ABOUT COVER

Editor-in-Chief of *World Journal of Hepatology*, Wan-Long Chuang, MD, PhD, Doctor, Professor, Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung 807, Taiwan

AIM AND SCOPE

World Journal of Hepatology (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Hepatology is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

Redox therapeutics in hepatic ischemia reperfusion injury

Abstract

Ischemia-reperfusion plays a major role in the injury experienced by the liver during transplantation. Much work has been done recently investigating the role of redox species in hepatic ischemia-reperfusion. As animal models are better characterized and developed, and more insights are gained into the pathophysiology of hepatic ischemia reperfusion injury in humans the questions into exactly how oxidants participate in this injury are becoming more refined. These questions include effects of cellular location, timing of injury, and ability of therapeutics to access this site are increasing our appreciation of the complexity of ischemia reperfusion and improving attempts to ameliorate its effects. In this review, we aim to discuss the various methods to alter redox chemistry during ischemia reperfusion injury and future prospects for preventing organ injury
during hepatic ischemia reperfusion.

Key words: Ischemia; Reperfusion; Pre-conditioning; Nitrite

Core tip: Reactive oxygen and nitrogen species play a central role in the pathology of ischemia-reperfusion injury. In this review we discuss the efforts of many groups to trial therapeutics to ameliorate this damage in animal models of disease as well as clinical trials in humans. The failure of some trials has served to highlight the complexity of timing and compartmentalization of Ischemia Reperfusion injury. Finally, we discuss the emerging potential of replenishing nitric oxide by nitrite therapy and the uniquely broad therapeutic profile of nitrite.

INTRODUCTION

Ischemia reperfusion injury (IRI) identified in animal models in the mid-70's was not a widely used clinical term until the mid-80's[1-3]. Ischemia reperfusion is a process whereby the initial damage caused to tissue by compromised blood flow (and associated deficit in oxygen and nutrient delivery) is then compounded by additional and more severe injury caused by restoration of blood flow (*i.e.*, reperfusion). Multiple participants play a role in the post ischemic stress that is caused by restoration of blood flow and oxidant formation, the interplay of these participants form the initial layer of complexity to the problem of IRI. An excellent review by Jaeschke and

Woolbright discusses in greater detail the cellular and molecular participants in post ischemic stress of IRI[4]. Adding to this complexity is the multiple and diverse situations in which IRI occurs in the clinic which we posit likely leads to unique signatures of IRI in different diseases. In this review we discuss IRI that occurs in liver transplantation and how our understanding of these redox mechanisms may be critical as we attempt to define and implement strategies aimed at expanding donation pools by utilizing marginal donors[5]. The term marginal donor refers to grafts from donors of old age, steatosis, viral infection or other known insults to the liver graft. The added complexity resulting from each distinct clinical scenario has required further development of our scientific models to more closely mimic the problem[6]. These models have revealed a more prominent role for IRI when marginal grafts are used. The goal of this review is to provide the reader a brief review of the pathophysiology of IRI and focus the discussion on attempts to ameliorate IRI and how these therapeutics are suggesting a direction forward for clinical strategies.

One emerging candidate for the inhibition of mitochondrial dysfunction and restoration of nitric oxide bioactivity during ischemia reperfusion injury is the Nitrite anion. Emphasis on nitrite within this review will discuss the unique profile of *in vivo* nitrite to address the multiple insults of IRI injury.

IRI

During the ischemic phase of injury liver tissue is left with anaerobic metabolism to keep up with the demand of various cellular processes for high energy phosphates. Eventually the supply of high energy phosphates becomes inadequate resulting in disruption of cellular homeostasis. Primarily disruption of Na^+/K^+ ATPase function results in loss of membrane gradients which then allows for Ca^{2+} influx to the cell. Further production of reactive oxygen and nitrogen species (ROS, RNS), H^+ and toxic metabolites amplify injury and attract water into the cell and the resultant edema further impairs cellular function. As cell death begins within the hepatocytes, nearby endothelial cells and Kupffer cells begin to express adhesion molecules and chemokines, that recruit neutrophils to the site of injury and amplify tissue injury[7]. Below we discuss individual cell types implicated in liver IRI during transplantation and their respective roles in controlling the redox milieu (Figure 1).

Kupffer cells

Kupffer cells are perhaps the most important producer of ROS during the ischemic stress that occurs during the cold preservation of transplantation. A general lack of appreciation of the details of the hepatic IRI led to studies providing more detail into the timing and compartmentalization of IRI. The observation that glutathione was oxidized in the extracellular space but not within the hepatocyte drew attention to leukocytes. Given that very few neutrophils had infiltrated the liver during the early phase of ischemia focus was directed at the resident macrophages of the liver, the Kupffer cells, as possible mediators of glutathione oxidation[8,9]. Given that circulating leukocytes have not begun to infiltrate the liver in the early phase of ischemia and that donor blood is largely flushed from the liver during the initiation of cold preservation it is likely that the role of Kupffer cells in ROS production is relatively more important during the IRI experienced by the transplanted organ. The main ROS generated by Kupffer cells has been demonstrated to be the superoxide anion radical, and selective inhibition of Kupffer cells has been shown to ameliorate IRI further emphasizing the role of ROS derived from these cells[8,10,11]. Targeting the Kupffer cells clinically is challenging given their multiple roles in normal liver function and defense. However, this work reveals the clinical relevance of inhibiting ROS within the more accessible extracellular or vascular space.

Neutrophils

As Kupffer cells contribute to the early ischemic phase, neutrophils infiltrate and cause much of the damage after reperfusion. Cytokines and chemokines produced by the activated Kupffer cells initiate expression of the cellular adhesion molecules such as ICAM-1 and VCAM-1. Neutrophils become activated, adhere, and begin to infiltrate the hepatic tissue. Once activated neutrophils are capable of producing large amounts of superoxide, hydrogen peroxide, and hypochlorous acid[2,12]. These ROS are then capable of injuring the hepatocyte with the mitochondria being principal targets[13,14].

Mitochondria

Mitochondria play a central and complex role in IRI as both sources and targets of reactive oxygen species (ROS). Mitochondria produce ROS such as the superoxide anion as a result of electron leak during normal respiration. This process is enhanced during ischemia leading to decreased ATP production and organelle dysfunction[15]. Ultimately, mitochondria become central to the fate of the cell as opening of the mitochondrial permeability transition pore (MPT) instantly short circuits the membrane potential resulting in the cessation of ATP production and necrosis ensues[16]. Interestingly, whilst opening of the MPT may occur if the ischemic phase is long enough, it has also been shown that the MPT opening can be triggered by oxidant stress that ensues with the restoration of oxygen supply thereby supporting the model of IRI in that the tissue injury is amplified during the post ischemic stress phase[14].

ANTI-OXIDANT BASED THERAPIES TO INHIBIT IRI

As described above, elucidation of the mediators, timing, and location of IRI has proven complex and presented many potential targets for therapy. Indeed further experiments to evaluate the role of many therapeutics within

Figure 1 Ischemia initiates injury leading to reactive oxygen species formation from mitochondria and Kupffer cells. Restoration of blood flow introduces neutrophils and substrate that further amplify injury. Nitrite reduction in the setting of hypoxia and acidosis restores nitric oxide bioavailability and augments mitochondrial tolerance to ischemia if administered prior to injury. ROS: Reactive oxygen species; ATP: Adenosine triphosphate; TNF: Tumor necrosis factor; IL: Interleukin; ICAM: Intercellular adhesion molecule; O_2^-: Superoxide anion; H_2O_2: Hydrogen peroxide; HOCL: Hypochlorous acid.

animal models of IRI have displayed promise[6]. Further appreciation for the complexities of IRI within humans will develop as we attempt to intervene with therapies in clinical trials. Further, attempts to expand organ donation pools to decrease mortality within the waiting list for organ transplantation will result in a greater need to optimize graft function by inhibiting IRI. The following will discuss several potential therapies of relevance to ROS and RNS during IRI and their translational potential.

Ischemic preconditioning
Since initial observations that exposure of organs to brief periods of non-lethal ischemia provides protection from injury against a subsequent lethal ischemic event[17], many studies have established the concept of ischemic preconditioning (IP) in multiple organs[18-20] and across various species, including humans[18,21,22]. Unlike many pathologies characterized by a period of ischemia, liver transplantation presents an ideal model for therapies such as ischemic preconditioning as liver is exposed to a defined, scheduled, and relatively controlled period of cold ischemia.

Animal models of IP have shown that IRI can be inhibited by a defined therapy period of multiple[3-5], brief (5-10 min) bouts of ischemia followed by a reperfusion phase of equal time. As alluded to above although organ transplantation may represent an ideal model for IP it also emphasizes that the greatest limitation to IP in other human diseases, such as myocardial ischemia, is the inability to predict when the injury may occur and provide the therapeutic IP. This limitation has led to the search for the mechanism and mediators of IP in hopes of duplicating its effects pharmacologically. Interestingly, this research has led to the finding that the effects of IP are not completely limited to the timing or location of the ischemic therapy in order to provide a protective effect and have led to the advent of ischemic post conditioning[23] and remote ischemic preconditioning[24].

The hypotheses to explain the phenomena of ischemic conditioning generally fall into the general categories of IP causing changes directly on the organ subjected to the repeated IP therapy or that a humoral factor is produced by the tissue undergoing IP that then provides a systemic effect of protection. Given the advent of remote IP the evidence would suggest the latter mechanism predominates. Further, blood taken from rabbits that have undergone preconditioning confer their protective effects during myocardial infarction in rabbits that have not undergone a preconditioning phase[25]. Mechanistic studies have revealed that adenosine, bradykinin, or perhaps other circulating factors signal through G-protein coupled receptors[26]. This initiates a signaling cascade involving activation of protein kinase C[27], heat shock factor 1[28], and mitogen-activated protein kinase[29]. Activation of these receptors during preconditioning result in up regulation of multiple systems capable of attenuating IRI including superoxide dismutase, heat shock proteins, and eNOS[30-32]. Interestingly, the mild oxidation associated with the sub-lethal insult of IP as opposed to the hypoxia itself has been shown to confer protection against a subsequent lethal insult. Specifically, inducing a mild oxidative insult of infusing a peroxide analog into the portal vein of a mouse protected the liver from a subsequent ischemic insult enforcing the concept that timing and amount of exposure to oxidants results in either protection by inducing anti-oxidant de-

fenses, or overwhelm the cell and initiate cell death[33].

Attempts to translate preconditioning whether pre-, post-, or remote into human disease has had mixed results[34]. In part this is due to variance in the research and clinical models such as the timing of preconditioning. Mechanistic studies into IP have led to many potential candidates to confer the protective effects of IP pharmacologically. Some of these molecules will be discussed further below and include redox active effectors. Ongoing work in humans will further assess the clinical relevance of IP on liver transplantation outcomes[35].

Volatile anesthetics

Further evidence to support the principle of providing a pharmacologic agent that imparts the benefits of ischemic preconditioning is the finding that volatile anesthetics impart a similar profile of protection against ischemia reperfusion injury in the heart[36]. Termed anesthetic preconditioning, this phenomenon has been reproduced in multiple species and by multiple volatile anesthetics. Mechanistically, it appears that anesthetic preconditioning does closely parallel ischemic preconditioning and interestingly *via* ROS species induces a minute stress that activates similar pathways of ischemic preconditioning within target cells. The net effect is the up regulation of anti-oxidant systems such as heme oxygenase, and eNOS that help protect the cell from an ensuing IRI[37,38]. Human studies have revealed that patients preconditioned with sevoflurane experienced a reduction in peak transaminase levels, an improvement in clinical outcomes, and enhanced benefit in those with steatotic livers. Interestingly, iNOS mRNA was significantly increased in the preconditioned group suggesting a role for NO although further investigation into mechanism or eNOS expression was not performed[39]. As the role of nitric oxide in IRI and protection is more complex a detailed discussion is saved for a later sub-section.

Glutathione/NAC

Glutathione (GSH) is an important intracellular anti-oxidant and reductant found in high concentrations within hepatocytes. The protective role of glutathione and its importance in intracellular detoxification is emphasized by the model of glutathione oxidation and depletion found in acetaminophen overdose. Glutathione may react directly with oxidants such as peroxynitrite and hydrogen peroxide, but also provides reducing equivalents to maintain catalytic antioxidant systems (*e.g.*, glutathione peroxidase) that provide protection against these ROS and RNS in intracellular compartments[40,41]. Additionally, hepatocytes export glutathione and thereby detoxify the important ROS produced by Kupffer cells within the vascular space as described above during the early phases of IRI. GSH can either be administered itself or reduced GSH levels can be replenished by N-acetylcysteine (NAC) administration. Both GSH and NAC have been shown to reduce ROS production and oxidant stress after IRI[42,43]. Additionally, clinical trials of NAC and GSH

have shown a reduction in biochemical markers of liver injury. However, few have reported differences in clinical outcomes associated with GSH or NAC infusion[44]. It should be noted that GSH or NAC therapy is limited in that non-specific effects are likely, and neither target oxidants in specific compartments. Emerging and exciting recent findings indicate that targeted expression of antioxidants for example in the mitochondria may result in more effective and safer strategies[45].

α-Tocopherol

α-Tocopherol is an orally administered analogue of vitamin E that limits lipid peroxidation. In general, α-tocopherol therapy studies have led to mixed results. In IRI of the liver, pre-treatment of α-Tocopherol in mice was shown to be protective. In humans, α-Tocopherol had no effect on biomarkers of hepatic damage after hepatic ischemia; however, patients in the α-Tocopherol treatment group had a reduction in ICU stay. Clearly, the implications on ICU length of stay are complex but suggest the potential for α-Tocopherol in human liver transplantation remains and require further testing.

Allopurinol

Xanthine oxidase has long been considered one of the major producers of ROS during IRI largely due to evidence of the protective effect of the xanthine oxidase inhibitor, allopurinol[46]. However, multiple studies have demonstrated the limited contribution of xanthine oxidase mediated generation of ROS to the post ischemic stress of IRI. These findings are further supported by the dose and length of pretreatment required to convey the protective effects of allopurinol relative to the much smaller dose and time demonstrated to effectively inhibit xanthine oxidase[47,48]. Additionally, the length of time required (d) for pretreatment with allopurinol to be effective will limit its potential clinically due to the limited lead time a patient has from notification until transplantation due to the nature of organ donation.

Superoxide dismutase

One of the problems with targeting ROS in IRI is the separation of intracellular and extracellular sources of the oxidant stress during IRI as well of the timing of ROS generation within these locations. Generally, Kupffer cells produce ROS early within the ischemic phase that injures intracellular targets within the hepatocytes. Later, during the reperfusion phase previously damaged and dysfunctional mitochondria in addition to infiltrating neutrophils contribute to the oxidant stress within the intra and extracellular spaces. This delineation of timing and location was emphasized by the failure of one of the early attempts of scavenging free radicals as a means to ameliorate IRI. In these studies catalase and superoxide dismutase were administered intravenously either in combination or alone[49]. This study found only partial protection from IRI implicating a significant role for other ROS or highlighting the weakness that this therapy

cannot target the intracellular effects of ROS. Subsequent studies have utilized carbohydrate modifications of these enzymes or gene delivery to up regulate the intracellular activity of these enzymes and have shown potential benefit and cause for further investigation[50,51].

Augmentation of endogenous nitric oxide and application of exogenous nitric oxide and Nitrite

Nitric oxide (NO) produced at low levels by endothelial nitric oxide synthase (eNOS) is associated with protection against IRI *via* multiple possible mechanisms including preventing leukocyte adhesion and limiting reactive oxygen species production by mitochondria. Moreover, deficits in eNOS-derived NO have been documented in numerous inflammatory disorders and IRI, although how eNOS activity is altered in human liver transplantation remains to be clearly defined[52,53]. Consistent with protective effects of eNOS are gene therapy studies that show overexpression of this enzyme in the liver protects against IRI in mice[54].

An alternate strategy to gene therapy is to augment NO using NO-repletion strategies. Many NO-donors exist but suffer from a lack of compartmentalized release that can result in unwanted effects (*e.g.*, hypotension)[55]. Recent studies are beginning to address this limitation. As alluded to above, targeting drugs to the mitochondria is now a possibility. This has also been demonstrated with NO, with a mitochondrial targeted S-nitrosothiol showing protection against IRI in the heart[56,57] in part by limiting ROS production in this organelle. The potential for this strategy in liver transplantation remains to be tested. In addition, recent studies have shown that nitrite administration can replete NO-signaling in areas of ischemia[58]. The underlying concept is that nitrite will only be reduced to NO by ischemia sensitive mechanisms and thus only produce NO in the environments where needed and avoid unwanted systemic effects (Figure 1). This concept has been validated in numerous experimental models, including hepatic IRI and lung and liver transplantation providing a rationale for testing in humans[59-64]. Supporting this rationale is the protective effects of inhaled NO in preventing IRI and improving graft function in liver transplant patients[52]; the protective effects of inhaled NO was posited to be mediated by increased circulating nitrite levels. In addition to a therapy that can be administered during the ischemic phase, nitrite may also be a candidate therapeutic to mimic IP exemplified by studies showing nitrite administration to normal rats, resulting in protection against myocardial and hepatic IRI 24#h thereafter *via* mechanisms that involved limiting mitochondrial dysfunction during the IRI period[61].

CONCLUSION

Further appreciation of the time course and mediators of IRI has led to the discovery of many potential

therapeutics. Each of these faces the hurdle of increased complexity and other unknowns when trying to translate to the pathology seen in human disease. Take for instance the IRI of liver transplantation and the question of when best to administer a proposed therapeutic to: the donor, the graft after harvest, the graft during flushing prior to reperfusion, or after reperfusion. Now, clinical trials must utilize the best data available to choose timing of administration and the most valuable targets to investigate whether the therapy is working by the proposed mechanism. These studies will provide the mechanistic insights currently needed into the IRI of human pathology.

Additionally, the demand for a better understanding of IRI is increasing as we try to reduce the significant wait list mortality caused by demand outpacing supply. This push is causing a closer look at marginal grafts deemed as such because they are steatotic or come from donors of advanced age. These conditions are important to the field of IRI as many of the therapeutics outlined above show an enhanced benefit in steatotic livers. In order to optimize these grafts system changes are occurring within the organ donation network primarily to reduce cold ischemic times associated with transportation. These proposed changes will result in donors being transported to specialized centers more experienced with organ harvest which should minimize organ harvest time and as the recipient will be located at the same medical center this will significantly limit cold ischemic time. Importantly, the advent of donation centers will also create an opportunity to further study these processes. As our clinical trials are often controlled for safety by regulatory boards it has been logistically difficult to administer a therapeutic to a donor that will conceivably affect multiple recipients at multiple institutions. Although donation centers do not remove all logistical barriers of such studies they will create more opportunities to address IRI prior to the ischemic phase and certainly allow for tissue collection to improve our understanding of the human disease.

Given the outlined complexity of IRI it seems that the ideal candidate therapeutic will function by multiple pathways. By preventing ROS production, scavenging ROS in the vascular space and preventing the intracellular damage and mitochondrial dysfunction caused by ROS in the reperfusion phase we may envision an ideal therapeutic against IRI. It is unlikely a single candidate will fulfill the multitude of needs of the ideal therapeutic but as we gain further information on the mechanisms of human IRI it will be possible to identify a combination of therapeutics to best ameliorate the effects of IRI.

REVIEW

Complementary and alternative medications in hepatitis C infection

Abstract

Chronic hepatitis C (CHC) infection affects almost 3% of the global population and can lead to cirrhosis, liver failure, and hepatocellular carcinoma in a significant number of those infected. Until recently, the only treatments available were pegylated interferon and ribavirin, which traditionally were not very effective and have considerable side effects. For this reason, interest in complementary and alternative medications (CAM) in the management of hepatitis C has been investigated. Some CAM has demonstrated therapeutic potential in chronic hepatitis C treatment. Unfortunately, some CAM has been shown to have the potential to cause drug-induced liver injury. This article will review and evaluate many of the natural molecules that interact with the hepatitis C virus (HCV) life cycle and discuss their potential use and safety in HCV therapy, as well as highlight some important interactions between medical and complementary treatments.

Core tip: Over the last 10 years there has been a substantial increase in reports of natural compounds displaying anti-viral activity against hepatitis C. At this time, there is no firm evidence supporting complementary and alternative medications for hepatitis C virus infection. Due to a limited number of trials and small numbers of subjects included in them, it is not possible to fully evaluate the risk of adverse events connected with the use of these products.

INTRODUCTION

Hepatitis C virus (HCV) infection affects an estimated 180 million people globally and is a leading cause of chronic hepatitis, cirrhosis, and liver cancer[1,2]. To prevent the complications of chronic hepatitis C (CHC), the goal of therapy is complete viral eradication. For the past decade, a combination of pegylated interferon-α (peg-IFN) and ribavirin was used to treat CHC with disappointing viral eradication rates. These rates were particularly suboptimal in patients with genotype 1 HCV, which is responsible for approximately 60% of worldwide infections[3]. Sustained virological response (SVR) rates for genotype 1 HCV are approximately 40% following 48 wk of peg-IFN/ribavirin and are even lower in patients with HIV co-infection, high baseline viral load, advanced fibrosis, or those of African descent[4-7].

The life cycle of HCV can be divided into three major steps: (1) entry of the virus into its target cells by receptor-mediated endocytosis; (2) cytoplasmic and mem-

brane-associated replication of the RNA genome; and (3) assembly and release of the progeny virions[8]. In recent years, there has been improvement in SVR rates with the development and approval of the first HCV-specific direct-acting antiviral agents (DAAs), namely boceprevir and telaprevir[9,10]. In contrast to the non-specific antiviral activity of peg-IFN and ribavirin, DAA are designed to inhibit viral proteins involved in the HCV life cycle. Still, the first DAAs require coadministration with peg-IFN and ribavirin, and many patients remain intolerant to treatment-associated side effects, including fevers, influenza-like symptoms, headache, cytopenias, fatigue, anorexia, rash, and depressive symptoms.

CAM is being used increasingly across the globe for many chronic diseases[11,12]. The Cochrane Library included nearly 50 systematic reviews of complementary medicine interventions as of 2003[13]. Many people turn to CAM when conventional medicine fails, or they believe strongly in its effectiveness. During the last few years, a substantial increase of reports on natural compounds displaying an anti-HCV activity has been published. There is data that some of these medicinal herbs might have therapeutic potential in CHC, or may alleviate side effects of conventional therapy[13]. CAM use is common among people with CHC. A survey of 1145 participants in the National Institutes of Health (NIH)-supported HALT-C (Hepatitis C Antiviral Long-Term Treatment Against Cirrhosis) trial found that 23% of the participants used herbal products[14]. Although sometimes thought by the public to be safer then conventional therapy, there are many reports about liver toxicity and other adverse events from some herbal products[11,15]. The aim of this review is to evaluate the efficacy and safety of treating HCV infection using complementary and alternative medicine.

MEDICINAL HERBAL AND DIETARY SUPPLEMENTS WITH ANTI-HCV ACTIVITY

Silymarin
An extract of the milk thistle plant, silymarin *(Silybum marianum)*, has been used to treat chronic liver disease since the time of the ancient Greeks[16]. Owing to its purported hepatoprotective properties, it is the most commonly used herbal product by individuals with chronic liver disease in the United States[16,17]. A recent publication from the HALT-C study group indicated that 33% of patients with CHC and cirrhosis reported current or past use of silymarin[14]. A follow-up study found silymarin use among CHC patients was associated with reduced progression from fibrosis to cirrhosis, but had no impact on clinical outcomes[16].

The major active component of silymarin, silibinin (a mixture of the two diastereoisomers silybin A and silybin B), is thought to be responsible for silymarin's hepatoprotective properties[18]. Silymarin appears to inhibit HCV infection at two or more different levels: (1)

it inhibits HCV replication in cell culture; and (2) it displays anti-inflammatory and immunomodulatory actions that may contribute to its hepatoprotective effect[19,20]. The inhibition of HCV replication has been attributed to inhibitory action on the NS5B RNA-dependent RNA polymerase.

Clinical studies that have evaluated milk thistle for a variety of liver diseases have yielded inconsistent results and low bioavailability of oral silymarin components[21]. Studies with IV silibinin have shown substantial antiviral effect against HCV in liver transplant recipients, and even in nonresponders with good safety outcomes[22-24]. Although oral administration of silymarin is not effective for the treatment of HCV, intravenous silibinin formulation may represent a future potential therapeutic option.

Green tea extract
Green tea, made from the unfermented leaves of *Camellia sinensis*, is comprised of several polyphenolic compounds called catechins, and can be concentrated into a green tea extract (GTE). Epigallocatechin-3-gallate (EGCG) is the most abundant and potent catechin contained within GTE, comprising typically approximately 40% of the total polyphenol content[25]. EGCG is a potent inhibitor of HCV entry in primary human hepatocytes independent of the genotype, by blocking virus attachment. This novel inhibitor may provide a new approach to prevent HCV infection, especially in the setting of liver transplantation of chronically infected HCV patients[26,27]. Beyond its antiviral effect on HCV, EGCG may have potential use as a chemopreventative agent for hepatocellular cancer as EGCG may inhibit cancer cell growth. This mechanism of action is thought to be due to tyrosine kinase inhibition and modulation of target gene expression associated with induction of apoptosis and cell cycle arrest in cancer cells[28-34].

GTE is a common ingredient in several dietary supplements, some of which have been withdrawn from the market due to safety concerns. An example of this is *Exolise* (Arkopharma, France), a weight loss supplement containing high EGCG levels that was withdrawn from the market in April 2003 due to 13 cases of attributable liver injury[35]. Between 1966 and 2008, 216 case reports of toxicity with green tea extracts were identified by the United States Pharmacopeia, of which 34 were concerning for liver toxicity[36]. Recent animal studies with high doses of GTE and EGCG have described dose-dependent hepatotoxicity resulting in severe morbidity and mortality[37]. However, chronic moderate to high dose daily GTE and EGCG use in healthy human volunteers, and selected patients with cirrhosis, was safe and did not impair liver function[38-40]. Although GTE may be very useful in further treatment of CHC and prevention of HCC, its hepatotoxic potential must be acknowledged and monitored carefully in future studies.

Naringenin
HCV associates with β-lipoproteins [very low density lipoprotein (vLDL) and low-density lipoprotein (LDL)]

circulating in blood[41]. In addition, HCV replication can be up-regulated by fatty acids and inhibited by statins; this suggests an interaction between HCV, cholesterol, and lipid metabolism[42]. Recent research has found that of HCV secretion is dependent on both apolipoprotein B (ApoB) expression and vLDL assembly in a chromosomally integrated complementary DNA (cDNA) model of HCV secretion[43].

Naringenin is the predominant flavanone present in the grapefruit and is responsible for its bitter taste. Naringenin has been shown to reduce cholesterol levels both *in vitro* and *in vivo*[44,45]. Furthermore, naringenin inhibits ApoB secretion by reducing the activity and the expression of the microsomal triglyceride transfer protein (MTP) and the acyl-coenzyme A cholesterol acyltransferase 2 (ACAT)[44,46]. Due to the close link between HCV assembly/secretion and lipoprotein metabolism, there has been extensive study on the impact of naringenin on the secretion of HCV particles[43]. A dose-dependent decrease of core protein, HCV-positive strand RNA, infectious particles, and ApoB has been observed in the supernatant of infected primary hepatocytes in culture after naringenin treatment[43]. Overall, naringenin blocked the assembly of intracellular infectious viral particles without affecting intracellular levels of the viral RNA or protein. Although still at the cell culture phase, naringenin may offer new insight into a promising and novel HCV therapeutic target.

Glycyrrhizin

Glycyrrhizin, a natural compound extracted from the roots of *Glycyrrhiza glabra*, has been used for more than 20 years as a treatment for chronic hepatitis[47]. It has been used for many centuries in traditional Chinese medicine as an anti-allergic agent. Because of its sweet taste it is also used as a food additive, for example in beverages and licorice[48]. In an attempt to use glycyrrhizin as a treatment for "allergic" hepatitis it was found to lower the transaminases. In a study by Suzuki *et al*[49] in 1977, plasma transaminases activity improved significantly with glycyrrhizin in patients with chronic liver disease compared to a placebo group.

The mechanism by which glycyrrhizin improves the biochemistry and histology in liver disease is unknown. It is thought to have anti-inflammatory, antioxidant and immunomodulatory activities. Due to this there has been much interest in use of glycyrrhizin in CHC. In the only randomized clinical trial of glycyrrhizin, ALT levels declined modestly during treatment, compared with placebo, but this was not sustained after cessation of treatment and there was no significant effect on HCV RNA levels[50]. In the another trial, statistically significant differences in liver enzyme levels, but not viral loads, between treatment groups were identified during treatment, however, again no sustained response occurred at follow-up[51]. Use of glycyrrhizin is not without side effects. It has been found to cause pseudo-aldosteronism, manifested by sodium retention, hypokalemia and hyper-

tension[52]. Cardiac arrhythmia and acute rhabdomyolysis due to severe hypokalemia caused by excess licorice consumption have also been reported[52-54].

Oxymatrine

Oxymatrine is the major alkaloid extract from the root of *sophora flavescens*, a deciduous shrub native to China, Japan, South Korea and Russia. It is reported to have antiviral activity against HCV in cell cultures and in animal studies[55-57]. Clinical studies have shown that oxymatrine has some hepatoprotective activity in alcohol toxicity and hepatitis B infection, but not carbon tetrachloride, acetaminophen or cadmium chloride-induced acute hepatitis[58,59]. Oxymatrine is considered to be an antifibrotic, likely through inhibition of lipid peroxidation[60-62]. In a study of HCV-infected subjects randomized subjects to receive either an intramuscular injection of oxymatrine 600 mg/d or other support products such as oral vitamins 47% of the treated cases had complete HCV viral suppression after 3 mo, compared with only 5% in the control group[61]. No serious adverse events were reported. The treated group had significantly more ALT normalizations than the control group in the first 2 mo, but this improvement waned by the end of the third month of treatment. While treatment with oxymatrine holds promise, it is difficult to draw conclusions from the small studies currently available.

Traditional chinese herbal medications

The primary goal of Chinese traditional medicine is to create wholeness and harmony within a person, allowing the mind/body/spirit to heal itself. There have been several randomized clinical trials of traditional Chinese medicine in the treatment of hepatitis C, however, the methodological quality of these studies is generally considered poor[63-70]. In two trials of herbal formulations in combination with interferon-alfa, there was a trend toward greater clearance of HCV RNA and ALT normalization with the combination treatment compared with patients receiving monotherapy[63,64]. In the only placebo-controlled trial of solo therapy with traditional Chinese medicine, a significant reduction in ALT levels during treatment occurred, though no virologic effect was identified[69]. Detailed descriptions of adverse events were not provided for most of these trials. The safety of these medicines is unclear due to the individualized nature of many of the herbal compounds involved, the large number of different herbs in each formulation, and the relatively small number of subjects within each clinical trial.

Vitamin D

The traditional role of Vitamin D (Vit D) was thought to be based upon its interaction in calcium homeostasis, *via* regulation of intestinal calcium absorption and of bone health. However, over the last several years Vit D has been shown to have a much more complex role in many other host functions, including its interaction with

chronic hepatitis C. 25-OH Vit D is made in the liver *via* cytochrome P450 (CYP27A1) activated hydroxylation of Vit D, brought into the body either by intestinal absorption or endogenous synthesis through sun-exposed skin. It is then converted to 1.25 OH Vit D (calcitriol) in the kidneys, the most active form, where it becomes available to bind to Vit D receptors throughout the body[71,72].

A growing body of clinical evidence has demonstrated an increased prevalence of Vit D deficiency in patients with CHC. As such, Vit D supplementation has been proposed as an adjunct to current standard regimens for treatment of hepatitis C[72]. One study found that mean 25-OH Vit D serum levels were significantly lower in CHC (25 μg/L) than in the controls (43 μg/L)[73]. Importantly, low Vit D has been linked to increased fibrosis and impaired sustained virologic response (SVR) in IFN-based therapy[71]. One clinical trial demonstrated that the addition of Vit D to the standard IFN plus ribavirin treatment significantly increased SVR in patients with genotype 1 CHC[74]. Regarding the underlying molecular mechanisms, an *in vitro* study showed that Vit D remarkably inhibits HCV production in Huh7.5 hepatoma cells[75]. These cells express Vit D hydroxylases and can eventually generate calcitriol. Notably, treatment with calcitriol resulted in HCV inhibition through induction of IFN-beta. Overall, 25-OH Vit D levels appear to be an important prognostic marker in helping determine the likelihood of SVR. 25-OH Vit D levels should be checked routinely before HCV treatment and supplementation provided to deficient patients, in an effort to enhance treatment response.

Antioxidants

Antioxidants are one of the most common dietary supplements taken by patients with CHC[14]. The use of these supplements is based on the fact that oxidative stress has been attributed to both host inflammatory processes and induction by viral proteins. By increasing antioxidants, one may be able to decrease oxidative stress and therefore decrease liver injury[76]. Existence of oxidative stress in CHC is well documented, as oxidized protein and nucleic acid markers are increased and antioxidant levels are decreased[77-80]. Studies have shown levels of oxidative stress markers to correlate with disease severity, HCV RNA, iron overload, and insulin sensitivity[78,79]. Oxidative stress has also been shown to be an early event in carcinogenesis and is a risk factor for development of HCC in patients with chronic HCV[81].

Multiple trials have shown antioxidants, such as Vitamin E and N-acetyl cysteine, only lead to small reductions in ALT after chronic administration in some instances[82-93]. Further, the decrease in ALT levels in most studies is marginal and is not sustained after stopping the treatment, raising the question of their clinical significance. No study has shown an improvement in outcome. In addition, no study has shown clear benefit of antioxidants as adjuvant to interferon based therapy of HCV. At the doses studied, these antioxidants appear to be well-tolerated, with no specific adverse events reported in any of the trials. However, very large oral doses of *N*-acetyl cysteine are commonly associated with nausea and vomiting and intravenous administration of *N*-acetyl cysteine can result in anaphylactoid reactions, which may be more common in patients with chronic liver disease[94]. Therefore, evidence supporting use of antioxidants as useful therapeutic agents in CHC is lacking.

HERBAL SUPPLEMENTS AND DRUG INDUCED LIVER INJURY IN CHRONIC HCV

Drug-related hepatotoxicity is a serious health problem, with broad implications for patients, healthcare providers, the pharmaceutical industry and governmental regulatory agencies. The Drug Induced Liver Injury Network (DILIN), a federally funded consortium of 12 centers in the United States, recently reported the preliminary results of its prospective study[94]. Dietary supplements were implicated in 9% of reported DILI cases. This may be potentially related to increasing use of herbal or dietary supplements in the US population. The importance of these supplements as a cause of DILI is further underscored by a retrospective Japanese study, in which 10% of 879 cases of single agent DILI from 1997 to 2006 were attributed to dietary supplements and 7% to Chinese herbal drugs[95].

In general, chronic liver diseases such as HCV infection are thought to be associated with an increased incidence of hepatotoxicity induced by several specific drugs. Furthermore, patients with underlying liver disease potentially have worse outcomes than healthy individuals if they do develop DILI[96]. For example, the presence of underlying CHC has been shown to increase the risk of DILI caused by the antituberculosis drugs isoniazid and rifampin, as well as ibuprofen and methimazole[15,97,98]. Due to this, patients with chronic hepatitis C should be counseled and screened by physicians on potential risks associated with herbal medications.

