was withdrawn and saved in eppendorf tubes, then the optical density (OD) value was tested on enzyme labeling meters. Positive and negative control tubes were included each time. When the OD value in the tested sample was 2.1 times that or more in negative control, it was regarded as positive.

Mites separated from environment Directicopy, waterenacopy and tullgren were used to separate mites from mill floor dust, stores of traditional Chinese medicine, and traditional Chinese herbs of wolfberry fruit, ophiopogon root liquorice, boat-fruited sterculia seed and safflower, etc.

Statistical analysis

The positive rates were expressed as percentage, and t and χ^2 tests were used in statistical analysis. A probability value of less than 0.05 was considered statistically significant.

RESULTS

Stool examination

The positive rate of mites in stool samples in all the individuals was 17.01 % (41/241), and was 15.86 % (23/145) and 18.75 % (18/96), respectively in samples from male and female subjects, without significant difference (χ^2=0.34, P>0.05). The mites separated from stool samples were confirmed to be *Acarus siro*, *TyroPhagus putrescentiae*, *Dermatophagoides farinae*, *D. pteronyssinus*, *Glycyphagus domesticus*, *G.ornatus*, *Carpoglyphus lactis* and *Tarsonemus granaries*. Among 41 cases with mites in stools, adult mites, larval mites, both adult and larval mites, adult mites and eggs, adult and larval mites and eggs, larval mites and eggs, and both hypopus and eggs were found in 15, 6, 11, 3, 2, 2 and 2 cases, and the constituent ratios of them were 36.59 %, 14.63 %, 26.83 %, 7.32 %, 4.88 %, 4.88 % and 4.88 %, respectively. In addition, the statistics of this investigation showed that the case number with concentration of mites of 1-2/cm^3, 2-4/cm^3 and >5/cm^3 was 6, 12 and 23, respectively. Among the 41 mite-positive cases, 3 cases had other intestinal parasites, 6 cases had pathogenic bacteria. The remaining 32 cases had mites in stool samples only.

Skin prick test

The percentages of cases with "+++", "++", "+", "±" and "-" were 9.13 % (22/241), 7.47 % (18/241), 5.81 % (14/241), 4.98 % (12/241) and 72.61 % (175/241), respectively. The positive number of skin prick test was 54, of which, 41 subjects with mites in stools were all included. In other words, all the 22 subjects with "+++" reaction were confirmed to be mite-positive, and 14 subjects with mites in stools were found in the 18 subjects with "++" reactions, 5 subjects with mites in stools were found in the 14 subjects with "+" reaction. However, all the 41 subjects with mites in stools were positive in skin prick test.

Detection of total IgE and specific IgE

The levels of total IgE and mite-specific IgE in 41 cases with mites were higher than those in individuals without mites (P<0.01) (Table 1).

Relationship between diarrhea caused by acaroid mites and occupation

Among the 241 patients with diarrhea, the positive rate of mites in experimental group was 26.74 % (23/86), which was higher than that in control group (χ^2=8.97, P<0.01) (Table 2).

Table 1 Serum total IgE and mite-specific IgE in patients with diarrhea (IU / ml, $\bar{x}\pm s$)

Group	n	Total IgE (IU / ml)	Specific IgE (IU / ml)
Mite-positive cases	41	165.72±78.55[a]	145.22±82.47[b]
Mite-negative cases	200	132.44±26.80	67.35±45.28
Total	241	138.10±35.37	80.59±53.62

[a]P<0.01, t=4.81; [b]P<0.01, t=8.52 *vs* mite-negative cases.

Table 2 Mites in stool samples in patients with different occupations (n, %)

Groups	Cases	Positive number	Positive rate
Experimental group	86	23[c]	26.74
Staffs working in traditional Chinese medicine storehouses	47	14	29.79

Others	23	3	13.04
Total	241	41	17.01

[c]P<0.01, χ^2=8.97 *vs* control group.

Mites separated from work environment

Samples of mill floor dust (30 shares), stores of traditional Chinese medicine, and traditional Chinese herbs (146 species) of wolfberry fruit, ophiopogon root liquorice, boat-fruited sterculia seed, safflower and other work environment and foodstuffs were collected and separated for mites. The results showed that the number of breeding mites per gram was 91-1862, 21-186, 0-483, 10-348, 51-712, and 311-1193, in mill floor dust, traditional Chinese medicine stores, traditional Chinese herbs such as candied fruit, dry fruit, brown sugar, and expired cake. Twenty-two species of mites were separated and identified belonging to nine families, i.e. *Acaridae*, *Lardoglyphidae*, *Glycyphagidae*, *Chortoglyphidae*, *Carpoglyphidae*, *Histiostomidae*, *Pyroglyphidae*, *Tarsonemus*, *Cheyletus*. The results of this study showed that the mites separated from work environment were identical to those from stored food.

DISCUSSION

In this study, *Acarus siro*, *TyroPhagus putrescentiae*, *Dermatophagoides farinae*, *D. pteronyssinus*, *Glycyphagus domesticus*, *G.ornatus*, *Carpoglyphus lactis* and *Tarsonemus granaries* were separated from stool of patients with diarrhea. This confirmed that acaroid mites were able to parasitize in human intestines, which might play an important role in diarrhea. Like other intestinal parasites, the mites living in intestinal tract may stimulate mechanically and damage intestinal tissues with its gnathosoma, chelicera and feet[17-25]. Certainly they may also intrude into mucous and deep tissues, and cause inflammation and necrosis.

The results of this study support the idea that the patients with mites in stool samples are allergic to acaroid mites. Skin

prick test is one of the specific methods for clinical diagnosis of allergic disease. After superficial layer of skin is pierced by a special needle, interaction occurrs between the test extract and mastocytes in the brain, which causes mastocytes degranulation and inflammation-media release like histamine that is able to increase capillary telangiectasia and permeability. Thereby wheal and flush appear on the surface of skin tested[26,27]. Among the 241 patients tested with skin prick test, 54 subjects had positive reactions. This demonstrated that some of the patients with diarrhea were allergic to acaroid mites. Moreover, the results of skin prick test on 41 patients with mites in their stools were all positive. It provided the evidence that acaroid mites in intestine might lead to the allergy of patients to acaroid mites. The reason why there were no mites found in stools taken from 13 patients with positive reaction of skin prick test is that mites live in other locus besides intestines, and that mites may be missed in detection with saturated saline flotation methods.

Although the serum level of total IgE is a marker of human sensitization to extrinsic allergen, the level of specific IgE is a sensitive index for allergic reaction to acaroid mites[28-34]. In this study, the levels of specific IgE in 41 patients with mites were higher than those without mites. This provides another evidence that acaroid mites can cause allergy. The dejecta, products of metabolism, and cleaved pieces of dead mites in intestine may stimulate lymphocytes and reticuloendothelial system, and produce specific antibodies, such as IgE.

This study confirms that the prevalence of diarrhea caused by acaroid mites was associated with the patients' occupation. The positive rates of mites in stools of staffs working in traditional Chinese medicine storehouses and rice storehouses or mills were 29.79 % (14/47) and 23.08 % (9/39), respectively, which were higher than those of patients with other occupations. However, no significant association was observed between diarrheas caused by the organism with the gender of patients. The positive rates of mites in male and female patients were 15.86 % (23/145) and 18.75 % (18/96), respectively.

Eight species of acaroid mites separated from stool samples could be found in the house dust collected from traditional Chinese medicine storehouses, rice storehouses and flourmills, suggesting that the source of diarrhea caused by acaroid mites is mites in our living environment and stored food. Generally speaking, the path of the mites invading human is related to ingestion of stored food. However, some mites in dust or in air might invade intestine through mouth, or nasal cavity, gorge[35-37]. We have set up eight sampling sites in traditional Chinese medicine storehouses by dust sampler, and separated thirteen mites from dust samples collected from 640 L of air in work environment of the storehouses.

In conclusion, acaroid mites in our living and working environments may invade human intestines and cause diarrhea. The levels of total IgE, mite-specific IgE of the patients with diarrhea caused by acaroid mites increased, the prevalence was associated with the patient' s occupation rather than gender. It is suggested that separation of mites from stool samples, skin prick test and detection of total IgE and mite-specific IgE should be used in the diagnosis of diarrhea caused by acaroid mites.

Abstract

AIM: As the conventional combined liver-small bowel transplantation is complicated with many postoperative complications, the aim of this study was to describe a modified technique for the combined liver-small bowel transplantation with preservation of the duodenum, partial head of pancreas and hepatic biliary system in pigs.

METHODS: Composite liver/small bowel allotransplantations were undertaken in 30 long-white pigs. The graft included liver, about 3 to 4 m proximal jejunum, duodenum and partial pancreatic head. Vessels reconstructions included subhepatic vena cava-vena cava anastomosis, aorta-aorta anastomosis and portal-splenic vein anastomosis.

RESULTS: Without immunosuppressive treatment, the median survival time of the animals was 6 days (2 to 12 days), and about 76.9 % (20/26) of the animals survived for more than 4 days after operation.

CONCLUSION: The modified technique is feasible and safe for the composite liver/small bowel transplantation with duodenum and pancreas preserved in pigs. And also this technique can simplify the operation and decrease possible postoperative complications.

INTRODUCTION

As a result of total parenteral nutrition (TPN) induced end-stage liver disease, 60 % to 70 % of recipients of intestinal transplant procedures require simultaneous liver allografts[1,2]. Although many clinical liver/small bowel transplantations (LSBT) were reported from different medical centers[3-5], it remains an experimental procedure[6]. Compared to the widely used rat LSBT model[7,8], large animal models such as LSBT in pigs were rarely reported.

As a conventional composite liver-small bowel graft requires a loop of defunctionalized (Roux) allograft small bowel for biliary drainage[9], its posttransplant biliary complications include anastomotic leaks and obstruction in 12 % of the cases, with significantly associated morbidity and mortality in clinical reports[1]. In the present study, we modified the technique for LSBT by preserving the duodenum, partial head of pancreas and hepatic biliary system, and also we modified the conventional vena cava and the portal drainage anastomotic methods. Experience with this technique for the LSBT in pigs has not been described previously.

MATERIALS AND METHODS

Donor preparation 60 long-white pigs weighing 20-40 Kg with random sex were undertaken 30 LSBTs. The weight of the donor was generally lower than that of the corresponding recipient. No immunosuppressive treatment was given in the group.

Preoperative treatment The animals were not allowed to eat for 24 hours and drink for 4 hours before operation respectively. The gut decontamination was attempted in all donors with an oral antibiotic preparation 3 days before surgery.

After anesthesia with 25 mg/kg of intravenous pentobarbital sodium, the animal was intubated and mechanically ventilated with a mixture of oxygen, nitrous oxide and isoflurane. In addition, the standard intravenous antibiotic prophylaxis was instituted with cefotaxime at the time of surgery.

Donor surgical technique

Initial exposure and isolation of the abdominal organs The procurement varied in details but followed the standard techniques for human multiorgan retrieval[10-12]. Briefly, the donor operation was performed through a midline laparotomy. Cares should be taken not to damage the urethra of male pigs when opening the abdomen. The liver was mobilized by dividing its suspensory attachments. The right gastric and right gastroepiploic vessels were divided, and the pylorus was transected, which allowed the stomach to be reflected craniad. The proximal 3 to 4 m of jejunum (the total porcine small bowel is about 15 m) together with the liver was procured as the graft. After the redundant small bowel was dissected, its supply vessels were ligated. Then the intestinal tract was transected at the beginning of the descending colon, and then the redundant small bowel and the colon were removed from the operative field. Thus the duodenum, proximal jejunum and the aorta could be well exposed. The left gastric artery was ligated at the celiac axis.

Dissection of the vessels The suprahepatic vena cava was firstly dissected and encircled. An extensive Kocher maneuver allowed visualization of the inferior vena cava and its branch. The subhepatic vena cava was dissected and encircled. The left and right renal veins were ligated respectively.

With division of the left retroperitoneal artery, the superior mesenteric and celiac arteries were identified by extending dissection of the aorta. The right and left renal arteries were then isolated and ligated. The subrenal aorta was isolated and encircled distally for the eventual insertion of an infusion cannula. The abdominal aorta was also encircled above the celiac axis for later crossclamping when cold fluid was infused through the distal aortic cannula[13]. It should be mentioned

that dissection of the celiac trunk would always open the diaphragm and result in pneumothorax.

The splenic vein was then freed and prepared for portal perfusion cannulation after division of the splenic artery. The splenic vein should be well protected when dividing the splenic artery[14].

***In situ* cooling and removal of the organs** Unlike the clinical transplantation, it was imperative to collect the donor' s blood for the recipient operation. Before the infusion with cold solution, the donor' s blood was collected from the iliac artery. After completion of the preliminary dissections and collection of the donor' s blood, the liver and small bowel connected by the portal vein and the aortic segment were lavaged *in situ* with UW solution. Briefly, the donor was fully heparinized and the previously encircled proximal aorta was crossclamped, and the distal donor aorta was cannulated with infusion of cold UW solution. For the simultaneous portal venous infusion, a venous cannula was placed into the splenic vein and infused with the UW solution. The intrapericardial inferior vena cava and the subhepatic vena cava were transected to decompress the infused solution as in other reports[15,16]. The amount of infusion was variable (between 50 mL/Kg and 100 mL/Kg), guided by blanching the organs and estimated by palpation of the degree of cooling. If the intestine did not feel cold after limited perfusion, there was no reason for concern, providing it was blanched, further surface cooling after immersion in cold fluid was rapid as the intestine is a hollow organ[11]. It is important to avoid both venous hypertension and overperfusion of the intestine and pancreas, as overperfusion might result in duodenopancreatic and small bowel edema[13,17]. Some solution was injected into the gallbladder to lavage the bile tract.

After infusion, the graft containing liver, hepatic hilus, pancreatic-duodeno complex, spleen together with the splenic vein, and small bowel was achieved with preservation of a segment of aorta containing the superior mesenteric artery and celiac trunk in continuity. The intestine was entrapped by stapling its two ends and carried with the specimen throughout the preservation. Thus the graft was *en bloc* removed and stored in UW solution at 0 to 4 ℃.

Back table procedure Back table procedure was performed in the cold UW solution. It included suturing the orifice of suprahepatic vena cava and the proximal end of the aorta. The spleen was removed and the splenic vein was well preserved. The body and tail of the pancreas along the portal vein were isolated and transected, leaving partial pancreatic head attached to the allograft duodenum. This preserved the superior and inferior pancreatic duodenal arcades. The stump of the pancreas was stapled and then oversewn with a running suture using 4-0 polypropylene. The gallbladder was removed and a catheter was placed into the cystic duct stump for the early decompression and study of the donor biliary system during the early postoperative period.

Recipient operation

After anesthesia, a monitor was placed on the recipient. Two venous catheters were inserted for transfusion and central venous pressure monitoring. The arterial blood pressure was monitored through a thigh artery catheter.

Intestinal resection When the abdomen was opened, the small bowel and its mesentery were dissected. Most of the intestine was removed for an artificial short bowel with only about 30 cm left at each end.

Vascular preparation The subrenal aorta was exposed and encircled 2 cm under the renal artery. Small arterial and lymphatic vessels along the aorta were ligated to avoid later bleeding or lymphorrhea. Subhepatic vena cava was also dissected and encircled. The place just above the left renal vein was routinely used for the donor out-flow anastomosis. The hilar of the recipient liver was dissected. The common bile duct and the liver artery were transected while the portal vein was crossclamped with a bulldog after transection.

Hepatectomy The resection of the recipient liver was another major step. The total vascular exclusive technique for hepatectomy in human being was not suitable to the pig, so the liver was removed lobe by lobe. Since the retrohepatic vena cava in the pig was passing through the liver with numerous small hepatic veins draining to this segment besides the major hepatic veins, it was hard to be skeletonized. In order to avoid massive bleeding when dissecting the retrohepatic vena cava, a small part of the liver around the retrohepatic vena cava was always saved and oversewn.

Graft implantation and revascularization The transplantation methods varied in details but followed the principles as described previously[11]. The typical reconstruction is shown in Figure 1.

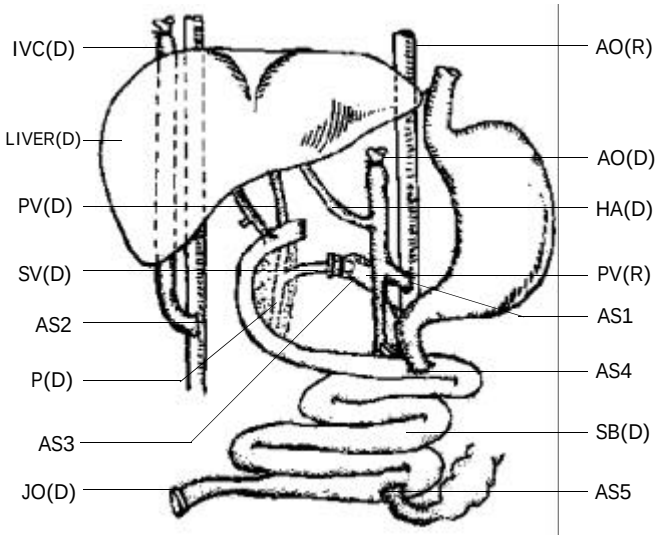

Figure 1 Composite liver/small bowel transplantation (D=donor, R=recipient, AO=aorta, HA=hepatic artery, PV=portal vein, SB=small bowel, IVC=inferior vena cava, SV=splenic vein, P=pancreas, JO=jejunum ostomy, AS1=aorta-aorta anastomosis, AS2=subhepatic vena cava- vena cava anastomosis, AS3=portal-splenic vein anastomosis, AS4=proximal jejuno-jejunal anastomosis, AS5=distal jejuno-ileal anastomosis).

The graft was placed in an orthotopic position. The arterial inflow was created via an end-to-side anastomosis of the graft aorta to the subrenal native aorta with a running polypropylene suture. Donor and recipient vena cava were anastomosed end to side. The venous outflow was a modification of the piggyback fashion with the end of the graft subhepatic vena cava anastomosed to the side of the native subhepatic vena cava.

Before reperfusion, unclamping and perfusion of the allograft liver were achieved after a lavage of 300 to 500 ml donor blood or Ringer' s solution through the splenic vein.

Anastomosis of the donor splenic vein to the recipient portal vein By using the graft splenic venous stump, a branch point left could be clamped separately and anastomosed to the recipient portal vein to allow outflow of the retained recipient viscera (stomach, pancreas, and spleen as well as the remaining native intestine). Since the splenic vein was smaller than the recipient portal vein, the cuff technique was always used for this anastomosis.

Gastrointestinal reconstruction The proximal duodenum was closed. The intestinal continuity was established proximally by end-to-side recipient-to-donor jejuno-jejunal anastomosis. The end of the recipient' s distal ileum was anastomosed to the side of the donor distal jejunum including a donor distal

intestinal vent for the early decompression and surveillance endoscopies as described in some clinical reports[18,19]. The bile was drained with a catheter in the donor' s cystic tract.

Postoperative management After operation, the animal was returned to the monitor room, where hemodynamic monitoring and mechanical ventilation were performed as needed 24 hours after operation. Due to the high rate of inflammatory complications, broad-spectrum antibacterial prophylaxis was administered once for 5 days. Lactated Ringer' s solution and parenteral nutrition were given daily until the animal was able to eat and drink.

The appearance of the allograft ostomy and the amount of ostomy output were useful clinical signs of graft dysfunction. Ostomy losses up to 100 cc/kg per day were acceptable and could be compensated by supplementary intravenous fluids.

RESULTS

After reperfusion, the liver was soft and pink with prompt bile production, evidenced through the cystic duct catheter. If the liver was harder than normal, the outflow of the liver might be obstructed and the vena cava anastomosis was required to be checked. The small bowel would be perfused well, with good mesenteric arterial inflow and venous outflow. The peristalsis and intraluminal mucous production were evident within 15 minutes after reperfusion.

Animals died suddenly after reperfusion were ruled out from the statistic series. 4 recipients died because of post reperfusion syndrome and operative techniques. The other 26 LSBT pigs had a median survival time of 6 days (from 2 to 12 days). The surgical records are shown in Table 1, and the values were expressed as median (range).

Table 1 Surgical records

Parameters	Values
Weight of the donor (KG)	22.5 (19-25)
Weight of the recipient (KG)	25 (22-38)
Length of the graft small bowel (m)	3.4 (2.8-4.2)
Weight of the graft liver (g)	760 (620-960)
Collection of the donor blood (ml)	800 (400-1200)
Cooling solution (ml)	1400 (1200-2000)
Donor operative time (hr)	3.3 (2.8-3.6)
Back table time (hr)	0.8 (0.5-1.1)
Preservation time (hr)	3.8 (3.0-4.5)
Total cold ischemia time (hr)	5.6 (3.8-6.6)
Total operative time (hr)	8.2 (7.0-11.4)
Postoperative survival time (day)	6 (2-12)
Survival rate (more than 4 days)	76.9%(20/26)

During the first three days, the intestinal graft stoma appeared healthy, and the mucosa was pink, moist, and well vascularized. No intestinal edema was found in most cases with stomal output averaging 500 ml/day and characterized by bile-stained stool. The high stomal output would decrease with time.

All liver grafts functioned immediately after serum bilirubin and transaminase levels peaked on the first postoperative day and fell rapidly thereafter.

Neither the duodenal allografts experienced signs of ischemia or stump leakage, nor experienced any biliary complication. Abdominal drains were monitored serially for amylase and lipase. Chemical pancreatitis was observed during the early postoperative period with lipase-rich fluid drainage. The biopsies of the dead animals indicated mild pancreatitis in the remained pancreas.

Histopathologic studies of the grafts showed no significant preservation injury. None of the biopsies obtained in the first postoperative week had histological evidence of submucosal bacterial invasion. The frequent cause of death was postoperative rejection convinced by the graft biopsies when the animal was dead.

DISCUSSION

Specialties of porcine anatomy and LSBT model Firstly, the porcine liver is divided into 4 relatively independent lobes. There are obvious borderlines between lobes. This is the reason why we can remove the liver lobe by lobe when total vascular exclusive technique can not be used in hepatectomy. Secondly, the porcine retrohepatic vena cava is passing through the liver parenchyma with numerous small hepatic veins outflow to this segment besides the major hepatic veins. It is dangerous to remove the liver parenchyma when dissecting the retrohepatic vena cava. This is the reason why the classic piggyback liver transplantation is not suitable to the pig. The vena cava anastomosis was modified by replacing the major hepatic vein (or suprahepatic vena cava) anastomosis in classical piggyback transplantation with the subhepatic vena cava anastomosis (Figure 1). This modification has at least three advantages in porcine LSBT: (1). It is safe to remove the liver, for the whole recipient liver is not moved to expose the retrohepatic vena cava. (2). The subhepatic vena cava anastomosis can be easily performed. (3). The subhepatic vena cava anastomosis can adjust a flexible anastomotic interval to make the aorta-aorta and the portal-splenic vein anastomosis easier.

The third difference of porcine anatomy is that the interval between the celiac axis and superior mesenteric artery is longer than that of human being. It is about 2 to 2.5 cm in general, so the Carrel patch with celiac axis and superior mesenteric artery in human LSBT is not suitable to the pig. The long segment of aorta with celiac axis and superior mesenteric artery was used in porcine LSBT. (Figure 1).

Feasibility and safety of the porcine LSBT with pancreatic head and duodenum In clinical practice, Abu-Elmagd suggested that LSBT with pancreatic head and duodenum had some advantages including avoidance of biliary complications and simplification of the operative procedure[20]. These possible advantages might exist in the animal LSBT.

The LSBT transplant procedure is a much more arduous surgical endeavor. The technique retaining the duodenum and the head of pancreas would simplify the back table preparation and avoid risks associated with dissection of the donor hepatic hilus.

Retrieval for composite grafts using the standard technique involves an obligatory reconstruction of the biliary system with a defunctionalized loop of proximal allograft jejunum[3]. In this porcine LSBT model, no biliary reconstruction is required to eliminate the source of complications such as bile leakage, bile tract stricture or even the death of recipient. Liver transplantation related biliary complication rate is about 12 %, which would result in about 19 % of death of them[21,22]. The LSBT with partial pancreas and duodenum would remarkably decrease such complications.

Without donor or recipient bowel for Roux-en-Y biliary reconstruction would enhance the potential benefits of any intestinal segment in freeing the pig for TPN, as it is directly kept in continuity with the alimentary tract.

The advantage of the composite technique is to maintain the hepatic hilus. The use of liver artery and superior mesenteric artery with a large arterial conduit would minimize the risk of hepatic artery thrombosis compared to isolated graft[18,23].

In the experiments, we found that the graft with duodenum and partial pancreas was also convenient to be implanted as compared to the standard LSBT. Only three vascular anastomoses were required, including aorta-aorta anastomosis,

vena cava-vena cava anastomosis and portal-splenic vein anastomosis. The liver artery anastomosis and biliary reconstruction are not necessary when this method is used. Since the aorta and vena cava are end-to-side anastomosed with the recipient' s aorta and vena cava partially excluded during the anastomosis. This method would avoid not only hemodynamic damages, but also possible kidney injuries, postoperative thrombus and lower limb ischemia.

Inclusion of the duodenum and pancreatic head to maintain continuity of the biliary system was associated with early postoperative allograft pancreatitis, and no significant morbidity was reported[17]. This complication was also found in our study. It could be detected by measuring pancreatic enzymes in peritoneal fluid from abdominal drains and serum pancreatic enzymes[20]. Early diagnosis and aggressive surgical management of the native pancreatitis have eliminated the need for repeated transplantation[18]. At present, the following possible ways are considered to protect the allografted pancreas from postoperative pancreatitis. (1). To limit the cold solution and the pressure of perfusion[13]. (2). To procure the pancreas entirely with the graft and avoid over-dissection of the tissue and vessels around the duodenum and pancreas[24]. (3). To ligate the pancreatic tract and suture the pancreatic interface definitely. (4). To use somatostatin after operation.

Some reports suggested that LSBT with duodenum and pancreas head preserved would neither increase the possibility of rejection nor require more immunosuppressive treatment than that of the standard LSBT without pancreas and duodenum[18,23]. The presence of allograft pancreas in the multivisceral allograft was not an important risk factor for mortality, and the incidence of rejection of the pancreas was only 12 % in some report[18]. So the technique with preservation of the pancreas is safe in composite LSBT.

In summary, the modified technique is feasible and safe for composite liver/small bowel transplantation with duodenum and pancreas preserved. This technique can simplify the operation procedure and decrease possible postoperative complications. The immunosuppressive treatment in this large animal LSBT model needs to be further studied.

Abstract

AIM: To produce the recombinant NS3 protease of hepatitis C virus with enzymatic activity in insect cells.

METHODS: The gene of HCV serine proteinase domain which encodes 181 amino acids was inserted into pFastBacHTc and the recombinant plasmid pFBCNS3N was transformed into DH10Bac competent cells for transposition. After the recombinant bacmids had been determined to be correct by both blue-white colonies and PCR analysis, the isolated bacmid DNAs were transfected into Sf9 insect cells. The bacmids DNA was verified to replicate in insect cells and packaged into baculovirus particles via PCR and electronic microscopic analysis. The insect cells infected with recombinant baculovirus were determined by SDS-PAGE and Western-blot assays. The recombinant protein was soluted in N-lauryl sarcosine sodium (NLS) and purifed by metal-chelated-affinity chromatography, then the antigenicity of recombinant protease was determined by enzyme-linked immunoabsorbant assay and its enzymatic activity was detected.

RESULTS: The HCV NS3 protease domain was expressed in insect cells at high level and it was partially solved in NLS. Totally 0.2 mg recombinant serine proteinase domain with high purity was obtained by metal-chelated-affinity chromatography from 5×10^7 cells, and both antigenicity and specificity of the protein were evaluated to be high when used as antigen to detect hepatitis C patients' sera in indirect ELISA format. *In vitro* cleavage assay corroborated its enzymatic activity.

CONCLUSION: The recombinant HCV NS3 proteinase expressed by insect cells is a membrane-binding protein with good antigenicity and enzymatic activity.

INTRODUCTION

Hepatitis C virus, the major etiological agent of post-transfusion non-A, non-B hepatitis, is an enveloped virus obtaining a single-stranded RNA genome of approximately 9.5kb[1-3]. A single polyprotein of 3 010-3 030 amino acids is translated from this genome in the order of NH2-C-E1-E2-p7-NS2-NS3-NS4A-NS4B-NS5A-NS5B-COOH. Proteolytic procession of the viral precursor protein is required for replication and is mediated by either viral or host cell proteinases[4-7]. HCV uses a serine proteinase located at the N- terminus of NS3, to process the cleavage of four sites (3/4A, 4A/4B, 4B/5A and 5A/5B). Since the NS3 protein is very important for releasing functional proteins from the polyprotein, it has been currently targeted in the development of drugs and diagnostics[8-11].

In the absence of satisfactory cell culture, protein expression is the primary technological methods for HCV[12-14]. In this report, we described the construction of the recombinant baculovirus, designed to express the NS3 proteinase in insects. The activity of the expressed enzyme has been demonstrated by *in vitro* assay.

MATERIALS AND METHODS

Cells, vectors and strains

Spodoptera frugiperda Sf9 cells were a gift from Professor Gu Shu-Yan, Institute of Virology, CDC, China. The vector pGEX-3X-NS3N containing the gene serine proteinase located at N-terminus of HCV NS3, was constructed in our lab before[15]. The expression vector pFastBacHTc and *E.coli* DH10Bac were purchased from Invitrogen Inc.

Primers

The primers flanking the vector transfer pFastBacHTc MCS were WB538P (5' -TATTC CGGAT TATTC ATACC-3') and WHT62P (5' -TGGTA TGGCT GATTA TGAT-3'). The primers for bacmid were pUC/M13-R (5' -CAGGA AACAG CTATG AC) and pUC/M13-F (5' -GTTTT CCCAG TCACG AC-3').

Construction of recombinant transfer vector

The gene HCV NS3N serine proteinase was excised from pGEX-3X-NS3N with restriction enzyme *BamHI* and *EcoRI*, and ligated with vector pFastBacHTc. The recombinant plasmids were transformed into *E.coli* DH5α. The positive recombinants were identified with PCR and restriction enzyme digestion, then termed as pFBCNS3N.

Transposition

The recombinant transfer vector pFBCNS3N was transformed into the competent DH10Bac cells. After growth in the shaking incubator at 37 ℃ for 6 h, the cells were placed on the plates (containing 50 mg/L kanamycin, 7 mg/L gentamicin, 10 mg/L tetracycline, 40 mg/L IPTG and 100 mg/L X-gal) with serial dilution, then incubated at 37 ℃ for 48 h. The white colonies containing the recombinant bacmid, therefore, were selected for the isolation of recombinant bacmid DNA. The bacmid, termed as bacmid-NS3N, was analyzed by 0.5 % agarose gel electrophoresis to confirm the presence of high molecular weight DNA.

Production and analysis of recombinant baculovirus

9×10^5 of Sf9 cells were seeded to each well of a 6-well plate in TNM-FH medium and incubated at 27 ℃. Bacmic-NS3N was transfected into Sf9 cells using Lipofectamine reagent (Gibco

BRL) after cells attached to the wells. The supernatant was collected as virus stock when cytopathic effect appeared. At the same time, virus particles in the supernatant were precipitated using PEG8000 to extract viral genome for PCR amplification with the primers WB538P, WHT62P and pUC/M13-R, F to confirm the recombinant virus containing the interested gene. The morpha of recombinant baculovirus was observed under transmission electron microscope.

Expression and purification of serine proteinase in insect cells

Monolayer insect cells were transfected by the recombinant baculovirus at a multiplicity of infection (MOI) of 10. The cells were harvested after incubation for 72 h at 27 ℃, resuspended in lysis buffer (0.5 % NP-40, 20 mmol/L Tris-HCl pH 7.4, 150 mmol/L NaCl, 100 mg/L PMSF), and disrupted by ultrasonic. The supernatant and precipitation of the mixture were collected for SDS-PAGE and Western blotting. 5×10^7 of Sf9 cells were collected by centrifugation after transfection for 72 h to purify the recombinant serine proteinase. The cell pellet was resuspended in TNG buffer (50 mmol/L Tris-HCl pH 7.4, 0.2 % NLS (N-Lauryl Sarcosine Sodium), 10 % glycerol, 150 mmol/L NaCl, 100 mg/L PMSF), and disrupted by ultrasonic. The interested protein was purified from the supernatant by means of affinity chromatography on Ni-NTA columns (Qiagen).

In vitro assay of HCV NS3 proteinase activity

Fifteen μg recombinant serine proteinase was mixed with 15 μg substrate HCV NS5ab in 100 μl of 25 mmol/L Tris-HCl pH 7.4, 10 % glycerol, 0.5 mol/L NaCl, 10 mmol/L DTT, 0.5 % NP-40. The incubation was carried out at room temperature for different time periods and the result was read through SDS-PAGE.

Antigenicity of recombinant HCV serine proteinase

The identity of recombinant proteins was confirmed by 50 HCV-positive and 10 HCV-negative sera. Microtitre cells were coated by overnight incubation at 4 ℃ with 100 μl recombinant protein solution (10 mg/L proteins in 0.1 mol/L sodium carbonate buffer, pH 9.6). Serum samples diluted at 1:20 in PBSTM (PBS+0.3 % Tween-20+3 % fat-free milk) were added, and incubated at 37 ℃ for 1 hour after blocking. The specific binding was revealed using HRP anti-human IgG detection system(Sigma, USA).

RESULTS

Construction of recombinant transfer vector

A 540 bp fragment was excised from the plasmid pFBCNS3N with restriction endonuclease enzymes *HindIII* and *EcoRI* (Figure 1). The result showed that the construction of recombinant transfer vector was successful.

Generation of recombinant baculovirus

The recombinant baculoviruses were generated after the site-specific transposition of transfer plasmids in *E.coli*, transfection and packaging in insect cells. Large amounts of baculoviruses were observed in the nuclei of cells under transmission electron microscope (Figure 2). In PCR detection, genome DNA of the recombinant baculoviruses as template, 800 bp and 3 000 bp fragments appeared respectively with primers WB538P, WHT62P and pUC/M13-R, F. The result conformed to our previous expectation and revealed HCV serine proteinase gene existed in the genome of recombinant baculoviruses.

Efficient expression of HCV serine proteinase by recombinant baculovirus

Sf9 cells were transfected with the recombinant baculovirus at a MOI of 10, and serious CPE appeared after 72 h. The total cell extracts were separated by 15 % SDS-PAGE and stained with Coomassie blue. A predominant band at 23 kDa (approximately 20 % of total proteins) was detected in the cell extracts from bacmic-NS3N infected cells but not in the uninfected cell extracts (Figure 3A). Immunoblot analysis with the HCV-positive sera (Figure 3B) revealed that the 23 kDa protein was clearly detected in cells infected with the recombinant baculovirus.

Analysis of solubility of recombinant HCV serine proteinase

Though HCV serine proteinase was expressed efficiently in insect cells, a little was laid in the supernatant of the cell lysate.

Only by immunoblot analysis was the protein in the supernatant detected. Did the protein's misfolding or binding with endomembrane system in cells lead to unsoluble protein? This question was analyzed by changing the composition of the lysis buffer. When the cell lysates were dissolved in TNG buffer containing N-lauryl sarcosine sodium, more interested protein was soluble because TNG as a detergent could dissolve proteins binding with membrane. Therefore, it was presumed that the recombinant HCV serine proteinase binding with membrane resulted in its unsolubility. The HCV serine proteinase was extensively purified from 5×10^7 Sf9 cells and demonstrated a single protein band of 23kDa (more than 90 % of the total proteins by densitometric analysis) by using Ni-NTA columns. The total yield of the purified protein was about 0.2 mg.

Activity of baculovirus-expressing HCV serine proteinase in trans

In order to determine whether the baculovirus-expressing cleavage N-terminus of HCV NS3 has a proteinase activity, an *in vitro* proteolytic assay with HCV NS5ab protein (235aa) as a substrate containing the cleavage site of HCV NS5a and NS5b was designed. Figure 4 shows that the baculovirus-expressing HCV serine proteinase could cleave the substrate HCV NS5ab (about 35kDa) into bands of 24kDa and 11kDa (Figure 4). This means that the baculovirus-expressing HCV serine proteinase has a high proteolytic activity.

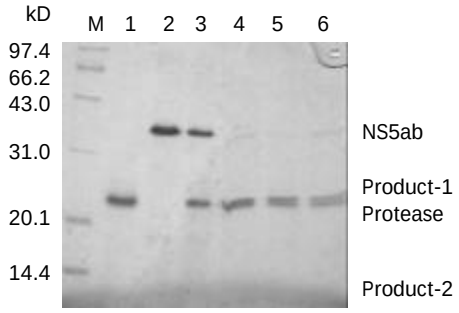

Figure 4 *In vitro* trans-cleavage at the NS5A/5B site of the recombinant HCV serine proteinase. Lane M. low molecular weight markers, lane 1. the purified HCV serine proteinase, lane 2. the substrate HCV NS5ab protetin, lanes 3-6. cleavage reaction after 0, 10, 20 and 30 min.

Antigenicity of recombinant HCV serine proteinase

Fifty HCV positive sera and 10 HCV negative sera were evaluated for their reactivities against the purified HCV serine proteinase. A high degree of immunoreactivity was observed in 30 HCV positive sera, showing good antigenicity of HCV serine proteinase.

DISCUSSION

It has been proved that HCV NS3 protein with 631 amino acids possesses both serine proteinase in its N-terminus and NTP/RNA helicase activity in its C-terminus[16]. Both *in vitro* translation and transient mammalian cells have shown that NS3 is a serine proteinase and is responsible for proteolytic processing of the non-structural region (NS3, NS4A, NS4B, NS5A and NS5B) of HCV polyprotein. Since the maturation of these non-structural proteins is the prerequisites for replication, and packaging of HCV, NS3 serine proteinase plays an important role in the life cycle of HCV and is an attractive target for antiviral therapy. We expressed only 181 amino acids in HCV NS3 N-terminus because previous experiments had corroborated it with good enzyme activity[17].

Baculovirus-insect cell expression system has two advantages over others: first, in most cases the recombinant protein in insect cells is processed, modified, and targeted to its appropriate cellular location, where it is functionally similar to its authentic counterparts. Second, high levels of heterogenous gene expression, up to 20 % of total cellular proteins, are often achieved compared with other eukaryotic expression systems[18-20]. Here we chose the Bac-to-Bac expression system which is based on site-specific transposition of an expression cassette into a baculovirus shuttle vecor (bacmid) propagated in *E.coli*[21,22]. Colonies containing the recombinant bacmid are white in a background of blue colonies that harbor the unaltered bacmid. Recombinant bacmid DNA can be rapidly isolated from small scale cultures and then is used to transfect insect cells, eliminating the need for multiple rounds of plaque purification.

In our experiment, the interested gene was efficiently expressed in insect cells through the recombinant virus BacNS3N containing HCV NS3 serine proteinase gene, and the identity of the protein was validated by use of immunoblot. But the recombinant protein predominantly lay in the insoluble part, and the solubility could not be improved even by adding 1 % NP-40 into the lysate. Overton *et al* illuminated that HCV NS3 serine proteinase expressed in insect cells was a membrane-associated protein through discontinuous sucrose density gradients and only by adding some detergents did part of the protein gain the enzyme activity[23]. Suzuki *et al* discovered that HCV serine proteinase from insect cells was soluble and active with 0.5 % NLS[24]. Therefore, the TNG buffer including NLS and glycerol was used to dissolve the pellet. The results showed that part of the recombinant protein became soluble and more proteins were soluble when enhancing the percentage of NLS and adding EDTA both. The recombinant protein fused with 6 His tag at its N- terminus could be purified through metal-chelating chromatography. Finally, 0.2 mg purified recombinant protein was obtained from 5×10^7 insect cells. An *in vitro* detection system with SDS-PAGE and staining was developed with the recombinant HCV NS5ab as a substrate. The system eliminates the need of expensive instrument and reagent, heavy work, as compared with other cleavage systems[25-27] and provides a simple and clear strategy for the screening of inhibitors against the HCV proteinase.

Abstract

Severe acute respiratory syndrome (SARS), also called infectious atypical pneumonia, is an emerging infectious disease caused by a novel variant of coronavirus (SARS-associated coronavirus, SARS-CoV). It is mainly characterized by pulmonary infection with a high infectivity and fatality. SARS is swept across almost all the continents of the globe, and has currently involved 33 countries and regions, including the mainland China, Hong Kong, Taiwan, North America and Europe. On June 30, 2003, an acumulative total reached 8450 cases with 810 deaths. SARS epidemic was very rampant in March, April and May 2003 in the mainland of China and Hong Kong. Chinese scientists and healthcare workers cooperated closely with other scientists from all over the world to fight the disease. On April 16, 2003, World Health Organization (WHO) formally declared that SARS-CoV was an etiological agent of SARS. Currently, there is no specific and effective therapy and prevention method for SARS. The main treatments include corticosteroid therapy, anti-viral agents, anti-infection, mechanical ventilation and isolation. This disease can be prevented and controlled, and it is also curable. Under the endeavor of the Chinese Government, medical staffs and other related professionals, SARS has been under control in China, and Chinese scientists have also made a great contribution to SARS research. Other studies in developing new detection assays and therapies, and discovering new drugs and vaccines are in progress. In this paper, we briefly review the current status of SARS in China.

INTRODUCTION

On November 16, 2002, the first case of SARS patient was found in Foshan city, Guangdong Province, China[1]. Severe acute respiratory syndrome (SARS) is different from ordinary pneumonias caused by bacteria, other viruses, chlamydia and mycoplasma. The disease starts with an abrupt onset of fever, progresses swiftly, and is subjected to acute respiratory failure. Furthermore, it results in multiple organ dysfunctions with a higher infectivity and fatality. The main clinical manifestations of the patient are high fever, non-productive cough, myalgia and dyspnea. The patient has no response to any antibacterial therapy. At the beginning, the experts in Guangdong Province believed that it might be caused by a novel virus infection, and designated it as "atypical pneumonia" based on its clinical manifestations. On April 8, 2003, the State Council of the People' s Republic of China classified this illness as a legal infectious disease, and named it as infectious atypical pneumonia according to its higher infectivity, quick transmission and high mortality. The same kind of patients was found in Hong Kong and Vietnam at the end of February[2,3]. Dr. Carlo Urbani, an Italian epidemiologist working at the Hanoi Office of the World Health Organization (WHO), first reported to WHO and named this disease as severe acute respiratory syndrome. Later, Dr. Urbani caught the disease himself and died on March 29, 2003. In memory of Dr. Urbani' s great contributions in fighting against this disease, WHO formally designated this disease with unknown causes as SARS on April 16, 2003[4]. Ksiazek and his colleagues proposed that their first isolate be named the Urbani strain of SARS-associated coronavirus (SARS-CoV)[4,5].

On March 12, 2003, WHO issued a global alert of SARS outbreak, and called upon 11 laboratories (including the Institute of Virology, Center of Disease Control and Prevention, China, and Guangdong Center of Disease Control and Prevention, China) in 9 countries to join a collaborative multi-center research project on SARS. Chinese medical and health care workers have been keeping abreast of the advances in SARS research, and have achieved a number of success while fighting against SARS. In this paper, we briefly reviewed the current status of SARS research in China.

EPIDEMIOLOGY

General situation

During the period from November 16, 2002 to April 16, 2003, 13 cities had reports of SARS cases in Guangdong Province, China. Among the 13 reported cases of SARS, 3 were cooks, 3 officers, 2 farmers, 2 retired persons, 2 workers, and 1 businessman. Their age ranged from 18 to 84 years, the majority (77 %) was between 30-50 years. No evidence of mutual transmission was found between the reported cases[6]. The first case of SARS in Guangzhou was found on January 2, 2003. The epidemic broke out and reached the peak early in February, and then the incidence started to decline. As to age distribution of the patients, most patients were between 20-50 years. The patients were present in all the 13 counties and cities, but concentrated in 7-city areas, accounting for 95 % of the total cases, in which 28.7 % of the patients were healthcare workers. Of the 36 deaths, their age ranged from 5 to 89 years, and half of them were older than 60 years. Some of the deaths (38.9 %) were complicated with underlying diseases, including hypertension, diabetes, heart disease, and pulmonary emphysema. There was also a clustering trend: more than 2 patients were found in 42 families, 277 cases of healthcare workers were from 28 hospitals and institutes[7]. The incidence in Beijing had a similar feature to Guangdong (Table 1)[8]. Till June 30, 2003, an acumulative total reached 8 450 cases with 810 deaths. In the mainland of China, there were 5 327 cases

Table 1 History of SARS contact and incubation period in 80 cases

	Male (*n*, %)	Female (*n*, %)	Age (year)	Contact history	Incubation period (d)
Total	28 (35 %)	52 (65 %)	31.6±10.1	72 / 80(90 %)	7.6±4.3
Healthcare worker	13 (24.5 %)	40 (7.5 %)	30.8±8.4	49 / 53(92.5 %)	7.8±4.5
Non-healthcare worker	15 (55.6%)	12(44.4%)	36.4±12.1	23 / 27(85.2 %)	7.7±3.1

of SARS in which 348 patients died, and 1 755 cases with 298 deaths and 681 cases with 84 deaths occurred in Hong Kong and Taiwan, respectively. The national case reports showed that SARS patients were distributed in almost all professions, and healthcare workers with the infection accounted for 20-30 % at the early stage of SARS epidemic. There was no difference between both sexes in the incidence. SARS patients were found in every age group, and predominant in 20-49 years group (about 80 % of cases). The mortality in senile patients was significantly higher than that in young patients[9,10].

A professor from Zhongshan University in Guangzhou suffering from SARS stayed at Jinghua Grand Hotel, and a 28-year-old resident in Hong Kong got infected there, leading to SARS outbreak in the Prince Wales Hospital. However, a study made by Medical College of Zhongshan University indicated that at least 3 sources contributed to the outbreak early in March, that is to say, the source of SARS outbreak in Hong Kong was more than one. The mainland of China reported for the first time that no new case was found on June 2, 2003. No confirmed, suspected cases and deaths occurred for the first time on June 19, 2003 in China. Xiaotangshan Hospital, a speciality SARS hospital in Beijing, was then closed, demonstrating that a decisive victory has been won in fighting against SARS in China.

Infectious source

Currently, the known patient with SARS is the only infectious source. In the primary stage, symptoms are more obvious and it has high infectivity, while in the recovery stage, its infectivity is lost. Not all the cases have the same infectivity. Highly contagious cases are those who deliver a large amount of viruses for a long time, especially with severe cough, or those who undergo an endotracheal intubation with a splashing of droplets. Few cases with very strong infectiousness are called "super-spreader", who usually are the first cases or the first cluster of SARS patients during the outbreak. Usually, the early cases of SARS have a high infectivity and a strong pathogenicity, which would decrease later with progression of the epidemic. It is still unclear that why some individuals exposed to the patient did not contract SARS. Does occult infection of SARS exist? If yes, what role it plays in transmission and what is its epidemiologic significance? All these need to be further studied.

The initial results of epidemiologic surveys showed that the first reported cases or the first cluster of SARS were cook and market purchasers in some cities of Guangdong Province. A certain number of the sporadic cases did not have a contact history of SARS patients, from which we could deduce that there might be some other route of transmission and animal-mediated route of transmission may play a role in pathogenesis. Sources of infection may include some species of animals and the detail is unclear.

From May 23, 2003, scientists in Hong Kong and Shenzhen have collaborated in search for the origins of SARS. On the basis of population epidemic investigations, researchers have been on the track of animals infected with SARS viruses and have targeted at the wild mammal animals in their study. They have confirmed the kinship relations between these animals and human SARS viruses based on an evolutionary analysis of the SARS virus genes of different genera. It seems that they have observed the origin of the human SARS viruses based on these findings. By nearly a month of painstaking efforts, researchers have isolated 3 SARS specimens from 6 Paguma larvata. The fully genetic sequencing of one specimen showed that the SARS viruses in Paguma larvata bore 99 % homology with the SARS viruses in the human body. A further genetic analysis confirmed that SARS viruses in animals were the precursors of the SARS viruses in humans. The testing and analysis of the SARS antibody were performed in 10 people who were engaged in wild animal businesses, among them, 5 people had a positive response, indicating that the SARS viruses in wild animals may infect those who have close contacts with them. These findings have provided important evidences for further investigation of the origins of SARS viruses in humans, and their associated chains, and will lay a foundation for the future development of SARS vaccines and treatment serum. Currently, there is no strong evidence that demonstrates SARS is transmitted through animals or insects.

Route of transmission

Airborne droplets from the patient are the main route of transmission. It is not clear whether there are other transmission routes, personal touch by hands, playthings contaminated by the secretions from the patient' s respiratory tract. Close contact refers to the direct touch of the patient' s secretions and body fluid during treatment and nursing of the patients. The transmission scope is closely correlated with the environment of the ward, course of treatment, patient' s condition, time of exposure and personal protection of healthcare workers and visitors. Improper protection increases the risk of infection. Rubbing nose and eyes with the contaminated hands may also be a route of the transmission. Sexual transmission of SARS has not been confirmed, but close contact during sexual intercourse may increase the chance to get infected.

Lin *et al*[11] from the Institute of Preventive Medicine, University of Taiwan, also believed that only when respiratory symptoms appeared did the patient have infectivity. As for the route of transmission they have made the following two conclusions. The first is that the special shell antigen of SARS-CoV might come from chromosome 6q in human tissues (MCH/HLA). Once the virus enters human body, the invader is wrapped by the special tissue antigens in some individual hosts, so that the virus loses its capacity to infect other persons. Clinically, this strong tissue antigen might relate to severe leukopenia or lymphopenia in SARS patients. Once the disease progresses to respiratory distress, the lungs would try to dissolve the mucus produced by acute inflammation, by activating the body defense system to secrete proteolytic enzymes for the mucus dissolution. Meanwhile, the enzymes would also dissolve the tissue antigens of the shell, and make the virus resume its infectivity to other individuals. This clear-cut route of transmission is characterized by SARS-CoV. It has been proposed that SARS be liable to transmit among the family members because of the same type of HLA. The second is that different strains of bacteria in the sewage are able to produce proteolytic enzymes and dissolve the shell protein of SARS-CoV, and promote its infectivity to others. This mechanism might explain why SARS outbreak occurred in Amoy Garden, as well as in sporadic individuals who had been

to the epidemic regions, without direct contact with the patients. This virus can enter the human body via any part of mucosa, including respiratory tract, oral cavity, and genital tract. Owing to the higher concentration of proteolytic enzymes in the lung, SARS patients have a strong infectivity even at the early stage of the disease. Although the above hypotheses could explain some phenomena in SARS epidemiology, they need to be further confirmed.

Susceptible population

The ordinary population is very susceptible to SARS, the healthcare workers who have close contacts to the patients during the treatment and nursing, are the high-risk group. Anyone who has a history of close contact to the patients is a high-risk individual, and may exist the occult infection. In view of professions, healthcare workers are the most easily infected persons. Compared with other infectious diseases, the rate of SARS infection was very high in medical professionals, accounting for 20-30 % in some areas. It might be due to the insufficient protective measures in the early epidemic stage of SARS. But in Beijing, the rate of infection was relatively low in healthcare workers both at hospitals and at CDC. It is suggested that personal protection plays an important role in prevention of SARS among the healthcare workers. In order to protect the doctors and nurses, the Chinese Government has taken almost all the necessary preventive measures to strengthen sterilization and ventilation in the wards and to forestall medical staffs to be overworked. This is why the incidence of SARS has been kept at a lower level in the healthcare workers.

Distribution characteristics in epidemic areas

There are four kinds of SARS epidemic situation in China: (1) Epidemic area of SARS (in Zhujiang Delta of Guangdong Province, China, there was no direct relationship among the primary cases in different cities). (2) Imported SARS cases, which caused local spreading (as in Shanxi Province and Beijing, etc.). (3) Imported SARS cases, which did not cause local spreading (as in Hunan Province and Sichuan Province, etc.), and (4) no SARS cases reported.

Epidemiological statistical analysis and prediction

How will the SARS epidemic situation develop? How to control SARS effectively? Are there any scientific ways to predict the SARS epidemic situation? According to the current actual SARS epidemic situation in the world, the Center of Geosystem Science and the Key Laboratory of Geodynamics of the Chinese Academy of Sciences have studied the relationship between SARS epidemic situation and its development based on their accumulated experience for years, established the systemic dynamics model of SARS contagion, and calculated the relationship between the control of SARS epidemic situation and its development in detail. The results were identical with the current actual SARS situation in the world, and the model could predict the SARS epidemic situation. The successful establishment of this model is important to evaluate and predict SARS epidemic situations. The task group of "SARS Epidemic Trend and Control System" in Xi' an Jiaotong University made use of computers to make computing simulation with the data and theories by using the statistical methods and parameters confirmed in the epidemic transmission, and then composed the software by modifications and got the predicting cuve to meet the actual demand. They finally put forward the epidemic patterns and trend of SARS. The predicted number of increasing cases of SARS was basically identical with that publicized by the Ministry of Public Health every day.

According to the data of the diagnosed, suspected and dead cases of SARS in the world, the task group of mathematical epidemiology in the University of Science and Technology of China has established the epidemic spatial statistical model of SARS, and predicted on June 10, 2003, that the number of SARS inpatients in Beijing would be decreased below 60[12].

There are so many problems which need to be further studied. For example, our understanding of the source of SARS infection remains on the conditions of SARS patients, and little is known about its effect on sub-clinical SARS patients and animals, as well as the blood transmission and fecal-mouth transmission ,except for the short distance transmission of droplets from respiratory tract and transmission by close contacts. The reason why the incidence rate is high in young people and low in children and elderly people is not clear. What are the influence factors of the superior infectors?

ETIOLOGY

At the beginning of the study conducted by the Chinese scientists, chlamydia-like and coronavirus-like granules were found by electron microscopy in the dead bodies of SARS patients in Guangdong Province, China. Though chlamydia was thought to be the possible pathogen of SARS, it could not be confirmed in foreign laboratories due to the limited specimens for assay. Furthermore, there was not much possibility that chlamydia was the pathogen of SARS according to the clinical manifestations and therapeutic efficacy of SARS patients. Thus it might be due to the secondary infection. After the outbreak of SARS in Hong Kong, researchers isolated the avian influenza virus from a symptomatic child in Hong Kong, which was soon excluded to be the pathogen of SARS. Not long after, paramyxovirus was found in many SARS patients, but not in all the SARS patients in the further studies. However, all these findings could not be further confirmed.