DRUG-CAM INTERACTIONS

Another major area of awareness when patients are considering using CAM is whether or not drug-CAM interactions may exist that could impact the medical therapy. This issue is becoming even more complicated with the addition of new medications for the treatment of CHC infection such as simeprevir and sofosbuvir approved for use in the U.S. in December 2013. St. John's wort (*Hypericum perforatum*), a common CAM used for the treatment of depression, is an inducer of cytochrome P450 3A4[99]. This cytochrome is also the primary metabolizer of many medications, including the HCV protease inhibitors: telaprevir, boceprevir, and simeprevir. Additionally, St. John's wort is a potent intestinal P-gp inducer and may lead to a reduced therapeutic effect of

Table 1 Herbal supplements to discontinue and/or avoid while taking hepatitis C virus treatment

Herbal Product	Effect
Milk thistle (*Silybum marianum*)	Concomitant use of milk thistle may result in increased plasma concentrations of simeprevir
St. John's wort (*Hypericum perforatum*)	Concomitant use of St. John's wort may result in decreased plasma concentrations of telaprevir, boceprevir, simeprevir and sofosbuvir

the HCV nucleotide polymerase inhibitor sofosbuvir[100]. Concomitant use of St. John's wort and these HCV treatments is contraindicated and can lead to treatment failure by reducing blood concentrations. Additionally, concomitant use of milk thistle use is contraindicated with simeprevir. This combination may increase levels of simeprevir by milk thistle CYP3A inhibition leading to possible toxicity[101] (Table 1). Garlic extracts, grapefruit juice, and germander also have cytochrome P450 3A4 interactions[102].

CONCLUSION

Many human studies have shown improvements in subjective symptoms and liver biochemistries in HCV patients with CAM, but there is no convincing data to suggest a definite histological and/or virologic improvement with any of the herbal agents currently available. Vit D seems to have the best available data as adjunctive therapy to antiviral medications in patients with Vit D deficiency. Poorly designed studies, heterogeneous patient populations, lack of standardized preparations, and poorly defined nonobjective end points may partly explain the conflicting reports in the literature.

The safety profiles of the interventions discussed within this review are encouraging at the doses studied. However, the long-term safety for use in the treatment of hepatitis C, either alone or in combination with conventional medicines, has not been established. Comparative and placebo-controlled trials suggest that patients experience no more adverse events with these interventions than with placebo or comparative medications, although short-term clinical trials are not designed to detect rare or delayed adverse events. Physicians need to be cognizant of known or occult use of CAM by their patients because hepatotoxicity and drug interactions may occur with many herbal medications, and may occur more frequently in patients with chronic liver disease.

There is an undoubted need for further research into the treatment of hepatitis C, and this review has identified several promising compounds, including Vit D, silymarin, oxymatrine, naringenin, and GTE. Some or all of these may be integral components of future HCV management.

Abstract

Causality assessment of suspected drug induced liver injury (DILI) and herb induced liver injury (HILI) is hampered by the lack of a standardized approach to be used by attending physicians and at various subsequent evaluating levels. The aim of this review was to analyze the suitability of the liver specific Council for International Organizations of Medical Sciences (CIOMS) scale as a standard tool for causality assessment in DILI and HILI cases. PubMed database was searched for the following terms: drug induced liver injury; herb induced liver injury; DILI causality assessment; and HILI causality assessment. The strength of the CIOMS lies in its potential as a standardized scale for DILI and HILI causality assessment. Other advantages include its liver specificity and its validation for hepatotoxicity with excellent sensitivity, specificity and predictive validity, based on cases with a positive reexposure test. This scale allows prospective collection of all relevant data required for a valid causality assessment. It does not require expert knowledge in hepatotoxicity and its results may subsequently be refined. Weaknesses of the CIOMS scale include the limited exclusion of alternative causes and qualitatively graded risk factors. In conclusion, CIOMS appears to be suitable as a standard scale for attending physicians, regulatory agencies, expert panels and other scientists to provide a standardized, reproducible causality assessment in suspected DILI and HILI cases, applicable primarily at all assessing levels involved.

Core tip: We propose that the attending physicians caring for patients with assumed drug induced liver injury and herb induced liver injury should use the Council for International Organizations of Medical Sciences (CIOMS) scale for causality assessment. This approach includes the option of subsequent refinement of the CIOMS based results by expert panels and regulatory agencies. The use of the CIOMS scale as an identical

tool for all involved parties will allow early and prospective collection of all relevant data required for a valid causality assessment in clinical hepatology.

INTRODUCTION

Drug induced liver injury (DILI) and herb induced liver injury (HILI) are complex diseases and often overdiagnosed[1-5]. An expert review of suspected DILI reports from primary and secondary care physicians to the UK Committee on the Safety of Medicine revealed that 47.1% of the cases were not DILI and that the misdiagnoses delayed arriving at the correct diagnoses, possibly worsening patient outcome[1]. Misdiagnosis was a common phenomenon in other DILI studies[2-4], including publications in which DILI was initially assumed, but hepatitis E virus infection later on evolved as the correct diagnosis[2,3]. Similarly, in a recent assessment of initially suspected HILI, correct diagnoses were missed in 278/573 cases, corresponding to 48.5%[5]. Given these frequencies because of insufficient case assessment, DILI and HILI represent major issues for physicians who care for patients with these diseases.

Physicians commonly are confronted with a wealth of published data about hepatic adverse drug and herb reactions and may use this information for evaluating the cases of their patients. Reviews addressed general aspects of DILI[6,7] or HILI[4,8-10], whereas other reports focused on various basic features like clinical course, prognosis, alternative causes, case definition and phenotype standardization[5,11-17]. They suggest a similar or identical clinical presentation of DILI and HILI, raising the question of whether HILI needs a separate term. However, major differences exist between DILI and HILI; DILI is caused by a single chemically characterized drug, whereas HILI is triggered by a chemical mixture constituted of the herbal extract, which often lacks the benefit of regulatory surveillance. Herbal product quality varies and is a major issue in HILI, adding to the complexity in evaluating causality for herbs. This may explain why HILI is considered as a poorly defined entity, is a neglected disease, and requires special attention.

Potential genetic risk factors and biomarkers, including micro-RNA, are presently being investigated to explain DILI and HILI disease[18-20]. These data provide promising clinical and scientific results but currently contribute little to diagnose DILI or HILI correctly and in time, or to exclude alternative causes. Recognizing that the best approach is still not available in clinical practice, the physician needs a pragmatic guideline to quickly evaluate suspicious cases and reach a conclusive diagnosis. This is at present best achieved by the combination of clinical judgement and a liver specific causality assessment algorithm like the CIOMS (Council for International Organizations of Medical Sciences) scale[21,22], as has been summarized recently[10,14,23-25]. For DILI and HILI case reports, the CIOMS scale based on international consensus meetings[21,22,26,27] is the commonly applied method to assess causality[4,5,10,14,23,24,28,29]. In clinical practice, causality assessment of suspected hepatotoxicity is hampered by the lack of a standardized approach, which is applicable to all levels of causality assessment[4,14,24] and requires simplicity of the assessment method rather than complexity to evaluate DILI and HILI cases.

This review analyzes the suitability of the liver specific CIOMS scale for causality assessment in DILI and HILI cases as a standard for attending physicians, regulatory agencies, expert panels and the scientific community. It focuses on the characteristic features of the CIOMS scale, discusses strengths and weaknesses, and suggests approaches for the clinician who lacks a stand-by panel of DILI or HILI experts.

The PubMed database was searched for the following terms: drug induced liver injury; herb induced liver injury; DILI causality assessment; and HILI causality assessment. The literature search was done on June 4, 2013. Several hundreds of records were initially obtained, depending of the term used. The first 50 publications of each search were analyzed in depth for suitability in the analysis of the CIOMS scale quality, with numerous duplicated reports found in each category. The final compilation of evaluated publications consists of original papers, case series, case reports, consensus reports and review articles. All relevant reports were included in the reference list to be presented in this review. Analyzed reports were published between 1977 and 2013, preferentially within the last decade.

GENERAL ASPECTS

The liver specific and quantitative CIOMS scale was conceptualized and developed in consensus meetings organized at the request of the Council for International Organizations of Medical Sciences (CIOMS), with details published in 1993[21,22]. This CIOMS scale represented a breakthrough in DILI causality assessment methods and extended, specified and quantified the preceding qualitative RUCAM (Roussel Uclaf Causality Assessment Method) of 1988[26] and qualitative CIOMS method of 1990[27]. The basis for the CIOMS scale was provided by eight experts in hepatology from 6 countries and included J P Benhamou (France), J Bircher (Germany), G Danan (France), W C Maddrey (United States), J Neuberger (United Kingdom), F Orlandi (Italy), N Tygstrup (Denmark) and H J Zimmerman (United States)[21]. This expert panel evaluated DILI cases for case characteris-

tics, hepatotoxicity criteria, liver injury pattern and reexposure criteria, standardized DILI case assessment with specific, quantitative items[21], and the experts validated their method with established positive reexposure DILI case results[22]. The CIOMS scale was developed for assessment of a single drug containing a synthetic product and may be used for a single herb containing multiple chemical constituents, but does not allow causality attribution to a specific constituent. The scale is a learning system and not immutable; room for improvement and refinement of the CIOMS scale has been outlined[29], with modifications of the CIOMS scale based on improved diagnostic instruments[14].

STRENGTHS

Prospective use

Its prospective application enables the CIOMS scale to provide an early causality grading for patients with suspected DILI or HILI; its results can be adapted further to diagnostic and therapeutic measures. This scale is easily used as a bedside tool at a time the disease is developing (Tables 1 and 2). Results do not depend on expert opinion and are quickly available for trained physicians to decide whether DILI and/or HILI should be considered as relevant differential diagnoses due to their clinical experience. Assessment is best started on the day of suspecting DILI or HILI, with a continuous update of the required data and a change in the diagnostic and therapeutic concept if needed. Finally, a complete data set for presentation to regulatory agencies, expert panels and eventually for publication is obtained[24,30-33], including a checklist with additional data helpful in overall case evaluation and causality assessment (Table 3). Therefore, the CIOMS scale should be considered as a standard for causality assessment of DILI and HILI, both for the attending physician and later evaluation stages. Using one single assessment method at all evaluating levels allows comparison of different assessment outcomes.

Liver specificity

Liver specificity is a hallmark of the CIOMS scale, in contrast to liver unspecific causality assessment methods or ad hoc approaches[4,24]. The CIOMS items are specially tailored to liver injury and not applicable to liver unrelated adverse drug reactions[24]. All current core elements of hepatotoxicity are considered in the CIOMS scale (Tables 1 and 2): time to onset of increased liver values or symptoms from the beginning and cessation of the drug/herb; course of liver enzymes after cessation; risk factors such as alcohol, age and pregnancy; comedication with other drugs/herbs; search for alternative causes, previously known drug/herb hepatotoxicity; and response to unintentional reexposure[21-25] based on specific criteria (Table 4). The individual items are transparent and facilitate quick and precise answers.

The CIOMS scale is structured and all its items undergo quantitative rather than qualitative assessment

and scoring (Tables 1 and 2)[4,5,10,14,21,23,24,29]. Each item is weighted with specific scores based on the answer. The sum of the individual scores gives a final score that may range from -9 to +14 points, allowing for sufficient discrimination. The final score provides causality levels for the individual synthetic drug or herb as highly probable, probable, possible, unlikely or excluded (Tables 1 and 2)[12,24,30-32].

Hepatotoxicity definition

The international CIOMS expert panel defined liver injury in its consensus report as increased alanine aminotransferase (ALT) and/or alkaline phosphatase (ALP) activities of at least 2N, with N as the upper limit of normal[21]. Conversely, the consensus of the international DILI Expert Working Group with participants from Europe, the United States and Japan raised the ALT cut off point to 5N or 3N if total bilirubin values exceeded 2N and considered the 2N of ALP as an appropriate definition criterion[14]. Whereas the DILI Expert Working Group recommendations were based on expert opinion alone[14], those of the CIOMS expert panel were derived from both expert opinion and assessment of reference reexposure DILI cases[21,22].

Raising the ALT cut off to 5N increases the specificity of the hepatotoxicity causality assessment[24], eliminates false positive cases and substantiates hepatotoxicity causality at a higher level of probability[16,24]. The lower threshold of ALT > 2N will include multiple cases with nonspecific enzyme increases and requires more stringent exclusion of causes unrelated to drug(s) and herb(s)[24]. Also for low threshold N values, the inclusion rate of alternative diagnoses must be higher; false positive fulfilment of a hepatotoxicity definition results in high numbers of misattributed cases due to overdiagnosing and overreporting[8,12,17,24,34-48]. This phenomenon is illustrated in a recent HILI study where initial ALT values were available in only 8/22 cases (36%), including 3 cases with a range of 50-69 U/L serum activity[36]. None withstanding, regulatory assessment attributed a possible causality for the incriminated herb to all 22 cases[36,42]. In other spontaneous case collections, initial ALT values were available in 5/24 cases (21%)[35], 19/22 cases (86%)[37], 12/15 cases (80%)[38], and 7/13 cases (54%)[39]. The corresponding figures for ALT in published case reports of HILI were 16/16 cases (100%)[35], 21/21 cases (100%)[32], and 5/8 cases (63%)[33]. ALT values were included in DILI reports for amoxicillin/clavulanic acid, troglitazone, pioglitazone and montelukast in 11% to 88% of the cases, which were not further scored for causality by the Drug Induced Liver Injury Network (DILIN)[6]. ALT underreporting is therefore an issue for both DILI and HILI.

Other arguments merit further considerations. An ALT cut off point of 5N may not be applicable to some types of chronic liver injury like methotrexate liver fibrosis or nodular regenerative hyperplasia; misinterpretation is also possible in some forms of acute liver injury by mitochondrial toxicity in cases of valproate or

Table 1 Council for International Organizations of Medical Sciences scale for the hepatocellular type of injury and cholestatic or mixed type of injury in drug induced liver injury and herb induced liver injury cases

Total score for patient		

The CIOMS scale is based on the original CIOMS scale[21] and was adapted from previous modifications[4,14,23,24,44,45]. The above items specifically refer to the hepatocellular type of injury rather than to the cholestatic or mixed type (shown in Table 2). Regarding risk factor of alcohol use, 1 drink commonly contains about 10 g ethanol and details were discussed recently[14,44,45]. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; CIOMS: Council for International Organizations of Medical Sciences; CMV: Cytomegalovirus; CT: Computer tomography; DILI: Drug induced liver injury; EBV: Epstein Barr virus; HAV: Hepatitis A virus; HBc: Hepatitis B core; HBsAg: Hepatitis B antigen; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HEV: Hepatitis E virus; HILI: Herb induced liver injury; HSV: Herpes simplex virus; MRC: Magnetic resonance cholangiography; N: Upper limit of the normal range; VZV: Varicella zoster virus. Total score and resulting causality grading: ⩽ 0: Excluded; 1-2: Unlikely; 3-5: Possible; 6-8: Probable; ⩾ 9: Highly probable.

fialuridine hepatotoxicity[14]. Aspartate aminotransferase (AST) activities may be used instead if ALT activities are unavailable[14,44,45] and other pathologies for AST increases are excluded[14]. ALP increases should be paral-

Total score for patient		

The CIOMS scale presented in this table is designed specifically for the cholestatic or mixed type of liver injury rather than for the hepatocellular type, which differs in a few items and is presented separately in Table 1. Additional details and abbreviations are provided in the legend of Table 1. Abbreviation: ALP, Alkaline phosphatase. Total score with resulting causality grading: ⩽ 0, excluded; 1-2, unlikely; 3-5, possible; 6-8, probable; ⩾ 9, highly probable.

leled by γ-glutamyltranspeptidase (γGT) to rule out isolated increases of ALP activities due to bone rather than hepatobiliary disease. However, γGT alone is not an appropriate parameter for liver cell injury[14,36], contrary to published claims[42]. In addition, isolated hyperbilirubinemia is not DILI or HILI specific and may be caused by Gilbert's syndrome[1,14].

Liver injury pattern

The CIOMS scale takes into account divergent laboratory constellations of the liver injury pattern in the hepatocellular and the cholestatic type of liver injury and

Varicella zoster virus (VZV) - VZV-PCR, titer change for anti-VZV-IgM and anti-VZV-IgG	□	□	□	-
Other virus infections - specific serology of Adenovirus, coxsackie-B-Virus, echovirus, measles virus, rubella virus, flavivirus, arenavirus, filovirus, parvovirus, HIV, and others	□	□	□	-
Other infectious diseases - specific assessment of bacteria (such as campylobacter, coxiella, leptospirosis, listeria, salmonella, treponema pallidum), fungi, parasites, worms, tropical diseases, and others	□	□	□	-
Autoimmune hepatitis (AIH) type Ⅰ - Gamma globulins, ANA, SMA, AAA, SLA/LP	□	□	□	-
Autoimmune hepatitis (AIH) type Ⅱ - Gamma globulins, anti-LKM-1 (CYP 2D6), anti-LKM-2 (CYP 2C9), anti-LKM-3	□	□	□	-
Primary biliary cirrhosis (PBC) - AMA, anti PDH-E2	□	□	□	-
Primary sclerosing cholangitis (PSC) - p-ANCA, MRC	□	□	□	-
Autoimmune cholangitis (AIC) - ANA, SMA	□	□	□	-
Overlap syndromes - see AIH, PBC, PSC, and AIC	□	□	□	-
Non alcoholic steatohepatitis (NASH) - BMI, insulin resistance, hepatomegaly, echogenicity of the liver	□	□	□	-
Alcoholic liver disease (ALD) - patient's history, clinical and laboratory assessment, sonography	□	□	□	-
Drug/herb induced liver injury - patient's history, clinical and laboratory assessment, sonography, use of the CIOMS scale	□	□	□	-
Toxin Screening - cocaine, ecstasy and other amphetamines	□	□	□	-
Rare intoxications - toxin screening for household and occupational toxins	□	□	□	-
Hereditary hemochromatosis - serum ferritin, total iron-binding capacity, genotyping for C2824 and H63D mutation, hepatic iron content	□	□	□	-

Wilson's disease - copper excretion (24 h urine), ceruloplasmin in serum, free copper in serum, coombs-negative hemolytic anemia, hepatic copper content, Kayser-Fleischer-Ring, neurologic-psychiatric work-up, genotyping	□	□	□	-
Porphyria - corphobilinogen in urine, total porphyrines in urine	□	□	□	-
α1 - antitrypsin deficiency - α1- Antitrypsin in serum	□	□	□	-
Biliary diseases - clinical and laboratory assessment, hepatobiliary sonography, endosonography, CT, MRT, MRC	□	□	□	-
Pancreatic diseases - clinical and laboratory assessment, sonography, CT, MRT	□	□	□	-
Celiac disease - TTG antibodies, endomysium antibodies, duodenal biopsy	□	□	□	-
Anorexia nervosa - clinical context	□	□	□	-
Parenteral nutrition - clinical context	□	□	□	-
Cardiopulmonary diseases with shock liver (cardiac hepatopathy, ischemic hepatitis) - cardiopulmonary assessment of congestive heart disease, myocardial infarction, cardiomyopathy, cardiac valvular dysfunction, pulmonary embolism, pericardial diseases, arrhythmia, hemorrhagic shock, and various other conditions	□	□	□	-
Addison's disease - plasma cortisol	□	□	□	-
Thyroid diseases - TSH basal, T4, T3	□	□	□	-
Grand mal seizures - clinical context of epileptic seizure (duration > 30 min)	□	□	□	-
Heat stroke - shock, hyperthermia	□	□	□	-
Polytrauma - shock, liver injury	□	□	□	-
Systemic diseases - specific assessment of M. Boeck, amyloidosis, lymphoma, other malignant tumors, sepsis, and others	□	□	□	-
Graft *vs* host disease - clinical context	□	□	□	-
Other diseases - clinical context	□	□	□	-

This checklist is far from complete and considered as a reminder for the physician. Some listed liver diseases like AIH require a liver biopsy to establish the diagnosis. Few elements are not directed to causality assessment but are important for overall case evaluation. AAA: Anti-actin antibodies; AMA: Antimitochondrial antibodies; ANA: Antinuclear antibodies; BMI: Body mass index; CT: Computed tomography; CYP: Cytochrome P450; HAV: Hepatitis A virus; HBc: Hepatitis B core; HBsAg: Hepatitis B antigen; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HEV: Hepatitis E virus; HILI: Herb induced liver injury; HIV: Human immunodeficiency virus; LKM: Liver kidney microsomes; LP: Liver-pancreas antigen; MRC: Magnetic resonance cholangiography; MRT: Magnetic resonance tomography; p-ANCA: Perinuclear antineutrophil cytoplasmatic antibodies; PDH: Pyruvate dehydrogenase; PCR: Polymerase chain reaction; SLA: Soluble liver antigen; SMA: Smooth muscle antibodies; TSH: Thyroid stimulating hormone; TTG: Tissue transglutaminase.

Table 4 Conditions of unintentional reexposure tests in drug induced liver injury and herb induced liver injury cases

Reexposure test result	Hepatocellular type of liver injury		Cholestatic or mixed type of liver injury	
	ALTb	ALTr	ALPb	ALPr
Positive	< 5N	≥ 2ALTb	< 5N	≥ 2ALPb
Negative	< 5N	< 2ALTb	< 5N	< 2ALPb
Negative	≥ 5N	≥ 2ALTb	≥ 5N	≥ 2ALPb
Negative	≥ 5N	< 2ALTb	≥ 5N	< 2ALPb
Negative	≥ 5N	NA	≥ 5N	NA
Uninterpretable	< 5N	NA	< 5N	NA
Uninterpretable	NA	NA	NA	NA

Conditions and criteria for an unintentional reexposure test are described in previous reports[4,21,22,24,26,27]. **Accordingly, required data for the hepatocellular type of liver injury are the ALT levels just before reexposure, designed as baseline ALT or ALTb, and the ALT levels during reexposure, designed as ALTr.** Response to reexposure is positive, if both criteria are met: first, ALTb is below 5N with N as the upper limit of the normal value, and second ALTr ≥ 2ALTb. Other variations lead to negative or uninterpretable results. **For the cholestatic or mixed type of liver injury, corresponding values of ALP are to be used rather than of ALT. ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; NA: Not available.**

therefore provides two different subscales[21,23,24] for the hepatocellular type of injury (Table 1) and for the cholestatic or mixed type (Table 2). These types are differentiated by the ratio R, calculated as the ALT/ALP activity measured at the time liver injury is suspected, with both activities expressed as multiples of N[21,24]. Injury is hepatocellular, if only ALT > 2N, alternatively if R ≥ 5; cholestatic injury is assumed, if only ALP > 2N or R ≤ 2; mixed damage is prevalent, if ALT > 2N and ALP is increased, with R > 2 and R < 5[21,23,24]. Of note, R may vary during the later course of the liver injury independent from the initial attribution of damage type.

Time to onset from the beginning of the drug/herb

Clear challenge criteria are defined with a time frame between beginning of the drug/herb use as the first day of intake and the onset of increased liver enzymes or symptoms at the time of ongoing use, with a high score for 5-90 d and a lower one for < 5 d or > 90 d (Tables 1 and 2). If drug/herb use has been terminated prior to the onset of challenge criteria, then this specific condition must be considered and scored exclusively. Scoring is only possible when the onset occurs within 15 d after cessation for the hepatocellular injury (Table 1) or 30 d for the cholestatic or mixed type (Table 2), a longer interval commonly excludes causality (Tables 1 and 2). An exemption is provided for slowly metabolized chemicals like amiodarone, leflunomide and clavulanate[44,45]; no definitive time frame can be provided in these cases due to varying half lives. The time frame of challenge and latency period were neither specified nor individually scored by other causality assessment methods[4,24], including the DILIN method[49,50].

Course of liver enzymes after cessation of the drug/herb

Precise dechallenge criteria are cornerstones of the CIOMS scale and facilitate causality assessment (Tables 1 and 2). In analogy to the periods mentioned, the physician can easily determine relevant future time points for repeated liver enzyme tests. When dechallenge data are missing in retrospective analyses, the CIOMS scale considers this and provides 0, but not negative points, so

Table 5 Frequency of risk factors of alcohol and age among herb induced liver injury patients

HILI study cohort	Total study cases (n)	Cases scored with risk factors (n)			Total cases scored with risk factors n (%)	Cases with references
		Alcohol	Age	Alcohol + Age		
Kava	26	0	6	1	7 (26.9)	Cases 2, 4, 10, 17, 20, 24, 26[12]

Black cohosh	9	1	1	0	2 (22.2)	Cases 4, 9[48]
Black cohosh	22	4	2	0	6 (27.3)	Cases 2, 8, 10, 16, 17, 21[36]
Greater Celandine	22	1	9	0	10 (45.5)	Cases 3, 5, 8, 11, 14-18, 21[37]
Greater Celandine	21	0	7	0	7 (33.5)	Cases 4,9, 11, 16-18, 20[32]
Pelargonium sidoides	15	0	3	0	3 (20.0)	Cases 1, 7, 14[38]
Pelargonium sidoides	13	0	7	0	7 (53.9)	Cases 2, 3, 5, 8, 9, 11, 13[39]
Herbalife	8	0	3	0	3 (37.5)	Cases 1, 2, 4[33]
Total	146	8	43	1	52 (35.6)	

The study cohort consisted of 146 herb induced liver injury patients patients assessed for the frequency of the risk factors alcohol and age ≥ 55 years. In 52/146 cases (35.6%), risk factors were evident.

that the overall score may still present a probable causality level. Of note, the dechallenge time frame was not specifically considered or scored by the DILIN method[49,50] or by virtually any of the other methods[4,24].

Risk factors

The consensus report of the international CIOMS expert panel considered alcohol and age ≥ 55 years as risk factors each scoring +1 point (Tables 1 and 2)[21], as suggested by DILI cases with positive reexposure[21,22]. The international DILI Expert Working Group specified alcohol intake of > 2 drinks per day (> 14 units/week) in women and > 3 drinks per day (21 units/week) in men as the lower threshold for alcohol intake as a risk factor (Tables 1 and 2)[14]. This limit is in line with the recommendations of NIH LiverTox equalling 1 drink to 10 g ethanol[44,45].

The impact of including alcohol as a risk factor on the overall CIOMS scoring was negligible as only 9/146 patients (6%) of a HILI study cohort were allotted an alcohol related scoring point (Table 5)[12,30,32,36-39,46-48]. In these 9 patients, CIOMS causality grading was changed in only one case (patient 16) and unchanged in the other 8 cases (patients 2, 13, 14, 17, 20, 21, 22, 32) (Table 6). In the single case (patient 16), alcohol as risk factor raised the overall CIOMS scoring from 0 to +01 point, *i.e.*, from excluded to unlikely causality (Table 6). Therefore, alcohol per se as risk factor upgrades the CIOMS causality level in virtually none of the cases in this study cohort.

Age ≥ 55 years was as a risk factor in 44/146 cases (30%) of the analyzed HILI study cohort (Table 5)[12,30,32,36-39,46-48]. In 35/44 patients, the overall CIOMS causality grading remained unchanged whether or not age as a risk factor was included in the CIOMS scale scoring (Table 6). Deletion of age as a risk factor reduced the overall CIOMS grading by one causality level in 9/44 patients, *i.e.*, from unlikely to excluded in 5 cases (patients 1, 3, 15, 42, 43), from highly probable to probable in 1 case (patient 23), and from probable to possible in 3 cases (patients 9,

25, 34). Therefore, within this cohort the risk factor age upgraded the causality levels only marginally, which appears to have no clinical relevance. Overall, age as a risk factor has a limited impact on the final causality gradings by the CIOMS scale.

Risk factors are not considered and/or not scored by various other methods[4,24,49,50], including the DILIN method[49,50]. Conversely, the international DILI Expert Group also accepts the risk factors defined in the CIOMS scale, with modified specifications and limitations, if risk factors for hepatotoxicity are present in addition to those listed in the CIOMS algorithm[14].

Concomitant drug(s) and herbs(s)

Concomitant drugs and herbs are individually assessed for temporal association and hepatotoxic potency (Tables 1 and 2). For reasons of comparison and transparency, each comedicated drug or herb requires a separate analysis by the complete CIOMS scale. This is feasible and easily tabulated (Table 7)[30,47,48]. In patients with multiple drug or herb intakes, causality should be attributed primarily to the product with the highest score.

Search for non drug/herb causes

In this section, the CIOMS scale considers the clinically most relevant alternative causes (Tables 1 and 2). There is no difference in alternative causes made between the two types of liver injury, avoiding the need of subsequent reassessment, if the laboratory based typology changes during the clinical course[45]. Complications of underlying disease(s) are exemplified, such as sepsis, autoimmune hepatitis, chronic hepatitis B or C, primary biliary cirrhosis and sclerosing cholangitis and genetic liver diseases (Tables 1 and 2), in accordance with recent suggestions[45]. Other rare alternative causes are included in a checklist of differential diagnoses as a reminder for the clinician in case of unclear clinical diagnosis (Table 3)[24].

To improve its performance when used as an investigational tool, criteria for competing liver injury causes have been proposed for the CIOMS scale[14,29,44,45,49,50]

Table 6 Changes of the Council for International Organizations of Medical Sciences gradings with considering the risk factors

HILI study	Scored risk		CIOMS assessment with RF	CIOMS assessment without RF	Grading change	Cases with references

Based on details described in Table 5, in all 52 patients with evident risks factors of alcohol, age ≥ 55 years, or both, scores and Council for International Organizations of Medical Sciences (CIOMS) gradings with risk factors were compared with conditions without risk factor consideration. In 9 patients, there was a CIOMS downgrading when risk factors would not have been considered. RF: Risk factor.

and were included in the updated CIOMS scale (Tables 1 and 2)[24]. This update ensures correct diagnosis of alternative causes but was limited to details of hepatitis serology and hepatobiliary sonography, as specified by the current knowledge in the field and adapted to actual diagnostic methods[23,24]. The update of the original CIOMS scale substantially improved specificity, *i.e.*, exclusion of alternative causes by hepatitis serology. HBsAg and HBV-DNA quantification were added to distinguish HBV infection from immunization, as was hepatitis C virus (HCV)-RNA to correctly assess HCV infections. Also, clinical and/or biological parameters for cytomegalovirus (CMV), Epstein Barr virus (EBV) or herpes simplex virus (HSV) infection were vague or

Other situations	0				
Total score for each individual herb used by the patient		7	5	5	5

The data of the patient with severe hepatotoxicity by four different Indian Ayurvedic herbs are derived from a published report[30], using the CIOMS scale for the hepatocellular type of liver injury (Table 1). The symbol of - signifies that this particular item has been evaluated and no abnormality was found. For the four herbs, the total score was either +7 (probable causality) or +5 (possible causality). Abbreviations see legend to Table 1.

unknown at the time of compilation[21] but specified in the updated CIOMS scale; also included and specified were infections by hepatitis E virus (HEV) and varicella zoster virus (VZV) (Tables 1 and 2)[24]. Specific diagnostic criteria include polymerase chain reaction detection and titer changes of the respective antibodies (IgM, IgG) for CMV, EBV, HEV, HSV and VZV infections. Hepatobiliary sonography was supplemented by color Doppler sonography, including assessments of the liver vessels, endosonography, computed tomography (CT) and magnetic resonance cholangiography (MRC), if these tests were indicated clinically (Tables 1 and 2). For comparison and method validation, causality has been evaluated in 101 hepatotoxicity cases by both the original and updated CIOMS scales, with identical causality results published in 6 studies[32,33,36-39]. Therefore, the updated CIOMS scale was validated and there is no need for further validation of the updated CIOMS scale versus the original CIOMS scale.

Previous information on hepatotoxicity of the drug/herb
Hepatotoxicity listed in the product information sheet must be checked; in addition, a quick literature search in PubMed will be sufficient to determine whether the observed reaction has been published before. Appropriate information may also be obtained from the NIH LiverTox database[44,45].

Response to unintentional readministration
To classify an unintentional reexposure test as positive, few criteria are required (Tables 1 and 2), as specified (Table 4)[21,22,24,26,27]. Although reexposure is an important domain, probable causality gradings with the CIOMS scale are achievable even in the absence of a reexposure (Table 7)[12,17,30-32,37].

Scoring system
Each item of the CIOMS scale receives an individual score and the sum of the individual scores provides the final score for the patient (Tables 1 and 2). With +14 down to -9 points, there is a wide range of the final scores, leading to the following causality levels: ≤ 0 points, excluded causality; 1-2, unlikely; 3-5, possible; 6-8, probable; and ≥ 9, highly probable (Tables 1 and 2)[21].

Sensitivity, specificity and predictive value
Cases with positive reexposure tests were proposed for validation of the CIOMS scale and used as gold standard[22]. Articles from two databanks were compiled with liver injury confirmed by a positive rechallenge. The mandatory information for inclusion in this series contained the type of liver injury, time interval between administration of the drug and occurrence of the reaction, and results of the positive response to readministration of the drug, in accordance with the conclusions of the International Consensus Meeting on drug induced liver injuries. For the final validation, 49 cases and 28 controls were assessed, as described in detail[22]. Most importantly, the discriminative power of the score was quantified

in terms of sensitivity, specificity and predictive values. The cut off point was offset to maximize the combined sensitivity and specificity. Using +5 points as the cut off, sensitivity was 86%, specificity 89%, positive predictive value 93%, and negative predictive value 78% for the CIOMS causality assessment. In another study with 81 cases and 46 controls, sensitivity was 78% and specificity 100% for the CIOMS scale[51], confirming the validation of the CIOMS scale.

The interrater reliability of CIOMS assessment was good by one group[52] but mediocre by the DILIN group[49]. In the latter report, however, 40 cases going back to 1994 were studied. Uncertainties arose from numerous missing, incomplete or outdated medical reports and charts, especially for older cases. In particular, there were high rates (28%) of preexisting liver diseases like chronic hepatitis C virus infection, hemochromatosis and unspecified cirrhosis. Liver sonography was reported in 26/40 cases and found abnormal in 15/26 (58%). These data were nevertheless described as "best-case scenario"[49]. Considering these limitations and numerous confounding variables, poor case data quality likely results in mediocre assessment quality, including low interrater reliability[49]. Moreover, problematic data presentation by the principal assessor to external reviewers may have influenced the results as the external reviewers received only a subset of the case report forms and had no access to the original data of the cases[49]. Of interest, no proof has been provided that an expert group opinion improves the CIOMS assessment evaluation, at least according to recent comments and studies[11,49]. In another study comparing the CIOMS scale with the DILIN method, there was considerable interobserver variability in both methods[50].

Usage frequency
The CIOMS scale for hepatotoxicity assessment in its original or updated form[4,5,10,14,23,24,28,29] has been extensively used in epidemiological studies, clinical trials, case reports, case series, regulatory analyses and genotyping studies[4]. Additional efforts are still needed to reevaluate causality in most HILI reports for 60 different herbs and herbal products[53]. CIOMS based results were published by the DILIN group[49,50] and by the European Medicines Agency (EMA)[54]. Individual studies[10,16,55,56], the NIH LiverTox[44,45], the international DILI Expert Working Group[14], the Spanish Group for the Study of Drug-Induced Liver Disease[29], and the Hong Kong Herb-Induced Liver Injury Network (HK-HILIN)[57] provided further support for the CIOMS scale.

Among various causality assessment methods, the original and updated CIOMS scales were the preferred tools in cases of DILI[28] and HILI (Table 8)[5], seen for 573 cases from 23 HILI reports evaluating alternative causes[12,32,34,36-39,42,43,47,48,54,57-67].

Transparency
CIOMS based assessments should be reported or published as an original data set suitable for subsequent and independent assessments, rather than as final scores and

The data are derived from a study evaluating alternative causes in suspected HILI cases (*n* = 573) comprising the study cohort[5]. For the 275 CIOMS cases, causality assessment was performed with the updated CIOMS scale the original CIOMS scale, or both. Ad hoc: ad hoc approach; CIOMS: Council for International Organizations of Medical Sciences scale; DILIN: Drug Induced Liver Injury Network method; KL: Karch and Lasagna method; Naranjo: Naranjo scale; WHO: World Health Organization method.

corresponding causality levels, to improve data transparency. Scientists, editors and reviewers should strive to obtain appropriate CIOMS based details for all DILI and HILI case reports. This can easily be achieved since the CIOMS scale provides all items in tabulated form for each individual case (Tables 1, 2 and 7). These forms may be communicated as a spontaneous report to regulatory agencies and expert panels or presented for publication to scientific journals as a case report[24,30,31] or case series[12,24,32]. This tabulation is a good basis for further regulatory or scientific assessments and discussions. For regulatory and expert based assessments, there is no need for other causality assessment algorithms to be used subsequently since CIOMS based data are also amenable to regulatory and expert panel evaluations.