The Pei Weishi Research Group of Hong Kong incubated the blood and tissue samples from SARS patients in cell lines which are not usually used to culture and isolate viruses. The genes of infected tissues were randomly screened in order to find the DNA fragments which could provide useful clues. On March 17, 2003, the cultured tissues isolated from two SARS patients could kill the cell line which is usually used to culture hepatitis A virus. In order to find the relationship between it and SARS, we observed the different reactions occurred when serum in the early and recovery stages was used to culture the tissues. Antibody reaction occurred in the former, while it did not occur in the latter. It was obvious that there was something in the culture, which was related to SARS. Nicols is the first who has found and isolated coronavirus in the tissue samples by electron microscopy. In the following days, three foreign laboratories including that in Hong Kong have confirmed almost at the same time that the pathogen of SARS is a novel kind of coronavirus.

On March 23, 2003, the Institute of Microbiology and Epidemiology, Academy of Military Medical Sciences of China, successfully isolated coronavirus from the pulmonary tissues of SARS patients and established its animal model. Based on the model, the pathogen was isolated by cell culture of samples from pulmonary tissues of the dead bodies and nasopharyngeal swabs. Coronavirus granules were found by electron microscopy in the pathological cells and their culture supernatant. The results of SARS patient serum detected by immunofluorescence staining showed that the isolated virus was closely related to SARS virus, which could induce infection of SARS in mice. The coronavirus-like granules were also found in the pulmonary tissues of mice. The cDNA fragments were amplified with RT-PCR, respectively from the pulmonary tissues of SARS dead bodies, the infected mice, and the infected

cell culture isolations. The whole genome of coronavirus was sequenced at 11pm, on April 15,2003. The sequence had 60 % homogeneity with the known coronavirus, and was about 30 000 bp long, which was identical with the results reported in Canada and USA, suggesting that it is a novel kind of coronavirus closely related with the epidemic of SARS, and may be the major pathogen of SARS.

Hong Kong University has found that some gene fragments have different sequences by comparing "6 SARS samples" from different regions (2 from Hong Kong, 2 from Guangzhou, China, 1 from Canada and 1 from USA), indicating that the "6 viruses" are different members of one family. However, it is not quite sure which one is their "mother". The inclination of the researchers is that one of the two samples from Hong Kong was similar with the two samples from Canada and USA respectively, the other one from Hong Kong was similar with the two from Guangdong, China. Further study is needed to clarify whether the members of such a family exist or they are deprived of a variety of SARS viruses.

Shanghai Institute of Life Science, Chinese Academy of Sciences, has successfully cloned the 6 main protein genes of S, M, N, E, RNA polymerase and proteinase (3CL), and found the expression samples of proteins E, N, and 3CL in the experiment of expression, isolation and purification of the important protein genes. The expression samples passed the drug virtual screening. This achievement is of great importance in the study of biological functions of SARS virus and in seeking after the vaccines and drugs against SARS virus.

The survival time of SARS virus in different conditions varies greatly. It can survive for a long time in 3 human discharges (sputum, feces, and urine) and in blood at 24 ℃, for 5 days in sputum and feces, for 10 days in urine, and for 15 days in blood, respectively. In the indoor condition, it can survive for 3 days on the surface of filter paper, cotton, wood block, soil, metal, plastic, glass, etc. SARS virus is sensitive to temperature. Its survival rate decreases with increasing temperature. It can survive for 4 days in the culture condition without serum at 37 ℃, and can be inactivated at 56 ℃ for 90 minutes, at 75 ℃ for 30 minutes, respectively.

PATHOLOGY

Macroscopically, the pulmonary tissue is swollen and extensively consolidated. The surface blood vessels are dilated and hyperemic, dot or sheet necrosis and hemorrhagic infarct can be found. Thrombi are formed in the pulmonary artery, and wine liquid flows out from the cut section.

Light microscopy

Chronic inflammatory cell infiltration can be found in trachea and bronchioles, and some necrosis tissues and a few inflammatory cells in the duct and some shed mucous epithelia. The pathology in the lung shows severe acute interstitial exudation, pulmonary interstitial and alveolar septum capillaries are severely dilated and congested, and there is a medium amount of lymphocytes, macrophages and polymorphonuclear white cells infiltrated. Some red blood cells are exudated into the alveolar septum and cavity. Pale and red fluids are exudated in most alveolar cavities, and hyaline membrane is formed in about 20-30 % alveolar cavities, but no inflammatory cells infiltrate into alveolar cavities, and focal compensatory emphysema can be seen. Diffuse alveolar epithelial cell injuries are manifested as pyknosis of chromatin to mass in alveolar epithelial cells which are distributed along the karyotheca, apoptosis of alveolar epithelial cells, vacuolar changes of nuclei in some alveolar epithelial cells. The necrosis in pulmonary tissue is not obvious and the phenomenon of lymphocytes attacking alveolar epithelial cells is not found. Regional proliferation is very active in the H type alveolar epithelial cells. Under light microscopy, some virus inclusion bodies-like structures can be observed in alveolar intraepithelial cells. The surface of pleura is smooth, subpleura stroma is edematous and loose, capillaries are dilated and congested with lymphocytes infiltrated.

Many superficial and deep lymph nodes show extensive or large regional hemorrhage and necrosis which are significant in the subcapsular region. Cell proliferation is obvious around the necrosis tissues and the phenomenon of red blood cells phagocytosed by macrophages . Hemosiderin is deposited in the cytoplasm. The lymphocyte infiltration is decreased , the lymphoid follicle structure can hardly be seen. The vascular and splenic sinusoids are greatly dilated and congested, the white pulp is decreased . Extensive and fused hemorrhage and necrosis as well as cell reactive hyperplasia are easily found.

Vacuolation can be found in a few cardiac myocytes, there are interstitial infiltration of a few lymphocytes and mild vascular dilation. The structure of hepatic lobule remains integrated. Mildly mixed hepatocellular fatty degeneration and mildly hydropic degeneration can be seen in the lobules, focal hemorrhagic inflammation and apoptotic body can be occasionally found. Liver sinusoid is dilated and congested, mild reactive hyperplasia occurs in Kupffer cells, and infiltration of lymphocytes is observed. Bilateral adrenal gland also shows focal hemorrhagic inflammation and lymphocyte infiltration which are obvious in the medulla. The structure of glomerulus is almost normal, the capillaries are dilated and congested, but no hyaline thrombus and fibrinoid necrosis can be found. Renal tubular epithelial cells are swollen, with few protein casts and tubular necrosis, there are focal hemorrhage and interstitial lymphocyte infiltration[8]. The structure of the walls of stomach and intestinal tract remains its integrity with a few lymphocytes infiltrated in the lamina propria mucosae and submucosa. Vasodilatation and congestion can also be seen. The intestinal tract shows segmental hemorrhage, and the rest changes are the same as in the stomach.

Transmission electron microscopy

The structure of pulmonary tissue remains very well, intracellular mitochondria and endoplasmic reticulum in alveolar epithelial cells and some endothelial cells of capillaries are swollen, the matrix is very loose, degranules can be found in some rough endoplasmic reticula. Chromatin in the nucleus is changed into mass shape and is not well distributed and is accumulated under the nuclear membrane. Type I alveolar epithelial cells show proliferation which is characterized by increased number, abundant chromatin, intracytoplasmic lamellar bodies, widened interspace of capillaries in the alveolar septum and increased pinocytosis vesicles in the endothelial cells. It is observed that there are many virus-like particles in most of the type II alveolar epithelial cells, bronchioles epithelial cells and intracytoplasma of some endothelial cells of capillaries in the alveolar septum which has an envelope with halation or in the shape of garland and is about 100-150 μm in size with low density in the centre, and these kinds of virus-like particles can also be seen in the dilated endoplasmic reticulum. In addition, chlamydia-like inclusion bodies at different stages which have reticular bodies, midbodies and elementary bodies can be seen in very few alveolar epithelial cells and endothelial cells. In the edema fluid of alveolar cavity, virus-like particles can be found. Proliferation of macrophages in which virus-like particles can also be found is mainly seen in the alveolar septum and alveolar cavity[19].

Many virus-like particles can be found in a few cardiac myocytes which are the same as in the lung tissues. Mild swelling of mitochondrion and endoplasmic reticulum is found in the hepatocytes, and lipid droplet with moderate electron

density is also found, and chlamydia-like inclusion bodies at different stages are seen in the cytoplasm. Some renal tubular epithelial cells show swelling and no villi, virus-like and chlamydia-like particles are also found in them. The injured immune organs mainly include the spleen, lymph nodes and bone marrow. Deposited plasma protein can be seen in the central arteries of splenic corpuscle, massive necrosis can be found in the white medulla and marginal sinus lymph tissues. Some remaining lymphocytes are at the apoptotic state. Blood vessels in the lymph nodes are severely dilated and congested, and lymphoid nodules are atrophied and disappeared, a lot of monocytes are found in the lymphatic sinus, the lymph tissue shows focal necrosis and lymphocytes show apoptosis. Hematopoietic area of myeloid tissue is decreased, granulocyte and macrophage systems are relatively inhibited, polychromatophil erythroblasts show little focal proliferation[20,21].

Tissues around the venules and the vascular walls of lung, heart, liver, kidneys, adrenal gland and striated muscles show swelling, and there are monocytes, lymphocytes, plasmocytes and neutrophilic granulocytes infiltrated.

After the nude mouse is inoculated with SARS virus, and onset of SARS occurs. The main lesions are found in the lung and liver, the alveolar cavity is microscopically very narrow even atelectatic, the alveolar septum is widened, bronchioles epithelial cells are shed. Swollen hepatocytes show hydropic degeneration and vacuolation and some hepatocyes show pyknosis and necrosis. And other anomalies include myocardial hyperemia and increased multinuclear giant cells in the spleen.

In the culture medium of Vero E6 cells infected with SARS virus, virus particles can be found under electron microscope with negative staining which is in the shape of ball with coronally arrayed processes, the end of the process is also a round shape and there is a wide interspace between processes. The diameter of the virus is about 80-120 μm. The viruses detected from the culture medium of cells infected with viruses from Beijing and Guangdong are similar.

PATHOGENESIS

The mechanism of the injury caused by SARS virus is unknown. It is suspected that there are auto-antibodies developed after the infection of SARS virus which induces the autoimmunity reaction, and the current studies cannot explain it.

The reasons why T cells of SARS patients are quickly declined in a short time after the onset of SARS are probable as following: (1) SARS virus directly attacks T cells and causes them splitting and to be destructed quickly which results in the sharp decrease of the count of T cells. (2) After the infection of SARS, SARS virus has no effect on the immune system and results in the abnormal distribution and leads to the decrease of T cells in the peripheral blood. (3) SARS virus, or its productions or its components act as a super-antigen and polyclonally activate T cells and lead the activated T cells to death and decrease of T cells in the peripheral blood.

CLINICAL MANIFESTATIONS

The analysis of the blood samples of SARS patients has shown that the latent period of SARS is at least 4 days and the longest is 17 days. This is related to the load of virus and individuality. The one who has been infected but without symptoms has no infectivity, no such cases have been reported so far.

After the patient is infected with SARS, he will have a high fever and dry cough without the symptoms of influenza such as nasal mucus, pharyngalgia, spitting white or yellow sputum. But sometimes there is some blood in the sputum, and the patient will feel short of breath, and even develop ARDS. Generally, the count of white blood cells will increase when a patient has a fever, but it is normal or below it when the SARS patient has a fever. The most prominent phenomenon is that the X-ray characteristics are not disassociated with its clinical situations. The patient with common pneumonia usually has very severe clinical manifestations and then the changes in the X-ray films can be found. But the X-ray films of SARS patients have very significant changes when the patient of SARS is not very severe, which show floccule shadows and have the trend of quick development[29-31].

The symptoms of SARS include high fever (more than 38 ℃), dry cough, shortness of breath, headache, anorexia, malaise, skin eruption and diarrhea without the common symptoms of influenza such as nasal mucus, pharyngalgia, spitting white or yellow sputum. But sometimes there is some blood in the sputum and the patient will feel short of breath, and even develop ARDS. About 7 % patients of SARS need artificial breathing. The clinical manifestations in different areas in China are shown in Table 2.

The manifestations of chest radiograph of SARS include patchy consolidation or reticular consolidation. Some patients' conditions develop very fast, large patchy consolidation is shown in the chest film and multiple lobes or bilateral lung are involved. The absorbance of the patchy consolidation is very slow. The sites and scope of pulmonary lesions in SARS patients are shown in Table 3.

Table 2 Clinical manifestations in different areas of China

	Fever (%)	Dry cough (%)	Shortness of breath (%)	Chest pain (%)	Bloody sputum (%)	Diarrhea (%)	Headache (%)	Muscle pain (%)	Inertia (%)
Guangzhou[22]	100	72.2	31.2	1.9	11.5	24.2	25.8		24.6
Guangzhou[23]	97.7	81.2	20	22.3		22.3	63.5	41.2	74.1
Guangzhou[24]	100	92		22	13	24	61	60	92
Beijing[25]	97.8	68.9	53.3		9.8	26.7		26.7	60
Beijing[26]	100	87.8	12.2						
Henan[27]	100	67	29	17		17		50	83
Hongkong[28]	100	62	20			10	20	54	

Table 3 Sites and scope of pulmonary lesions in SARS patients

	Superior lung field	Medial lung field	Inferior lung field	Hilum of lung	Multiple lobes	Total
Pachy-lung markings, small shadow	3(2.5)	5(4.2)	10(8.5)	2(1.7)	0(0)	20(16.9)
Unilateral inflammation	8(6.8)	11(9.3)	16(13.6)	0(0)	0(0)	35(29.7)
Bilateral inflammation	3(2.5)	7(5.9)	15(12.7)	0(0)	37(31.4)	62(52.5)
Total	14(11.9)	23(19.5)	41(34.7)	2(1.7)	37(31.4)	117(99.2)

The count of white blood cells of SARS patients is normal or below it, and CD4+ and CD8+ T lymphocytes are also decreased, but all these will be in the normal range after patients are fully recovered.

LABORATORY EXAMINATION

Theoretically, there are three ways to diagnose SARS: cell culture, RT-PCR and detection of antibody. All these ways are mature, so progress in the detecting techniques can be achieved in the work of prevention and cure of SARS easier than that in the study of vaccines and drugs. But cell culture and detection of antibody have no effect at the early stage of clinical diagnosis. Cell culture needs very high requirements of laboratory conditions and experienced operators, it takes a long time to isolate viruses or bacteria, and its positive rate is low. The time of the generation of antibody against SARS virus in the body is at least 10 days, and the time of the generation of IgG is at least 15-20 days. The antibody has interactions with the *in vivo* immune system, the mechanism of the generation of antibody is not clear. Whether all SARS patients have antibody after 3 weeks of infection needs to be further studied. RT-PCR is the simple and easy diagnostic method of SARS at the early stage[33-35]. Although there are many kinds of RT-PCR kits in China, it needs further improvement for its clinical use. It is needed to explore how to get the best virus nucleic acid and the best sampling time. Till today, the diagnosis still depends on the epidemiology and clinical symptoms, no methods have been found to be effective in the prevention and cure of SARS. The natural immunity adhesive function of red blood cells in two SARS cases in China was detected, and it was found that its adhesive function was lowered with aggravation of SARS. It is thought that it may be a good index indicating the degrees of the conditions of SARS patients.

Laboratory examinations, points for attention and evaluation of data

The Ministry of Public Health of PRC proposed the precautions on June 7, 2003 for guidance in practice and applications of tests supposed to be of diagnostic value for SARS.

Virus isolation by cell culture The method is used to isolate SARS virus from human respiratory secretion, blood, urine, stool and autopsy tissue samples. The positive result is considered as a reliable evidence for the presence of replicating SARS virus, and for the diagnosis of the disease or a virus-carrier status in combination with the clinical symptoms. The test must be performed by specialists in a BSL-3 laboratory. Thus, it is difficult at present to be widely used. Another weak point is that this assay is laborious and time-consuming, thereby not suitable for the quick diagnosis. Usually, the positive rate of this assay is not high, and the negative result cannot be regarded as a reliable evidence to exclude SARS. For these reasons, it is not a routine examination in clinical laboratories of most medical centers.

Detection of viral nucleic acid by polymerase-chain reaction following reverse transcription (RT-PCR) The procedure can be used for detection of SARS virus from human respiratory secretion, blood, serum, urine, stool and autopsy tissue samples. It is a quick and convenient method.

Up to date, it is not clear what time is best for sampling and what samples are optimal for the assay. Its sensitivity remains to be improved. The possibility of false negativity is considerably high. In addition, inappropriately handling of the samples often leads to laboratory pollution by the viral nucleic acids and false negative results. When the virus is detected in different samples from the same individual, or the amplification product is demonstrated repeatedly in the same sample, the positivity is established, meaning that the sample contains nucleic acids of SARS virus. For the clinically suspected patients, the positive reaction is a diagnostic parameter for SARS. For apparently healthy individuals, the positive result is a reliable evidence for the establishment of their virus-carrier status. Apparently, a negative reaction cannot be regarded as an evidence to exclude SARS or the suspected either.

Immunofluorescence test and enzyme-linked immunosorbent assay (ELISA) for antibodies to SARS virus The procedures are used to demonstrate specific SARS virus antibody from the serum. The antibody is detectable in a majority of samples from asymptomatically infected individuals and SARS patients for about 10 days, or even later for some cases, after being infected or onset of the disease.

The assays are used mainly for verification of the clinical diagnosis and for epidemiological surveys. A positive reaction obtained using sera from the convalescent suspected patients, or a four-time increase in its titer during recovery compared to that in the acute stage can be regarded as a diagnostic parameter for SARS. Occurrence of the antibody is also found in healthy individuals, reflecting the past infection of SARS virus. As for the replicating virus and its nucleic acids as described above, the antibody is not always detectable in SARS patients. A negative result, therefore, cannot be regarded as a reliable evidence to exclude the possibility of SARS.

Laboratory approaches for assays of SARS in China

A chip covering genomic sequences of all the reported coronaviruses, including SARS virus, was prepared and the detection has been established based on the microarray, as declared by Benyuan-Zhengyang Gene Technology Company Limited, China and its partner organizations in May 2003. The genotyping, conducted based on this system and similar assays, may be useful for determination of pathogenic factors and monitoring of mutations in the genomes of these viruses from different geographic areas, possibly providing some clues to the origin of SARS virus. Moreover, this system and database were designed to be an open platform, allowing the online processing and analysis of data by customers through Internet. In addition, the online exchange and management of detection data from all registered customers can provide an opportunity for the related administrations to obtain statistic information about the disease epidemics on time[37].

The virus-collecting facility, prepared by a group in Wu Jianxiong Laboratory, Dongnan University allows collection and concentration of viral particles from air, claiming to be able to process 30 liters of air per minute. According to the manufacturer, its collection efficiency can be as high as 90 %, as tested using protein particles and the inactivated viral particles. It can be used for sampling from air and viral particle concentration. In combination with PCR, the device may be applied for the detection of SARS virus contamination of the air, providing timely and dynamic data of the viral load.

A preliminary observation was made on dynamic changes of circulating T cells and serum immunoglobulin contents in 124 SARS patients by the Beijing Group of the National Emergent and Technological Action on SARS Prevention and Treatment. A marked decrease was found for all subsets of T lymphocytes examined, including those expressing CD3, CD4 and CD8, with their cell counts reduced to about one third of those of healthy individuals. This shows that the immune functions of SARS patients are severely impaired. The counts of CD4- and CD8-positive T cells were found to decrease quickly at the same time, the change was more pronounced during the period between the 10^{th} day and the 14^{th} day. This is in accordance with the disease course for most cases, its levels going up gradually two weeks after the onset with the recovery

of the patients. It appears reasonable to consider T cells to be involved in the pathogenesis of SARS.

Another apparatus, invented by Gene Company Limited and the Molecular Medical Diagnosis Center in Hong Kong based on the fast DNA hybridization, was claimed to allow the detection of SARS-associated coronavirus in patients' samples and identification of the mutated viruses within 15 minutes. Rong-An Tan, the technical spokesman of the diagnosis center, declared that the system could be used to detect SARS-associated virus from blood, saliva and secretion samples. According to him, the times requested for the detection range from 1 to 15 minutes, with 5 or 6 mutated viruses demonstrated as conducted in Guangzhou, Taiwan and Hong Kong for separate cases.

A seroassay for circulating antibody to SARS virus, namely immuno-chromatography test (ICT), is now being established in Taiwan University Hospital. As claimed by the laboratory, it is possible to determine the diagnosis of SARS at the 7th or 8th day by this assay, much earlier than RT-PCR that cannot show the positive result till the 21st day after the disease onset. The project, currently, is reported to arrive at the ultimate stage of sensitivity assessment. ICT is hoped to be an assay faster than RT-PCR by 13 days[27].

Dalian Institute of Chemistry and Physics, the Chinese Academy of Sciences, recently claimed to have established an early detection system for the virus-induced respiratory diseases with fever based on a controlled micro-current chip. They have finished the preparation of the chip and established the system. Currently, the system is under the evaluation using 9 primer pairs for the amplification following RT, with the SARS virus and parainfluenza virus RNA samples as the templates and a negative control, respectively. The system is characterized by its early detection of viral RNA even if the target sequence contained in samples is minimal in quantity. The controlled micro-current chip is also known as a chip laboratory, which is greatly different from the ordinary gene chips regarding their principles, preparation and applications. It is characterized by high-throughout and large-scale integration. Several fundamental units, involving sample preparation, biological and chemical reactions, isolation and detection, are integrated onto a single chip as small as several cm, being able to finish different reactions and to characterize their minimal-amount products[39].

Recently, artificial virus-like particles were prepared, with the SARS coronavirus nucleic acid enveloped within liposome, by a group in the Laboratory of Clinical Chemistry, Beijing Hospital under the Ministry of Public Health. The reagent may prompt technical improvement, standardization and quality control of the RT-PCR for SARS, as the kits currently available are not stable enough and require further clinical verification. The virus-like particles have been characterized by two properties: safety (non-infectious) and stability. This is of application value for the quality control of RT-PCR for SARS virus in clinical laboratories of medical centers, as well as for evaluation of new diagnostic reagents for the disease[40].

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Criteria for clinical diagnosis of SARS proposed by Ministry of Public Health of PRC

Epidemiological history The history evidences indicative for SARS include close contact with the patient, individuals from an infected group, having infectivity to others, and a tourist back, or a resident moving away from the epidemic regions two weeks before onset of the disease where there are SARS patients reported and the secondary infection has taken place.

Symptoms and signs The onset of the disease is acute. Fever is the first symptom, with the body temperature above 38 ℃ for most cases and chilling as one of the complaints occasionally. Headache, joint pain, fatigue and diarrhea may also be the complaints. Usually respiratory catarrh symptom is not evident. Coughing may be the manifestation, mostly a dry cough with very little sputum. Occasionally, little blood is present in the sputum. Chest distress is common, with the quick respiration, short ness of breath and even breathing difficulty in unfavorable cases. Signs of the lung disorder are usually not obvious, with some moist rales heard or pulmonary consolidation found in some cases. In a small number of the patients, fever is not the first symptom. This is particularly true for those cases operated recently or having some accompanying diseases.

Laboratory tests Usually, the count of peripheral blood leukocytes is not increased, or even decreased. The count of lymphocytes decreases in most cases examined.

Chest roentgenological examination There are various degrees of pulmonary infiltration, with many small pieces of lungs involved or in a meshwork pattern. In the fast progressing cases, massive shadows are present frequently, with multiple or bilateral lobes involved. Their resolution is usually slow. Occurrence and resolution of the roentgenological changes are not necessarily in accordance with the related symptoms and signs. For the cases not showing the changes, reexamination should be performed one or two days later.

Response to antibiotics Treatment with various antibiotics is not effective.

Diagnotic criteria For suspected cases: With positive findings in the epidemiological history + symptoms and signs + laboratory tests, or the epidemiological history + symptoms and signs + laboratory tests, or the symptoms and signs + laboratory tests + X-ray examination.

For cases with a clinical diagnosis of SARS: With positive findings in the epidemiological history + symptoms and signs + X-ray examination , or more, or the symptoms and signs + X-ray examination + no response to antibiotics , or the history + symptoms and signs + laboratory tests + X-ray examination.

For cases under medical observation: With findings in the symptoms and signs + laboratory tests.

For severe cases of SARS: SARS cases with one of the following findings: (1) a breathing difficulty, with respiratory rate exceeding 30 times per minute; (2) hypoxemia even during O_2 inhalation at 3-5 L/min, with PaO_2 below 70 mmHg and SpO_2 below 93 %, or having acute lung injury (ALI) or acute respiratory distress syndrome (ARDS); (3) multiple-lobe lesions involving more than one third of the lungs in area, or enlargement of the pulmonary lesion by more than 50 % within 48 hours as shown by chest roentgenograms; (4) shock or multiple organ dysfunction syndrome (MODS); (5) with a severe accompanying disease or a complicating infection, or with the age exceeding 50 years.

Differential diagnosis

Attention should be paid to the exclusion of other diseases or clinical syndromes such as infection of the upper respiratory tract, influenza, bacterial or fungous pneumonia, pulmonary infection complicating AIDS, legionnaires disease, pulmonary tuberculosis, epidemic hemorrhagic fever, pulmonary neoplasms, non-infectious interstitial pulmonary diseases, pulmonary edema, atelectasis, pulmonary embolism, pulmonary eosinophilic pneumonia and pulmonary vasculitis.

TREATMENT

Patients under the medical observation should receive treatment and observation in the appointed isolation ward or hospital, or under isolation observation in their homes. For the later case, the patients should live in a well-ventilated room and avoid

any close contact with other family members. They should be still under the observation of the disease-control department with their body temperature measured every day during the period. The patients, whose conditions are found to progress and to meet the criteria for SARS or the suspected during the observation, should be sent immediately to the appointed hospital by the special vehicles for isolation and treatment.

The key procedures of prevention and treatment of SARS are early detection, report, isolation and early treatment.

Treatment protocol for SARS and its suspected cases recommended by Chinese Center for Disease Control and Prevention (China CDC)

General therapy The general treatment includes adequate rest and supplement of nutrients such as fluid and vitamins, avoidance of intense and vigorous coughing. The patient' s condition should be observed intensively, since the onset of SARS within 14 days probably belongs to the progressive period in the majority of patients. Regular reexamination of chest x-rays and the functions of heart, liver and kidney are also necessary. The interval for the reinspection of chest x-rays in early phase of SARS should not be more than 3 days. SpO_2 should be checked daily.

Expectant treatment (1) Antipyretic analgesics should be used for patients with fever more than 38.5 ℃ and systemic prominent soreness. For the patients with hyperpyrexia, cooling measures should be applied such as ice compress and sponge bath with alcohol. (2) Antibechic and expectorant should be given when the patients suffer from cough and expectoration. (3) Corresponding measures should be taken when dysfunctions of multiple organs such as heart, liver and kidney take place. (4) Persistent oxygen inhalation by nasal tube should be applied early to the patients with obvious tachypnea and mild hypoxemia. (5) Aspirin medication should be avoided in children for fear of resulting in Reye syndrome.

Antibacterial treatment It is recommended to use antibiotics such as macrolides, fluoroquinolones, β-lactams and tetracyclines early in the course of SARS. Vancomycin or norvancomycin should be chosen as the preferable therapy when the infection caused by antimicrobial-resistant cocci is evidenced either clinically or experimentally.

Glucocorticoid therapy The following indications for the use of corticosteroids are proposed: Patients with severe toxic reaction and persistent high fever, and those with rapid deterioration of the chest film by increased infiltration progressing to a critical condition. The drug should be given regularly with the doses matching the actual condition of the disease and should be used with caution in children.

Selective therapy Selective therapy includes the use of antiviral agents, immunopotentiators and Chinese herbs.

Treatment of critical cases (1) Intensive care and monitoring should be applied to the patients with severe dyspnea or those who meet the criteria of a critical case. (2) Noninvasive and positive pressure ventilation is recommended for those with SaO_2 less than 93% while the oxygen inspiration is at 3-5 L/min and breath rate $\geqslant$ 30/min, in which CPAP with nasal mask is preferable. Routine level of inspiratory positive airway pressure should be set at 4-10 cmH_2O. Selection of adequate breathing masks, and persistent use of noninvasive ventilation that is interrupted no more than 30 min including hora decubitus till the disease remission are required. (3) For patients with severe dyspnea and hypoxemia, SaO_2 < 90 % or oxygenation index < 200 mmHg at 5 $L \cdot min^{-1}$ of oxygen inhalation, failure to tolerate or respond to noninvasive ventilation should be promptly followed by invasive ventilation after intubation. (4) Timely therapeutic measures should be taken once shock or MODS takes place in SARS patients and consultations of relevant experts are indicated when the treatment is limited by professional skill or poor medical equipments.

Standard treatment protocol for SARS (suspected and probable) in adult patients in Hong Kong[41]

Antibacterial treatment Levofloxacin 500 mg is given once daily intravenously or orally, or clarithromycin 500 mg is given twice daily orally plus co-amoxiclav (amoxicillin and clavulanic acid) 375 mg three times daily orally if patient is younger than 18 years, or pregnant, or suspected to have tuberculosis.

Ribavirin and methylprednisolone Combination treatment with ribavirin and methylprednisolone is given when the patient has extensive or bilateral chest radiographic involvement, or persistent chest radiographic involvement and persistent high fever for 2 days, or clinical and chest radiographic or laboratory findings suggestive of worsening, or oxygen saturation < 95 % in room air.

Standard corticosteroid regimen for 21 days Methylprednisolone 1 mg/kg is given every 8 h (3 mg/kg daily) intravenously for 5 days, then methylprednisolone 1 mg/kg is given every 12 h (2 mg/kg daily) intravenously for 5 days, followed by prednisolone 0.5 mg/kg twice daily (1 mg/kg daily) orally for 5 days, prednisolone 0.5 mg/kg daily orally for 3 days, prednisolone 0.25 mg/kg daily orally for 3 days, withdrawal of drugs.

Ribavirin regimen for 10-14 days Ribavirin 400 mg is given every 8 h (1 200 mg daily) intravenously for at least 3 days (or until condition becomes stable), followed by ribavirin 1 200 mg twice daily (2 400 mg daily) orally.

Pulsed methylprednisolone Pulsed methylprednisolone is given if clinical condition, chest radiograph, or oxygen saturation worsen (at least two of these), and lymphopenia persists, followed by methylprednisolone 500 mg twice daily intravenously for 2 days, and then standard corticosteroid regimen.

Ventilation

Non-invasive ventilation or mechanical ventilation should be considered if oxygen saturation < 96 % while O_2 > 6 L per min or if the patient complains of increasing shortness of breath.

Indications for intubation: (1) Failure to respond to non-invasive ventilation, SaO_2 less than 93 % while oxygen inspiration with facial/nasal mask at 5 L/min and progressive deterioration on chest radiography. (2) Failure to tolerate noninvasive ventilation while with severe dyspnea and hypoxemia. (3) With serious toxic reaction and rapid deteriorating conditions[42-46].

One of the important principles that should be noted in mechanical ventilation is the permission of hypercapnia that is usually performed when there are extensive pulmonary consolidation, poor compliance, and possible pneumothorax. In this way, the tidal volume and oxygen supply per minute could be reduced at the moment. SaO_2<90 % and positive end expiratory pressure (PEEP) at 10-15 cmH_2O may prevent atrophy of pulmonary alveoli and improve oxygen supply.

Academician Zhong Nanshan has recently emphasized 4 important therapies for SARS, including paying attention to fever and myalgia at the acute onset with a combination of traditional Chinese and Western medicine, prompt medication with large-dose of corticosteroids to prevent development of pulmonary fibrosis, timely application of nasal (facial) mask ventilation to improve the supply of oxygen, preventing alveolar collapse thus reducing the need for intubation and timely treatment of complications (especially super infections).

Therapeutic approaches in research

The SARS therapy with convalescent sera was firstly proposed

and used for himself by Dr. Su-Chun Jiang. Later, It was also used for the critically ill patients by Hong Kong scholars and achieved some beneficial effects[48]. However, detailed information about it has not been available.

Theoretically, the therapy is specific, but ineffective when used before severe and irreversible pathological changes take place. On the other hand, it should be screened for the pathogens that are probably transmitted via blood such as HBV, HCV and HIV in patients before the sera are used. Meanwhile, more attention should be paid to the possibility of serum sickness reaction[49, 50]. Other drugs such as protease inhibitors[51] and pulmoalveolar surfactant[52] have been under research and development.

Immunomodulators or immunopotentiators such as thymosin or thymopeptide and glutamine dipeptides have been proposed to be used in the treatment of SARS, though the current evaluation of these approaches remains absent. The therapy is based on the finding that the number of peripheral blood T lymphocytes, especially subgroups of CD4+ and CD8+, is significantly decreased in acute phase of SARS patients, suggesting that impairment of cellular immunity does occur in the early stage of SARS.

The therapies described above are the components of the whole treatment protocol for SARS. Their effectiveness and safety have not been systemically evaluated by prospective, randomized and controlled clinical trials. Therefore, it is hard to conclude which is better. SARS, a disease coming all of a sudden, is highly contagious. The researchers working in the first line of anti-SARS battle are engaged in clinical therapeutic activities. Meanwhile, they are also facing the risk to be infected. Under the circumstances, it is more difficult to perform a well and strictly designed clinical trial, and further more, plenty of concrete problems such as ethnics, research time, and lack of investigators and experimental control may also exist. Therefore it is difficult to make sure the effectiveness and safety of different therapies used in the coming months and years, if well designed trials are not performed. Notwithstanding these difficulties and problems, a reasonably designed clinical trial for SARS therapy remains to be very necessary[53].

Development of new anti-SARS drugs in China

Sivelestat sodium is the first newly developed anti-SARS drug in China that has been approved to enter clinical trials on May, 19, 2003, by State Food and Drug Administration of China. It is also the first one that has been approved to be tested in clinical trial since the rapid ratification program for anti-SARS drugs came into operation. It is an injection of chemical medicine used mainly to prevent and alleviate acute lung injury induced by PMN elastase via a mechanism of inhibiting systemic inflammatory response, with an attempt to improve pulmonary function, shorten the period of ventilation, decrease ventilator-related lung injury and other complications.

On May 21, 2003, the researchers in the Fourth Military Medical University discovered 3 polypeptides that exhibit prominent inhibitory effects on SARS virus *in vitro*, which may lay a solid foundation for the development of new polypeptide-type anti-SARS drugs. They found that a corona-like ring existed in the periphery of SARS virus and there were 4 constitutive proteins within this structure, in which the protein S plays a central role in the virus replication and invasion to human cells. These polypeptides were observed to be able to prevent coronavirus from invading the cells. Currently, these polypeptides have acquired the identification from Institute for Viral Disease Control and Prevention of China CDC. On May 15, State Intellectual Property Office of China has accepted the patent application for these findings.

A research group in the Second Military Medical University currently developed a kind of suspension containing porcine pulmoalveolar surfactant for SARS therapy, which has been approved to enter clinical trial by State Food and Drug Administration of China. It has been demonstrated by the animal study that its primary actions are to reduce pulmoalveolar surface tension, improve pulmonary ventilation and gas exchange, as well as prevent the formation of atelectasis and pulmonary edema. Furthermore, the safety, simplicity, sufferingless of this therapy make it possible to be applied in county or even in rural hospitals[54].

National Center for Drug Screening and Shanghai Institute of Materia Medica have received a considerable variety of pharmaceutical compounds, totally more than 4 000 samples, from more than 50 institutes of drug research in more than 20 domestic provinces and municipalities, as well as from that in USA and South Korea for screening new anti-SARS drugs. Co-operations among National Center for Drug Screening, Shanghai Institute of Materia Medica, Shanghai Municipal Center for Disease Control and Prevention and Academy of Military Medical Sciences have made more than 400 samples screened, in which 3 compounds, namely ZZ-I natural unity compound, an empirical prescription of Chinese medicine "Jieduwan" (detoxicating pill) and 5-hydroxytryptamine receptor antagonist DDDC-AS-001, were found to be the most powerful agents in anti-SARS efficiency among those currently screened all over the world.

TRADITIONAL CHINESE MEDICINE

The clinical characteristics of SARS are mainly manifested as prominent symptoms due to noxious heat and pathogenic dampness in most cases, which may lead to the rapid exhaustion of yin-qi and body fluids, and severe complications. Accordingly, the preventive strategy against SARS is to clear away the lung heat and toxic substances, to remove the pathogenic dampnes' s by aromatics and to supplement qi and promote the production of body fluids.

Prevention and treatment protocol for SARS and suspected cases by State Administration of Traditional Chinese Medicine of China

In order to improve the curative effects on the basis of recommended treatment protocol for SARS or suspected cases and discharge criteria by Ministry of Public Health, the following therapeutic approaches of the traditional Chinese medicine are proposed to be used in the anti-SARS treatment. It is recommended that the therapeutic principles of traditional Chinese medicine, namely diagnosis and treatment based on an overall analysis of the illness and the patient' s condition, should be performed in the treatment of SARS and suspected cases. Meanwhile, the treatment protocols should be adjusted as the patient' s condition changes.

In the early phase, the SARS patients are characterized by the impairment of pulmonary function due to noxious heat and stagnation of damp-heat, which are symptomatically categorized into 3 types of pulmonary impairment due to noxious heat, stagnation of damp heat and exterior cold and interior heat with dampness. For the cases manifested as pulmonary impairment due to noxious heat, it is suitable to promote pulmonary function by eliminating toxic heat via activating superficial channels and choosing a modified prescription of Yinqiao Powder plus Maxing Shigan Decoction. For the patients displaying stagnation of damp-heat, it is recommended to disperse the pathogenic factor out of the body by a revised recipe of Sanren Decoction plus Shengjiang Powder. When the condition is dominated by more dampness and less heat in these cases, Huopu Xialing Decoction should be adopted. For those with a manifestation of exterior cold

and interior heat, the therapeutic strategy is to clear the interior heat and ventilate the lung to get rid of toxic heat, which can be achieved by a modified prescription of Maxing Shigan Decoction plus Shengjiang Powder.

In the metaphase of SARS, the manifestations of the patients are displayed as the invasion of lung by epidemic pathogenic factors, abundant heat both in exterior and interior, accumulation of noxious heat, obstruction of Shaoyang by pathogenic factors and excessive epidemic pathogenic factors both in exterior and interior. For these patients, it is suitable to clear away heat and toxic materials, expell the lung heat and suppress the pathogenic factors with Qingfei Jiedu Decoction. A modified prescription of Ganlu Xiaodu Pill can exert the function of clearing away heat and toxic materials, eliminating dampness and keeping away filthiness, which is favorable for those with accumulated toxic heat. For patients with obstruction of Shaoyang by toxic heat, the therapeutic principles are to clear away the toxic heat at Shaoyang channel and to remove the damp-heat and a modified recipe of Haoqin Qidan Decoction should be adopted. For the patients with predominating toxic heat, pathogenic heat should be removed from blood and excessive heat should be purged. For this purpose, a modified recipe of Qiwen Baidu Decoction should be used.

In the critical phase, SARS cases are manifested as excessive accumulation of toxic heat with impaired body resistance, consumption of both qi and yin, and loss of consciousness and collapse. Accordingly, they are divided into accumulation of phlegm damp-heat blocking pulmonary vessels, stagnation of excessive pathogenic heat with deficiency of both qi and yin, excessive damp-heat weakening body resistance and blockage of breath. For the accumulation of phlegm toxic damp-heat blocking pulmonary vessels, it is helpful to invigorate qi for detoxication, eliminate phlegm for dispersing toxic damp-heat and remove blood heat for activating the channels. To achieve this purpose, Huoxie Xiefei Decoction should be used. For the patients with pulmonary stagnation of damp-heat with deficiency of both qi and yin, it is beneficial to clear away heat and promote diuresis, and to invigorate qi and nourish yin. Under the circumstances, Yifei Huazhuo Decoction is indicated. For the patients with hyperpyrexia weakening body resistance and blockage of breath, the preferable choice is to invigorate qi for restoring the vitality, dredge channels for promoting resuscitation, and choose Shenfu Decoction for getting the therapeutical purpose.

In the recovery phase, the symptoms of deficiency of both qi and yin, and deficiency of the lung and spleen, and the stagnant damp-heat are noted as the primary characteristics of SARS cases. For the former, it is recommended to nourish qi and yin, dispel pathogenic dampness to activate the channels, and to choose a modified prescription of Lishi Qinshu Yiqi Decoction. For the latter, it is reasonable to nourish qi and invigorate the spleen, which can be achieved by a modified prescription of Shenglin Baishu Powder plus Gegen Qinlian Decoction.

PROBLEMS AND COGITATION[55-57]

(1) The SARS cases reported in domestic medical literatures are all diagnosed on the basis of clinical experience without pathogenic evidences. (2) It is not worthwhile to advocate that the same contents are repeatedly reported by several papers or the same paper are repeatedly published by different journals. (3) Researches are lack of creative and constructive results or even simply repeat what have been performed overseas. (4) Most of the papers published are empty in contents with no substantive conclusions. Besides, some clinical reports are published by different journals. (5) The reasons why such inferior papers have been published are the insufficient collection of data and a lack of experience. (6) The achievements of SARS related research are exaggerated sometimes in certain domestic media, which mislead the public and should be prohibited. (7) Co-operations and communications in SARS research are seldom carried out among domestic research institutes, which deeply impressed the author when he was working in Beijing Xiaotangshan Hospital.

Abstract

Inflammatory bowel disease (IBD) includes two clinical subtypes: Crohn disease (CD) and ulcerative colitis (UC). The general prevalence is about 1.0-2.0 % in Western countries. It is predominantly regarded as a multifactorial disorder involving environmental factors and polygenic defects. The view was confirmed by a lot of evidences from clinical attributions and animal models, especially from epidemiological investigations. So the etiological study of IBD has been focused on searching for susceptibility genes by positional cloning, which consists of two steps: linkage analysis and association analysis. Linkage analysis has been an important method of searching for susceptibility genes to polygenic diseases as well as single-gene disorders. IBD, as a polygenic disease, has been widely investigated by linkage analysis for susceptibility gene since 1996. The paper reviewed 38 articles, which covered almost all original researches in relation to IBD and linkage analysis. So far, several loci, such as 16q, 12q, 6p and 3p, have been identified by the studies. The most striking is 16q12 (IBD1), which linked only with CD not UC in the majority of studies. Association analysis, as one essential step for positional cloning, is usually carried out by genotyping candidate genes selected by means of linkage analysis or other methods, for figuring out the frequencies of alleles and comparing the frequencies between IBD group and healthy control group to identify the specific allele. It has been established that IBD is implicated in immune disorder. So the studies were centered on the genes of NOD2/CARD15, HLA-II, cytokine, cytokine receptor and adhesion molecule. This paper reviewed 14 original articles on association between NOD2 and IBD that have been published since 2001. All results, with the exception of one report from a Japanese group, provide evidences that the three kinds of variants of NOD2 are susceptibility factors for IBD. This article also comprehensively analyzed 18 original researches of HLA gene polymorphism in IBD. We found extensive discrepancy among the conclusions and a novel hypothesis was put forward to explain the discordance. Most studies published recently on association between IBD and cytokine gene polymorphism were reviewed.

INTRODUCTION

Inflammatory bowel disease (IBD) is composed of two clinical subtypes: Crohn disease (CD) and ulcerative colitis (UC). Its general prevalence is 0.1-0.2 % in Western countries[1]. There has been no epidemiological investigation of large scale for the prevalence or incidence of IBD in China so far, despite the facts that UC is common in China and CD has been more frequently diagnosed by clinical physicians in recent years[2]. The pathogenesis of IBD has not been clearly identified. Today, the most generally accepted pathogenesis of IBD is that IBD is resulted from abnormal immune response to enteric bacteria in individuals with susceptibility due to genetically polygenic defects. Therefore, investigators have searched human genome for the loci of susceptibility genes by linkage analysis and have achieved great success. On the other hand, association analysis, as one of the essential steps for positional cloning, was carried out by many investigators to identify the specific allele. It has established that IBD is implicated in immune disorder. Biochemical substances involved in immunoregulation are very rich and the corresponding genes are widely distributed in genome. Genome-wide linkage analysis has suggested multiple candidate regions in several chromosomes for IBD, therefore, considerable numbers of candidate genes should be selected for association analysis. In recent years, these studies were centered on the genes of NOD2/CARD15, HLA-II, cytokine, cytokine receptor and adhesion molecule. These studies were summarized in this review.

IBD IS A MULTIFACTORIAL DISEASE

There have been a number of hypotheses about the pathogenesis of IBD, but neither environmental factors, such as habit of diet and behavior, infection of microorganisms and contact of chemical or physical pathogenic agents, nor single-gene genetic disorder alone can fully explain its complex phenotypes. Thereby, it is thought to be a multifactorial disease. The view was supported by a larger amount of evidences from clinical attributions and animal models, especially epidemiologic investigations and linkage analyses.

Persuasive evidences of genetic contribution to IBD[3-12]

A. The first-degree relatives of affected individuals show about 20-50-fold increased risk of developing the disease compared with the general population for CD, and 10-20-fold increased risks for UC. Moreover, the affected siblings frequently present at similar ages and concordance rates reach up to 80 % for disease site, behavior and presence of extraintestinal manifestation. B. Twin studies have shown that the concordance rate of CD is about 20-44 % for monozygotic twins, and 3.8-6.5 % for dizygotic twins; the concordance rate of UC is about 6-16 % and 3 % respectively[6,7]. C. There are significant ethnic differences in disease frequency. For instance, the prevalence in Ashkenazi Jews is much higher than that in other races, even though they share similar living environment in the same community[8,9]. D. All genome-scanning linkage analyses detected some linkage loci, certain of which were subsequently confirmed by replication studies only involving certain

chromosomes; NOD2 was consistently identified as the susceptibility gene for CD in recent years. E. Simulation studies on animal models have showed that transgenic mice or gene-knockout mice are subject to colitis similar to human IBD, and that spontaneous colitis or hapten-induced colitis manifests fairly different in different strains of mice[10-12].

Evidence of environmental contribution

A. The concordance rate of IBD for monozygotic twins is much less than 100 %. The identical genotype with different phenotypes means that environmental factors take part in the pathogenesis of the disease[6,7]. B. Intestinal bacteria are suggested as the main environmental contributions demonstrated by many evidences: antibiotic therapy can usually induce temporary remission for most IBD cases[13], diversion of faeces stream can make distal improvement in patients with CD[14], some studies suggested that certain strains of intestinal bacteria were associated with IBD[15,16], colonization with normal enteric bacterial flora was required for the occurrence of disease in animals with CD irrespective of the underlying defect[10-12]. C. smoking is likely to be associated with the progress of IBD[17,18]. D. Migrant epidemiological studies demonstrated that population of identical ethnic background, when lived in different communities, showed discordant incidence[8,9,19,20].

IBD is not a disorder of simple mendelian inheritance[3,21-25]

Genetic disease of classic Mendelian model, which consists of Mendelian dominant and recessive genetic disorders, is a phenotype of single-gene defect and called single-gene disorder. IBD has previously been interpreted as genetic disease of Mendelian recessive model. But segregation analyses offered counter-evidence that IBD followed the principle of Mendelian inheritance. Parents of most IBD probands were healthy, frequency of siblings or children of the patients was much less than 50 %, the decline in frequency of affected second-degree relatives compared with first-degree relatives was greater than that predicted by autosomal dominant inheritance, in which the frequency was expected to decrease by 1/2 with each step. Incidence of IBD in children of affected spouses was sharply less than 100 % and a similar proportion of affected siblings and children of affected probands was inconsistent with autosomal recessive inheritance. Linkage analysis has detected several linkage loci that are distributed on a number of chromosomes.

LINKAGE ANALYSIS

It is very difficult to find the biochemical substances, which express qualitative difference between patients and healthy population by means of classical functional cloning. So linkage analysis, as the first step of positional cloning, may serve as a unique and practicable substitution for the time being. Figuring out genetic distance between marked loci and susceptibility gene by means of pedigree investigation and genotyping, then defining the approximate position of susceptibility gene in genomic map are the essential courses of linkage analysis. The dramatic progress of human genome project, which has located nearly 10 000 marker loci in genomic map, has greatly boosted positional cloning for complex genetic diseases. Epidemiological studies have identified striking genetic contributions to the etiology of IBD, but so far, studies with traditional biochemical methods have not yet identified the products with quantitative defects. Many investigators have turned to linkage analysis and have achieved great success. The important data from 38 original researches, which covered almost all articles in relation to IBD and linkage analysis that have been published since 1996, are listed in Table 1[26-63], and some aspects were reviewed as follows.

The common course of linkage analysis for IBD is: collecting families with affected sibling pairs (ASP) or affected relative pairs (ARP) $\geqslant$2 by strict ascertainment, genotyping of genome-wide or certain chromosomes according to microsatellite polymorphisms, figuring out multi-point maximal non-parametric LOD score (MLOD) and two-point LOD score by means of statistical software, inferring genetic distances of susceptibility genes to marker loci and locations in physical genome map, offering candidate genes for association analysis. The majority of investigations found certain suggestive linkage loci with various LOD score, but when defined according to different LOD thresholds, the locations or number of linkage loci were variable. In view of the traits of statistical software and quantity of subjects in most studies, we only displayed the results with MLOD $\geqslant$2.0 or 3.0, represented by ± and +. The chromosomes, on which the linkage loci strongly supported (MLOD$\geqslant$3.0) by at least one of 8 linkage analyses of genome-wide scanning located, include chromosomes 1, 3, 5, 6, 7, 12, 14, 16, 18 and 19, as well as chromosomes 4, 10, 17 and x with suggestive evidence (2.0$\leqslant$MLOD<3.0). Although there was striking discrepancy among the genome-wide scans in respect of linkage loci, almost all studies detected more than 3 linkage loci. This shows that the pathogenesis of IBD is involved in multiple genes and manifests obvious genetic heterogeneity. Several loci were supported by relative more studies, such as 16q, 12q, 6p, and 3p. Because Hugot *et al*[26] and Satsangi *et al*[27] detected strong linkage evidences for chromosomes 16, 12, 6, 3 and 7 in 1996, subsequent studies mainly focused on these chromosomes. It can be seen from Table 1 that more evidences were offered for these loci, with the exception of 16q, simply because these loci were investigated by more studies. Some loci supported by certain genome-wide scans, such as 14q, 5q, 19p, likely to harbor susceptibility genes, were less investigated.

Stratification studies demonstrated significant variances as to the degree and loci of linkage between families with severe IBD and those with only slight IBD, male patients and female patients, Jewish people and non-Jewish people, as well as between UC and CD. Some investigators examined families with CD patients only; others examined families with UC patients only, but most studies detected both families and those with mixed patients and compared the differences of linkage loci between the two groups. As shown in Table 1, there were some differences between UC and CD. The most striking is 16q12 (IBD1), which linked only with CD not UC in the majority of studies. This shows that CD and UC have some common susceptibility genes, as well as certain individual susceptibility genes. Three studies[32,47,48] found that certain loci linked only with the families with early onset of CD. All subjects examined by the studies listed in Table 1 included Caucasian or Jewish patients from Europe, Australia and northern America, but no Mongolian patients. Three studies[28,29,42] demonstrated significant differences between Jewish patients and non-Jewish patients. In respect of nationality of patients, it seems there are no remarkable differences among American, English, German, Australian, Canadian, Italian, Dutch and Belgian. But Paavola *et al*[40] examined chromosomes 1, 3, 7, 12, 14 and 16 in Finnish patients and did not find linkage loci. Fisher *et al*[33] found that some loci on chromosomes 6p, 1, 14 and 18 linked only with IBD of male sufferer. These results confirm the extensive genetic heterogeneity of IBD.

Linkage analysis is intended as an essential tactic to offer candidate genes for association analysis. We should focus our attention on the linkage loci containing some candidate genes, products of which have been suggested as pathogenic factors by other methods, as well as confirmed by subsequent replication studies. The loci meeting these conditions were briefly reviewed here.

Note: CD, CD-only family; UC, UC-only family; IBD=UC+CD+mixed family; +, convincing linkage (LOD≥3.0); ±, suggestive linkage (3.0>LOD≥2.0); —, no suggestive linkage (LOD<2.0); [a], including Jewish; [b], family from English, German and Dutch; [c], family from Northern American, European and Australian; [d], family from French and Belgian; [e], linkage only for Jewish; [f], linkage only for IBD with early onset.

Chromosome 16 As shown in Table 1, 14 out of 25 related studies found linkage loci for CD with MLOD more than 2.0 on the chromosome, additionally, some loci with suggestive score (MLOD between 1.0 and 2.0) were detected. Only 3 studies found linkage loci with UC, furthermore, 2 of them also detected linkage with CD, and the other one merely examined UC families. It can be inferred from these studies that chromosome 16 contains susceptibility gene for CD rather than UC. Chromosome 16 is comparatively short, with 98 Mb of physical length, 130.8 cm of genetic distance, and has been spaced by about 200 microsatellite markers[64]. The linkage loci suggested by the studies in Table 1 were distributed in most part of chromosome 16 (for instance, D16S409-419[26], D16S748-764[28], D16S411[42,43], D16S3136[50]), but only pericentromeric region on 16q was the most consistent linkage region. The important candidate genes in the region are NOD2, CD11integrins, CD19, Sialophorin, IL-4 receptor gene etc. NOD2 gene has been established as susceptibility gene to CD. It remains unanswered if there are other susceptibility genes in the chromosome. Hampe *et al*[51] examined additional regions with high-density experiment using 39 microsatellite markers and found three-peak logarithm of odds (LOD) scores of 2.7, 3.2, and 3.1 on proximal 16p, proximal 16q, and central 16q, respectively. Taking account of the differences of suggestive markers, it is probable that there are other susceptibility genes for CD in the chromosome.

Chromosome 12 Six out of 19 studies found suggestive linkage loci in the chromosome, 4 of them for CD, and one for UC. Though the studies with suggestive MLOD are rare, several studies found linkage loci with slightly suggestive significance (MLOD between 1.0 and 2.0) with IBD, especially with UC. This may result from the fact that the sample sizes in most studies were not large enough; furthermore, they were predominantly consisted of CD families. Parkes *et al*[59] examined 581 affected relative pairs, of which 252 were from CD-only families, 138 from UC-only families, and 191 from mixed families (the sample size was much larger than that in most of other studies, especially for UC), and found that MLOD at certain marker on chromosome 12 was 5.26 for all IBD, 3.91 for UC and 1.66 for CD. In summary, it is probable that

Note: CD=Crohn disease; UC=ulcerative colitis; CD-GRR=CD-genotype relative risk; SHEM=simple heterogeneous mutation; HOM= Homozygous mutation; CHEM=complex heterogeneous mutation; *P* value is uniformly set at $\leqslant$0.05; Nomenclatures were not uniform among the studies, R675W=R702W, G881R=G908R, 1007fs=980fs=3020insC.

chromosome 12 contains susceptibility genes both for CD and UC, but with only weak contributions. The most consistent microsatellite markers lay in 12q13, which is also called IBD2. The main candidate genes in the region are IFN-γ, natural resistance associated macrophage protein (MRAMP2), vitamin D receptor genes etc.

Chromosome 6 Eight out of 14 studies found linkage loci in the chromosome. There was no remarkable difference between CD and UC in terms of the number of suggestive studies or LOD score in most studies. This shows that common susceptibility genes for both CD and UC are probably located in chromosome 6. Linkage markers of most studies were distributed in 6p13, which was called IBD3 in some studies. The important candidate susceptibility genes in the region include HLA-A, HLA-B, HLA-C, HLA-E, HLA-F, HLA-G, MIC-A, MIC-B, HLA-DR, HLA-DP, HLA-DQ, HLA-DM, LMP-2, LMP-7, transporterin antigen processing (TAP)-1, TAP-2, TNF-α, TNF-β, (LT-α), heat shock proteins (HSP), complement C4, C2 genes etc.

Chromosome 3 Four out of 16 related studies found linkage loci with LOD score more than 2.0. It should be noticed that the LOD scores in 4 studies for all IBD were always higher than that for CD or UC alone and no LOD score for CD or UC alone reached 2.0 in all related studies. It may be partly due to the fact that the sample sizes were much smaller after stratifications and could not reach the threshold of statistical significance. It is very likely that there are some common susceptibility genes for CD and UC, but they probably confer slight genetic contribution to IBD, since some studies found linkage loci in the chromosome only with weakly suggestive LOD score[30,39,60]. The considerable linkage region was proximal 3p. The principal candidate genes in the region include CCR2, CCR5, IL-4RA, IL-5RA, lactotransferrin, IFN-α A2, cathelicidin antimicrobial peptide genes etc.

Chromosome 5q It was confirmed by only 3 studies involved in the chromosome. The linkage loci were located in 5q32-35, which happened to be in the region of cytokine-rich cluster and was called IBD5 in some studies. The main candidate genes are IL-3, IL-4, IL-5, IL-13, CSF-2 genes etc. The cytokines have been accepted as playing important roles in initiating IBD. So further investigations are needed.

14q11(IBD4) and 19p13 They were suggested as linkage loci in some studies. 14q11 contains the immunoloregulation members TCR-α/δ gene and 19p13 contains ICAM1, C3, TBXA2 and LTB4H genes.

ASSOCIATION ANALYSIS

Association analysis, as an essential step for positional cloning, was usually carried out by genotyping candidate genes selected by means of linkage analysis or other methods, for figuring out the frequencies of alleles and comparing the frequencies

between IBD group and healthy control group to identify the specific allele. It has established that IBD is implicated in immune disorders. So studies have been centered on genes of NOD2/CARD15, HLA-II, cytokine, cytokine receptor and adhesion molecule.

NOD2/CARD15 mutations

Identification of NOD2 as susceptibility gene for IBD is supported by linkage analysis, association analysis and immunological function analysis. In this review, crucial information from 14 original studies on the relationship between IBD and NOD2 mutations are listed in Table 2[49, 65-77] and were comprehensively analyzed as follows. NOD1 is an intracellular protein composed of a N-terminal caspase recruitment domain (CARD), a centrally located nucleotide binding domain (NBD), and a leucine rich repeat (LRR) domain at its C-terminus which could activate nuclear factor κB (NFκB) and also promote apoptosis[78]. NOD2 was identified by searching the public database for genes encoding similar proteins to NOD1. The gene happens to be located on chromosome 16q12, a domain called IBD1 supported by most linkage analysis. NOD2 has one more CARD at its N-terminal than NOD1. It is expressed primarily in monocytes and following stimulation by bacterial lipopolysaccharide (LPS), which occurs at LRR domain, activates NF-κB.

So far, approximately one hundred sequence variants have been detected in NOD2 gene, most of which were rare mutations, and located in LRR domain. Lesage *et al* discovered 67 sequence variants in the gene, 9 out of them with gene frequencies more than 5 %. This demonstrates that NOD2 gene has high polymorphism. Of these alleles, P268S, R702W, G908R and 1007fs are consistently confirmed to be the genetic susceptibility factors to IBD. Gene frequency of P268S in general population was about 20-28 %, a little higher than other three variants. While it was remarkably higher in CD patients, transmission disequilibrium test (TDT) suggested that this was very likely to be the result of transmission disequilibrium with other three variants, but not the independent susceptibility factor to CD. R702W, G908R and 1007fs are widely considered as independent susceptibility factors. 1007fs allele frequency was different among all reports: about 1.6-3.3 % in control population and 6.6-23.7 % in CD patients. All the studies, with the exception of a report from Japanese group, strongly support the association of 1007fs with CD. Allele frequency of R702W was slightly higher than that of 1007fs, and was significantly higher in CD patients than in control population. Allele frequency of G908R was about 1.5 % and has been suggested as an independent susceptibility factor to CD, but the statistical values in some reports did not reach significant level. This may be due to its lower gene frequency. The CD-genotype relative risk of the three mutations was about 3.0 for simple heterozygote mutation, and more than 20.0 for homozygote mutation or compound heterozygote mutation. This supports the fact that mutations in NOD2 gene show a gene-dosage effect and somewhat recessive trait. Five studies, in which subjects included UC patients, did not find any persuasive evidences that the three mutations were associated with UC. It' s worthy to point out that association of the three mutations with CD was not confirmed in study by the Japanese group. The discordance is usually explained by the view that CD is a genetic disease with high locus heterogeneity or allele heterogeneity among patients from different races or different geographic territories. With respect to the association of three mutations with clinical phenotypes, most reports suggested 3 mutations were only associated with ileum CD and certain reports found they were associated with fibrostenosis, fistula or effect of medicine.

How can the mutations of NOD2 initiate CD[65,66,79-82]? Some

studies have provided evidences that NOD2 is an intracellular receptor for bacterial pathogenic agents, and expresses only in monocytes. LRR of NOD2, after being activated by lipopolysaccharide (LPS), can trigger NF-κB signal pathway, which promotes the expression of certain proinflammatory cytokines. LRR can also promote apoptosis. So it is the most likely mechanism that the mutations in NOD2 either raise sensitivity of monocyte to bacterial pathogenic agents, with the result of overexpression of certain proinflammatory cytokines, or cause deficiency of apoptosis, leading to monocyte accumulation in intestinal mucosa and chronicity of the course. There are some questions about the relation between mutations in LRR and activity of NF-κB. Though high activity of NF-κB is always found in monocytes in lamina propria of intestinal mucosa from CD patients, it descends in cells with frame-shift mutation in LRR *in vitro* when stimulated by LPS. Functional study by Hugot *et al* demonstrated that expression of a NOD2 mutant form lacking the entire LRR region results in enhanced NF-κB activity, whereas the frame-shift mutation causing a truncated protein missing the final 33 amino results in low NF-κB activity. The potential explanation may be that the truncated protein leads to elevated NF-κB when stimulated by an untested bacterial LPS and that the frame-shift mutation may have a differential effect on caspase 9 induced apoptosis. To understand the mechanism how mutations in NOD2 confer susceptibility to CD, more functional analyses should be ingeniously performed. Identification of NOD2 was a great achievement in the history of exploring genetic susceptible factor for IBD. Detecting of the mutations may well have some clinical benefits for the prediction of onset risk, classification of disease, individualization of therapy and future gene therapy, but it should not be used as a tool for diagnosis since there is about 6-9 % overall allele frequency of the three single nucleotide polymorphisms (SNPs) in general population.

HLA gene polymorphisms

HLA gene is composed of three regions: HLA-I, HLA-II and HLA-III. HLA-I mainly includes HLA-A, HLA-B and HLA-C, and HLA-II mainly contains HLA-DR, HLA-DQ, HLA-DP. The primary immunity relative genes in HLA-III region are TNF-α, TNF-β, (LT-α), complement 2 (C2), complement 4(C4). Genes in the regions are highly polymorphic. HLA-II is expressed primarily in macrophages, dendritic cells and thymic epithelial cells, playing important parts in presenting exogenous antigen. Immunologic studies have shown strong evidences that IBD is closely associated with disturbance of Th lymphocyte subclass, and that the major environmental factor inducing immune disorder is intestinal bacterial flora. T lymphocytes accept enteric antigens presented by microphages, so it is naturally viewed that sequence variants of HLA-II are likely to cause disorder of antigen presenting and result in imbalance of Th lymphocyte subclass. HLA genes located in IBD3 (6p13) were identified by linkage analysis, it is sensible to select HLA gene as candidate gene for association analysis. This review collected 18 studies published since 1995 and listed the main results in Table 3[52,77,87-98]. Most studies published before 1995 usually typed HLA by examining serum HLA antigen through immunologic assay. The studies shown in Table 3 tried to identify HLA alleles by using reliable and precise molecular biological techniques, such as specific sequence primer polymerase chain reaction (PCR-SSP), specific sequence oligonucleotide probe assay (PCR-SSO) and gene sequencing.

It could be summarized from Table 3 that polymorphisms positively or negatively associated with UC or CD are mainly located in DRB1 or DQB1, which are the key regions to determine the polymorphism of peptide-binding cleft. The sequence variants in the regions could change the affinity for distinct antigen peptides. According to serum typing, results from more than two studies suggest that UC is positively associated with DR2, DR9 and negatively associated with DR4, and that CD is positively associated with DR7, DQ4, negatively with DR2, DR3. Further genotypings by molecular biological technique found that only DRB1*0103, DRB1*1501 and DRB1*1502 were associated with UC in more than two studies. Other variants in the regions have not been confirmed to be positively or negatively associated with UC or CD. Many investigators studied the association between polymorphism and clinical phenotype (p-ANCA, sex, extent, age of onset, site of disease, effect of certain medicine, complication, certain extraintestinal symptoms), but their conclusions were not consistent. The heterogeneity was obvious between UC and CD in respect of association with polymorphisms of HLA-II genes. The alleles associated with UC or CD were not associated with the others. On the contrary, DR2, positively associated with UC in some reports, was negatively associated with CD in other reports.

Stokkers *et al*[94] carried out a meta-analysis involving 29 pieces of related reports published from 1980 to 1999 (there were some overlaps between those and reports listed in Table 2). Taking a wider view of all these studies, we discovered a remarkable characteristic: the vast majority of studies discovered certain positively or negatively associated alleles, but all the suggested alleles showed significant discrepancy (there were always both evidences and counterevidences of the association as to any of the alleles among the studies). The contradiction cannot be explained by race heterogeneity because there are discrepancies both in white people and yellow people. It cannot be convinced that sequence variants in HLA-II gene are not associated with IBD and positive results are due to confusions either from linkage disequilibrium or from coincidences resulted from high polymorphisms. In view of the functional property of HLA-II and the widespread contradictions in association analysis, we consider that polymorphism in the regions, to some extent, plays a role in initiating IBD, but the involved alleles differ between different communities (in view of geographic situation, climatic condition and dietary culture) and even between individuals in the same community. The constituent characteristics (sort, ratio, total amount and time order of all antigens) of antigen compound (all kinds of antigens) derived from intestine in one community are distinct from that in an other community. The antigen presenting cells (APC) containing certain HLA-II allele, only when disposing and presenting the antigen compound with matching constituent characteristic, can cause pathologic response. There are different predominant antigen compound in different communities, so the predominantly matching alleles implicated in IBD might be different among communities, and therefore no particular or unchanged antigen and HLA-II allele can take part in pathologic lesions in all IBD. Nevertheless, some of them may play a more dominant role in one community than in another community.

Cytokine, cytokine receptor and adhesion molecule polymorphisms

IL-1β, excreted mainly by microphages, up-regulates the expression of HLA-II, adhesion molecule and IFN-γ in an autocrine manner. It can also, through paracrine, promote activity of Th lymphocyte and play an important part in triggering immune response. IBD is regarded as the result of imbalance of Th lymphocyte subclass, thereby, IL-1β, IL-1β receptor (IL-1R), IL-1 receptor antagonist (IL-1RA), balance of IL-1β/IL-1RA may be associated with IBD. Up to date, many investigators have tried to explore association between IBD and gene polymorphism, but studies in recent years did not

find any positive results[99-101]. Nemetz *et al* found that IL-1β-511*2 allele was associated with the overexpression of IL-1β and descent of bone mineral density[102], and that IL-1β(+3953,-511) allele is associated with pathological course and patient' s condition[103]. Mwantembe *et al*[104] examined the polymorphism of IL-1β, IL-1R and IL-1RA genes by *TaqI, Pst I* and VNTR and discovered IL-1R (*TaqI-*) allele frequency was significantly higher in white patients than that in white healthy controls and Negro patients, whereas IL-1R (*Pst I-)* allele frequency was higher in Negro patients than those in white patients. IL-1β and IL-1RA genes were not located in the region which was strongly supported by linkage analysis.

TNF-α is suggested as a pathogenic factor for IBD because its concentration is usually increased in intestinal mucosa of IBD patients, and therapy of anti-TNF-α antibody Infliximb has shown satisfactory effects on refractory IBD. The gene is located in IBD3 (6p13) which is supported by linkage analysis. Most studies in recent years discovered certain alleles were associated with IBD. Van Heel *et al*[105] found (-857C) TNF-α allele was associated with IBD. Sashio *et al*[106] found TNF-α (-308G/A, -238 G/A) allele was associated with UC. Mitchell *et al*[107] found that TNF-α (-308G/A) was associated with sclerosis cholangitis. Koss *et al*[108] found that different haplotypes of TNF-α gene were associated with the expression of TNF-α. Louis *et al*[109] discovered (-308) TNF-α was associated with certain clinical phenotypes of CD. Negoro *et al*[110] discovered (-1031C, -803A, -857T) TNF-α was associated with CD. These results show that sequence variants of TNF-α gene, especially (-308G/A) may take part in the pathogenesis of IBD by enhancing the expression of TNF-α and promoting activity and proliferation of Th lymphocytes.

IL-4, expressed mainly in Th2 lymphocytes, plays an important role in regulating the balance of Th lymphocyte subclasses and induces differentiation and proliferation of B lymphocytes or microphages, thereby it is regarded as a principal factor in initiating UC. IL-4 and IL-4 receptor (IL-4R) gene are separately located in 5q31-33 (IBD5) and 16q12 (IBD1) which are supported by linkage analyses. Klein *et al* [111] and Aithal *et al*[112] found that certain alleles of the genes were associated with CD. Peng *et al* examined IL-4 polymorphisms in Chinese people and found IL-4-RP2 allele frequency was obviously higher in UC patients than in healthy control, whereas RP1 allele frequency was higher in healthy control than in UC patients[99].

IL-10, mainly excreted by Th3 or Th2 lymphocytes, can suppress the expression of IL-12 and TNF-α in natural killer cells or microphages, restrain activity or proliferation of Th1 lymphocytes. The functional deficiency of IL-10 may be an important maintenance factor for chronicity of IBD. The fact that IL-10 gene knockout mice are subject to colitis similar to human IBD is a persuasive evidence. But studies in recent years did not discover any allele was associated with IBD (allele IL-10 (-627, -1117, -1082, -592, -819) etc.)[101,107,113,114]. Koss *et al*[108] found IL-10 (-1082G/A) allele was associated with the down-regulation of IL-10 expression.

ICAM-1 plays an important role in regulating the homing of lymphocytes. Overexpression of ICAM-1 and significant lymphocyte infiltration have been found in intestinal mucosa of IBD patients. ICAM-1 gene is located in 19p13, which is supported by some linkage analysis. Yang *et al*[115,116] found that R241 allele was associated only with ANCA-positive UC. Contrarily, Braun *et al*[117] reported that ICAM-1 R241 allele and R/G241 heterogeneous mutation were much more frequent in UC patients than in healthy control irrespective of ANCA-positive or ANCA-negative.

Other investigators examined E-selection, L-selection, CCR2, CCR5, IL-6, NRAMP1 and IFN-r genes and found they had no association with IBD[95,118-121].

PROBLEMS AND PERSPECTIVES

Taking a wide view of these studies, we could find extensive discrepancies, which are usually interpreted by the view that IBD is a genetic disease with widespread heterogeneity[122]. It means that the complicated clinical phenotypes of IBD are determined by interaction of multiple genes with environmental factors. Single gene contributes little to IBD, and only polygenic defects with corresponding conformation underlie the complicated phenotypes of IBD. One phenotype may be determined by more than one conformation models of polygenic defects. Nevertheless, we should take into account of other aspects to resolve the discordant results in linkage analyses. A. Entrance criteria and clinical classifications of subjects must be controled more strictly and uniformly, since a minor mistake may influence the outcomes[123,124]. B. The microsatellite markers used by different investigators were not uniform, some investigators selected high-density markers, and others used somehow lower density markers. This could result in discrepancy conclusion. C. The sizes of sample were different among the studies, ranging from about 100 patients to more than 600 patients. Stratification studies performed using small sample sizes may cause false-negative error. Cavanaugh *et al*[41] carried out an international multicenter study, which involved 613 families from 12 study centers. By pooling of data sets, which were acquired from 12 independent centers using the same statistical method, despite the lack of convincing evidence for linkage based on data from individual center, they discovered unequivocal linkage for IBD on chromosome 16 (MLOD 5.79). D. The principle of linkage analysis is based on the view that crossing over in meiosis I is random and physical distance on chromosomes is necessarily in accord with genetic distance. The findings that significant association was found, but no linkage was suggested for the same subject group and the same loci demonstrated somehow theoretical disability of linkage analysis[49,125,126]. E. Other molecular biological mechanisms such as epigenetics may also play a role in initiating IBD[127]. In addition, if IBD is thought as a genetic disorder like familial adenomatous polyposis (certain mutations were inherited from parents, then somatic mutations were accumulated in certain cells such as macrophages or epithelial cells in intestinal mucosa or lymphoid tissue), all phenomena observed so far would not produce counterevidence. Today, linkage analysis has shed lights on genetic diseases such as diabetes mellitus, hypertension, asthma, Alzheimer' s disease and arteriosclerosis, as well as single-gene disorders. As for IBD, we have identified several linkage loci, which harbor a number of important candidate genes pending further confirmation by association analysis and functional analysis.

At present, about 30 candidate genes have been investigated by means of association analysis, and the majority of them either have no association with IBD or have not been confirmed by replication studies. With respect to HLA gene, though the majority of investigations discovered certain positively or negatively associated alleles, all the suggested alleles showed significant discrepancy. The three mutations in NOD2 gene have been consistently confirmed to be the independent susceptibility factors for CD in all-14 original studies except for one from a Japanese group, but how the variants can cause CD remains to be answered. Taking a wide view of all reports, which reached statistic significance, we discovered that frequencies of any alleles ever suggested by association analysis did not manifest a great absolute difference between patients and healthy controls. For instance, only about 20 % CD patients carried at least one of the three alleles of NOD2, whereas about 4-7 % healthy population also carried one of them. This shows that no allele ever studied demonstrates high specifity and sensitivity of the association with IBD and other

alleles need to be explored. It should be noted that the results of most studies, irrespective of positive or negative, did not absolutely ascertain the involvement of genes as susceptibility genes to IBD, since these could be confounded by a number of factors such as type I error or type II error caused by linkage disequilibrium or coincidence. In addition, there are many sequence variants in most genes, some of them are rare mutations and can only be properly analyzed in study of very large samples. Most investigators only detected variants in certain regions of the genes, instead of sequencing of whole gene of these alleles, therefore these results cannot represent the whole genes. The associations of some alleles with clinical phenotype of IBD have been detected by stratification study in many studies, but studies on the associations with the expression of cytokines involving the regulation of Th lymphocytes, were far less and more studies need to be carried out. The biochemical substances, which were ever suggested to be pathogenic factors for IBD, are of great variety, so it' s important to select proper candidate genes for association analysis. Since 1996, nearly 40 linkage analyses have identified several linkage loci in different chromosomes, such as IBD1, IBD2, IBD3, IBD4, and IBD5. Therefore, the genes located in such loci, and their products widely established as pathogenic factors for IBD, should be preferentially selected as candidate genes. Association analysis is an important method for unraveling the pathogenesis of IBD at gene level and will contribute tremendously to the understanding of IBD in the near future.

Abstract

RNA interference (RNAi) is a remarkable type of gene regulation based on sequence-specific targeting and degradation of RNA. The term encompasses related pathways found in a broad range of eukaryotic organisms, including fungi, plants, and animals. RNA interference is part of a sophisticated network of interconnected pathways for cellular defense, RNA surveillance, and development and it may become a powerful tool to manipulate gene expression experimentally. RNAi technology is currently being evaluated not only as an extremely powerful instrument for functional genomic analyses, but also as a potentially useful method to develop specific dsRNA based gene-silencing therapeutics. Several laboratories have been interested in using RNAi to control viral infection and many reports in *Nature* and in *Cell* show that short interfering (si) RNAs can inhibit infection by HIV-1, polio and hepatitis C viruses in a sequence-specific manner. RNA-based strategies for gene inhibition in mammalian cells have recently been described, which offer the promise of antiviral therapy.

INTRODUCTION

RNA, long upstaged by its more glamorous sibling, DNA, is turning out to have star qualities of its own. *Science* hails the electrifying discoveries of RNA interference as 2002's breakthrough of the year. RNA interference, also named RNA silencing or post transcriptional gene silencing (PTGS), is a phenomenon in which small double-stranded RNA molecules induce sequence-specific degradation of homologous single-stranded RNA[1]. RNAi activity plays a role in host-cell protection from viruses and transposons in plants and insects. From a practical perspective, RNAi can therefore be used to target gene expression and has been proved to be a very powerful technique to knock down specific genes to evaluate their physiological roles in *Caenorhabditis elegans*, *Drosophila melanogaster*, and humans[2-5].

Previous reports have show that RNAi has following important characteristics[7-11]. (1) RNAi can be induced through transfection or microinjection of long double-stranded RNA. In plants and invertebrates, the double-stranded RNA is cleaved into 19- to 23-nt RNA fragments known as small interfering RNAs (siRNA). siRNAs are double-stranded RNA (dsRNA) molecules with characteristic 2-nucleotide over hanging 3' ends. They act as intermediates in the RNA interference (RNAi) pathway, which is thought to protect cells from harmful transposons and highly repetitive sequences by targeting their RNA transcripts for endonucleolytic cleavage and subsequent exonucleolytic degradation. siRNA-directed RNA degradation is central to the antiviral response in plants, where it represents a potent form of sequence-based immunity. Only RNA molecules <30 bases in length can be used to exclusively induce RNAi in mammalian cells because longer molecules also activate the nonspecific double-stranded RNA-dependent response. (2) RNAi has amplification activity and different durations. In plants and nematodes, RNAi activity is long-term and disseminates throughout the organism via an uncharacterized amplification mechanism. In mammalian cells, amplification activity seems absent, and interference activity is transient, lasting for only 3-5 days. More recently, DNA expression vectors have been developed to express hairpin or duplex siRNA, which employ the type III class of RNA polymerase promoters to drive the expression of siRNA molecules. In addition, stable cell lines containing siRNA expression plasmids have been produced to induce RNAi over longer durations. (3) RNAi can be induced locally and then spread throughout the organism in plants, and this aspect of the process likely reflects its role in viral defense.

The power of siRNAs springs from the cellular biochemistry of the RNAi pathway. Like antisense oligonucleotides, siRNAs use sequence complementarity to target an mRNA for destruction. Unlike the antisense pathway, the RNAi pathway couples the specificity of an RNA guide to the stability and efficiency of a multiple-turnover protein enzyme. The ability to manipulate RNA interference thus sets the stage for realizing a wide variety of practical applications of biotechnology ranging from molecular farming to possibly even gene therapy in animals. Gitlin *et al*[12] showed that RNAi drastically reduced polio infection in HeLa cells. While analysing the antiviral effects of siRNA over a course of viral infection, they found that siRNA-resistant viruses turned out to carry silent base-pair mismatches in the siRNA complementary sequences. The authors argued, therefore, that if RNAi was to be used for therapeutic reasons, siRNA needed to be designed against highly conserved parts of the viral genome. Adelman et *al*[13] demonstrated that dsRNA-mediated interference also could act as a viral defense mechanism in mosquito cells. These observations are consistent with RNA interference as the mechanism of resistance to DEN-2 in transformed mosquito cells. Kay *et al*[14] went beyond the *in vitro* systems and genetically engineered mice that expressed siRNA against hepatitis C RNA to show that this technique also worked well *in vivo* to prevent viral replication. After this bumper crop of promising results, it remains to be seen how close we are to RNAi-mediated antiviral therapy. Because siRNA taps into natural gene-silencing pathways, a new form of intracellular immunization against viral infection might be just around the corner.

INTERFERING HCV

HCV genome is a single-stranded RNA that functions as both a messenger RNA and a replication template, making it an

attractive target for the study of RNA interference[15-21]. Previous results from Izumi RE' s laboratory[22] identified a small (60 nt) RNA from the yeast S. cerevisiae that specifically inhibited internal ribosome entry site (IRES)-mediated translation programmed by poliovirus (PV) and hepatitis C virus (HCV) 5' -untranslated region (5' UTR). The yeast inhibitor RNA (called RNAi) was found to efficiently compete with viral 5' UTR for binding to several cellular polypeptides that presumably play important roles in IRES-mediated translation. RNA interference offers further hope that a novel approach to silencing troublesome genes will become a valuable disease-fighting tool. But the therapy must leap many hurdles before it can be safely applied to humans. The power of small RNAs to shut down specific gene activities has now been brought to bear on an animal model of hepatitis. Mice infused with a siRNA against a cell death receptor recovered their liver function after experimentally induced injury. The work of Song *et al*[23] suggests that one type of entirely natural nucleic acid, small interfering RNAs (siRNAs), may hold promise as a therapeutic agent even without further engineering. These investigators provided the first *in vivo* evidence that infusion of siRNAs into an animal could alleviate disease, in this case hepatitis. Assembly of a siRNA strand into an RISC seemed to protect it from rapid degradation, the normal fate of small single-stranded RNA in cells. With this durability in mind, Song *et al*. set out to test whether direct infusion of siRNAs into mice might protect them from fulminant hepatitis. Both mice and humans with this disease suffered severe hepatic failure complicated with consequent encephalopathy, cerebral edema, metabolic imbalance and organ collapse. Infusing a solution of siRNA into a mouse' s tail, in massive amount, equivalent to half the animal' s blood volume protected it against hepatitis. And in animals that were already ailing, RNAi shut down the inflammation enough to allow the liver to recover. Despite the traumatic delivery method, the mice didn' t appear to suffer side effects. They gave mice injections of siRNA designed to shut down a gene called Fas, when over-activated during inflammatory response, it induced liver cells to self-destruct. The next day, the animals were given an antibody that sent Fas into hyperdrive. Control mice died of acute liver failure within a few days, but 82 % of the siRNA-treated mice remained free from serious disease and survived. About 80 % and 90 % of their liver cells incorporated the siRNA. Furthermore, the RNA molecules functioned for 10 days before fading completely after 3 weeks, lasting roughly three times longer than in previous studies. Another set of animals faced a different challenge: injections of cells with ConA, which compelled the immune system to attack the liver and produced the scarring seen in viral hepatitis. Animals infused with siRNA developed no liver damage. Silencing Fas expression with RNAi holds some therapeutic promise to prevent liver injury by protecting hepatocytes from cytotoxicity. In addition, biologists have agreeed that the best strategy would be to aim siRNA directly at hepatitis B or C viruses, but that would require a different siRNA than the one used by Song' s team. Evidences from several laboratories suggest that, in petri dishes, siRNA can stop hepatitis C from replicating. McCaffrey *et al*[24] showed that transgene expression could be suppressed in adult mice by synthetic small interfering RNAs and small-hairpin RNAs transcribed *in vivo* from DNA templates. They also showed the therapeutic potential of this technique by demonstrating effective targeting of a sequence from hepatitis C virus by RNA interference *in vivo*. Wilson *et al*[25] found RNA interference blocked gene expression and RNA synthesis from hepatitis C replicons propagated in human liver cells. Double-stranded small interfering RNA (siRNA) molecules designed to target the HCV genome were introduced through electroporation into a human hepatoma cell line (Huh-7) that contained an HCV subgenomic replicon. Two siRNA dramatically reduced virus-specific protein expression and RNA synthesis to levels that were 90 % less than those seen in cells treated with negative control siRNA. These same siRNA protected naive Huh-7 cells from challenge with HCV replicon RNA. Treatment of cells with synthetic siRNA was effective for more than 72 h, but the duration of RNA interference could be extended beyond 3 weeks through stable expression of complementary strands of the interfering RNA by using a bicistronic expression vector. These results suggest that a gene-therapeutic approach with siRNA can ultimately be used to treat HCV.

The utility of siRNA as a therapy against HCV infection will depend on the development of efficient delivery systems that induce long-lasting RNAi activity[26]. HCV is an attractive target for its localization in the liver, an organ that can be readily targeted by nucleic acid molecules and viral vectors. In future, chemically modified synthetic siRNA, with improved resistance to nucleases coupled with enhanced duration of RNAi, may become a possibility for therapeutic applications. On the other hand, gene therapy offers another possibility to express siRNA that targets HCV in a patient' s liver. Based on the above experiments, the use of siRNA as a treatment for HCV infections has great potential for use alone or in combination with conventional IFN/ribavirin therapy as means to decrease virus loads and eventually clear the persistent viruses from its host[27]. As therapeutic agents, siRNAs have enticing properties. Their actions appear to be short-lived in mammals, they are sequence specific and natural, cellular products and may therefore not produce toxic metabolites. Nonetheless, caveats for clinical use remain. Delivering siRNAs to the appropriate cells is a major challenge. siRNAs have thus far only been administered intravenously to mice by ' hydrodynamic transfection' , the rapid infusion of siRNA in a volume one-tenth the mass of the animal. Furthermore, the liver seems to be particularly receptive to exogenous RNA. Better delivery methods-such as formulation of siRNAs with compounds that promote transit across cell membranes-are clearly required before siRNAs can be used in therapy, especially to suppress gene expression in tissues other than in the liver. Nonetheless, the results of Song *et al*[23] have revealed the power of siRNAs in a disease model.

FACILITATING FUNCTIONAL GENOMICS

Until recently, RNA interference has been viewed primarily as a thorn in the side of plant molecular geneticists, limiting expression of transgenes and interfering with a number of applications that require consistent, high-level transgene expression. With our present understanding of the process, however, it is clear that RNA interference has enormous potential for engineering control of gene expression, as well as for a tool in functional genomics. It can be experimentally induced with high efficiency and targeted to a single specific gene or to a family of related genes. Likewise, dsRNA-induced TGS (transcriptional gene silencing) may have similar potential to control gene expression. Unwanted RNA interference, on the other hand, can be alleviated using viral suppressor technology or mutants impaired in silencing[28-30].

Genome-sequencing projects have provided tremendous amount of information about the genetic make-up of an organism. One way for finding out what genes do is to inactivate them, and to study the effects, in ' model' organisms. Kamath *et al*[4] used double-stranded RNAs to rapidly and transiently inactivate 16 757 of the worm' s predicted protein-coding genes. Meanwhile, Ashrafi and co-workers[31] have analysed these genes specifically to see if they had a role in regulating body fat. Together, their work has set a new standard

for systematic, genome-wide genetic studies. RNAi-based loss-of-function screens like these are tremendously powerful. Yet they have some disadvantages compared with classical genetic screening. For instance, some genes are more difficult to target by RNAi than others. And there are many non-coding RNAs, which are not translated into proteins. It remains to be seen if they are susceptible to RNAi. But there are still a vast number of protein-coding genes, from many different organisms, to study in detailed RNAi-based functional analyses, and this will keep the army of cell and molecular biologists busy for some time. Soon it will be possible to carry out RNAi-based screens in animal and human cells, using short synthetic double-stranded RNAs or plasmid- or virus-based DNA molecules that encode hairpin RNAs[32-34]. With the development of phenotypic read-outs based on cell biology, the hunt will begin.

SILENCING HIV-1

RNA interference represents an exciting new technology that may have therapeutic applications in the treatment of viral infections such as HCV and HIV. RNA interference is also found in HIV. Previous reports have shown that siRNA directed against the HIV genome can effectively inhibit virus production in cell-culture systems[35-38]. In addition, RNAi activity directed toward the major HIV receptor protein, CD4, led to decreased entry of HIV into cells[39-41]. However, replication of HIV occurred through an integrated DNA genome. Does it mean that RNAi is ineffective in clearing the virus? By targeting several regions of the HIV-1 genome, Jacque *et al*[42] showed that siRNA mediated viral genome degradation and caused downregulation of viral gene expression and they proved that RNAi worked even when the viral genome was contained within the nucleoprotein complex. They also showed that intracellularly made siRNA (transcribed from a plasmid) worked well, providing possible ways for delivering gene-therapy agents against HIV. To assess the effects of RNAi on HIV-1 infection, Novina *et al*[43] targeted both cellular and viral RNAs. The HeLa-derived cell line Magi-CCR5 (which expresses human CD4, and the chemokine receptors CCR5 and CXCR4) was transfected with short interfering RNA specific for the gene of interest and then infected with HIV-1. Cells transfected with siRNA specific for CD4 expressed CD4 mRNA at a level eight times lower than control cells, which led to a four-fold reduction in HIV-1 entry. Therefore, siRNA-directed silencing of CD4 specifically inhibited HIV entry and hence replication. Next, the viral structural protein Gag was targeted by transfecting cells with siRNA specific for the p24 component of this polyprotein. p24-siRNA-transfected cells showed a four-fold decrease in viral protein compared with controls, implying that viral amplification was inhibited by this approach. The authors also carried out transfection assays on human T cells, to assess the effect of RNAi on viral infectivity in a more physiological context. H9 cells were transfected with siRNA against green fluorescent protein (GFP) and were infected with an HIV-1 strain in which the *nef* gene was replaced with GFP. Again, silencing of viral gene expression occurred, resulting in reduced GFP and HIV-1 protein expression. These and other recent studies[44-46] show that siRNA can inhibit viral replication at several stages of infection, including very early stages, when viruses are most vulnerable. Infection can also be blocked by targeting either viral genes or host genes that are involved in the viral life cycle. It has been shown that siRNA directed against HIV-1 has the potential to be useful treatments. This study extended work by Lee *et al*[47,48] who used a vector-based RNAi strategy to silence an HIV-1 gene, and established that siRNA technology could be used to suppress multiple steps of the HIV-1 life cycle. They described a mammalian Pol III promoter system capable of expressing functional double-stranded siRNA following transfection into human cells. In the case of the 293 cells cotransfected with the HIV-1 pNL4-3 proviral DNA and the siRNA-producing constructs, they were able to achieve up to 4 logs of inhibition of expression from the HIV-1 DNA. Martinez *et al*[49] found that suppression of chemokine receptor expression by RNA interference could inhibit HIV-1 replication. Their results demonstrate that RNAi may be used to block HIV entry and replication through the blockade of cellular gene expression. Park *et al*[50] showed that HIV-1 replication was totally suppressed in a sequence-specific manner by six long dsRNAs containing the HIV-1 gag and env genes in HIV-1-infected cells. Especially, E2 dsRNA containing the major CD4-binding domain sequence of gp120, dramatically inhibited the expression of the HIV-1 p24 antigen in PBMCs for a relatively long time. Coburn *et al*[51] demonstrated that siRNA duplexes targeted against the essential Tat and Rev regulatory proteins encoded by HIV-1 could specifically block Tat and Rev expression and function. More importantly, they showed that these same siRNAs could effectively inhibit HIV-1 gene expression and replication in cell cultures, including those of human T-cell lines and primary lymphocytes. These results demonstrate the utility of RNAi for modulating the HIV replication cycle and provide the evidence that genomic HIV-1 RNA, existing within a nucleoprotein reverse-transcription complex, is amenable to siRNA-mediated degradation.

But does it actually work as an antiviral weapon? More recent studies have suggested that it does, at least in cells in culture dishes. Gitlin *et al*[12] reported that specific siRNA administered to human cells from the outside, like a drug, could enter them and protect them against infection by the rapidly multiplying poliovirus. Jacque *et al*[42], meanwhile, reported similar results in their studies with the AIDS virus HIV-1. These authors further demonstrated that if the siRNA were expressed from inside cells, rather than simply administered from the outside, the cells became largely immune to subsequent HIV-1 is infection. These results are exciting, and suggest that RNAi perfectly suitable to many antiviral applications. But one important factor is that not all viral RNA sequences are equally accessible to siRNA. Some sequences might be buried within secondary structures or within highly folded regions in target RNAs, whereas others might come form tight complexes with proteins that obscure their recognition. Optimal targets must be chosen by trial and error. Another issue is that viruses often produce mutated progeny molecules. Some of these naturally help the viruses escape immune surveillance or inhibition by drugs, but they might also prevent recognition by siRNA. To overcome this obstacle, one might need to target viral RNA sequences that are conserved and normally invariant between different strains, or to simultaneously target several viral sequences. Finally, the problem of how to deliver siRNA to cells needs to be addressed. They can certainly be delivered efficiently to cells in culture, but methods must be improved before RNAi can be used in animals, let alone patients.

FUTURE DIRECTIONS

The field of RNAi is moving at an impressive pace and generating exciting results that are clearly associated with RNA interference, transgene silencing and transposon mobilization[52-55]. Possible links to X-chromosome inactivation, imprinting and interferon response have also been suggested, but not yet firmly established. RNAi also has a considerable economic potential, especially in agriculture. A better understanding of PTGS should allow a more efficient response to viral infection and the development of transgene/host associations that can override silencing to allow the expression of interested proteins. Now that early mouse embryos are known to be susceptible to

RNAi, it will be critical to determine whether this technique can also be applied to tissue culture[56-60]. The possible repercussions of RNAi in mammals are potentially far-reaching in the fight against certain diseases such as cancer or virus/ parasite infection, as well as for the analysis of more fundamental problems in neurobiology and cell and developmental biology. In the next ten years, RNAi will probably be regarded as one of the major breakthroughs of the 2000s. A new report has shown that incubating a target mRNA with *Drosophila* embryonic extracts and the cognate dsRNA *in vitro* leads to its degradation in a process that recapitulates many of the features of RNA interference *in vivo* (including sequence specificity, length dependence and amplification). This important study has paved the way for a biochemical analysis of RNA interference. In relation to RNA interference in mammals, it is important to note that in contrast to the sequence-specific RNAi effect observed in mouse embryos, this new study has shown that incubation of an mRNA with rabbit reticulocyte lysates and dsRNA induces nonspecific mRNA degradation, one possible reason for this difference could be that the interferon response present in rabbit reticulocyte lysate is not functional in early mouse embryos[61-65].

Although antiviral RNAi technology has not yet been optimized, the phenomenon does appear to be both general and effective. In 1988, the concept of "intracellular immunization" was proposed, whereby one could express within cells inhibitory molecules (usually proteins) that could protect these cells from specific viral infections in the future[66-75]. The promise of intracellular immunization now appears to be closer to reality - although amazingly, through the use of small RNAs rather than peptides or proteins. The potential of using RNAi activity for the treatment of viral diseases and cancer has aroused a great deal of interests in the scientific community. Many laboratories have reported the use of RNAi activity in cultured cells infected with HIV, human papillomavirus, and polio or containing a variety of cancer genes. The clinical applications of RNA is just around the corner.

Abstract

AIM: To investigate expression of PTEN in gastric cancer and to explore its roles in tumorigenesis and progression of gastric cancer.

METHODS: Formalin-fixed and paraffin-embedded tissues of adjacent non-tumor mucosa and primary foci from 113 cases of gastric cancers were studied for the expression of PTEN and Caspase-3 and microvessel density (MVD) by streptavidin-peroxidase (S-P) immunohistochemistry with antibodies against PTEN, Caspase-3, and CD34. The relationship between PTEN and Caspase 3 expression and clinicopathological parameters of tumors was compared.

RESULTS: Primary gastric cancer cells expressed PTEN less frequently than adjacent epithelial cells of primary foci (54.9 % *vs* 89.4 %; P=0.000, χ^2=33.474). PTEN expression was significantly associated with invasive depth (P=0.003, rs=0.274), metastasis (P=0.036, rs=0.197), growth pattern (P=0.008, rs=0.282), Lauren's classification (P=0.000, rs=0.345), and histological classification (P=0.005, rs=0.262) of tumors, but not with tumor size (P=0.639, rs=0.045), Borrmann's classification (P=0.544, rs=0.070) or TNM staging (P=0.172, rs=0.129). PTEN expression was negatively correlated with MDV in primary gastric cancer (P=0.020, F=5.558). Primary gastric cancer cells showed less frequent immunoreactivity to Caspase-3 than adjacent epithelial cells of primary foci (32.7 % *vs* 50.4 %; P=0.007,χ^2=7.286). Caspase-3 expression was dependent of PTEN expression in primary gastric cancer cells (P=0.000, χ^2=15.266).

CONCLUSION: Down-regulated expression of PTEN plays an important role in tumorigenesis, progression, growth, differentiation and angiogenesis of gastric cancer. Low expression of PTEN can decrease expression of Caspase-3 to disorder apoptosis of tumor cells, which might explain the molecular mechanisms of PTEN contributions to tumorigenesis and progression of gastric cancer.

INTRODUCTION

Human suppressor gene, PTEN/MMAC1/TEP1 (phosphatase and tensin homology deleted from chromosome ten/mutated in multiple advanced cancer 1/TGF-β-regulated and epithelial cell enriched phosphatase 1), located on chromosome 10q23. 3 encodes a dual specific protein- phospholipid phosphatase that is involved in regulation of a variety of signal transduction pathways[1]. PTEN inhibits shc' s (src-homology collagen) phosphorylation following epidermal growth factor (EGF) stimulation and therefore blocks the activation of the Ras/MAP-kinase (MAPK) pathway[2]. Another mechanism that involves the protein phosphatase activity of PTEN is dephosphorylation and inactivation of focal adhesion kinase (FAK), thus playing a crucial role of PTEN in the interaction between extracellular matrix and cytoskeleton[3,4]. Besides its function as the protein phosphase, PTEN acts as a phospholipid phosphatase with phosphatidylinosiol 3,4,5-triphosphate (PIP_3) as a substrate[5-7]. Recently, many studies have shown that there are several putative mechanisms relating to tumor suppression as follows: inhibiting cell invasion and metastasis by dephosphorylating FAK, inhibiting cell apoptosis and increasing cell growth by dephosphorylating PIP_3, restraining cell differentiation by inhibiting MAPK signal pathway[5,8,9]. Mutation or abnormal expression of PTEN protein occurs commonly in multiple tumors and significantly correlates with tumorigenesis and progression of different malignancies[10-20]. It was reportedly suggested that deletion or mutation of PTEN could enhance the expression of vascular epithelial growth factor (VEGF) and matrix metalloproteinases (MMPs), which in turn closely correlated with tumor angiogenesis and metastasis[10-14]. Jones *et al*.[15] found that activation of PTEN signal pathway could reduce expression of Caspase-3, resulting in inhibition of cellular apoptosis.

Gastric cancer is one of the commonest malignancies in China, and even in the world. In patients with gastric cancer, the natural disease process consists of carcinogenesis, metastasis and eventual death. However, the molecular aspects of carcinogenesis and progression of gastric cancer remain elusive[16-18]. In the current study, we evaluated the expression of PTEN in adjacent epithelial cells, primary gastric cancer cells and intented to find if there was any correlation between its expression and clinicopathological features and microvessel density (MVD) of gastric cancer, as well as between PTEN and Caspase-3 expression in primary foci in order to clarify its role in tumorigenesis and progression of gastric cancer.

MATERIALS AND METHODS

Patients

One hundred and thirteen cases of surgically resected specimens of gastric cancer were collected from the Second Affiliated Hospital of China Medical University from Sept, 1997 to Feb, 2001, including 83 men and 30 women. Their age ranged from 26 to 83 years, with the mean age of 57.1 years. Among them, 38 tumors were accompanied by lymph node or organ metastasis. None of the patients had received radiotherapy or chemotherapy before operation.

Preparation of tissue samples

Adjacent mucosa and primary lesions of each case were fixed in 4 % formaldehyde solution, embedded in paraffin, incised into 4 μm sections and mounted on poly-lysine-coated slides. These sections were stained by hematoxylin-and-eosin method to confirm their histological diagnosis and other microscopic characteristics.

Evaluation of clinicopathological parameters

Clinical staging for each gastric carcinoma was evaluated according to the TNM system. Gross appearance of the tumors was described according to the Borrmann' s classification. Histomorphological architecture of the tumor samples was expressed on the basis of Lauren' s and Nakamura' s classifications. Growth patterns of gastric cancer were classified in the light of Zhang' s classification. Tumor diameter, invasive depth and metastasis were determined as well.

Immunohistochemistry

Representative and consecutive sections were studied with streptavidin-peroxidase immunohistochemistry (S-P kit from Zhongshan Biotech., China). Anti-PTEN, anti-CD34 and anti-Caspase-3 antibodies were purchased from Antibody Dignostica (USA), Zhongshan (China), and DAKO (Japan), respectively. All procedures were implemented according to the product recommendation. For negative controls, sections were processed as above but treated with PBS (0.01 mol/L, pH7.4) instead of primary antibodies.

Evaluation of PTEN and Caspase-3 immunostaining

The immunoreactivity to PTEN and Caspase-3 was localized in the cytoplasm. From 5 randomly selected representative fields of each section, two independent observers counted one hundred cells. According to the proportion of positive ones in counted cells, the degree of immunostaining was graded as follows: negative(-), ≤5 %; weakly positive (+), 5-25 %; moderately positive (++), 25-50 %; and strongly positive (+++), ≥50 %.

Microvessel density counting

Modified Weidner' s method was used to calculate MVD by anti-CD34 immunohistochemistry, which was described as follows. Microvessels in sclerotic areas within tumor, where microvessels were sparse and immediately adjacent areas of unaffected gastric tissue were considered as hot points in vessel counts. Observers selected five such areas and counted individual microvessels in a 400×field (i.e. 40×objective lens and 10×ocular lens, 0.1885 mm^2 per field). Any brown staining endothelial cell or endothelial cell cluster that was clearly separated from adjacent microvessel, tumor cells, and other connective tissue elements was considered as a single, countable microvessel. They must agree on what constituted a single microvessel.

Statistical analysis

Statistical evaluation was performed using chi-square test to compare the rates between different groups, using Spearman test to analyze the rank data, and using the one-way ANOVA to differentiate the means of different groups. $P<0.05$ was considered as statistically significant. SPSS 10.0 software was employed to analyze all data.

RESULTS

PTEN expression in adjacent epithelial cells and cancer cells of primary gastric cancer

Figures 1-3 show that PTEN was positively expressed in the nuclei of adjacent epithelial cells, lymphocytes and cancer cells of primary foci of gastric cancer. In this study, epithelial cells and cancer cells were immunostained for PTEN protein in 89.4 % and 54.9 % of the tumors, respectively. There was a significant difference between them ($P<0.05$) (Table 1).

Table 1 PTEN expression in adjacent epithelial cells and cancer cells of primary gastric cancer

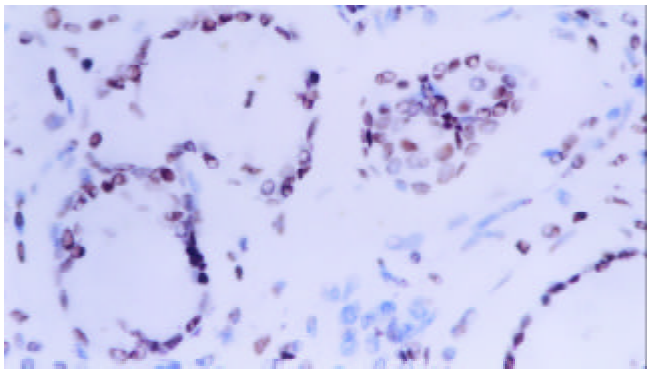

Figure 1 PTEN was immunostained in cell nuclear. It was strongly expressed in gastric epithelial cells (+++) (S-P, ×400).

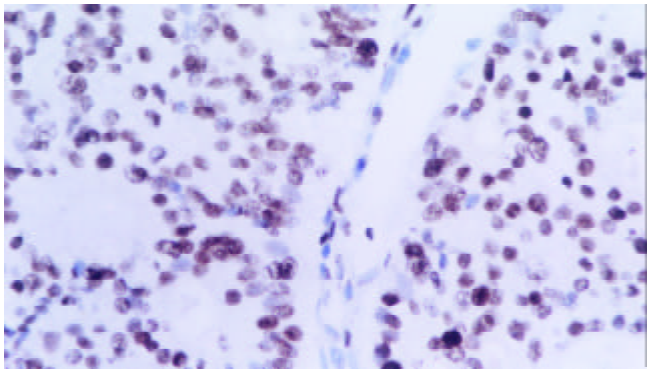

Figure 2 PTEN was strongly expressed in gastric well-differentiated adenocarcinoma (+++) (S-P, ×400).

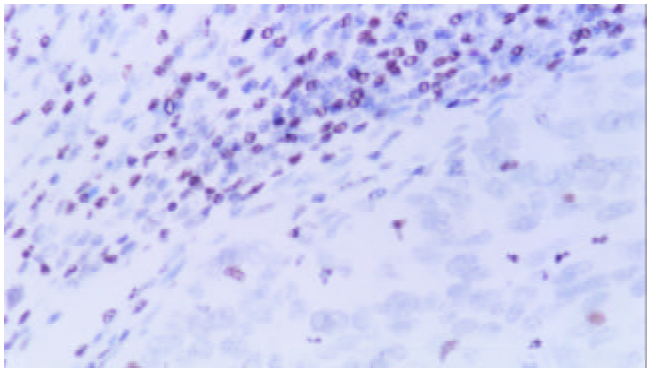

Figure 3 PTEN was negatively expressed in poorly-differentiated adenocarcinoma cells (-) and tumor infiltrated lymphocytes showed strong expression of PTEN (+++) (S-P, ×400).

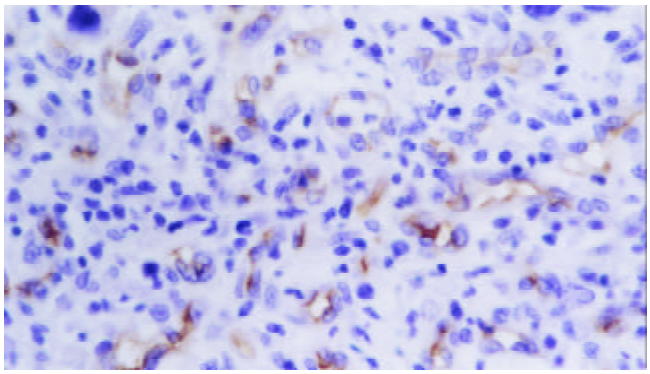

Figure 4 CD34 was located in cytoplasm and cellular membrane of vascular endothelial cells (S-P, ×400).

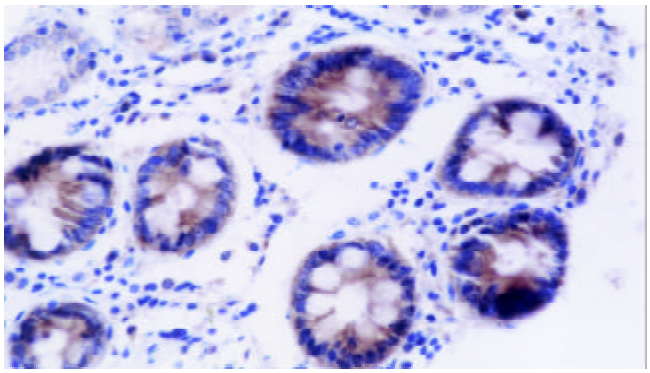

Figure 5 Caspase-3 was distributed in cytoplasm. Caspase-3 was strongly expressed in gastric epithelial cells (+++) (S-P,×400).

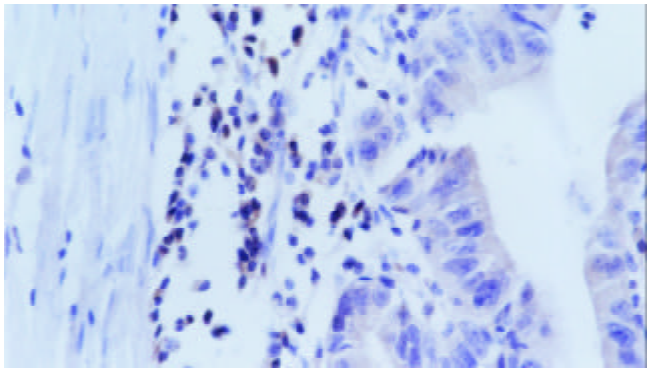

Figure 6 Caspase-3 was positively expressed in well-differentiated adenocarcinoma of stomach (++), and strongly in tumor infiltrated lymphocytes (+++) (S-P, ×400).

Correlation between PTEN expression in primary cancer cells and clinicopathological features of gastric cancer

PTEN expression in primary cancer cells was significantly associated with invasive depth, metastasis, growth pattern, Lauren's Classification, and histological classification of gastric cancer ($P<0.05$). There was no close correlation between PTEN expression and tumor size, Borrmann's Classification or TNM staging ($P>0.05$). One ANOVA analysis showed PTEN expression was negatively correlated with MDV in primary gastric cancer ($P<0.05$) (Tables 2-3, Figure 4).

Table 3 Relationship between expression of PTEN expression and MVD in primary gastric cancer

PTEN expression	*n*	MVD (mean± standard error)	*F* value	*P* value

Notes: PR: positive rate. [a]$P=0.000$ ($\chi^2=15.266$, Pearson's R=0.368).

Relationship between PTEN and Caspase-3 expression in primary gastric cancer cells

Figures 5-6 showed positive immunostaining of Caspase-3 in

the cytoplasm of adjacent epithelial cells, infiltrating lymphocytes, and cancer cells of primary gastric cancer. Cancer cells showed less frequent immunoreactivity to Caspase-3 than adjacent epithelial cells (32.7 % *vs* 50.4 %; $P<0.05$). Moreover, Caspase-3 expression was dependent of PTEN expression in primary gastric cancer cells ($P<0.05$) (Table 4).

DISCUSSION

Deletion or down-regulation of tumor suppressing genes plays an important role in the multiple steps of tumorigenesis and progression of gastric cancer. PTEN, a tumor-suppressing gene, makes a great contribution to cellular differentiation, reproduction and apoptosis, as well as cellular adhesion and mobility[8,9]. Some studies showed down-regulation of PTEN protein expression was due to genetic changes such as mutation, loss of heterozygosity, hypermethylation in gastric cancer, prostate cancer and breast cancer[19-21]. Our results showed that expression of PTEN decreased in primary gastric cancer cells, compared with that in adjacent epithelial cells. This revealed that genetic changes of PTEN gene could play an important role in malignant transition of gastric epithelial cells.