Comparison to precursor scales
The CIOMS scale resulted from intensive expert discussions[21], integrating medical progress and improving the initial qualitative RUCAM[26] and the qualitative CIOMS method[27]. The qualitative RUCAM represented the first objective attempt to assess causality in drug induced liver injury and considered some characteristic features of liver injury, but it had a qualitative rather than a quantitative approach[26]. As an improved version of the qualitative RUCAM[26], the qualitative CIOMS method differentiated the hepatocellular, the cholestatic and the mixed type of liver injury[27]. However, both the qualitative

RUCAM[26] and the qualitative CIOMS method[27] were not quantitative, as opposed to the current quantitative CIOMS scale[21] that is now the preferred tool[24].

Other liver specific methods
The scale of Maria and Victorino (MV)[68] was developed to improve upon the CIOMS scale by deleting laboratory items and adding clinical elements, along with simplifying and changing the relative weight of elements in their algorithm[23,44,45]. No data are available for specificity, sensitivity, positive and negative predictive values for the MV scale[68]. Compared to the original CIOMS scale[21], the MV scale[68] showed shortcomings and the results are not equivalent, causing major concern[10,14,23,24,29,44,45,69-71]. This may explain why the MV scale was used in a few DILI studies[1,72,73], but not in 38 other publications of DILI cases[28] or in 23 publications of HILI cases[5]. The MV scale is not commonly recommended for assessing causality in assumed DILI and HILI cases and is certainly no substitute for the CIOMS scale[24].

The TTK scale[25], named for the first three authors Takikawa, Takamori, Kumagi *et al*[74], is a modification of the CIOMS scale[21] with different evaluations of the chronology, exclusion of comedication, inclusion of the drug lymphocyte stimulation test (DLST) and of eosinophilia in their assessment system[74,75]. The TTK scale is widely used in Japan[74], as recently reviewed[75]. In other countries, this scale is not or rarely

considered[5,10,14,24,28,29,44,45,76]. Limited access and lack of standardization have prevented general clinical use of the DLST and consequently TTK scale applications outside Japan[29]; this may be due to methodological difficulties with false positive and false negative cases in the DLST[25,75]. For clinicians, the TTK scale cannot replace the CIOMS scale[25].

The DILIN method provided by the DILIN group requires an expert panel[3,6,11,24,44,45,49,50,77,78], in contrast to the CIOMS scale[21,24]. Consequently, the DILIN method is of limited availability to physicians in need of early results for therapeutic decisions[24]. In particular, the DILIN method is not an appropriate substitute for the CIOMS scale, nor are other expert panel based approaches[24]. This includes the **novel Causality Assessment Tool (CAT)** specifically designed for herbs and dietary supplements (HDS), which was presented as an abstract[15]. As opposed to CIOMS based results with transparent data presentation (Table 7)[12,30,32,36-39,47,48,71], publications based on the DILIN method lack transparency for individual cases regarding assessed and scored items since only final causality levels are published without details and thereby open for discussions, not allowing valid conclusions[3,6,11,49,50,77,78]. The DILIN method also lacks data on specificity, sensitivity and predictive values, as an expert opinion based method no items can be validated. Individual weighing and scoring of items remain undisclosed and undiscussed, hampering thorough analysis of assessment results by the DILIN method.

Liver unspecific methods

In contrast to the liver specific core elements of the original and updated CIOMS scale (Tables 1 and 2)[4,21-24], numerous causality algorithms are liver unspecific[4,24,76,79,80], including the Naranjo scale[81], the World Health Organization (WHO) global introspection method as the WHO method in short[82], and the KL method of Karg and Lasagna[83]. Particularly intensive discussions focused on the Naranjo scale[4,24,25,84-87], the WHO method[4,24,84,87], and the KL method[24,25]. All these methods are obsolete for causality assessment of assumed hepatotoxicity as they lack liver specificity and do not consider hepatotoxicity characteristics.

WEAKNESSES

Retrospective use

Retrospective analysis of case data is problematic and may require some assistance evaluating the CIOMS items[14,44,45]; unselected and sometimes undefined, low quality data have to be adapted into a structured algorithm like the CIOMS scale. Therefore, physicians should prospectively use the CIOMS scale, which then may provide complete case data (Table 7)[30].

Dechallenge criteria

Missing ALT dechallenge data are factored as 0 points given (Table 1); this condition has been interpreted as a

limitation of the CIOMS scale[14]. Retrospective studies commonly lack dechallenge results[6,12,32,34-39] which are included in prospective evaluations (Table 7)[30]. CIOMS performs inaccurately in acute liver failure and liver transplantation if liver values are not available within 30 d after cessation of the incriminated drug or herb. Under these circumstances, 0 but not negative points are credited due to lacking ALT data (Tables 1 and 2).

Risk factors

The CIOMS scale includes only the risk factors of alcohol and age ≥ 55 years[21]. Diabetes, metabolic syndrome, sex, ethnicity and body mass index[14], as well as genetic predisposition[29], are also proposed as potential risk factors; the lack of inclusion in the CIOMS scale has been considered as a limitation[14,29]. However, these factors have not been validated as risk factors; their inclusion into the CIOMS scale requires evidence as independent contributors and a subsequent new validation.

Alternative causes

It may be argued that rare alternative causes were not listed in the CIOMS scale (Tables 1 and 2) but this shortcoming was compensated for by the checklist for numerous rare liver diseases as a reminder for the clinician (Table 3)[24].

Previous information on hepatotoxicity of drug/herb

Safety labels are available for both synthetic and herbal drugs but rarely for other herbal products. This shortcoming of the CIOMS scale may be compensated by a thorough search for prior publications of hepatotoxicity by herbal products; published reports provide an even higher scoring than information obtained only from safety labels.

CONCLUSION

The major strength of the CIOMS is its potential as a standard scale for DILI and HILI causality assessment by attending physicians, regulatory agencies, expert panels and the scientific community. Other advantages include its liver specificity and its validation for hepatotoxicity cases, with excellent sensitivity, specificity and predictive validity based on results obtained from cases with a positive reexposure test. This scale will allow the physician treating patients with suspected DILI and HILI an early preliminary result of the likelihood, facilitates timely and prospective collection of all relevant data required for a subsequent valid causality assessment, does not require an expert panel, and has the option of subsequent refinement by regulatory agencies, expert panels and the scientific community. With the CIOMS scale, an identical causality assessment algorithm can used by all evaluating parties, which facilitates the overall procedure of causality association. Minor weaknesses of the CIOMS scale include the limited exclusion of alternative causes and the handling of poor case data in

retrospectively rather than prospectively assessed cases.

Abstract

Fatty liver is a growing health problem worldwide. It might evolve to nonalcoholic steatohepatitis, cirrhosis and cause hepatocellular carcinoma. This disease, which has increased because of eating habits, changes in food content and lifestyle, affects people from childhood. The most important risk factors are obesity and insulin resistance. Besides these factors, gender, ethnicity, genetic predisposition and some medical problems are also important. Cirrhosis in children is rare but is reported. Nonalcoholic fatty liver disease (NAFLD) has no specific symptoms or signs but should be considered in obese children. NAFLD does not have a proven treatment. Weight loss with family based treatments is the most acceptable management. Exercise and an applicable diet with low glycemic index and appropriate calorie intake are preferred. Drugs are promising but not sufficient in children for today.

Core tip: Nonalcoholic fatty liver disease (NAFLD) consists of steatosis in liver, steatohepatitis and cirrhosis. Histological type 2 pattern (macrovesicular steatosis with portal inflammation and/or fibrosis, generally without evidence of cellular injury or lobular inflammation) is seen differently in children than in adults. The most important risk factors are obesity and insulin resistance, as well as gender, ethnicity, genetic predisposition and some medical problems. Progression to cirrhosis in children is rare but possible. NAFLD does not have a proven treatment. Losing weight and increasing physical activity provide improvement in histological and biochemical findings in fatty liver. Drugs are used in specific situations. More research is needed for drug therapy.

INTRODUCTION

Fat is stored as triglyceride (TG) in human liver. Steatosis is defined as fat accumulation in hepatocytes and is seen in many liver diseases[1-3].

Nonalcoholic fatty liver disease (NAFLD) defines the spectrum of histological changes in liver in which macrovesicular steatosis is outstanding[3]. NAFLD includes simple hepatic steatosis due to obesity and/or insulin resistance, nonalcoholic steatohepatitis (NASH) and cirrhosis. Hepatosteatosis usually limits itself but it may advance to NASH. NASH differs from simple steatosis by hepatocyte damage, inflammatory infiltrate and collagen deposition[4-6].

In many ways, the NASH pattern and characteristics differ between children and adults[7]. In adults, common features are the combination of macrovesicular steatosis with ballooning degeneration and lobular inflammation

with or without pericellular fibrosis localized primarily in acinar zone 3 (type 1). Pediatric NASH is characterized by macrovesicular steatosis with portal inflammation and/or fibrosis, generally without evidence of cellular injury or lobular inflammation (Type 2). Type 1 and type 2 NASH are distinct subtypes of pediatric NAFLD associated with different clinical demographic and possible pathophysiological features. In children with NAFLD aged 2-18 years, 51% is type 2 and 17% is type 1. In most of the children with extensive fibrosis, type 2 pattern is demonstrated[8]. These children are younger and more obese compared to children displaying type 1 pattern. Type 2 NASH is more common in boys than girls. Asian, Native American race and those of Hispanic ethnicity predominantly demonstrate type 2. Among children with type 2 NASH, it is not known whether the pattern evolves into a more characteristically adult type 1 pattern as the children grow older[9].

There has been an increase in NAFLD frequency in the last 30 years[1,8-11]. Nowadays, NAFLD is the most common form of liver disease in children[7]. A chronic obesity associated condition, NAFLD can lead to cirrhosis and liver failure over time[8]. It is also an independent risk factor for cardiovascular disease and liver cancer[9]. Studies have demonstrated differences in NAFLD prevalence rates across race/ethnicity, gender and weight status[12-14].

EPIDEMIOLOGY

In developed countries, hepatosteatosis is seen in 20%-30% of an unselected population[15]. The prevalence of NAFLD in Hong Kong Chinese is 27.3%. Around 4% of patients with fatty liver in the community had advanced fibrosis, as estimated by transient elastography[16].

The frequency of NASH is considered to be 2%-3%. It is reported that 10%-29% of NASH cases develop cirrhosis in 10 years[17]. Cirrhosis may progress to liver cancer. Hepatocellular carcinoma may occur in 4%-27% of the individuals with NASH-induced cirrhosis[18-20].

Since childhood obesity became epidemic in developed countries, NAFLD became the most common cause of chronic liver disease in pediatrics[7].

In fact, the true NAFLD prevalence in children is unknown. A population based autopsy study reported that 13% of children and adolescents are affected with NAFLD, 23% of the subjects with NAFLD had evidence for steatohepatitis, whereas bridging fibrosis or cirrhosis was observed in 9% of the children with NASH. Overweight and obese children accounted for 81% of all of the cases of NAFLD. A male-to-female ratio was 2: 1[7,20-23].

It is suggested that NAFLD prevalence increases with age, with a mean age at diagnosis between 11 and 13 years[24]. This tendency is explained by adolescent hormonal changes which result in an increase in serum insulin levels and fat accumulation in the liver[25,26].

Obesity and insulin resistance are the most common

risk factors for NAFLD. However, differing amounts of fat accumulation in individuals with similar adipose tissue suggests that other factors are also responsible. Gender, ethnicity and genetic predisposition are emphasized[27-35].

The prognosis of children with NAFLD is still unknown. Patients with simple steatosis may still develop NASH and fibrosis progression. It is reported that weight reduction is associated with non-progressive disease in adult patients[28]. It is suggested that long term survival of NAFLD pediatric patients is shorter than non-affected patients[29].

PATHOGENESIS

Triglycerides are preferred as storage nutrients in cells to regulate the changes between intake and usage. Triglycerides supply high calories. Additionally, because they are not dissolved in water, they might be stored intracellularly in high amounts without causing any colloidal or osmotic problems. Triglycerides are basic material stocks of adipocytes and are not accumulated in other cells, except in unusual situations. Steatosis in liver is not an adaptive process; indeed it may cause severe chronic problems[1].

Fat droplets should be seen in at least 5% of hepatocytes in order to be named as steatosis. Another definition is TG deposition in the liver above 95th percentile or more than 55 mg per gram of liver tissue in a healthy lean person[2].

Hepatosteatosis might be seen in two different types; macrovesicular and microvesicular. In macrovesicular steatosis, one or a few lipid droplets are present, filling the total hepatocyte. These lipid droplets propel the nucleus to the edge. In microvesicular type, multiple small lipid droplets are seen, giving a foamy appearance[3].

Microvesicular steatosis might be seen in Reye syndrome, salicylate, sodium valproate or ethanol intake, fulminant hepatitis D, mitochondrial fatty acid beta oxidation defects and urea cycle disorders. In these disorders, liver function tests are usually affected and the patient is comatose. If the patient survives, permanent damage will not occur in the liver. Macrovesicular type occurs in alcoholic liver disease, obesity, diabetes, kwashiorkor, AIDS, total parenteral nutrition therapy, phosphorus intoxication and steroid treatment[3].

High concentration of serum saturated free fatty acids is important in the pathogenesis of steatosis. This high concentration of saturated free fatty acids creates hepatotoxic impulse. Besides, esterification of these free fatty acids into TGs is a process of detoxification. The balance between TG deposition and removal is disrupted. There are three sources of fatty acids causing TG deposition in liver: from diet, 15%; *de-novo* synthesis (carbohydrates from diet), 26%; and adipose tissue circulating, 59%[1,5].

Twenty percent of the fat present in the systemic circulation (100 g/d) is taken by the liver. Daily intake of

TGs from diet (approximately 20g/d) and free fatty acids from adipose tissue (approximately 20 g/d) enter the liver as TG[1,36]. There has been an increase in NAFLD frequency in the last 30 years. It is considered that this is due to changes in the amount and content of food. Changes in food composition cause steatosis in liver. Generally, carbohydrates and fructose play the most important role in this issue. Fructose influences the dietary carbons to move to liver and participate in lipogenesis. Despite glucose, fructose is almost totally taken from the systemic circulation. Fructose is phosphorylated at C1 instead of C6 and because of this it cannot be used in glycogen synthesis. Instead, fructose is changed to glyceraldehyde-3-phosphate, which provides substrate for *de-novo* lipogenesis. Yearly fructose intake of the population is increasing day by day and consequently NAFLD incidence is rising[1,37]. As the adipose tissue increases in obesity, death receptors in adipose tissue and apoptosis pathway are activated. Increase in adipocyte death causes more macrophage migration. Insulin resistance and hepatosteatosis occur as a result. Approaches blocking apoptosis of adipose cells are considered to improve complications related to obesity, including NAFLD. Lipoapoptosis is related to AST/ALT > 1 and liver fibrosis[38-40].

Insulin stimulates fatty acid production while preventing glucose production in the liver. As insulin resistance develops in the liver, the effect of insulin on preventing glucose production diminishes. However, the effect of insulin on stimulating fat synthesis in the liver is preserved. When the insulin level decreases with therapy, steatosis in the liver also decreases. Additionally, high insulin levels increase hepatotoxicity by preventing FFA oxidation[41].

It is suggested that NAFLD pathogenesis is multifactorial with many factors affecting disease development and progression. The "multiple-hit" hypothesis is currently the established pathogenetic model[42]. At the onset, NAFLD is characterized by fat accumulation in the liver and insulin resistance, influenced by genetic susceptibility, epigenetic mechanisms, a sedentary lifestyle and hypercaloric diets[43]. Hepatic fat accumulation leads to exacerbating insulin resistance by interfering with phosphorylation of insulin receptor substrates[44]. Free fatty acid accumulation and insulin resistance predispose the fatty liver, including oxidative stress, inflammatory cytokines, stellate cells activation and mitochondrial disturbance, which lead to inflammation, necrosis and fibrosis[45]. A changing of gut microbiota and excess gut permeability increase liver exposure to gut-derived bacterial products in NAFLD. These products stimulate innate immune receptors and trigger liver inflammation and fibrogenesis[46].

Hepatic progenitor cell activation is correlated with fibrosis and NASH progression[47]. Adiponectin, leptin, resistin and tumor necrosis factor-alpha are also thought to be involved in the progression of steatosis to NASH. Adipocytes or inflammatory cells infiltrating the adipose tissue in insulin resistance are responsible for adipocytokine secretion. Leptin may activate hepatic stellate cells. The expansion of adipose tissue, especially visceral fat, is associated with a decrease in the release of insulin-sensitizing and anti-inflammatory cytokines and an increase in the release of pro-inflammatory molecules[48]. Tumor necrosis factor-α and interleukine-6 levels are elevated in the liver and blood of NASH patients. These cytokines are involved in Kupffer and hepatic stellate cell activation in myofibroblasts[49]. NAFLD results from the relationship between multiple organs, including adipose tissue, liver, gut and the pancreas[50,51].

CLINICAL FINDINGS

Most of the cases are asymptomatic but nonspecific symptoms like abdominal pain may be present[30]. The most common admission reason is slightly elevated transaminases or coincidentally noticed hepatomegaly. Multiple diseases like Wilson's disease, drug-induced liver injury and autoimmune hepatitis should be excluded before a diagnosis of NAFLD[30,31].

Obesity is distinctive[7-15,31]. In adults, 10%-75% of fatty liver occurs with insulin resistant type 2 diabetes. Fatty liver is defined in poorly regulated type 1 diabetes (Mauriac syndrome) in children. Children with typical NAFLD have insulin resistance with hyperinsulinemia but they are euglycemic. Type 2 diabetes mellitus is present in 5.5% of NASH cases[15,32]. Acanthosis nigricans, defined as hyperplasia of pigmented skin cells, is an important physical examination seen with insulin resistance. This can be found in more than 50% of children with NASH. Family story is important in NAFLD because familial clustering is common[33-35].

Obesity is reported, especially after ALL chemotherapy, hypothalamic dysfunction or hypothalamic surgery. Even NAFLD progressing to cirrhosis is defined in these children. NAFLD is also seen in Prader-Willi syndrome. Besides these, fatty liver may be seen concurrently with some inborn errors of metabolism and genetic diseases. Insulin resistance, obesity, type 2 DM and NAFLD progressing to cirrhosis may be seen in Alström syndrome. Liver fibrosis is reported in Turner's syndrome. Also, in lipodystrophy, cases are present with cirrhosis with liver transplantation[35,52].

LABORATORY FINDINGS

In NAFLD, serum aminotransferases are moderately high with ALT being higher than AST. Increase in AST and reversing of the AST/ALT ratio in NAFLD predicts a bad prognosis. Raised ALT and GGT levels, especially if they are within normal ranges, are found to be related to hepatic steatosis evaluated by USG or magnetic resonance imaging. Therefore, changing the normal ranges is being discussed. Serum GGT > 96.5 U/L is a marker of advanced fibrosis. Serum bilirubin levels are normal or near normal. Biochemical findings of cholestasis are

not present[32-57]. Serum IgG and nonspecific tissue auto-antibodies imply autoimmunity. Mostly, the anti-smooth muscle antibody is positive at low titer[52-54].

The other markers synthesized in liver, like sex hormone binding globulin, ferritin and plasminogen activating inhibitor-1, may be used in the diagnosis of NAFLD[54]. Homocysteine levels may increase in steatohepatitis. High hyaluronic acid levels are the most powerful independent marker of severe fibrosis and distinguishes steatosis and NASH[15,55-57]. Laminin and ELF (enhanced liver fibrosis) scores may also be used. Low adiponectin with low adipokines are important in NASH diagnosis. A combination of serum adiponectin, homoeostasis model assessment of insulin resistance (HOMA-IR) and type IV collagen 7S, at cut-off limits of $\leq$ 4.0 μg/mL, $\geq$ 3.0 and $\geq$ 5.0 ng/mL respectively, was shown to have a sensitivity of 94% and specificity of 74% for identifying early NASH[58]. Cut-off values of HOMA-IR for insulin resistance are higher than in adults. When an obese patient loses weight, normal ALT decreases more and a decrease in HOMA-IR also occurs with insulin resistance.

Hypoadiponectinemia and high tumor necrosis factor-alpha levels were found to be related to NAFLD[59-71]. However, adiponectin and tumor necrosis factor-alpha gene polymorphism were not shown to be associated with NAFLD or significant fibrosis in Chinese people[72].

Urea, electrolytes, thyroid function tests, glucose, HbA1c and serum lipids should be controlled. The most common lipid disorder is hypertriglyceridemia. Autoantibodies, immunoglobulins, viral markers for hepatitis B, hepatitis C, cytomegalovirus and Ebstein-Barr virus are important in excluding chronic liver diseases. Chronic hepatitis C, Wilson's disease, cystic fibrosis and drug intoxication (*e.g.*, methotrexate) should especially be excluded[72].

Steatosis may be diagnosed by ultrasound, computed tomography or MRI scanning. Ultrasound, the cheapest option, has been reported to have a sensitivity of 89% and specificity of 93% for the identification of fatty liver[73]. Abdominal USG does not reflect changes in liver histology and it is not useful in distinguishing steatosis and NASH. Microvesicular steatosis is due to hereditary inborn errors of metabolism, urea cycle disorders and valproic acid toxicity, and it is more severe. USG with a good history taking and metabolic tests may be sufficient in diagnosis of microvesicular steatosis[15]. ALT and AST levels are not always in parallel with the histological state and therefore, in children with risk factors, USG should be performed even if ALT and AST are normal[74,75].

New non-invasive tests such as proton-magnetic resonance spectroscopy and transient elastography allow relatively accurate estimation of hepatic steatosis and fibrosis in the community[74-81].

Liver biopsy may be essential in the diagnosis of NAFLD and distinguishing NASH from other disorders. In obese patients, biopsy may be needed to differentiate NAFLD from hepatitis. Optimal timing for this is not certain. Some physicians delay biopsy for 3-6 mo, make the patient lose weight and perform biopsy if ALT is still high. In younger children and cases with acanthosis nigricans, biopsy may be performed but there is insufficient data for this[30,82].

TREATMENT

In childhood, fatty liver does not have a proven treatment[83]. In a meta-analysis evaluating studies on adults, losing weight is reported to improve histological activity in NASH but > 50% of the patients could not reach the estimated weight[84,85]. In the literature, results of the studies about antioxidants in NASH therapy are conflicting and heterogeneous. In studies with pentoxifylline, telmisartan, L-carnitine and polyunsaturated fatty acids, it is stated that these agents may improve different parameters (radiology, biochemistry, histology) of NASH[86-88]. Vitamin E or metformin is not efficient in fatty liver in children[89].

As apoptosis is the key pathogenic mechanism in NAFLD, antiapoptotic agents are considered to be efficient in treatment. Studies are proceeding on chemical chaperones (glycerol, 4-phenyl butyric acid, TUDCA), PUFA (decreases ER stress and cell death in liver caused by saturated FFA), protease inhibitors (pan-caspase inhibitor Z-VAD-fmk, VX-166) and kinase inhibitors[11,90-94].

Drugs increasing insulin sensitivity are also studied in NASH. Indeed, the best management of insulin resistance is losing weight but drugs are also used. In pediatric NASH, 1000 mg/d metformin decreased ALT, in 40% ALT became normal, and in 90% steatosis in liver detected by MR spectroscopy decreased 23%. Metformin is effective on SREBP-1c and it is used in adulthood NASH. If evidence of childhood obesity and insulin resistance is present, it is useful and advised to be used. It is used in childhood type 2 diabetes, PCOS and Prader-Willi syndrome[92]. Thiazolidinedione is reported to improve steatosis and inflammation but causes severe weight gain[85].

Exercise, diet and bariatric surgery improve liver histology. Standard obesity surgery is not studied in children and the effect on NAFLD is not known. None of the drug therapies in children is efficient in NAFLD[9,66,71,95,96].

Multi-disciplinary management is needed in obesity treatment. Decrease in weight normalizes transaminases and liver histology. The most acceptable strategy is lowering weight gain and regular medium level exercise. For losing weight, diets with a low glycemic index and realistic portions are helpful. Special diets bringing hyperinsulinism to a minimal level instead of standard low calorie diets are more effective in childhood obesity. Diets with low postglycemic index may be carried out longer than calorie restriction[96-98]. In the management of obesity, family based behavior therapies increase success. The other valuable factor is exercise because it decreases hyperinsulinemia[99-101].

CONCLUSION

Fatty liver is a growing health problem worldwide. It might evolve to nonalcoholic steatohepatitis, cirrhosis and cause hepatocellular carcinoma. There are two distinct subtypes of pediatric NAFLD associated with different clinical, demographic and possible pathophysiological features. In children with NAFLD aged 2-18 years, 51% is type 2 and 17% is type 1. The most important risk factors for NAFLD are obesity and insulin resistance. In general, NAFLD has no specific symptoms or signs but should be considered in obese children. The most common admission reason is slightly elevated transaminases or coincidentally noticed hepatomegaly. In NAFLD, serum aminotransferases are moderately high, ALT being higher than AST. Increase in AST and reversing of the AST/ALT ratio in NAFLD predicts a bad prognosis. Progression to cirrhosis in children is rare but possible. The treatment of this disease is not certain. It is demonstrated that decrease in weight normalizes transaminases and liver histology. Therefore, weight loss with regular medium level exercise and an applicable diet with low glycemic index and appropriate calorie intake are preferred. Drugs are promising but not sufficient in children for today.

In conclusion, since childhood obesity became epidemic in developed countries, NAFLD has become the most common cause of chronic liver disease in pediatrics. Therefore, it should be taken into consideration in obese children. After excluding other diseases, multidisciplinary management should be started for weight loss.

Abstract

Understanding the mutual relationship between the liver and the heart is important for both hepatologists and cardiologists. Hepato-cardiac diseases can be classified into heart diseases affecting the liver, liver diseases affecting the heart, and conditions affecting the heart and the liver at the same time. Differential diagnoses of liver injury are extremely important in a cardiologist's clinical practice calling for collaboration between cardiologists and hepatologists due to the many other diseases that can affect the liver and mimic haemodynamic injury. Acute and chronic heart failure may lead to acute ischemic hepatitis or chronic congestive hepatopathy. Treatment in these cases should be directed to the primary heart disease. In patients with advanced liver disease, cirrhotic cardiomyopathy may develop including hemodynamic changes, diastolic and systolic dysfunctions, reduced cardiac performance and electrophysiological abnormalities. Cardiac evaluation is important for patients with liver diseases especially before and after liver transplantation. Liver transplantation may lead to the improvement of all cardiac changes and the reversal of cirrhotic cardiomyopathy. There are systemic diseases that may affect both the liver and the heart concomitantly including congenital, metabolic and inflammatory diseases as well as alcoholism. This

review highlights these hepatocardiac diseases

Core tip: Acute and chronic heart failure may lead to acute ischemic hepatitis or chronic congestive hepatopathy. Treatment in these cases should be directed to the primary heart disease. In patients with advanced liver disease, cirrhotic cardiomyopathy may develop including hemodynamic changes, diastolic and systolic dysfunctions, reduced cardiac performance and electrophysiological abnormalities. Cardiac evaluation is important for patients with liver diseases especially before and after liver transplantation. Liver transplantation may lead to improvement of all cardiac changes and reversal of cirrhotic cardiomyopathy. There are systemic diseases that may affect both liver and heart concomitantly including congenital, metabolic, inflammatory diseases and alcoholism.

Fouad YM, Yehia R. Hepato-cardiac disorders. World J Hepatol 2014; 6(1): 41-54 Available from: URL: http://www.wjgnet.com/1948-5182/full/v6/i1/41.htm DOI: http://dx.doi.org/10.4254/wjh.v6.i1.41

INTRODUCTION

The heart and liver are organs that are closely related both in health and disease. According to traditional medicine, each body has its organ own specific temperament composed of four qualities (elements): "warmth", "coldness", "wetness" and "dryness". "Wetness" and "dryness" are considered on a spectrum of "tissue moistures" and "warmth" and "coldness" may be regarded as the basic metabolism of the organ. In his famous book ,"Canon" (The Law), Avicenna pointed to some of the interactive

effects occurring in the heart and the liver. Some of the most important include: (1) dominance of the "heart warmth" over "liver coldness" and (2) the dominance of "liver dryness" over "heart wetness". The impact and position of "heart temperament" as well as its effect on "liver intemperaments" may be definitive in diagnosis and assessment of the general prognosis of liver disease and in the treatment process[1,2].

Chronic liver diseases may affect cardiac functions in the absence of other heart disease. These effects are called cirrhotic cardiomyopathy and may aggravate the course during orthotropic liver transplantation (OLT). Most of these effects are reversed after OLT[3,4]. In case of ischemic hepatitis, patients with severe heart failure usually remain asymptomatic, while for patients with congestive hepatopathy, signs of right-sided heart failure could mask hepatic injury. However, changes in hepatic function, that are proven by laboratory tests are significant in predicting the survival of patients with severe heart failure. Therefore, the evaluation of cardiac and hepatic function is very important in patients with severe heart failure and hepatic injury. Their treatment options should be revised in order to ensure stable hemodynamics, as well as optimal liver function, and so in this way their survival and prognosis could be improved[5]. This review highlight the liver diseases affecting the heart, heart diseases affecting the liver and some systemic diseases affecting both heart and liver.

LIVER DISEASES AFFECTING THE HEART

Chronic hepatitis C virus

In hepatitis C virus (HCV) heart disease, most patients develop chronic inflammation of the myocardium and, later, dilated cardiomyopathy attributable to necrosis and loss of myocytes. However, because myocytes do not replicate, the proliferative stimuli induced by HCV infection may promote myocyte hypertrophy and hypertrophic cardiomyopathy[6]. A role of direct effect of HCV core proteins was suggested in the pathogenesis of cardiomyopathy[7]. Cardiac damage is a rare manifestation of HCV-related mixed cryoglobulinemia vasculitis. Despite favourable early outcomes, patients with cardiac damage had poorer survival than those without[8]. Chronic hepatitis C viral infection is independently associated with presence of metabolic conditions (insulin resistance, type 2 diabetes mellitus and hypertension) and congestive heart failure[9].

The connection between hyperlipidemia and atherosclerosis is not linear in people with hepatitis C. In a population-based study, although chronic HCV infection was associated with severe insulin resistance, the patients only had mild atherosclerosis, suggesting a unique characteristic of HCV-related metabolic abnormality. Chronic HCV-associated steatosis was suggested as a leading cause of coronary artery diseases through the modulation of atherogenic factors, such as inflammation and dysmetabolic milieu. Interestingly, interferon-based therapies

in patients with chronic HCV were found to reduce the long-term risk of stroke. Thus, atherosclerosis in patients with hepatitis C is likely due to an inflammatory process rather than to a lipid related source[10-12]. Thus, even patients having healthy cholesterol and triglyceride levels in the presence of chronic hepatitis C infections should not engage in activities that could further increase the disease risk of their cardiovascular vessels.

Liver cirrhosis

Patients with liver cirrhosis (LC) frequently experience autonomic cardiovascular dysfunction, such as increased activity of the sympathetic nervous system and reduced vagal cardiac function, which has important implications for liver dysfunction and poor survival[13-15]. Baroreflex has been shown to be an important determinant of electrical stability in the heart and can predict increased mortality and end-organ damage[16-19]. Patients with liver cirrhosis have an enhanced activity of the sympathetic nervous system and hyperdynamic circulation showing increased cardiac output and reduced systemic vascular resistance. These changes may induce myocardial remodelling and LV hypertrophy (LVH), resulting in systolic and diastolic functional abnormalities and cardiomyopathy[20-22]. Cirrhotic cardiomyopathy was defined by a working group as a cardiac dysfunction in patients with cirrhosis characterized by impaired contractile responsiveness to stress and or altered diastolic relaxation with electrophysiological abnormalities in the absence of known cardiac disease[23]. The criteria for the diagnosis of cirrhotic cardiomyopathy are shown in Table 1[24].

Systolic dysfunction is related to the inability of the heart to meet its demands with respect to the generation of an adequate arterial blood pressure and cardiac output. This dysfunction can be unveiled by physical exercise that increases left ventricular pressure, volume, and left ventricular ejection fraction and heart rate in some cirrhotic patients. Similarly, the administration of vasoconstrictors, such as angiotensin II and terlipressin, increases the SVR and thereby the left ventricular afterload unmasking a latent left ventricular dysfunction in cirrhosis. In contrast, vasodilators, such as angiotensin-converting enzyme inhibitors and other afterload-reducing agents, should be used with caution due to the risk of further aggravation of the vasodilatory state[24]. Systolic dysfunction may have an impact on the development of complications, such as sodium and water-retention and ascites formation, as well as development and prognosis of renal dysfunction[25,26].

Diastolic dysfunction in cirrhosis is due to an increased stiffness of the myocardial wall owing to myocardial hypertrophy, fibrosis, and subendothelial edema. The prevalence of diastolic dysfunction has been reported to range from 45% to 56%. Diastolic dysfunction is most prominent in patients with severe decompensation, in whom, the combination of myocardial hypertrophy, contractile dysfunction, changes in heart volumes, and diastolic dysfunction may represent an essential element

Table 1 Proposal for diagnostic and supportive criteria for cirrhotic cardiomyopathy agreed upon at a working party held at the 2005 World Congress of Gastroenterology

A working definition of cirrhotic cardiomyopathy
A cardiac dysfunction in patients with cirrhosis characterised by impaired contractile responsiveness to stress and/or altered diastolic relaxation with electrophysiological abnormalities in the absence of other known cardiac disease
Diagnostic criteria
Systolic dysfunction
Blunted increase in cardiac output with exercise, volume challenge or pharmacological stimuli
Resting EF < 55%
Diastolic dysfunction
E/A ratio < 1.0 (age-corrected)
Prolonged deceleration time (> 200 ms)
Prolonged isovolumetric relaxation time (> 80 ms)
Supportive criteria
Electrophysiological abnormalities
Abnormal chronotropic response
Electromechanical uncoupling/dyssynchrony
Prolonged QTc interval
Enlarged left atrium
Increased myocardial mass
Increased BNP and pro-BNP
Increased troponin I

BNP: Brain natriuretic peptide; E/A: Early diastolic/atrial filling ratio; EF: Left-ventricular ejection fraction.

in cirrhotic cardiomyopathy[26-28]. The diastolic dysfunction may adversely affect the prognosis of patients with cirrhosis, by favouring the occurrence of complications and impairing the outcomes of manoeuvres that lead to rapid increases in preload, such as transjugular intrahepatic porto-systemic shunt (TIPS) insertion[24].

Patients with advanced cirrhosis usually exhibit tachycardia. The inability to increase the heart rate further contributes to an impaired ability to keep the cardiac output at a level adequate to meeting the needs of systemic circulation. At this point, the effective volemia suddenly worsens, similar to the events of post-paracentesis circulatory dysfunction and hepatorenal syndrome[29-31]. The prolongation of the electrocardiographic QT interval is common in cirrhosis, with a prevalence that exceeds 60% in patients with an advanced disease. In this case, drugs affecting QT should be avoided or used with caution and under close ECG monitoring[32]. Systemic and cardiac changes in patients with liver cirrhosis are shown in Figure 1.

Almost all cardiovascular abnormalities reverse a few months after liver transplantation[4,24,33].

Nonalcoholic fatty liver disease

It has been shown that the leading cause of death in patients with nonalcoholic fatty liver disease (NAFLD) is coronary events. In patients with diabetes mellitus, NAFLD is associated with cardiovascular disease (CVD) independent of the classical risk factors, glycaemic control, medications, and metabolic syndrome features. When diabetic patients with and without NAFLD were compared, those with NAFLD had a higher prevalence of coronary vascular disease, hypertension, central obesity, poor glycaemic control, and dyslipidaemia and greater carotid intimal thickness. Furthermore, with the development of steatohepatitis, the degree and severity of CVD became directly proportional to the severity of inflam-

mation on liver biopsy. Cardiovascular mortality is also increased at least two-fold in non-alcoholic steatohepatitis (NASH). The presence of liver fat is associated with lower adiponectin levels and increased levels of fibrinogen, C-reactive protein (CRP), and plasminogen activator inhibitor 1 (PAI-1), which are markers of inflammation and risk factors of coronary vascular disease independent of BMI and intra-abdominal obesity. Patients with NAFLD also have significantly higher mean values of intima-media thickness and prevalence of plaques resulting in an increased risk of atherosclerosis in subjects with metabolic syndrome. It has also been shown that NASH predicts plasma inflammatory biomarkers independent of visceral adiposity and other potential confounders. These findings suggest that NASH is not simply a marker of CVD but may also be involved in its pathogenesis. Steatosis has been found to be the strongest independent risk predictor of vascular damage, followed by age and blood pressure. Patients with NAFLD and systolic BP ≥ 130 mmHg are 4.7 times more likely to have a positive treadmill test[34-36].