Low expression of PTEN gene product was involved in clinicopathological stage and metastasis of various malignancies. We found that the positive rate of PTEN was lower in gastric cancer with metastasis than that without metastasis. Additionally, the positive rate of PTEN expression tended to decrease with increase of invasive depth. These results were similar to other kinds of tumors[22-29]. Mass-type gastric cancer showed more expression of PTEN than nest-type one, the latter more than diffuse-type one, demonstrating that PTEN expression was implicated in the growth pattern of gastric cancer. These results suggest that deletion or reduced expression of PTEN protein probably facilitates the invasive and metastatic ability of gastric cancer cells. Several studies revealed that PTEN could enhance mobility and metastasis of tumor cells by regulating MMPs and VEGF[10-14]. There was another report that PTEN dephosphorylated FAK so as to be involved in cellular adhesion[30]. Deletion or reduced expression of PTEN could result in decreased cellular adhesion, increased synthesis of MMPs and VEGF, which subsequently contributed to invasion and angiogenesis of tumor tissues. These biological effects possibly underlay the prelude of invasion and metastasis of tumor. Our results revealed that reduced expression of PTEN was implicated in progression of gastric cancer probably by decreased cellular adhesion, increased cellular mobility and angiogenesis, and could act as an objective and effective marker to reflect the pathobiological behaviors of gastric cancer.

In addition, undifferentiated carcinomas showed the lower expression of PTEN than differentiated ones, suggesting that down-regulated expression of PTEN was closely associated with differentiation of gastric cancer. Diffuse-type gastric cancer showed fewer expression of PTEN than intestinal-type one. It supported that there were different tumorigenetic pathways between diffuse- and intestinal-type gastric cancer. Diffuse-type gastric cancer, the main part of which was undifferentiated, showed diffusely invasive growth pattern. It was possible that down-regulation of PTEN expression could influence the function of cellular skeleton, mobility and adhesion of cancer cells.

Angiogenesis was necessary for tumor growth, invasion and metastasis, and tumor-host interaction induced several sorts of tumor angiogenetic factors such as VEGF and MMPs to stimulate the intratumoral and peritumoral neovascularization[31,32]. In this study, we found that mean MVD was negatively related to PTEN expression in primary gastric cancer. Huang *et al.*[12] found that inhibition of endogenous endothelial PTEN by adenovirus-mediated over-expression of a dominant negative PTEN mutant in cultured endothelial cells potently enhanced a variety of VEGF-mediated cellular responses by PIP_3-kinase signaling, including cell survival, mitogenesis, and migration. In contrast, these effects of VEGF were significantly inhibited by over-expression of wild-type PTEN. Moreover, overexpression of wild-type PTEN modulated endothelial tube formation *in vitro* and vascular sprouting in an *ex vivo* model of angiogenesis. On the other hand, decreased and loss of expression of wild-type PTEN would facilitate MMPs expression which played an important role in angiogenic processes, including proliferation of endothelial cells, breakdown of the extracellular matrix and endothelial cell migration[33]. These *in vivo and in vitro* observations suggested that down-regulated expression of PTEN in gastric cancer increased angiogenesis by up-regulating VEGF and MMPs.

Some investigators found that PTEN could promote cell apoptosis, which in turn inhibited tumor growth[34]. Additionally Caspase-3 played an important role in apoptosis as an effector. Krajewska *et al.*[35] delineated for the first time some of the *in vivo* patterns of Caspase-3 expression in human tissues. Their observation that Caspase-3 was detectable in almost all types of cell implied its role in the regulation of cell life and death in a variety of types of cells as a proteinase. Our finding showed that Caspase-3 was less frequently expressed in gastric cancer cells than in adjacent epithelial cells. In addition, our study showed that expression of PTEN was positively correlated with expression of Caspase-3 in primary gastric cancer cells. Schwartzbauer *et al.*[36] found increased PTEN expression by recombinant adenovirus in cultured neonatal rat primary cardiomyocytes caused cardiomyocyte apoptosis as evidenced by increased caspase-3 activity and cleaved poly (A) DP-ribose polymerase. Furthermore, several studies suggested PTEN could enhance Fas/FasL-mediated or cytochrome-c-mediated apoptosis, whose apoptotic pathway evoked Caspase-3[34,37]. Consequently, we could infer that low expression of PTEN could decrease expression of Caspase-3 to make tumor cells apoptosis dysfunction, which underlay the theoretic basis of contribution of PTEN to tumorigenesis and progression of gastric cancer.

In conclusion, expression of PTEN and Caspase-3 is down-regulated in tumorigenesis of gastric cancer. Decreased expression of PTEN is implicated in progression of gastric cancer by decreased cell adhesion and increased angiogenesis and cell mobility. Moreover, low expression of PTEN can reduce expression of Caspase-3 to make tumor cells apoptosis disorder, which forms molecular mechanisms of PTEN contribution to tumorigenesis and progression of gastric cancer. However, a further study is necessary to directly clarify regulatory roles of PTEN and MMP-7 expression in angiogenesis of gastric cancer.

Abstract

AIM: To characterize enhancement patterns of focal hepatic lesions using C-cube gray scale sonography with a microbubble contrast agent and to evaluate its usefulness in differential diagnosis of hepatic lesions.

METHODS: Fifty-four patients with 58 focal hepatic lesions were examined with Levovist-enhanced C-cube gray scale sonography. The final diagnosis of hepatic lesions was 29 primary liver cancers, 4 metastases, 8 hemangiomas, 12 focal nodular hyperplasias, 2 inflammatory pseudotumors of the liver and 3 angiomyolipomas. The initiation time of enhancement in various lesions and enhancement duration after administration of contrast agent were compared. Vascular findings in lesions were classified as peripheral enhancement, homogenous enhancement, mosaic enhancement and no enhancement depending on microbubble signals in the lesion relative to the liver parenchyma.

RESULTS: The initiation time of enhancement in hemangioma (48±12 s) was significantly later compared to other lesions ($P<0.05$). The enhancement duration of malignancies (69±33 s in primary liver cancer, 61±23 s in metastasis) was significantly shorter compared to benign lesions ($P<0.05$). Intranodular enhancement appearing at arterial phase and decreasing at portal venous phase was considered characteristic for malignancy. Intranodular enhancement did not appear earlier than the liver parenchyma, and peripheral enhancement pattern was regarded as positive findings for hemangioma. Intranodular enhancement appeared in the arterial phase, and homogenous enhancement pattern sustained in the whole portal venous phase were regarded as positive findings for focal nodular hyperplasia. No microbubble signals appeared in two inflammatory pseudotumors of the liver.

CONCLUSION: C-cube gray scale sonography can demonstrate dynamic intranodular enhancement in various focal hepatic lesions. The information provided by this methodology may be useful in the differential diagnosis of hepatic lesions.

INTRODUCTION

Color Doppler ultrasonography (US) is the most widely used imaging modality in screening detection of hepatic tumors and differential diagnosis of malignancies based on tumor vascularity. Unfortunately, conventional Doppler US does not provide satisfactory results in the evaluation of tumor vascularity because of limitations such as a lack of sensitivity to slow flow and deeply located flow, inevitable motion artifacts from either respiratory or cardiac activity, and poor showing of tumor stain.

Over the past decade, great efforts have been made to improve both ultrasound instruments and echo-enhancing agents to demonstrate tumor flow more sensitively with non-invasive modalities. Harmonic imaging is a newly developed technique used with microbubble contrast agents that interact with the imaging process. The microbubbles reflect ultrasonic echoes with a low acoustic power, additionally, they resonant and emit multiple frequencies when acoustic power is sufficiently elevated[1]. Second harmonic imaging, which transmits sonographic pulses at one frequency and then selectively receives echoes at twice that frequency, has been shown to be excellent in eliminating clutter noises and displaying the slower blood flow in smaller vessels when compared to conventional Doppler US[2-5].

However, the intensity of second harmonic frequency of some microbubble contrast agents (e.g., Levovist) is lower than that of fundamental ones[1, 6]. In addition to second harmonics, the microbubbles emit multiple frequencies such as subharmonic, ultraharmonic, etc. Recently, a commercially available C-cube gray scale US (C^3-Mode™, Esaote Biomedica, Genoa, Italy) technique uses comparative digital decorrelation and a digital adaptive band pass filtering process, providing a combination of gray scale, Doppler and contrast signals. It utilizes the signal coming from the microbubbles with not only the second harmonics, but also the fundamental, sub- and ultra-harmonics from the contrast agent. Therefore, this new technique might be able to provide increased sensitivity in demonstrating slow blood flow in focal liver lesions with good spatial resolution in comparison to contrast-enhanced conventional US or second harmonic imaging.

The purpose of this study was to characterize enhancement patterns in focal hepatic lesions with contrast-enhanced C-cube gray scale US.

MATERIALS AND METHODS

Subjects

Between October 2001 and March 2002, 54 patients with clinically and histopathologically diagnosed hepatic tumors who were referred for hepatic color Doppler US were examined with C-cube gray scale US in combination with a microbubble contrast agent. All the patients gave fully informed consent for the study that had received approval from our institutional review board.

The patients consisted of 31 men and 23 women aged between 20-68 years (mean, 47 years). Contrast-enhanced C-cube gray scale US was performed 2-3 days before treatment. In patients with multiple lesions, the largest one was selected for contrast

study except 4 patients with different types of hepatic lesions. Therefore, a total of 58 hepatic lesions were studied with contrast agents. They were 29 cases of primary liver cancer (PLC) (hepatocellular carcinoma, HCC, 27; cholangiocarcinoma, 2), 8 of hemangiomas, 12 of focal nodular hyperplasias (FNH), 2 of inflammatory pseudotumors of the liver (IPT), 3 of angiomyolipomas, and 4 of metastases (gastric cancer, 1; breast cancer, 2; nasopharyngeal carcinoma, 1). Histopathological diagnosis was obtained by surgical resection or US-guided percutaneous biopsy in all the 33 malignancies, 3 hemangiomas, 7 FNHs, 2 IPTs and 3 angiomyolipomas. Other 5 hemangiomas and 5 FNHs were diagnosed according to the typical imaging findings on contrast-enhanced computed tomography (CT), magnetic resonance imaging, as well as clinical follow-up which showed no change of lesion size for more than one year.

The maximal diameters of the 58 hepatic lesions measured on conventional US were as follows: PLC, 1.1-8.2 cm (mean, 3.3 cm); metastasis, 2.2-3.5 cm (mean, 2.8 cm); hemangioma, 1.0-8.0 cm (mean, 5.5 cm); FNH, 1.1-7.3 cm (mean, 4.5 cm); angiomyolipoma, 2.4-7.3 cm (mean, 6.3 cm) and IPT, 1.7-4.1 cm (mean, 2.9 cm).

Contrast agent

The contrast agent was Levovist (Schering AG, Berlin, Germany), which is a suspension of monosaccharide microparticles (galactose) in sterile water. Microbubbles were stabilized in the microparticle suspension with an average diameter of 1.3 μm, which could traverse the pulmonary capillary bed and enhance the signal of blood. Before US examination, the agent was prepared with 5 mL of water by shaking vigorously for 5-10 s. After standing for 2 min for equilibration, a total of 2.5 g Levovist (6 mL 400 mg/mL concentration) was injected manually through a 20-gauge canula placed in an antecubital vein at a speed of 1 mL/s and flushed by an additional 5 mL of normal saline.

Imaging

Contrast-enhanced C-cube gray scale US was performed with a commercially available US system, Technos DU6 US system (Esaote Biomedica, Genoa, Italy), equipped with C^3-Mode™ technology. A convex-arrayed wide band transducer CA 421 was used at a frequency of 2-5 MHz. There were two states in contrast examination: LOW state and C^3-Mode state. At the LOW state, the system transmitted pulses at a low acoustic power with a mechanical index of 0.2-0.4 that theoretically would not destroy microbubbles. At C^3-Mode state, the system transmitted pulses at a high acoustic power with a mechanical index of 1.0-1.4 to destroy microbubbles in the scanning plane. We could transfer from the LOW state to the C^3-Mode state by simply pressing a keyboard button to obtain signals of microbubble collapse, and the system automatically returned to the LOW state then.

Conventional US was performed on all lesions before contrast-enhanced study started. An ideal plane was selected for clearly showing the lesion and the surrounding liver parenchyma. Following administration of Levovist, we monitored the same scanning plane using LOW state and obtained a series of C^3-Mode images by pressing the key button manually for 7-8 minutes. During 15-120 s after injection of Levovist, we obtained C^3-Mode images of high mechanical index every 5-10 s. After that (121-480 s after injection of Levovist), we obtained C^3-Mode images every 20-30 s. During the entire scanning procedure, we held the transducer and unfroze it during the same stage of the patient's respiration to maintain the same scanning plane. The time delay between the initiation of contrast injection and the time at which the C^3-Mode image obtained was automatically recorded on the US system.

Analysis

All US images were recorded on digital videotapes and still images were stored digitally on a hard disk in the US system. Videotapes and still images were reviewed by two authors who were unaware of the findings on other imaging modalities and the final diagnosis of the lesions.

The time of occurrence of microbubble signals in the lesion and in surrounding liver parenchyma after administration of Levovist (injection-enhancement delay time), and subsequent time of microbubble signals decreased in the lesion on C^3-Mode images (injection-decrease delay time) were carefully recorded. Enhancement decrease in a lesion was defined as the echogenicity lower in the lesion than that in the same-depth of surrounding liver parenchyma. In this way, we calculated enhancement duration of various lesions.

The entire procedure of contrast-enhanced C-cube gray scale US was classified into three phases. As vascular transit time of blood through the liver was associated with liver diseases, such as hepatic cirrhosis[7-9], we modified the scheme that Kim *et al*[10] used on dynamic CT. Arterial phase prior to the enhancement appeared in the liver parenchyma, approximately 15-50 s after administration of Levovist, and portal venous phase appeared 51-120 s after administration of Levovist, and delayed phase appeared 121 s after administration of Levovist.

Based on the enhancement of microbubble signals in the lesion relative to the surrounding liver parenchyma, vascular findings in lesions on C^3-Mode images in the arterial phase were classified as peripheral enhancement (continuous or discontinuous ring enhancement occurred in the periphery of the lesion), homogenous enhancement (enhancement occurred in the whole lesion), mosaic enhancement (enhancement occurred in some area of the lesion), and no enhancement (no microbubble signal occurred in the lesion while enhancement in the liver parenchyma occurred). All the enhancement patterns including peripheral, homogenous and mosaic enhancements were defined as positive enhancement, namely positive detection of intranodular vascularity.

All the data were normal distribution and homogeneity of variance after tested. The data were analyzed using SAS (SAS 6.04 for windows). Continuous variables were compared by means of independent *t*-test. Categorical data were analyzed with chi square test. A P value <0.05 was considered to be significant.

RESULTS

The detection rate of intranodular vascularity was 96.6 % (56/58) on C-cube gray scale US with administration of Levovist. All PLCs, metastases, hemangiomas, FNHs, and angiomyolipomas presented positive enhancement. No microbubble signals appeared in the lesions of IPT, resulting in a vascular defect when liver parenchymal perfusion was observed on C-cube gray scale US.

The initiation time of microbubble enhancement in various lesions and in the surrounding liver parenchyma after administration of Levovist, as well as enhancement duration of various lesions are listed in Table 1. Except hemangioma, all other lesions enhanced earlier than the liver parenchyma. The initiation time of enhancement in hemangioma (48±12 s after administration of Levovist) was significantly later when compared to other lesions ($P<0.05$). The enhancement in HCC (Figure 1), cholangiocarcinoma (Figure 2), and metastasis (Figure 3) decreased more rapidly when compared to benign liver lesions. The enhancement duration of malignancies (69±33 s in PLC, 59±22 s in metastasis, respectively) was significantly shorter when compared to benign liver lesions ($P<0.05$).

If the intranodular enhancement appeared at arterial phase

and enhancement decreased at portal venous phase in a lesion was considered characteristic for malignancy, the sensitivity, specificity and positive predictive values for contrast-enhanced C-cube gray scale US to differentiate malignancies from benign liver lesions were 90.9 % (30/33), 92.0 % (23/25), and 93.8 % (30/32), respectively.

Vascular findings in all lesions at the arterial phase on contrast-enhanced C-cube gray scale US are shown in Table 2. Peripheral enhancement was detected in 50.0 % (2/4) of metastases and 87.5 % (7/8) of hemangiomas, homogenous enhancement in 55.2 % (16/29) of PLCs, 100 % (12/12) of FNHs, and mosaic enhancement in 41.4 % (12/29) of PLCs, and 66.7 % (2/3) of angiomyolipomas.

With respect to the enhancement patterns on contrast-enhanced C-cube gray scale US, no specific enhancement pattern was found among malignancies. For benign liver lesions, however, the enhancement patterns were specific. After administration of Levovist, hemangioma enhanced later than the liver parenchyma, and peripheral enhancement was obtained in most hemangiomas (Figure 4). All FNHs enhanced earlier than the liver parenchyma and presented homogenous enhancement (Figure 5). Most angiomyolipomas enhanced early and showed mosaic enhancement pattern (Figure 6).

If the intranodular enhancement did not appear earlier than the surrounding liver parenchyma after administration of Levovist, and the peripheral enhancement patterns were regarded as positive findings for hemangioma, the sensitivity, specificity and positive predictive values were 87.5 % (7/8), 94.0 % (47/50) and 70.0 % (7/10), respectively.

If the intranodular enhancement appeared in the arterial phase, and the homogenous enhancement pattern sustained in the whole portal venous phase were regarded as positive findings for FNH, the sensitivity, specificity and positive predictive values were 100 % (12/12), 95.7 % (44/46) and 85.7 % (12/14), respectively.

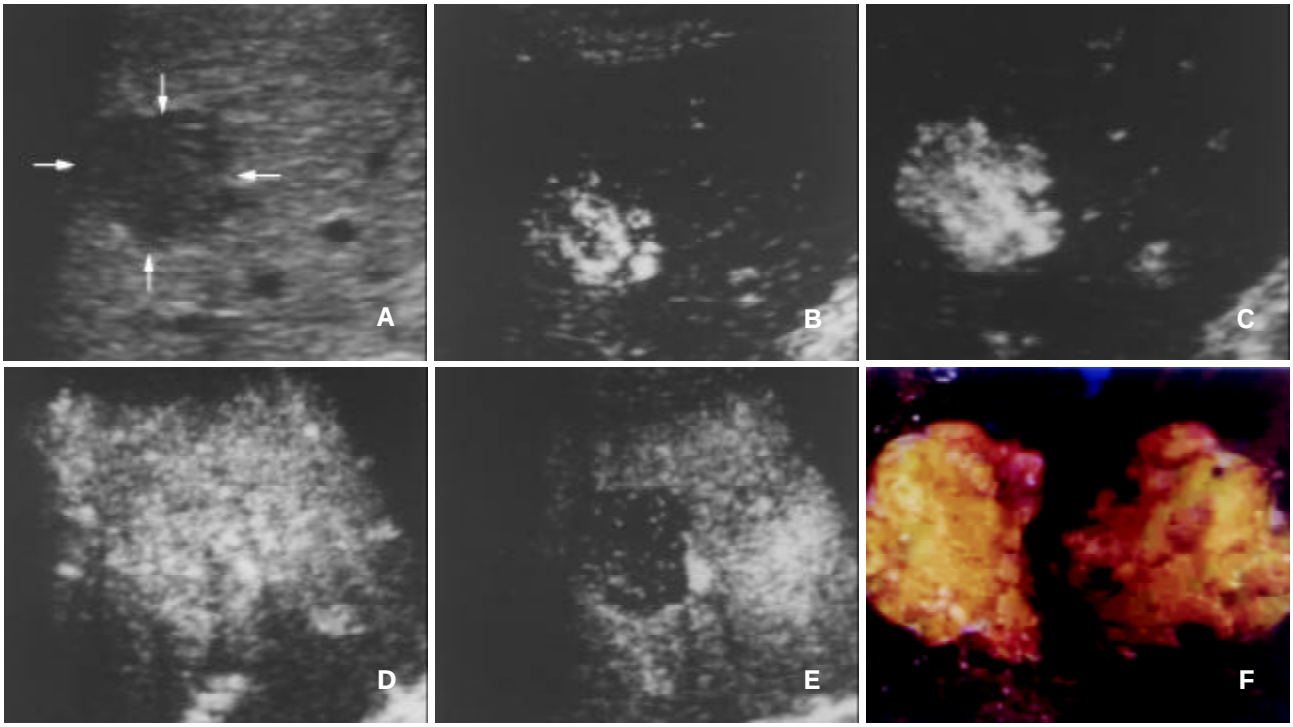

Figure 1 A 47-year-old man with hepatocellular carcinoma. A. Intercostal precontrast conventional sonography exhibits a hypoechogenic lesion (arrows) of 2.7 cm in diameter. B-E. Contrast-enhanced C-cube gray scale sonography at 23 s (B), 28 s (C) and 43 s (D) after injection of Levovist shows that intranodular signals enhance gradually and earlier than the liver parenchyma, and enhancement decreases rapidly in the portal venous phase (110 s, E). This suggests hypervascularity of hepatocellular carcinoma with an early enhancement and early wash-out of contrast. F. Gross specimen of the resected tumor exhibits a gray fish-like profile and suggests the typical appearance of hepatocellular carcinoma.

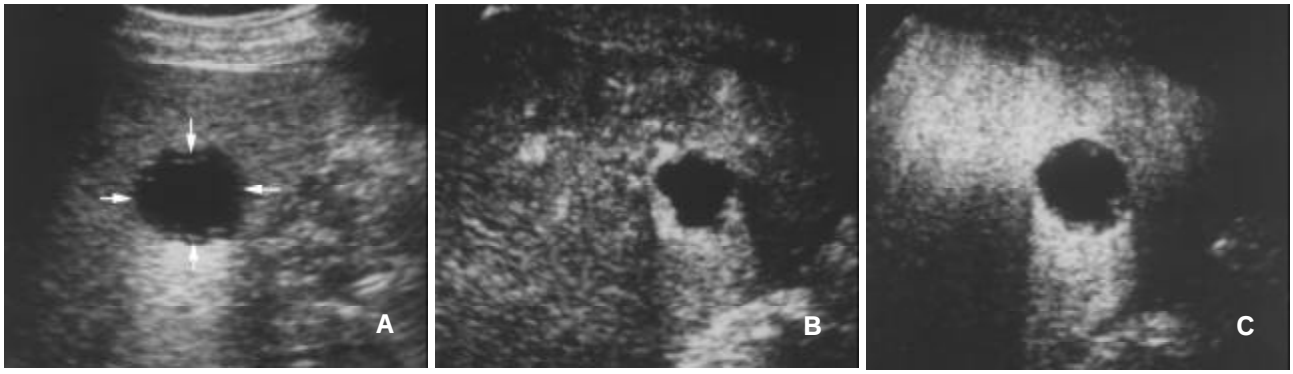

Figure 2 A 48-year-old man with metastasis of nasopharyngeal carcinoma. A. Intercostal section of precontrast conventional sonography exhibits a hypoechogenic lesion (arrows) with a diameter of 3.5 cm. B. Contrast-enhanced C-cube gray scale sonography at 24 s after injection of Levovist shows that peripheral enhancement appears at the same time with the liver parenchyma. C. Intranodular enhancement decreases at 107 s in the portal venous phase, earlier than that in the liver parenchyma.

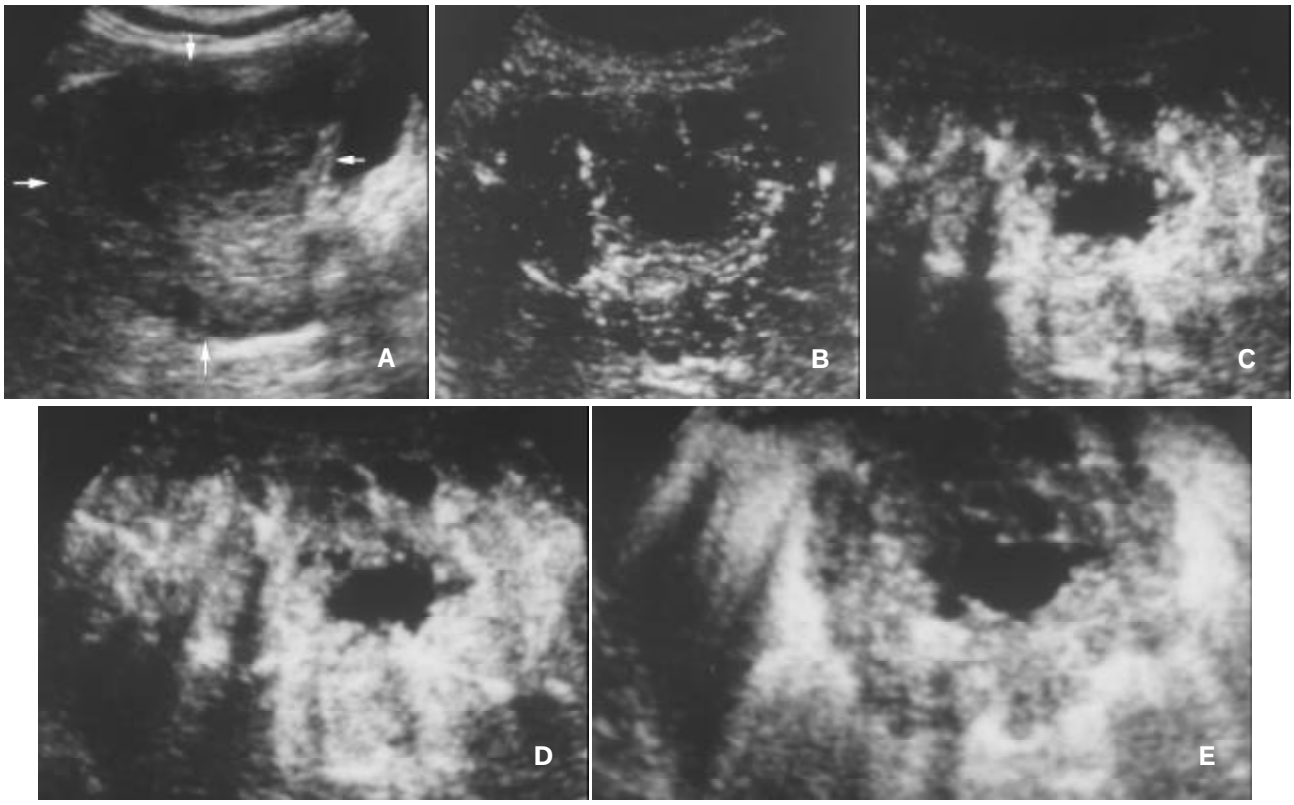

Figure 3 A 62-year-old woman with cholangiocarcinoma. A. Subcostal section of precontrast conventional sonography shows a hypoechogenic lesion (arrows) in segment V of the liver with a diameter of 8.0 cm. B-E. Contrast-enhanced C-cube gray scale sonography at 16 s (B), 20 s (C) and 25 s (D) after injection of Levovist shows that intranodular signals enhance gradually and earlier than the liver parenchyma, and enhancement decreases rapidly in the portal venous phase (78 s, E). Histopathology of US-guided percutaneous biopsy reveals cholangiocarcinoma of the liver.

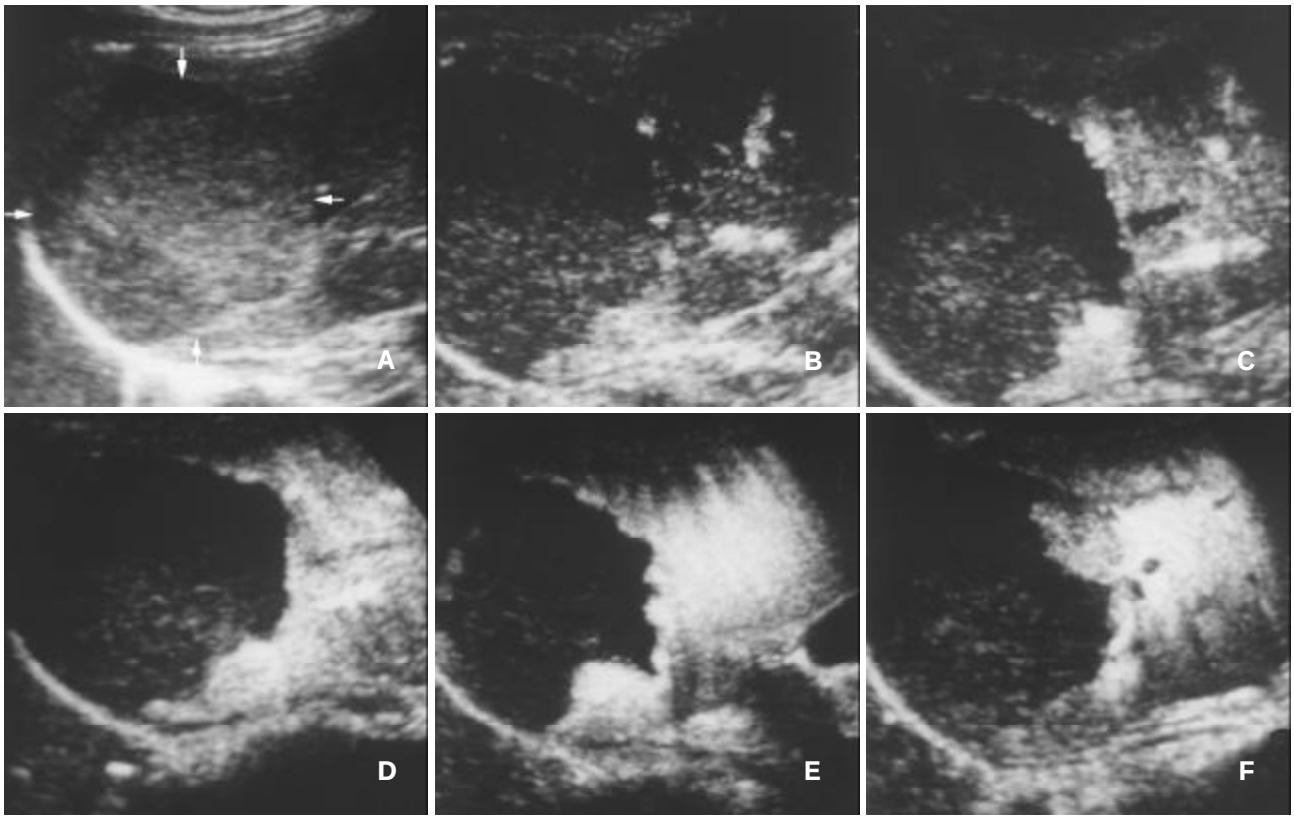

Figure 4 A 45-year-old female with hemangioma. A. Intercostal section of precontrast conventional sonography exhibits a hypoechogenic lesion (arrows) of 6.5 cm in diameter. B. Contrast-enhanced C-cube gray scale sonography at 23 s (B) after injection of Levovist shows that no microbubble signal appears in the lesion while enhancement in the liver parenchyma begins. C-F. C-cube gray scale sonography demonstrates gradual peripheral enhancement at 32 s (C), 47 s (D), 113 s (E) and 370 s (F) with a long enhancement duration.

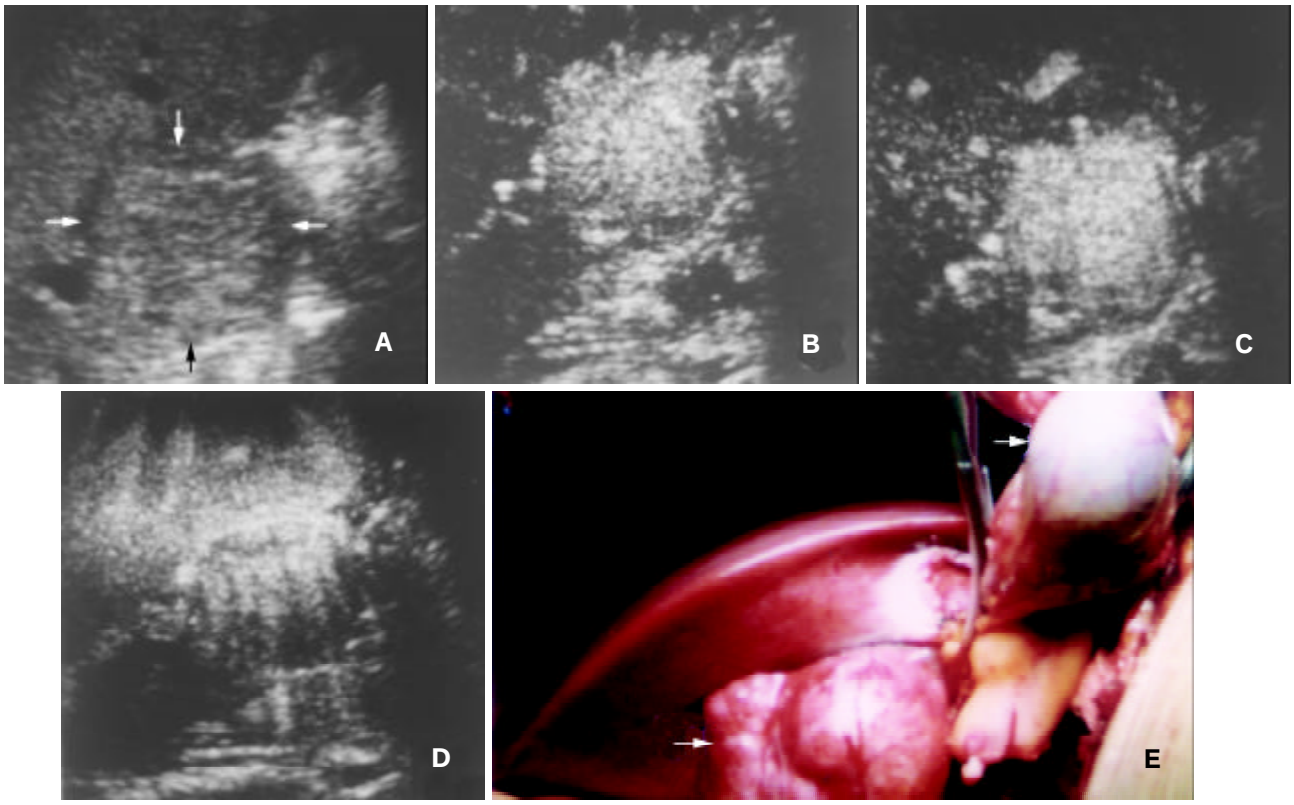

Figure 5 A 29-year-old man with focal nodular hyperplasia. A. Intercostal section of precontrast conventional sonography exhibits an isoechoic lesion (arrows) in segment V of the liver with a diameter of 4.8 cm. B-D. Contrast-enhanced C-cube gray scale sonography at 49 s (B) and 60 s (C) after injection of Levovist shows that intranodular signals enhance earlier than the liver parenchyma, and enhancement sustains in the portal venous phase until the delayed phase (140 s, D), suggestive of slow wash-out of contrast in the lesion. E. Appearance of the lesion and its surrounding organs in laparotomy. The lesion (arrow) protrudes from the liver with a smooth capsule while the gallbladder (arrowhead) is lifted with hemostatic forceps. Histopathology of the tumor revealed focal nodular hyperplasia.

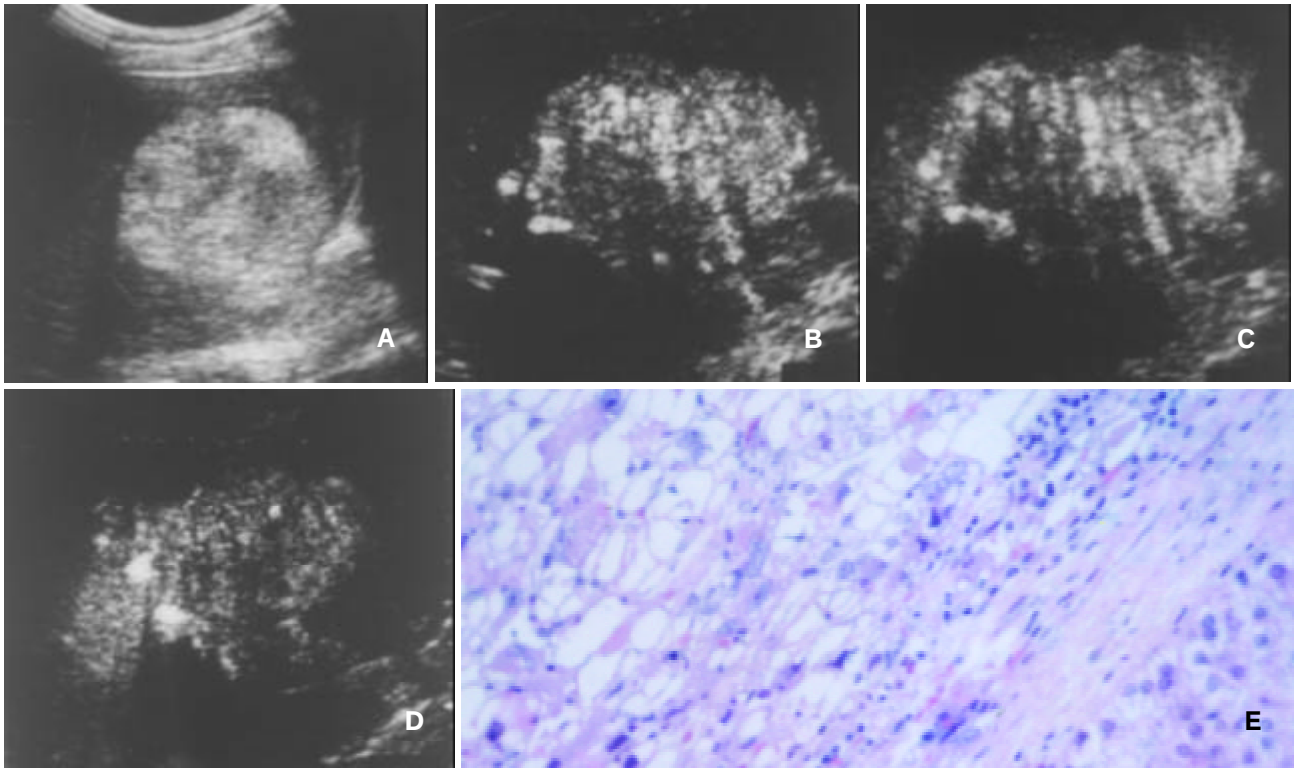

Figure 6 A 51-year-old female with angiomyolipoma. A. Subcostal section of precontrast conventional sonography exhibits a hyperechogenic lesion of 7.3 cm in diameter. B-D. Contrast-enhanced C-cube gray scale sonography at 54 s (B) and 110 s (C) after injection of Levovist shows that intranodular signals enhance earlier than the liver parenchyma with an inhomogenous enhancement pattern, and enhancement decreases in the delayed phase (206 s, D). E. Photomicrography shows defuse sheets of adipocytes and muscle cells adjacent to the noncirrhotic liver tissue, presenting a typical appearance of angiomyolipoma (HE 400).

Table 1 Hemodynamics of focal hepatic lesions on contrast-enhanced C-cube gray scale ultrasonography

Types of lesion	No. of lesions	Injection-enhancement delay time (mean±SD) (s)			Enhancement duration (mean±SD) (s)	
		Liver	Lesion	*P* Value	Lesion	*P* Value
Primary liver cancer	29	33±10	23±6	<0.05	69±33[b]	–
Metastasis	4	26±7	26±11	<0.05	59±22[c]	–
Hemangioma	8	36±8	48±12[a]	–	221±47	<0.05
Focal nodular hyperplasia	12	29±9	20±6	<0.05	196±96	<0.05
Angiomyolipoma	3	37±12	26±6	<0.05	177±90	<0.05

[a]The injection-enhancement delay time after administration of Levovist in hemangioma was significantly longer than that in other types of lesions ($P<0.05$). [b]The enhancement duration in primary liver cancer was significantly shorter than that in benign lesions ($P<0.05$). [c]The enhancement duration in metastasis was significantly shorter than that in benign lesions ($P<0.05$).

Table 2 Enhancement patterns of focal liver lesions in the arterial phase on contrast-enhanced C-cube gray scale ultrasonography

Enhancement patterns	Peripheral	Homogenous	Mosaic	Negative	Total
Primary liver cancer	1	16	12	0	29
Metastasis	2	0	2	0	4
Hemangioma	7	0	1	0	8
Focal nodular hyperplasia	0	12	0	0	12
Angiomyolipoma	0	1	2	0	3
Inflammatory pseudotumor	0	0	0	2	2
Total	10	29	17	2	58

Note: Values are number of lesions.

DISCUSSION

The characterization of focal liver lesions depends closely on their specific intranodular hemodynamics[11-14]. Various imaging modalities have been studied for demonstrating the typical vasculature of focal liver lesions. Contrast-enhanced US may be especially promising for depicting intranodular vascularity not only because of its easy performance, but also because of its particular advantages of providing dynamic flow information on a tomographic plane basis[4, 15, 16].

Levovist is the most widely used microbubble contrast agent for intravenous administration in the clinical setting. The backscatter signals caused by vibration or disruption of the microbubbles are received and used for image formation. Interval delay imaging or intermittent harmonic imaging[4, 16-19], which transmits an ultrasound beam with a flexible interval, destroys most of the microbubbles in a region of interest with high acoustic power, and permits refreshment of microbubbles in the scanning plane during the low acoustic power period due to fresh blood inflow. C-cube gray scale US is a newly available technique using interval delay scanning to destroy microbubbles in the scanning plane. With the help of the low acoustic power image on LOW state, we could obtain intranodular capillary flow signals on the same sonographic scanning plane. Moreover, a series of C^3-Mode images with microbubbles collapse provide dynamic information of enhancement patterns of focal liver lesions. Therefore, we could continuously observe the lesion of interest from the arterial phase to the delayed phase. The detailed enhancement process of each lesion could be obtained just as a single-level dynamic CT study[20]. In the present study, positive enhancement was detected in all focal liver lesions except for two IPT with complete necrosis. No false negative nodule was found on contrast-enhanced C-cube gray scale US.

The blood of normal liver is supplied both by the portal vein and by the hepatic artery, whereas the blood of most neoplastic tumors of the liver are supplied by the hepatic artery. The typical vascular patterns of PLC are high velocity signals on color Doppler US[21, 22], and high attenuation at the early phase and low attenuation at the portal venous phase relative to the liver parenchyma on dynamic CT[23]. In this study, the injection-enhancement delay time of PLC was shorter than that of the liver parenchyma after administration of Levovist, presenting an early enhancement at the arterial phase. As the portal venous phase arrived, the concentration of microbubbles in the hepatic artery decreased. We recorded the injection-decrease delay time of various focal liver lesions and found that the injection-decrease delay time of PLC was relatively shorter compared to benign liver lesions. The difference of enhancement duration between PLC and benign liver lesions was statistically significant ($P<0.05$). The hemodynamics of PLC was that, namely, it enhanced early in the arterial phase and washed out rapidly in the portal venous phase. These findings were highly corresponding to the appearance of PLC on contrast-enhanced dynamic CT[23-25].

As to intranodular enhancement patterns of PLC in the arterial phase, homogenous or mosaic enhancements were found in most lesions of PLC (96.7 %, 28/29), which were also found in other focal liver lesions.

Similarly, 4 liver matestases enhanced early in the arterial phase and the enhancement decreased rapidly in the portal venous phase, resulting in a shorter enhancement duration compared to benign liver lesions ($P<0.05$). This was probably due to their hemodynamics of mainly arterial blood supply. The enhancement patterns of metastases were peripheral or mosaic enhancements, which were also nonspecific and found in other liver lesions. Further study may be needed to clarify this results.

Hemangioma is usually rich in vessels with a sluggish blood circulation. After administration of a contrast agent, the enhancement of most hemangiomas on helical CT was a peripheral puddle pattern in the arterial phase and cotton wool sign in post vascular phase[25, 26]. On contrast-enhanced C-cube gray scale US, similarly, the injection-enhancement delay time of hemangioma was significantly longer compared to other types of focal liver lesions (Table 1). As the arterial phase ended, the

enhancement in hemangioma sustained and lasted over a long period. With respect to the enhancement patterns, peripheral enhancement was shown in most hemangiomas (87.5 %, 7/8). Since microbubbles were destroyed when they were imaged by ultrasound beam, intratumoral enhancement could not be obtained with C-cube gray scale US using 5-10 s interval transmission in relatively large hemangioma. Based upon our preliminary experience, we supposed that at least one minute of interval transmission would be needed to image the microbubbles in the center of hemangioma. The specific characteristics of hemangioma after administration of Levovist was that, in short, it enhanced slowly and mainly at the periphery of the lesion with a long period of enhancement.

Except hemangioma, other benign liver lesions including 12 FNHs and 3 angiomyolipomas demonstrated positive enhancement on contrast-enhanced C-cube gray scale US, presenting their hypervascular characteristics. These lesions enhanced early in the arterial phase and positive enhancement lasted over a long period until the delayed phase. Their enhancement duration was relatively longer compared to hepatic malignancies (P<0.05).

FNH is not a neoplasm but a hyperplastic response of liver parenchyma to the presence of a preexisting vascular malformation. FNH is a hypervascular lesion bypassing the portal venous system and exhibiting a varying degree of arteriovenous shunting[27]. On contrast-enhanced C-cube gray scale US, all FNH lesions showed early enhancement and appeared homogenously. In the portal venous and delayed phase, the intranodular enhancement was somewhat greater than that in the same-depth of surrounding liver parenchyma (Figure 5). The enhancement pattern of FNH seemed to be exclusively caused by arterial vascularization in the lesion, an absent capillary bed, and a vascular volume in excess of that of the normal liver[27-29].

Hepatic angiomyolipoma is a rare benign mesenchymal tumor, composed of a varying heterogenous mixture of three tissue components: blood vessels, smooth muscle and adipose cells. Most angiomyolipoma markedly enhanced with curved vessels in the arterial phase, and remained enhancement in the portal venous phase on spiral CT[30]. Its appearance on contrast-enhanced C-cube gray scale US was corresponding to that on helical CT. It enhanced inhomogenously because of the presence of the multiple ingredients within the lesion.

Contrast-enhanced C-cube gray scale US images microbubbles intermittently with a high mechanical index. This technique allows the detection of blood in the capillary bed, where the flow velocity is too low to be detected with Doppler US flow techniques. On the other hand, however, tumor vessel cannot be shown real-timely. It is because the microbubbles in small vessels (i.e. tumor vessels) cannot be detected with a low mechanical index on the LOW state, and real time C^3-Mode state with a high mechanical index breaks microbubbles when they are imaged. This is one limitation of C-cube gray scale US.

In conclusion, C-cube gray scale US with administration of Levovist can demonstrate dynamic intranodular enhancement in various focal hepatic lesions. The information provided by this methodology may be useful in the differential diagnosis of hepatic lesions on the basis of demonstrating characteristic appearances of various hepatic lesions. Additional study with a greater number of cases is in progress to gather additional data to support and replenish these results.

Abstract

AIM: To evaluate the possibility of using insulin as a carrier for carcinoma-targeted therapy mediated by receptor, and to investigate the expression of insulin receptor in human hepatocellular carcinoma and the receptor binding characteristics of insulin-IUdR (iododeoxyuridine).

METHODS: IUdR was covalently conjugated to insulin. Receptor binding assays of ^{125}I-insulin to human hepatocellular carcinoma and its adjacent tissue were performed. Competitive displacements of ^{125}I-insulin by insulin and insulin-IUdR to bind to insulin receptor were respectively carried out. Statistical comparisons between the means were made with paired t-test at a confidence level of 95 %.

RESULTS: The data indicated that there were high- and low- affinity binding sites for ^{125}I-insulin on both hepatocellular carcinoma and its adjacent tissue. Hepatocellular carcinoma had a significantly higher Bmax for high affinity binding site than its adjacent liver tissue (P<0.05, t=2.275). Insulin-IUdR competed as effectively as insulin with ^{125}I-insulin for binding to insulin receptor. Values of $IC_{50}1$, $C_{50}2$, KI1 and KI2 for insulin-IUdR were 11.50±2.83 nmol·L^{-1}, 19.35±5.11 nmol·L^{-1}, 11.26±2.65 nmol·L^{-1} and 19.30±5.02 nmol·L^{-1} respectively, and for insulin were 5.01±1.24 nmol·L^{-1},17.75±4.86 nmol·L^{-1}, 4.85±1.12 nmol·L^{-1} and 17.69±4.81 nmol·L^{-1}, respectively. Values of $IC_{50}1$ and KI1 for insulin-IUdR were significantly higher than that for insulin (P<0.01, t=4.537 and 4.813).

CONCLUSION: It is possible to use insulin as a carrier for carcinoma-targeted therapy mediated by receptor.

INTRODUCTION

Hepatocellular carcinoma is one of the most common cancers with highly uneven geographic distribution and its treatment by conventional methods is still difficult. In recent years receptor-based radiopharmaceuticals have been used for localization diagnosis and therapy of certain tumors[1-5]. Insulin may be a convenient carrier for anticancer drugs or radionuclides in targeted therapy of carcinoma, because several studies have shown there is an increased expression of insulin receptor on a variety of malignant tumor cells[6-11]. Moreover, insulin is internalized by cells possessing insulin receptor and reported in the cell nuclei subsequent to endocytosis[12-14].

S-iodo-z-deoxyuridine (IUdR), a thymidine analog, can be incorporated into the DNA of cells in the S phase. ^{125}I-IUdR has been successfully applied for the treatment of bladder cancer and hepatic metastases[15-18]. Short-range Auger electrons emitted by ^{125}I-IUdR can cause DNA double-strand broken and deliver a lethal radiation dose to the cell when it is incorporated into DNA. But when killing malignant cells, ^{125}I-IUdR also brings damage to normal tissues, such as the bone marrow, the small intestine and the large intestine. To reduce the damage, we presented a strategy for IUdR targeting delivery to hepatocellular carcinoma which exploited the efficiency and specificity of internalization afforded by the process of receptor-mediated endocytosis. IUdR was primarily used in this investigation, because it had the identical chemical and biological properties with ^{125}I-IUdR. The expression of insulin receptor in human hepatocellular carcinoma and the receptor binding characteristics of insulin-IUdR conjugate were investigated.

MATERIALS AND METHODS

Preparation of cell membrane

Hepatocellular carcinoma and its adjacent liver tissue specimens were obtained from six patients at surgery whose diagnosis was confirmed by histopathology and immediately frozen at -70 ℃ for further use. Cell membrane fractions were prepared according to established techniques[19]. Tissues were cut into pieces, put into Tris-HCL buffer (pH 7.5) and homogenized. The cell membrane fractions purified by centrifugation in a discontinuity sucrose density gradient were stored at -70 ℃. The protein concentration was determined according to Lowrry method[20].

Radioiodination of insulin

Porcine insulin was radioiodinated with the Ch-T method and purified by polyacrylamide gel electrophoresis. The radiochemical purity of ^{125}I-insulin was measured by TLC (thin layer chromatogray).

Preparation of insulin-IUdR

Insulin-IUdR was kindly synthesized by Department of Pharmaceutical, Sichuan University. Briefly, both IUdR (1.2 g) and succinic anhydride (1.5 g) were dissolved in 25 ml of pyridrine and the mixture was stirred at 70-80 ℃ for 24 hours. The solvents were evaporated under vacuum and the residue was crystallized from isopropanol.

Conjugation of IUdR-succinin to insulin was done as follows: IUdR-succinin (50 mg), EDC (100 mg) and HOBt (50 mg) were dissolved in 3 ml phosphate-buffered saline (pH=8.9) and mixed with 1 ml phosphate-buffered saline (pH=8.9) containing 25 mg insulin. The mixture was stirred at

4 ℃ for 48 hours. The precipitation was removed by filtration and pH of the solvent was adjusted to 5.5 with 0.5 mol· L^{-1} HCl. The reaction mixture was kept at 4 ℃ overnight. Thereafter, white solid precipitation was collected with filter and purified by polyacrylamine agarose gel electrophoresis. The solvents were evaporated under vacuum.

Isolated insulin-IUdR was analyzed by analytical HPLC (Beckman) with 4×200 mm ODS column. The mobile phase was 27 % (v/v) acetonitrile and 73 % 0.1 mol· L^{-1} NaH_2PO_4 (pH=0.3) at a flow rate of 0.5 ml· min^{-1}.

SDS-polyacrylamine gel electrophoresis (SDS-PAGE) was performed in 15 % polyacrylamine gel to calculate the molecular weight of insulin-IUdR.

Saturation binding assay

Cell membrane fractions (80 μg protein) of hepatocellular carcinoma or its adjacent liver tissue were incubated for 20 hours at 4 ℃ with binding buffer (NaCl 118 mmol· L^{-1} $CaCl_2$ 1.3 mmol· L^{-1} KCl 5 mmol· L^{-1} $MgSO_4$ 1.2 mmol· L^{-1} KH_2PO_4 1.2 mmol· L^{-1} pH 7.5) containing increasing concentration (5×10^3-5×10^5 cpm) of ^{125}I-insulin. The free ligands were removed by centrifugation at 2 000×g for 10 minutes after addition of 0.1 ml 0.3 % bovine γ-globulin and 0.8 mL 15.8 % PEG. Radioactivity of the membrane pellets was determined in a gamma counter for one minute as the total binding. The nonspecific binding was estimated by incubating membrane with ^{125}I-insulin in the presence of 4.3 nmol unlabeled insulin. Specific binding was obtained by subtracting nonspecific binding from total binding.

Competition binding assay

Cell membrane fractions (80 μg protein) were incubated with 5 nmol ^{125}I-insulin in the presence of increasing concentrations (10^{-12}-10^{-7} mol/L) of the unlabeled insulin or insulin-IUdR. After incubated for 20 hours at 4 ℃, the unbound ligands were removed as saturation binding assay. Radioactivity of the membrane pellets was determined in a gamma counter for one lmin as the total binding. The nonspecific binding was estimated by incubating membrane with ^{125}I-insulin in the presence of 4.3 nmol unlabeled insulin.

Statistical analysis

Binding data were calculated on a computer with receptor binding analysis software. Values are presented as means ±SD. Statistical comparisons between the means were made with paired *t*-test at a confidence level of 95 %.

RESULTS

Radioiodination of insulin

The radiochemical purity of ^{125}I-insulin was 98 % and remained over 95 % after 14 days stored at -20 ℃.

Analysis of insulin-IUdR

The recovery of insulin-IUdR was about 76.3 %. HPLC showed that isolated insulin-IUdR (retention time 13.91 min) yield was about 98 % (shown in Figure 1). The other 2 % was the insulin (8.81 min) and IUdR (3.87 min).

The calculated molecular weight of insulin-IUdR was 7179Da according to its relative position to the molecular weight marker in the SDS-PAGE pattern.

Saturation binding assay

For cell membrane of hepatocellular carcinoma and its adjacent tissue, as concentration of the radioligand increased, binding amount went up and then plateaued rapidly (Figure 2). The Scatchard plot corresponding to the saturation binding curve had a slightly curvilinear shape (Figure 3). Curvilinear Scatchard plots were characteristic of insulin binding in many other systems and had been attributed to interaction of ligand with two or more classes of sites that exhibited different affinities. Using the RBA software, the Scatchard plot of hepatocellular carcinoma could be resolved in a component with Kd=2.20 nmol· L^{-1} (Bmax=0.36 nmol/L) and another component with Kd=18.8 nmol· L^{-1} (Bmax=1.58 nmol· L^{-1}) by the computer. And that of adjacent tissue could be resolved in a component with Kd=2.21 nmol· L^{-1} (Bmax=0.33 nmol· L^{-1}) and another component with Kd=17.89 nmol· L^{-1} (Bmax=1.09 nmol· L^{-1}). Remarkably higher Bmax of high affinity insulin binding sites was identified in hepatocellular carcinoma (P<0.05).

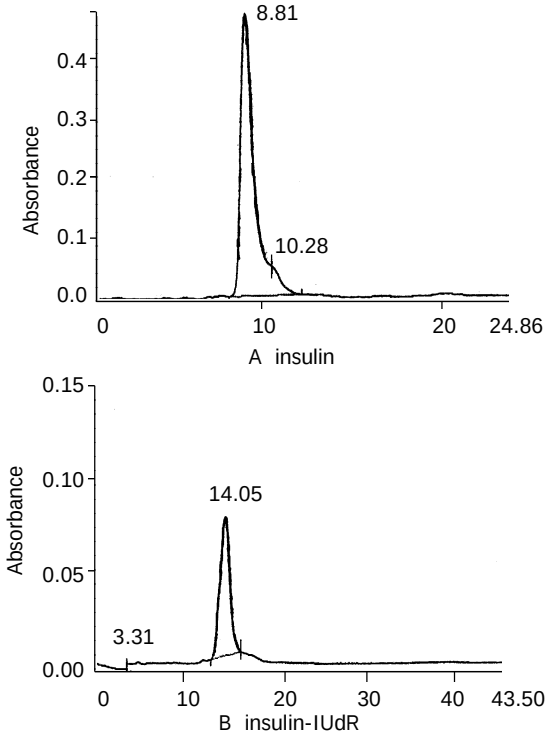

Figure 1 Insulin and insulin-IUdR analysis by HPLC. Retention time of insulin was 8.81 minutes (A); Retention time of insulin-IUdR was 13.91 minutes (B).

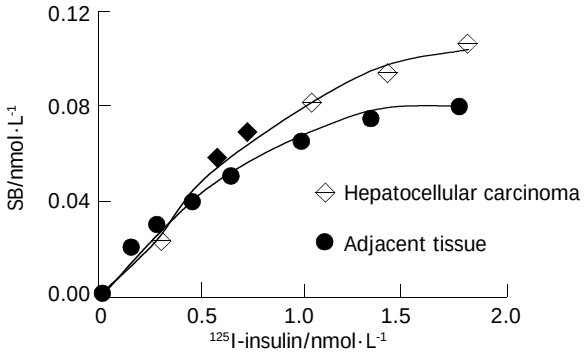

Figure 2 Saturation binding curves of ^{125}I-insulin in hepatocellular carcinoma and its adjacent tissue.

Competition binding assay

Competition displacement assays compared the ability of insulin-IUdR and unlabeled insulin to compete with ^{125}I-insulin for binding to insulin receptor in hepatocellulor carcinoma (Figure 4). The conjugate competed as effectively as insulin for binding to the insulin receptor in a dose-dependent manner. IUdR had no effect on ^{125}I-insulin binding (data not shown). Values of IC_{50} and KI for insulin-IUdR and insulin are shown

in Table 2. Although there were increased $IC_{50}1$ and KI1, the data showed that most of the receptor-binding activity of insulin-IUdR remained.

Table 1 Values of Bmax and Kd of ^{125}I-insulin binding to insulin receptor in hepatocellular carcinoma and its adjacent liver tissue (mean ±SD for six identical experiments)

	High affinity sites		Low affinity sites	
	Bmax (nmol·L^{-1})	Kd (nmol·L^{-1})	Bmax (nmol·L^{-1})	Kd (nmol·L^{-1})
Hepatocellular carcinoma	1.58±0.16[a]	2.20±0.66	0.36±0.11	18.80±7.85
Adjacent liver tissue	1.09±0.51	2.21±0.72	0.33±0.74	17.89±7.87

[a]P<0.05 *vs* adjacent liver tissue. Bmax was the maximal amount of ligand bound; Kd was the dissociation constant of the binding site for the ligand.

Table 2 Values of IC_{50} and KI for insulin-IUdR and insulin competing with ^{125}I-insulin for binding to insulin receptor on hepatocellular carcinoma (mean ±SD for four identical experiments)

	High affinity sites		Low affinity sites	
	IC_{50} (nmol·L^{-1})	KI (nmol·L^{-1})	IC_{50} (nmol·L^{-1})	KI (nmol·L^{-1})
Insulin-IUdR	11.50±2.83[b]	11.26±2.65[b]	19.35±5.11	19.30±5.02
Insulin	5.01±1.24	4.85±1.12	17.75±4.86	17.69±4.81

[b]P<0.01 *vs* insulin. IC_{50} was the concentration of competing ligand to displace radioligand binding by 50 %; KI was the dissociation constant of competing ligand.

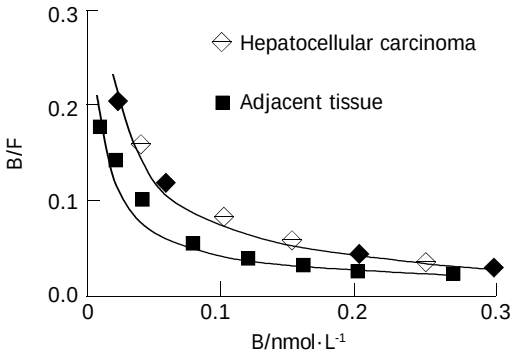

Figure 3 The Scatchard plot corresponding to the saturation binding.

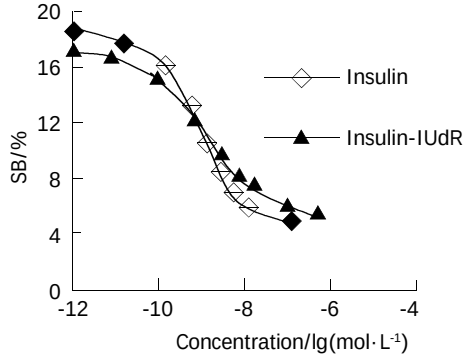

Figure 4 Competitive binding curves of ^{125}I-insulin against insulin-IUdR or insulin.

DISCUSSION

In recent years, there have been several studies on target delivery of specific gene to living cells mediated by insulin receptor. For example, Ivanova *et al* introduced a foreign DNA into early mouse and rabbit embryos by using insulin as a carrier[21], and Alexder carried out transfection of H-11 murine epithelial mammary cells as well as murine and sheep mammary glands using insulin-containing constructs that deliver DNA by receptor-mediated endocytosis[22]. Sosenkranz *et al* synthesized a soluble construct consisting of a plasmid carrying the gene of SV40 large T-antigen and an insulin-poly-L-lysine conjugate which is able to selectively transfect PLC/PRF/S human hepatoma cells possessing insulin receptors[23]. Moreover, Zhang *et al* measured the levels of luciferase gene expression in human or rat glioma cells after targeting the PIL-encapsulated plasmid DNA via human insulin receptor, the human epidermal growth factor receptor, or rat transferrin receptor. The highest levels of gene expression were obtained after targeting the insulin receptor, and this may derive from the nuclear targeting properties of this receptor system[24].

In the present study, we presented a procedure for tumor treatment which combined the targeted transportation function afforded by insulin receptor mediating endocytosis with radiotoxicity of ^{125}I-IUdR to cells at the S phase. IUdR is usually administrated by local infusion or intratumor injection. Systemic therapy is not indicated because of potential severity of undesirable side effects. Insulin used as a carrier might offer an advantage in this aspect. Firstly, most of ^{125}I-IUdR is directly delivered into the liver by insulin. Thereby, other actively dividing normal tissue can efficiently avoid being damaged. Secondly, because of overexpression of insulin receptor in tumor cells, there will be very little conjugate entering normal liver cells. At last, Auger electron' s range is about 10 nm, it is hardly harmful to cells until it is incorporated in the DNA of cells. Since IUdR can only be incorporated in the DNA of cells at the S phase[25], non-dividing tissues possessing insulin receptor will not be injured.

We found that hepatocellular carcinoma bound more ^{125}I-insulin than its adjacent liver tissue. Amir kurtaran has successfully applied ^{123}I-insulin for *in vivo* scintigraphy in the diagnosis of hepatocellular carcinoma[26]. Kuang Anren reported that ^{131}I-insulin was localized within H22 hepatoma in mice, and cleared rapidly from the rest of the body[27]. Schars reported that insulin receptor might play a role in the regulation of hepatocellular carcinoma[28]. Our finding was consistent with theirs. The results demonstrated that escalated binding site for ^{125}I-insulin was expressed in hepatocellular carcinoma. The Bmax values indicated that the increased binding of ^{125}I-insulin in hepatocellular carcinoma was due to an apparent increase in high affinity insulin receptor rather than an increase in low affinity insulin receptor. Our studies also showed that high affinity insulin receptor, constituting 87.72 % of insulin receptor on cell surface of hepatocellular carcinoma, predominated over low affinity insulin receptor. These observations indicated that more IUdR covalently linked to insulin could be transferred to the carcinoma through mediation of the overexpressed high affinity insulin receptor.

It has also been verified in *in vitro* studies that insulin-IUdR is capable of binding specifically to insulin receptor in human hepatocellular carcinoma with high affinity. Chakrabarti *et al* conjugated ^{125}I-IUdR with T101 antibody via polylysine, but the conjugate remained only 68 % immunoactivity[29]. The conjugate used was prepared by covalently linking IUdR to insulin via succine. This complex has an advantage over the conjugate linked via poly-L-lysine[30] or albumin[31] or other large molecules. Both succine and IUdR are small molecules. The small size of the complex may result in less interference in insulin binding to its receptor or other cellular proteins and may permit this complex to be processed intracellularly in a manner more identical to that of unlabelled insulin.

Why insulin-IUdR has an increased IC_{50} and KI for high affinity insulin receptor but not for low affinity receptor is unclear. It is possible that the functional sites of structural microheterogeneity in the two receptors have different sensitivity to the structural change of ligand. Competition binding assays showed that insulin-IUdR still maintained the greater part of affinity for insulin receptor. Therefore, it is not necessary to administer insulin-IUdR in a micromolar range, which may result in glucopenia.

SDS-polyacrylamine agarose gel electrophoresis showed the molecular weight of insulin-IUdR was 7 179 Da, which was equal to the total weight of one molecule of insulin (M_r=5 800 Da) and three molecules of IUdR (M_r=454 Da). It might be concluded that the ratio of insulin molarity to the IUdR is 1:3. On the basis of this molar ratio, it is calculated that for administration 100-300 MBq ^{125}I-IUdR, about 10^{-9}mol insulin was required. Administration of such a low dose of insulin in therapy would not result in glucopenia.

In summary, hepatocellular carcinoma overexpressing insulin receptor and insulin-IUdR conjugate can specifically bind to insulin receptor. This new conjugate holds promise for therapy of hepatocellular carcinoma, but further investigation into transportation of IUdR and its interactions with tumor cells during subsequent intracellular processing would be a desirable prerequisite.

Abstract

AIM: To investigate the possible clinical application value of second harmonic imaging under low acoustic pressure.

METHODS: Six New Zealand rabbits, averaging 2.7±0.4 kg, were selected and operated upon to construct hepatic VX2 tumor carrier model. Hepatic VX2 tumors were imaged with B mode Ultrasonography (US), and second harmonic imaging (SHI) under high mechanic index (1.6) and low mechanic index (0.1). Echo agent was intravenously injected through ear vein at a dose of 0.01 mL/kg under B mode US and high MI SHI, and 0.05 mL/kg under low MI SHI, and then the venous channel was cleaned with sterilized saline. All the images were recorded by magnetic optics (MO), and they were analyzed further by at least two independent experienced sonographers.

RESULTS: Totally 6 hypoechoic and 3 hyperechoic lesions were found in the six carrier rabbits with a mean size about 2.1±0.4 under B mode ultrasound, they were oval or round in shape with a clear outline or a hypoechoic halo at the margin of the lesions. Contrast agent could not change the echogenicity of the lesions under B mode US and SHI under high acoustic pressure. However, it could greatly increase the real time visualization sensitivity of the lesions with SHI under low acoustic pressure.

CONCLUSION: Our results suggest that contrast enhanced SHI with low MI and a bubble non-destructive method would be much more helpful than conventional SHI in our future clinical applications.

INTRODUCTION

Second harmonic imaging (SHI) technique has been shown more valuable than conventional B mode ultrasonography (US). SHI involves transmitting at frequency *f* and receiving at frequency *2f*, and the contrast enhanced echoes can therefore be obtained at second harmonic frequency because of the non-linear motion of the gas bubbles when destroyed by high acoustic pressures[1,2]. However, the use of second harmonic technique under high acoustic pressure (mechanical indexes 0.6-1.2) does not usually provide ideal images because of the short duration of enhancement and no quantitative evaluation and other technical difficulties. To avoid this, new dedicated software operating at low acoustic pressure (mechanical index <0.4) has been demonstrated to produce significant harmonic answer together with a real time imaging based on the maintenance of microbubbles. Only very small amount of microbubbles would allow the evaluation of blood flow volume and blood flow in normal and pathologic tissues. Liver image has been recently proven to be the first area where microbubbles manifest similarly to that of computed tomography or magnetic resonance imaging contrast media. In particular, this technique, applied to the evaluation of perfusional pattern of hepatic mass lesions, provides a significant contribution to their detection and characteristics. In this study, we aimed to find out the features of these two ultrasonographic methods in the depiction of hepatic metastasis.

MATERIALS AND METHODS

Preparation of animal models

Six New Zealand rabbits weighing 2.6-3.2 kg, average 2.7±0.4 kg, were anaesthetized by Sumianxin (a product of the Changchun Argo-Pastoral University) at 0.2 mL/kg through intramuscular injection. Hairs over the abdominal region were moulted by 8 % sodium sulfide, then the region was cleaned by saline water. Median incision right beneath the metasternum was made to expose the right lobe of liver. A tunnel about 3 cm deep at the lobe was constructed with an ophthalmic nipper. Viable VX2 tumor masses about 2-3 mm^3 were implanted into the tunnel, locally stanched and then each layer of the abdominal wall was sutured accordingly. 2 or 3 weeks later, these rabbits were ready for use. VX2 tumor is a kind of skin squamous cancer induced by Shope virus, viable VX2 tumor could be transplanted and underwent passages in the New Zealand rabbits, and therefore was used as mimicking metastatic hepatic tumor models.

Preparation of echo contrast agent

Self made echo contrast agent was made from 5 % (g/L) human albumin and 40 % (g/L) Dextran at a ratio of 1:3 (v/v), the mixture was then undergone electromechanical sonication (Sonication machine JY92-2D was manufactured by Ninbo Xinzhi Research Institute) for 90 seconds under mechanical energy of 280 W. During the sonication process, perfluropropane gas was mixed into the mixture. Microbubbles manufactured in this way were counted by a Coulter counter, at a concentration of 1.6×10^9 bubbles/L averaging 4.3±2.1 μm.

Equipment

A transducer S8 connected to HP-5500 ultrasound system was used, second harmonic imaging was transmitted at frequency 3MHz receiving at frequency 6 MHz, conventional mechanic index was tuned to 1.6, while low mechanic index was tuned

to 0.1. During the whole process of experiment, the image depth, compensation and TGC should be kept constant.

Methods

Hepatic VX2 tumors were imaged with conventional B mode US, and second harmonic imaging (SHI) under conventional mechanic index (1.6) and low mechanic index (0.1). An intravenous bolus echo agent was injected through ear vein at a dose of 0.01 mL/kg under conventional B mode US and high acoustic pressure SHI, and 0.05 mL/kg under low acoustic pressure SHI, and then the venous channel was cleaned with sterilized saline. All the images were recorded real-timely by magnetic optics (MO), and they were analyzed further by at least two independent but experienced sonographers.

RESULTS

Features of VX2 tumor under conventional and harmonic B mode US

A total of 6 hypoechoic and 3 hyperechoic lesions were found in the six carrier rabbits with a mean size of 2.1±0.4 cm under conventional B mode ultrasound, no hyperechoic or iso echoic lesions were found. They were oval or round in shape with a clear outline or a hypoechoic halo at the margin of the lesions. Contrast images under conventional B mode US also showed no improvement at all (Figure 1).

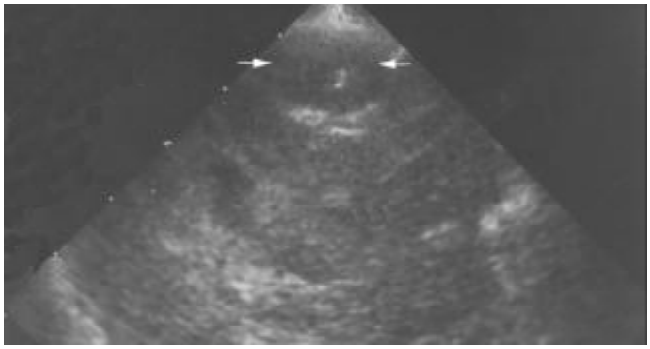

Figure 1 Image of VX2 tumor lesion under conventional B mode US. Arrow indicated the VX2 tumor lesion at the anterior part of the right lobe. It was oval and hypoechoic with a small hyperechoic scar at the center of the lesion.

VX2 tumor lesions assessed by SHI under high and low acoustic pressures

SHI under high acoustic pressure (Mechanic index 1.6) could reveal a short duration enhancement of the hepatic arteries and tumor lesions at the early phase, and an enhancement of the liver parenchyma and a decreased echo at the later phase. A pronounced arterial enhancement was also found at one side of the lesion, which might be considered as the nutrient artery of the tumor. In addition, branches of the afferent artery were seen at the same time. Interestingly, a branch vessel was also found coming from the same artery going to the other side of the lesion as shown in Figure 2a. The whole process of contrast enhanced SHI under high acoustic pressure lasted only for a few seconds.

Visualization by second harmonic imaging under low acoustic pressure was quite different from that by SHI under low acoustic pressure. The echogenicity of liver parenchyma and hepatic VX2 tumor lesions was extremely low, and no structures were observable at first. About five seconds after injection of contrast agent, image of the inferior vena cava could be observed. Again about fifteen seconds later, the contrast agent could be observed within the tumor lesion, as time went by, the afferent artery and its branches of the lesion could gradually and clearly be visualized. A suspicious branch artery was also observed going to the other side of the lesion near the afferent vessels, as what we observed by second harmonic imaging under high acoustic pressure (Figure 2b). As the contrast agent accumulated in the lesion, VX2 tumor appeared as a hyperechoic contour and even satellite lesions could also be observable just beside the original lesion (Figure 3). About 40 seconds later, arteries in the liver parenchyma gradually appeared markedly, and about 20 to 30 seconds afterwards the portal venous system could be visualized. At this stage, the tumor lesion was revealed as hypoechoic. During the last stage period, about 2 minutes after injection of contrast agent, the echogenicity of the liver parenchyma became hyperechoic, while the tumor lesion and its satellite lesion became typically hypoechoic. The whole process of visualization by second harmonic imaging under low acoustic pressure lasted for almost four minutes.

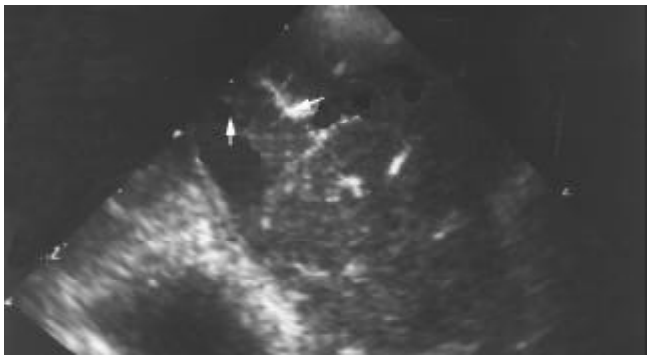

Figure 2a Image of VX2 tumor lesion under high MI second harmonic imaging. Arrow indicated the nutrient artery of same VX2 tumor lesion, and the suspicious artery of a satellite lesion.

Figure 2b Contrast enhanced second harmonic image under low MI revealed the enhancement of nutrient arteries of VX2 tumor lesion and the nutritive artery of satellite lesion.

Figure 3 Image of second harmonic under low MI. It showed the clear tumor and its satellite lesion.

DISCUSSION

The accurate recognition or exclusion of focal liver lesions was a primary objective of diagnostic imaging in patients who were suspected to have a tumor, and the detection of tumor lesions should include their number, location and size. Detection of small liver lesions may be difficult when the acoustic properties of the lesions were similar to those of the surrounding liver parenchyma[3]. The overall accuracy of US imaging in the detection of liver lesions has been shown to range from 53-77 %, but the sensitivity of milimeter nodules has been found to be as low as 20 %[4-6]. US contrast agents were originally developed and used to overcome some of the shortage of US in the assessment of lesional and parenchymal microcirculation by increasing the linear backscattering from the microvascular blood pool. The latest generation of US contrast agents prepared from perflurocarbon gases has been shown to be highly effective in enhancing Doppler signals within the macrovasculature and the microvasculature for several minutes following an intravenous bolus injection[7-9]. However, US contrast agents do not enhance the tumor lesion or parenchyma microvasculature on the fundamental gray-scale image, since the echoes from the tissues are too strong compared to the small volume of microbubbles in the microcirculation[10]. Thus these agents do not significantly improve the detectability of liver lesions when used in association with fundamental imaging, as what we have found in this study. It is necessary to take advantage of their nonlinear characteristics and selectively detect their emission of harmonics in order to increase the US sensitivity to contrast.

A dramatic improvement of contrast enhanced US was the discovery that the bursting of air-based microbubbles caused by high mechanic acoustic pressure US generated large quantities of harmonic frequencies (non-linear response). By decreasing the fundamental frequency, the contrast between highly vascularized lesions containing microbubbles and poorly vascularized tissues were increased[11-14]. Therefore, both macrovasculature and microvasculature of the liver tumor lesions could be well visualized. Some significant limitations about this technique have also been found. Due to the need of breaking air based microbubbles in order to achieve harmonics, the scans have to be started only 2-3 minutes following contrast agent bolus injection, and thus would miss completely the arterial and early portal phases. Furthermore, since all malignancies appear as hypoechoic and all benign tumors isoechoic in late phase[15], discrimination between hepatocellular carcinoma and metastasis, hemangiomas and focal nodular hyperplasia cannot be achieved. In our experiment, although contrast enhanced second harmonic imaging under high acoustic pressure could reveal an increased visualization of the tumor lesions and its surrounding liver parenchymal arteries, the major defect of this method was the short duration of visualization. A suitable method for the detection of hypervascular and hypovascular focal liver lesions should be a bubble non-destruction method with very low MI and high sensitivity for harmonics, allowing continuous real-time imaging of the whole liver and the visualization at the arterial, portal, and late phase during the same examination period with a single contrast agent administration only[16-21]. Furthermore, it should allow us to carry out perfusion and reperfusion studies following the planned bubble destruction and characterization of either hyper- or hypovascular lesions simultaneously[21-25]. We herewith reported our experimental results using this new technique, using a low MI SHI, a nearly complete cancellation of signals from stationary tissues was achieved. Prior to the injection of self-made albumin contrast agent, only high amplitude signals were visualized, such as large vessel walls and the diaphragm. After albumin contrast agent injection, a true subtraction effect was obtained due to the high level harmonic signals coming from the bubbles and the dynamic threshold suppressing low amplitude signals moving toward the transducer. In all rabbits, the whole vasculatures could be observed and studied, including an arterial phase about 15-40 seconds, an early portal phase about 40 to 50 seconds, and a complete portal phase about one and a half minutes. This result is in agreement with what has been described by Solbiati, and this "portal phase" is suggested to be "hepatic sinusoidal phases"[26-31]. The scans could be performed to study the changes of enhancement in these areas by moving the transducer throughout the liver visualizing not only the vascular phases in real time, but also any peculiar region of interest. Using this technique of second harmonic imaging under low acoustic pressure, we could therefore achieve the best visualization of macrocirculation and microcirculation simultaneously. Most interestingly, some satellite lesions, which were not found by high MI SHI, were now clearly revealed by low MI SHI as shown in Figures 2b and 3. It can be concluded that contrast enhanced ultrasonography with second harmonic imaging under low acoustic pressure is currently more sensitive than that with second harmonic imaging under high acoustic pressure in the detection of metastatic lesions as VX2 tumors. This study suggests that this new technique of low MI and microbubble non-destructive method would be much more helpful in our future clinical applications.

Abstract

AIM: To investigate the characteristics of PPAR gamma ligands induced apoptosis in liver cancer cells.

METHODS: The effects of ligands for each of the PPAR gamma ligands on DNA synthesis and cell viability were examined in BEL-7402 liver cancer cells. Apoptosis was characterized by Hochest33258 staining, DNA fragmentation, TUNEL and ELISA, and cell cycle kinetics by FACS. Modulation of apoptosis related caspases expression by PPAR gamma ligands was examined by Western blot.

RESULTS: PPARgamma ligands, 15-deoxy-^{12,14}-prostaglandin J2 (15d-PGJ2) and troglitazone (TGZ), suppressed DNA synthesis of BEL-7402 cells. Both 15d-PGJ2 and TGZ induced BEL-7402 cell death in a dose dependent manner, which was associated with an increase in fragmented DNA and TUNEL-positive cells. At concentrations of 10 and 30 μM, 15d-PGJ_2 or troglitazone increased the proportion of cells with G_0/G_1 phase DNA content and decreased those with S phase DNA content. There was no significant change in the proportion of cells with G_2/M DNA content. The activities of Caspases-3, -6, -7 and -9 were increased by 15d-PGJ2 and TGZ treatment, while the activity of Caspase 8 had not significantly changed.

CONCLUSION: The present results suggest the potential usefulness of PPAR gamma ligands for chemoprevention and treatment of liver cancers.

INTRODUCTION

Peroxisome proliferator-activated receptors (PPARs) are members of the nuclear hormone receptor family. Three distinct PPARs, termed PPAR-α, PPAR-β and PPAR-γ, have been identified. PPAR-α is abundant in primary hepatocytes, where it regulates the expression of proteins involved in fatty acid metabolism. PPAR-β is the most widely distributed subtype and is often expressed at high levels. PPAR-γ is predominantly seen in adipose tissue, where it plays a critical role in regulating adipocyte differentiation. The ability of PPAR-γ to regulate cell differentiation and proliferation has inspired a number of researchers to explore the use of PPAR-γ agonists as chemotherapeutic agents[1-7]. PPAR-γ is highly expressed in human lipocarcinomas and various other human tumors including breast, lung, colon, prostate, bladder and gastric cancer[8-13]. Furthermore, prostaglandin 15d-PGJ_2 and/or troglitazone induce apoptosis and growth inhibition of human breast, lung, colon, prostate, bladder, gastric and thyroid carcinoma cells *in vitro*.

In support of the *in vitro* data, there are now many reported examples of tumor growth suppression/arrest in tumor-bearing rodent models treated with PPAR-γ agonist therapies. For example, troglitazone treatment of nude mice implanted with papillary thyroid tumors reduced tumor growth and prevented distant metastasis. Both estrogen receptor positive (MCF-7) and negative (MDA-MB-231) breast cancer cell lines undergo cell cycle arrest when treated with15d-PGJ_2 or troglitazone and similar effects are observed in rodent breast cancer *in vivo* models[14-18]. PPAR-γ ligands have been shown to inhibit growth and induce terminal differentiation of liposarcoma cells, and to inhibit growth and induce apoptosis of breast cancer cells, prostatic carcinoma, and lung cancer cells.

In the field of gastroenterology, many investigators have focused on the role of PPAR-γ in colon cancer, since PPAR-γ is highly expressed in human colon and colon tumors. The effects of PPAR-γ on colon cancer are still unclear and controversial[19-25], since PPAR-γ ligands have been reported both to promote the development and to reduce the growth rate of colon tumors. PPAR-γ ligands also inhibit the growth of human gastric carcinoma cells through induction of apoptosis[25]. However, the effects of PPAR-γ ligands on growth of human liver cancer cells have not been examined. In this study, we investigated the effects of PPAR-γ ligands 15d-PGJ_2 and troglitazone on growth of human liver cancer BEL-7402 cells and whether 15d-PGJ_2 and troglitazone affected the cell cycle, apoptosis, and Caspases activity of BEL-7402 cells.

MATERIALS AND METHODS

Cell line and reagents

Human liver cancer cell line BEL-7402 was provided by the American Type Culture Collection. Cells were grown in RPMI-1640 medium supplemented with 15 % new born bovine serum, penicillin G (100 kU/L) and kanamycin (0.1 g/L) at 37 ℃ in a 5 % CO_2-95 % air atmosphere. Anti-Caspases-3, -6, -7, -8 and -9 antibodies were obtained from Sigma Chemical Co. 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 (15d-PGJ_2) and troglitazone were

obtained from Cayman Chemical Co. All other chemicals were purchased from Sigma Chemical Co (St Louis, MO, USA).

Determination of cell proliferation rate

BEL-7402 cells (1×10^5) were seeded in 24 well plates and cultured for 24 h. The cultures were divided into three groups: the first group (control) was cultured in the RPMI1640 medium, the second group was cultured in the continuous presence of 20 μM 15-deoxy-$\triangle^{12,14}$-prostaglandin J_2 (15d-PGJ_2), the third was cultured in the continuous presence of 20 μM troglitazone. Cells were then harvested every 24 h by trypsinization and cell numbers were counted with a hemocytometer, three cultures were used for experiments at each time point.

[^{3}H] thymidine incorporation

Subconfluent cells were cultured in 24-well plates and incubated for 24 h with 5uCi of [^{3}H] thymidine. The cells were then washed 3 times with HBSS, lysed with 1M NaOH, and lysate was counted by liquid scintillation.

Hoechst 33258 staining

Cells were fixed with 4 % formaldehyde in phosphate buffered saline (PBS) for 10 min, stained by Hoechst33258 (10 mg/L) for one hour, and subjected to fluorescence microscopy. After treated with 15d-PGJ_2 or troglitazone, the morphologic changes including reduction in volume, nuclear chromatin condensation were observed.

Electron microscopy (EM)

Control BEL-7402 cells or those treated with 15-deoxy-$\triangle^{12,14}$-prostaglandin J_2 (15d-PGJ_2) or troglitazone for 48 h and that remained attached to the surface of the culture dishes were gently washed with serum-free medium, and then fixed with 2.5 % glutaraldehyde in 0.1 M sodium cacodylate buffer. These cells were scraped from the surface of the dishes and pelleted by spinning for 5 min at 10 000×g. The cells were osmicated with 1 % osmium tetroxide, then block was stained, dehydrated in graded ethanol, infiltrated with propylene oxide, and embedded with EMBED overnight and cured in a 60 ℃ oven for 48 h. Silver sections were cut with an Ultracut E microtome, collected on a formvar and carbon-coated grid, stained with uranyl acetate and Reynold's lead citrate, and viewed under a JEOL100 CX electron microscope.

Ladder detection assay

After induction of apoptosis, cells (7×10^6/sample, both attached and detached cells) were lyzed with 150 μl hypotonic lysis buffer (edetic acid 10 mM, 0.5 % Triton X-100, Tris-HCl, ph7.4) for 15 min on ice and were precipitated with 2.5 % polyethylene glycol and NaCl 1 M for 15 min at 4 ℃. After centrifugation at 16 000×g for 10 min at room temperature, the supernatant was incubated in the presence of proteinase K (0.3 g/L) at 37 ℃ for one hour and precipitated with isopropanol at -20 ℃. After centrifugation, each pellet was dissolved in 10 μl of Tris-EDTA (pH 7.6) and electrophoresed on a 1.5 % agarose gel containing ethidium bromide. Ladder formation of oligonucleosomal DNA was detected under ultraviolet light.

Detection of apoptotic DNA fragmentation

BEL-7402 cells were grown in 96-well culture plates. The cells were incubated with various doses of 15d-PGJ_2 and troglitazone for 6 h. Apoptotic DNA fragmentation was determined using a commercially available enzyme-linked immunosorbent assay (ELISA) kit from Roche Co. This assay was based on a quantitative sandwich enzyme-immunoassay directed against cytoplasmic histone-associated DNA fragments. Briefly, the cells were incubated in 200 μl of lysis buffer provided in the kit, the lysates were centrifuged, and 20 μl of the supernatant containing cytoplasmic histone-associated DNA fragments was reacted overnight at 4 ℃ in streptavidin-coated microtitrator wells with 80 μl of the immunoreagent mixture containing biotinylated anti-histone antibody and peroxidase-conjugated anti-DNA antibody. After washed, the immunocomplex-bound peroxidase was probed with 2,2' -azino-di[3-ethylbenzthiazoline sulfonate] for spectrophotometric detection at 405 nm.

TUENL assay

TUNEL assay was performed using the apoptosis detection system. Cells were fixed by 4 % paraformaldehyde in PBS overnight at 4 ℃. The samples were washed three times with PBS and permeabilized by 0.2 % Triton X-100 in PBS for 15 min on ice. After washed twice, cells were equilibrated at room temperature for 15 to 30 min in equilibration buffer(potassium cacodylate 200 mM, dithiothreitol 0.2 mM, bovine serum albumin 0.25 g/L, and cobalt chloride 2.5 mM in Tris-HCl 25 mM, pH 6.6) and then incubated in the presence of fluorescein-12-dUTP 5 μM, dATP 10 μM, edetic acid 100 μM, and terminal deoxynucleotidyl transferase at 37 ℃ for 1.5 h in the dark. The tailing reaction was terminated by 2×standard saline citrate (SSC). The samples were washed three times with PBS and analyzed by fluorescence microscopy. At least 1000 cells were counted, and the percentage of TUNEL-positive cells was determined.

Flow cytometry

For DNA content analysis, cells were treated with different concentrations of 15-deoxy-$\triangle^{12,14}$-prostaglandin J_2 (15d-PGJ_2) and troglitazone for 24 h. 1×10^6 cells were harvested, pelleted and washed with phosphate-buffered saline (PBS), and resuspended in PBS containing 20 mg/L PI and 1 g/L ribonuclease A. 10^6 fixed cells were examined under each experimental condition by flow cytometry, and percentage of degraded DNA was determined by the number of cells displaying subdiploid (sub-G_1). DNA divided by the total number of cells was examined. Cell cycle analysis was performed under the same experimental conditions and distributions were determined using the CellFit program. All measurements were carried out under the same instrumental settings.

Western blot analysis

The cells were lysed in lysis buffer [hepes 25 mM, 1.5 % Triton X-100, 1 % sodium deoxycholate, 0.1 %SDS, NaCl 0.5 M, edetic acid 5 mM, NaF 50 mM, sodium vanadate 0.1 mM, phenylmethylsulfonyl fluoride (PMSF) 1 mM, and leupeptin 0.1 g/L, pH7.8] at 4 ℃ with sonication. The lysates were centrifuged at 15 000 g for 15 min and the concentration of the protein in each lysate was determined with Coomassie brilliant blue G-250. Loading buffer (Tris-HCl 42 mM, 10 % glycerol, 2.3 % SDS, 5 % 2-mercaptoethanol and 0.002 % bromophenol blue) was then added to each lysate, which was subsequently boiled for 3 min and then electrophoresed on a SDS-polyacrylamide gel. Proteins were transferred to nitrocellulose and incubated sequentially with anti-Caspases-3, -6, -7, -8 and -9 antibodies and then with peroxidase-conjugated secondary antibodies in the second reaction. Detection was performed with enhanced chemiluminescence reagent. The results on Western blot analysis represented the average of three individual experiments.

Statistical analysis

Data were presented as the mean ± standard error of the mean, unless otherwise indicated. Multiple comparisons were examined for significant differences using analysis of variance, followed by individual comparisons with the Bonferroni post-test. Comparisons between two groups were made with the Student's *t* test. A $P<0.05$ was considered significant.

RESULTS

Effects of 15d-PGJ$_2$ and troglitazone on proliferation and cell cycle

Cells were cultured in the presence or absence of 15d-PGJ$_2$ or troglitazone and cell numbers were determined over three days. In the absence of 15d-PGJ$_2$ or troglitazone, the number of control cells doubled approximately every 24 h in RPMI 1640 medium supplemented with 10 % fetal calf serum. By contrast, in the continuous presence of 20 μM 15d-PGJ$_2$ or troglitazone' the growth of BEL-7402 cells was significantly inhibited (Figure 1A). We next examined by [^{3}H]-thymidine incorporation whether 15d-PGJ$_2$ or troglitazone affected DNA synthesis of BEL-7402 cells. Cells were treated with various doses of 15d-PGJ$_2$ or troglitazone (10, 20, 30 μM). The results showed that 15d-PGJ$_2$ or troglitazone significantly and dose-dependently inhibited [^{3}H]-thymidine incorporation into BEL-7402 cells (Figures 1B, 1C). Table 1 indicates the effects of 15d-PGJ$_2$ or troglitazone on the cell cycle distribution of BEL-7402 cells. 15d-PGJ$_2$ or troglitazone at 10 μM induced limited or no change in the cell cycle distribution of cells. At concentrations of 20 and 30 μM, 15d-PGJ$_2$ or troglitazone increased the proportion of cells with G_0/G_1 phase DNA content and decreased those with S phase DNA content. There was no significant change in the proportion of cells with G_2/M DNA content.

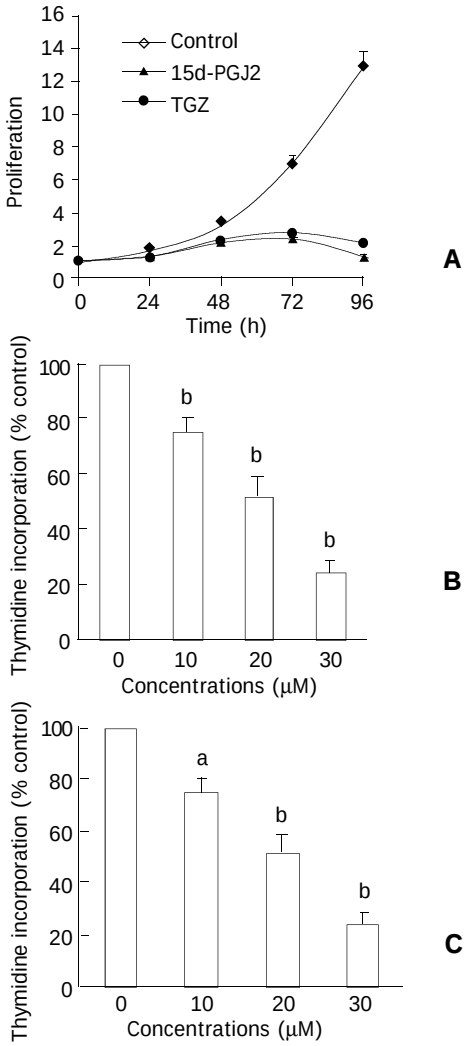

Figure 1 Concentration and time effect of 15d-PGJ2 or TGZ on growth of BEL-7402 cells. (A) BEL-7402 cells were incubated with 20 μM 15d-PGJ2 or TGZ for 12, 24, 48, 72, 96 h. (B) BEL-7402 cells were incubated with various concentrations of 15d-PGJ2 for 48 h; (C) BEL-7402 cells were incubated with various concentrations of TGZ for 48 h. The value was represented as mean ±SEM (n=3). [a]P<0.05 and [b]P<0.01 versus corresponding control group.

Effect of 15d-PGJ$_2$ or troglitazone on induction of apoptosis in BEL-7402 cells

Morphological changes 15d-PGJ$_2$ or troglitazone treatment of BEL-7402 cells altered their morphology and induced DNA strand breaks in a manner consistent with apoptosis. That the changes were indeed induced by apoptosis and not necrosis was confirmed by EM and Hoechst 33258 staining. 15d-PGJ$_2$ or troglitazone-treated cells showed compacted nuclear chromatin with fine granular masses marginated against the nuclear enveloped and condensed cytoplasm, the nuclear outline was convoluted and the organelles were preserved.

TUNEL assay To determine whether 15d-PGJ$_2$ or troglitazone has a capacity to induce apoptosis in BEL-7402 cells, exponentially growing cells were exposed to various concentrations of 15d-PGJ$_2$ or troglitazone. TUNEL assay was performed. 15d-PGJ$_2$ or troglitazone dramatically increased the number of TUNEL-positive cells in a dose-dependent manner.

DNA fragments Agarose gel electrophoresis exhibited DNA ladder formation in BEL-7402 cells after exposed to different concentrations of 15d-PGJ$_2$ or troglitazone for 48 h. Compared with control, the DNA laddering was more clearly observed by the treatment with 15d-PGJ$_2$ or troglitazone. ELISA assay also showed that 15d-PGJ$_2$ or troglitazone induced DNA fragment in a dose-dependent manner (Figure 2).

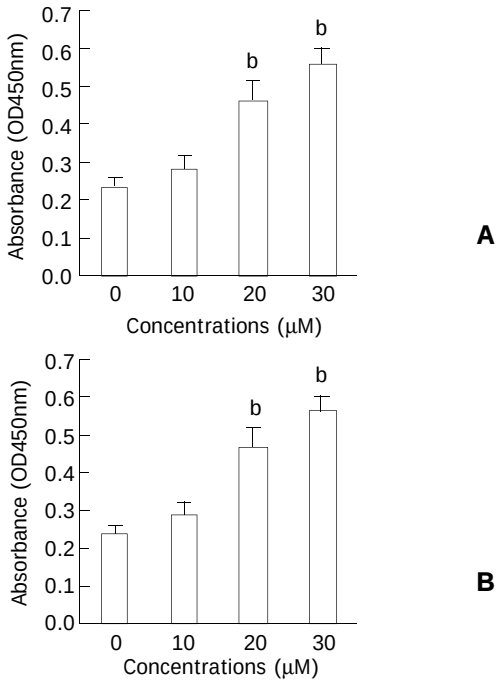

Figure 2 DNA fragmentation by ELISA assay, as measured by absorbance (OD 450 values). Culture of BEL-7402 cells for 48 h in the presence of 15d-PGJ2 / TGZ resulted in dose dependent DNA fragmentation. A) 15d-PGJ2; B) TGZ. [b]P<0.01 compared to respective control. The value was represented as mean ± SEM (n=3).

Flow cytometry In order to determine the effect of 15d-PGJ$_2$ or troglitazone on apoptosis in BEL-7402 cells, cells were exposed to 15d-PGJ$_2$ or troglitazone for 48 h, apoptotic damage of DNA was detected according to the sub-G_1 peak on a flow cytometer. Cells in sub-G_1 phase were increased from 2.1±0.3 % to 55.8±4.7 % or 50.0±4.1 % after 15d-PGJ$_2$ or troglitazone treatment (Table1).

Effect of 15d-PGJ$_2$ or troglitazone on the activities of Caspase-3, -6, -7, -8 and -9

In order to elucidate the pathway leading to apoptosis, we

examined the activation of Caspases-3, -6, -7, -8 and -9, which were reported to initiate apoptosis upon various stimuli. BEL-7402 cells treated with15d-PGJ_2 or troglitazone for 24 h were analyzed for the enzymatic activity by Western blot. The results showed that Caspases-3, -6, -7, -8 and -9 were activited after 15d-PGJ_2 or troglitazone treatment in BEL-7402 cells, while the activity of Caspase 8 had not significantly changed (Figure 3).

Table 1 Effect of 15d-PGJ2 and TGZ on cell cycle distribution and apoptosis in BEL-7402 cells

Treatment (μm)	%Cell cycle distribution			%apoptosis
	G_0/G_1	S	G_2/M	
Control	49.7±1.5	34.8±2.1	15.5±1.1	2.1±0.3
15d-PGJ2				
10	50.5±2.6	34.2±1.7	15.3±0.5	13.9±1.1[b]
20	64.8±2.9[b]	19.5±1.5[b]	15.7±0.2	33.5±2.3[b]
30	71.6±4.2[b]	14.1±0.6[b]	14.4±1.3	55.8±4.7[b]
TGZ				
10	54.2±2.1	29.4±1.3	16.6±0.9	10.3±1.1[b]
20	61.5±3.1[b]	28.2±1.7[b]	14.9±1.7	25.5±1.8[b]
30	68.9±4.8[b]	14.2±0.8[b]	16.9±1.4	50.0±4.1[b]

Cell cycle distribution was determined after 24 h of treatment in one group and apoptosis was determined after 48 h of treatment in the other group. The tabulated percentages were an average calculated on the results of three separate experiments. The value was represented as mean±SEM (n=3). [b]P<0.01 versus corresponding control group.

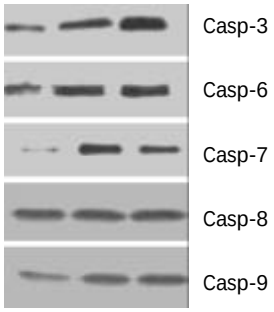

Figure 3 Western blot analysis of the activities of Caspases-3, -6, -7, -8 and –9 in human liver cancer cell line BEL-7402 cells: lane 1: control, lane 2: 30 μM TGZ treated BEL-7402 cells; lane 3: 30 μM 15d-PGJ2 treated BEL-7402 cells.

DISCUSSION

Several members of the family of nuclear hormone receptors (NHR) play crucial roles in the control of cellular homeostasis, and administration of their cognate ligands has successfully been used in cancer treatment[26-33]. The nuclear receptor superfamily includes members such as the estrogen, thyroid and glucocorticoid receptors as well as the subfamily of peroxisome proliferator-activated receptors. The PPAR family comprises PPAR-α, PPAR-β and PPAR-γ. The PPARs bind as heterodimers with retinoic-x acid receptor (RXR) to a subset of DR-1 elements, peroxisome proliferator response elements and have been shown to regulate expression of genes involved in the transport, metabolism and storage of fatty acids. Transcriptional activation of the PPAR-RXR heterodimers is enhanced upon binding of a large variety of ligands including saturated and unsaturated fatty acids, arachidonic acid derivatives and a wide range of synthetic drugs with different subtype specificities.

For the last 10 years, administration of peroxisome proliferators, PPAR-α agonists, has been known to induce hepatocarcinogenesis in rodents. However, cancer development is probably induced by mechanisms secondary to PPAR-α transcriptional activation. A role in growth regulation for the two remaining PPAR subtypes has also been suggested. Whichever, upregulaties PPAR-β expression has been associated with colon cancer and activation of PPAR-β stimulates post-confluent proliferation of pre-adipocytes. Opposite effects on cell proliferation are mediated by activation of PPAR-γ. PPAR-γ agonists could be promising therapeutic or chemopreventive agents in oncology, since they can induce apoptosis or differentiation in several tumors, by acting as inhibitors of malignancy progression. PPAR-γ activation inhibits the growth of several tumors as shown by *in intro* and *in vivo* studies performed on liposarcoma, breast cancer and leukemia. However, conflicting evidence exists on the role of PPAR-γ activation in colon cancer, where different studies have shown that PPAR-γ activation promotes tumor development or, in contrast, protects against colon cancer, depending on the cell model[34-42]. In the present study, in order to examine the effects of PPAR-γ ligands 15d-PGJ_2 or troglitazone on the BEL-7402 cell growth, we employed cell counting and [^{3}H]-thymidine incorporation assay. The results showed 15d-PGJ_2 or troglitazone significantly and concentration-dependently inhibited the growth of BEL-7402 cells. To examine whether growth inhibition of BEL-7402 cells by 15d-PGJ_2 or troglitazonem was a result of cell cycle arrest, BEL-7402 cells treated with either vehicle or 15d-PGJ_2/troglitazone were analyzed by FACScan. BEL-7402 cells treated with 15d-PGJ_2 and troglitazone exhibited decreased fractions of S phase cells from 34.8±2.1 % in controls to14.4±1.3 % and 16.9±1.4 %, respectively, resulting in a remarkable increase in accumulation if cells at G_1 phase, increased from a control level of 49.7±1.5 % to 71.6±1.5 % and 68.9±4.8 %. Therefore, the inhibitory effect of 15d-PGJ_2 or troglitazone on growth of BEL-7402 cells may thus be due in part to PPAR-γ-mediated G_1 cell cycle arrest. Similar findings of G_1 cell cycle arrest by PPAR-γ ligands have been reported for colon cancer cells and prostate cancer cells. Several reports suggested that PPAR-γ ligands affected cell cycle-related genes and proteins. Others demonstrated that PPAR-γ activation caused G_1 cell cycle arrest of fibroblasts and SV40-transformed adipogenic HIB1B cells, and that this arrest was strongly associated with loss of E2F/DP DNA binding through modulation of phosphorylation by phosphatase 2A[43-47].

Previous studies have shown that PPAR-γ activation generally promotes apoptosis and/or differentiation in several normal and tumor cells such as human breast cancer cells, human gastric cancer cells, human non-small cell lung carcinoma, human glioblastoma cells, macrophages, endothelial cells and liposarcoma. In the present study, to determine the underlying mechanisms of the growth inhibitory effect of PPAR-γ ligands, we investigated whether 15d-PGJ_2 or troglitazone acted by inducing apoptosis of liver cancer BEL-7402 cells. We performed DNA fragments and morphological changes assay EM or Hoechst 33258. The results showed that 15d-PGJ_2 or troglitazone induced apoptosis in a dose-dependent manner, indicating that growth inhibition of BEL-7402 by PPAR-γ ligands was, in part, associated with apoptosis.

Recent evidence indicates that increased expression and activation of some Caspase zymogens in tumor cells can lead to efficient inhibition of tumor cell growth, invasion and metastasis and tumor regression[48-56]. Such a Caspase-dependent cessation of tumor cell proliferation and dissemination is accomplished via an active process of tumor cells death collectively named as apoptosis. It has been demonstrated that a high level of activity of effector Caspases-3, -6, -7 and -8, in tumor cells plays a decisive role in their commitment to apoptosis[57-66]. To-date studies on zymogens of the effector

Caspases in primary human tumors showed an increased expression of procasp-3 and -6 in breast carcinoma, pancreatic carcinoma and non-small cell lung carcinoma compared to normal tissue and benign or premalignant lesions. This suggests that tumor cells of some epithelial neoplasms may acquire an increased apoptotic potential during progression at the levels of primary tumor. The zymogens of casp-3 and -7 in tumor cells can be activated by the initiator Caspases, such as casp-8 and casp-9, and by the aspartyl-specific serine proteinase granzyme B upon its perforin-assisted entry into the cytoplasm of tumor cells. Procasp-6 can be activated by casp-3 while the generated casp-6 can activate in turn the zymogen of casp-3. In the present study, in order to elucidate the pathway leading to apoptosis, we examined activation of Caspases-3, -6, -7, -8 and -9, which have been reported to initiate apoptosis upon various stimuli. BEL-7402 cells treated with15d-PGJ_2 or troglitazone for 24 h were analyzed for the enzymatic activity by Western blot. The results showed that Caspases-3, -6, -7, -8 and -9 were activited after 15d-PGJ_2 or troglitazone treatment in BEL-7402 cells, while the activity of Caspase 8 had not significantly changed, indicating that activation of Caspases plays an important role in the apoptosis induced by 15d-PGJ_2 or troglitazone.

In conclusion, the present results, together with reports by other investigators, suggest a potential usefulness of PPAR gamma ligands for chemoprevention and treatment of liver cancers. Further basic as well as clinical studies are required to develop new strategies to fight liver cancers using PPAR gamma ligands.

Abstract

AIM: To clarify the mechanisms of integrin overexpression in negatively regulating the cell cycle control of hepatocellular carcinoma cells SMMC-7721.

METHODS: The cell cycle pattern was determined by flow cytometry. The mRNA and protein expression levels were assayed by RT-PCR and Western blot, respectively. Stable transfection was performed by Lipofectamine 2000 reagent, and cells were screened by G418.

RESULTS: Overexpression of α5β1 or β1 integrin induced S-phase delay in SMMC-7721 cells, and this delay was possibly due to the accumulation of cyclin-dependent kinase inhibitors (CKIs) $p21^{cip1}$ and $p27^{kip1}$. The decrease of protein kinase B (PKB) phosphorylation was present in this signaling pathway, but focal adhesion kinase (FAK) was not involved. When phosphorylation of PKB was solely blocked by wortmannin, $p27^{kip1}$ protein level was increased. Moreover, S-phase delay was recurred when attachment of the parental SMMC-7721 cells was inhibited by the preparation of poly-HEME, and this cell cycle pattern was similar to that of β1-7721 or α5β1-7721 cells.

CONCLUSION: S-phase delay induced by overexpression of integrin β1 subunit is attributed to the decrease of PKB phosphorylation and subsequent increases of $p21^{cip1}$ and $p27^{kip1}$ proteins, and may be involved in the unoccupied α5β1 because of lack of its ligands.

INTRODUCTION

Extracellular matrix (ECM) is consisted of many components, such as collagen, glycoproteins, elastin, and proteoglycans that in addition to providing a scaffold for tissue, regulate many fundamental cellular processes such as proliferation, survival, migration and differentiation[1,2]. Many cell types require anchorage to ECM to proliferate[3]. If lacking attachment to ECM, they will undergo anoikis[2, 4]. Integrins activate growth-promoting signaling pathways that are responsible for the anchorage, and two such pathways appear to be involved. One is that integrins facilitate growth factor-mediated activation of extracellular signal-regulated protein kinase (ERK); the other is that integrins activate the c-Jun NH_2-terminal kinase (JNK)[2, 5]. In addition, serine/threonine protein kinase, PKB, has emerged as a crucial regulator in the integrin pathway, which can be controlled through phosphatidylinositol-3' kinase (PI3K)[6]. Integrins, often together with growth factor receptors, up-regulate cyclins D and E and down-regulate CKIs $p21^{cip1}$, $p27^{kip1}$, and $p57^{kip2}$[2, 7]. This action allows cells to pass through the G1/S transition and complete the cell cycle.

Many studies, however, have demonstrated that integrins give rise to growth inhibition rather than growth stimulation[8-13]. Integrin α5β1 has been often observed to be lost in cancerous areas other than in its normal counterpart tissues[14]. It is apparent from these studies that integrin signaling may play a major role in negative control of cell growth, which may be lost in some cancer cells, and the mechanisms of this effect are not completely known yet.