In a recent study, asymptomatic obese children with NAFLD exhibited features of early LV diastolic and systolic dysfunction. These abnormalities were more severe in those with NASH[37].

Primary biliary cirrhosis

Circulating cholesterol levels are elevated in most with primary biliary cirrhosis. Hypercholesterolemia in patients with primary biliary cirrhosis should be considered a cardiovascular risk factor only when other factors are present. Ursodeoxycholic acid, the standard treatment for primary biliary cirrhosis, improves cholestasis, thereby lowering the circulating levels of cholesterol. Thus, hypercholesterolemia in the absence of other cardiovascular risk factors does not require specific therapeutic interventions in patients with primary biliary cirrhosis.

Figure 1 **Proposal of changes in cardiac output during the course of the liver disease.** DT: Deceleration time; LAV: Left atrial volume; LVEDV: Left end-diastolic volume; LVEF: Left ventricular ejection time.

Epidemiological studies have shown significantly increased all-cause mortality rates in comprehensive PBC patient groups, with a significant component of this increased mortality coming from non-liver-related causes[38,39]. These studies were not designed to address the cause of this increase in non-liver-related mortality. There is, however, convincing evidence from the same populations to suggest that malignant disease makes little or no contribution to this excess non liver mortality[38,40]. Given the importance of cardiovascular mortality in the general population, the possibility must be considered that cardiac mechanisms contribute to the excess non liver mortality rates seen in these populations. Autonomic dysfunction has been seen in PBC and was associated with an increased cardiac mortality risk in non-liver chronic disease states[41,42]. Furthermore, a significant peripheral muscle bioenergetics abnormality has also been reported in PBC[43]. Raising the possibility that similar bioenergetic abnormalities may also be present in the cardiac muscle. The effects of autonomic dysfunction may alter the perfusion patterns in tissues, potentially reducing muscle perfusion and contributing to peripheral mechanisms of fatigue. A generic tendency towards altered myocardial function was shown in PBC and did not typically appear to be symptomatic in terms of "classical" myocardial dysfunction symptoms[44].

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic inflammatory disease of affecting the large bile ducts and is characterized by periductal fibrosis and stricture formation. Arteriosclerosis involves the accumulation of altered lipids and lipoproteins in large arteries; this drives inflammation and fibrosis and ultimately leads to the narrowing of the arteries and hypoperfusion of dependent organs and tissues. Knowledge of the causative factors is crucial to the understanding of disease mechanisms and the development of specific treatment. Based on the pathogenic similarities and common molecular, cellular, and morphological features that provide the conceptual framework for a deeper understanding of their pathogenesis between PSC and arteriosclerosis, it has been hypothesized that PSC represents "arteriosclerosis of the bile duct" initiated by toxic biliary lipids[45]. This hypothesis should stimulate translational research to facilitate the search for novel treatment strategies for both diseases.

Hepatocellular carcinoma

Cardiac complications of hepatocellular carcinoma hepatocellular carcinoma are rare. Cases of right atrial invasion of HCC had been reported[46], which led in some

cases to right ventricular outflow obstruction and Budd Chiari syndrome[47,48]. Hepatocellular carcinoma patients with cardiac metastases are usually found in advanced stages. These patients have limited survival from the diagnosis of cardiac metastases. The most common causes of death are related to HCC itself or to the underlying liver disease. Only a few patients will die due to cardiac metastases[49]. The palliative treatments for tumor thrombi may include transcatheter chemotherapy, transarterial chemoembolization and radiation therapy with a partial improvement of patient symptoms[50].

Budd-chiari syndrome

Primary Budd-chiari syndrome (BCS) is a rare clinical entity characterized by hepatic venous outflow obstruction at various levels from the small hepatic veins to the inferior vena cava. There are three main types of BCS: Type Ⅰ, occlusion of the IVC; type Ⅱ, occlusion of the hepatic veins; and type Ⅲ, occlusion of the IVC and the hepatic veins. The incidence of HCC combined with BCS varies among the types of BCS[50,51]. Type Ⅰ BCS is more prone to inducing HCC and the incidence ranges between 10.7% and 43.5%. The mechanisms of HCC induction unknown. The therapeutic treatments of BCS combined with HCC includes TACE, surgery and more recently angioplasty followed by percutaneous microwave ablation[52-55].

Portal hypertension

Three important complications are associated with portal hypertension hepatopulmonary syndrome, portopulmonary hypertension, and hepatic hydrothorax.

The hepatopulmonary syndrome: This entity is defined by an oxygenation defect caused by the development of intrapulmonary vascular dilation in patients with either advanced liver disease and/or portal hypertension[56]. Angiogenesis was shown to be induced by an increased level of nitric oxide and vascular endothelial growth factor in patients with advanced liver disease or portal hypertension[57,58]. Patients with the hepatopulmonary syndrome (HPS) may present with the insidious onset of dyspnea or remain completely asymptomatic during the early stages. Dyspnea upon standing (platypnea) and hypoxemia exacerbated in the upright position (orthodeoxia) are present in almost 25% of HPS patients[59]. Patients with severe HPS may display digital clubbing and cyanosis.

Chest radiographs may be normal or show bibasilar nodular or reticulonodular opacities, reflecting diffuse vascular pulmonary dilation[60,61]. Pulmonary function tests typically demonstrate a reduced diffusion capacity for carbon monoxide[61]. There is no established medical therapy currently available for HPS. In patients with $PaO_2 < 60$ mmHg at rest or with exertion, the administration of supplemental oxygen is appropriate, because chronic hypoxemia itself may contribute to the mortality in HPS[62,63]. The administration of garlic resulted in im-

provements in the PaO2, in two uncontrolled trials and a small randomized study[64].

Portopulmonary hypertension: Portopulmonary hypertension (POPH) is characterized by pulmonary arterial hypertension (PAH) that occurs in the setting of portal hypertension, with or without advanced liver disease[65]. The severity of POPH does not correlate with the degree of liver dysfunction or the severity of portal hypertension[66,67]. The pathophysiology of POPH is not fully understood. The histopathology of POPH is similar to that of idiopathic PAH, and is triggered by vascular injury as reflected by the development of plexiform arteriopathy, concentric intimal fibrosis, and proliferation and muscularization of the pulmonary arterioles[68]. Dyspnea on exertion is the most common initial symptom of POPH and fatigue, orthopnea, chest pain, peripheral edema, syncope, and dyspnea at rest may develop as the disease progresses[69,70]. Medical treatment includes the following: prostacyclin analogs (prostanoids), Endothelin receptor antagonist and Phosphodiesterase-5 inhibitors[71-73]. A single short-term study in patients with moderate to severe POPH, found that the use of β-blockers was associated with worsening exercise capacity[72].

Hepatic hydrothorax: This entity is characterized by a transudative pleural effusion in the absence of underlying cardiac or pulmonary disease. Its prevalence has been estimated to be 5%-10% in cirrhotics, based on retrospective observational data[73]. The most important mechanism leading to the passage of ascitic fluid from the peritoneal into the pleural cavity is the presence of diaphragmatic defects. These defects were corroborated by showing passage of 99mTc-human albumin from the abdominal into the pleural cavity, even in the absence of underlying ascites[74]. Symptoms include cough, dyspnea, chest discomfort, hypoxia, and in the most severe cases respiratory failure with or without ascites[74,75]. Spontaneous bacterial pleuritis (SBPL) results when hepatic hydrothorax (HH) becomes infected in the absence of pneumonia. Symptoms in SBPL vary from fever and pleuritic chest pain to subtle worsening of encephalopathy or renal function, necessitating a high index of suspicion. A PMN > 500 cells/mm^3 is diagnostic for SBPL in a pleural effusion, although SBPL with PMN between 250-500 cells/mm^3 is documented by positive pleural fluid culture[76]. Chest tube placement is contraindicated in SBPL, in the absence of empyema, due to the risk of protein loss, prolonged drainage, secondary infection and hepatorenal syndrome[77]. Treatment of HH includes the restriction of sodium intake with the administration of diuretics. This approach is effective in controlling HH, although fluid mobilization from the pleural cavity may be slower than from the peritoneal cavity and approximately 20% of patients develop refractory HH[77]. Percutaneous drainage, and chest tube placement can be used in some cases[77,78]. The standard of care treatment for refractory HH is TIPS placement with response rates

of 70% to 80%[79,80]. Video assisted thoracoscopy (VATS) with pleurodesis is a potential treatment alternative for patients with refractory HH, who are not eligible for or who have failed TIPS[81-83].

Liver transplantation

Patients with cirrhosis requiring liver transplantation (LT) usually demonstrate increased cardiac output. Low systemic vascular resistance and bradycardia are also commonly seen in cirrhosis and can be aggravated by beta-blocker use. These physiologic changes increase the risk of cardiovascularn complications, in addition to altered hemodynamic stresses that LT patients face in the immediate post-operative period. Post-transplant reperfusion may result in cardiac death due to a multitude of causes, including arrhythmia, acute heart failure (HF), and myocardial infarction[84].

The unusually high perioperative mortality in transplant patients with CAD warrants a systematic evaluation in every patient that thought to have a greater risk of atherosclerotic coronary disease. No single test has a predictive value of 100%. Therefore, diagnostic protocols must account for the variation in prevalence that occurs in subsets of transplant candidates and the limitation of each type of test[85]. In contrast to ischemic heart disease, most patients with advanced liver disease have myocardial defects that cause systolic and diastolic impairments not always evident at rest. There are also underlying electrophysiological defects that cause an uncoupling of the mechanical and electrical activity. Diagnosis of "cirrhotic cardiomyopathy" is difficult because the findings can be subtle as some patients develop frank heart failure when exposed to pharmacological or physiological stressors such as during liver transplantation[85].

Almost all cardiovascular abnormalities can be reversed 6 to 12 mo after liver transplantation. Namely, indices of both systolic and diastolic function, cardiac workload, and exercise capacity can be substantially improved or normalized. QT interval prolongation can also revert after OLT, even though this occurs in about half of cases suggesting that liver disease may not be the only pathogenic factor[4,24,33].

CARDIAC CAUSES OF HEPATIC DISORDERS

Heart failure

The cardiac causes of hepatic dysfunction include constrictive pericarditis, severe pulmonary arterial hypertension (PAH), mitral stenosis, tricuspid regurgitation (TR), corpulmonale, ischemic cardiomyopathy, and postoperative consequences of the Fontan procedure for pulmonary atresia and hypoplastic left heart syndrome. All of these causes can lead to passive congestion due to the elevated right ventricular (RV) pressure and right sided heart failure. The outcomes of heart failure have dramatically improved, due to the increased efficiency of medical treatment, as a result, cardiac cirrhosis prevalence is declining[24,86].

Pathophysiology: In chronic heart failure (backward failure), the increase in venous pressure caused by RV dysfunction leads to the atrophy of hepatocytes and causes perisinusoidal edema which can impair the diffusion of oxygen and nutrients to the hepatocytes[87,88]. This backward failure is also responsible for the enhanced hepatic lymph formation, leading to ascites when its production rate exceeds the draining capacity of the lymphatic system. Moreover, increased pressure within the hepatic sinusoid favours bile duct damage by disrupting endothelial cells and the interhepatocyctic tight junctions that separate the extravascular space from the bile canaliculus. Finally, stagnant flow favors thrombosis within sinusoids, hepatic venules, and portal tracts; thereby contributing to liver fibrosis[24,89,90].

On gross examination, the congestive liver is enlarged, with a purple or reddish hue and prominent hepatic veins. The cut surface shows a classic nutmeg appearance, reflecting an alternating pattern of haemorrhage and necrosis of zone 3 with normal or slightly steatotic areas in zones 1 and 2. Microscopically, the hallmark features of hepatic venous hypertension are the prominence of the central veins, central vein haemorrhage, and sinusoidal engorgement[87,91,92]. Untreated, longstanding congestion can lead to cardiac fibrosis and,ultimately cardiac cirrhosis[93]. Acute HF (forward failure): most commonly arises in the context of profound systemic hypotension from acute cardiopulmonary collapse after myocardial infarction, exacerbation of HF, or pulmonary embolism. In the absence of established hypotension, ischemic hepatitis has been shown in instances of severe hypoxemia, such as obstructive sleep apnea, respiratory failure, and in conditions of increased metabolic demand, such as those seen in toxic/septic shock[94-96]. Ischemic liver injury is characterized by centrolobular necrosis of zone 3 hepatocytes in the absence of histological evidence of inflammation characteristic of viral hepatitis[97-101].

Oxygen consumption can be easily increased when the hepatic blood flow is decreased. The mechanism by which the liver protects itself from damage in hypoxia is increasing oxygen extraction by the hepatocytes up to 95% as the blood passes through the liver. When inadequate end-organ perfusion and tissue hypoxia is persistent or when acute shock develops this protecting mechanism against hypoxic liver damage is overwhelmed. Hepatocellular injury ensues, accompanied by a sharp elevation of the serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), lactic dehydrogenase (LDH), prolongation of the prothrombin time, and occasionally functional renal impairment. These abnormalities reach their peak 1 to 3 d after the onset of cardiogenic ischemic hepatitis and return to normal within 5 to 10 d from onset of the disorder[102].

These forward and backward factors often coexist and potentiate each other. Additionally, the presence of hepatic steatosis due to diabetes, obesity, or other causes may increase liver susceptibility to the ischaemic reperfu-

sion injury[24,103].

Clinical presentations: As for the acute ischemic hepatitis, no specific symptoms but patients may present with symptoms of nausea, vomiting, anorexia, malaise, right-upper quadrant pain, jaundice, oliguria, and flapping tremors representing cerebral hypoperfusion rather than hepatic encephalopathy. Ischemic hepatitis is usually benign and self-limited. The clinical diagnosis of liver injury is almost always incidental when liver enzymes are found to be massively elevated 1 to 3 d after an episode of systemic hypotension. This condition may be associated with increased serum creatinine level from acute tubular necrosis[102].

Congestive hepatopathy: The term congestive hepatopathy replaced cardiac cirrhosis. Patients experience mild, dull right upper quadrant pain caused by the stretching of the liver capsule. Hepatomegaly with a firm, tender liver edge and peripheral edema are typically the most prominent findings in patients with chronic right-sided HF, but these may also occur rapidly in acute HF. Ascites may be present in up to 25% of these patients and splenomegaly is characteristically absent[86]. Jaundice is not commonly reported. In patients with considerable TR, a prominent systolic pulsation of the liver, attributable to an enlarged right atrial V wave, is often noted. A presystolic pulsation of the liver, attributable to an enlarged right atrial A wave, can occur in tricuspid stenosis, constrictive pericarditis, restrictive cardiomyopathy involving the RV, and pulmonary hypertension[5].

Laboratory data: As for the acute ischemic hepatitis, severe jaundice is common, with a bilirubin level as high as 15 to 20 mg/dL, elevation of AST to more than 10 times the upper reference range limit, a marked increase in serum LDH, an elevated ALP level, and prolongation of the prothrombin time. Increases in LDH tend to be massive and an ALT/LDH ratio of less than 1.5 helps distinguishing ischemic injury from other forms of acute hepatitis[104,105].

As for the congestive hepatopathy, the usual findings are moderate elevations of the biochemical parameters of liver function 2 to 3 times the upper normal reference level. These parameters include AST, ALT, LDH, gamma-glutamyl transpeptidase (GGT), and alkaline phosphatase (ALP). Hyperbilirubinemia, secondary to an increase in both the direct and indirect bilirubin, is also common. The total bilirubin level is rarely greater than 3 mg/dL. In patients with long-standing HR, albumin synthesis may be impaired, leading to hypoalbuminemia and intensifying the accumulation of fluid[102].

Treatment: Treatment of the cardiac problem is the key to improvement in hepatic dysfunction.

As for the AHF and ischemic hepatitis, correcting underlying circulatory or respiratory disturbances is the main treatment. It is recommended that doctors identify and remove any precipitating cause, such as medications with negative inotropic or hypotensive effects (certain antiarrhythmic drugs, calcium-channel blockers, and vasodilators), medications likely to cause impairment of renal function (high doses of angiotensin-converting enzyme (ACE) inhibitors, angiotensin Ⅱ receptor blockers), or medications likely to accumulate with evolving renal failure (like digoxin)[106]. Oxygen should be administered as early as possible in hypoxemic patients to achieve an arterial oxygen saturation > 95%. Administration of intravenous diuretics is recommended with caution in acute HF patients in the presence of symptoms secondary to congestion and volume overload. Inotropic agents should be considered in patients with low output states and low systolic blood pressure. When needed, inotropic agents should be administered as early as possible and withdrawn as soon as adequate organ perfusion is restored and/or the congestion is reduced. Vasopressors are only indicated in cases of cardiogenic shock when the combination of an inotropic agent and fluid challenge fails to restore systolic blood pressure > 90 mmHg, with inadequate organ perfusion, despite an improvement in cardiac output[5,106].

As for the chronic HF and congestive hepatopathy, the main lines of treatment are angiotensin-converting enzyme (ACE) inhibitors and beta blockers. The addition of a low-dose aldosterone antagonist should be considered in all patients with an LV systolic dysfunction. ACE Inhibitors increase cardiac output and decrease LV filling pressure due to their vasodilatory effect. Some ACE inhibitors are prodrugs, which require transformation by the liver into active metabolites. These drugs include enalapril, ramipril, fosinopril, trandolapril, quinapril, benazepril, and moexipril. With liver dysfunction, decreases in the prodrug transformation and inactivation of the active drug may occur[107]. For those patients who cannot tolerate ACE inhibitors due to cough, angiotensin receptor blockers (ARBs) are recommended instead. ARBs reduce morbidity and mortality in patients with systolic HF. Losartan is metabolized to the active metabolite *via* hepatic carboxylation. In patients with hepatic impairment, the bioavailability is doubled and the total plasma clearance is halved. Therefore, lower initial doses are recommended. Valsartan undergoes little metabolic conversion. Caution is recommended in patients with mild to moderate liver dysfunction but dosage adjustments are generally not needed. Similar to valsartan, irbesartan does not require biotransformation, thus dosage modification is not necessary[108-111].

The use of *b*-blockers is associated with a 30% reduction in total mortality in HF. Propranolol should be administered cautiously in patients with hepatic impairment. No dose adjustments are necessary for atenolol, nadolol, esmolol, sotalol, or acebutolol[112-116].

Diuretics: Loop diuretics, such as furosemide, bumetanide, and torsemide, are used for volume management in HF because of their superior natriuretic effects compared with other classes of diuretics. For unknown

Table 2 Comparison between acute and chronic hepatic complications of cardiac failure

	Chronic congestive hepatopathy	Acute ischemic hepatitis
Aetiology	Chronic heart failure	Acute heart failure
Pathophysiology	Perisinusoidal edema	Tissue hypoxia
	Increased lymph flow	Zone 3 necrosis
	Zone 3: alternating necrosis and hemorrhage	
	Sinusoidal thrombosis	
Manifestations	Right hypochondrial pain	Asymptomatic or nonspecific
	Edema, ascites, jaundice	(nausea, vomiting, jaundice, right hypochondrial pain)
Laboratory data		
Bilirubin	Mild increase	Marked elevation
ALT and AST	Normal mild elevation	Marked elevation
LDH	Normal or mild elevation	Marked elevation
Prothrombin time	Prolonged	Normal or prolonged
ALP	Normal or mild elevation	Increased
Albumin	Hypoalbuminemia	Normal
Traetment	ACE inhibitors	Oxygen therapy
	b-blockers	Avoid precipitating factors
	Diuretic	Inotropic agents with caution
	Amiodarone	Vasopressor with caution
	Statins with caution	Diuretics in hypervolemia
Prognosis	Slowly progressive course	Benign and usually self limited

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; LDH: Lactic dehydrogenase; ALP: Alkaline phosphatase; ACE: Angiotensin-converting enzyme.

reasons, the pharmacologic response in patients with liver dysfunction and HF is diminished, and there is a net decreased in sodium excretion when compared with healthy individuals taking the same dose. No adjustments are necessary if renal function is normal[115].

In patients with severe HF, amiodarone has proven to be effective for suppressing ventricular arrhythmias, reducing sudden death and cardiac mortality, and improving exercise tolerance and ejection fraction. This drug undergoes an extensive hepatic metabolism to active metabolite, but no dosage reduction is indicated in hepatic impairment[116].

Statins undergo extensive hepatic metabolism. In patients with active liver disease or persistent unexplained elevations in serum transaminases to above 3 times the upper limit of normal, the use of statins is contraindicated as they may worsen liver function[117].

For patients, who are refractory to medical therapy and who may be candidates for cardiac surgery, CH due to chronic HF can improve and reverse after temporary LV assistive device support or for selected patients or cardiac transplantation[118,119]. The differences between acute and chronic hepatic impairment are summarized in Table 2.

Ventricular assist devices

Ventricular assist devices (LVADs) lead to volume shifts from the intrathoracic area to the systemic circulation, thus improving liver blood flow, as assessed by indocyanine green clearance. Studies have shown improvement in the liver function in patients with mild abnormalities in pre-implant liver tests, and no deterioration in those with normal baseline values, up to 6 mo[118,120]. However, pre-existing or post-LVAD severe liver dysfunction strikingly influences patients' prognosis and endangers their sur-

vival[121]. Liver dysfunction can also occur or worsen after LVAD implantation. Pre-, peri-, and post-operative factors, such as large doses of vasopressors, prolonged cardiopulmonary bypass time, arterial hypotension, systemic inflammatory responses and, mainly, right ventricular failure predispose a patient to liver damage, often presenting with intrahepatic cholestasis[121]. The model for end-stage liver disease (MELD), a scoring system assessing the severity of chronic liver disease based on serum bilirubin, creatinine and INR for prothrombin time that is widely used to determine prognosis and prioritize the receipt of a liver transplant, is able to predict mortality and morbidity following LVAD. The severity and course of post-ventricular assist devices liver damage can be monitored by sequential assessment of MELD-XI, a modified MELD score excluding INR to overcome the problem posed by concomitant anticoagulation[24,122].

Heart transplantation

Chronic cardiac hepatopathy is common in patients evaluated for heart transplantation-x (HTx), and liver dysfunction predicts an adverse outcome following transplantation. At the same time, altered pre-HTx liver tests can significantly improve after surgery, suggesting that chronic cardiac hepatopathy is a potentially reversible disease. In a large cohort study over 10 years among patients who had received LTx, all cholestatic parameters, transaminases and LDH improved after the procedure. Interestingly, a complete reversal of cardiac cirrhosis 10 years after HTx has even been reported[123,124].

A careful assessment of liver function and detection of liver cirrhosis is required in all candidates for HTx. An ultrasound of the abdomen with an echo-Doppler study of portal and tributary veins should be performed. Endoscopy may be necessary to assess the presence of

Table 3 Diseases affecting both the liver and the heart concomitantly		
	Hepatic manifestations	**Cardiac manifestations**
Congenital		
Allagile syndrome	Cholestasis	Congenital heart defects
Situs Inversus totalis	Concerns with liver or heart transplantation	
Infections		
Sepsis	Acute liver failure	Acute heart failure
Hepatitis C	Hepatitis	Myocarditis, cardiomyopathy
Cytomegalovirus	Hepatiitis	Myopericarditis
HIV	Hepatitis, granuloma	Myocarditis , cardiomyopathy
Malaria	Hepatic necrosis	Cariac failure
Dengue fever	Hepatic necrosis	Myocarditis
Amebiasis	Hepatitis, hepatic abscess	Pericarditis, effusion
Metabolic		
Wilson disease	Cirrhosis, hepatitis	Left ventricular remodeling
Hemochromatosis	Cirrhosis, hepatitis	Cardiomyopathy
Systemic		
SLE	Steatosis, hepatomegaly	Endocarditis, pericarditis
Amyloidosis	Hepatomegaly, cholestasis	Cardiomyopathy
Sarcoidosis	Granuloma, cholestasis	Conduction defects, HF
Chronic alcoholism	Cirrhosis	Cariomyopathy
Autoimmune		
Grave's disease	Hepatitis, cholestasis	HF
Autoimmune hepatitis	Hepatitis, cirrhosis	Carditis

HF: Heart failure.

gastro-esophageal varices and congestive gastropathy in patients with portal hypertension. Liver biopsy may be needed in some cases. MELD or modified MELD scores should be calculated. Higher MELD scores predict higher postoperative complication rates, including reoperation for bleeding, bacterial infections, and in-hospital death[124].

Patients with chronic hepatitis C or chronic hepatitis B should be treated before HTx to avoid antiviral drug intake after HTx which may be associated with graft rejection[125]. Finally, patients with heart failure and irreversible cirrhosis could be offered combined heart and liver transplantation[126].

DISEASES AFFECTING BOTH THE HEART AND THE LIVER

There are many systemic diseases in addition to chronic alcoholism, that affect both the liver and the heart. This fact may have important implications, because the heart and the liver also interact particularly during surgical procedures, OLT, and TIPS insertion, thereby influencing the outcomes. The spectrum of these diseases include congenital , autoimmune, metabolic and infectious causes (shown in Table 3). We highlight some examples of these diseases.

Congenital causes
The famous example is Alagile syndrome (AS), which is a multisystemic disease that is autosomal dominant, with variable expression. The major clinical manifestations are as follows: chronic cholestasis, congenital heart disease, posterior embryotoxon in the eye, characteristic facial phenotype, and butterfly vertebrae. AS is caused by mutations in JAGGED1 (more than 90%) and in NOTCH2. Cholestasis, pruritus and xanthomas have been successfully treated with choleretic agents (ursodeoxycholic acid) and other medications (cholestyramine, rifampin, naltrexone). In certain cases, partial external biliary diversion has also proven successful. Liver transplantation is indicated in children with cirrhosis and liver failure[127].

Infections
Cytomegalovirus (CMV) infection in inmunocompetent hosts generally is asymptomatic; whoever, it rarely can lead to severe organ complications. A rare, but serious complication of cytomegalovirus infection is the presence of myopericarditis concomitant with hepatitis with a possible role of oral valganciclovir in these patients[128].

Metabolic causes
Wilson disease: Wilson disease is an inherited autosomal recessive disorder of the copper metabolism resulting in the pathological accumulation of copper in the liver, brain and other tissues. One of the reported manifestations is cardiac involvement. Cardiac involvement in Wilson disease patients is characterized by LV parietal thickening with an increased prevalence of concentric LV remodelling. Children with Wilson diseases were asymptomatic upon cardiological examination, but had significantly lower mitral E velocities, mitral E/A ratios as estimated by pulsed wave Doppler echocardiography[129,130].

Hemochromatosis: Hemochromatosis is an autosomal recessive disorder affecting the white population. In this disorder, the inappropriate absorption and deposi-

tion of dietary iron may result in the development of hepatic and non-hepatic end-organ injury, leading to liver cirrhosis, hepatocellular carcinoma, diabetes, arthritis, skin pigmentation and cardiac diseases[131]. Cardiac involvement in hemochromatosis affects mainly the myocardium: iron overload of the myocytes reduces left ventricular distensibility. Heart failure is the most frequent manifestation of cardiac involvement. Diagnosis of cardiac involvement depends essentially on Doppler echocardiography showing abnormal left ventricular filling and, later, ventricular dilatation with left ventricular systolic dysfunction. Magnetic resonance imaging can quantify intrahepatic and intramyocardial iron levels. The two principal means of treatment by iron depletion are phlebotomy in primary hemochromatosis and excretion of iron by chemical chelation in secondary hemochromatosis. Early diagnosis and iron depletion improve survival by reducing the organ iron overload, especially in the liver and myocardium. The recent guidelines issued by Anaes (national agency for health evaluation) make it possible to identify risk factors for complications early, to determine the disease stage, and to provide appropriate management as a function of disease severity. Combined liver transplantation and cardiac surgery may be needed in cases of hemochromatosis with end stage liver disease and heart failure[132].

Autoimmune diseases: The atypical clinical presentations of Graves' disease (GD) include anemia, vomiting, jaundice, and right heart failure. Hyperthyroidism may present with jaundice, and on the other hand, deep jaundice may develop with the onset of overt hyperthyroidism in previously compensated chronic liver disease patients. Jaundice may be caused by hepatitis or intrahepatic cholestasis. Pulmonary hypertension is reported to be associated with GD and to respond to its treatment. GD-related pulmonary hypertension may be so severe that it produce isolated right-sided heart failure, which is occasionally identified as the presenting manifestation of GD[133].

Chronic alcoholism: Patients with chronic alcoholism can be presented with both hepatic and cardiac complications. Actively drinking alcoholics with cirrhosis have significantly lower mean ejection fraction and shortening fraction, as well as a greater mean end-diastolic diameter and left ventricular mass than abstaining alcoholics with cirrhosis. Alcoholics admitted solely for cardiomyopathy have a higher prevalence of cirrhosis than unselected alcoholics without heart disease. Actively drinking alcoholics admitted only for cirrhosis show impaired cardiac performance, whereas abstaining alcoholics with liver disease tend to manifest normal cardiac function[134]. Patients with alcoholic cirrhosis should be screened for cardiomyopathy for at least three reasons: (1) asymptomatic systolic and diastolic dysfunctions can precede the overt manifestation of cardiomyopathy; (2) hyperdynamic circulatory syndrome may disguise the clinical expression of initial heart failure; and (3) prevention or treatment

of some complications of cirrhosis, such as hepatorenal syndrome, is based on plasma expansion with albumin and the administration of vasoconstrictors. This would lead to deleterious effects if latent heart failure goes unrecognized[135].

CONCLUSION

Chronic liver diseases may induce systolic and diastolic dysfunctions in addition to electrophysiological changes, and the prolongation of QT interval in conditions of cirrhotic cardiomyopathy; all of these may improve completely after liver transplantations. Recent studies have found cardiac changes in patients with NAFLD, hepatitis C and primary biliary cirrhosis. On the contrary, acute and chronic heart failure have been shown to lead to acute hepatic injury and chronic congestive hepatopathy with manifestations of liver failure and laboratory data specific to ischemic hepatitis or congestive hepatopathy. There are systemic diseases that affect both the heart and the liver, thus necessitating good cardiac and hepatic evaluation. Collaboration between hepatologists and cardiologists is needed in these categories of patients for better diagnosis, treatment and prognosis. Liver and cardiac transplantation may solve this problem in some patients with heart and liver failure.

Abstract

AIM: To investigate the diagnosis, pathogenesis, natural history, and management of nodular regenerative hyperplasia (NRH) in patients with human immunodeficiency virus (HIV).

METHODS: We performed a systematic review of the medical literature regarding NRH in patients with HIV. Inclusion criteria include reports with biopsy proven NRH. We studied the clinical features of NRH, in particular, related to its presenting manifestation and laboratory values. Combinations of the following keywords were implemented: "nodular regenerative hyperplasia", "human immunodeficiency virus", "noncirrhotic portal hypertension", "idiopathic portal hypertension", "cryptogenic liver disease", "highly active antiretroviral therapy" and "didanosine". The bibliographies of these studies were subsequently searched for any additional relevant publications.

RESULTS: The clinical presentation of patients with NRH varies from patients being completely asymptomatic to the development of portal hypertension – namely esophageal variceal bleeding and ascites. Liver associated enzymes are generally normal and synthetic function well preserved. There is a strong association between the occurrence of NRH and the use of antiviral therapies such as didanosine. The management of NRH revolves around treating the manifestations of portal hypertension. The prognosis of NRH is generally good since liver function is preserved. A high index of suspicion is required to make a identify NRH.

CONCLUSION: The appropriate management of HIV-infected persons with suspected NRH is yet to be outlined. However, NRH is a clinically subtle condition that is difficult to diagnose, and it is important to be able to manage it according to the best available evidence.

Key words: Human immunodeficiency virus; Nodular regenerative hyperplasia; Ascites; Systematic review; Liver complications

Core tip: Liver complications in patients with human immunodeficiency virus (HIV) is emerging as a public health concern. The appropriate management of HIV-infected persons with suspected nodular regenerative hyperplasia (NRH) is yet to be outlined. However, NRH is a clinically subtle condition that is difficult to diagnose, and it is important to be able to manage it according to the best available evidence. We believe the implications of our manuscript will have immediate clinical implications.

Sood A, Castrejón M, Saab S. Human immunodeficiency virus and nodular regenerative hyperplasia of liver: A systematic

INTRODUCTION

Nodular regenerative hyperplasia (NRH) is the diffuse transformation of the liver parenchyma into micronodules without intervening fibrosis[1]. NRH is associated with a number systemic diseases, including human immunodeficiency virus (HIV) infection, and over the past several years, it has become an increasingly recognized entity that causes noncirrhotic portal hypertension (NCPH)[2].

The pathogenesis of NRH is thought to be vascular in origin, initiated by endothelial damage and causing an uneven distribution of obliteration of the small portal venules throughout the liver parenchyma[3]. In addition to endothelial damage, recurrent micro-thrombosis of the portal vasculature is also thought to contribute to the obliterative phenomenon. These micronodules tend to form in areas of preserved blood flow and are thought to represent a compensatory hypertrophic response to the neighboring acini with impaired blood flow[2,4]. The diagnosis of NRH is definitively made with the histological presence of micronodules not greater than 3 mm thick and without intervening fibrosis[1].

The pathogenesis of NRH in HIV infection remains unclear. Several theories have been proposed, including a "two-hit" model in which recurrent gut bacterial translocation to the portal tract in combination with vascular endothelial damage ultimately results in portal hypertension[5]. Other theories suggest that direct viral or immune-mediated damage contribute to the obliterative venopathy[6]. However drug-induced hepatotoxicity has become the prevailing theory. The prolonged exposure to highly active antiretroviral therapy (HAART), namely didanosine (DDI) has been strongly correlated, and in all cases of proposed HAART-associated NRH, DDI has been present in each[5-15].

The significance of the association between NRH and HIV is underscored by the evolving patterns of disease in HIV-infected persons. Approximately 34 million people are currently infected with the virus worldwide. In developed nations, where individuals have ready access to HAART the mortality of HIV is decreasing[5]. The causes of death are shifting and studies have shown that liver disease accounts for as high as 18% of deaths in the post-HAART era[6]. These findings place liver disease in the top three causes of mortality in HIV-infected persons, out ranking opportunistic infections and acquired immune deficiency syndrome (AIDS)-defining illnesses. While hepatic viral co-infection accounts for a majority of the liver disease in HIV patients, both alcoholic and non-alcoholic liver diseases are also important. Of emerging relevance, is the burden of NCPH, namely NRH.

The purpose of this paper is to perform a systematic review of the clinical syndrome and outcomes in patients with NRH specifically related to HIV. The manifestations of NRH in HIV patients are similar to those that have previously been well defined in patients with NRH of other etiologies. We will focus on the clinical manifestations reported and suggest a methodical approach to the HIV patient with known or suspected NRH.

MATERIALS AND METHODS

We performed a search of the MEDLINE database for all published studies in all available languages on NRH in HIV-infected patients. Combinations of the following keywords were implemented: "nodular regenerative hyperplasia", "human immunodeficiency virus", "noncirrhotic portal hypertension", "idiopathic portal hypertension", "cryptogenic liver disease", "highly active antiretroviral therapy" and "didanosine". The bibliographies of these studies were subsequently searched for any additional relevant publications.

Our search yielded 68 unique hits (Figure 1). These publications were reviewed for relevance to the topic of interest. A total of 49 publications pertaining to the phenomenon of NCPH in the context of HIV-infection and its treatment were found. The papers were then reviewed in further detail to identify cases where the specific diagnosis of NRH was made, and cases were only included if diagnosis was based on histologic identification. A total of 95 cases that met our inclusion criteria were found. We excluded any cases where the diagnosis of NCPH was attributed to conditions other than NRH, therefore cases of hepatoportal sclerosis (HPS) and other obliterative portal venopathies not meeting diagnostic criteria for NRH were excluded. Of note, we did include cases where both HPS and NRH were found in the same liver. We excluded any cases where liver biopsy was not done and therefore no definitive diagnosis of NRH could be made.

RESULTS

Epidemiology
NRH is a rare condition, and although it has become increasingly recognized, its epidemiology remains poorly understood. The incidence in the general population is approximately 2.6%, an estimate that comes from a large autopsy study done in 1990[1]. The majority of the existing data is based from case reports and case series, and the incidence appears to be increasing as NRH is becoming more widely recognized[7]. The diagnosis is frequently missed as liver biopsy is usually only undertaken in symptomatic patients and NRH often exists subclinically. Moreover, diagnosis requires adequate specimen, appropriate use of reticulin staining and evaluation by a skilled pathologist, making histologic confirmation difficult[8].

to have NRH was reported from Spain in 1993 in a patient with HIV infection and visceral leishmaniasis[9]. We identified a total of 94 additional cases of biopsy-confirmed NRH in HIV-positive patients, most of which were reported within the last decade (Table 1). Given that the same limitations in diagnosis apply to HIV-infected persons, the incidence is likely grossly underestimated in this patient population as well. Epidemiological studies geared toward select patient populations are needed and

may shed more light on the actual incidence of NRH in HIV patients as well as in the general population.

Clinical presentation

The clinical presentation of the cases found was highly variable. The diagnosis was prompted by incidental lab abnormalities in asymptomatic patients, and in other cases, patients presented with manifestations of portal hypertension such as esophageal varices, ascites, and

Portal thrombosis	11 (12)	[4,12,19,20,31,52,53,54,58]

hypersplenism (Table 1). Jaundice was universally not reported. According to our findings, the most common manifestation of NRH in HIV-positive patients was esophageal varices, which were identified in at least 66 of 95 cases. Only 28 patients developed gastrointestinal bleeding in the setting of esophageal varices (Table 2). In many cases, once the clinical syndrome of portal hypertension was identified, patients underwent screening esophagogastroduodenoscopy and were placed on prophylactic non-selective beta-blockers (NSBB) if varices were found. Patients were reported to be on NSBB in almost all cases.

Liver synthetic function as indicated by INR and albumin is well preserved across all cases in which it was reported. Liver associated enzymes may be only mildly elevated (Table 3). Patients were also not uncommonly found to have thrombophilias including protein C and protein S deficiencies, which may be associated with the pathogenesis of NRH and the development of portal vein thrombosis in these patients (Table 3).

When compared to the clinical presentation of patients with NRH without HIV, similar findings have been reported. In one recent series including 42 patients, the most common presenting abnormality was an abnormal liver profile, existing in 76% of cases. Varices were detected in 26% of patients. None of these patients had synthetic liver dysfunction as implicated by normal INR[10]. In another series of 24 patients, similar rates of various clinical features of NRH were reported[11]. These findings mimic those of other similar case reports and are also similar to the findings presented in patient's specifically with NRH and HIV.

Diagnosis
Tthe diagnosis of NRH is a histologic one, requiring liver biopsy. Histologic features are shown in Figure 2. The use of a reticulin stain is usually necessary to make the diagnosis. Important features on the reticulin stain include: nodular apperance, characterized by alternating hypertrophic and atrophic hepatocytes. Highlighting the frequent delay in diagnosis, in one report of 13 patients on HAART who developed NRH, the mean time from presentation to diagnosis of NRH was approximately 38 mo[12]. This point highlights the sub-optimal diagnosis of NRH, leading to its under-appreciation as an important clinical entity in the HIV population. Diagnosis is further limited by the presence of a clear workup bias in that it

is usually either the symptomatic patient, or the patient with long-term DDI exposure who undergoes diagnostic testing for NRH. Furthermore, consideration of NRH is certainly more common in the academic setting[13].

Radiologically, the diagnosis of NRH is also difficult. Findings are variable and range from none to diffuse hypoechoic nodules. On ultrasound, findings may include widespread nodularity of the liver can mimic cirrhosis[14]. On computed tomography, the nodules are usually hypodense and typically do not enhance with contrast. Finally on magnetic resonance imaging, suface nodularity and nodules of similar signal intensity to the liver may be noted[14]. Because the findings on imaging are non-specific and non-diagnostic, clinical correlation is key in determining the next best step in diagnosis.

Natural history
The natural history of NRH is poorly understood. There is likely an inherent bias to diagnose and report symptomatic cases, and NRH is likely more indolent than appreciated. This notion is supported by the large autopsy study by Wanless in which only one of 64 patients had been diagnosed with NRH prior to death. Few of these patients had developed manifestations of portal hypertension prior to death[1]. These findings are likely explained by the preservation of hepatic synthetic function observed in patients with NRH. From the available data, the presentation of NRH is variable and ranges from subtle findings on serum liver tests, to vague abdominal symptoms, to overt gastrointestinal hemorrhage and other severe manifestations of portal hypertension. To date, the overall prognosis has not been well defined, as there have not been substantial outcomes data reported in the literature. In one long-term follow up study of a cohort of eight HIV-infected patients with NCPH, there was only one death, which was attributed to non-NCPH related causes. The remainder of the patients underwent regular screening EGD and was placed on NSBB therapy. If the patients were found to have NCPH prior to the development of variceal bleeding, they tended to remain minimally symptomatic with supportive and preventative care. On the other hand patients who were not treated in a timely manner tended to develop refractory bleeding. One patient with severe NRH required repeated TIPS and was placed on the liver transplant waiting list while another underwent surgical hepatorenal shunt[15].

Associated conditions and medications
Nodular regenerative hyperplasia has long been associated with rheumatologic, autoimmune, hematologic and myeloproliferative disorders[7]. Of particular clinical consequence is the link between NRH and thrombophilias. The association is theoretically attributed to the increased chronic micro-thrombosis of the small portal venules, leading to their constriction, obliteration and eventually to intrahepatic portal hypertension[16]. Many of these patients are also predisposed to the development of portal vein thrombosis, which can lead to end-

Figure 2 Needle liver biopsy of male infected with human immunodeficiency virus. A: His risk factor for the development of Nodular Regenerative Hyperplasia was long term use of didanosine. Hepatocytes size varies zonally, occasional areas of small hepatocytes with increased nuclear cytoplasmic ratio alternate with areas of a more normal appearing morphology in the hematoxylin-eosin stain (original magnification × 100); B: The reticulin stain highlights and confirms nodular regeneration throughout the specimen with nodular areas of regenerative hepatocytes as characterized by widened hepatocellular plates alternating with areas of normal appearing lobular architecture and then areas of narrowed, attenuated hepatocytes (original magnification × 100).

stage disease. In one study, 12 out of 2600 persons with HIV infection were found to have NCPH, and NRH was a common histologic diagnosis. Of the 12 patients with NCPH, half were found to have portal thrombosis[17]. Among all cases, the percentage of patients with portal thrombosis was close to 15% (Table 2).

The association between NRH and antiretroviral therapy has been identified mostly through case reports and small case-control studies. In particular, specific associations have been made with DDI. One of the earliest associations with DDI and NCPH and NRH was from a case-control analysis[18]. Their findings were supported in a number of succeeding publications[14,15,17,19-23]. More recently, the results of another analysis suggested that patients with NRH had a longer exposure not only to DDI, but stavudine, tenofovir, and a combination of DDI and stavudine and DDI and tenofovir as well[12].

Aside from HAART, other medications have also been linked to NRH. Its association with azathioprine (AZA), 6-mercaptopurine, 6-thioguanine, busulphan, cyclophosphamide and most recently, oxaliplatin-based therapies have also been reported[24,25]. A presumed mechanism is damage of the endothelium in the small hepatic veins leading to the phenomenon of obliterative portal venopathy. Interestingly, in one report of AZA-induced NRH, some patients demonstrated normalization of liver enzyme markers and histological regression of NRH after

withdrawal of AZA[26]. Such histological regression has never been reported in the case of HAART and HIV-associated NRH.

Treatment

There is no definitive treatment for NRH. The mainstay of management is removal of the offending agent and prevention and supportive care of disease manifestations. It is important to note that in many of the cases in which NRH was linked to DDI, the exposure had been long-since stopped prior to the time of NRH diagnosis. Cessation of DDI or other implicated HAART agents may improve outcomes, however it has not been shown to result in reversal of the disease process[27]. In part because of its associated hepatotoxicity, the use of DDI has declined substantially and it is now regarded as a lower-tier anti-retroviral medication[12]. Although it is clear that DDI-induced NRH does persist for years after cessation of the medication; interruption has still been associated with an overall better prognosis[27-29].

Treatment of the clinical manifestations of NRH revolves around the primary prophylaxis of esophageal variceal bleeding in asymptomatic patients. For cases in which details were provided, we observed that in almost all asymptomatic cases of esophageal varices, primary prophylaxis with NSBB was started, and propranolol was the usual drug of choice. Many patients also under-

went endoscopic band ligation (EBL), either as primary prophylaxis or after manifestation with bleeding. There were several cases of failure of NSBB or EBL, for which patients underwent transjugular intrahepatic portosystemic shunt (TIPS). At least one of these cases was documented as refractory and TIPS was done as bridge to transplant[15]. In contrast to non-HIV related NRH, ascites was not uncommonly reported in our review of HIV patients with NRH. At least 12 cases of ascites were reported, however the need for paracentesis was not reported. Ascites is infrequently reported in NRH with patients without HIV[10].

The utility of anticoagulation in patients with NRH is a burgeoning concept. Mallet *et al*[30] described a series of 21 patients with clinical evidence of prothrombotic state in the setting of NCPH. The median protein S level in this group was nearly half of normal. The coagulation abnormalities in patients with NRH have particular significance as suggested by Bihl *et al*[31], who reported a case in which the patient's clinical course improved dramatically after initiation of anticoagulation. It appears that the benefit of anticoagulation in these patients may be multifactorial. One theory is that it slows disease progression by preventing the micro-thrombosis thought to play a pathogenic role in NRH. In addition, given the noted thrombophilias in these patients, anticoagulation prevents portal vein thrombosis, which can lead to refractory manifestations of portal hypertension and end-stage liver disease[30-32]. These findings suggest potential benefit of anticoagulation therapy and warrant further studies specifically in the context of NRH.

Patients with severe liver disease and intractable symptoms of portal hypertension should be considered for liver transplant, which has been successfully described in 7 cases of patients with HIV and NRH[13,30]. In most of these cases, the indication for liver transplant was severe and intractable symptoms portal hypertension, with or without complete portal vein thrombosis. In one case, the indication to consider transplant was hepatic encephalopathy secondary to TIPS placement[33]. All 7 patients who underwent liver transplant reportedly had excellent survival. However, it is important to note that there have been cases in which NRH reappears in the transplanted liver[34], although this has yet to be described in a patient with NRH in the setting of HIV. Regardless, for this reason, continued anticoagulant therapy even after transplant may be warranted and necessitates further investigation.

DISCUSSION

The burden of liver disease in HIV-infected persons is substantial and a comprehensive and interdisciplinary approach to management is crucial. All HIV-positive individuals should undergo regular liver function testing at least biannually as they are routinely exposed to hepatotoxic medications and are generally at increased risk for both viral and non-viral hepatitides[35]. NRH should be considered in all HIV-positive patients with unexplained signs and symptoms of portal hypertension. A thorough history of past and current antiretroviral drug regimens should be obtained as it has been shown that the effects of NRH persist long after cessation of the offending agent.

Diagnosis of NRH requires a high index of suspicion given its uncommon incidence and varied presentation of portal hypertension. Imaging techniques, such as abdominal ultrasound or computed tomography (CT) are frequently used to further evaluate patients with liver disease. Hepatic nodularity may be appreciated on liver ultrasound, and when combined with a clinical context of relatively preserved hepatic function, NRH should remain high on the differential. The hepatic nodularity on ultrasound is often followed up with CT imaging, however findings of diffuse micronodularity can also mimic cirrhosis[14,56].

NRH is one of the potential causes of non-cirrhotic portal hypertension in patients with HIV. Other potential causes of non-cirrhotic intrahepatic portal hypertension include schistosomiasis, sinusoidal obstruction syndrome, and idiopathic portal hypertension (hepatoportal sclerosis)[7,22,37]. In particular, antiretroviral therapy has been associated with both NRH and idiopathic portal hypertension. It has been hypothesized that idiopathic portal hypertension can lead to both NRH and portal vein thrombosis[2].

Accurate diagnosis of NRH requires the histological assessment[7]. Since the nodularity is often heterogeneously distributed, liver biopsy requires an ample sized tissue. The transjugular route is often used to minimize bleeding complications[38]. However, there have been cases where diagnosis was initially missed and later found only *via* wedge biopsy[39]. Classification of non-neoplastic, diffuse parenchymal liver disease necessitates a sample of at least 2-3 cm in length and at least a 16-gauge caliber needle[40]. The hepatocyte atrophy, a key histologic feature is best identified with reticulin staining which must be employed to make the diagnosis[41].

The pathogenesis of NRH is believe to be related to the differential of blood supply to the liver that leaves some areas ischemic, and other with compensatory hypertrophy which leads to the formation of hepatic nodules. There are multiple diseases, conditions, and medications associated with its development[7]. In contrast to non-HIV patients, patients with HIV and NRH tend to have a higher incidence of ascites. It is unclear why the incidence differs but the variance may be potentially related to the underlying cause of NRH in HIV patients being largely pharmacologic from antiretroviral drugs.

DDI which has been most strongly linked to the development of NRH, belongs to a class of medications known as nucleoside reverse transcriptase inhibitors (NRTI). It functions as a purine analogue and interferes with the transcription of DNA and RNA[27]. Azathioprine, 6-mercaptopurine 6-thioguanine and other chemotherapeutic agents that have been previously linked to NRH have a similar mechanism of action[42]. Although

current knowledge suggests that NRH is not a reversible condition, several studies have shown improved outcomes with cessation of causative medications.

Treatment of NRH generally revolves around manifestations of portal hypertension. Once the diagnosis is confirmed, patients should undergo screening for esophageal varices with esophagogastroduodenoscopy (EGD)[43]. Patients with NRH should be considered for screening for HCC. Although this remains a relatively controversial topic, a possible pathogenetic relationship between NRH and HCC has been described[1,25,44-50]. The inability to conclusively establish a propensity of NRH to develop into HCC may be a result of its underestimated incidence, rather than a lack of association between the two conditions. Liver transplantation is an uncommon treatment for NRH since liver function is usually preserved. In a recently published systematic review, the authors found severe portal hypertension as the most common indication for liver transplantation[51].

The importance of NRH in HIV-infected individuals is growing, especially as patients are experiencing increased longevity and longer exposure to medications. High index of suspicion is required to make a diagnosis since there are patients with HIV who develop manifestations of portal hypertension such as ascites and variceal bleeding from cirrhotic and non-cirrhotic causes. Treatment generally revolves around treating the manifestation of portal hypertension.

COMMENTS

Background
Nodular regenerative hyperplasia (NRH) causes portal hypertension in patients with human immunodeficiency virus (HIV). Unlike cirrhosis, NRH is not associated with liver synthetic function. On imaging, NRH and cirrhosis appear similar with nodular liver contours. Patients with NRH can present with ascites and variceal bleeding.

Research frontiers
Further research in needed in the utility of non-invasive methods of making the diagnosis of NRH. Studies are essential to determine the long term consequences of NRH. More research is needed to understand the pathogenesis of NRH.

Innovations and breakthroughs
There is increasing appreciation of the epidemiology and association of NRH with HIV. There is also enhanced awareness of the association of certain antiretroviral medications such as didanosine and NRH.

Applications
The article adds to the literature the current understanding of the diagnosis, risk factors, natural history and, management of NRH.

Terminology
The diagnosis of NRH requires a liver biopsy. Liver parenchymal cells are clustered in nodules. Unlike cirrhosis, there are fibrotic bands encompassing the nodule.

Peer review
One of the most important issues raised during peer review was that there may be differences in the presentation in patients affected by NRH with and without HIV. Patients with NRH and HIV are more likely to have ascites than those patients with NRH without HIV.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Hepatology (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

Aim and scope

WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

WJH is edited and published by Baishideng Publishing Group (BPG). BPG has a strong professional editorial team composed of science editors, language editors and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15471 editorial board members or peer reviewers, and is a world first-class publisher.

Columns

The columns in the issues of *WJH* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future research directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being

published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers; (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, *etc.*; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in hepatology; (12) Brief Articles: To briefly report the novel and innovative findings in hepatology; (13) Meta-Analysis: Covers the systematic review, mixedtreatment comparison, meta-regression, and overview of reviews, in order to summarize a given quantitative effect, *e.g.*, the clinical effectiveness and safety of clinical treatments by combining data from two or more randomized controlled trials, thereby providing more precise and externally valid estimates than those which would stem from each individual dataset if analyzed separately from the others; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJH*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of hepatology; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

Institute of Molecular Biology and Pathology, Rome 00161, Italy

Wan-Long Chuang, MD, PhD, Doctor, Professor, Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung 807, Taiwan

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including t-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (n). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the P value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJH* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS
Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copyedit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now

available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1948-5182/g_info_20100316080002.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to bpgoffice@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION
All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province,

country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-85381892 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract
There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/…"), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, *e.g.*, 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Core tip
Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a

second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1948-5182/g_info_20100107115140.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

Examples for paper writing
All types of articles' writing style and requirement will be found in the link: http://www.wjgnet.com/esps/NavigationInfo.aspx?id=15

RESUBMISSION OF THE REVISED MANUSCRIPTS
Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1948-5182/g_info_20100107114726.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1948-5182/g_info_20100107114601.htm.

Proof of financial support
For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

STATEMENT ABOUT ANONYMOUS PUBLICATION OF THE PEER REVIEWERS' COMMENTS
In order to increase the quality of peer review, push authors to carefully revise their manuscripts based on the peer reviewers' comments, and promote academic interactions among peer reviewers, authors and readers, we decide to anonymously publish the reviewers' comments and author's responses at the same time the manuscript is published online.

PUBLICATION FEE
WJH is an international, peer-reviewed, OA online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium and format, provided the original work is properly cited. The use is non-commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 600 USD per article. All invited articles are published free of charge.

ABOUT COVER   Editorial Board Member of *World Journal of Hepatology*, Chun-Fang Xu, MD, PhD, Professor, Department of Gastroenterology, The First Affiliated Hospital of Soochow University, Suzhou 215006, Jiangsu Province, China

AIM AND SCOPE

World Journal of Hepatology (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Hepatology is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

Abstract

Portal vein thrombosis (PVT) is considered to be a frequent complication of liver cirrhosis. However, unlike PVT in patients without cirrhosis, very few data are available on the natural history and management of PVT in cirrhosis, despite its association with potentially life-threatening conditions, such as gastroesophageal bleeding and acute intestinal ischemia. Moreover, no consensus regarding PVT in cirrhosis exists. Suggested causes of PVT in cirrhosis include reduced portal blood flow velocity, multiple congenital or acquired thrombophilic factors, inherited or acquired conditions, and derangement of liver architecture. However, the understanding of PVT in cirrhosis is incomplete. In addition, information on the management of PVT in cirrhosis is inadequate. The aims of this review are to: (1) assemble data on the physiopathological mechanism, clinical findings, diagnosis and management of PVT in cirrho-sis; (2) describe the principal factors most frequently involved in PVT development; and (3) summarize the recent knowledge concerning diagnostic and therapeutic procedures.

INTRODUCTION

Portal vein thrombosis (PVT), an obstruction of the portal vein or its branches by a blood clot, is encountered in a variety of clinical settings, such as myeloproliferative disease, cirrhosis, cancer and infection. More patients with cirrhosis are being diagnosed with PVT be-

cause current imaging techniques allow for the detection of asymptomatic PVT during routine ultrasonographic examination. PVT has a variety of clinical presentations, from asymptomatic to life-threatening conditions such as gastroesophageal bleeding and acute intestinal ischemia[1-3]. Although liver transplantation has altered the prognosis of patients with cirrhosis, the presence of PVT can exclude a patient from a transplant listing or negatively impact post-transplantation survival[4].

It remains unclear whether PVT is a consequence of severe liver disease, a factor aggravating underlying liver disease, or both. PVT is considered to be a frequent complication of liver cirrhosis; however, unlike PVT in patients without cirrhosis, very few data are available on its natural course and management despite its association with potentially life-threatening conditions. In addition, no consensus regarding PVT with cirrhosis exists. There is a growing need for optimal, evidence-based management of PVT in cirrhosis.

The aims of this review are to: (1) assemble evidence regarding the physiopathological mechanism, clinical findings, diagnosis and management of PVT in cirrhosis; (2) describe the principal factors most frequently involved in PVT development; and (3) summarize the most recent knowledge concerning diagnostic and therapeutic procedures.

DEFINITION OF ACUTE AND CHRONIC PVT

From a clinical point of view, PVT comprises two different entities: acute PVT and chronic PVT. Each represents a successive stage of the same disease. Although they share similar causes, they differ with respect to their management[5].

Acute PVT is characterized by the sudden formation of a thrombus within the portal vein[6]. The thrombus can involve variable portions of the mesenteric veins and/or splenic vein. Occlusion can be complete or partial, leaving a peripheral circulating channel.

In patients with chronic PVT, also known as portal cavernoma, the obstructed portal vein is replaced by a network of hepatopetal collateral veins connecting the patent portion of the vein upstream of the thrombus to the patent portion downstream. The number, size and location of these collaterals are extremely variable from patient to patient[6].

However, in patients with cirrhosis, it may be difficult to establish the "age" of the thrombosis because the criteria commonly used in patients without cirrhosis to define acute or chronic PVT (presence of collateral circulation and signs of portal hypertension) are already features of liver disease[7,8].

PREVALENCE

The prevalence of PVT in patients with cirrhosis has been reported more frequently in recent years. The reported prevalence of PVT is in the range of 0.6%-15.8% in patients with liver cirrhosis or portal hypertension[9-15]. The presence of PVT is reportedly 0.6% when evaluated by angiographic studies[9], 4.4% when evaluated by ultrasound[10], and 10%-12% when evaluated by computed tomography and magnetic resonance imaging[1,11]. Moreover, the prevalence of PVT increases with patient age and liver disease severity, reaching 15% in patients awaiting liver transplantation[12-15].

The etiology of liver disease influenced the prevalence of PVT in a study of 885 patients who underwent liver transplantation. The prevalence of PVT was 3.6% in primary sclerosing cholangitis, 8% in primary biliary cirrhosis, 16% in alcoholic and hepatitis B virus-related cirrhosis, and 35% in hepatocellular carcinoma (HCC)[12].

ETIOLOGY OF PVT IN CIRRHOSIS

Inherited and acquired thrombophilic disorders, bacterial infection[16,17] and sluggish portal flow[2,18,19] may all play a role in the high prevalence of PVT in patients with cirrhosis.

Cirrhosis was recently considered to be a hypercoagulable state, not a hypocoagulable state. The levels of both pro- and anti-coagulation proteins are reduced under conditions of hepatic synthetic impairment in patients with liver cirrhosis. Coagulation and anticoagulation mechanisms remain balanced but are carried out at a lower level[20-22]. The net result is a hemostatic balance that is compensated under normal circumstances, with no tendency for bleeding or thrombosis[22]. In cirrhosis, however, this equilibrium can easily tilt towards either bleeding or thrombosis[19,23-26]. Some authors have demonstrated that elevated levels of factor VIII (a procoagulant driver) in combination with decreased levels of protein C (an anticoagulant driver), both of which are typically found in patients with cirrhosis (*i.e.*, procoagulant imbalance), are probably related to partial resistance to the *in vitro* anticoagulant action of thrombomodulin[27-30]. However, in patients with impaired synthetic function and low plasma levels of natural coagulation inhibitors, there is currently no simple way to ascribe such a low level to a pre-existing deficiency[31].

A thrombophilic genotype, including factor V Leiden G1691A mutation[32,33], methylenetetrahydrofolate reductase (TT677) mutation[34,35] and prothrombin (G20210A)[11,36], is associated with the formation of PVT. However, they may play a minor pathogenic role in the formation of PVT.

Reduced portal flow velocity seems to be the most important predictive variable for PVT development in patients with cirrhosis[37-39]. Amitrano *et al*[38] suggested that portal blood stasis in patients with cirrhosis is the main change favoring thrombosis, even in the presence of other local, systemic, congenital and acquired factors. Kinjo *et al*[39] performed Doppler ultrasonographic examinations after splenectomy in patients with cirrhosis and showed that portal venous flow was dramatically decreased by 49.2% in the PVT group but only by 6.6% in

the non-PVT group.

Splenectomy has recently been reported to play a role in the surgical strategy for HCC and interferon-based therapy for hepatitis C[40-45]. In addition, it can improve the prognosis for patients with cirrhosis by allowing them to receive interferon therapy or undergo treatment for HCC[44,45]. Despite the good results demonstrated in these studies, the high prevalence of PVT after splenectomy in patients with cirrhosis remains problematic[39,46]. It has been suggested that blood turbulence or stasis in the stump of the splenic vein after splenectomy might result in increased coagulability, leading to the propagation of splenic venous thrombus formation in the portal system after splenectomy[47]. Splenomegaly and a large splenic vein diameter are independent risk factors for PVT after splenectomy in patients with concomitant cirrhosis and portal hypertension[39,46,47].

The role of sclerotherapy as a potential trigger for PVT is controversial[48,49]. Some recent reports showed that thrombopoietin receptor agonists might be associated with an increased incidence of PVT in patients with cirrhosis[50,51].

CLINICAL FINDINGS

Clinical findings of PVT in cirrhosis vary from asymptomatic to life-threatening conditions. Partial PVT, which is now often detected by routine ultrasonography or computed tomography, might be associated with few symptoms. However, complete PVT may present as abdominal or lumbar pain with sudden onset or progression over a few days. Rapid, complete obstruction of the portal vein or mesenteric veins without involvement of the mesenteric venous arches induces intestinal congestion, which manifests as severe, continuous, colicky abdominal pain and occasionally as nonbloody diarrhea[1-3]. The bleeding risk appears to be higher in patients with PVT and cirrhosis than in patients with cirrhosis alone (39% *vs* 27%, respectively)[52]. In many patients, however, the thrombus is partial and its aspects and location change in follow-up images. Laboratory findings, including the levels of aminotransaminase, fibrin and fibrinogen degradation products, and d-dimers, are often normal in many cases of developing PVT.

Chronic PVT is commonly diagnosed after a fortuitous finding of hypersplenism or portal hypertension. In the majority of patients it is asymptomatic. Gastrointestinal bleeding is better tolerated by patients with chronic PVT than in those with other forms of portal hypertension, probably because patients with PVT are usually younger and have no liver dysfunction. The occurrence of ascites or encephalopathy in patients with chronic PVT is uncommon and is usually encountered only transiently following gastrointestinal bleeding or when unrelated renal failure or marked sepsis is present in older patients[3]. Liver test results are typically normal in patients with portal cavernoma in the absence of underlying liver disease. Biliary symptoms related to portal cholangiopathy (jaundice, biliary pain, cholangitis, cholecystitis or pancreatitis) rarely reveal the presence of a cavernoma[53,54]. Hepatopulmonary syndrome is present in about 10% of patients.

DIAGNOSIS

More of these patients are being diagnosed with PVT because current imaging techniques allow for the detection of asymptomatic PVT during routine ultrasonography in patients with cirrhosis.

Ultrasound and Doppler ultrasound are almost always sufficient for a diagnosis of PVT[55,56]. In most patients, the diagnosis of acute PVT can be rapidly established using noninvasive imaging. Ultrasound sonography can show hyperechoic material in the vessel lumen with distension of the portal vein and its tributaries. Doppler imaging shows the absence of flow in part or all of the lumen.

Enhanced computed tomography (CT) can show a lack of luminal enhancement in the portal vein, increased hepatic enhancement in the arterial phase, and decreased hepatic enhancement in the portal phase[57]. CT and magnetic resonance (MR) angiography are more sensitive techniques than Doppler imaging with respect to assessment of the extent of the thrombus within the portal venous system[56-58]. Definitive diagnosis of PVT can be obtained by MR imaging (MRI) and CT; the former provides a better evaluation of the extent of the thrombosis, particularly in the mesenteric vein, reaching a sensitivity and specificity of 98%-100%. CT provides information not only about the extent of the thrombosis and the development of collateral circulation, but also about the state of the abdominal organs. It is the procedure of choice when intestinal ischemia or hepatocellular carcinoma is suspected[59,60]. A diagnosis of cavernoma is readily achieved by abdominal imaging with ultrasound, CT or MRI, which shows serpiginous structures while the main portal vein and/or its main branches are not visible.

A recent study showed that positive intrathrombus enhancement on contrast-enhanced sonograms is an accurate predictor of recanalization in patients with recent portal thrombosis[61].

TREATMENT

Optimal management of PVT in cirrhosis is not addressed in any current consensus publication. There are a few reports about the factors that influence recanalization or the extent of thrombosis; however, the actual impact of PVT treatment on the natural course of cirrhosis has not been investigated. No randomized controlled trials have been performed and most existing evidence concerning PVT treatment is based on case series and is of low quality.

PVT increases the risk of variceal bleeding and is reportedly an independent risk factor for the inability to

control variceal bleeding[62]. In addition, PVT can be a life-threatening emergency when it extends to the superior mesenteric vein, leading to intestinal infarction. Anticoagulated patients with cirrhosis have better recanalization rates and PVT extension than non-anticoagulated patients[63]. Therefore, in patients with concomitant cirrhosis and PVT, a treatment algorithm that includes anticoagulation and transjugular intrahepatic portosystemic shunting (TIPS) provides a good chance of complete repermeation, reduces portal hypertensive complications and decreases the rate of thrombosis progression[63]. Francoz *et al*[4] evaluated patients with cirrhosis awaiting liver transplantation and found that survival was significantly lower in those with complete PVT at the time of surgery ($P = 0.04$). Furthermore, the rate of partial or complete recanalization was significantly higher among patients receiving anticoagulation therapy than among those not receiving anticoagulation therapy ($P = 0.002$).

Conversely, some reports have shown that PVT has little influence on prognosis in patients with cirrhosis. Maruyama *et al*[64] evaluated 150 patients with virus-related cirrhosis but without PVT at baseline; PVT developed in 28% of patients (42/150), with a cumulative incidence of 12.8%, 20% and 38.7% at 1, 5 and 8-10 years, respectively. The natural course of thrombosis was improvement in 47.6% of patients, unchanged in 45.2%, and worsened in 7.2%. Spontaneous resolution or an unchanged appearance was the most common outcome of PVT; therefore, cirrhotic PVT had little influence on prognosis. In their multivariate analysis, Luca *et al*[65] noted that there was no clear association between progression or regression of partial PVT and clinical outcome and that the Child-Pugh score at the time of diagnosis was the only independent predictor of survival.

In the field of liver transplantation, there is accumulating evidence that PVT, especially thrombus extension to the superior mesenteric vein, may adversely affect the outcome of transplantation. Thus, patients with concomitant cirrhosis and PVT who are on the waiting list for liver transplantation should be treated with anticoagulation therapy[66,67]. PVT prior to liver transplantation is an independent prognostic factor for post-transplant survival[68,69] and complete or partial PV recanalization has been associated with a better survival rate after liver transplantation[4]. It has also been shown that individuals with PVT at the time of liver transplantation are at higher risk of recurrent PVT after transplantation and of requiring retransplantation[30,70]. The increased mortality and morbidity rates associated with PVT are mostly restricted to the first year after liver transplantation[4,62] and actuarial survival after 1 year is good. Therefore, PVT cannot be considered to be a contraindication to liver transplantation[71].

Anticoagulation therapy is of proven benefit in patients with acute deep vein thrombosis[72]. The optimal anticoagulation regimen for the treatment and monitoring of PVT has not yet been fully explored and no clear recommendations exist regarding this issue in recent guidelines or consensus publications[6,28]. Treatment strategies most often include the use of anticoagulation, while thrombectomy and TIPS are considered second-line options.

The goal of anticoagulation therapy for acute PVT is to recanalize the obstructed veins, which will prevent intestinal infarction and portal hypertension. Correction of the causal factors should be achieved as soon as possible.

Vitamin K antagonists (VKA) have been used in some studies to treat PVT in patients with cirrhosis. The rate of PV recanalization in patients with cirrhosis treated with VKA is about 40%[4,73]. Orally administered VKA is more acceptable to patients; however, treatment with VKA is particularly difficult in patients with cirrhosis, mostly because anticoagulation monitoring is complex in this particular situation. Notably, international normalized ratio (INR) monitoring in patients with liver disease probably overestimates the bleeding risk because this international sensitivity index is determined using plasma from patients taking VKA[74]. The INR has only been validated in individuals with normal liver function on stable anticoagulation. A 29% variation in the mean INR was reported in patients with cirrhosis in a study in which three different thromboplastin reagents were used[75]. It is also unclear whether a target INR between 2 and 3 is adequate in individuals with an abnormal INR before anticoagulation therapy[30].

No consensus exists regarding the optimal duration of anticoagulation therapy in these settings. Complete recanalization can be delayed until the sixth month of anticoagulation therapy[5,76]. However, whether this is also true for patients with cirrhosis who develop acute PVT remains to be determined.

Randomized controlled trials of anticoagulation therapy for the prevention of recurrent thrombosis are lacking in cirrhotic PVT. In patients with deep vein thrombosis, a lack of complete recanalization indicates a high risk of recurrence after cessation of anticoagulation therapy[77]. The frequent association with permanent prothrombotic disorders and the risk of intestinal infarction support the use of anticoagulation. However, an increased risk of bleeding secondary to portal hypertension raises concerns. Delgado *et al*[73] reported that re-thrombosis after complete recanalization occurred in 38.5% of patients with cirrhosis after anticoagulation therapy was stopped. Thatipelli *et al*[78] stated that prolonged anticoagulant therapy does not appear to be justified based on the low rate of recurrence and substantial rate of major hemorrhage. To avoid the extension of thrombosis to the splanchnic vessels, prophylactic anticoagulation should be continued in patients with underling thrombophilic conditions or in patients who are likely candidates for future liver transplantation[4,63].

The choice of the anticoagulation regimen must also account for the potential need to reverse the effect of anticoagulation. There is no current consensus or guideline on whether nonselective beta blockers, endoscopic

variceal ligation or combination therapy is better for variceal bleeding prophylaxis[7,79].

An attractive alternative to oral anticoagulants could be the use of low-molecular-weight heparin (LMWH), the dosing of which is weight based and thus does not necessitate screening. A 50%-80% portal vein recanalization rate was recently reported with the use of LMWH in 38 patients with cirrhosis, with only a few episodes of non-severe variceal bleeding[62,80]. Villa *et al*[81] performed a randomized controlled trial to evaluate the safety and efficacy of enoxaparin, a LMWH, in preventing PVT in patients with advanced cirrhosis. They demonstrated that the actuarial probability of PVT was lower in the enoxaparin group ($P = 0.006$). The actuarial probability of survival was higher in the enoxaparin group ($P = 0.020$). No relevant side effects or hemorrhagic events were observed in their study. Enoxaparin appeared to delay the occurrence of hepatic decompensation and improve survival. However, an increased volume of distribution, such as that produced by ascites and edema, in patients with cirrhosis makes it difficult to determine the optimal dose of LMWH[82].

The administration of antithrombin Ⅲ (AT-Ⅲ) could be an attractive alternative to PVT in cirrhosis. Kawanaka *et al*[83] demonstrated that the low AT-Ⅲ activity and further decreases in this activity are associated with PVT after splenectomy in patients with cirrhosis and that treatment with AT-Ⅲ concentrates is likely to prevent the development of PVT in these patients.