In this study we have further investigated the inhibition role of integrin α5β1 in human hepatocellular carcinoma cell line, SMMC-7721. We analyzed the effect of these cells with or without adhesion to ECM. These studies identified overexpression of β1 subunit or α5β1 inhibited cell cycle progression at S-phase, and this inhibition maybe resulted from the up-regulation of cdk2 inhibitors $p21^{cip1}$ and $p27^{kip1}$ and involved in the unoccupied β1 because of relative lack of its ligands.

MATERIALS AND METHODS

Materials and antibodies

Poly-HEME, wortmannin, FN and LN were all obtained from Sigma, and geneticin (G418) was purchased from Calbiochem (San Diego, CA). Monoclonal antibodies used were directly against cyclin D1 (Santa Cruz), cdk2 (Santa Cruz), integrin β1 (BD Transduction Laboratories, Lexington, KY), phosphorylated FAK (anti-phosphotyrosine clone PT-66, Sigma) and β-actin (Santa Cruz). Goat anti-human integrin α5 polyclonal antibody was also purchased from Santa Cruz. Other antibodies used were those against FAK (Santa Cruz), $p21^{cip1}$ (Santa Cruz), $p27^{kip1}$ (Oncogene Research Products, Cambridge, MA), Ser473-phosphorylated form of PKB and PKB (Cell Signaling). Horseradish peroxidase conjugated anti-mouse, rabbit or goat IgG were purchased from Calbiochem (San Diego, CA).

Cell culture

Human hepatocellular carcinoma cell line SMMC-7721 was obtained from the Liver Cancer Institute, Zhongshan Hospital (Shanghai, China). SMMC-7721 cells were grown in RPMI 1640 medium (Gibco BRL) supplemented with 100 $mL \cdot L^{-1}$ calf bovine serum (CBS), 100×10^3 $U \cdot L^{-1}$ penicillin and 100×10^3 $U \cdot L^{-1}$ streptomycin sulfate. Integrin-overexpressing transfectant

cell lines were maintained in the same medium as above plus 500 μg/ml geneticin (Gibco BRL).

Plasmid construction and stable transfections

pECE vector containing human full-length cDNA of integrin β1 was presented generously by Dr. Mara Brancaccio (Department of Genetics, University of Torino, Torino, Italy). Complementary DNA of β1 integrin cleaved from the pECE plasmid by *EcoR* I was subcloned into pcDNA3 vector to generate pcDNA3-β1. pcDNA3-α5 expression vector was presented kindly by Dr. Sue E. Craig (School of Biological Sciences, University of Manchester, Manchester, UK). Stable transfections were performed using LIPOFECTAMINE™ 2000 (LF2000) reagent (Life Technologies, Grand Island, NY) according to the manufacturer's instructions. Briefly, logarithmically growing cells were transfected with 1 μg of plasmids and 2 μl of LF2000 reagent. At 48 h after transfection, the selective medium containing 1 mg/ml geneticin (G418) antibiotic (Calbiochem) was replaced, and then the cell clones were selected and identified.

Plating experiments

Mock and integrin transfected cells were seeded on the tissue culture plates coated with either FN (15 μg/ml) or LN (15 μg/ml), grown for 60 minutes, and followed by phase-contrast microscopy or protein extraction.

Flow cytometry

Cells were starved by exposure to SFM for 48 h, the harvested cells were then grown in normal growth medium containing 10 % CBS for 12-16 h, the time span covered the duration of normal S phase. At the end of incubation, the cells were digested with 2 mM EDTA in PBS and rinsed twice with ice-cold PBS solution, then fixed by adding them dropwise into 75 % ice-cold ethanol while vortexing, followed by incubation on ice for 60 min. The fixed cells were washed with ice-cold PBS and incubated at 37 ℃ for 30 min in 0.5 ml PBS solution containing 20 μg/ml RNase A, 0.2 % Triton X-100, 0.2 mM EDTA and 20 μg/ml of propidium iodide. DNA content was determined by FACS analysis (Becton Dickinson). The percentage of cells in G0/G1, S, and G2/M phases was determined using the Modfit program.

RNA isolation and RT-PCR

RT-PCR was performed to quantify the level of mRNA, which was isolated using Trizol system (Watson Biotechnologies, Shanghai, China) according to the manufacturer's guidelines. Complementary DNA synthesis was performed essentially as described previously[15], except that 2 μg of total RNA was used for cDNA synthesis, and the primer used was oligo $(dT)_{15}$. For amplification, 2-μl cDNA product was used in a final volume of 50 μl with 5 units of Taq polymerase (SABC, Luoyang, China). The primer pairs for $p27^{kip1}$ and $p21^{cip1}$ were described previously[16,17]. Primers for β-actin[16] were used as the internal control. The expected product sizes were p27, 471 bp; p21, 159 bp and β-actin, 412 bp.

Cell lysis and immunoblotting

Cells cultured under the same conditions as cell cycle analysis were collected, and then washed twice with ice-cold PBS and lysed in 1×SDS lysis buffer (50 mM Tris (pH 6.8), 2 % SDS, 10 % glycerol, 100 μg/ml PMSF, 10 μg/ml leupeptin and 5 mM Na_3VO_4) for 10 min on ice. Cell lysates were boiled and clarified by centrifugation at 12 000 g at 4 ℃ for 10 min. Protein concentration was determined with Hartree assay. Immunoblotting analyses using the enhanced chemiluminescence (ECL) detection system (Perfect, Shanghai, China) were carried out as described previously[18].

RESULTS

Overexpression of integrin α5β1 in SMMC-7721 cells

We transfected the full-length cDNA of genes ITGA5 (α5) or ITGB1 (β1) alone, or α5 and β1 together into a human hepatocellular carcinoma cell line, SMMC-7721, respectively. The pcDNA3 empty vector was the control plasmids, and cells transfected with pcDNA3 were regarded as the mocked cells. The overexpressed transfectant cell lines were mainly screened for increased expression of α5 or β1 in protein levels by Western analysis, and designated as α5-7721, β1-7721 and α5β1-7721, respectively. As shown in Figure 1A, integrin α5 expression was increased to 2-fold in α5-7721 or α5β1-7721 cells compared with the mocked cells. Meanwhile, β1-7721 and α5β1-7721 transfectants had more than 2.5-fold amount in integrin β1 protein level (Figure 1B). The β1 subunits appeared as two bands in Western blot because of variable post-translational modification (mainly N-glycosylation). The hypoglycosylated lower band (Figure 1B) was tentatively identified as biosynthetic precursor of β1 subunit. The band with lower migration rate (upper band in Figure 1B) of integrin β1 subunit was in hyperglycosylated forms, and mainly located in plasma membrane[19-21].

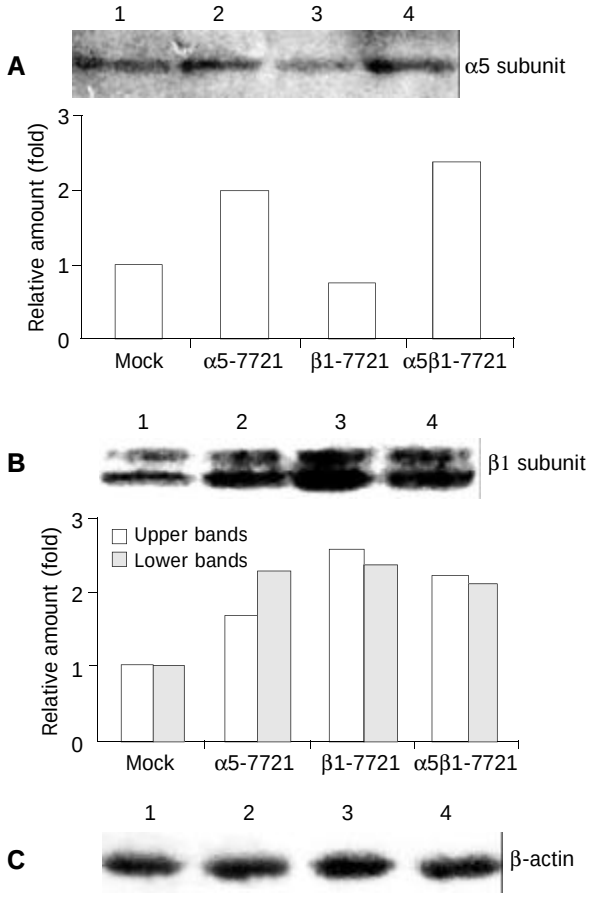

Figure 1 Integrin α5 and β1 protein levels in α5-, β1- and α5β1 transfected SMMC-7721 cells. (A) The expression level of α5 chain was increased in α5-7721 and α5β1-7721 cells. (B) Two forms of β1 integrin were due to different levels of β1-chain glycosylation. The hypoglycosylated lower band was tentatively identified as biosynthetic precursor of β1 subunit, the hyperglycosylated upper band was mature subunits, exposed in part on the cell surface (the 130-kDa product). Immunoblot assay showed that protein levels of the mature form were elevated in the transfectants, especially in β1-7721 and α5β1-7721 cells. (C) The protein level of β-actin showed an equal loading amount in each well. Lane 1, mock cells; lane 2, α5-7721; lane 3, β1-7721; lane 4, α5β1-7721. Each point in the graphs was the mean value from three separate experiments.

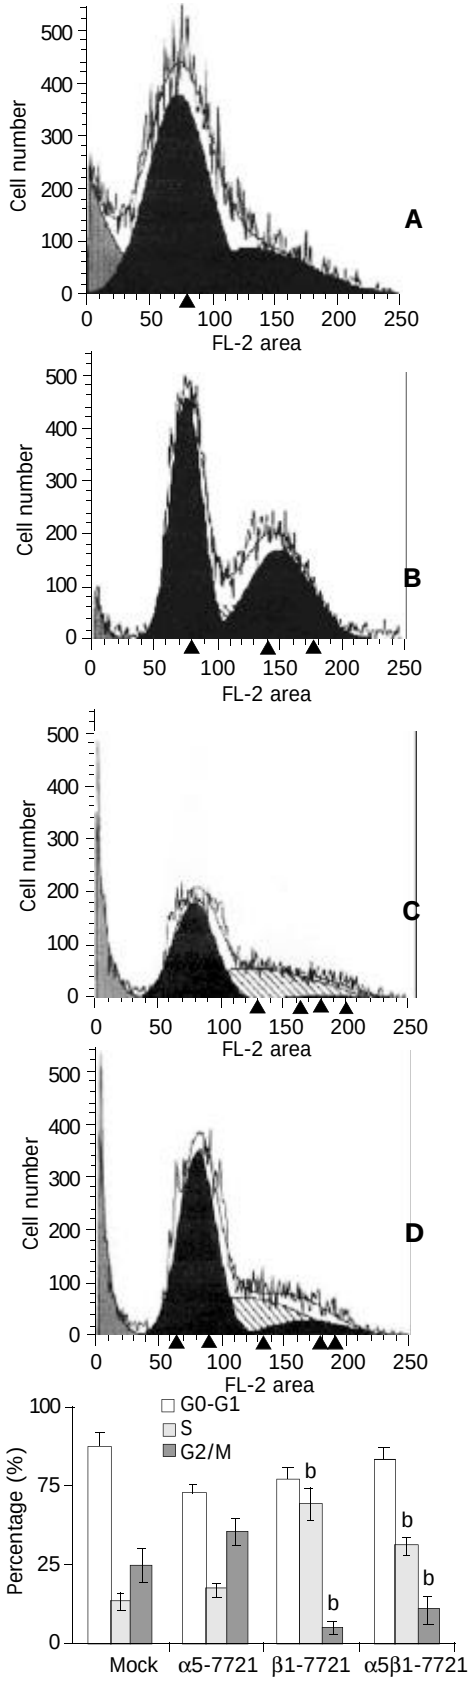

Figure 2 S-phase delay was induced in β1- and α5β1-transfectant cells. For cell cycle analysis, transfected and mocked cells were synchronized by exposure to SFM for 48 h, then grown in RPMI1640 medium containing 10 % CBS and penicillin / streptomycin solution. Twelve or 16 h later, the cells were collected and analysed for flow cytometry as described under "Materials and Methods". A, mocked cells; B, α5-7721 cells; C, β1-7721 cells; D, α5β1-7721 cells. Each bar in graph represented the mean ± SD obtained from three independent experiments. The S-phase delay was significantly different in β1-7721 and α5β1-7721 cells (n=3, ^bP<0.01 *vs* mocked cells).

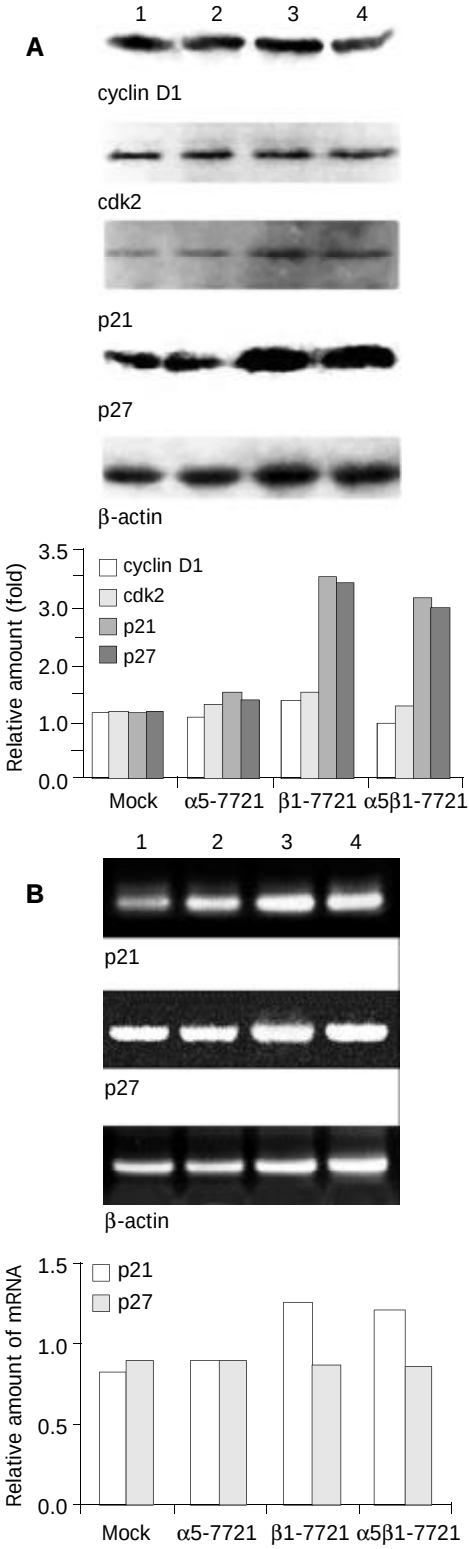

Figure 3 Message RNA and / or protein levels of cell cycle regulatory genes $p21^{cip1}$ and $p27^{kip1}$ in β1-7721 and α5β1-7721 transfectants, but not that of cyclin D1 and cdk2. (A) Immunoblot assay showed the protein level of cyclin D1 and cdk2 were not apparently affected, but $p21^{cip1}$ and $p27^{kip1}$ protein levels were increased in β1-7721 and α5β1-7721 cells. The protein level of β-actin was detected to assess the loading amount in each well in SDS-PAGE gel. (B) Message RNA levels of $p21^{cip1}$ and $p27^{kip1}$ were assessed by RT-PCR, and normalized by that of β-actin. It was apparent that mRNA level of $p21^{cip1}$ was increased in β1- and α5β1- transfected cells. However, the $p27^{kip1}$ mRNA amount was the same as control. Each result represented three separate experiments. Lane 1, mocked cell; lane 2, α5-7721; lane 3, β1-7721; lane 4, α5β1-7721.

Induction of S-phase delay by transfection of integrin β1 subunit

In the previous study, we showed that overexpression of integrin α5β1 or β1 subunit had negative effects on cell growth[11]. To elucidate the mechanisms of cell cycle perturbation induced by overexpressing integrins, flow cytometry analyses were applied. Cell cycle parameters were compared between transfected cells and mocked cells. Similar patterns of the cell cycle were found in α5-7721 and mocked cells (Figure 2). But in β1-7721 and α5β1-7721 transfectants, we observed a significant increase in fraction of cells in S phase of the cell cycle, as shown in Figure 2. This was accompanied by a decrease in proportion of cells in G2/M phases of the cell cycle. These changes were specific for the transfection events containing β1-plasmids, that is, at this point, the pattern of α5β1-7721 was similar to that of β1-7721 cells. These results were obtained from the cells synchronized partly in G0/G1 phase by exposure to serum-free medium. Therefore, these data showed that S-phase delay was probably due to enhanced production of exogenous β1 integrin.

$p21^{cip1}$ and $p27^{kip1}$ were up-regulated in β1 or α5β1 transfectant cell lines

To clarify the mechanism by which S-phase delay was induced in β1-7721 and α5β1-7721 cells, we investigated whether cyclins and cdks were involved in this situation. Expression level of cyclin D1 was examined because this protein was always referred to as a sensor molecule to the extracellular cues[22]. It was shown that cyclin D1 expression was not changed, neither was the cdk2 protein (Figure 3A). As evidenced recently, enhanced $p21^{cip1}$ and/or $p27^{kip1}$ expression was considered to be associated with G1 cell cycle arrest[23, 24], and under some circumstances, with S-phase delay in some cell types[25, 26]. So, we further examined whether β1-chain overexpression could induce $p21^{cip1}$ and $p27^{kip1}$ in β1-7721 and α5β1-7721 cells. As shown in Figure 3A, a significant increase (2-fold amount) of $p21^{cip1}$ protein levels was noted in β1-7721 and α5β1-7721 cells compared with the mocked cells or α5-7721 cells. Meanwhile, $p27^{kip1}$ protein level was also increased to 2.5-fold. We also found that the mRNA level of $p21^{cip1}$ increased, although that of $p27^{kip1}$ maintained the same as control (Figure 3B). Interestingly, we found that overexpression of β1 gene in SMMC-7721 cells induced S-phase delay in this study. The above findings showed that this S-phase delay might be attributed to the increased expression of $p21^{cip1}$ and $p27^{kip1}$.

Phosphorylated form of PKB was inhibited in β1 and α5β1 transfectants and this might result in accumulation of $p21^{cip1}$ and $p27^{kip1}$

To determine how overexpressing α5β1 integrins transferred signals from membrane to cytosol or nucleus to modulate the expression of CKIs $p21^{cip1}$ and $p27^{kip1}$, we examined the two important signaling molecules mediated by integrins, FAK and PKB. The results showed that neither FAK nor its tyrosine phosphorylated form was affected (Figure 4A). However, levels of Ser473-phosphorylated form of PKB were decreased in β1-7721 and α5β1-7721 cells in comparison with the control cells, but total amount of PKB protein was not apparently affected (Figure 4B).

In recent years, evidences have shown that activated PKB protein may phosphorylate $p21^{cip1}$, and induce its degradation through the ubiquitin-26S proteasome pathway[6,27]. But evidences indicating $p27^{kip1}$ phosphorylation by PKB are few. In this study, decrease of phosphorylated PKB (Figure 4B) and accumulation of $p27^{kip1}$ (Figure 3A) occurred concomitantly in β1-7721 or α5β1-7721 cells. To obtain support, we further performed an experiment to block the phosphorylated form of PKB. It is well known that Ser-473 phosphorylation of PKB, on behalf of its active forms, appears to be catalyzed by phosphoinositide-dependent kinase 1 (PDK1) and integrin-linked kinase (ILK)[28, 29], and that PI3K is located upstream of both ILK and PKB[6]. So the PI3K inhibitor wortmannin was explored in this study. Following serum starvation, cells were cultured in the medium with 100 nM wortmannin for 24 h or 48 h. We investigated the level of phosphorylation of PKB and $p27^{kip1}$ by immunostaining. The data showed that phosphorylation of PKB was blocked, and expression of $p27^{kip1}$ was increased at the same time compared with control cells (Figure 5). Therefore, the decrease of phosphorylated form of PKB was at least in part, responsible for $p27^{kip1}$ protein accumulation.

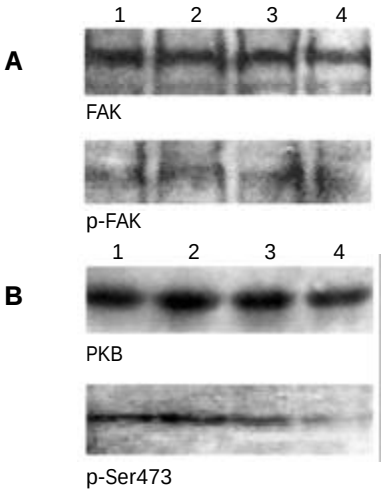

Figure 4 Activation of PKB, but not FAK, was downregulated in β1- and α5β1- transfected cells. (A) FAK activation was assessed by phosphotyrosine- specific antibody, followed by stripping and reprobing with anti-FAK antibody. (B) PKB and its Ser473-phosphorylated forms were determined by 10 % SDS-PAGE with the equal loading amount. The loading amount control is shown in Figures 1C and 3A. Lane 1, mock cells; lane 2, α5-7721; lane 3, β1-7721; lane 4, α5β1-7721. Results were representative of 4 repeated experiments.

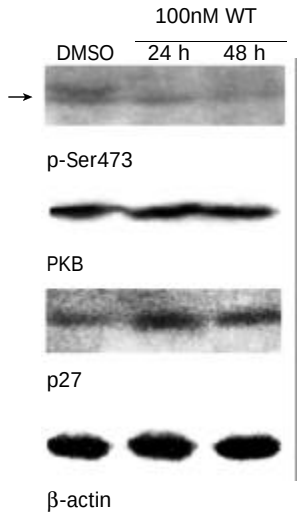

Figure 5 Ser473-phosphorylated form of PKB was decreased, but $p27^{kip1}$ protein level was increased concomitantly in SMMC-7721 parental cells treated with the PI3K inhibitor wortmannin. The parental SMMC-7721 cells were starved with serum-free medium for 48 h, then grown in normal medium / 10 % CBS containing DMSO (as control, 24 h) or 100 nM wortmannin for

the indicated times. The amount of DMSO did not exceed 0.1 %, which was determined not to damage the cells. Equal amount of wortmannin was added again after grown for 24 h. The level of Ser473-phosphorylated form of PKB (*arrow*) was declined, but $p27^{kip1}$ protein level was elevated with the treatment of wortmannin in SMMC-7721 cells. Results were representative of at least 3 repeated experiments. Abbreviation: DMSO, dimethylsulfoxide; WT, wortmannin.

Inhibition of cell cycle was possibly due to the relative lack of ECM

Integrins, in general, promote the focal adhesion protein activities such as FAK and cell cycle progression[2]. So we ponder why overexpression of integrin β1 subunit can repress the level of phosphorylated PKB and the cell cycle. Here, we performed plating experiments to elucidate its mechanism. First, we observed the morphological change of cells that were plated on LN- or FN- coated dishes and grown for 60 minutes (Figure 6). It was found that β1-7721 and α5β1-7721 cells were prone to attachment and spreading, perhaps to the cell cycle progression. Next, we determined the changes of phosphorylated FAK and phosphorylation of PKB in cells attaching on LN and FN. As mentioned above (Figure 4A), total amount of FAK and its phosphorylated forms were not affected in cells cultured in the flasks without coating of LN or FN. But the level of tyrosine phosphorylated FAK was increased in cells, which were plated on LN- or FN- coated dishes and grown for the indicated times (Figure 7A, and data not shown for FN-coated dishes). Moreover, the level of Ser473 phosphorylated form of PKB was similar to that of phosphorylated FAK under the same condition (Figure 7B, and data not shown for FN-coated dishes). Finally, protein level of $p27^{kip1}$ was declined in β1-7721 and α5β1-7721 cells (Figure 7C). These findings demonstrated that an important role of LN or FN in the molecular changes of β1-7721 or α5β1-7721 cells, especially, in PKB phosphorylation and $p27^{kip1}$ protein levels. On the contrary, when attachment of the parental cells to ECM was blocked by plating them onto poly-HEME-coated petri dishes, the percentage of cells in S-phase was increased from 13.08 % to 37.33 % (Figure 8). That is, when the parental SMMC-7721 cells were prevented from interaction with ECM through the preparation of poly-HEME, the same effects of S-phase accumulation took place as that in β1-7721 or α5β1-7721 cells. These results suggested that S-phase delay induced by overexpressing β1 in SMMC-7721 cells might be the result of the relative lack of ECM.

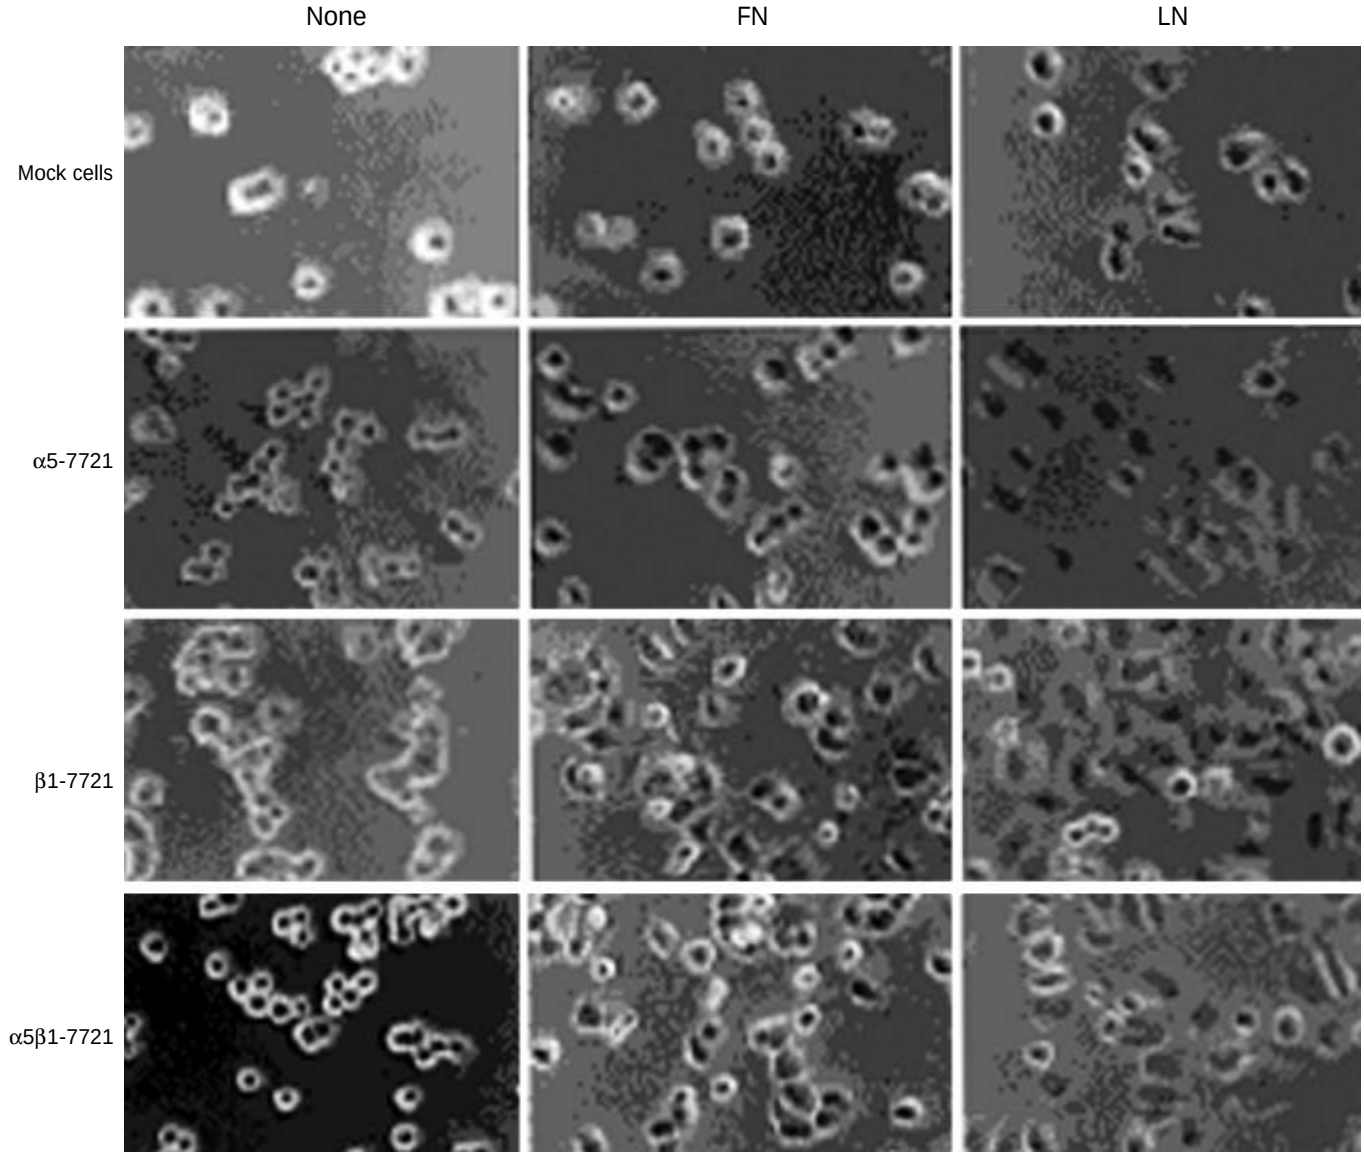

Figure 6 β1-7721 and α5β1-7721 cells subjected to spreading on fibronectin- or laminin- coated culture dishes. The mocked and transfected cells were plated on FN- or LN- coated tissue culture plates in normal medium for 60 min, then cells on the plates were photographed by phase-contrast microscopy with a digital camera. Abbreviations: FN, fibronectin; LN, laminin.

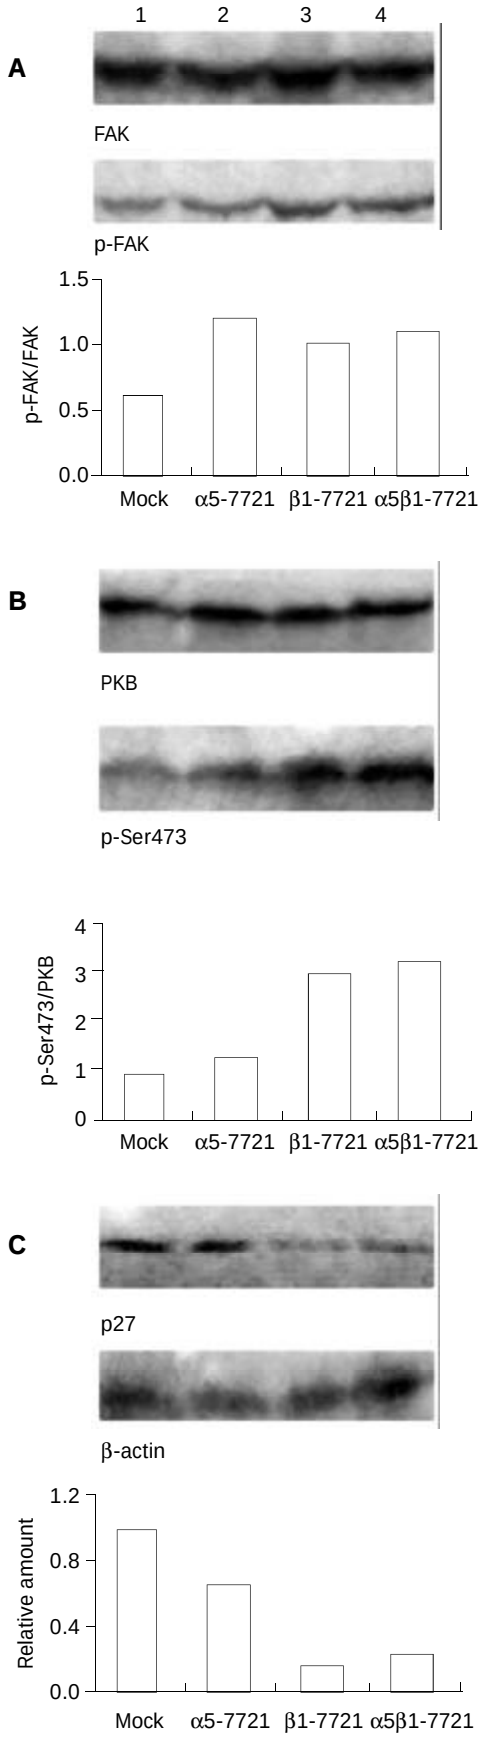

Figure 7 Effects of laminin on transfected cells. Protein levels of phosphorylated FAK (A) and Ser473-phosphorylated form of PKB (B) were increased in the transfected cells, especially in β1-7721 and α5β1-7721 cells grown in the LN-coated culture dishes for 60 minutes. (C) Under the same condition, $p27^{kip1}$ protein level was decreased in β1-7721 and α5β1-7721 cells. Lane 1, mock cells; lane 2, α5-7721; lane 3, β1-7721; lane 4, α5β1-7721. Each result represented at least 3 independent experiments.

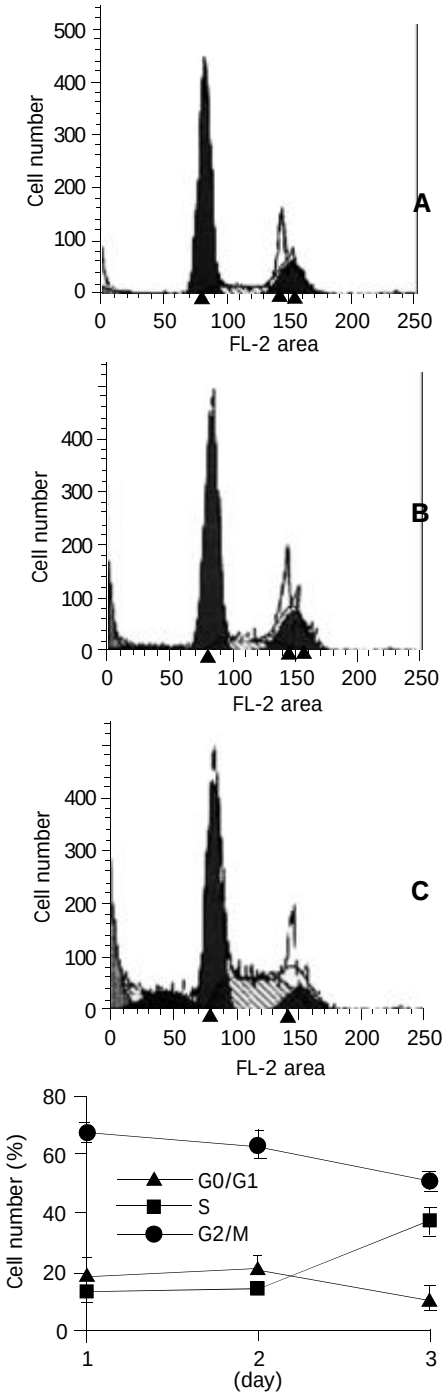

Figure 8 The percentage of cells in S phase was increased in SMMC-7721 cells plated on poly-HEME-coated petri dishes. The parental SMMC-7721 cells were plated on poly-HEME-coated petri dishes, and cultured in normal medium for 24 h (A), 48 h (B) or 72 h (C), respectively, then collected and analysed by flow cytometry. The cell cycle pattern (C) was similar to that of β1-7721 or α5β1-7721 cells.

DISCUSSION

We examined the effects of overexpressed α5β1 or β1 on tumor cell proliferation, which provide the evidence that overexpression of α5β1 or β1 inhibits the proliferation of human hepatocellular carcinoma cell line SMMC-7721 and this inhibition may be related to the insufficient ligands for overexpressed β1 integrins. This finding also demonstrated that the inhibition of cell cycle was due to a specific growth arrest at S-phase that involved an increase in the protein level of $p21^{cip1}$ and $p27^{kip1}$.

This study showed that cyclin D1 expression was not affected by transfection events. So the early G1 phase

progression may not be influenced under this condition. However, the protein levels of $p21^{cip1}$ and $p27^{kip1}$ were increased in β1 or α5β1 transfectant cells, which might be the major reason why S-phase delay occurred. It was previously reported that $p21^{cip1}$ and $p27^{kip1}$ were assembly factors rather than inhibitors of cdk4/6 kinases[30], but were inhibitors of cdk2 kinase, which is the key kinase contributing to G1/S transition and S phase progression. One CKI protein, $p21^{cip1}$, the first cyclin-dependent kinase inhibitor to be identified[31], has also a separate cdk2 binding site in its N-terminal region (amino acid 53-58) and optimal cyclin/cdk inhibition requires binding to this site as well as one of the cyclin binding domains. Furthermore, $p21^{cip1}$ interacts with proteins such as PCNA, c-Myc and E2Fs that control DNA replication and other S phase events[32]. Meanwhile, evidences have shown that $p27^{kip1}$ plays a key role in the regulation of the proliferation of tumor cells in response to signals from ECM[13]. Therefore, increased $p21^{cip1}$ and $p27^{kip1}$ proteins can induce S-phase delay in β1- and α5β1-transfected cells.

In many cell types, the intracellular concentration of $p27^{kip1}$ is mainly controlled at the posttranscriptional level, and its degradation is initiated by phosphorylation with a target enzyme, cdk2[33] or other enzymes, such as PKB[6], and completed by the ubiquitin-proteasome pathway. $p21^{cip1}$ protein can also be phosphorylated by PKB[6]. In this study, we found that PKB level of phosphorylated form was decreased in β1- or α5β1- transfected cells, accompanied by the increase of $p21^{cip1}$ and $p27^{kip1}$ to a certain extent. These findings indicate that the decrease of active form of PKB may interpret the accumulation of $p21^{cip1}$ and $p27^{kip1}$ *bona fide*, which in turn, interferes with the cell cycle at S phase.

This study suggested that overexpression of β1 or α5β1 integrin in SMMC-7721 cells could induce S-phase delay. The mechanism underlying this phenomenon may be due to two kinds of possibilities. One is "integrin-mediated death" (IMD) described by Stupack and his colleagues[34, 35], that is, an unligated integrin promotes apoptosis of cells. It is well known that α5β1 integrin, in general, acts as the effector protein of cell proliferation, such as endothelial cells in the vascular system[36]. In this study, however, we showed that overexpression of β1 or α5β1 induced S-phase delay. When cells were plated on FN/LN-coated culture dishes, they were subjected to attachment and spreading compared with the mocked and α5-7721 cells. Moreover, for the parental cells, they underwent S-phase delay and apoptosis when they were deprived of attachment by plating them on poly-HEME-coated petri dishes. Therefore, we postulated that the relative lack of ECM might be involved in S-phase delay triggered by overexpression of β1 or α5β1 integrin gene in SMMC-7721 cells. Another possibility is the trans-dominant integrin inhibition, which is defined as the occupancy of one integrin by its ligand, can inhibit the functions of other integrins[37-40]. For example, integrin α5β1 is essential for angiogenesis[36], but $\alpha_v\beta3$ may suppress the functions of integrin α5β1, if β3 integrins prevail in the endothelial cells[41]. It was reported that the basal integrin repertoire in hepatocellular carcinoma cells was characterized by the expression of several potential laminin receptors of the integrin family, such as α1β1, α2β1 and α6β1[42-47]. So the overexpression of β1 may preferentially dimerize with α1, α2 and α6, the subunits of the receptors of laminin or collagen (they were lost in this *in vitro* model). Therefore, if these α subunits are occupied, the functions of integrin α5β1 may be suppressed, including its capacity to block cell cycle arrest.

ACKNOWLEDGEMENTS

We are grateful to Dr. Mara Brancaccio from the University of Torino (Torino, Italy), and Dr. Sue E. Craig from the University of Manchester (Manchester, UK) for their gifts of the plasmids. We also acknowledge the Chinese Medicine Board (CMB) in New York, U.S.A. for its kind support to our research.

Abstract

AIM: To investigate the efficacy of transcatheter arterial chemoembolization (TACE) combined with radiotherapy for unresectable large hepatocellular carcinoma (HCC).

METHODS: From June 1994 to June 1999, a total of 76 patients with large unresectable HCC were treated with TACE followed by external-beam irradiation. 89 patients with large HCC, who underwent TACE alone during the same period, served as the control group. Clinical features, therapeutic modalities, acute effects and survival rates were analyzed and compared between TACE plus irradiation group and TACE alone group. A multivariate analysis of nine clinical variables and one treatment variable (irradiation) was performed by the Cox proportional hazards model.

RESULTS: The clinical features and therapeutic modalities except irradiation between the two groups were comparable ($P>0.05$). The objective response rate (RR) in TACE plus irradiation group was higher than that in TACE alone group (47.4 % *vs* 28.1 %, $P<0.05$). The overall survival rates in TACE plus irradiation group (64.0 %, 28.6 %, and 19.3 % at 1, 3, 5 years, respectively) were significantly higher than those in TACE alone group (39.9 %, 9.5 %, and 7.2 %, respectively, $P=0.0001$). Cox proportional hazards model analysis showed that tumor extension and Child grade were significant and were independent negative predictors of survival, while irradiation was an independent positive predictor of survival.

CONCLUSION: TACE combined with radiotherapy is more effective than TACE alone, and is a promising treatment for unresectable large HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common cancer in Asia. In China, there has been an increasing trend in the incidence and mortality of HCC during the past two decades. The age-adjusted rate of death per 100 000/year was 20.37 in 1990's. Patients with HCC usually have a poor prognosis. Surgery is the only potential cure, and there has been a great progress in surgery over the past decades[1]. However, the overall 5-year survival rates are still not above 5 % as the number of resected cases is limited due to advanced lesions or associated liver disease[2-4]. Most of the patients with HCC are subjected to various forms of non-surgical therapy. Transcatheter arterial chemoembolization (TACE) has become one of the most popular forms of nonsurgical treatment in Asia. TACE application to HCC has demonstrated good results in reducing the size of tumor and improving survival[5-10]. However, within or around the capsule, which is supplied by both arterial and portal blood, tumor cells remain viable, which are often responsible for later recurrence[11]. Even in several prospective randomized trials, TAE failed to improve significantly the survival of patients with HCC[12,13]. Further treatment was needed to eradicate the residual tumor cells. We have found in a clinical trial that TACE combined with irradiation may be a good method for large unresectable HCC[14]. In the present study, we compared the effects of TACE plus irradiation with that of TACE alone for the treatment of large unrectable HCC.

MATERIALS AND METHODS

Patients

During the past decade, patients with unresectable HCC underwent TACE therapy as the first line treatment at the Cancer Hospital of Fudan University, but parts of patients underwent TACE combined with radiotherapy or were given percutaneous ethanol injection (PEI) in clinical trials by some doctors. Included in the present study were 76 patients with unresectable large HCC who underwent TACE combined with radiotherapy between June 1994 and June 1999. The criteria for entry into this study were as follows: (1) The tumor / liver volume ratio was not above 0.7:1. (2) The lesion was detectable by ultrasound (US) and computed tomography (CT). (3) The level of serum transaminase was under 80 IU/L. (4) There was no evidence of extrahepatic metastasis, or ascites, or severe cirrhosis (class C according to Child's classification). (5) Karnofsky performance score $\geqslant$70. During the same period, a total of 127 patients underwent TACE alone as a routine therapy. 89 patients who complied with the above criteria served as the control group. In 61 (80.0 %) patients in TACE plus irradiation group and 73 patients (82.0 %) in control group, the diagnosis of HCC was confirmed by cytological examination. Diagnosis in the remaining patients was made on the basis of characteristic findings by ultrasound, CT and angiography, and high serum α-fetoprotein (AFP) levels. None of the patients underwent surgical resection owing to advanced tumor stage and/or location of the lesion, or because of refusal of surgery. Informed consent was obtained from all patients and their relatives.

Treatments

TACE procedure was performed as follows. The tip of a catheter

was introduced into the appropriate hepatic artery, and 5-fluorouracil (1.0 g, 5-Fu, Xudong Haipu Pharmaceutical Inc., Shanghai, China) and cisplatin (40-60 mg, CDDP, Qilu Pharmaceutical Factory, Jinan, China) or doxorubicin hydrochloride (30-50 mg, Adriamycin, Main Luck Pharmaceutical Inc., Shenzhen, China) were injected, followed by a mixture of iodized oil (5-20 ml, Lipiodol, Huaihai Pharmaceutical Factory, Shanghai, China) and mitomycin C (10-20 mg, MMC, Kyowa Hakko Kogyo Co., LTD, Tokyo, Japan) was injected slowly under fluoroscopic control. In some patients embolization with a gelatin sponge (1×1×10 mm, Gelfoam. the 3rd Pharmaceutical Factory of Nanjing, Nanjing, China) was performed at the same time. TACE procedures were performed at 4 to 10 week intervals, and patients received 1 to 4 times of TACE.

In the TACE plus irradiation group, radiotherapy was started 4 to 8 weeks after TACE. Twenty-six patients with a solitary tumor within a 9 cm diameter received limited-field radiotherapy. Radiation was delivered through a pair of opposed anterior-posterior fields using a 6 MV or 18 MV linear accelerator. Field sizes ranged from 64 cm^2 to 144 cm^2. The fractions were 1.8 to 2.0 Gy daily, given five times a week. The total dose ranged from 30 Gy to 50 Gy, depending on the proportion of normal liver excluded from the high-dose volume and the Child' s grade. For 50 patients with a solitary tumor of more than 9 cm diameter or with multinodular or diffuse lesions, whole or partial liver irradiation with a moving strip technique[14] was performed. The total midline dose ranged from 19.5 to 30 Gy. Ten patients whose tumor reduced to 9 cm or smaller after whole or partial liver irradiation had a boost to residual disease to a total dose of 36 to 42Gy.

Effects evaluation

The effects on the tumor were assessed by US and CT, together with AFP levels in cases with increased baseline values. Changes in tumor size were assessed in terms of percent regressing on CT and US, using World Health Organization criteria. Cumulative survival was determined by the Kaplan-Meier method from the first day of treatment.

Statistical analysis

The difference of clinical features, therapeutic modalities, response rate (RR) and AFP decreasing rate between the 2 groups were analyzed by chi-square test. The difference of survival was assessed by log-rank test. *P* value <0.05 was considered significant.

To assess the relatively prognostic importance of factors in predicting survival, a multivariate analysis of nine clinical variables, including sex, age, AFP level, number of lesions, tumor size, tumor extension, portal thrombosis, Child grade, and Okuda stage, and one treatment variable (irradiation), was performed by Cox proportional hazards model.

RESULTS

Clinical features and therapeutic modalities

The nine clinical features before treatment in the two groups are shown in Table 1. Only the rate of two lobes invasion in TACE plus irradiation group was slightly, but not significantly higher than that in control group. The other features in two groups were similar (*P*>0.05). There was no significant difference of TACE times and spongostan use between two groups (Table 1). Thus, the clinical features and therapeutic modalities, except irradiation, were comparable between these two groups.

Effects on tumor

In the TACE plus irradiation group, 5 patients (6.6 %) showed a complete response (CR), and 31 patients (40.8 %) showed a partial response (PR). Tumor size was unchanged in 30 cases (39.5 %), and increased in 10 cases (13.2 %). The objective response rate (RR) was 47.4 %. 48 patients had increased AFP values (>20 ng/ml) before treatment. In 23 of these cases (47.9 %), AFP level reduced by more than 50 %. In the control group, CR was observed in 2 patients (2.3 %) and PR was observed in 23 patients (25.8 %). Tumor size was unchanged in 44 cases (49.4 %) and increased in 20 cases (22.5 %). The RR was 28.1 %. The rate of AFP level, reducing by more than 50 %, was 29.0 % (20/69). The RR and AFP reduction rate in the TACE plus irradiation group increased significantly compared with that in the control group (*P*<0.05).

Table 1 Clinical features and therapeutic modalities in two groups

		TACE group cases (%)	TACE plus irradiation group cases (%)	*P* value
Sex	Male	75 (84.3)	68 (89.5)	
	Female	14 (15.7)	8 (10.5)	0.327
Age	<60 years	66 (74.2)	57 (75.0)	
	⩾60 years	23 (25.8)	19 (25.0)	0.901
AFP	<400 ng/ml	45 (50.6)	42 (55.3)	
	⩾400 ng/ml	44 (49.4)	34 (44.7)	0.547
No. of lesions	Solitary	59 (66.3)	51 (67.1)	
	Multiple	30 (33.7)	25 (32.9)	0.912
Tumor	1 lobe	72 (81.9)	52 (68.4)	
extension[a]	2 lobe	17 (19.1)	24 (31.6)	0.064
Tumor size	5-10 cm	51 (57.3)	47 (61.8)	
	>10 cm	38 (42.7)	29 (38.2)	0.554
Portal	Absent	67 (75.3)	62 (81.6)	
thrombosis	Present	22 (24.7)	14 (18.4)	0.329
Child grade	A	74 (83.2)	63 (82.9)	
	B	15 (16.8)	13 (17.1)	0.996
Okuda stage	I	24 (27.0)	29 (38.2)	
	II	65 (73.0)	46 (60.5)	
	III		1 (1.3)	0.155
TACE times	1	27 (30.3)	27 (35.5)	
	2	42 (47.2)	28 (36.8)	
	3	15 (16.9)	11 (14.5)	
	4	5 (5.6)	10 (13.2)	0.253
Spongostan use	No	48 (53.9)	44 (57.9)	
	Yes	41 (46.1)	32 (42.1)	0.610

[a]Hepatic lobes were classified as two lobes: right lobe and left lobe.

Survival and Cox model analysis

In the TACE plus irradiation group, the median follow-up time was 26 months (ranged from 10 to 84 months). Fifty-two patients died, 21 patients were still alive, and the remaining 3 patients were lost to follow-up. In the control group, the median follow-up time was 24 months (ranged from 10 to 70 months). Seventy-five patients died, 9 patients were still alive, and 5 patients were lost to follow-up. The data were obtained and analyzed in January 2001.

The survival curve for patients from the two groups is shown in Figure 1. The overall survival rates at 1, 3, and 5 years from the TACE plus irradiation group were 64.0 %, 28.6 %, and 19.3 %, respectively (median survival, 19 months), and 39.9 %, 9.5 %, and 7.2 %, respectively from the control group (median survival, 10 months). The survival rates in TACE plus irradiation group were significantly higher than those in control group (*P*=0.0001).

Multivariate analysis using the Cox proportional hazards model showed that both tumor extension and Child grade were significant and independent negative predictors of survival, while irradiation was an independent positive predictor of survival (Table 2).

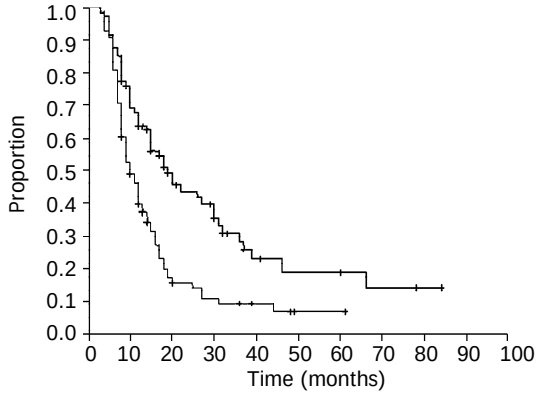

Figure 1 Cumulative survival curves for patients in two groups. The patients in TACE plus irradiation group survived significantly longer than did those in TACE alone group (P=0.0001).

Table 2 Multivariate analysis of major prognostic factors by the Cox proportional hazards model

Variabes	Regression coefficient	Hazard ratio	*P* value
Tumor extension	0.8708	2.3888	0.0016
Child grade	0.5685	1.7655	0.0200
Irradiation or not	-0.7256	0.4840	0.0002

DISCUSSION

TACE is a combination of target chemotherapy and arterial embolization that has both selective ischemic and chemotherapeutic effects on HCC. TACE is an excellent debulking procedure. Surgically resected specimens showed that TACE effectively destroyed malignant cells, not only in the main tumors, but also in daughter tumors, extracapsular invasion, and intraportal neoplastic thrombi. TACE was proved to be effective in treating HCC, and has been widely used for patients with unresectable HCC in Asia[5-10]. It was even found that the effects of TACE was comparable to that of resection in some subpopulations of patients with operable HCC[15]. However, TACE is not a curative method. Tumor cells remain viable, especially in and around the capsule, and tumors may recur by the blood supply from the collateral circulation or portal vein[11]. The long-term efficacy of TACE was disappointing. 1, 3, and 5 year survival rates were around 50 %, 20 %, and 6 %, respectively[5-10]. In the present study, the RR and 5 year survival rate in the TACE control group were 28.1 % and 7.2 %, respectively, which were approximate to the results in the literature. Nevertheless, in some prospective randomized trials, TACE therapy failed to improve the survival of patients significantly[12,13]. Segmental TACE has been shown to yield 5 year survival rate (30 %) for patients with lesions less than 5 cm, but it is suitable only for small tumors. Thus, multimodality treatments are necessary, especially for large HCC.

Radiotherapy has not played a significant role in treating HCC because of the poor tolerance of the liver. The benefit of radiotherapy is still uncertain. Whole liver irradiation at or above 35Gy in a 3-4 week period is known to cause a high incidence of radiation hepatitis, yet this dose level is not enough to control the tumor. In contrast to whole liver irradiation, small portions of the liver can be irradiated up to 50-60 Gy in 5-6 weeks without significant long-term morbidity. Limited-field high dose irradiation (40-60Gy) and three-dimension conformal radiotherapy have been found to be effective for relatively small unresectable HCC, even with portal vein thrombosis[16-20].

The combination of TACE with radiotherapy may remedy the limitation of each alone and have synergistic effects. Tumor shrinkage after TACE allows the use of smaller irradiation fields, which permits higher tumor doses and improves the normal liver tolerance. Combination therapy also serves the purpose of eliminating residual cancer cells after TACE. Furthermore, the anticancer drug retained in the tumor may have a radiosensitizing effect[21]. The anticancer drug, when it is mixed with lipiodol, has been reported to maintain relatively high concentrations in tumors as long as 27 days and decrease to a trace level after 47 days[22]. In 1990, Yoshikawa *et al*.[23] reported that the combination therapy was more effective than TACE or radiotherapy alone in a preliminary study encompassing a small number of cases. From then on, this combination regimen was carried out to treat HCC by more investigators, and was found to be an effective method for HCC[24-29]. Seong *et al*.[26] reported that 30 patients with HCC who were treated by TACE combined with radiotherapy had 3 year survival rate of 22.2 %, and a median survival of 17 months. The results of our study also suggested that TACE followed by irradiation was a promising approach for large HCC. The RR and 5 year survival rate were 47.4 % and 19.3 %, respectively, in 76 patients with very large tumors ($\geqslant$5 cm in all cases, >10 cm in 38.2 % of the cases, while two hepatic lobes were involved in 31.6 % of the cases). In addition, the results of the Cox proportional hazards model analysis showed that irradiation was an independent positive predictor of survival, and further confirmed that TACE combined with radiotherapy was more effective than TACE alone.

The results of combination therapy in the present study appeared to be comparable to those in other reports of multimodality therapy. Second-look resection after TACE yielded the highest 5 year survival rate (56 %)[30, 31], but only a few patients had the opportunity of resection following TACE. PEI after TACE yielded higher survival rates at 1, 2, and 3 years than TACE alone did[32-37], but the survival rates after 4 years dropped, and it was suitable only for tumors <8 cm. Tanaka *et al*.[37] reported that 83 patients with HCC who were treated by TACE-PEI had 5 and 7 year survival rates of 35 % and 14 %, respectively, but most of the patients (71.1 %) in their study had tumors of less than 5 cm in diameter. The results of our study showed that TACE combined with radiotherapy was effective even for very large tumors.

The optimal radiation dose in the combined therapy is unclear. It is well known that the inhibiting effect of radiotherapy on most tumors depends on the irradiation dose. It has been found that the radiation dose is a significant factor for predicting the objective response and the survival in treating HCC[14, 19], but liver tolerance should be considered at the same time. Recently, conformal radiotherapy has been introduced for the treatment of intrahepatic malignancies and dose-volume histogram analysis was used to quantify the tolerance of the liver by some investigators[20,38-40]. They suggested the irradiation dose level by normal liver volume to be radiated depended on the percentage of normal liver receiving more than 50 % of the prescribed isocenter dose, 66Gy for less than 33 %, 48Gy for 33-66 %, and 24Gy (whole liver) for more than 66 % in 1.5Gy twice a day fractionation with concurrent bromodeoxyuridine[38,39]. Introduction of conformal radiotherapy and dose-volume histogram analysis into the study of the combined therapy will help to give an optimal and tangible dose.

The Cox proportional hazards model showed that tumor extension was a significant and independent negative predictor

of survival. The prognosis of patients with invasion in two hepatic lobes was worse than that of patients with one hepatic lobe invasion. This may be because the tumor was barely controlled by combined therapy or TACE alone treatment plus the chance of metastases rose when there was invasion in two lobes. The degree of cirrhosis (classified by Child grade) is also an independent negative predictor of survival. This is in agreement with previous studies[35, 36].

In summary, our results demonstrate that TACE combined with radiotherapy is a promising treatment for large HCC. Prospectively randomized, controlled multi -center clinical trials are needed to confirm the advantageous effects of combined therapy over TACE or radiotherapy alone. In addition, further clarification about an optimal radiation dose and the optimal interval between TACE and radiotherapy are also needed.

Abstract

AIM: To determine the feasibility and role of ultrasound-guided preoperative selective portal vein embolization (POSPVE) in the two-step hepatectomy of patients with advanced primary hepatocellular carcinoma (HCC).

METHODS: Fifty patients with advanced HCC who were not suitable for curative hepatectomy were treated by ultrasound-guided percutaneous transhepatic POSPVE with fine needles. The successful rate, side effects and complications of POSPVE, changes of hepatic lobe volume and two-step curative hepatectomy rate after POSPVE were observed.

RESULTS: POSPVE was successfully performed in 47 (94.0 %) patients. In patients whose right portal vein branches were embolized, their right hepatic volume decreased and left hepatic volume increased gradually. The ratio of right hepatic volume to total hepatic volume decreased from 62.4 % before POSPVE to 60.5 %, 57.2 % and 52.8 % after 1, 2 and 3 weeks respectively. The side effects included different degree of pain in liver area (38 cases), slight fever (27 cases), nausea and vomiting (9 cases). The level of aspartate alanine transaminase (AST), alanine transaminase (ALT) and total bilirubin (TBIL) increased after POSPVE, but returned to preoperative level in 1 week. After 2-4 weeks, two-step curative hepatectomy for HCC was successfully performed on 23 (52.3 %) patients. There were no such severe complications as ectopic embolization, local hemorrhage and bile leakage.

CONCLUSION: Ultrasound-guided percutaneous transhepatic POSPVE with fine needles is feasible and safe. It can extend the indications of curative hepatectomy of HCC, and increase the safety of hepatectomy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors of mankind. It threatens our life severely[1-5]. In China, HCC is responsible for about 130 000 deaths every year. It has ranked second of cancer mortality since 1990[6,7]. Surgical resection of the tumors is considered the only potentially curative therapy, and it is regarded as the first choice for the treatment of HCC. Many factors can affect hepatectomy, such as tumor size, location, multifocality and patients' status, hepatic function. Besides, 80 % of them are complicated with cirrhosis in China. So the extension of hepatectomy of HCC is greatly limited. Hepatectomy with less hepatic volume resected may be helpful to the safety of the operation, but this may not be a radical cure, and even lead to tumor residual. Hepatectomy with more hepatic volume resected will lead to postoperative hepatic failure, infection, hemorrhage and even death. So only 15 % to 30 % patients have a chance of receiving curative hepatectomy[8-10]. Most HCC patients are in late stages at the time of diagnosis. They are considered not suitable for operation. Researchers have proposed the concept of "two-step hepatectomy", and some progresses have been made in the past decades[11-15]. In 1986, Kinoshita *et al*[16] reported the experience of two-step hepatectomy after POSPVE. This is a completely new method. The purpose is to induce atrophy of the embolized (tumor) lobe and compensatory hypertrophy of the remnant lobe. The result is an increase of the remnant liver volume and a decreased ratio of resected volume to total liver volume. In recent years, reports of two-step hepatectomy after preoperative selective portal vein embolization (POSPVE) gradually increased[17-22]. But there are no such clinical reports in China.

In this study, based on an analysis of the feasibility and safety of ultrasound-guided percutaneous transhepatic POSPVE with fine needles in 50 HCC patients, we discussed the role of POSPVE in the two-step curative hepatectomy for moderate and advanced HCC.

MATERIALS AND METHODS

Eligibility of patients

This study involved 50 HCC patients. There were 36 males and 14 females. Forty three (86.0 %) patients were hepatitis surface antigen (HBsAg) positive, and 34 (68 %) were complicated with cirrhosis. Child-Pugh' s classification showed that 14 (28 %) patients were grade A, 33 (66 %) grade B, 3 (6 %) grade C. The diameter of space occupying lesions ranged from 8.1 to 16.3 cm, averaging 13.6 cm. The criteria of these patients included: HCC located in one side of the liver, with no confirmed portal vein thrombosis and distant metastasis. The ratio of hepatic volume to be resected to total hepatic volume was more than 50 % for those patients with cirrhosis and 60 % for those without cirrhosis. Those patients with coexisted morbidity-related diseases, poor life expectancy, multinodular or diffuse intrahepatic tumor, prothrombin activity less than 50 %, or platelet count lower than 50×10^9/L were excluded from the study.

Methods

One hundred microgram dolantin and 25 mg phenergan were

injected into the muscle before POSPVE. The liver, tumor and the portal vein branch to be embolized were carefully examined, located and confirmed by ultrasound. Local anesthesia was adopted with 2 % lidocaine transcutaneously down to liver surface. Under ultrasound guidance, we punctured percutaneously and transhepatically with a 21-gague PTC needle from the side of ultrasound head. When the needle was inserted into the portal vein branch to be embolized, the internal part of the needle was taken away, and dark red portal vein blood could be seen (Figure 1). Then embolic material was slowly injected into the portal vein. It consisted of a mixture of ethanol and iodized oil with a rate of 1:2. And 0.4 ml/kg was regarded as the standard dosage. Real-time ultrasonic scan showed that tiny spot echoes in the embolized portal vein branch appeared and diffused into the carcinoma. Intensified echoes appeared in some areas. After that, the fine needle was slowly pulled out. Flexible fabric bandage was used to cover the puncture spot. The patients inhaled oxygen after returning back to the ward. Changes of vital signs were monitored for 12 to 24 hours. They were given fluid infusion and anti-inflammation, hemorrhage prevention, liver function protection and analgesics treatments.

The successful rate of POSPVE, side effects and complications after POSPVE, changes of blood routine, liver function, and renal function were observed to evaluate the feasibility and safety of ultrasound-guided percutaneous transhepatic POSPVE with fine needles. Serial changes of hepatic lobe volume calculated with volume CT, ratio of right hepatic lobe volume to total hepatic volume, two-step curative hepatectomy rate after POSPVE were observed to evaluate the role of POSPVE in the two-step hepatectomy of HCC.

Statistical method

Quantitative variables were expressed as mean ± standard error of the mean. The statistical software SPSS10.0 was used. *P* value <0.05 was considered significant.

RESULTS

Feasibility and safety of POSPVE

Ultrasound-guided percutaneous transhepatic POSPVE with fine needles was successfully performed in 47 of 50 patients. The successful rate was 94.0 % (Figure 1). Three patients failed to finish the operation. The right portal vein branches were difficult to locate under ultrasound guidance because of the tumor compression in 2 of them, and one patient could not tolerate the irritation of embolic material. There were 44 right portal vein embolizations and 3 left portal vein embolizations. The side effects included different degree of pain in liver area (38 cases), slight fever (27 cases), nausea and vomiting (9 cases). The level of aspartate alanine transaminase (AST), alanine transaminase (ALT) and total bilirubin (TBIL) increased in 31 cases after POSPVE, but returned to preoperative level in 1 week. There were no such severe complications as ectopic embolization, local hemorrhage and bile leakage.

Role of POSPVE in two-step curative hepatectomy of HCC

In 44 patients whose right portal vein branches were embolized, the right hepatic volume decreased, the left hepatic volume increased and the ratio of right liver volume to total liver volume decreased gradually (Figures 2-3) (Table 1). Two to four weeks later, curative hepatectomies were successfully performed in 23 (52.3 %) patients (Figures 4-5). There were 6 irregular right hepatectomies, 15 regular right hepatectomies, and 2 right trisegmentectomies. All these 23 patients recovered smoothly, without any severe complications like hepatic failure, hemorrhage and infection. They were discharged 11 to 20 days after operations. The other 27 patients who could not receive curative hepatectomy after POSPVE were treated by transcatheter artery embolization (TAE) or chemotherapy, immune therapy and so on.

Table 1 Serial changes of liver volume and ratio of right hepatic lobe volume to total hepatic volume after right portal vein embolization

	Right liver volume (cm^3)	Left liver volume (cm^3)	Right liver volume / total liver volume (%)
Before POSPVE	592.4±98.5	352.2±65.2	62.4±7.6
1 week after POSPVE	571.7±104.0	378.6±127.9	60.5±9.3
2 weeks after POSPVE	547.7±118.3[a,c]	405.9±130.2[a,c]	57.2±11.2[a,c]
3 weeks after POSPVE	509.1±123.8[b,c,e]	446.1±143.5[b,d,e]	52.8±12.3[b,c,e]

[a]$P<0.05$, [b]$P<0.01$, *vs* before POSPVE; [c]$P<0.05$, [d]$P<0.01$, *vs* 1 week after POSPVE, [e]$P<0.05$, [f]$P<0.01$, *vs* 2 weeks after POSPVE.

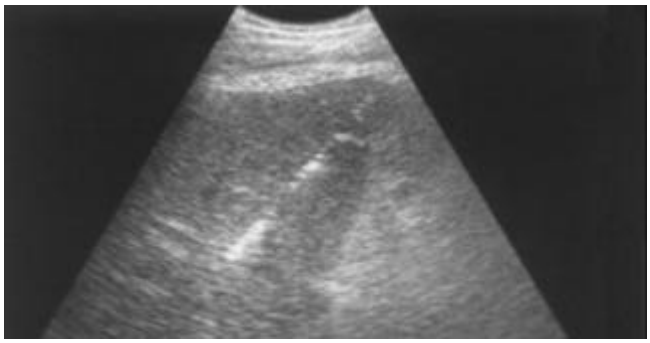

Figure 1 The fine needle was inserted into the right portal vein branch under ultrasound guidance. After embolization material was injected, tiny spot echoes appeared in the portal vein branch and diffused to the carcinoma area.

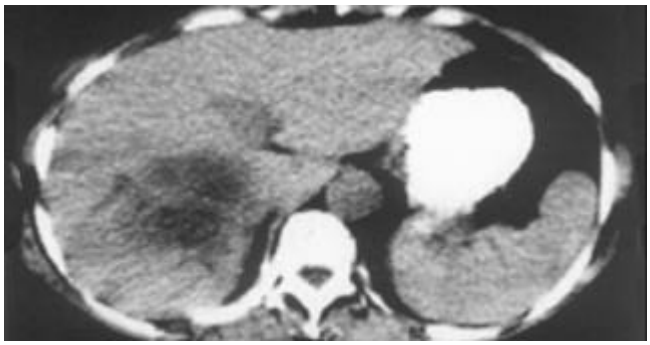

Figure 2 Before POSPVE, CT scan showed a 13.2 cm×10.8 cm HCC in the right lobe of liver. A right semihepatectomy was scheduled to perform.

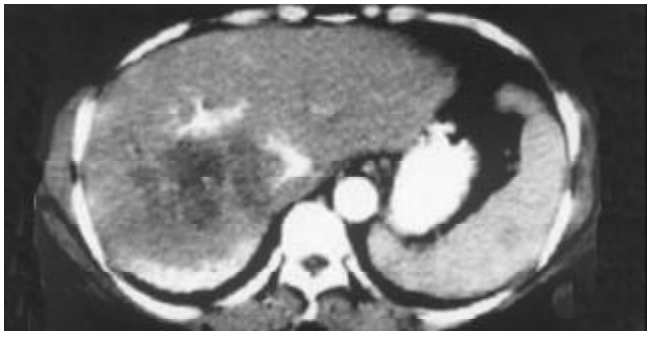

Figure 3 Three weeks after right POSPVE, CT scan showed increased volume of left lobe and decreased volume of right lobe. Iodized oil deposit still could be seen in the right portal vein branch.

Figure 4 Three weeks after right POSPVE, a right semihepatectomy was performed. In the operation, significant hypertrophy of left lobe was confirmed.

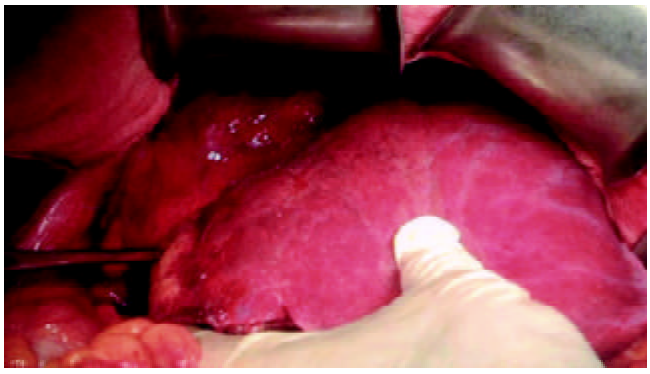

Figure 5 In the same operation, significant atrophy of right lobe and HCC could be seen. There was iodized oil deposit in the carcinoma area.

DISCUSSION

Rous and Larimore observed in 1920 that portal vein ligation in rabbit led to atrophy of the ipsilateral hepatic lobe and hypertrophy of the contralateral lobe. In 1956, Schalm confirmed it by occluding the portal vein branch. These observations provided the foundation for the study of liver regeneration after portal vein branch embolization. In 1975, Honjo found that portal vein ligation could significantly prolong the survival span of advanced HCC patients whose tumors could not be resected during operations. In 1986, Kinoshita published the first report demonstrating the efficacy of POSPVE before curative resection on primary and metastatic HCC. After that, POSPVE was gradually accepted in preparing large hepatectomy for HCC. It has been confirmed that POSPVE can extend the indication of curative hepatectomy for HCC, increase the safety of hepatectomy, and improve the long-term survival rate after the operation[23-32].

Portal vein blood supply is very important for both liver and HCC. Portal vein branch ligation or embolization results in redistribution of portal vein blood that is essential to liver regeneration. Most portal blood rich in hepatatrophic substances, such as insulin, glucagon and hepatocyte growth factor, flows toward the future remaining lobe. This leads to atrophy of the ipsilateral hepatic lobe and hypertrophy of the contralateral lobe. Harada *et al*[33] observed that POSPVE induced hepatocyte apoptosis and atrophy of the embolized lobe. Increased sinusoidal volume in this lobe may be attributable to hepatocyte deletion. Cells in the nonembolized lobe entered a highly active phase of proliferation within 2 weeks after POSPVE. Further evidences of cellular proliferation were provided by the increased nonembolized lobar volume and numerical density of hepatocyte nuclei (Nv). They concluded that the favorable role of POSPVE was attributed to a net gain of functional hepatocyte mass and early induction of hepatocyte proliferation. Shimizu *et al*[34] demonstrated that expression of proliferating cell nuclear antigen (PCNA) and mitotic index (MI) of hepatocytes in nonembolized lobe increased greatly. The amount of mitochondrial DNA-binding proteins increased 200-300 % of the preoperative level at 12 hours after ligation of left branch of the portal vein, before an increase of 390 % in mitochondrial DNA content at 24 hours, and was parallel to an increase of 240 % in mitochondrial mRNA at 12 hours. These results suggest that the energy supply for liver regeneration is achieved through enhancement of mitochondrial DNA replication as well as transcription, in which mitochondrial DNA-binding proteins probably play regulatory roles. Chijiiwa *et al*[35-37] found that the volume of nonembolized left lobe significantly increased after right POSPVE, with a significant increase in percentage of the left lobe to total liver volume. Concentrations of AMP, ADP, and ATP, and hepatic energy charge levels in the nonembolized left lobe were similar to those of the control liver. These results suggest that right POSPVE increased the volume of nonembolized left lobe, while keeping the hepatic engery charge and ATP levels similar to the control liver, thereby increasing the total amount of ATP and hepatic energy reserve of the nonembolized lobe in proportion to its volume increase at the time of surgery.

Two major techniques have been reported to access the portal vein: direct catheterization of the ileocolic vein and the percutaneous approach[38,39]. The former involves an open technique in which the ileocolic vein is cannulated at laparotomy. It is usually used when the carcinoma can not be resected during operation. This method can also be used when interventional facilities are not available for the percutaneous approach. The later can be finished under ultrasound guidance with local anesthesia. There are two major kinds of methods. One is to insert a catheter percutaneously into the portal vein branch, the other is to puncture the portal vein branch by a fine needle under ultrasound guidance. Most reports used the catheterization method. But it is technically complicated and expensive. Percutaneous approach with a fine needle is easy to perform, and patients suffer less and resume faster. But it has not been widely accepted. Its feasibility, safety and efficiency have not been discussed based on a large sample[40,41]. In this study, POSPVE with a fine needle was feasible in 47 of 50 HCC patients. The successful rate was 94.0 %. The complication rate was low, and there was no severe complication. The side effects were moderate. In 44 patients whose right portal veins were embolized, their right hepatic volume decreased and left hepatic volume increased, the ratio of hepatectomy decreased gradually. By inducing hypertrophy of the remaining liver, hepatectomies were successfully performed in 23 patients. The two-step curative hepatectomy after POSPVE was 52.3 %. All the patients recovered smoothly. It is concluded from this study that ultrasound-guided percutaneous transhepatic POSPVE with a fine needle is feasible, safe and effective. It extends the indication of curative hepatectomy for moderate and advanced HCC. This is the first report on the role of POSPVE in the treatment of HCC in China. Estimating the volume of the lobe that will remain after hepatectomy is thought to be mandatory for all patients undergoing extensive hepatic resection. If this volume is not large enough in terms of the risk of postoperative liver failure, then POSPVE is indicated. According to a criterion based on liver volumetry, POSPVE is usually indicated for patients who will undergo right trisegmentectomy, left trisegmentectomy, or right hepatectomy for cirrhosis patients. Many methods have been used to estimate the lobar volume. In this series, we used volume CT to calculate the exact volume of every lobe, and regard the ratio of hepatic volume to be resected to total hepatic

volume is more than 50 % for those patients with cirrhosis and 60 % for those without cirrhosis. The degree of hypertrophy induced in nonembolized lobe showed a large interindividual difference. It has been reported that male, diabetes mellitus and cirrhosis are negative factors, and cholestasis is a positive factor. Other factors that may influence the role of POSPVE include embolization materials and their dosage and extent[42-46]. Cyanoacrylate, lipiodol, gelatin sponge, thrombin, fibrin glue, gelfoam, and alcohol have been used as embolization materials. Their effects are controversial. We used lipidol and alcohol routinely as embolization materials throughout the study period. The functional burden placed on the liver by POSPVE using these materials was minimal and transient, as reflected in the slight elevation of AST, ALT and total bilirubin level. It was reported that the average future remaining hepatic volume increased by 28 % within 2 weeks after POSPVE. The rate of average hepatectomy decreased from 70.0 % before POSPVE to 62.2 %, and the two-step hepatectomy rate was 63.3 % to 77.4 %. But in this series, the two-step curative hepatectomy rate after POSPVE was 52.3 %. We think the main reason is that most patients in our study were male and coexisted with cirrhosis. They have been reported to be the negative regulatory factors of POSPVE. Besides, we used the method of ultrasound-guided percutaneous transhepatic POSPVE with a fine needle. It is safe, feasible and effective. The disadvantage of this method lies in that the embolization materials usually used are ethanol and iodized oil. So, it is mainly the distant branches of portal vein that are embolized. Besides, the role of ethanol is dosage dependent, while a large dosage is unbearable for most patients.

Although the concept of POSPVE appears to be well accepted and the procedure is performed ever more widely, there are a number of issues on which a general consensus has not yet been reached, such as the optimum duration between POSPVE and hepatectomy, the most suitable embolizing material and method of portal vein cannulation, the rate of technical failure and complications, and factors that accelerate or suppress the effect of POSPVE[32]. The fact that POSPVE is well tolerated might enlarge its indications in the future. POSPVE will be used not only for patients with possibly insufficient remaining liver volume after hepatectomy, but also for those whose curative operation may not be very safe.

Abstract

AIM: Heparanase degrades heparan sulfate proteoglycans (HSPGs) and is a critical mediator of tumor metastasis and angiogenesis. Recently, it has been cloned as a single gene family and found to be a potential target for antimetastasis drugs. However, the molecular basis for the regulation of heparanase expression is still not quite clear. The aim of this study was to determine whether the expression of eukaryotic initiation factor 4E (eIF-4E) correlated with the heparanase level in tumor cells and to explore the correlation between heparanase expression and metastatic potential of LS-174T cells.

METHODS: A 20-mer antisense s-oligodeoxynucleotide (asODN) targeted against the translation start site of eIF-4E mRNA was introduced into LS-174T cells by lipid-mediated DNA-transfection. eIF-4E protein and mRNA levels were detected by Western blot analysis and RT-PCR, respectively. Heparanase activity was defined as the ability to degrade high molecular weight (40-100 kDa) radiolabeled HS (heparan sulfate) substrate into low molecular weight (5-15 kDa) HS fragments that could be differentiated by gel filtration chromatography. The invasive potential of tumor cell *in vitro* was observed by using a Matrigel invasion assay system.

RESULTS: The 20-mer asODN against eIF-4E specifically and significantly inhibited eIF-4E expression at both transcriptional and translational levels. As a result, the expression and activity of heparanase were effectively retarded and the decreased activity of heparanase resulted in the decreased invasive potential of LS-174T.

CONCLUSION: eIF-4E is involved in the regulation of heparanase production in colon adenocarcinoma cell line LS-174T, and its critical function makes it a particularly interesting target for heparanase regulation. This targeting strategy in antisense chemistry may have practical applications in experimental or clinical anti-metastatic gene therapy of human colorectal carcinoma.

INTRODUCTION

For a malignant tumor cell to metastasize, it must break away from its neighbors, force its way through the surrounding stroma, and penetrate basement membranes to enter the stroma and the circulation. When it arrives at its destination, these steps must be repeated in reverse order[1]. A critical event in the process of cancer invasion and metastasis is therefore degradation of various constituents of the extracellular matrix (ECM) including collagen, laminin, fibronectin, and heparan sulfate proteoglycans (HSPGs). The malignant cell is able to accomplish this task through the concerted sequential action of enzymes such as metalloproteinases, serine proteases, and endoglycosidases[2,3]. Among these enzymes, an endo-β-glucuronidase (heparanase) selectively degrades the heparan sulfate chains of HSPGs which are essential and ubiquitous macromolecules associated with the cell surface and ECM of a wide range of cells and tissues[4,5]. Heparanase cleaves heparan sulfate (HS) and has been implicated in many important pathological processes, including tumor metastasis and angiogenesis[6, 7]. Therefore, heparanase plays an essential role in these pathological processes which makes it a potentially important target for cancer therapy and be helpful to investigate the mechanism, by which the expression of heparanase is regulated.

Eukaryotic initiation factor 4E (eIF-4E) is a 25 kDa mRNA cap-binding phosphoprotein that is rate-limiting for the initiation of cap-dependent mRNA translation by the eIF-4F translation initiation complex[8,9]. Overexpression of eIF-4E has been found in human carcinoma tissues and tumor cell lines. The factor (eIF-4E)[10] dramatically impacts upon the quantitative expression of key malignancy-related genes and can be considered as a critical determinant of malignancy. It seems that involvement of eIF-4E in tumor progression is more closely associated with the impact of enhanced eIF-4E activity on specific, malignancy-related molecules such as ODC, c-myc, cyclin D1, VEGF or MMP-9. Cooperative overexpression of these potent molecules leads to occurrence of tumorigenic phenotype that conspires to drive metastatic progression. The aim of this study was to determine whether eIF-4E was involved in the regulation of heparanase expression and to postulate the probable mechanism.

MATERIALS AND METHODS

Materials

Cell lines Human colon adenocarcinoma cell line LS-174T was an ATCC cell line and was maintained in RPMI 1640 supplemented with 2 mM L-glutamine and 10 % FCS at 37 ℃ in a humidified atmosphere containing 5 % CO_2.

Antisense oligonucleotides Oligonucleotides containing

phosphorothioate were customarily-made and purified with high-performance liquid chromatography. The eIF-4E antisense oligonucleotide comprised the following sequence[11]: 5' -AGTCGCCATCTTAGATCGAT-3' (20 mer), complementary to nucleotides (nt) -11 to +9 of human eIF-4E mRNA. The complementary sense sequence used was 5' -ATCGATCTA AGATGGCGACT-3' . Sense oligonucleotide was used as controls in each of the antisense oligonucleotide experiments.

Methods

Antisense oligonucleotide treatments The day before transfection, the cells were trysinized, counted and plated in a 5×10^6 cells/60-mm dish so that 90-95 % confluency was reached on the day of transfection. As it was a unique cationic lipid formulation, LIPOFECTAMlNE 2000 was more convenient in that it could be used in the presence of serum containing media, by adding it directly to the culture without washing the cells. For transfecting oligonucleotides to cells, the LIPOFECTAMlNE 2000 reagent (Invitrogen) was used according to the manufacturer' s instructions. Briefly, LIPOFECTAMlNE 2000 reagent and oligonucleotides (ODNs) were diluted separately into RPMI 1640 medium and ODNs were mixed with liposome in a charge ratio of 1:2. The mixtures were incubated at room temperature for 20 min to form complexes and then ODN-LIPOFECTAMlNE 2000 reagent complexes was added directly to each well and mixed gently by rocking the plate back and forth. The ODNs were delivered to tumor cells at the final concentration of 2 μmol/L. Tumor cells were incubated in the presence of oligonucleotides/ LIPOFECTAMlNE 2000 reagent mixture for 24 h and 48 h for RT-PCR assays or Western blot.

Semi-quantitative RT-PCR analysis of eIF-4E mRNA Total RNA was extracted by the guanidine salts and phenol-chloroform method. cDNA was prepared from 2 μg of total RNA, using poly-T as primer and MuLV reverse transcriptases (Promega). For PCR amplification, one-fourth of the reverse transcription product and 0.3 μmol/L of each oligonucleotide as primers were used. After one denaturation step at 96 ℃ for 3 minutes, 30 cycles of amplification were performed: denaturation at 94 ℃ for 45 s, annealing at 55 ℃ for 45 s, synthesis at 72 ℃ for 1 minute, and extension at 72 ℃ for 5 minutes. Oligonucleotides for eIF-4E expression analysis were sense primer 5' AGATGGCGACTGTCGAACC3' , antisense primer 5' CAGCGCCACATACATCAT3' [12]. To check cDNA quality, GAPDH was amplified using sense primer 5' CTGGCGCTGAGTACGTCGTG3' and antisense primer 5' CAGTCTTCTGGGTGGCAGTG3' . One-tenth of the amplified products was run on 2 % agarose gels in 1×Tris borate buffer and visualized with ethidium bromide.

Western blot analysis Total proteins were extracted at 48 h after transfection. Cells were lysed in RIPA buffer [10 mM Tris-HCl (pH 7.4), 1 % deoxycholate, 1 % NP40, 150 mM NaCl, 0.1 % SDS, 0.2 mM phenylmethylsulfonyl fluoride, 1 μg/ml aprotinin and 1 μg/ml leupeptin. The lysates were then centrifuged at 10 000×g for 15 min to remove debris. Protein content of the lysate was determined by using Bradford assay (Bio-Rad). For each sample, equal amounts (50 μg) of protein lysates were analyzed on a sodium dodecyl sulfate-10 % or 12 % polyacrylamide gel. Proteins were electroblotted onto Immobilon PVDF membranes (Millipore, Bedford, MA), blocked for 1 h in 5 % dry skim milk, and then incubated with the indicated antibodies. The antibodies used and their dilutions were as follows: 1:500 mouse monoclonal anti-eIF-4E (BD Biosciences), 1:700 rabbit polyclonal anti-heparanase (a kind gift from Mark D. Hulett). The secondary antibodies used were those in an enhanced chemiluminescence detection kit (Amersham) and were chosen according to the species used for the primary antibodies. Exposure times varied with the antibodies used and ranged from 5 to 60 s.

Assays for heparanase activity Heparanase activity was defined as the ability to degrade high molecular weight (40-100 kDa) radio-labeled HS substrate into low molecular weight (5-15 kDa) HS fragments[13-15], which could be differentiated by gel filtration chromatography[16,17]. Radiolabeled HS substrate was prepared by metabolically labeling the extracellular matrix with [^{35}S] as described[16,17]. Soluble substrate was made by releasing ^{35}S-labeled HS proteoglycans from the culture plate with trypsin, and incubated with cell homogenates which were prepared by suspending 10^6 cells in 0.2 ml of aq. 0.1 % (v/v) Triton X-100 and disrupted by freezing and thawing three times in a solid CO_2/ethanol mixture. Samples were taken from the above supernate fractions. Protein concentrations were estimated by a Bio-Rad Coomassie protein assay kit (Bio-Rad Laboratories) using BSA as a standard. Cell lysates containing 50 μg of protein were incubated at 37 ℃ for 24 h in 10 mM sodium phosphate-citrate buffer, pH 6.0, with 20-25 000 cpm of ^{35}S-labeled HS substrate. The incubation medium was centrifuged and the supernatant was analyzed by gel filtration on a Sepharose CL-6B column (0.7×25 cm). Fractions (0.2 ml) were eluted with PBS and their radioactivity was measured. Degradation fragments of HS side chains were eluted from Sepharose CL-6B at 0.5<Kav<0.8 (peak II). A nearly intact HSPG was eluted just after the Vo (Kav<0.2, peak I). Each experiment was repeated at least three times and the variation of elution positions (Kav values) did not exceed ±15 %. Blue dextran and phenol red were added to the sample to mark the excluded (V_0) and included (Vt) volumes, respectively.

***In vitro* invasion assays** *In vitro* invasion assays were performed using modified Boyden chambers, 24-well plates. Polycarbonate filters (8 μm porosity), used to separate the upper compartment, were coated with 50 μg Matrigel. After the lower wells were filled with 600 μl of culture media, supplemented with 0.1 % BSA and 50 μg solubilized Matrigel as a chemo-attractant. The cells in media containing 2 μM oligonucleotides, 1 % FBS at a density of 10^6 cells/ml were resuspended. Gelled Matrigel was gently washed with warmed serum free-culture media. 100 μl of the cell suspension was put onto the Matrigel. Chambers were placed in a 37 ℃ incubator with 5 % CO_2/95 % air for 48 h. Then, the cells remaining on the upper surface of the membrane were removed with a cotton swab and the filters were fixed and stained with a solution of methanol/Coomassie blue 0.1 % in acetic acid (1:3). Cells that had invaded the lower surface of the filter were counted under an inverted microscope. 10 fields per well were counted. The invasion score of untreated control cells was taken as 100 % and that of treated cells was expressed as a percentage of control. All experiments were performed in duplicate and the results from 3 separate sets of experiments were averaged.

RESULTS

Down-regulation effects of antisense oligonucleotides on eIF-4E expression

LS-174T cells were treated with either antisense oligonucleotides, sense control oligonucleotides or saline for 24 h or 48 h in the presence of liposome. By using quantitative RT-PCR analysis, a high level of eIF-4E mRNA was shown in LS-174T cell lines, and treatment with antisense oligonucleotides at concentrations up to 2 μM, induced a significant decrease in the eIF-4E mRNA expression levels compared to control groups. There was no down-regulation of eIF-4E expression in the sense oligonucleotide-treated cells (Figure 1). In order to verify that the decrease in mRNA expression levels corresponded also to

decreases in protein levels, Western blot analysis was performed (Figure 2). We used eIF-4E standard antigen (BD Transduction Laboratories) as a positive control. A significant reduction of eIF-4E protein level was observed in LS-174T cell line, treated with antisense oligonucleotides. In contrast, there was no apparent down-regulation of eIF-4E protein levels in the cells exposed to sense oligonucleotides in comparison with untreated ones.

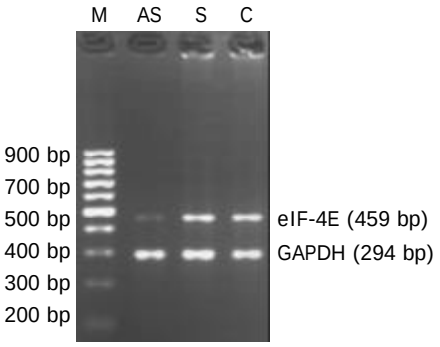

Figure 1 eIF-4E and GAPDH mRNA expression in oligonucleotide-treated human colon adenocarcinoma cells. AS. anti-sense oligonucleotide-transfected cells; S. sense oligonucleotide-transfected cells; C. cells treated with liposome only as control. LS-174T cells were treated with 2 μM oligonucleotides, according to the optimal condition of this cell line in the preliminary experimental results. The numbers under each band showed the relative amount of eIF-4E fragments normalized to that of GAPDH by densitometry. The results suggest that antisense oligonucleotides against eIF-4E inhibit eIF-4E mRNA expression in LS-174T cells, and sense oligonucleotides have no inhibitory effect on eIF-4E mRNA expression.

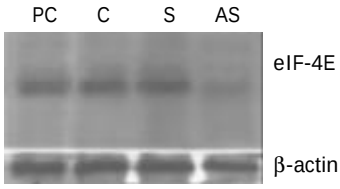

Figure 2 eIF-4E protein expression in oligonucleotide-treated colon adenocarcinoma cells. Protein extracts were prepared from oligonucleotide-treated cells at 48 h after transfection. Cell lysates were size-fractionated by 12 % SDS-PAGE, and immunodetection on the blotted membrane was performed using the eIF-4E MAb. AS, antisense oligonucleotide-treated cells; S. sense oligonucleotide-treated cells; C, cells treated with liposome only; PC, eIF-4E standard antigen (derived from a human neuroblastoma cell line) as a positive control marker.

eIF-4E down-regulation is correlated with alterations in expression of heparanase protein

It has shown that eIF-4E may be involved in regulating a variety of tumor invasion-associated molecules[10]. We investigated the relationship between eIF-4E overexpression and the effects of this expression on heparanase levels in metastatic colon adenocarcinoma cell line. Substantial alterations in the levels of both 50 kDa and 65 kDa heparanase protein expression were observed in the transfectants. In LS-174 cell lines treated with asODN, eIF-4E down-regulation appeared to be associated with the decrease in heparanase protein expression. A 50 kDa protein, corresponding to the expected active mature heparanase according to published data[18], was detected at lower levels in LS-174T cells transfected with antisense oligonucleotides. And so did a 65 kDa protein, which corresponded to the expected size for unprocessed heparanase. In the meantime, heparanase protein levels did not change apparently in the cells treated with sense oligonucleotides or liposome only. Our data demonstrated that eIF-4E did affect the expression of heparanase protein of LS-174T cells under these experimental conditions (Figure 3).

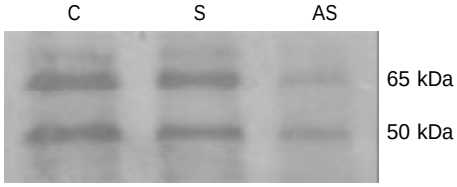

Figure 3 Western blot analysis of heparanase expression in LS-174T cells. The colon adenocarcinoma cells were lysed, and Western blot analysis was performed with an anti-human heparanase polyclonal antibody. AS, antisense oligonucleotide-treated cells; S. sense oligonucleotide-treated cells; C, cells treated with liposome only. Cells treated with antisense oligonucleotides showed markedly reduced levels of heparanase protein compared to cells treated with sense oligonucleotides or saline in the presence of liposome. The approximately 65-kDa protein represents a heparanase precursor, whereas the 50-kDa protein is a processed form, and data showed that both of them were less expressed while eIF-4E was inhibited.

Alteration in heparanase activity

Heparanase activity was determined by degradation of purified ECM [^{35}S] HS using gel filtration chromatography analysis. Degradation fragments eluted in peak II were shown to be degradation products of HS. In this experiment, incubation of an equal amount of protein with sulfate-labeled ECM resulted in release of high level HS degradation fragments (Peak II) in the samples derived from the cells treated with sense oligonucleotides or liposome alone, whereas degradation was less pronounced during incubation of ECM with extracts derived from the cells treated with antisense oligonucleotides (Figure 4). Heparanase activity was also expressed as the total amount of radioactivity eluted in peak II multiplied by the Kav of peak II, thereby representing both the total amount and the size of HS-degradation fragments. The result was consistent with heparanase expression at the protein level. Thus, the alteration of heparanase protein seen by immunostaining was also reflected by a decreased heparanase activity found in the extracts derived from the tumor cells treated with antisense oligonucleotides. These results suggested that the high levels of heparanase were parallel to over-expressed eIF-4E in LS-174T cells and the expression of heparanase might be regulated by eIF-4E in these tumor cells.

Inhibition of heparanase suppresses in vitro invasiveness of LS-174T cells

We first examined whether the variation of eIF-4E expression was associated with heparanase activity in LS-174T cells and its consequent influence on the invasive potential of these tumor cells (Figure 5). The effect of this antisense sequence on invasive capacity was studied *in vitro* by measuring the ability of tumor cells to cross a barrier composed of Matrigel. In these conditions, the invasiveness of LS-174T cells was reduced to 23 % by this antisense sequence. In a control experiment, cells treated at the same concentration of sense oligonucleotides did not show any significantly inhibitory effect on tumor cells invasion as compared to the untreated ones. These results argued that eIF-4E was involved in the regulation of heparanase expression and might further influence the invasive potential of tumor cells.

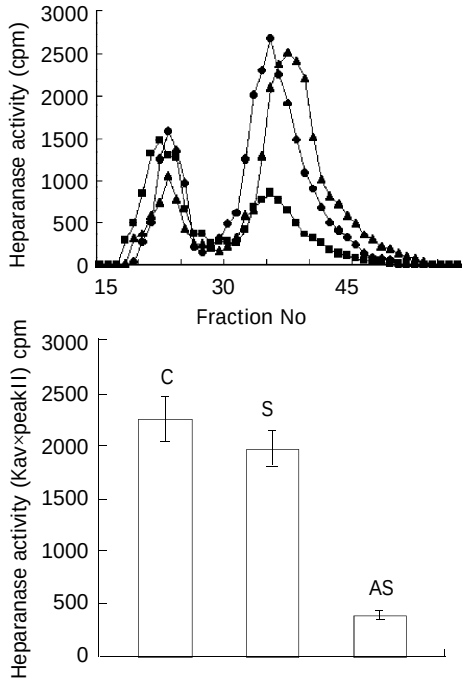

Figure 4 Effects of eIF-4E down-regulation upon enzyme activity of heparanase. Cells were treated for 48 h with antisense oligonucleotide (■), sense oligonucleotide (▲) or liposome only(◆). The soluble fraction from transfected, freezed and thawed LS-174T cells was incubated with ^{35}S-labeled HS. The incubation medium was then subjected to gel filtration over Sepharose CL-6B. Low-molecular-weight HS degradation fragments (peak II) were mainly produced during incubation with medium conditioned by sense oligonucleotide infected cells. The cells treated with antisense oligonucleotide exhibited low levels of heparanase activity as compared to untreated ones. Heparanase activity was also expressed as Kav×total cpm eluted in peak II.

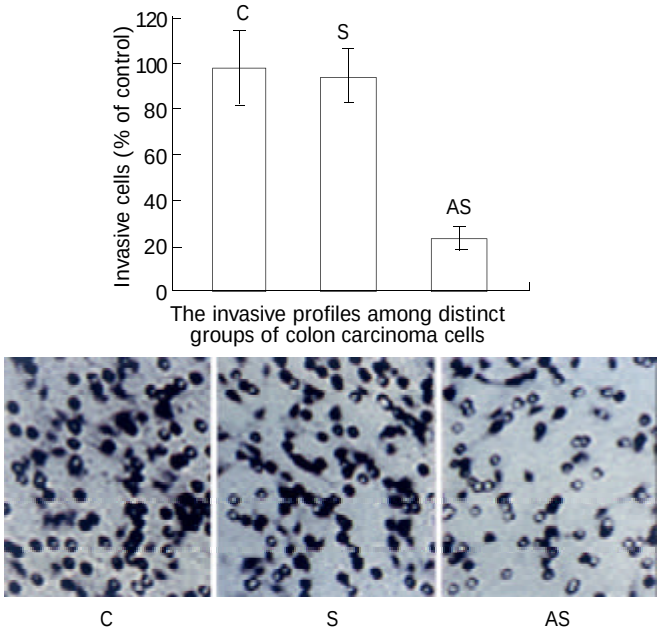

Figure 5 Invasive profiles of LS-174T cells measured *in vitro* using Matrigel as ECM barrier in modified Boyden chambers. The invasiveness of the cells on Matrigel was normalized to 100 % (control, untreated cells). Compared with the control, antisense oligonucleotide reduced invasion to 23 %. Sense sequence didn't have a significant influence on invasive potential of LS-174T cells. These results suggest that alteration of heparanase activity via inhibition of the expression of eIF-4E results in decreased invasiveness in LS-174T cells. The small rings are membrane pores.

DISCUSSION

Inhibition of tumor invasion is an attractive approach for the treatment of highly malignant tumors. Tumor cell invasion is characterized by secretion of enzymes that facilitate tumor cell spread by degrading ECM surrounding the tumors and solubilizing the vascular basement[19]. Thus, heparanase, which degrades HSPG in ECM, is an attractive target for the development of new antimetastatic drugs because of evidences implicating the enzyme in tumor cell invasion. Heparanase facilitates tumor cell invasion and metastasis by at least two different mechanisms. First, it breaks down physical barriers to invasion through degradation of HS chains of HSPGs which are the chief components in BM and ECM, not cleaved by MMPs. Second, it may regulate angiogenesis, tissue repair, inflammation and lipid metabolism by releasing HS-bound growth factor (bFGF) and lipoprotein lipase, which may be a pertinent molecular mechanism for tumor metastasis. Prior reports have mentioned that heparanase is involved in the metastatic potential of various tumor cells, however heparanase as a key regulator of tumor metastasis has not been established with regard to the lack of purified enzymes and cDNA of the gene[20-24]. Two studies concerned with cloning and sequencing of mammalian heparanase and new findings not only confirmed previous studies but revealed that heparanase played an important role in invasion and metastasis of tumor cells[25,26].

As judged by semi-quantitative RT-PCR, heparanase mRNA was increased in human malignancies and xenografts of human breast, colon, lung, prostate, ovary, and pancreas tumors, compared with the corresponding normal tissues[27]. Further support for the role of heparanase in tumour metastasis came from transfection studies where the metastatic ability of lymphoma and melanoma cell lines was substantially enhanced when they were stably transfected with the heparanase gene[25,28]. Additional evidences for heparanase involvement in tumour metastasis came from the *in vivo* administration of heparanase inhibitors, with a dramatic reduction (90 %) in the incidence of tumour metastases reported in a number of tumour models when animals were treated with heparanase inhibitors[29,30]. As to human colon carcinoma[31], heparanase mRNA and protein accumulated even at early stages in the progression of neoplastic disorders, and their levels increased gradually as cells progressed from severe dysplasia through well-differentiated to poorly differentiated colon carcinoma. Adjacent, morphologically normal colonic tissue showed no expression of the enzyme. Deeply invading colon carcinoma cells and the adjacent desmoplastic stromal fibroblasts showed high levels of heparanase mRNA and protein. These results suggest that increased expression of heparanase as in tumor cells indicates less differentiation and more invasive ness. Considering the key role of heparanase in the metastasis of tumor cells, it seems very important to investigate the mechanism by which the expression of heparanase in tumor cells is regulated. Virtually nothing is known about the factors that upregulate heparanase expression and activity in malignant cells, and the molecular basis of this upregulation at the gene level has not been delineated yet. Our research dealed with the translational regulation of heparanase via modulation of the mRNA cap-binding phosphoprotein, eIF-4E and probed the subsequent alterations of invasive potential in LS-174T cells.

To date, Overexpression of eIF-4E has been found in human carcinoma tissues and tumor cell lines. A recent publication[32] also suggested that increased expression of eIF-4E might be an early event in the development human colon cancer. Investigators have found that eIF-4E is increased in both colon adenomas and carcinomas. A compelling body of evidences now indicates that eIF-4E is centrally involved not only in

cellular transformation, but also in tumor formation, invasion and metastasis. The major intracellular signaling pathways involved in tumor growth and malignancy induce eIF-4E activity. MAP kinase activation stimulates MNK-mediated phosphorylation and activation of eIF-4E directly, while activation of the pI3 kinase/PTEN/AKT pathway ultimately yields phosphorylation and inactivation of 4E-BP1, and subsequent release of eIF-4E. Zimmer *et al*[10] indicated that increased eIF-4E activity might provide a central regulatory step facilitating tumor invasion and metastasis via upregulation of selected, potent gene products (such as bFGF, VEGF, MMP-9 and CD44v6). In this report, the colon adenocarcinoma cell line also showed expression of eIF-4E. By transfecting LS-174T cells with a 20-mer antisense s-oligodeoxynucleotide targeted against eIF-4E at well tolerated doses, eIF-4E expression was specifically and significantly inhibited at transcriptional and translational levels. Furthermore, as eIF-4E protein expression decreased, the expression and activity of heparanase were effectively retarded as well and the tumor cells also displayed a reduced invasive potential. It seems that heparanase down-regulation is closely correlated with alterations in the expression of eIF-4E. This study firstly demonstrated that eIF-4E might be involved in the regulatory processes of heparanase in colon adenocarcinoma cell line LS-174T. However, the mechanisms underlying these regulatory events remain unclear, since eIF-4E has the potential to alter gene expression at levels including translational initiation, mRNA splicing, mRNA 3' -end processing, mRNA nucleocytoplasmic transport, and protection against 5' -exonucleolytic degradation[33]. Possible roles of eIF-4E in regulatory processes of heparanase expression remain unidentified and the mechanism deserves further investigation.

Our results, together with the previous reports, indicate that constitutively high-level expression of eIF-4E in tumor cells is involved in the regulation of heparanase expression, although the exact mechanism is not quite certain. Since matrix metalloprotease 9 (MMP-9) and CD44 expression are directly related to metastatic capacity, they are certainly to be governed by enhanced eIF-4E activity. Therefore, eIF-4E antisense strategy should be an effective treatment against tumour invasion and metastasis. This targeting strategy in antisense chemistry may have practical applications in experimental or clinical anti-metastatic gene therapy of human colorectal carcinoma.

Abstract

AIM: To refine the loss of heterozygosity on chromosome 5p15 and to identify the new tumor suppressor gene (s) in colorectal tumorigenesis.

METHODS: Sixteen polymorphic microsatellite markers were analyzed on chromosome 5 and another 6 markers were applied on chromosome 5p15 in 83 cases of colorectal and normal DNA by PCR. PCR products were electrophoresed on an ABI 377 DNA sequencer. Genescan 3.1 and Genotype 2.1 software were used for LOH scanning and analysis.

RESULTS: We observed 2 distinct regions of frequent allelic deletions on Chromosome 5, at D5S416 on 5p15 and D5S428-D5S410 on 5q. Another 6 polymorphric microsatellite markers were applied to 5p15 and the minimal region of frequent loss of heterozygosity was established on 5p15 spanning the D5S416 locus.

CONCLUSION: Through our detailed deletion mapping studies, we have found a critical and precise location of 5p deletions, 5p15.2-5p15.3, which must contain one or more unknown tumor suppressor gene (s) of colorectal cancer.

INTRODUCTION

Colorectal cancer is one of the most common malignant tumors threatening people' s health[1,2]. Its occurrence has been rising over the past 3 decades[3]. Now, colorectal cancer is the second cause of death in Western countries, and the fourth in China[4]. It is clear that improvement in its prognosis will not be achieved without a better understanding of its etiology and tumor biology. In recent years, the genetic basis of human tumors has been increasingly elucidated. A growing number of studies have shown that the molecular events controlling tumorigenesis involve abnormal cell growth promoted by activation of proto-oncogenes and/or inactivation of tumor suppressor genes[5,6]. Identification of novel tumor suppressor genes has been facilitated by loss of heterozygosity (LOH) studies that have guided the localization of minimally deleted regions on chromosomes[6,7]. In colorectal cancers, frequent allelic loss has been identified on chromosomes 5q (30 %), 8p (40 %), 17p (75-80 %), 18q (80 %), and 22q (20-30 %)[8,9].

Previous allelotype analyses of chromosome 5 in colorectal cancer mainly focused on the long arm (5q), where a high frequency of allelic deletions of 5q21-22 was reported, implicating the *APC/MCC* genes[10-13]. However, alterations of the short arm of chromosome 5 have not been studied extensively in colorectal cancers. In this study, 16 polymorphic microsatellite markers were applied to chromosome 5. As a result of the high frequence of LOH on the loci of D5S416, another 6 microsatellite markers from chromosomal region 5p15, spanning the D5S416 were precisely localized.

MATERIALS AND METHODS

Materials

This study was based on 83 patients with colorectal cancer including 40 men and 43 women, who were treated at the Surgical Department in Shanghai First People' s Hospital, China, between 1998 and 1999. The patients' age ranged from 31 to 84 years with a median of 66. All the patients were confirmed by pathology, and staged by Duke' s criteria. Eight, 21, 40, 14 cases were of Duke' s stages A, B, C and D, respectively. 23 cases were well differentiated, 39 moderately differentiated, 6 poorly differentiated adenocarcinoma, and 15 cases were mucinous adenocarcinoma. HNPCC patients were ruled out by Amsterdam criteria[14,15]. Each patient gave his were or her informed consent for the use of his or her tissues in this study.

Methods

DNA extraction The cancerous and adjacent normal tissues were freshly frozen within 30 min after being removed. These tissues were then cut into cubes of approximately 2 mm^3 and immediately frozen in liquid nitrogen. DNA was extracted using standard methods with proteinase K digested and phenol/chloroform purified.

Microsatellite markers and PCR Initially, 83 cases of colorectal cancer were analyzed by PCR using 16 microsatellite markers which were mapped to chromosome 5. DNA samples were analyzed as normal/tumor pairs using primers for the following microsatellite loci(location/heterozygosity): D5S1981-(5P15.3/0.73), D5S406-(5P15.3/0.78), D5S630-(5P15.3/0.89), D5S416(5P15.2/0.77), D5S419-(5P13.3/0.80), D5S418-(5P13.1/0.80), D5S407-(5q11.2/0.86), D5S647-(5q12.2/0.82), D5S424-(5q13.2/0.76), D5S428-(5q14.1/0.76), D5S2027-(5q21.1/0.78), D5S471-(5q23.1/0.75), D5S2115-(5q31.1/0.76), D5S410-(5q33.2/0.79), D5S400-(5q35.1/0.81), D5S408-(5q35.3/0.73). As a result of the high frequency of LOH in D5S416, 6 additional microsatellite markers from chromosomal region 5p15 were employed to span the D5S416 locus. DNA samples were also analyzed as normal/tumor pairs for the following microsatellite loci (location/heteozygosity): D5S1987-(5p15.3/0.87), D5S1991-(5p15.3/0.68), D5S1954-

(5p15.3/0.69), D5S1963-(5p15.2/0.69), D5S2114-(5P15.2/0.87), D5S486-(5p15.1/0.74). Polymorphic microsatellite markers were analyzed by PCR (GeneAmp PCR System 9700, PE Applied Biosystems Fostercity CA, USA). PCR conditions were as follows: 5 μl total volume with approximately 1.4 ng of DNA as a template with 10× standard buffer, 0.3 μl Mg^{2+}, 0.8 μl deoxynucleotide triphosphates, 0.3 unit of Hot-start taq polymerase and 0.06 ml of each oligonucleotide primer, with the forward primer fluorescence labeled with HEX, FAM or NED. The "touch-down" was applied. Cycling conditions consisted of 3 stages: an initial denaturation at 96 ℃ for 12 min in stage I; 14 cycles each at 94 ℃ for 20 s, at 63-56 ℃ for 1 min (decrease 0.5 ℃ per cycle) and at 72 ℃ for 1 min in stage II, 35 cycles each at 94 ℃ for 20 s, at 56 ℃ for 1 min and at 72 ℃ for 1 min in stage III.

LOH analysis A portion of each PCR product (0.5 μl) was combined with 0.1 μl of Genescan 500 size standard (PE Applied Biosystems Fostercity CA, USA) and 0.9 ul of formamide loading buffer. After denaturation at 96 ℃ for 5 min, the products were electrophoresed on a 5 % polyacrylamide gel on an ABI 377 DNA sequencer (PE Applied Biosystems Fostercity CA, USA) for 3 hours. Genotype 2.1 software displayed individual gel lanes as electrophoretograms with a given size, height, and area for each detected fluorescent peak. Stringent criteria were used to score the samples. Alleles were defined as the two highest peaks within the expected size range. A ratio of T1:T2/N1:N2 of less than 0.67 or greater than 1.50 was scored as a loss of heterozygosity (Figure 1). Most amplifications of normal DNA produced two PCR products indicating heterozygosity. A single fragment amplified from normal DNA (homozygote) and those PCR reactions in which fragments were not clearly amplified, were scored as not informative. The LOH frequency of a locus was equal to the ratio between allelic loss and informative cases.