TIPS and anticoagulation therapy are considered to be optimal treatment choices for PVT in cirrhosis[84]. TIPS completely recanalized the portal venous system in 57% of patients with cirrhosis and resulted in a marked decrease in 30% without major procedure-related complications. Despite problems associated with patency (bare stents, 38% in 12 mo and 85% in 24 mo; covered stents, 21% in 12 mo and 29% in 24 mo) and encephalopathy (27% at 12 mo, 32% at 24 mo), the long-term outcome of TIPS placement for cirrhotic PVT is excellent[85]. In addition, PVT prior to liver transplantation is an independent prognostic factor for post-transplant survival and TIPS prevents total portal vein occlusion in liver transplantation candidates with partial PVT[86].

In patients with both cirrhosis and chronic PVT, there is no consensus on the indication for anticoagulant therapy. As described in the consensus for PVT in patients without cirrhosis, therapy for chronic PVT can be separated into prevention and treatment of gastrointestinal bleeding, prevention of recurrent thrombosis and treatment of portal cholangiopathy. When PVT is longstanding and cavernous transformation has occurred in the portal vein, prophylactic anticoagulation is reversed only in patients with thrombophilic conditions and/or a high risk of thrombus extension into the superior mesenteric vein. There is still sufficient evidence in favor of interventional therapy such as TIPS[87]. Data on endoscopic ligation are lacking in adult patients with chronic PVT.

CONCLUSION

PVT is a common problem in patients with cirrhosis, mostly in individuals with advanced liver disease. However, many unknown pathophysiological aspects of PVT and unresolved issues encountered in everyday practice remain to be addressed. The most optimal, most efficient and safest modalities for treatment, screening and monitoring must be established in future controlled trials.

Abstract

AIM: To investigate oxidative stress (OS)-mediated damage and the behavior of extracellular matrices in various rat models because shear stress with portal hypertension and cold ischemia/warm reperfusion injury trigger the liver regeneration cascade after surgery. These injuries also cause fatal liver damage.

METHODS: Rats were divided into four groups according to the surgery performed: control; hepatectomy with 40% liver remnant (60% hepatectomy); orthotopic liver transplantation (OLT) with whole liver graft (100% OLT); and split OLT (SOLT) with 40% graft (40% SOLT). Survival was evaluated. Blood and liver samples were collected at 6 h after surgery. Biochemical and histopathological examinations were performed. OS-induced damage, 4-hydroxynonenal, ataxia-telangiectasia mutated kinase, histone H2AX, phosphatidylinositol 3-kinase (PI3K) and Akt were evaluated by western blotting. Behavior of extracellular matrices, matrix metalloproteinase (MMP)-9, MMP-2, tissue inhibitor of metalloproteinase (TIMP)-1 and TIMP-2 were also evaluated by western blotting and zymography.

RESULTS: Although 100% OLT survived, 60% hepatectomy and 40% SOLT showed poor survival. Histopathological, immunohistological, biochemical and protein assays revealed that 60% hepatectomy, 100% OLT and 40% SOLT showed liver damage. PI3K and Akt were decreased in 60% hepatectomy and 40% SOLT. For protein expression, 40% SOLT showed differences in MMP-9, MMP-2 and TIMP-2. TIMP-1 showed differences in 60% hepatectomy and 40% SOLT. For protein activity, MMP-9 demonstrated significant differences in 60% hepatectomy, 100% OLT and 40% SOLT.

CONCLUSION: Under conditions with an insufficient liver remnant, prevention of OS-induced damage *via* the Akt/PI3K pathway may be key to improve the postoperative course. MMP-9 may be also a therapeutic target after surgery.

Key words: Free radicals; Akt; Phosphatidylinositol 3-kinase; Matrix metalloproteinase; Tissue inhibitors of metalloproteinase

Core tip: Although shear stress with portal hypertension and cold ischemia/warm reperfusion injury trigger the liver regeneration cascade after surgery, these injuries also cause fatal liver damage. Postoperative liver damage is still a critical matter in the field of liver surgery. Oxidative stress and extracellular matrices are important for liver regeneration after surgery and these may be important keys to overcome current problems in the field of liver surgery. Here, we investigated oxidative stress-mediated damage and the behavior of extracellular matrices in various rat models with liver surgery.

INTRODUCTION

Liver resection is considered the standard treatment for primary malignant tumors and liver metastases. Advanced surgical techniques for hepatectomy, development of preoperative evaluation, and improvements in intensive postoperative care have resulted in a decline in perioperative morbidity and mortality. However, postoperative liver failure still occurs despite these developments. Extended hepatectomy has the advantage of high curability but increases morbidity and mortality[1]. Insufficient volume of the remnant liver is correlated with perioperative morbidity and mortality[1]. Prognosis of postoperative liver failure due to insufficient liver remnant is poor[1,2].

Orthotopic liver transplantation (OLT) is an accepted therapy for end-stage liver disease and currently provides long-term survival and good quality of life. However, cold ischemia/warm reperfusion (CIWR) injury is still a major cause of morbidity and mortality after OLT[3]. Currently, strategic procedures are needed to improve the liver tolerance against CIWR injury. A small-for-size graft (SFSG) is used for deceased donor liver transplantation (DDLT) and living donor liver transplantation (LDLT)[4,5]. The SFSG is defined as a ratio of graft weight against standard liver volume < 40%[6,7]. An inevitable insufficiency of graft size cannot be avoided in the LDLT or split orthotopic liver transplantation (SOLT) for DDLT. The SFSG in LDLT or SOLT is accompanied with CIWR injury and shear stress with portal hypertension. Hence, the SFSG results in high mortality and morbidity. The choice of a left-side graft is preferred from the viewpoint of greater donor safety and expanded donor candidates in LDLT[7,8]. Guaranteed SOLT with successful outcomes resolves a donor shortage in DDLT[4,5]. Currently, the 40% SFSG is a critical matter to overcome the donor shortage in DDLT and ensure donor safety in LDLT[4].

Oxygen is required for cell survival. However, it also poses a potential hazard *via* reactive oxygen species (ROS) and reactive nitrogen species (RNS), with biological and functional alterations of lipids, proteins and DNA[9-11]. Control of ROS/RNS production plays physiological roles, especially in regulating cell signaling, cell proliferation, differentiation and apoptosis[9-11]. Oxidative stress (OS) mediated by free radicals is defined as an imbalance between the production of ROS/RNS and the antioxidant capacity of the cell[9-11].

The extracellular matrix has important effects on inflammation, carcinogenesis and regeneration[12-14]. There are diverse types of proteases that control remodeling of the extracellular matrix, trigger liver regeneration and drive tumor progression[12-14]. Matrix metalloproteinases (MMPs) are a family of enzymes that degrade constituents of extracellular matrices and basement membranes. Currently, a total of 28 MMPs have been identified[14]. MMPs have been intensively studied and shown to play key roles in inflammation, carcinogenesis and regeneration[12-15]. MMP-2 and MMP-9 are implicated in liver injury and remodeling. In particular, previous researchers reported that MMP-9 and MMP-2 contribute to liver failure after liver surgery[12-21]. Tissue inhibitors of metalloproteinases (TIMPs) are a family of endogenous inhibitors of MMPs. Alteration in the MMP-TIMP balance is linked to pathophysiological conditions[22,23]. Currently, four members have been identified in the TIMP family which can inhibit various MMPs[24]. In particular, many researchers have focused on TIMP-1 and TIMP-2 during liver regeneration[25-28].

Although shear stress with portal hypertension and CIWR injury trigger the liver regeneration cascade after liver surgery, these injuries also cause fatal liver damage[29-31]. Initial damage is confirmed at the early postoperative period after liver surgery[3,12,13,18,29-31]. Therapeutic strategies to reduce this damage have the advantage of improving clinical results after liver surgery and overcoming the current issue of insufficient liver volume in the field of liver surgery. In the present preliminary study, we investigated OS-mediated damage and the behavior of extracellular matrices in various rat models with shear stress and portal hypertension and/or CIWR injury.

MATERIALS AND METHODS

Animals

Lewis rats (RT-1^l) were purchased from Harlan Laboratories (Indianapolis, IN, United States). Male rats were 8-12 wk old and weighed 250 g. The experimental protocols were approved by the Ethical Committee of our institution (Mayo Clinic, Institutional Animal Care and Use Committee, No. A19609). Rats were cared for in accordance with the Institutional Guidelines for Animal Welfare based on The National Institutes of Health Guide for the Care and Use of Laboratory Animals.

Surgical procedures and postoperative care

Comprehensive details of the surgical procedures for rat

Table 1 Study design			
Group	Hepatic remnant volume	Cold ischemia warm reperfusion	Shear stress portal hypertension
Control	100%, native liver	-	-
60%-hepatectomy	40%, native liver	-	+
100%-OLT	100%, syngeneic graft	+	-
40%-SOLT	40%, syngeneic graft	+	+

OLT: Orthotopic liver transplantation; SOLT: Split orthotopic liver transplantation.

and postoperative care in our institution have been previously described[32-34]. In the hepatectomy model, 40% of liver remnant consisted of the left median and lateral segments[32,33]. In the transplantation model, the syngeneic graft had a cold ischemic time of 3-4 h at 4 ℃ in normal Ringer's solution[33]. The 40% SFSG was also formed by the left median and lateral segments at the back table[34]. To avoid any irrelevant signaling, the hepatic artery was reconstructed by ultramicrosurgery[33]. Each rat was kept separately after surgery and body temperature was maintained by a heating pad. Postoperative observation was performed every 30 min until 6 h after surgery and 1.0 mL of warm lactate Ringer's solution was routinely administered every 1 h until 6 h after surgery. In the transplantation model, we previously demonstrated the importance of a shortened anhepatic phase and exclusion of unreliable samples based on autopsy findings[33,34]. In this study, the anhepatic phase was kept within 20 min in the transplantation model. No surgical complications were observed in each case at sampling autopsy.

Study design

Rats were divided into four groups according to the surgery performed: (1) laparotomy only (control); (2) hepatectomy with 40% liver remnant (60% hepatectomy); (3) OLT with whole liver graft (100% OLT); and (4) SOLT with 40% SFSG (40% SOLT) (Table 1). The survival study was performed on 10 rats in each group. Cell signaling involved in proliferation, differentiation and apoptosis was confirmed at the early postoperative period after liver surgery and subsequently progressive necrosis was observed, as described previously[3,12,13,18,29-31]. Serum and plasma were collected at 6 h after surgery (*n* = 5, in each group). Liver samples were also collected at 6 h after surgery for histopathological/immunohistological assessments, western blotting and gelatin zymography (*n* = 5, in each group).

Biochemical assays and coagulation profile

Aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (T-Bil), the international normalized ratio of prothrombin time (PT-INR) and hyaluronic acid (HA) were measured. Serum AST, ALT and T-Bil were assessed by commercial kits (SGOT, SGPT and total bilirubin reagent, respectively; Biotron, Hemet, CA, United States). The PT-INR in the plasma was measured by the i-STAT System (Abbott, Princeton, NJ, United States). Serum HA was measured using a commercial kit (Quantikine Hyaluronan ELISA Kit; R

and D Systems, Minneapolis, MN, United States).

Histopathological and immunohistological assessments

Liver tissue was fixed in 10% neutral-buffered formalin, embedded in paraffin, and sliced into 4-μm sections. The morphological characteristics and graft injury scores were assessed after hematoxylin-eosin (HE) staining. The graft damage score has been described previously[34]. Scores were counted in 10 fields (× 100 magnification) in each slide and these scores were averaged in each HE slide.

Induction of apoptosis was assessed by immunostaining of terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick-end labeling (TUNEL) (ApopTag Peroxidase *In Situ* Apoptosis Detection Kit, S7100; Chemicon International, Billerica, MA, United States) and cysteine aspartic acid protease (caspase) 3 [Cleaved Caspase-3 (Asp175) Antibody, 9661S; Cell Signaling Technology, Danvers, MA, United States]. A TUNEL-positive nucleus was stained brown and a negative nucleus was counterstained light blue. A caspase-3-positive nucleus was stained brown and a negative nucleus was counterstained blue. Slides were scanned with an automated high-throughput scanning system (Scanscope XT, Aperio Technologies, Vista, CA, United States). To quantify the immunohistological findings, positive-stained nuclei were counted by Aperio Imagescope software (Aperio Technologies). All nuclei were classified into four color intensity levels and the higher two levels were considered as positive. The ratio of positive-stained nuclei to all nuclei was calculated and the mean ratio/mm^2 was determined.

Western blotting and gelatin zymography

The primary antibodies for malondialdehyde (MDA) (Anti-Malondialdehyde antibody, ab6463; Abcam, Cambridge, MA, United States); 4-hydroxynonenal (4-HNE) (4 Hydroxynonenal antibody, ab46545; Abcam); ataxia telangiectasia mutated kinase (ATM) (Phospho-ATM/ATR Substrate Rabbit mAb, 2909; Cell Signaling Technology); phosphorylated histone H2AX (γH2AX) (Phospho-Histone H2A.X Antibody, 2577; Cell Signaling Technology); phosphatidylinositol 3-kinase (PI3K) (Phospho-PI3K p85/p55 Antibody, 4228; Cell Signaling Technology); Akt (Phospho-Akt Rabbit mAb, 4058; Cell Signaling Technology); superoxide dismutase (SOD) (Cu/Zn Superoxide Dismutase, LS-B2907; LifeSpan Biosciences, Seattle, WA, United States); catalase (Catalase, LS-B2554; LifeSpan BioSciences); MMP-9 (Anti-MMP-9, Catalytic domain, AB19016; Millipore, Temecula, CA,

Figure 1 Survival curves. OLT: Orthotopic liver transplantation; SOLT: Split orthotopic liver transplantation.

United States); MMP-2 [MMP-2 antibody (MMP2/8B4), ab7032; Abcam]; TIMP-1 [Anti-TIMP-1 Mouse mAb (102D1), IM63; Calbiochem, San Diego, CA, United States]; and TIMP-2 [Anti-TIMP2 antibody (3A4), ab1828; Abcam] were used. Glyceraldehyde-3-phosphate dehydrogenase served as a control. Signals were quantified using ImageQuant 5.0 software (Molecular Dynamics, Sunnyvale, CA, United States). Gelatinase activity was visualized by fluorescence microscopy (Olympus BX50; Olympus Optical, Tokyo, Japan).

Statistical analysis

The results were presented as mean $\pm$ SD. Student's t test was used for the comparison of unpaired continuous variables between groups. Survival curves were constructed by the Kaplan-Meier method (Log-rank test). Statistical calculations were performed using SPSS version 16.0 (SPSS Inc., Chicago, IL, United States). $P < 0.05$ was considered statistically significant.

RESULTS

Survival curves

Survival curves for each group are shown in Figure 1. All rats that underwent a laparotomy or 100% OLT survived. The 60% hepatectomy and 40% SOLT groups clearly showed poorer survival than the controls ($P < 0.0001$). Insufficient liver remnant resulted in poor survivals after 60% hepatectomy. Especially, 40% SOLT showed very poor survivals.

Liver parenchymal damage

In comparison with the controls (0.1 $\pm$ 0.1 points), there were significant differences in the graft damage score for 60% hepatectomy (3.7 $\pm$ 0.7 points, $P < 0.0001$), 100% OLT (4.0 $\pm$ 0.6 points, $P < 0.0001$) and 40% SOLT (5.8 $\pm$ 1.1 points, $P < 0.0001$) (Figure 2A).

Immunohistological assessment of apoptosis induction

In comparison with the controls (0.003 $\pm$ 0.004), the rates of TUNEL-positive nuclei showed significant dif-

ferences in 60% hepatectomy (0.017 $\pm$ 0.009, $P = 0.0278$), 100% OLT (0.107 $\pm$ 0.012, $P = 0.0001$) and 40% SOLT (0.166 $\pm$ 0.052, $P < 0.0001$) (Figure 2B). In comparison with the controls (0.002 $\pm$ 0.002), the rates of caspase-3-positive nuclei revealed significant differences in 60% hepatectomy (0.044 $\pm$ 0.023, $P = 0.0033$), 100% OLT (0.063 $\pm$ 0.014, $P < 0.0001$) and 40% SOLT (0.115 $\pm$ 0.019, $P < 0.0001$) (Figure 2C).

Conventional liver function tests, coagulation profile and endothelial damage

In comparison with the controls (42.5 $\pm$ 8.6 U/L), AST levels showed significant differences in 60% hepatectomy (202.4 $\pm$ 41.9 U/L, $P < 0.0001$), 100% OLT (290.5 $\pm$ 31.9 U/L, $P < 0.0001$) and 40% SOLT (387.4 $\pm$ 36.8 U/L, $P < 0.0001$) (Figure 3A). In comparison with the controls (59.8 $\pm$ 9.6 U/L), ALT levels showed significant differences in 60% hepatectomy (213.8 $\pm$ 57.0 U/L, $P < 0.0001$), 100% OLT (309.4 $\pm$ 38.3 U/L, $P < 0.0001$) and 40% SOLT (392.2 $\pm$ 76.7 U/L, $P < 0.0001$) (Figure 3B). In comparison with the controls (0.41 $\pm$ 0.13 mg/dL), there were no significant differences in T-Bil levels in 60% hepatectomy (0.50 $\pm$ 0.26 mg/dL, $P = 0.4798$) and 100% OLT (0.58 $\pm$ 0.15 mg/dL, $P = 0.0801$), but there was in 40% SOLT (1.37 $\pm$ 0.29 mg/dL, $P = 0.0001$) (Figure 3C).

In comparison with the controls (0.99 $\pm$ 0.04), PT-INR values revealed significant differences in 60% hepatectomy (1.16 $\pm$ 0.09, $P = 0.0052$), 100% OLT (1.12 $\pm$ 0.04, $P = 0.0008$) and 40% SOLT (1.22 $\pm$ 0.06, $P < 0.0001$) (Figure 3D).

In comparison with the controls (76.6 $\pm$ 14.9 ng/mL), HA levels demonstrated significant differences in 60% hepatectomy (264.0 $\pm$ 58.8 mg/dL, $P = 0.0001$), 100% OLT (188.0 $\pm$ 29.0 mg/dL, $P < 0.0001$) and 40% SOLT (350.2 $\pm$ 136.6 mg/dL, $P = 0.0021$) (Figure 3E).

Oxidative stress

The western blotting intensities of MDA in each group are shown in Figure 4A. In comparison with the controls (1.00 $\pm$ 0.10), normalized MDA showed significant differences in 60% hepatectomy (1.64 $\pm$ 0.39, $P = 0.0074$), 100% OLT (2.12 $\pm$ 0.78, $P = 0.0133$) and 40% SOLT (2.30 $\pm$ 0.26, $P < 0.0001$) (Figure 4B).

Lipid peroxidation

In comparison with the controls (1.00 $\pm$ 0.09), normalized 4-HNE showed significant differences in 60% hepatectomy (1.30 $\pm$ 0.20, $P = 0.0152$), 100% OLT (1.41 $\pm$ 0.20, $P = 0.0028$) and 40% SOLT (1.40 $\pm$ 0.19, $P = 0.0032$) (Figure 4C).

Responses and repairs to DNA damage

In comparison with the controls (1.00 $\pm$ 0.098), normalized ATM showed significant differences in 60% hepatectomy (1.15 $\pm$ 0.09, $P = 0.0336$), 100% OLT (1.28 $\pm$ 0.10, $P = 0.0015$) and 40% SOLT (1.21 $\pm$ 0.09, $P = 0.0053$) (Figure 4D). In comparison with the controls (1.00 $\pm$ 0.17), normalized γH2AX showed significant differences

in 60% hepatectomy (1.39 ± 0.29, P = 0.0071), 100% OLT (1.67 ± 0.38, P = 0.0303) and 40% SOLT (2.59 ± 0.66, P = 0.0008) (Figure 4E).

Promotion of cell survival
The western blotting intensities of PI3K and Akt in each group are shown in Figure 4F.

In comparison with the controls (1.00 ± 0.08), there was no significant difference in normalized PI3K in 100% OLT (0.92 ± 0.09, P = 0.1726), but there were significant differences in 60% hepatectomy (00.36 ± 0.11, P < 0.0001) and 40% SOLT (0.42 ± 0.19, P = 0.0002) (Figure 4G). In comparison with the controls (1.00 ± 0.12), there was no significant difference in normalized Akt in 100% OLT (0.92 ± 0.37, P = 0.6486), but there were significant differences in 60% hepatectomy (0.37 ± 0.23, P = 0.0007) and 40% SOLT (0.34 ± 0.24, P = 0.0006) (Figure 4H).

Activities of antioxidant enzymes
In comparison with the controls (1.00 ± 0.09), normalized SOD did not show significant differences in 60%

hepatectomy (0.97 ± 0.09, P = 0.6503), 100% OLT (0.96 ± 0.11, P = 0.5461) and 40% SOLT (0.87 ± 0.09, P = 0.0595) (Figure 4I). In comparison with the controls (1.00 ± 0.17), normalized catalase also revealed no significant differences in 60% hepatectomy (0.91 ± 0.11, P = 0.3665), 100% OLT (0.90 ± 0.15, P = 0.3365) and 40% SOLT (0.95 ± 0.14, P = 0.6454) (Figure 4J).

Behavior of MMP-9, MMP-2, TIMP-1 and TIMP-2
Protein expression and activity of MMP-9 are shown in Figure 5A. Protein expression was evaluated by western blot densitometry (Figure 5B-D). In comparison with the controls (1.00 ± 0.34), there were no significant differences in normalized MMP-9 in 60% hepatectomy (1.14 ± 0.43, P = 0.5811) and 100% OLT (1.18 ± 0.35, P = 0.4254), but there was a significant difference in 40% SOLT (2.16 ± 0.26, P = 0.0003) (Figure 5B). In comparison with the controls (1.00 ± 0.16), there were no significant differences in normalized MMP-2 in 60% hepatectomy (0.78 ± 0.17, P = 0.0716) and 100% OLT (0.80 ± 0.23, P = 0.1437), but there was a significant difference in 40% SOLT (0.78 ± 0.12, P = 0.0385) (Figure

Figure 3 Biochemical and coagulation profiles. 5C). In comparison with the controls (1.00 ± 0.30), there was no significant difference in normalized TIMP-1 in 100% OLT (0.82 ± 0.43, $P = 0.4654$), but there were significant differences in 60% hepatectomy (1.41 ± 0.26, $P = 0.0491$) and 40% SOLT (1.46 ± 0.32, $P = 0.0486$) (Figure 5D). In comparison with the controls ($1.00 \pm$ 0.24), there were no significant differences in normalized TIMP-2 in 60% hepatectomy (1.23 ± 0.24, $P = 0.1605$) and 100% OLT (0.95 ± 0.17, $P = 0.6846$), but there was a significant difference in 40% SOLT (1.28 ± 0.12, $P = 0.0471$) (Figure 5E).

Protein activities were evaluated by intensity in zy-

Figure 4 Protein expression of malondialdehyde, 4-hydroxynonenal, ataxia-telangiectasia mutated kinas/H2AX, phosphatidylinositol 3-kinase/Akt and antioxidant enzymes. mography (Figure 5F-I). In comparison with the controls (1.00 ± 0.15), relative MMP-9 clearly demonstrated significant differences in 60% hepatectomy (1.37 ± 0.23, P = 0.0156), 100% OLT (1.47 ± 0.33, P = 0.0211) and 40% SOLT (2.10 ± 0.75, P = 0.0125) (Figure 5F). In comparison with the controls (1.00 ± 0.17), relative MMP-2 did not reveal significant differences in 60% hepatectomy (1.03 ± 0.12, P = 0.7444), 100% OLT (0.98 ± 0.15, P = 0.8821) and 40% SOLT (1.04 ± 0.13, P = 0.6847) (Figure 5G). In comparison with the controls (1.00 ± 0.15), relative TIMP-1 did not reveal significant differences in 60% hepatectomy (0.96 ± 0.29, P = 0.7926), 100% OLT (0.98 ± 0.09, P = 0.8217) and 40% SOLT (0.91 ± 0.26, P = 0.5347) (Figure 5H). In comparison with the controls (1.00 ± 0.12), relative TIMP-2 did not show significant differences in 60% hepatectomy (1.04 ± 0.09, P = 0.5974), 100% OLT (1.03 ± 0.11, P = 0.6845) and 40% SOLT (1.03 ± 0.16, P = 0.7495) (Figure 5I).

Statistical differences between groups

As described above, the data in comparisons with the controls are shown. Statistical differences between groups are summarized in Table 2.

DISCUSSION

In survival and histopathological studies, 40% SOLT involved dual damage (*i.e.*, shear stress with portal hypertension and CIWR injury) and showed the poorest survival and most severe liver damage. Although 100% OLT showed good survival, CIWR injury was observed by histopathological and biochemical findings. Here, we used plasma PT-INR and serum HA levels as markers of sinusoidal endothelial damage and all groups showed significant differences. Survival in the 60% hepatectomy and 40% SOLT groups seemed to be higher than in

the 100% OLT group and this may reflect the damage induced by shear stress and portal hypertension. Our histopathological, immunohistological and biochemical findings revealed that liver damage and apoptotic induction were observed in the early postoperative period after liver surgery, as in previous studies[3,12,13,18,29-31]. Paradoxically, the early postoperative period may have a therapeutic potential for a subsequent course after liver surgery.

OS causes DNA damage and subsequent apoptosis and is an imbalance between production of free radicals and antioxidant defenses[9-11]. From the viewpoint of production of free radicals, ROS/RNS can attack and damage a variety of critical biological molecules, including lipids, essential cellular proteins and DNA[9-11]. Products of lipid peroxidation can be easily detected in biological fluids and tissues and can reliably and rapidly reflect the sensitive and specific signals of lipid peroxidation that occur *in vivo*[35,36]. The compound 4-HNE is an end product of lipoperoxidation with antiproliferative and proapoptotic properties[35,36]. Our results with MDA and 4-HNE confirmed that OS occurred even in the early postoperative period.

With regard to DNA damage responses, the protein kinase ATM can be initiated through rapid intermolecular autophosphorylation induced by DNA damage, phosphorylate various proteins and subsequently amplify the responses to DNA damage[36,37]. This DNA damage-inducible kinase activates H2AX[38]. H2AX is required for cell cycle arrest and DNA repair following double-stranded DNA breaks[38,39]. DNA damage results in the rapid phosphorylation of H2AX by ATM[38,40]. Within minutes of DNA damage, H2AX is phosphorylated at the sites of the DNA damage[38]. This early event in the DNA-damage response is required for the recruitment of many DNA-damage response proteins. Therefore, histone H2AX is activated by ATM after DNA dam-

age[38]. Thus, the ATM/H2AX signaling pathway is important in the response to and repair of DNA damage induced by OS[38,41]. Our results with ATM and H2AX clearly showed that OS after liver surgery caused DNA damage signaling and triggered subsequent DNA repair. In this study, groups with only CIWR injury (*i.e.*, 100%

OLT) caused OS-induced damage and subsequent apoptotic process. However, this group showed differences not in PI3K/Akt, but in ATM/H2AX. These results suggested that CIWR injury induce apoptosis due to OS *via* the ATM/H2AX pathway.

Akt also plays a critical role in controlling apoptosis

and promotes cell survival to prohibit apoptosis[42-44]. Apoptotic machinery is inhibited by the activation of Akt[42-44]. Akt is an integral component of the antiapoptotic process related to the activation of PI3K[42-45]. Our results clearly showed that groups with accompanying shear stress and portal hypertension (*i.e.*, 60% hepatectomy and 40% SOLT) had decreased PI3K and Akt. This suggested that a subsequent apoptotic process was triggered in these groups. Shear stress and portal hypertension due to insufficient liver volume induce apoptosis due to OS *via* the Akt/PI3K pathway.

With regard to antioxidant defense, scavenging enzymes of free radicals, such as SOD and catalase, also play an important role in reducing DNA damage and subsequent apoptosis[10,11]. Cells are normally able to defend themselves against OS-induced damage through this scavenging system[10,11]. Our results revealed that this scavenging system did not appear to be triggered, although these scavenging enzymes can cope with large amounts of ROS[46]. Shear stress with portal hypertension and/or CIWR injury after liver surgeries in this study caused considerable liver damage. A possible explanation is that this scavenging system failed to stimulate some reactive molecules because of considerable damage after liver surgery.

MMPs have been intensively studied and shown to play key roles in inflammation, carcinogenesis and regeneration and many researchers have already focused on MMP-2 and MMP-9 after liver surgery[12-21]. In the present study, 40% SOLT increased protein expression of MMP-2 in western blotting, although zymography did not show any differences. Contrary to MMP-2, postoperative MMP-9 clearly showed differences in protein expression and function. Additionally, MMP-9 showed high reproducibility in our previous studies[20,47,48]. The present results for MMP-9 suggested that MMP-9 clearly increased even in the early postoperative period after liver surgery and MMP-9 is a major therapeutic target after liver surgery.

TIMPs are also important after liver surgery. Many researchers have focused on TIMP-1 and TIMP-2 during liver regeneration[25-28]. Some researchers have focused on postoperative behavior of TIMP-1[28]. In particular, TIMP-1 has extrahepatic effects during liver failure[23,49-52] and therefore we initially expected that TIMP-1 would show differences in the liver samples. However, zymography for TIMP-1 did not show any differences, although groups with shear stress and portal hypertension (*i.e.*, 60% hepatectomy and 40% SOLT) showed increased protein expression of TIMP-1 in western blotting. TIMP-1 is an endogenous inhibitor of MMP-9 and a balance of MMP-9/TIMP-1 is linked[22,23]. However, the behavior of TIMP-1 in the postoperative liver is still unclear and further studies are required.

Liver damage and apoptotic induction are confirmed even in the early postoperative period after liver surgery but liver injury triggers the liver regeneration cascade after surgery. Once hepatic failure occurs after liver surgery, this damage is usually intractable and fatal.

Therefore, the early postoperative period may be a suitable time for treatment to achieve a good postoperative course after liver surgery and our lab focused on OS-mediated damage and the behavior of extracellular matrices after liver surgery[20,48,51,53-56]. The inhibition of apoptotic induction due to OS *via* the ATM/H2AX pathway may be important for a strategy against CIWR injury, even in the condition of sufficient liver volume. Under conditions with insufficient liver remnant, the prevention of apoptotic induction due to OS *via* the Akt/PI3K pathway may be key to improving postoperative course. Also, MMP-9 may be a reliable therapeutic target, especially in the condition of CIWR injury with insufficient liver volume. We hope that our results will be informative for researchers in the hepatology field.

COMMENTS

Background
After liver surgery, shear stress with portal hypertension and cold ischemia/warm reperfusion injury trigger the liver regeneration cascade and also cause fatal liver damage.

Research frontiers
Changes and behaviors of oxidative stress and extracellular matrices are still unknown.

Innovations and breakthroughs
Here, the authors investigate the oxidative stress-mediated damage and the behavior of extracellular matrices after liver surgery in various rat models.

Applications
Under conditions with insufficient liver remnant, prevention of oxidative stress-induced damage *via* the Akt/PI3K pathway may be key to improve postoperative course. MMP-9 may be also a therapeutic target after liver surgery.

Terminology
Regulations for oxidative stress and MMP-9 may have a therapeutic potential, in order to resolve the current problems after liver surgery.

Peer review
This is a very interesting paper about the pathophysiology of hepatic failure after hepatectomy and liver transplantation.

Abstract

AIM: To assess differing patterns and levels of ascitic fluid cyctokine and growth factors exist between those with a high risk and low risk of spontaneous bacterial peritonitis (SBP).

METHODS: A total of 57 consecutive patients with ascites requiring a large volume paracentesis were studied. Their age, gender, specific underlying disease conditions were recorded after a review of their clinical records. Each underwent a routine assessment prior to their paracentesis consisting of a complete blood count, complete metabolic profile and prothrombin time/international normalized ratio (INR) determination. The ascitic fluid was cultured and a complete cell count and albumin determination was obtained on the fluid. In addition, blood and ascitic fluid was assessed for the levels of interleukin interleukin (IL)-1A, IL-1B, IL-2, IL-4, IL-8, IL-10, monocyte chemotactic protein (MCP)-1, tumor necrosis factor (TNF)-α, interferon (IFN)-γ, vascular endothelial growth factor (VEGF) and epidermal growth factor (EGF) utilizing the Randox Biochip platforms (Boston, MA). A serum-ascites gradient, for each cytokine and growth factor was calculated. The results are reported as mean ± SEM between disease groups with statistical analysis consisting of the student t-test (two tailed) with a P value of 0.05 defining significance.

RESULTS: No clinically important demographic or biochemical differences between the 4 groups studied were evident. In contrast, marked difference in the cytokine and growth factors levels and pattern were evident between the 4 disease groups. Individuals with alcoholic cirrhosis had the highest levels of IL-1A, IL-1B, IL-4, IFNγ. Those with malignant disease had the highest levels of IL-2. Those with hepatitis C virus (HCV) associated cirrhosis had the highest value for IL-6, IL-8, IL-10, MCP-1 and VEGF. Those with cardiac disease had the highest level of TNF-α and EGF. The calculated serum-ascites gradients for the cardiac and malignant disease groups had a greater frequency of negative values signifying greater levels of IL-8, IL-10 and MCP-1 in ascites than did those with alcohol or HCV disease.

CONCLUSION: These data document important differences in the cytokine and growth factor levels in plasma, ascitic fluid and the calculated plasma - ascites fluid gradients in cirrhotics requiring a large volume paracentesis. These differences may be important in determining the risk for bacterial peritonitis.

Core tip: Previous studies have examined factors relative to the pathogenesis of spontaneous bacterial peritonitis (SBP) in patients with cirrhosis of the liver. This study was designed to examine the role of cytokines in decompensated cirrhotics requiring a large-volume paracentesis for ascites management and to compare the biomarker responses present in both the plasma and ascitic fluid of cirrhotics of differing etiologies. Factors likely to represent protective cytokines associated with a reduced risk for SBP include epidermal growth factor, tumor necrosis factor-α, interleukin (IL)-1A, IL-8, and IL-10. Those are more likely to be associated with potential for SBP include: IL-1B, IL-4, monocyte chemotactic protein -1, and interfero-γ.

INTRODUCTION

Large-volume ascites occurring in cirrhotic patients has been shown to manifest an inflammatory response characterized by increased levels of cytokines, interleukins and several growth factors[1]. The pathophysiologic mechanisms responsible for the development of cirrhosis and ultimately decompensated cirrhosis vary as a function of the underlying hepatic disease[2,3]. These differences in pathophysiology may be reflected in the cytokine, interleukin and growth factor induced response that occurs. Moreover, depending upon the site of inflammatory cell activation, differences in plasma and ascitic fluid levels of inducible cytokines and growth factors may exist. These differences may explain in part an increase rate of bacterial translocation and subsequent spontaneous bacterial peritonitis (SBP) development.

Previous studies have reported that cytokine characteristics of the Th1 response are increased in decompensated cirrhosis especially with infection[4]. Interleukin (IL)-4 which is a major cytokine of the Th2 response was not significantly different between decompensated cirrhotic patients with infected or non-infected ascites[4]. The current study was designed to confirm these findings and expanding it to study the role of growth factors in cirrhotics with non-infected ascites.

The aim of this investigation was: (1) to identify and quantitate the plasma and ascitic fluid biomarkers of inflammation in decompensated cirrhotics requiring a large-volume paracentesis for ascites management and (2) to compare and contrast the biomarker responses present in both the plasma and ascitic fluid of cirrhotics of differing etiologies.

MATERIALS AND METHODS

Subjects

A total of 57 consecutive cirrhotics requiring a large-volume paracentesis for clinical reasons were studied. Their age, gender and the specific disease etiology for their cirrhosis was determined by a review of their clinical records and, when necessary additional clinical testing procedures. Four distinct etiologic groups of cirrhotics were identified and the cytokine levels were compared between groups in an effort to examine the role of the etiologic factor responsible for cirrhosis in each subgroup.

Inclusion and exclusion criteria

Inclusion criteria: (1) cirrhosis documented by imaging (either an abnormal CT or US) or liver biopsy; (2) ascites requiring a large volume paracentesis because of tense ascites and failure to control the ascites with diuretics (furosemide and spironolactone); and (3) willingness to undergo a large volume paracentesis and sign an informed written consent documenting their participation and allowing for the additional studies required as a result of their participation.

Exclusion criteria: (1) no evidence for cirrhosis; (2) no ascites or adequate ascites control with diuretics; and (3) unwillingness to participate and sign an informed written consent.

Investigations

Each subject had the following routine laboratory studies determined: complete blood count, complete metabolic profile consisting of blood urea nitrogen, creatinine, glucose, total bilirubin, alkaline phosphatase, aspartate and alanine aminotransferases, total protein, albumin, and prothrombin time/INR. Each patient had a calculated Child-Turcotte-Pugh (CTP) score and the following studies were obtained on their ascitic fluid: cell counts for red blood cells, white blood cells and differential, albumin and ascitic fluid cultures. In addition to these routine measures, the plasma and ascitic fluid of each subject was assayed for a panel of biomarkers of inflammation to include the following: procalcitonin, IL-1A, IL-1B, IL-2, IL-4, IL-8, IL-10, monocyte chemotactic protein (MCP)-1, tumor necrosis factor (TNF)-α, interferon (IFN)-γ, vascular endothelial growth factor (VEGF) and epidermal growth factor (EGF). Procalcitonin was assayed utilizing the BioMerieux Vidas assay (Lombard, Illinois). The interleukins, inflammatory cytokines and growth factors were assayed utilizing Randox Biochip assay Platforms (Boston, Massachusetts). All results were compared to that of a normal human plasma panel utilized as a control sample which was obtained commercially from Bioreclamation, LLC (Liverpool, NY, United States). In addition, the levels of the analytes

Table 1 Characteristics of the 57 subjects' studies and of procalcitonin cytokines, and growth factors in plasma (mean ± SEM)

Parameter	ETOH	HCV	Malignancy	Cardiac

No significant difference between any of these groups $P > 0.05$. HCV: Hepatitis C virus; PCT: Procalcitonin cytokines; IL: Interleukin; MCP-1: Monocyte chemotactic protein-1; IFN-γ: Interferon-γ; TNF-α: Tumor necrosis factor-α; EGF: Epidermal growth factor; VEGF: Vascular endothelial growth factor.

present in plasma were compared against those in the patients' ascitic fluid. Plasma- Ascites gradients were calculated for each analyte and the mean for each disease group was calculated.

Human research approval

The IRB of Cook County Health and Hospital System approved this study prior to its initiation. Each subject signed an informed written consent before their participation in the study. Moreover, the Cook County Health and Hospital System funded the study in its entirety.

Statistical analysis

The mean and standard error of the mean for each parameter was determined and the differences between the means of the various disease groups studies were calculated utilizing the students *t*-test. A *P* value < 0.05 was considered to be significant.

RESULTS

The characteristics of the 57 subjects studied are shown in Table 1. No clinically important differences between the 4 disease groups studied were evident. In contrast, the procalcitonin levels in plasma varied substantially between groups with the greatest values being present in the group with malignancy (Table 1). The lowest procalcitonin values were seen in those with cardiac cirrhosis. The alcoholic and hepatitis C positive groups had plasma procalcitonin levels that were midway between these two extremes (Table 1).

The ascitic fluid procalcitonin levels mirrored the plasma levels with the greatest values being found in the group with malignancy and the lowest levels being pres-

ent in those with cardiac disease. Again the other two groups had values midway between these two extremes (Table 2). Interestingly, however the alcoholic subgroup had an ascitic fluid procalcitonin value that was greater than that of the hepatitis C positive subgroup such that the relative position of the procalcitonin level in the two subgroups was reversed as compared to that found in plasma (Tables 1 and 2).

The cytokine and growth factor values varied markedly between groups for each parameter studied (Tables 3 and 4). The mean levels of the various factors measured in plasma aligned from the highest to the lowest for each disease group is reported in Table 3. Individuals with alcoholic liver disease had the highest IL-1a, IL-1b, IL-4 and interferon gamma levels. Individuals with malignant the liver disease had the highest values for IL-2. Those with hepatitis C had the highest levels IL-6, IL-8, IL-10, MCP-1 and VEGF.

The mean values for the ascitic fluid levels of the same 12 factors aligned from the highest to the lowest is presented in Table 4. The cardiac group had the greatest values for 5 of the 12 factors measured followed by the alcoholic group with 3 and the other 2 groups with 2 each. The malignancy group at the lowest value for 5 factors followed by the cardiac group with 3 and the other 2 groups with 2 each. Because of the variability in the measured values, the groups did not differ statistically, but when one examines the mean values per se considerable differences are seen between the various groups with mean plasma values ranging from 1.5-20 times the values of the lowest value for each parameter (Table 4). Similarly, when one examines the mean values in the ascitic fluid, the range of values for a given factor between groups ranged from 1.3-10 times the value

of the lowest value (Table 5). The plasma-ascitic fluid gradients for each parameter were determined and are reported in (Table 5). A positive value for the plasma-ascitic fluid gradient identifies those factors wherein the plasma level was greater than the ascitic fluid level. In contrast, a negative value for the plasma-ascitic fluid gradient identifies those factors wherein the greater value was present in the ascitic fluid. A positive value suggests that the cytokine assayed arose from a systemic response while a negative value suggests that the response arose primarily in the abdominal cavity and that either a peritoneal or mesenteric origin for the cytokine.

DISCUSSION

This study extends the finding of an earlier study evaluating cytokine, and growth factor levels in the plasma and ascitic fluid of cirrhotics[1]. In both studies, the inflammatory cytokines IL-4, IL-6, IL-8, IL-10, TNF-α and MCP-1 have been shown to be increased in both the ascitic fluid and plasma of cirrhotics with large volume ascites. The present study performed in a completely different and slightly larger patient population extends the earlier study by documenting differences in the cytokine profiles based on the individuals underlying disease etiol-

No significant difference between any of these groups $P > 0.05$. HCV: Hepatitis C virus; IL: Interleukin; MCP-1: Monocyte chemotactic protein-1; IFN-γ: Interferon-γ; TNF-α: Tumor necrosis factor-α; EGF: Epidermal growth factor; VEGF: Vascular endothelial growth factor.

ogy for the cirrhosis[1]. The current data suggests therefore that the pathophysiologic responses to the various hepatic disease etiologies in some way may determine, at least in part, the innate immune responses that occur and account for the differences in the cytokine and growth factor levels in the ascitic fluid and plasma[2,3]. The IL-6 and MCP-1 levels were universally increased in all four cirrhotic groups. VEGF levels were increased most markedly in those with malignancy and to a lesser degree in those with cardiac and alcohol induced disease. Individuals with cirrhosis due to hepatitis C had the lowest VEGF levels. In contrast, the hepatitis C positive group had the greatest levels of IL-4 present in both plasma and ascitic fluid.

The finding of an increase in VEGF levels in cirrhotics with malignancy is interesting but not particularly surprising as malignant disorders are known to be associated with increased VEGF levels[5,6]. The increase of VEGF levels in cardiac and alcohol induced liver disease is surprising and differs markedly from that seen in those with hepatitis C. This observation is consistent with the data reported in other studies wherein increased organ remodeling has been observed in individuals with cardiac and alcohol related disease but not so in those with hepatitis C virus[2,3].

These data also support the role of the peritoneal based immune response in the pathogenesis of both bacterial translocations spontaneous bacterial peritoni-

tis[1,7-14]. More specifically, they are consistent with the clinical observations that spontaneous bacterial peritonitis occurs less frequently in patients with cardiac and malignant ascites as contrasted to those with alcoholic liver disease and chronic viral induced liver disease.

As shown in Table 4, cardiac disease associated ascites has the highest ascetic fluid levels of IL-1A, IL-8, IL-10, TNF-α, and EGF. Conversely, the cardiac disease associated ascites has the lowest levels of IL-2 and MCP-1. Those with malignancy associated ascites have the highest levels of IL-2 and VEGF and the lowest levels of IL-1A, IL-4, IL-8, IL-10, and TNF-α.

The present findings for these two distinct etiologic groups suggest that the ascitic fluid immune response manifested in the ascitic fluid may account in some way for the lower rate of spontaneous bacterial peritonitis in individuals with ascites due to these two unique causes of cirrhosis.

Factors likely to represent protective cytokines associated with a reduced risk for SBP include EGF, TNF-α, IL-1A, IL-8, and IL-10. Those are more likely to be associated with potential for SBP include: IL-1B, IL-4, MCP-1, and IFN-γ (Table 4).

The data shown in Table 5 consisting of the serum-ascites gradient enables one to determine whether the primary source of the measured factor arose from the vascular space or the peritoneal cavity. Specifically, those with the positive value identify a primary vascular source of the measured factor while a negative value identifies these factors having their origin in the peritoneal cavity.

In summary, the present data suggest the well-recognized factors that include a reduced plasma oncotic pressure, increased splanchnic venous congestion and pressure, increased vascular permeability and an overwhelmed lymphatic mechanism for removing ascitic fluid account substantially for the development of clinical ascites. They suggest that unique immune related responses that differ between various hepatic disease states may also contribute to the development of ascites and the likelihood of developing spontaneous bacterial peritonitis. Further, these data suggest further that a better understanding of the different immune response characteristics present in cirrhotics of different etiologies may enable disease specific modulation of the immune response in each and thereby contribute to the development of improved therapies that control not only to the development of ascites but also overall disease progression.

COMMENTS

Background
Large-volume ascites occurring in cirrhotic patients has been shown to manifest an inflammatory response characterized by increased levels of cytokines, interleukins and several growth factors. The pathophysiologic mechanisms responsible for the development of cirrhosis and ultimately decompensated cirrhosis vary as a function of the underlying hepatic disease.

Research frontiers
This study extends the finding of an earlier study evaluating cytokine, and growth factor levels in the plasma and ascitic fluid of cirrhotics.

Innovations and breakthroughs
The current data suggests therefore that the pathophysiologic responses to the various hepatic disease etiologies in some way may determine, at least in part, the innate immune responses that occur and account for the differences in the cytokine and growth factor levels in the ascitic fluid and plasma.

Applications
The authors suggest that unique immune related responses that differ between various hepatic disease states may also contribute to the development of ascites and the likelihood of developing spontaneous bacterial peritonitis.

Peer review
The authors performed plasma and ascitic cytokines among various etiologies of cirrhosis.

Abstract

AIM: To determine the frequencies of mutations that cause inherited monogenic liver disorders in patients with chronic hepatitis C.

METHODS: This study included 86 patients with chronic hepatitis C (55 men, 31 women; mean age at diagnosis, 38.36 ± 14.52 years) who had undergone antiviral therapy comprising pegylated interferon and ribavirin. Viral load, biochemical parameter changes, and liver biopsy morphological data were evaluated in all patients. The control group comprised 271 unrelated individuals representing the general population of Latvia for mutation frequency calculations. The most frequent mutations that cause inherited liver disorders [gene (mutation): *ATP7B* (H1069Q), *HFE* (C282Y, H63D), *UGT1A1* (TA)7, and *SERPINA1* (PiZ)] were detected by polymerase chain reaction (PCR), bidirectional PCR allele-specific amplification, restriction fragment length polymorphism analysis, and sequencing.

RESULTS: The viral genotype was detected in 80 of the 86 patients. Viral genotypes 1, 2, and 3 were present in 61 (76%), 7 (9%), and 12 (15%) patients, respectively. Among all 86 patients, 50 (58%) reached an early viral response and 70 (81%) reached a sustained viral response. All 16 patients who did not reach a sustained viral response had viral genotype 1. Case-control analysis revealed a statistically significant difference in only the H1069Q mutation between patients and controls (patients, 0.057; controls, 0.012; odds ratio, 5.514; 95%CI: 1.119-29.827, $P = 0.022$). However, the H1069Q mutation was not associated with antiviral treatment outcomes or biochemical indices. The (TA)7 mutation of the *UGT1A1* gene was associated with decreased ferritin levels (beta regression coefficient = -295.7, $P = 0.0087$).

CONCLUSION: Genetic mutations that cause inherited liver diseases in patients with hepatitis C should be studied in detail.

Key words: Hepatitis C; Hepatolenticular degeneration (Wilson's disease); *ATP7B*; *SERPINA1*; *UGT1A1*; *HFE*

Core tip: This is the first study to evaluate the association between hepatitis C and the most frequently inherited monogenic liver diseases (hereditary hemochromatosis, alpha-1 antitrypsin deficiency, Gilbert's syndrome, and Wilson's disease) and their causative mutations. This case-control study revealed an association between hepatitis C and the mutation that causes Wilson's disease. In addition, biochemical data analysis

revealed an association between hepatitis C and the mutation that causes Gilbert's syndrome.

INTRODUCTION

Hepatitis C is an infectious disease caused by the hepatitis C virus (HCV), which primarily affects the liver. An estimated 130 to 200 million people worldwide are infected with HCV[1]. The most common monogenic inborn errors of metabolism associated with liver disease are hereditary hemochromatosis, alpha-1 antitrypsin deficiency, Wilson's disease, and Gilbert's syndrome. These diseases have a particularly high frequency in Northern Europe and Latvia[2-4]. Hereditary hemochromatosis is characterized by excessive iron overload and is most commonly caused by *HFE* gene mutations[2]. The frequency of the most common *HFE* mutation, C282Y, is 0.035 in Latvia and 0.026 Lithuania; however, the frequency of hereditary hemochromatosis is lower at 0.013[5]. Alpha-1 antitrypsin deficiency is caused by the absence of the proteinase inhibitor alpha-1 antitrypsin, and affected patients develop liver disease and emphysema in the third or fourth decade of life[3]. Wilson's disease is a progressive autosomal recessive disorder of copper metabolism. The carrier frequency of the causative mutation is 1:80 in Latvia and 1:90 in Europe[4]. Finally, Gilbert's syndrome is characterized by benign unconjugated hyperbilirubinemia with a frequency of 5.0% to 14.8% in Europe[6]. Most reports on the coexistence of monogenic liver diseases and HCV infection have focused primarily on hereditary hemochromatosis[7] because elevated iron levels are necessary for viral replication[8,9]. Although the associations of HCV infection with alpha-1 antitrypsin deficiency[10,11] and Gilbert's syndrome[12-14] have been investigated, the association of HCV infection with Wilson's disease remains unclear. Copper reportedly plays a potential role in the development of HCV infection[15,16].

The aim of the present study was to determine the frequency of mutations that cause inherited monogenic liver disorders in patients with chronic HCV infection who have undergone antiviral therapy and in whom the viral response status is known.

MATERIALS AND METHODS

Ethics

This study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the *Central Medical Ethics Committee* of *Latvia*. All study participants signed an informed consent form that was issued according to the regulations of the *Central Medical Ethics Committee* of *Latvia*.

Subjects

Eighty-six patients with HCV infection who had undergone antiviral treatment with ribavirin and pegylated interferon were included in this study. These patients comprised 55 men and 31 women with a mean age at diagnosis of 38.36 ± 14.52 years (men, 37.27 ± 15.69 years; women, 40.25 ± 12.26 years). All patients were of European descent. The pretherapeutic alanine transaminase level, iron level, ferritin level, viral load, and HCV genotype were evaluated in all patients. The Knodell histology activity index was used for morphological examination.

The control group comprised 271 unrelated individuals chosen to represent the general population of Latvia. Participants in the control group underwent polymorphism frequency determination only. Biochemical association analysis, clinical examination, and exclusion of HCV infection were not performed in this group.

Genotyping methods

Peripheral blood genomic DNA was purified by standard phenol: chloroform extraction and ethanol precipitation with slight modification as described elsewhere[17] using reagents from Sigma Aldrich, Inc. (St. Louis, MO, United States). A summary of the methods used in this study is presented in Table 1[4,18-20]. Reagents used for polymerase chain reaction (PCR) (buffers, dNTP mix, Taq polymerase, and agarose) were obtained from Thermo Fisher Scientific (Waltham, MA, United States). Synthetic oligonucleotides, the sequences of which have been previously published[4,18-20], were obtained from Metabion GmbH (Martinsried, Germany). Fluorescent PCR products were analyzed with an ABI Prism 310 Genetic Analyzer (Applied Biosystems Inc., Foster City, CA, United States) using the reagents described in the manufacturer's protocol.

Statistical analysis

PLINK software[21] was used for genotyping data analysis and quality control. Analysis adhered to a call rate of < 98% and Hardy-Weinberg equilibrium P value of $\leqslant$ 0.05. The chi-square test was used to compare the patient and control groups with a significance threshold of $P < 0.05$. SPSS software v.16.0 (SPSS Inc., Chicago, IL, United States) was used to compare mean biochemical marker values between the patient and control groups and between the two patient groups [with and without a sustained viral response (SVR), defined as the inability to detect viral RNA six months after therapy][22]. Parametric values were compared using ANOVA, and nonparametric data were evaluated with the Mann-Whitney test. Genotype association analysis with biochemical markers was conducted using a full linear model comprising

three genetic effects: additive effects of allele dosage, dominance deviation from additivity (a negative value indicates a recessive allele), and the 2-df joint test of both additive and dominance. Beta was evaluated as the regression coefficient. Data were accepted as statistically significant at a *P* value of < 0.05. Sex and age (with confirmed HCV infection) were used separately as covariates. The adjusted beta coefficient and *P* value were applied for each covariate. The association of the HCV genotype with the therapy response was assessed using the χ^2 test.

RESULTS

Viral RNA was not detectable in 50 (58%) of the 86 patients (30 men, 20 women) in the third month of antiviral therapy. Sixteen (19%) patients (13 men, 3 women) did not reach an SVR. The HCV genotype was determined in 80 patients; genotypes 1, 2, and 3 were present in 61, 7, and 12 patients, respectively. All patients who did not reach an SVR had viral genotype 1; for this reason, the odds ratio (OR) and 95%CI were not calculated (*P* = 0.015).

Genetic marker analysis revealed a significantly higher frequency of the *ATP7B* H1069Q mutation in patients than in controls (0.057 *vs* 0.012, respectively; OR = 5.514; 95%CI: 1.119-29.827, *P* = 0.022). Further results of the genetic marker analysis are shown in Table 2.

The presence of inherited liver disease was confirmed in nine patients (eight had Gilbert's syndrome with genotype (TA)7/(TA)7, and one had hereditary hemochromatosis with genotype C282Y/H63D). The presence of inherited liver disease was confirmed in 30 (11%) controls; all had Gilbert's syndrome.

In the comparison of patients who had reached an SVR with those who had viral persistence (*i.e.*, nega-

tive response to treatment), a significant association was found between the iron level and the presence of viral persistence (Table 3). Neither the other biochemical markers nor the histology activity index showed statistically significant differences between the patient and control groups.

In the patient group, association analysis was performed between genetic markers and the biochemical markers alanine transaminase level, ferritin level, iron level, and viral load. A statistically significant association was found only between the ferritin level and the (TA)7 allele of the *UGT1A1* gene. The strongest model for the association of the *UGT1A1* gene with the ferritin level was dominance deviation from additivity (beta = -295.7, *P* = 0.0087), and the statistical significance remained after adjusting for age (beta$_{adjusted}$ = -264.4, *P*$_{adjusted}$ = 0.0219) and sex (beta$_{adjusted}$ = -249.3, *P*$_{adjusted}$ = 0.0305). The associations between the other biochemical indices and genetic markers were not statistically significant for any of the analyzed models.

DISCUSSION

Numerous studies have been conducted to identify host and viral factors that influence antiviral therapy efficiency in patients with HCV infection. Approximately 40% to 50% of individuals with viral genotype 1 and 80% with genotypes 2 and 3 reach an SVR[1]. Compared with these previously reported rates, a higher number of patients with genotype 1 in the present study reached SVR. In addition, all patients with genotypes 2 and 3 reached an SVR. These differences between our study results and those in the literature are likely due to our small patient group and relatively young patient age (38.36 ± 14.52 years) because increasing age is a risk factor for ineffective therapy[22]. Various risk factors are reportedly

Table 3 Characterization of the patient group

	Result of antiviral therapy	Mean	95%CI of mean		P value
			Lower bound	Upper bound	
Age in year at diagnosis	Sustained viral response	38.76	34.88	42.64	0.788
	Viral persistence	37.87	32.07	43.66	
	Total	38.43	35.24	41.61	
Alanine transaminase level	Sustained viral response	106.45	81.73	131.17	0.056
	Viral persistence	153.75	104.27	203.23	
	Total	123.65	99.86	147.44	
Iron level	Sustained viral response	20.84	18.19	23.49	0.015
	Viral persistence	29.92	22.05	37.80	
	Total	24.71	20.98	28.45	
Ferritin level	Sustained viral response	298.67	185.52	411.82	0.354
	Viral persistence	397.79	197.96	597.62	
	Total	336.09	231.98	440.20

	Viral persistence	4.21E + 06	5.15E + 05	7.90E + 06	
	Total	2.75E + 06	1.35E + 06	4.14E + 06	

associated with an individual patient's response to antiviral treatment, including the homocysteine level, vitamin D level, and many other parameters[23,24]. However, only sex, age, liver disease progression, viral genotype, and insulin resistance are included in the clinical guidelines as possible risk factors[22]. In the present study, the only markers that significantly influenced the efficacy of antiviral therapy were the alanine transaminase level (P = 0.056) and the iron level (P = 0.015). Iron is necessary for the replication of HCV; however, iron depletion therapy before antiviral therapy has not been proven to be effective[25]. The small size of our patient group is the main reason why the other data did not show a statistically significant impact on the efficacy of antiviral therapy.

Of all mutations that cause inherited liver diseases, the most extensively studied are those that cause hereditary hemochromatosis[26]. Although we did not detect a statistically significant association between HCV infection and the C282Y or H63D mutation in our study, the C282Y mutation was found to be more common in the patient group than in the control group (frequency of 0.048 *vs* 0.035, respectively) (Table 2). We also failed to detect an association between the iron or ferritin level with either the C282Y or H63D mutation. This result may have been due to our small patient group and/or the ages of our patients (men, 37.27 ± 15.69 years; women, 40.25 ± 12.26 years). Our patients may have been too young to manifest the symptoms characteristic of hereditary hemochromatosis because symptoms related to iron overload usually appear between the ages of 40 and 60 years in men and after menopause in women[27]. In addition, the higher serum iron levels seen in our patients with HCV infection may have been caused by various factors other than *HFE* gene mutations; *e.g.*, hepatocyte necrosis or increased intestinal iron uptake[28].

In contrast to previous reports[10,11], we did not detect an association between HCV infection and alpha-1 antitrypsin deficiency. Again, this may have been due to the small number of patients in our study and/or the fact that liver symptoms in patients with alpha-1 antitrypsin deficiency more commonly manifest in childhood or late adulthood. Advanced liver disease generally occurs around the age of 66 years in individuals heterozygous for the PIZ mutation[29]. The mean age of our patients was 38.43 years at the completion of analysis.

Gilbert's syndrome, also termed benign hyperbilirubinemia[30], was included in our study because an estimated 10% to 15% of European descent individuals are affected by this syndrome and because previous data have demonstrated anti-inflammatory and antioxidant functions of bilirubin[31,32]. The (TA)7 polymorphism of the *UGT1A1* gene was shown to be significantly associated with the ferritin level (beta = -295.7, P = 0.0087). Some studies have proposed that ferritin, being an acute-phase reactant, behaves as a marker of more active and advanced liver disease. Patients with chronic HCV infection and high serum ferritin levels reportedly have significantly more severe liver inflammation and fibrosis than do patients with normal serum ferritin levels[7,33]. In our study, patients with viral persistence had slightly elevated ferritin levels. Based on the analysis of the association of the ferritin level with genetic markers, the (TA)7 polymorphism could be associated with less prominent liver inflammation and lower ferritin levels in patients with HCV infection. This may in turn lead to a better antiviral treatment response, and future studies should address this notion. Our results also support the idea that more extensive liver inflammation can lead to viral persistence as evidenced by the fact that alanine transaminase levels were higher in patients with viral persistence.

Interestingly, the H1069Q mutation of the *ATP7B* gene was found to be associated with chronic HCV infection. We included this mutation in our analysis because a high rate of Latvians reportedly carry this mutation[4]. The *ATP7B* gene is involved in copper metabolism. Copper is well known to be critical for the proper functioning of both the humoral and innate immune systems; however, its precise mechanisms of action are unknown[34]. The spontaneous elimination or

persistence of HCV infection depends on the host's immune status[35]. Previous reports have stated that the host response to HCV infection may be primarily dependent on the human leukocyte antigen system. However, other factors, such as copper, may also influence the host response because changes in copper levels in patients with HCV infection have been reported[15,36,37]. We propose that the H1069Q mutation of the *ATP7B* gene may be an important modifier in patients with HCV infection. Future studies should investigate this in detail, especially considering the fact that Wilson's disease is treatable.

The main limitation of our study was the small number of patients and controls. No analysis was performed to exclude HCV infection in the control group. However, this was a pilot study. Research involving larger numbers of patients and controls in whom HCV infection has been excluded is warranted.

COMMENTS

Background
Inherited monogenic liver diseases and their causative mutations may represent genetic factors responsible for changing the host response to hepatitis C virus (HCV) infection. Although the association between HCV infection and hereditary hemochromatosis has been extensively studied, only a few studies on the associations between HCV and the mutations causing alpha-1 antitrypsin deficiency, Gilbert's syndrome, and Wilson's disease have been performed.

Research frontiers
Mutations that cause inherited liver diseases are highly distributed and associated with chronic inflammation and liver damage. This is one of the critical points in HCV infection.

Innovations and breakthroughs
Many studies have been performed in an attempt to identify host genetic factors that can influence the efficacy of antiviral therapy in patients with chronic HCV infection. This is first study to analyze all of the most common genetic disorders in one patient group. The results of this pilot study show that this research should be continued with a larger group of patients.

Applications
Therapy for inherited liver disorders is either already available or is currently under investigation. If the importance of such therapies with respect to alleviating liver damage in HCV infection is proven, the efficacy of antiviral therapy may be improved by establishing treatment that is more specifically targeted not only to the viral life cycle, but also to factors directly associated with the development of liver damage. Alpha-1 antitrypsin deficiency is a liver disease caused by the absence of the proteinase inhibitor alpha-1 antitrypsin. Wilson's disease is a progressive autosomal recessive disorder of copper metabolism. Gilbert's syndrome is characterized by benign unconjugated hyperbilirubinemia.

Terminology
Hepatitis C is an infectious liver disease caused by the HCV, that affects an estimated 130 to 200 million people worldwide. Inherited monogenic liver disorders are inherited diseases, caused by mutations in one gene (autosomal recessive inheritance), in which the primary manifestation is liver damage.

Peer review
This case-control study is the first to examine the association between HCV and frequently inherited monogenic liver diseases (hereditary hemochromatosis, alpha-1 antitrypsin deficiency, Gilbert's syndrome, and Wilson's disease) and their causative mutations. This study revealed an association between HCV and the mutation responsible for Wilson's disease. Biochemical experiments revealed an association between HCV and the mutation that causes Gilbert's syndrome. This is a well-designed study that brings new insight into the association between inherited liver diseases and HCV.

Abstract

AIM: To investigate the effect of methylsulfonylmethane (MSM), recently reported to have anti-cancer effects, in liver cancer cells and transgenic mice.

METHODS: Three liver cancer cell lines, HepG2, Huh7-Mock and Huh7-H-*ras*[G12V], were used. Cell growth was measured by Cell Counting Kit-8 and soft agar assay. Western blot analysis was used to detect caspases, poly (ADP-ribose) polymerase (PARP), and B-cell lymphoma 2 (Bcl-2) expressions. For *in vivo* study, we administered MSM to H-*ras*[12V] transgenic mice for 3 mo.

RESULTS: MSM decreased the growth of HepG2, Huh7-Mock and Huh7-H-*ras*[G12V] cells in a dose-dependent manner. That was correlated with significantly increased apoptosis and reduced cell numbers in MSM treated cells. Cleaved caspase-8, cleaved caspase-3 and cleaved PARP were remarkably increased in the liver cancer cells treated with 500 mmol/L of MSM; however, Bcl-2 was slightly decreased in 500 mmol/L. Liver tumor development was greatly inhibited in the H-*ras*[12V] transgenic mice treated with MSM, compared to control, by showing reduced tumor size and number. Cleaved PARP was significantly increased in non-tumor treated with MSM compared to control.

CONCLUSION: Liver injury was also significantly attenuated in the mice treated with MSM. Taken together, all the results suggest that MSM has anti-cancer effects through inducing apoptosis in liver cancer.

Core tip: Methylsulfonylmethane (MSM) is an organic sulfur-containing compound. MSM suppressed hepatic tumor growth through activation of apoptosis. MSM could be a potential candidate as an anti-liver cancer agent.

INTRODUCTION

Liver cancer is the sixth most common malignancy and the third most common cause of cancer-related mortality worldwide[1]. Approximately 560000 cases are diagnosed each year and 550000 deaths are due to liver cancer. In most countries, 75%-90% of liver cancers are hepatocellular carcinomas[2]. The main risk factors of liver cancer include infection with hepatitis B virus (HBV) or hepatitis C virus (HCV)[3]. Other risk factors include excessive alcohol consumption, nonalcoholic steatohepatitis, autoimmune hepatitis, primary biliary cirrhosis, particularly aflatoxin B and various genetic metabolic diseases[4]. However, mortality is diminishing with the development of vaccine and therapy methods. In particular, therapy using natural extracts with no side effects has been reported. It was recently reported that tetrandrine induces apoptosis in human hepatocellular carcinoma[5] and berbamine induces apoptosis and tumor growth inhibition[6].

Apoptosis is a physiological process for involution and atrophy of various tissues and organs during development and maintenance of tissue homeostasis[7]. The apoptosis pathway is mediated by death receptors that include tumor necrosis factor receptor (TNFR), Fas and TNF-related apoptosis-inducing ligand (TRAIL). These ligands lead to the recruitment and activation of initiator cysteine aspartic proteases (caspases) such as caspases-8 and 10. These lead to the activation of caspase-3. The active caspase-3 involves DNA fragmentation, nuclear fragmentation, membrane blebbing and other morphological and biochemical changes[8]. Otherwise, apoptosis is initiated by the stress-mediated release of cytochrome-c. The cytochrome-c activates initiator caspase, typically caspase-9, which leads to the activation of the executioner caspase-3. In response to apoptotic stimuli, pro-apoptotic members of the B-cell lymphoma 2 (Bcl-2), Bcl-2-associated X protein (Bax) and Bcl-2 homologous antagonist killer (Bak) become activated and act on the mitochondria to induce the release of cytochrome-c[8].

Methylsulfonylmethane (MSM), an organic sulfur-containing compound, inhibits LPS-induced release of pro-inflammatory mediators in murine macrophages through downregulation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) signaling[9]. Moreover, the effect of MSM has been reported in cancer. MSM suppresses breast cancer growth by down-regulating signal transducer and activator of transcription 3 (STAT3) and signal transducer and activator of transcription 5b (STAT5b) pathways[10]. Apoptotic effects in other cancer cells, such as esophageal, gastric and liver cancer cells, were reported[11].

To further understand the effect of MSM in prevention of hepatic tumorigenesis, we have examined it in liver cancer cell lines and liver cancer mouse model.

MATERIALS AND METHODS

Cell culture and stable cell lines

HepG2 and Huh7 cell lines were maintained in a DMEM (HyClone, United States), supplemented with a 10% FBS (HyClone, United States), penicillin/streptomycin (HyClone, United States) in a CO_2 incubator at 37 ℃. Huh7-H-ras^{G12V} cell lines were generated by stably transfecting H-*ras*^{G12V} in Huh7 cells. The pCAG-HA-H-*ras*^{G12V}-neo was constructed as follows. The coding sequences for mutated H-*ras*^{G12V} were inserted by PCR cloning into the EcoR I site of the pCAG-HA-neo vector and confirmed by restriction mapping and DNA sequencing. Huh7 cells were plated in 6-well culture plates for 24 h prior to transfection. Cells were transfected with 3 μg of pCAG-HA-H-*ras*^{G12V}-neo construct using a Lipofectamine 2000 reagent (Invitrogen, United States), according to the manufacturer's instructions. After 48 h, cells were trypsinized and plated in a medium containing 400 μg/mL neomycin (G418). Following selection for 2 wk, total populations of neomycin-resistant cells were pooled and single-cells sorted into 96-well plates with a growth medium containing 400 μg/mL neomycin. Sorted single cells were grown under selection for an additional 2 wk and expanded into stable cell lines. The candidate clones were analyzed by Western blot analysis using a HA (Roche, Germany) antibody.

Animals

The generation of H-*ras*^{12V} transgenic liver cancer mouse model was previously described[12]. We used 3 mo old H-*ras*^{12V} transgenic male mice. H-*ras*^{12V} transgenic mice were divided into two groups and administered with PBS (control group, $n = 5$) and methylsulfonylmethane (MSM, 100 μg/g) (treated group, $n = 6$) every day for 3 mo. The genotyping of PCR primers for the H-*ras*^{12V} were 5'-CTAGCGCTGCAGGAATTC-3' and 5'-GTAGTT-TAACACATTATACACT-3'. The mice were housed in a pathogen-free animal facility under standard 12 h light/dark cycle. All animal procedures were conducted in accordance with the guidelines of the institutional Animal Care and Use Committee, Korea Research Institute of Bioscience and Biotechnology (KRIBB).

Reagents

MSM and crystal violet were purchased from Sigma-Aldrich Co. (United States).

Cell growth assay (anchorage-independent)

The cell growth after treatment with MSM was measured by Cell Counting Kit-8 (CCK-8) (Dojindo, Japan). HepG2 and Huh7 (Mock, H-*ras*^{G12V}) cells were suspended at a concentration of 5×10^3 cells/well and cultured in 96-well flat bottomed microplate. After exposure to MSM at different time points (0, 24, 48, 72 and 96 h),

CCK-8 (10 μL) was added to each well of a 96-well flat bottomed microplate containing 100 μL of culture medium and MSM (0, 200 μmol/L, 200 mmol/L, and 500 mmol/L) and the plate was incubated for 2 h at 37 ℃. Viable cells were counted by absorbance measurements at 450 nm using auto microplate reader (VERSAmax™, United States).

Soft agar assay (Anchorage-dependent)

HepG2, Huh7 - Mock, and Huh7-H-*ras*[G12V] (5×10^3 cells) were suspended in 1 mL of DMEM containing 0.3% agar in cell-growth medium and plated in triplicates over a first layer of 0.6% agar in cell-growth medium. The cells were grown at 37 ℃ and 5% CO_2. Then the viable colonies were stained with 0.01% crystal violet (Sigma, United States) for 2 h. We treated with MSM (0, 200 μmol/L, 200 mmol/L, and 500 mmol/L) on the top agar on day 0. The MSM contained medium was changed every day.

Flow cytometry analysis

Apoptosis was also evaluated by flow cytometry after Annexin V-FITC/PI (BD Bioscience, United States) staining. The cells were digested with trypsin and resuspended in 100 μL of binding buffer, 5 μL of Annexin V-FITC and added with 5 μL of PI, and the mixture was incubated at room temperature for 15 min in the dark. The cells were analyzed using a BD FACSCalibur (BD Bioscience, United States) and divided into four groups: normal cells (Annexin V negative and PI positive), early apoptotic cells (Annexin V positive and PI negative), late apoptotic cells (Annexin V positive and PI positive) and necrotic cells (Annexin V negative and PI positive). The percentages of the different cell groups were determined by a scatter plot analysis.

Western blot analysis

We homogenized liver cancer cell lysates in lysis buffer (20 mmol/L HEPES, 150 mmol/L NaCl, 2 mmol/L EGTA, 1 mmol/L EDTA, 20 mmol/L glycerol phosphate, 1% Triton X-100 and 10% glycerol) with protease (Sigma, United States) and a phosphatase-inhibitor cocktail (Roche, Germany). Proteins were separated by SDS-PAGE and transferred to nitrocellulose membranes. For Western blot analysis, 30 μg protein lysates were separated on 12% sodium dodecyl sulfate polyacrylamide gels and transferred onto nitrocellulose membranes (Millipore, United States). The membranes were primarily blotted with primary antibodies against GAPDH (Lab Frontier, South Korea), HA (Roche, Germany), cleaved caspase-3, cleaved caspase-8, cleaved PARP [Poly (ADP-ribose) polymerase] or Bcl-2 (Cell Signaling Technology Inc., United States) at 4 ℃ overnight. They were washed five times with 10 mmol/L Tris-HCl (pH 7.5) containing 150 mmol/L NaCl and 0.2% Tween-20 (TBST) and incubated with horseradish peroxidase conjugated goat anti-rabbit IgG or anti-mouse IgG (Pierce, United States)

for 1 h at room temperature. After the removal of excess antibodies by washing with TBST, specific binding was detected using a SuperSignal chemiluminescent substrate (Pierce, United States) according to the manufacturer's instructions.