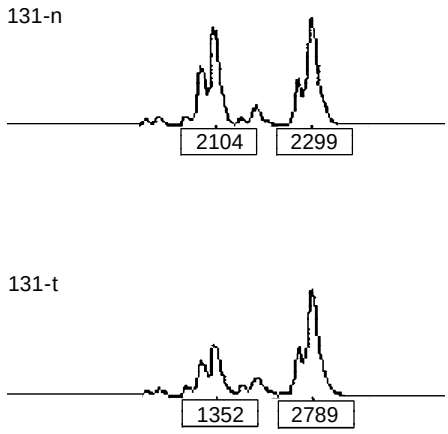

Figure 1 Representative LOH in tumor. "*n*" is normal DNA, "*t*" is tumor DNA. The peak heights are indicated below the corresponding alleles. Allele ratio=(t1:t2)/(n1:n2)=(1 352:2 789)/(2 104:2 299)=0.53. Allele ratio of less than 0.67 or greater than 1.50 was scored as LOH.

RESULTS

LOH analysis of colorectal cancers

Eighty-three colorectal cancers were analyzed for LOH at the 16 marker loci spanning chromosome 5 with the following most likely order: pter-D5S1981-D5S406-D5S630-D5S416-D5S419-D5S418-D5S407-D5S647-D5S424-D5S641-D5S428-D5S2027-D5S471-D5S2115-D5S410-D5S400-D5S408-qter[16] (Table 1 and Figure 2). We observed 2 distinct regions of frequent allelic deletions on chromosomes at D5S416 on 5p15 and D5S428-D5S410 on 5q.

LOH mapping of 5p15 region

The chromosomal region spanning D5S416 locus on chromosome 5p was further investigated using a saturation mapping strategy with another 6 microstellite markers that are localized and closely spaced within this region (Figure 3). Eighty-three paired normal and tumor DNA samples were analyzed for LOH at these loci which further refined the resolution of the deletion map to a genomic segment of approximately 1 centimorgan (cM) and established the minimal region of frequent chromosomal loss at D5S416 locus. Based on the databases described previously, the most likely order of these markers was pter-D5S630-D5S1987-D5S1991-D5S1954-D5S1963-D5S416-D5S2114-D5S486[16] (Table 2). Overall, preferential deletions of D5S416 were observed in 26/54 colorectal cancers and deletions of the 2 markers, D5S1954 and D5S1963 (approximately 1 cM centromeric to D5S416), were seen in 33.3 % (16/48) and 21.1 % (12/57), respectively. Thus, the majority of observed interstitial deletions were localized within a 1 cM genomic segment encompassing the D5S416 locus.

Table 1 The ratios of LOH of all loci on chromosome 5

Loci	Map location	Number of informative cases (%)	LOH No (%)
D5S1981	p15.3	24 (28.92)	3 (12.50)

DISCUSSION

Inactivation of tumor suppressor genes appears to be one of the genetic mechanisms involved in the development of colorectal cancer[17-19]. This process includes mutation of one allele, followed by a deletion of the remaining one (LOH) or homozygous deletion of both alleles[20]. Allelic deletions detected as LOH have been proved useful for mapping regions of DNA that contain tumor suppressor genes. LOH at specific chromosomal regions strongly suggests the existence of tumor suppressor genes at the relevant segment[21,22]. We performed deletion mapping analyses of chromosome 5 markers in 83 sporadic colorectal cancers, using 16 microsatellite markers. Analysis of the deletion map (Figure 2), together with the frequency of LOH obtained for each locus (Table 1) allowed us to identify two regions on chromosome 5 displaying high rates of LOH.

The 5q14-q22 region (D5S428-D5S410) has been frequently deleted in colorectal cancer. Ashton-Rickardt is the first author to describe the *APC/MCC* region as being frequently deleted in sporadic colorectal cancer[10]. Since then, several reports have indicated a high frequency of LOH at this region[11-13]. Our study also identified it, which proved our ways right.

The other region is 5p15 (D5S416). Further mapping of 5p15 region defined a minimal region of frequent deletion spanning the D5S416 locus (Figure 3). Based on this map, the majority of allelic deletions were localized within 1 cM chromosomal segment encompassing the 3 loci (D5S1954, D5S1963 and D5S416). Of these, D5S416 was the most frequently deleted locus (48.15 %), while the other 2 markers, D5S1954 and D5S1963, demonstrated allelic losses of 33.33 % and 21.05 %, respectively. Thus, the high LOH frequency and the patterns of allelic losses of chromosome 5p15.2-5p15.3 suggest that this region may be preferentially deleted in colorectal cancer and could potentially harbor important tumor suppressor genes in colorectal development and progression. A database search has identified four candidate genes, *PDCD6*[23-27], *TERT*[28-29], *T RIP13*[30,31] and *POLS*[32-34] with suggestive tumor suppressor gene functions. The programmed cell death gene, *PDCD6*, is a member of the family of intracellular Ca^{2+}-binding proteins and a part of the apoptotic machinery controlled by T-cell receptor (TCR) Fas, and glucocorticoid signals[23-27]. *TERT* encodes a reverse transcriptase required for the replication of chromosome termini and plays a role in telomere elongation. Although telomerase expression is a hallmark of cancer[35], the mice lacking the RNA component of telomerase (mTERC) exhibit progressive telomere shortening and chromosomal instability associated with epithelial tumors[28]. *TRIP13*, thyroid receptor interacting protein 13, is a transcription factor that regulates expression of a variety of specific target genes such as the human papilloma virus type16 E1(HPV16E1) which is important in cervical carcinoma[30,31]. *POLS* gene, a topoisomerase-related functional protein-4-1, encodes polymerase (DNA directed) signal within the deleted region. The yeast homolog TRF4 plays a critical role in chromosome segregation by coordinating between DNA replication and sister chromatid cohesion[32, 33]. The data strongly support the importance of the *POLS* gene, which is critical for TRF4' s essential and repair functions. Cell cycle analysis has revealed that *TRF4/POLS* is associated with chromosomes in G1, S and G2 phases[34]. The presence of these genes at the 5p15.2-5p15.3 interval suggests that they may target tumor suppressor genes of these deletions in colorectal cancer. It will be helpful for us to find the tumor suppressor genes through studying their functions.

In summary, through our detailed deletion mapping studies, we have found a critical and precise location of 5p deletions, 5p15.2-5p15.3, which must contain one or more unknown tumor suppressor gene(s) of colorectal cancer.

Abstract

AIM: APMCF1 is a novel human gene whose transcripts are up-regulated in apoptotic MCF-7 cells. In order to learn more about this gene's function in other tumors, we cloned its full length cDNA and prepared its polyclonal antibody to investigate its expression in colon cancers with immunohistochemistry.

METHODS: With the method of 5' rapid amplification of cDNA end (RACE) and EST assembled in GenBank, we extended the length of APMCF1 at 5' end. Then the sequence encoding the APMCF1 protein was amplified by RT-PCR from the total RNA of apoptotic MCF-7 cells and cloned into the prokaryotic expression vector pGEX-KG to construct recombinant expression vector pGEX-APMCF1. The GST-APMCF1 fusion protein was expressed in *E. coli* and used to immunize rabbits to get the rabbit anti-APMCF1 serum. The specificity of polyclonal anti-APMCF1 antibody was determined by Western blot. Then we investigated the expression of Apmcf1 in colon cancers and normal colonic mucosa with immunohistochemistry.

RESULTS: A cDNA fragment with a length of 1 745 bp was obtained. APMCF1 was mapped to chromosome 3q22.2 and spanned at least 14.8 kb of genomic DNA with seven exons and six introns contained. Bioinformatic analysis showed the protein encoded by APMCF1 contained a small GTP-binding protein (G proteins) domain and was homologous to mouse signal recognition particle receptor β(SRβ). A coding region covering 816 bp was cloned and polyclonal anti-APMCF1 antibody was prepared successfully. The immunohistochemistry study showed that APMCF1 had a strong expression in colon cancer.

CONCLUSION: APMCF1 may be the gene coding human signal recognition particle receptor β and belongs to the small-G protein superfamily. Its strong expression pattern in colon cancer suggests it may play a role in colon cancer development.

INTRODUCTION

Apoptosis or programmed cell death (PCD) is a form of cell death in human and other multicellular organisms[1-15]. It is a genetically controlled program of cellular selfdestruction, which is of central importance to the development and homeostasis of almost all animals, and also a highly regulated process involving a large number of genes that are conserved in all metazoans. A variety of genes have been found to take part in the process of apoptosis, such as the TNF/FasL family, the Bcl-2 family, the ICE/CED-3 family, oncogenes, tumor suppressor genes and the genes encoding heat shock proteins[16-24]. APMCF1 is a novel human gene fragment we cloned in 1999. Its transcript was found to be up-regulated in apoptotic MCF-7 cells, which might play a role in apoptosis of tumor cells[25]. As its 5' end is not complete, the functional study of this gene has not been performed. In order to learn more about this gene' s biological functions, we extended its 5' cDNA end and found it was a gene homologous to mouse SRβ. Then polyclonal antibody against this gene' s product was prepared and protein expression of APMCF1 in human colon cancer and normal colonic mucosa was examined with immunohistochemistry method.

MATERIALS AND METHODS

Main reagents

Reverse transcription kit was from TaKaRa. Pfu and Tf1 Taq DNA polymerase were from Promega. TRIzol Reagent was from Gibco. Retinoid acid (RA) was from Sigma.

Cell lines and specimens

MCF-7 cell line was kept by our lab oratory and maintained in DMEM medium supplemented with 100 mL/L fetal bovine serum. The cells were induced to apoptosis by RA with the method described before[25]. Fifty five tissue specimens of colon cancer and 5 tissue specimens of normal colonic mucosa were obtained from surgically resected tissues of patients with hepatocellular carcinoma in Xijing Hospital of Fourth Military Medical University. The tumor tissues consisted of 25 well-differentiated, 23 moderately differentiated, and 7 poorly differentiated colon cancer specimens, All the tissues were fixed in 100mL/L buffered formalin phosphate and embedded in paraffin wax.

5' RACE

A human EST named AGENCOURT_8343738 was initially identified with APMCF1 cDNA sequence(AF141882) by running a BLASTN search against the public database of ESTs (dbEST). It shared 98 % identification with APMCF1 but had more than 325 nucleotide acids at the 5' end. Then we designed a reverse transcription primer against this sequence. The total RNA extracted from the apoptotic MCF-7 cells with TRIzol reagent according to the manufacturer' s instructions was used as reverse transcription template. While transcription, 5' cap sequence was added according to the protocol of SMART™ PCR cDNA synthesis kit (Clontech). RT-PCR was

performed using the cap sequence as a sense primer, reverse transcription primer as a antisense primer. The sequences of the primers were as follows: sense primer (cap sequence), 5' TACGGCTGCGAGAAGACGACAGAA 3', and antisense primer, 5' CAGGCAATTTTAGCCAGCCATTT 3' (reverse transcription primer). A total of 30 cycles of PCR reactions were performed: at 95 ℃ for 15 s, at 68 ℃ for 5 min. Then 5 μL PCR products was extracted as a template for the next 30 cycles with the same PCR parameters. The resulting PCR fragment (810 bp) was subcloned into the pEGM-T easy vector (Promega) for sequencing.

Bioinformatics

The fragment of 810 bp was used as a bait to search the Genbank database and a homologous sequence FLJ14619 was found. Then all these ESTs were retrieved and a coontig was assembled from overlapping ESTs. A full length cDNA sequence of APMCF1 was obtained and identified in human genomic database. The putative cleavage site of the signal peptide was predicted by using Signal P server (http://www.cbs.dtu.dk/services/Signal P). The gene localization of APMCF1 on the chromosome was analyzed with the HTGS database (http://www.ncbi.nlm.nih.gov).

Construction of recombinant pGEX-APMCF1

The entire APMCF1 coding region was amplified by PCR by using upstream and downstream primers, which introduce a *Bam*HI and *Sal* I site respectively according to the conjunct sequence. The sequences of the primers were as follows: sense primer, 5' AGGATCCTCATCCATGGCTTCCG 3', and antisense primer, 5' ACGCGTCGACCTGCCTCTCAGGCAAT 3'. The PCR product was cloned into the pGEM-T easy vector for sequencing. Then the fragment containing the ORF of APMCF1 was released from the recombinant plasmid by cutting with *Bam*HI and *Sal* I, and subcloned into the prokaryotic expression vector pGEX-KG. The recombinant plasmid was termed pGEX-APMCF1.

Preparation of polyclonal antibody to APMCF1

The GST-APMCF1 fusion protein was expressed in *E. coli* DH5α and purified on glutathione-Sepharose 4B according to the manufacturer's instructions. After the purified protein was separated by 100 g/L sodium dodecylsulfate-poluacrylamide gel electrophoresis (SDS-PAGE), it was then transferred from the gel to nitrocellulose. The specific strip corresponding to the antigenic protein was excised and cut into very small pieces for immunizing rabbits. The specificity of the anti-APMCF1 antibodies was identified by Western blot.

Immunohistochemical staining

All the colon cancer specimens were fixed in 100 mL/L buffered formalin and embedded in paraffin. ABC technique was adopted for immunohistochemical staining. Briefly, deparaffinized sections were treated with 30 mL/L H_2O_2 in methanol for 30 minutes to abolish the endogenous peroxidase activity. Sections were further blocked with 10 mL/L normal goat serum for 0.5 hour, followed by incubation with polyclonal rabbit anti-APMCF1 serum (1:100) at 4 ℃ overnight. The sections were then washed in phosphate buffer solution (PBS) (0.01 mol/L, pH 7.2) and sequentially incubated with biotinylated goat anti-rabbit IgG followed by avidin-biotin horseradish peroxidase complex following the manufacturer's instructions (ABC kit, Sigma. USA). Staining was developed by immersing slides in 0.5 g/L diaminobenzidine tetrahydrochloride (DAB) with 3.3 g/L hydrogen peroxide. All slides were counterstained with haematoxylin, dehydrated and mounted. PBS substituting for the primary antibody was used as the negative control.

The intensity of staining for APMCF1 in colon cancer tissues and normal colonic mucosa tissues was scored for each specimen on a scale of 0 to 3, in which 0=negative staining, 1=weakly positive staining, 2=moderately positive staining, and 3=strongly positive staining. The percentage of positive cells in each specimen was estimated and scored on a scale of 0 to 4, in which 0=negative, 1=positive staining in 1 % to 25 % of cells counted, 2 in 26 % to 50 %, 3 in 51 % to 75 %, and 4 in 76 % to 100 %. Each section was evaluated for the sum of these two parameters. Group means of expression scores of APMCF1 antigens were compared by using ANOVA followed by Fisher's protected *t* test. $P<0.05$ was considered statistically significant.

RESULTS

Identification of human APMCF1

With 5' RACE and assembled homologous ESTs, the 5' end of original APMCF1 cDNA sequence was extended successfully. The length of new sequence was 1 745 bp. It was mapped to chromosome 3q22.2 and spanned at least 14.8 kb of genomic DNA with seven exons and six introns contained. Sequence analysis revealed that APMCF1 encoded a protein of 271 aa, with an ATG initiation codon at nt 17-19. The deduced APMCF1 protein contained no putative N-glycosylation site, and no typical signal cleavage site was revealed by searching on the signal P server. There was a transmembrane helice from 37 aa to 54 aa predicted by the method of TMpred. It contained a small GTP-binding protein (G proteins) domain and it was homologous to mouse signal recognition particle receptor β(SRβ) both in nucleic acid and amino acid sequence by 86 % and 89 % respectively. Further analysis showed that APMCF1 protein was homologous to gene products of SRβ from species ranging from mice to yeast. This indicated that APMCF1 protein was a human SRβ gene and also was a well conserved protein (Figure 1).

Identification of polyclonal antibody to APMCF1

To detect APMCF1 protein, we generated anti-human APMCF1 antibody by immunizing rabbit with the purified GST-APMCF1 fusion protein. On immunoblots, this anti-APMCF1 antibody specifically recognized GST-APMCF1 fusion protein, the dominant band was the expected 56-ku molecular size. No band was evident in the blot of the same samples using a preimmune rabbit serum. When the antibody was preabsorbed with GST-APMCF1 fusion protein, the corresponding band was no longer observed, confirming the antibody specificity (Figure 2).

Expression of APMCF1 in colon cancer

Fifty five cases of colon cancer tissues and 5 cases of normal colonic mucosa were examined for expression of APMCF1 by using immunohistochemistry. Specific cytoplasmic staining for APMCF1 was observed in 44 out of 55 cases of carcinomas (80 %) and 4 out of 5 normal mucosa. All of the positive samples had cytoplasmic staining, suggesting that APMCF1 might be a cytoplasmic protein. The positive ratios of APMCF1 in well-differentiated, moderately differentiated, and poorly differentiated carcinomas were 80 %, 74 % and 86 % respectively. A significantly high expression level of APMCF1 was found in poorly and moderately differentiated colon cancer, compared with that of normal tissue (Figures 3). There were also differences between different histological grades of colon cancer, but these differences did not reach statistical significance (Table 1).

Figure 1 Nucleotide and Predicted Amino Acid Sequence of the APMCF1 cDNA and sequence alignment of APMCF1 wth the protein from other species. A: The full-length gene sequence and amino acids sequence of APMCF1; B: Alignment was done by using the Align software in Vector NTI. Dark gray background shows identity with at lease five aligned residues in different species. The gray region represents the sequence conserved among different species.

Table 1 Expression of APMCF1 in colon cancer and normal colon

Histological type	*n*	Expression of APMCF1	Positive rate (%)
A) Well differentiated	25	4.20±1.02	80
B) Moderately differentiated	23	4.78±1.10	74
C) Poorly differentiated	7	5.18±1.89	86
D) Normal	5	3.84±1.73	80

Expression score (mean ± SE) in different histological grades of colon cancer and normal colon tissue. Statistically significant differences: B *versus* D, $P<0.05$; C *versus* D, $P<0.01$.

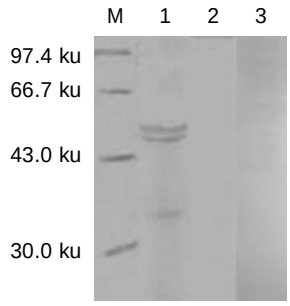

Figure 2 Immunoblotting of APMCF1 in GST-APMCF1 (56 ku) using antiserum, normal rabbit serum before immunization and antiserum preabsorbed with GST-APMCF1. M: Protein marker; 1: antiserum; 2: rabbit serum before immune from GST-APMCF1; 3: antiserum absorbed in the peptides used for immunization (control antibody).

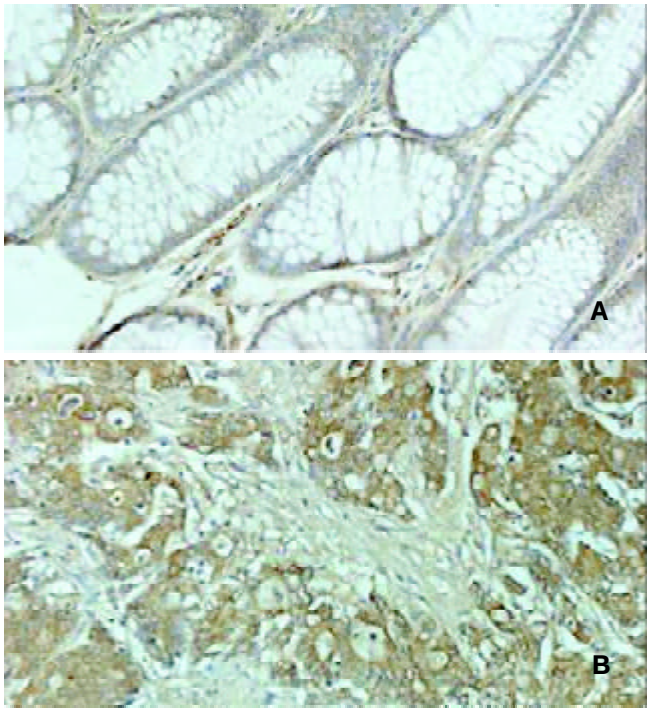

Figure 3 Expression of AMPCF1 in normal colon tissue and colon cancer (×200). A. Normal colon tissue; B. Colon cancer.

DISCUSSION

We have successfully extended the 5' end of APMCF1. The new sequence contains an open-reading frame of 816 bp that encodes a protein with a predicted molecular mass of 30ku. By searching the GenBank, it was found that the amino acid sequence of APMCF1 was homologous to mouse signal recognition particle receptor β(SRβ) and conserved in several other species, including *Caenorhabditis elegans*, *Saccharomyces cerevisia* and *Drosophila melanogaster*. This indicates that APMCF1 is likely a human SRβ gene and also a well conserved protein. The conservation of APMCF1 implies that it may have a very important function, since it remains stable during the evolution of species[26,27].

The mammalian SRP receptor, also known as docking protein, is composed of two subunits, SRα and SRβ. Based on the study results in mouse and canine, both of them are required to target nascent secretory and membrane proteins to the membrane of endoplasmic reticulum (ER). SRβ anchors alpha subunit to the ER membrane during this course[26,28-30]. The result of conserved domain searching showed that APMCF1 containd a GTPase domain closely related to ADP-ribosylation factor family (ARF) and Sar1p-like members of the Ras-family of small GTPases, suggesting it belongs to the small GTP-binding protein (G proteins) superfamily[31-36].

Over 100 members of the Ras superfamily of GTPases have been found so far. Based on both their sequence homology and function, they have been subdivided into at least six families: Ras, Rho, Rab, Arf, Ran, and Rad/Gem[37-42]. Each family, in turn, is comprised of several members with distinct expression, cellular localization and biological activities. Among these members, both Ras and Rho GTPases can mediate key cellular processes in response to diverse stimuli, such as cell growth, apoptosis, lipid metabolism, cytoarchitecture, membrane trafficking, and transcriptional regulation. The Rab and Sar1/Arf families regulate vesicle trafficking, and the Ran family regulates nucleocytoplasmic transport and microtubule organization. However, the negative aspect of these multifunctional proteins arises in the context of scenarios that cause their constitutive activation (i.e. point mutations or overexpression) and render them insensitive to regulatory signals. In this case, these GTPases trigger specific signals that lead to uncontrolled cell growth, enhanced angiogenesis, inhibition of apoptosis, and genetic instability, all of which result in tumor development[43-48].

From the analysis of bioinfomatics we can see that APMCF1 might be a new member of small-G protein superfamily. It may have the potential function to regulate the survival, proliferation, differentiation and apoptosis of cells as well as other small-G protein members such as Ras and Rho. Preliminary studies also showed that transcripts of APMCF1 were up-regulated in apoptotic MCF-7 cells, indicating it might play a role in apoptosis of tumor cells. So it is necessary to know expression pattern of APMCF1 in various tissues, especially in tumors. In the present study, APMCF1 was expressed highly in poorly and moderately differentiated colon cancers compared with that in normal colon mucosa, perhaps indicating its possible biological function in tumor development. It is early to say there are some relationship between the expression of APMCF1 and tumorigenesis before further study has been done. But it will be very interesting and worthy to further study these aspects in the future.

Abstract

AIM: To investigate the effect of retinoic acid (RA) on cell proliferation kinetics and retinoic acid receptor (RAR) expression of colorectal mucosa.

METHODS: One hundred sixty healthy male Wistar rats were randomly divided into 4 groups. Rats in groups I and II were subcutaneously injected with dimethylhydrazine (DMH) (20 mg/kg, once a week,) for 7 to 13 weeks, while groups III and IV were injected with normal saline. Rats in groups II and III were also treated with RA (50 mg/kg, every day, orally) from 7th to 15th week, thus group IV was used as a control. The rats were killed in different batches. The expressions of proliferating cell nuclear antigen (PCNA), nucleolar organizer region-associated protein (AgNOR) and RAR were detected.

RESULTS: The incidence of colorectal carcinoma was different between groups I (100 %) and II (15 %) (P<0.01). The PCNA indices and mean AgNOR count in group II were significantly lower than those in group I (F=5.418 and 4.243, P<0.01). The PCNA indices and mean AgNOR count in groups I and II were significantly higher than those in the groups III and IV (in which carcinogen was not used) (F=5.927 and 4.348, P<0.01). There was a tendency in group I that the longer the induction with DMH the higher PCNA index and AgNOR count expressed (F=7.634 and 6.826, P<0.05). However, there was no such tendency in groups II, III and IV (F=1.662 and 1.984, P>0.05). The levels of RAR in normal and cancerous tissues in groups treated with RA were significantly higher than those in groups not treated with RA (F=6.343 and 6.024, P<0.05).

CONCLUSION: RA decreases the incidence of colorectal carcinoma induced by DMH. Colorectal cancer tissue is associated with abnormal expression of PCNA, AgNOR and RAR. RA inhibits the expression of PCNA and AgNOR, and increases RAR concentration in colorectal tissues.

INTRODUCTION

The occurrence and development of colorectal carcinoma usually need a long and multistep process. Intervention treatment to block the canceration course from precancerous lesion of colorectal carcinoma is an important step to decrease the incidence of colorectal carcinoma. Some results obtained from *in vitro* experiments have shown that retinoic acid (RA) plays a role in blocking canceration induced by carcinogen and promotes normal differentiation of leucocythemia cells[1-3]. However, the effect of RA on colorectal carcinoma, especially on cell proliferation kinetics and the expression of retinoic acid receptor (RAR) of colorectal mucosa, has not be reported. To provide theoretic data on prevention and treatment of colorectal carcinoma, we investigated the effect of RA on cell proliferation kinetics and expression of RAR of colorectal mucosa.

MATERIALS AND METHODS

Animals and groups

One hundred sixty healthy male Wistar rats (body weight 134±12 g) were randomly divided into 4 groups. There were 40 rats in each group. Rats in group I and II were subcutaneously injected with dimethylhydrazine (DMH) (20 mg/kg, once a week,) for 7 to 13 weeks, while groups III and IV were injected with normal saline. Rats in groups II and III were treated with RA (50 mg/kg, every day, orally) from 7th to 15th week, group IV was used as a control. Eight rats in each group were killed randomly at 7th, 14th and 21st week in each group. The other rats were killed at 28th week. The number of colorectal carcinoma lesions was examined, and the normal colorectal tissues were also collected. The colorectal samples were fixed with 10 % formalin and embedded in paraffin. The expression of proliferating cell nuclear antigen (PCNA) and nucleolar organizer region-associated protein (AgNOR) was studied.

Detection of PCNA and AgNOR

Normal colorectal tissues (n=8) and the colorectal tissues (n=8) free of cancer induced by DMH after 7, 14, 21 and 28 weeks, were included. The samples including well-differentiated adenocarcinoma (n=8) and poorly differentiated adenocarcinoma (n=8) were also collected.

The immunohistochemical staining method was used to detect PCNA indices[4-7]. Representative regions with a double blind method were selected, and at least 1 000 cells were counted. The rates of positive cells over total cells counted were defined as the PCNA indices. Ploton one-step method was used for the detection of AgNOR count[8-11].

Detection of retinoic acid receptor (RAR)

Specimen disposal The mesentery tissues were removed and

part of the colorectal tissues was cut to pieces and placed in DMEM buffer. A tissue was homogenated by a high speed disperser, 4 000 r.min^{-1} for 10 min and a homogenizer 4 000 r.min^{-1} for 30 min and then by centrifugation 1 000 r. min^{-1} for 30 min. The buffer was added to the deposit, and the suspension was centrifugated, 750 r. min^{-1}for 15 min. Finally, the deposit was made to nucleus fluid. DNA concentration was determined by the dimethylamine method. The rest part of tissues was treated with liguid nitrogen and preserved in an ultra cold storage freezer.

Receptor radio-ligand binding test[16-20] All the procedures of the test were carried out at 4 ℃. 0.1 ml of nucleus fluid and 0.05 ml of 3H-atRA (2×10^{-6} mol/L) and 0.05 ml of buffer were mixed at different concentrations (the end concentration was 0.1-10 nM, with 6 concentration points). At the same time, the control test tube of non-specific binding was 200-time of unlabelled 9-cis-atRA. After 20 h, the reaction mixture was filtered with a multi-head collecting device and the free RA was removed, and examined by the filter membrane method. Saturation binding curve, Scatchard diagram and receptor maximum dissociation constant KD were analyzed by a receptor radio-ligand binding analyzing software.

Statistical analysis

Experimental results were analyzed by variance analysis and chi-square test with SPSS software. Statistical significance was determined at $P<0.05$.

RESULTS

Incidence of colorectal carcinoma

At the 14th week after induction, 12.5 % of rats in group I developed colorectal carcinoma, but colorectal carcinoma was not found in group II. At the 21st and 28th weeks, the incidence of colorectal carcinoma reached 60 % and 100 % respectively in group I, compared with 12 % and 20 % respectively in group II. There were significant differences between the two groups ($P<0.05$ and $P<0.01$). All the carcinomas were adenocarcinomas. In group I, 12 cases of adenocarcinoma were well-differentiated and 9 cases were poorly-differentiated. All the 4 cases in group II were well-differentiated (Table 1).

Table 1 Incidence (%) of colorectal carcinoma in the groups

Weeks	*n*	Number of cancer			
		I	II	III	IV
7	8	0	0	0	0
14	8	1(12.5)	0	0	0
21	8	5(60.5)	1(12.5)	0	0
28	15	15(100.0)	3(20.0)	0	0

Expression of PCNA indices

At the 7th week, PCNA indices reached 96.75±6.88 and 95.50±14.01, respectively, in group I and group II, which were significantly higher than those in group III and group IV (34.38±6.30 and 33.63±4.75, respectively, $P<0.01$). In metaphase and late-phase, PCNA indices in group I and group II were continuously increased, especially in group I. PCNA indices in group I reached 168.13±14.34 at the 28th week and approached the level of well-differentiated adenocarcinoma (169.13±11.68), but were still significantly lower than that of poorly-differentiated adenocarcinoma (181.63±23.38, $P<0.05$). Analysis of variance showed that there was a tendency in group I that the longer the induction with DMH the higher the PCNA index ($F=7.634$, $P<0.05$). However, there was no such tendency in groups II, III and IV ($F=1.662$, $P>0.05$).

In comparison between the groups, the results showed that PCNA indices in group I and group II were significantly higher than those in groups III and IV at all stages of carcinoma induction ($F=5.927$, $P<0.01$). Moreover, PCNA index in group I was significantly higher than that in groups II at all stages ($F=5.418$, $P<0.01$), except at the 7th week (Table 2).

Table 2 Expression of PCNA indices in groups

Weeks	*n*	I	II	III	IV
7	8	96.75±6.88	95.50±14.01	34.38±6.30	33.63±4.75
14	8	110.88±15.51	97.88±8.90	35.13±3.91	35.88±2.17
21	8	149.50±15.15	98.25±25.09	36.00±3.46	34.13±4.39
28	8	168.13±14.34	98.88±25.30	35.88±4.29	33.13±4.32
Well-differentiated adenocarcinoma	8	169.13±11.68	-	-	-
Poorly differentiated adenocarcinoma	8	181.63±23.38	-	-	-

Expression of AgNOR count

At the 7th week, AgNOR count reached 3.78±0.88 and 3.71±9.95, respectively, in group I and group II, which was significantly higher than that in group III and group IV ($P<0.05$). As the time of induction with DMH prolonged, the AgNOR count in group I was continuously increased. Analysis of variance showed that there was a tendency in group I that the longer the induction with DMH the higher the AgNOR count ($F=6.826$, $P<0.05$). However, there was no such tendency in groups II, III and IV ($F=1.984$, $P>0.05$). At the 28th week, the AgNOR count already approached the level of well-differentiated adenocarcinoma, but was still significantly lower than that of poorly-differentiated adenocarcinoma ($P<0.05$).

In comparison between the groups, the results showed that the AgNOR counts in group I and group II were significantly higher than those in groups III and IV at all stages of carcinoma induction ($F=4.348$, $P<0.05$). The AgNOR count was significantly higher in group I than that in group II at all stages ($F=4.243$, $P<0.05$), except at the 7th week (Table 3).

Table 3 Expression of AgNOR count in groups

w	*n*	AgNOR count ($\bar{x}\pm s$)			
		I	II	III	IV
7	8	3.78±0.88	3.71±0.95	2.17±0.53	2.45±1.06
14	8	5.15±1.87	4.30±0.84	2.20±0.86	2.16±0.80
21	8	7.54±0.73	4.39±0.62	2.20±0.77	2.49±0.90
28	8	9.37±0.71	4.75±0.98	2.35±1.01	2.38±1.04
Well-differentiated adenocarcinoma	8	9.93±1.47	-	-	-
Poorly-differentiated adenocarcinoma	8	11.14±1.86	-	-	-

Table 4 RAR count (fmol/μg DNA) and KD (nmol) in cells. ($\bar{x}\pm s$)

Group	*n*	Bmax	KD
I	6	1.16±0.34	1.99±0.25
II	6	1.78±0.36	2.16±0.18
III	6	2.61±0.55	2.39±0.43
IV	6	2.64±0.22	2.45±0.23
Cancer tissue	6	1.02±0.21	1.74±0.16

Expression of RAR

Six samples of colorectal and cancer tissues were collected randomly from groups I, II, III and IV respectively. Expressions

of RAR were detected, Bmax and KD were calculated. The Bmax and KD in group I approached the level of cancer tissues (1.02±0.21 and 1.74±0.16, $P>0.05$). The Bmax and KD in group II were significantly higher than those in group I, but significantly lower than those in groups III and IV, ($F=6.343$ and 6.024, $P<0.05$).

DISCUSSION

Recently, the mechanism of preventing carcinoma by RA has been studied by scholars all over the world. Some researchers reported that leukaemia cells could respond to the effect of differentiation induced by RA to put up the potential of diphasic differentiation[21-23]. Some reported that RA could result in reversion of liver cancer cells[24,25]. In our research, we found that the incidence of carcinoma developed in RA treatment group (group II) was significantly lower than that in group I during inducetion. The results showed that retinoic acid (RA) had an effect on blocking canceration induced by carcinogen and decreased the incidence of colorectal cancer.

PCNA is the 36 KD polypeptide which is synthesized and expressed just in proliferating cells. It has been proved that PCNA expression is related to cell generation cycle[11,12]. Expression of PCNA increases in G_1 phase gradually, reaches pinnacle in S phase, and decreases in G_2/M phase. It plays an important role in understanding cell generation state to detect PCNA indices. The higher the PCNA expression, the higher the cell malignancy trend[12-15]. Our experimental results showed that there was a tendency in group I that the longer the interval induced by DMH, the higher the PCNA index would be ($P<0.05$). At the 28th week, the PCNA indices already approached the level of well-differentiated adenocarcinoma, but were still significantly lower than that of poorly-differentiated adenocarcinoma ($P<0.05$). The PCNA indices in group II were higher than those in groups III and IV, but still lower than those in group I. RA may have an effect on blocking canceration induced by carcinogen and decreasing the incidence of colorectal carcinoma. The mechanism is not clear, maybe it is related to blocking the transition of cancer cells from G_0/G_1 phase to S_1,G_2+M phase. Our results also showed that RA could not block canceration entirely.

AgNOR is the biochemical symbol of rDNA and transcription. AgNOR count can reflect the cell active state and cell malignant trend of carcinoma[8-10]. We found that AgNOR count of colorectal mucosa cells in group II was significantly lower than that in group I, but significantly higher than that in groups III and IV during the period of inducement. The reasonable explanation was that RA could inhibit the process of canceration induced by carcinogen but could not block canceration entirely.

Our results showed that there were plenty of RARs in colorectal tissues. The normal RAR contents in colorectal cells were 2.64 f mol/μg DNA, and KD was 2.45 nmol. However, RAR contents in colorectal cancer cells decreased significantly (1.02 f mol/μg DNA, and 1.74 nmol). It is possible that the development of colorectal carcinoma is related to abnormal expression of RAR, and especially decrease of RAR content. After interference treatment with RA, the expression of RAR increased. The carcinogenic course induced by DMH was slowed down distinctly. The results revealed that RA had an effect on inhibiting cellular proliferation and RA could regulate the expression of RAR[24-30].

There are plenty of similarities between human colorectal cancer and experimental colorectal cancer. However, it is possible that colorectal cancer occurs in total colorectal mucosa under the action of carcinogenic factor. It is possible that clinical application of RA can inhibit the precancerous lesion of colorectal carcinoma, block the canceration course, and decrease the incidence of colorectal cancer[31-35]. It is expected that clinical application of RA after colorectal operation would prevent and decrease the recurrence of carcinoma.

Abstract

AIM: NGX6, NAG-7 and BRD7 genes are tumor related genes, which have been newly cloned by positional candidate cloning strategy. This study was designed to investigate the expression levels of NGX6, NAG-7 and BRD7 genes in human gastric and colorectal cancer tissues, and their corresponding normal tissues, and to investigate whether these genes play a role in the pathogenesis of gastric and colorectal cancers.

METHODS: Reverse transcription-polymerase chain reaction (RT-PCR), dot hybridization and Northern blot analysis were used to compare the expression levels of NGX6, NAG-7 and BRD7 genes in 34 gastric cancer tissues and 34 colorectal cancer tissues with their corresponding normal tissues of the same patients, respectively.

RESULTS: Among the 34 colorectal cancer specimens and the 34 gastric cancer specimens, the expression of NGX6 in 25 colorectal cancer tissues was absent or very weak (73.5 %) by RT-PCR analysis. The down-regulation rate of NGX6 in colorectal cancer tissues was significantly higher than that in corresponding normal tissues (26.5 %,9/34) ($P<0.005$). Moreover, the down-regulation of NGX6 was significantly correlated with lymph node and/or distance metastases. Patients with lymph node and/or distance metastasis had much higher down-regulation rate of NGX6 than patients without metastases (93.8 % *vs* 55.6 %, $P<0.05$). However no correlation was found between the expression of NGX6 and pathologic type of colorectal cancer in this study, and also the expression of NGX6 did not display any difference between gastric cancer and corresponding normal tissues (58.8 % *vs* 70.6 %, $P>0.25$). Dot hybridization and Northern blot analysis confirmed the results of RT-PCR. Furthermore, NAG-7 and BRD7 mRNA was not up- or down-regulated in gastric and colorectal cancers compared with their corresponding normal tissues in our study.

CONCLUSION: The down-regulation of NGX6 may be closely associated with tumorigenesis and metastasis of colorectal carcinoma. However, it may not contribute to the development and progression of gastric carcinoma. In addition, the expression levels of NAG-7, and BRD7 did not alter in gastric and colorectal cancers. This seems to suggest that NAG-7 and BRD7 genes may not play a role in gastric and colorectal carcinogenesis.

INTRODUCTION

Gastric cancer (GC) is a leading cause of carcinoma morbidity and mortality in China[1]. Meanwhile, the occurrence of colorectal cancer (CRC) has been rising in the past 3 decades. At present, CRC is the fourth cause of death in China[2,3]. It is well known that a multistep process associated with multiple gene abnormalities including inactivation of tumor suppressor genes and activation of oncogenes may be related to the occurrence of these diseases, but the molecular basis of these diseases is still not well understood[4-11]. Recently modern molecular genetic analyses have clarified that multiple chromosome alterations are frequently found in GC and CRC[12-16]. Nonrandom and significant losses of heterozygosity (LOH) at 9p, 3p and 6q have been detected to be more significant by cytogenetic studies, indicating that there may be more than one tumor suppressor gene (TSG) associated with GC and CRC located in these regions[17-24]. Unfortunately, homozygous deletions and point mutations of the known tumor suppressor genes such as p16/MTS1 gene (9p21),VHL gene (3p25-26), PPARγ gene (3p24.2-25) and FHIT gene (3p14.2) have seldom been observed in GC and CRC. These results suggest that these genes might not play important roles in gastric and colorectal tumorigenesis, and several other tumor suppressor genes in these region may contribute to the occurrence and development of GC and CRC[25-33]. NGX6, NAG-7 and BRD7 genes located at 9p21-22, 3p25 and 6q22.1-6q22.33, respectively, are novel tumor related genes cloned by positional candidate cloning strategy. In previous studies, all of them were found to be potential tumor suppressor genes associated with nasopharyngeal carcinoma (NPC)[34-39]. To investigate whether NGX6, NAG-7 and BRD7 genes also play a role in the pathogenesis of gastric and colorectal carcinoma, we analyzed the expression levels of NGX6, NAG-7 and BRD7 genes in 34 human gastric carcinoma tissues, 34 human colorectal carcinoma tissues and their corresponding normal tissues by RT-PCR, dot hybridization and Northern blot analysis.

MATERIALS AND METHODS

Tumor specimens

Fresh surgical specimens of thirty-four gastric carcinomas (GC), thirty-four colorectal carcinomas (CRC) and their corresponding normal tissues were obtained from the Xiang

ya Hospital Affiliated to Central South University from January 2000 to July 2000. All tumor specimens were confirmed by pathological diagnosis. Each freshly resected specimen was immediately stored in liquid nitrogen until analysis. Histologically, in the 34 cases of gastric carcinoma, 4 were well-differentiated adenocarcinomas, 22 poorly-differentiated adenocarcinomas, 6 signet ring cell carcinomas and 2 mucoid carcinomas. There were 18 males and 16 females, their age ranged from 30 to 68 years (mean age, 51.7 years). Six cases had lymph node and/or distance metastases. In the 34 cases of colorectal carcinoma, 6 were poorly-differentiated adenocarcinomas, 27 well-differentiated adenocarcinomas and 1 signet ring cell carcinoma. There were 20 males and 14 females, their age ranged from 17 to 72 years (mean age, 47.4 years). Sixteen cases had lymph node and/or distance metastases. No patient had received chemotherapy or radiation therapy before surgery.

RT-PCR

Total RNA was isolated using Trizol reagent (Gibco-BRL, Gaithersburg, MD, USA) according to the protocol provided by the manufacturer. After being treated with DNase-I (Promega), 1-2 μg of total RNA was reversely transcribed into complementary DNA (cDNA) with oligo (dT) using cDNA synthesis kit (Promega). Then 1 μl cDNA product was used as the template to amplify specific fragments in a 25 μl reaction mixture. The PCRs were performed using Taq polymerase and the buffer (Promega) supplied with 0.2 mM dNTPs and 0.2 μM primers. RT-PCR reaction was carried out with an initial denaturation at 95 ℃ for 5 min, followed by 35 cycles at 94 ℃ for 50 s, annealing temperature (56 ℃) for 50 s, at 72 ℃ for 60 s, and final extension at 72 ℃ for 10 min. At the same time, a housekeeping gene, $GAPDH_1$ or $GAPDH_2$ was amplified as an internal control to normalize the relative levels of cDNA, in which primers generated a PCR product of 475 bp or 760 bp. An aliquot (10 μl) of each reaction products was analyzed by 1.0 % agarose gel electrophoresis.

Primers corresponding to NGX6, NAG-7 and BRD7 sequences were designed with WWW Primer Picking (Primer 3) and synthesized by TaKaRa. Gene-specific forward and reverse primers for NGX6, NAG-7 and BRD7 genes were designed to produce PCR products of 780 bp, 466 bp and 270 bp, respectively. Primer sequences were as follows: NGX6F1, 5'-GAA CGT GGT GGA AAT ACA GA-3'; NGX6R1, 5'-TTC TAC ATC TTC TTT GGC CC-3'; NAG-7F1, 5'-ACATCAGCTTGGAGTTATTGA-3'; NAG-7R1,5'-GAAATGTACCACCCTACA-3'; BRD7F1, 5'-TGGAAGCCTCTCACAAGCT-3'; BRD7R1, 5'-TGTGTACTAATGCCATGAT-3'; $GAPDH_1$F1, 5'-GTCATCCATGACAACTTTGGTATC-3'; $GAPDH_1$R1, 5'-CTGTAGCCAAATTCGTTGTCATAC-3'; $GAPDH_2$F1, 5'-CGAGATCCCTCCAAAATCAA-3'; $GAPDH_2$R1, 5'-TGCTGTAGCCAAATTCGTTG-3'.

Northern blot analysis

Total RNA was isolated from human gastric and colorectal carcinomas and their corresponding normal tissues by Trizol reagent (Gibco-BRL), and transferred to nylon membrane according to the standard procedure. Hybridization was performed as previously described. 30 μg RNA was separated by electrophoresis through denaturing agarose gels, and blotted onto the nylon membranes (Clontech). RNA was permanently attached to the membrane by UV illumination for 150 s (GS Gene Linker, Bio-Rad, USA), and the membranes were dried in a vacuum at 80 ℃ for 2 h and sealed in a plastic bag for use. The hybridization probes were obtained by RT-PCR amplification. NGX6, NAG-7 and BRD7 cDNA probes were random-prime labeled with [α-^{32}P]dCTP using primer-a-gene random labeling kit (Promega, USA) following the protocol. Hybridization with RNA blots was carried out at 68 ℃ overnight in Express Hyb TM hybridization solution (Clontech) in rolling bottles. The membranes were washed twice at room temperature in 2×saline sodium citrate (SSC), 0.05 % SDS for 10 min, once at 42 ℃ in 1×SSC, 0.1 % SDS for 15 min and once at 50 ℃ in 0.1×SSC, 0.1 % (w/v) SDS for 30 min, exposure to film (Eastman Kodak, Rochester, NY, USA) for 4 d at -70 ℃. After exposure, the blot was again hybridized with a GAPDH probe.

Dot blot analysis

GAPDH and NGX6, NAG-7 and BRD7 cDNA fragments containing open reading frame from cDNA of gastric or colorectal carcinoma samples were obtained by RT-PCR. These cDNAs were reclaimed and purified by using a Kit according to the instruction of its manufacturer (Shanghai Huashun Co.). After alkali dissolution, GAPDH and NGX6, NAG-7 and BRD7 cDNA were blotted onto nylon membranes. cDNA permanently was attached to the membrane by UV illumination for 150 s, and the membranes were dried in a vacuum at 80 ℃ for 2 h to fix the cDNA. 10 μg total RNA was isolated from 10 cases of human gastric carcinomas, 10 cases of colorectal carcinomas and 10 cases of each corresponding normal tissues respectively, and was reversely-transcribed into cDNA probes with oligo (dT) and [α-^{32}P] dCTP using cDNA synthesis kit after treated with DNase I and RNasin at 37 ℃ for 1 h to remove contaminated DNA (1 μg total RNA of each case was used). Then the four cDNA probes were hybridized with GAPDH and NGX6, NAG-7 and BRD7 cDNA blots respectively as Northern hybridization described above.

Statistical analysis

Chi-square test was used for the comparison between two groups. A P value less than 0.05 was considered statistically significant.

RESULTS

Expression of NGX6, NAG-7 and BRD7 genes in gastric and colorectal cancer tissues by RT-PCR

In 34 pairs of CRC and corresponding normal tissues, 25 (73.5 %) showed decreased or absent expression of NGX6 in cancer samples compared with their corresponding normal tissues. The expression of NGX6 in colorectal carcinoma was significantly lower than that in normal tissues (χ^2=15.06, P<0.005). Representative cases of NGX6 expression detected by RT-PCR are shown in Figure 1. The down-regulation rate of NGX6 in the patients with lymph-node and/or distance metastases was 93.8 % (15/16), significantly higher than that in those without lymph-node or distance metastases (55.6 %, 10/18) (P<0.05). The down-regulation rates of NGX6 in well differentiated and poorly differentiated adenocarcinomas were 46.2 % and 85.7 %, respectively. There was no apparent relevance between NGX6 down-expression and pathologic type of colorectal carcinomas (P>0.05).

In 34 pairs of GC and their corresponding normal tissue specimens, NGX6 expression was detected in 20 GC tissues (58.8 %) and 24 corresponding normal tissues (70.6 %) as an expected PCR product of 780 bp in length. The expression level of NGX6 did not display any difference between gastric carcinoma and its corresponding normal tissues (χ^2=1.03, P>0.05).

NAG-7 expression was detected in 88.2 % (30/34) GC tissues and 82.3 % (28/34) corresponding normal tissues as well as in 76.2 % (26/34) CRC tissues and 76.2 % (26/34) corresponding normal tissues as an expected PCR product of 466 bp in length. BRD7 expression was detected in all samples

as an expected PCR product of 270 bp in length. The expression level of NAG-7 and BRD7 did not display any significant difference between cancer samples and normal tissues (P>0.05).

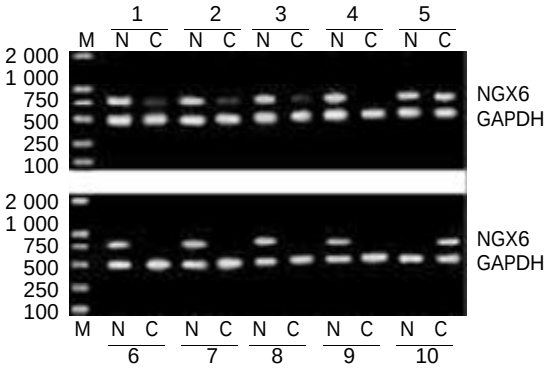

Figure 1 Expression of NGX6 in colorectal carcinoma and its corresponding normal tissues was examined by RT-PCR. The RT-PCR products with NGX6 primers produced 780 bp fragments and GAPDH primers produced 466 bp fragments. Lane M, DL-2000 marker; Lane N, normal tissues; Lane C, colorectal carcinoma tissues. This figure showed the representative results from several individual patients.

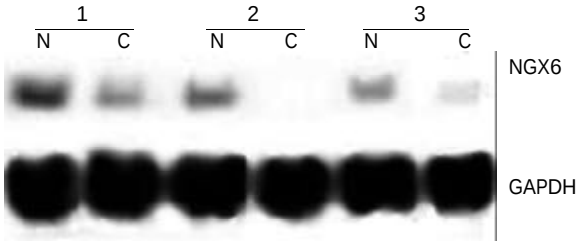

Figure 2 Northern blot was used to detect the expression abundance of NGX6 gene in human colorectal carcinoma and its adjacent normal tissues. The expression level of NGX6 was down-regulated in colorectal carcinoma tissues. C, human colorectal carcinoma tissue; N, adjacent normal colorectal tissue.

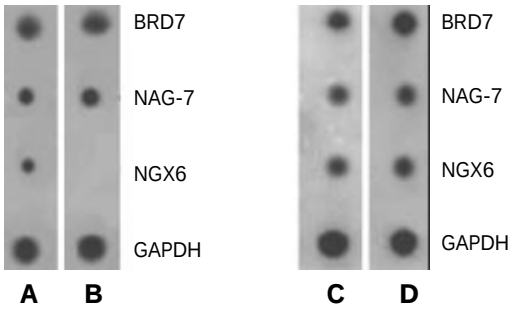

Figure 3 Dot hybridization analysis of NGX6, NAG-7 and BRD7 gene expression profiles in human colorectal and gastric carcinomas and their corresponding normal tissues. NGX6, NAG-7 and BRD7 cDNAs obtained by RT-PCR were blotted onto nylon membranes (Clontech) respectively. The membranes were respectively hybridized with each type of cDNA probes. (A: corresponding normal colorectal epithelial tissues, B: colorectal carcinoma, C: corresponding normal gastric epithelial tissues, D: gastric carcinoma.) NGX6 was down-regulated in colorectal carcinoma tissues, however it was expressed at the same level in the gastric cancer samples and normal tissues.

Expression of NGX6, NAG-7 and BRD7 genes in gastric and colorectal carcinoma tissues by Northern blot analysis and dot hybridization

Northern blot analysis and dot hybridization were performed to further investigate the expression of NGX6, NAG-7 and BRD7. Northern blot analysis showed that NGX6 was expressed as one single transcript of 2.4 kb, corresponding well with the size of the cloned cDNA. NGX6 was strongly expressed in its corresponding normal colorectal epithelial tissues, whereas faint signals or no signals were found in colorectal carcinoma tissues. Representative cases of NGX6 expression detected by Northern hybridization are shown in Figure 2. However, no signals were discerned in gastric carcinoma and its corresponding normal epithelial tissues. NAG-7 and BRD7 mRNA was expressed at the same level in the cancer samples and normal tissues. The results of dot hybridization were consistent with those of Northern analysis. Both dot hybridization and Northern analysis confirmed the results of RT-PCR. The expression of NGX6 was significantly down-regulated in colorectal carcinoma tissues.

DISCUSSION

NGX6, NAG-7 and BRD7 genes located at 9p21-22, 3p25 and 6q22.1-6q22.33 respectively are novel tumor related genes that were cloned by positional candidate cloning strategy. The cDNA sequence of NGX6, NAG-7 and BRD7 genes compared with Genbank and EMBO database using the BLAST program has verified that all of them are unique genes with no homology to any previously reported human genes, and their GenBank accession numbers are AF188239, AF086709 and AF179285, respectively. The NGX6 gene encodes a transmembrane protein of 338 amino acids containing four transmembrane regions, an EGF-like domain signature and a number of potential phosphorylation sites for protein kinase C (PKC), casein kinase II, tyrosine kinase and several N-myristylation sites. The NAG-7 gene encodes a transmembrane protein of 94 amino acids including one PKC phosphorylation site and one myristylation site. The BRD7 gene encodes a protein of 508 amino acids including a bromodomain and several important phosphorylation sites. In our previous study, their mRNA expression levels in nasopharyngeal carcinoma (NPC) cells were all significantly lower than those in normal nasopharyngeal epithelium. The proliferation rate of NPC cells was slower after transfection with these genes. The growth of xenografts was also inhibited after the transfected cells were injected into nude mice *in vivo*. These results suggest that the downregulation of these genes might play important roles in the occurrence and development of NPC[34-39].

Allelic imbalance or loss of heterozygosity (LOH) studies have been used to identify regions on chromosomes that may contain putative tumor suppressor genes. Deletions of chromosome 9p, 3p, and 6q regions have been observed at a high frequency in many types of sporadic tumors, including gastric and colorectal cancers[17-24]. NGX6, NAG-7 and BRD7 genes located at 9p21-22, 3p25 and 6q22.1-6q22.33 respectively, are the frequent sites of LOH in GC and CRC. We were interested in investigating if expression of NGX6, NAG-7 and BRD7 genes was altered in GC and CRC. In this study, RT-PCR, Northern blot and dot hybridization were used to detect the expression abundance of the three genes in gastric and colorectal carcinoma tissues, as well as their corresponding normal tissues. The results of RT-PCR showed that the down-regulation rate of NGX6 in colorectal carcinoma tissues with lymph-node or distant metastases was significantly higher than that both in its corresponding normal tissues (P<0.005) and in carcinomas without lymph-node or distant metastases (P<0.05). Dot hybridization and Northern analysis confirmed the results of RT-PCR. However, no significant correlation was found between the expression of NGX6 and pathologic type of colorectal carcinomas. The results suggest that down-regulation of NGX6 might be closely associated with the