Live cell counting by trypan blue stain

Huh7-H-*ras*[G12V] cells were suspended at a concentration of 0.3×10^6 cells/well and cultured in 6-well plate. After exposure to MSM for 24 h, cells were calculated by trypan blue stain through an electron microscope (Nikon, Japan).

Blood plasma analysis

Once a mo during the experimental period, blood samples were taken from orbital venous congestion. Plasma was prepared by centrifugation of the blood at 10000 rpm for 5 min at 4 ℃ and stored at -70 ℃ until analysis. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels were measured with an automatic chemistry analyzer (Hitachi 7150, Japan).

Liver histology

The liver was removed from the mice and immediately fixed in a buffer solution of 10% formalin for pathological analysis. Fixed tissues were processed routinely for paraffin embedding and 5 μm sections were prepared and stained with hematoxylin and eosin (H and E). Stained areas were viewed using an optical microscope.

Statistical analysis

Data were analyzed using SigmaStat 3.1 software. All data are presented as the mean ± the standard error of the mean (SEM) from at least three independent experiments. Comparisons between groups were analyzed by Student's *t*-test for paired and unpaired measure. *P* value < 0.001 was considered statistically significant.

RESULTS

MSM inhibits cell growth in liver cancer cell lines

To investigate the effect of MSM in cell growth, cell lines such as HepG2, Huh7-Mock, and Huh7-H-*ras*[G12V] were exposed to MSM in a dose-dependent manner. Cell growth was analyzed at 0, 24, 48, 72 and 96 h using CCK-8. HepG2 cell growth was significantly inhibited with treatment of 500 mmol/L but the growth of Huh7-Mock and Huh7-H-*ras*[G12V] cells was significantly reduced with treatment of 200 mmol/L and 500 mmol/L of MSM (Figure 1A). To assess the effect of MSM in colony formation, we conducted a soft agar assay. As shown in Figure 1B, colony size and number of HepG2 cell were decreased in a dose-dependent manner. However, Huh7-Mock and Huh7-H-*ras*[G12V] cells were remarkably inhibited in 200 mmol/L and 500 mmol/L (Figure 1B). These results suggest that MSM treatment inhibits cell growth significantly in liver cancer cell lines.

Cells were treated with MSM (0, 200 μmol/L, 200 mmol/L, and 500 mmol/L) at different time points (0, 24, 48, 72 and 96 h); B: Anchorage-independent growth assay was performed in liver cancer cells treated with MSM in a dose-dependent manner. [b]P < 0.001 *vs* control. MSM: Methylsulfonylmethane.

MSM induces apoptosis in liver cancer cell lines

To determine whether MSM induces apoptosis in liver cancer cell lines, we utilized Annexin V/PI staining, observed morphology and counted live cells. The Annexin V/PI staining was performed to examine the reversion of phosphatidylserine, a marker for apoptosis. Our results showed that the proportion of apoptotic cells was induced by treatment of 200 mmol/L and 500 mmol/L in liver cancer cell lines. Particularly, the apoptosis rate was increased 6-fold in all liver cancer cell lines treated with 500 mmol/L compared to control (Figure 2A). We examined the morphology and counted live cells of Huh7-H-*ras*[G12V]. Morphological changes were observed in 200 mmol/L and 500 mmol/L. Also, adherent cells were decreased in 200 mmol/L and 500 mmol/L treated with MSM. In addition, live cell number was significantly reduced in 500 mmol/L of MSM compared to control (Figure 2B). The data indicate that MSM treatment induces apoptosis in liver cancer cell lines.

MSM activates caspase-3, -8 and PARP in liver cancer cell lines

The expression of HA-H-*ras*[G12V] in Huh7-H-*ras*[G12V] was confirmed by Western blot. HA-H-*ras*[G12V] was overex-

Figure 2 Methylsulfonylmethane induces apoptosis in liver cancer cell lines. A: Detection of apoptotic cells by Annexin Ⅴ. Cells were treated with MSM in a dose-dependent manner for 24 h; B: Dose-dependent effects of MSM on the morphology and live cell counting of Huh7-H-*ras*[G12V] cell line for 24 h. pressed in Huh7-H-*ras*[G12V] cell (Figure 3A). To understand the mechanisms involved in MSM-induced apoptosis in liver cancer cell lines, we first determined caspase activity. The protein levels of cleaved caspase-3, cleaved caspase-8 and cleaved PARP were significantly increased in liver cancer cell lines treated with 500 mmol/L (Figure 3B). To investigate whether mitochondrial anti-apoptosis proteins are involved in regulating MSM-induced apop-

Figure 3 Methylsulfonylmethane increases caspase-3, -8 and PARP activation in liver cancer cell lines. A: Expression levels of HA-H-*ras*[G12V] in Huh7-H-*ras*[G12V]; B: Expression levels of cleaved caspase-3, cleaved caspase-8 and cleaved PARP in liver cancer cells were determined by Western blotting analysis. Cells were treated with MSM in a dose-dependent manner for 24 h; C: Expression of Bcl-2 in liver cancer cells treated with MSM in a dose-dependent manner for 24 h. Numbers under each result indicate a fold increase of band density as compared to control, GAPDH. MSM: Methylsulfonylmethane; PARP: Poly (ADP-ribose) polymerase.

tosis of liver cancer cell lines, we examined the protein level of Bcl-2. The result indicated that Bcl-2 was decreased in liver cancer cell lines treated with 500 mmol/L (Figure 3C). It suggests that MSM induced apoptosis by regulating the expression of cleaved caspase-3, cleaved caspase-8 and cleaved PARP.

MSM inhibits hepatic tumorigenesis in H-ras[12V] transgenic mice

To investigate the suppression effects of MSM in hepatic tumorigenesis, H-*ras*[12V] transgenic mice were orally administered with MSM (100 μg/g) for 3 mo. Tumor volume and number were significantly reduced in the MSM treated group compared to the control group (Figure 4A). To determine histological changes, we examined the H and E staining in mouse liver. As shown in representative photomicrographs of liver histology, the tumor size in the MSM treated group was dramatically decreased compared to the control group. Moreover, necrosis was observed in the MSM treated group (Figure 4B). To confirm in vitro data on apoptosis, we examined the protein levels of cleaved PARP. Cleaved PARP was

increased in MSM treated non-tumors compared to PBS treated control; however, not in tumor (Figure 4C). To examine the effect of MSM in liver function of H-*ras*[12V] transgenic mice, we checked AST and ALT levels. AST levels were significantly lower in the MSM treated group for 3 mo than the control group. ALT levels were also lower in the MSM treated group for 1 mo than the control group (Figure 4D). These data suggest that MSM suppresses liver damage in H-*ras*[12V] transgenic mice.

DISCUSSION

MSM is naturally obtained from various species of fruits, vegetables, grains, animals and animal products. The chemical structure of MSM is a combination of oxygen in dimethyl sulfoxide (DMSO), so also called dimethyl sulfone (DMSO₂). The anti-inflammatory effects of MSM on lipopolysaccharide-induced inflammatory responses in murine macrophages[9] and effects of MSM in breast cancer by down regulating STAT3 and STAT5b pathways[10] were reported. However, the effect of MSM has not been studied in liver cancer. In the present study,

Figure 4 Methylsulfonylmethane inhibits hepatic tumorigenesis in H-*ras*[12V] transgenic mice. H-*ras*[12V] transgenic mice were administered with PBS and MSM (100 μg/g) every day for 3 mo. A: Liver morphologies of PBS (control) group (left) and MSM group (right) after administration for 3 mo; B: Hematoxylin and eosin stained section in livers of PBS and MSM treated H-*ras*[12V] transgenic mice (Scale bars, 500 μm); C: Expression levels of cleaved PARP in H-*ras*[12V] livers; D: The levels of AST and ALT in plasma of H-*ras*[12V] transgenic mice treated with MSM. MSM: Methylsulfonylmethane; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

we found that MSM dramatically inhibits hepatic tumor cell growth. We performed CCK-8 and soft agar assay. Anchorage dependent tumor cell growth inhibition was found in liver cancer cells, such as HepG2, Huh7-Mock and Huh7-H-*ras*[G12V] treated with 500 mmol/L of MSM (Figure 1A). Anchorage independent cell growth was also inhibited in the liver cancer cells treated with both 200 mmol/L and 500 mmol/L of MSM (Figure 1B). The results indicate that MSM is effective in inhibiting liver cancer cell growth.

To further investigate the apoptosis in liver cancer cells treated with MSM, we examined apoptotic cells by Annexin V/PI staining. Apoptotic cells were significantly increased by treatment of 500 mmol/L in liver cancer cell lines (Figure 2A) and the morphology of Huh7-H-*ras*[G12V] cells was changed in 200 mmol/L and 500 mmol/L. The numbers of live cells were reduced in 500 mmol/L (Figure 2B). The result indicated that MSM caused apoptosis in liver cancer cell lines.

Cancer chemotherapy is known to induce tumor cell death in a variety of cell types in part by promoting the intracellular ROS. Recently, salinomycin-induced apop-

tosis of human prostate cancer cells was due to accumulated ROS[13]. In our study, ROS levels were significantly increased in 500 mmol/L of MSM in Huh7 cell lines (Supplemental Figure 1), suggesting that MSM treatment regulated ROS levels in liver cancer cell lines.

To clarify the apoptotic mechanism stimulated by MSM, we studied both the death receptor pathway and the mitochondrial pathways[14]. Cell surface death receptors, such as Fas which bind their ligands, initiate signaling to activate caspase-8, caspase-3 to induce apoptosis, and signaling involved in mitochondrial release of cytochrome-c, which activates caspase-9 and caspase-3[15]. We performed Western blot. Bcl-2 was decreased in all of the cell lines treated with 500 mmol/L (Figure 3C) and MSM treatment led to an increased apoptotic response involving caspase-3, caspase-8 and PARP activation in liver cancer cell lines (Figure 3B). The results demonstrate that MSM induces apoptosis through activation of the caspase pathway.

We performed *in vivo* studies to investigate the liver tumor growth suppressive function of MSM. We orally administered MSM (100 μg/g) to H-*ras*[12V] transgenic

mice for 3 mo. During the administration, body weight ratio was not changed between MSM treated group and control group (Supplemental Figure 2). However, the AST and ALT levels of MSM treated group were lower than the control group (Figure 4D). In addition, tumor volume and number were noticeably reduced in the MSM treated group (Figure 4A). The expression of cleaved PARP was increased in MSM treated non-tumors compared to PBS treated control; however, similar in tumors between the PBS and MSM treated group (Figure 4C). As shown in photomicrographs of liver histology, tumor size of the MSM treated group was decreased compared to the control group (Figure 4B). All the data suggest that MSM improves liver function and suppresses hepatic tumorigenesis through activation of apoptosis.

MSM was efficacious with treatment of 500 mmol/L in inhibition of hepatic tumor cell growth. In addition, the apoptosis rate was increased 6-fold in all of liver cancer cell lines treated with 500 mmol/L compared to control. These results indicate that MSM is efficacious with treatment of the highest dose in liver cancer cells, consistent with the result that MSM suppresses breast cancer cell growth at 300 mmol/L[10]. MSM is an edible natural organic compound present in many food items and is not associated with any toxic effects, even at higher concentrations[16,17]. MSM administration with high dose (100 μg/g) to H-*ras*[12V] transgenic mice for 3 mo did not affect body weight ratio but improved liver function by showing lowered AST and ALT levels and remarkably retarded hepatic tumor growth in the MSM treated group. All the results suggest that MSM could be available for inhibition of hepatic tumor growth. Further research is needed to be feasible in humans.

In summary, we showed that MSM induced growth inhibition and apoptosis in hepatic tumorigenesis. Therefore, MSM could be a potential candidate as an anticancer agent.

COMMENTS

Background
Liver cancer is the third most common cause of cancer-related mortality worldwide. However, there are only a few effective ways to prevent or treat liver cancer. Therefore, studies are going on in the area of liver cancer. Methylsulfonylmethane (MSM), an organic sulfur-containing compound, is naturally obtained from various species of vegetables, grains, animals and animal products. Recently, a study has reported that MSM can be used to inhibit breast cancer growth.

Research frontiers
MSM is an edible natural organic compound present in many food items and is not associated with any toxic effects, even at higher concentrations. Research is focused on finding the efficacy of higher doses of MSM treatment in cells and mice with H-ras activated liver cancer.

Innovations and breakthroughs
MSM decreased the growth of Huh7-H-rasG12V cells in a dose-dependent manner. That was correlated with significantly increased apoptosis in MSM treated cells. Cleaved caspase-8, cleaved caspase-3 and cleaved PARP were remarkably increased in the liver cancer cells treated with 500 mmol/L of MSM. Liver tumor development was greatly inhibited in the H-ras12V transgenic mice treated with MSM compared to control, by showing reduced tumor size and number.

Applications
The results suggest that MSM could be a potential candidate for prevention of liver cancer.

Terminology
MSM is a very simple organic sulfur-containing compound with a molar mass of 94.13 g/mol. MSM contains only eleven atoms and is found in foods, including fruits, vegetables, grains and beverages.

Peer review
This study described the efficacy of MSM treatment in cells and mice with H-ras activated liver cancer well. The results are interesting and indicate that MSM could be used for preventing hepatic tumor growth.

ABOUT COVER   Editorial Board Member of *World Journal of Hepatology*, En-Qi Liu, PhD, Director, Professor, Laboratory Animal Center, Xi'an Jiaotong University, Xi'an 710061, Shaanxi Province, China

AIM AND SCOPE   *World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING   *World Journal of Hepatology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

Abstract

Radiofrequency ablation (RFA) has become an important option in the therapy of primary and secondary hepatic tumors. Surgical resection is still the best treatment option, but only a few of these patients are candidates for surgery: multilobar disease, insufficient liver reserve that will lead to liver failure after resection, extra-hepatic disease, proximity to major bile ducts and vessels, and co-morbidities. RFA has a low mortality and morbidity rate and is considered to be safe. Thus, complications occur and vary widely in the literature. Complications are caused by thermal damage, direct needle injury, infection and the patient's co-morbidities. Tumor type, type of approach, number of lesions, tumor localization, underlying hepatic disease, the physician's experience, associated hepatic resection and lesion size have been described as factors significantly associated with complications. The physician in charge should promptly recognize high-risk patients more sus-

ceptible to complications, perform a close post procedure follow-up and manage them early and adequately if they occur. We aim to describe complications from RFA of hepatic tumors and their risk factors, as well as a few techniques to avoid them. This way, others can decrease their morbidity rates with better outcomes.

Core tip: This article is an interesting and updated compilation of the complications of radiofrequency ablation of liver tumors. Several complications are described, as well as their risk factors and incidence. Some strategies to avoid them from happening are also reported.

Fonseca AZ, Santin S, Gomes LGL, Waisberg J, Ribeiro Jr. MAF. Complications of radiofrequency ablation of hepatic tumors: Frequency and risk factors. *World J Hepatol* 2014; 6(3): 107-113 Available from: URL: http://www.wjgnet.com/1948-5182/full/v6/i3/107.htm DOI: http://dx.doi.org/10.4254/wjh.v6.i3.107

INTRODUCTION

Radiofrequency ablation (RFA) has become an important option in the therapy of primary and secondary hepatic tumors. Surgical resection is still the gold standard treatment, but only 5%-15% of these patients are candidates for surgery[1]. For a few selected patients who have hepatocellular carcinoma (HCC), the most common primary cancer, liver transplantation is an option but the inclusion criteria are strict and organ donation is still insufficient. Inadequate liver function, multilobar lesions, extra-hepat-

ic disease, proximity to major hepatic vessels and the biliary tract, and co-morbidities are factors that make these patients not eligible for surgery[2].

Complications rates of RFA vary widely in the literature. They are divided into major and minor[3]. The former are those that need some type of medical intervention (*e.g.*, drainage), increase morbidity and mortality, increase hospital stay or require blood transfusions. All of the rest are considered minor[3]. Authors have reported rates as low as 2% to 5.7% for major complications[4-6]. Mortality related to the procedure is low, reported in the literature to be less than 1%[7-9]. Tumor type, type of approach, number of lesions, tumor localization, underlying hepatic disease, the physician's experience, associated hepatic resection and lesion size have been described as factors significantly associated with complications[9-12]. In one of their papers, Poon *et al*[10] concluded that after the physician's first 50 procedures, the incidence of complications is lower, as well as a shorter hospital stay and higher complete ablation rate.

In this article, we present the frequency and risk factors for complications after RFA. Complications are summarized in Table 1.

HEMORRHAGIC COMPLICATIONS

Intra-abdominal bleeding is the most common complication encountered in many studies[5,6,12,13]. In Mulier's review, it occurred in 0.7% of the procedures in 3670 patients[12]. Similar results were reported by Curley *et al*[9] (0.9% in 608 patients) and Livraghi *et al*[6] (0.5% in 2320 patients). It is believed to be a result of direct trauma from needle positioning rather than thermal injury (due to the protective "heat-sink" effect)[14,15]. Injuries to small vessels not visible on ultrasonography (US) are usually responsible for its origin. Increasing abdominal pain following the procedure is generally the most common symptom[9,15]. US or computed tomography (CT) confirms the diagnosis. Bleeding complications are more likely to happen in patients with HCC due to their underlying liver disease. In a study addressing this issue, tumor size, low platelet count and tumors located in segment VII were significant risk factors for intra-peritoneal bleeding[15]. Intra-hepatic bleeding may also occur and can be prevented by avoiding hepatic vessels while positioning the needle. This makes the imaging guidance essential. Both of them tend to have a benign course and stop spontaneously. Venous bleeding is usually treated conservatively or with blood transfusions only; arterial bleeding is more severe and may require surgical or endovascular intervention[9,14,16]. Tract cauterization by the withdrawal of the needle in high temperatures may prevent this kind of complication and should be performed in all cases[12]. Groups performing this have less or even no bleeding complications[7]. Rhim, in one of his articles, states that the open or the laparoscopic approach can decrease this kind of complication since needle positioning and withdrawal is under direct vision[16]. Transcatheter arterial embolization

Table 1 Complications of radiofrequency ablation	
Hemorrhagic	Intra-abdominal bleeding
	Intra-hepatic bleeding
	Hemothorax
	Hemobilia
	Subcapsular hematoma
	Abdominal wall hematoma
Infection	Hepatic abscess
	Wound infection
	Sepsis
Biliary tract	Bile duct injuries
	Biliary stricture
	Bilomas
	Bilioperitoneum
	Biliopleural fistula
Liver failure	
Pulmonary	Pneumothorax
	Pleural effusion
	Pneumonia
Skin burn	
Tract seeding	
Vascular damage	Portal vein thrombosis
	Hepatic veins thrombosis
	Hepatic artery damage
	Pseudoaneurysm
Visceral damage	Colon
	Stomach
	Gallbladder
	Kidney
	Diaphragm
	Abdominal wall
	Small intestine

is the treatment of choice for this hemorrhagic complication[9,14,17].

Several authors have also described hemothorax[8,12,15]. It is less frequent than intra-abdominal bleeding, with an incidence ranging from 0.1% to 0.3%[8,12,15,17]. It usually occurs due to injuries to intercostal arteries while percutaneously ablating tumors in the right liver through an intercostal approach. Chest pain and dyspnea are the most common symptoms[15]. US, chest CT and chest X-Ray confirm the diagnosis. Circulation stabilization and thoracic drainage are often necessary[15]. An open approach for these patients should prevent this from happening.

Another hemorrhagic complication is hemobilia, with an incidence from 0.1% to 0.5%[12,15]. It is caused by the puncture at the same time of the biliary tract and a vessel[15]. The most common symptoms are abdominal pain, hematemesis and melena. The main risk in these cases is biliary obstruction by blood clots, causing jaundice and liver failure. In this matter, the timing of drainage is essential. Goto *et al*[15] indicates bile duct drainage when bilirubin concentrations exceeds 4 mg/dL; they think that an early indication of the procedure may delay hemostasis. They also found that tumors in liver segment I was a significant risk factor for this type of bleeding. Avoiding puncturing dilated biliary radicles should prevent such complications to occur[14].

Subcapsular hematoma and abdominal wall hematoma have also been described. The first one occurs more often in subcapsular tumors, when tract cauterization is

not possible, due to its depth. The open or laparoscopic approach rather than the percutaneous is an option to avoid them.

This illustrates the need for vigilance for any signs of bleeding after the procedure and adequate screening for coagulation disorders, including the use of medications that affect the coagulation cascade[18,19]. Post procedure imaging is also essential since these complications usually occur in the first hours after the ablation.

INFECTION

Abdominal infection is also a common complication encountered[12,20]. This group of complications consists of hepatic abscess, wound infection and sepsis. Hepatic abscess is a potentially dangerous complication with an incidence ranging in the literature from 0.3% to 1.7%[6,9,11,12,21-23]. It can appear up to more than 60 d after the procedure[23]. Significant risk factors for its development are the presence of biliary abnormality or manipulation, prone to ascending biliary infection (bilioenteric anastomosis, endoscopic papillotomy and tumor with retention of iodized oil from a previous chemoembolization)[6,12,16,22,24]. In a study conducted by Elias *et al*[23] in 2006, the authors studied 11 patients with enterobiliary anastomosis or biliary stent and found an incidence of 44% of hepatic abscess in these specific subjects. They also stated an interesting issue: when the biliary procedure was synchronous with the RFA, no hepatic abscesses were observed; only when it was performed prior to the ablation was it considered a risk factor. Enteric bacteria coming from the injured colonized bile ducts contaminate the tumor necrosis generated by RFA[22]. Patients with hepatic abscess may present with fever and abdominal pain. The onset of these symptoms and signs usually occur within the first month after RFA[22]. Suspicion should arise when patients present with high body temperatures after the procedure, especially if it lasts longer than two weeks, although fever can be a symptom of the postablation syndrome. CT scan confirms the diagnosis; air bubbles are usually seen in the abscess. Thus, they may be seen in the ablated area after the procedure and this must not be misdiagnosed as an abscess[20]. Antibiotic prophylaxis is controversial in all patients, but in high risk cases it is recommended[6,12,22,23]. A question that comes up in these patients is if prolonged antibiotic prophylaxis is useful in reducing its incidence. Hoffmann *et al*[24] addressed this issue and tried to reduced this risk by maintaining the antibiotics for over 10 d after the procedure in 8 patients with prior bilioenteric anastomosis. The majority of the interventions (9/10) had prior administration of intravenous piperacillin/tazobactam and after the RFA, patients received Ciprofloxacin orally; 4 of the patients received additional antibiotics (metronidazole, cefpodoxime and cefazolin). Only one patient developed a hepatic abscess; he had a chemoembolization 8 d before the RFA. Despite the low number of patients and the lack of a control group, the authors suggest that this regimen may decrease the incidence of hepatic abscess. Elias *et al*[23] and de Baère *et al*[5] also debated this matter. Both groups administered prolonged antibiotics prophylaxis for 5 d (longer than usual) on these high-risk patients and a high incidence of hepatic abscess was encountered. Further studies with control groups and larger series of patients are necessary to resolve this question.

The most frequent organisms found in these abscesses were *Enterococcus*, *E. coli*, *Bacteroides fragilis*, *E. faecalis*, *C. perfringens* and *Klebsiella pneumonia*[5,21,23]. The best treatment option is percutaneous drainage in combination with systemic antibiotics[19-21,24]. Early suspicion, diagnosis and treatment are essential for a good outcome so the physician should be alert to the patient's clinical follow up, especially in those with risk factors.

BILIARY TRACT DAMAGE

Biliary tract damage includes bile duct injuries, biliary stricture, bilomas and, most rarely, bilioperitoneum and biliopleural fistula. Its incidence can be as low as 0.1% and up to 12%[9,12,25,26]. Bile ducts changes are expected and most of these changes have no clinical significance with the patient being asymptomatic with low rates of progression[9,12,26]. This explains its low and underestimated frequency since authors ignore those minor changes[12,26]. In a paper studying this matter, most of these changes seen on CT were mild dilatation of the upstream intrahepatic bile duct surrounding the ablation zone[26]. The authors did not mention the distance between the tumors and major bile ducts and stated that these changes are irreversible. In an Italian study, only two of 3554 patients required therapy after this kind of complication[6]. Another 15 patients presented with asymptomatic biliary tree abnormalities. These injuries are due to thermal damage from heating and direct mechanical damage from the needle. It is more likely to happen in hilar tumors or in tumors closer than 1 cm to major bile ducts when the safety margin is impossible to be obtained without injury. Biliary stricture is the most common complication in this group[12]. It may develop weeks to several months after RFA[26]. In a study where 28 high-risk patients were analyzed, the incidence of stenosis in this specific group of subjects increased up to 46% (13/28 patients with tumors closer than 5 mm to central bile duct on CT)[25]. Peripheral stenosis is usually asymptomatic, but central strictures may lead to serious complications. These strictures are believed to lead to liver atrophy and its consequent malfunction[25]. This is very important for cirrhotic patients because, due to their already impaired liver function, they may easily develop liver failure and cholangitis after bile duct stenosis[21,25]. Cholestasis and biliary infection may also occur.

Diagnosis is usually done by CT during follow-up and can also be detected by endoscopic retrograde cholangiography. The latter can also be used therapeutically by stenting the injured bile duct. The strictures are also well treated by endoscopic sphincterotomy[27].

Figure 1 Third-degree grounding pad skin burn on the right thigh.

The association of RFA with transarterial chemo-embolization (TACE) or percutaneous ethanol injection (PEI) is an option in these cases as these procedures, prior to the RFA, decrease tumor size and makes it possible for the ablation to be safer with a larger margin. Ohnishi *et al*[25] reported a method to prevent this complication by infusing intraductal chilled saline solution through an endoscopic nasobiliary drainage tube. Only one patient (2.5%) developed a stricture (left hepatic duct); the 39 remaining subjects were able to avoid thermal injury with this procedure. The incidence of this complication was significantly lower than the control group. This also significantly decreased the worsening of their liver function compared to the control group. The authors did not mention recurrence and other complications related to this procedure. Elias *et al*[23] also used this in 13 high-risk patients after the procedure. Two questions arise. The first one is if this protection is due to the low temperature itself or the heat sink effect caused by the solution's flow leading to inefficient ablation. The second one is if this procedure increases the incidence of hepatic abscesses. These questions need to be answered with future studies. Another concern regarding this issue is recurrence. This procedure also has a cooling effect on tumor cells near the cooled bile duct; thus, more insertions and more heat are necessary for adequate ablation which may lead to higher rates of complications[28]. Future studies are needed to address this. Curley *et al*[9] and Huang *et al*[29] suggested an open approach in these high-risk subjects for better needle placement with intra-operative ultrasonography. Patient selection is vital to avoid this type of complication.

Biloma is also encountered in this group of complications, with an incidence ranging from 0.1% to 5.8%[6,12,26,30]. It is defined as an encapsulated bile collection outside the biliary tree due to biliary leakage. This leakage can be caused by direct damage from the needle, direct thermal damage and by thermal damage to the microvasculature of the biliary tract caused by RFA. On CT, it is characterized as a circumferential fluid collection surrounding the ablation site or a communication between the bile duct and circumferential collection confirmed on cholangiography or CT[26,30]. Most bilomas develop within

the first 4 mo but can occur as late as 17 mo[30]. Almost all patients are asymptomatic and the fluid formation has spontaneous regression in half of the cases[30]. Percutaneous drainage is a good treatment option when required. Sphincterotomy should always be considered to exclude biliary stenosis and increased biliary pressure as a cause for biloma formation.

LIVER FAILURE

Liver failure is also a potentially fatal complication, especially in patients with cirrhosis whose liver function is often already impaired. Patients who have undergone previous hepatectomy are also at risk for this complication[14]. Its incidence ranges from 0.2% to 4.3%[4,9,11,12]. Child Pugh classification has been significantly related to post treatment liver failure[4,11]. Hepatic infarction due to injuries to major feeding vessels is believed to be responsible for its occurrence. Proper and careful needle placement is essential to avoid this from happening[14]. Other causes of liver failure are extensive ablation (overtreatment causes destruction of cirrhotic tissue around the lesions), portal vein thrombosis and extensive resection[6,12,16].

PULMONARY COMPLICATIONS

Pneumothorax, hemothorax (described in hemorrhagic complications), pleural effusions and pneumonias are in this group of complications. Its incidence varies from 0.8% to 2.1%[9,12]. Pneumothorax is more likely to happen in patients with tumors located directly under the diaphragm when an intercostal approach is chosen[12]. Some authors have described the use of artificial pleural effusion[28]. The idea is to separate the lung from the diaphragm and avoid these lesions. Inoue *et al*[28] published a series of 64 patients with 82 nodules near the diaphragm using this technique and encountered complications in 5 subjects. The treatment should be considered individually. Thoracentesis, underwater seal drainage and diuresis have been described[6,9,14]. Adequate needle positioning with a safe window (in the percutaneous approach) can avoid this complication[20]. Positioning the patient on the right side can also avoid it by limiting respiratory excursion[14]. Use of the epipericardial fat pad has also been described to avoid entering the pleural cavity[31]. Further investigation with CT is required if the patient experiences dyspnea or chest pain after RFA.

SKIN BURNS

Skin burns can occur at the point of needle entry and at the ground pad sites (Figure 1). This complication had a higher incidence in earlier studies due to smaller pads. In recent papers, it became a rarity because of their larger sizes and increased awareness, with a low incidence from 0.2% to 0.6%[6,14,20]. Third-degree skin burns are rare, but have been described, even leading to deaths[5,7,19,20]. Adequate pad placement and sizes are essential to avoid

Figure 2 Tumor seeding on needle entry site after percutaneous radiofrequency ablation.

this complication, as well as good contact with the skin. Large and sometimes multiple ground pads are necessary to disperse the high amount of energy generated by RFA. They should be equidistant from the needle due to the asymmetric distribution of the electrical current. This asymmetry makes the temperature beneath the pads not uniform, with greater heat on the edges and in the pads closest to the needle[19]. This was confirmed by de Baère *et al*[5], describing patients with first and third degree burns on the edges of one the pads facing the active electrode (needle).

TRACT SEEDING

Tumor seeding in the needle tract has an incidence from 0.2% to 0.9%[5,6,12,32]. Low rates of tumor seeding may be explained due to its underestimation in most papers due to a lack of follow-up. It usually occurs 3 to 12 mo after RFA[19]. Viable tumor cells that adhere to a biopsy needle or the electrode during its extraction, tumor cells carried into the needle tract with the bleeding and tumor cells forced into the tract by intratumoral hyperpressure are mechanisms that explain the seeding[12,33] (Figure 2). Decreasing the number of punctures and transversing a large amount of hepatic tissue before entering the tumor may avoid this complication[14,20]. Groups performing needle tract cauterization have not experienced tumor seeding or have very low rates[5,7,14]. Livraghi *et al*[32] reported their series with 1314 patients aiming to determine the risks of this complication in subjects with HCC treated by percutaneous RFA with a long follow-up (median 37 mo). They encountered seeding in 12 patients; tumors were located mostly in intercostal muscle and successfully treated by resection. The only significant risk factor described was a previous biopsy. They concluded that needle biopsy should be avoided. Other risks factors described by other authors are poorly differentiated, subcapsular location (where heating of the needle tract is not possible) and multiple needle insertions[5,6,33,34]. Optimal and meticulous first attempt electrode positioning is desirable[6]. Besides resection, RFA is also an option for treating tumor seeding. Some authors suggest the open approach in subcapsular lesions to avoid this complication[35].

HEPATIC VASCULAR DAMAGE

Portal vein thrombosis, hepatic vein thrombosis, hepatic artery damage and pseudoaneurysm represent this group of complications, with an overall complication rate from 0.5% to 1%[6,12,19,36].

Portal vein thrombosis is a potentially fatal complication, with a 0.2% incidence[12]. Thrombosis and coagulation of vessels larger than 3 mm are rare when normal flow is granted[37]. Most of these thromboses are asymptomatic even in larger vessels and no further therapy is required[5,36]. They are caused by heat damage to the endothelial cells of the portal or hepatic vein, leading to platelet aggregation and subsequent thrombosis[38]. It can be defined as being adjacent to the ablation zone and developing within 4 mo after RFA[36]. Liver function tests are usually normal but if elevated should normalize with no clinical significance[36]. Its occurrence should be avoided, especially in cirrhotic patients, as it may lead to liver failure in a patient with an already impaired liver function. Risk factors are the central location of the tumor, vein compression by the tumor and the Pringle maneuver. The latter stops blood flow into the liver and with that, vessels lose their cooling protection from the "heat-sink" effect, leading to vessels thrombosis. de Baère *et al*[5] showed in their paper that 30% of their procedures with balloon occlusion (for blood flow stop) led to complete thrombosis of the ballooned vessel. They also had more significant portal vein thrombosis in cirrhotic patients after performing the Pringle maneuver than in noncirrhotic subjects. It is suggested by the authors that it should be avoided in these patients, even for short durations[5].

Hepatic artery damage has a 0.2% incidence[12]. Small arterioportal shunts may occur after RFA and the majority of them heal spontaneously[12]. They can be successfully treated by endovascular or percutaneous therapies.

VISCERAL DAMAGE

Visceral damage is rare, with an incidence varying from 0.5% to 0.7%[6,12]. Damage to the colon, stomach, gallbladder, kidney, diaphragm, abdominal wall and small intestine has been described. Attention should be paid when tumors are closer than 1 cm to adjacent organs. Early diagnosis and adequate treatment are essential since it may lead to death. Risk factors are percutaneous approach, subcapsular tumors, previous abdominal surgery and chronic cholecystitis as the patient may have adhesions between the liver and the bowel[6,12,16]. Livraghi *et al*[6] suggest some issues in these patients: they should be treated by the open or laparoscopic approach for direct visualization of the organs, assuring they are in fact separated, and CT guidance is preferable for better adjacent bowel identification.

The colon is believed to be at greater risk of being

damaged due to its thin wall and fixed nature[5,6]. This complication has an incidence from 0.1% to 0.3%[5,6,12]. Some techniques have been developed to avoid bowel injuries: patient positioning in a steep oblique and prone position and breath holding during mechanical ventilation in patients under general anesthesia has also been described[14]. Another technique is creating a barrier between the liver and the colon, the hydrodissection. The use of 5% dextrose and saline solutions has been reported[14,28,39]. The former is preferred due to its properties since it does not conduct electricity and hence provides a thermal barrier around the organ[39]. Song *et al*[39] and Inoue *et al*[28] used artificial ascites and had no gastrointestinal injuries. The stomach and small bowel are less injured because adhesions along the gastrohepatic ligament are rare as the gastric wall is very thick and the small bowel has great mobility and peristalsis[6,19]. One should keep in mind that the onset of the symptoms of perforation is delayed; therefore, treatment is also usually delayed and the patient presents with a severe clinical status, eventually leading to death. A high level of suspicion is essential and close follow-up is important in these subjects.

Ribeiro *et al*[7] in their series routinely performed open cholecystectomy prior to RFA in tumors near the gallbladder, with the intention to avoid cholecystitis and incomplete ablation. Minimal wall thickening is expected on imaging after RFA, usually with no clinical significance. This probably happens due to the capacity of the fluid inside the gallbladder to dissipate the heat[16].

Injury to the diaphragm occurs in 0.1% of the cases[6,12]. It frequently results in severe shoulder pain[14]. Usually, RFA causes thickening of the muscle but perforation and hernia have been described[40]. Artificial ascites can also be used to decrease it.

CONCLUSION

Complication rates of RFA are low, making it a safe and feasible procedure. Every component of the treatment should be thoroughly analyzed. Proper patient selection is essential; subjects with exclusion criteria may lead to higher complication rates. Type of approach is also vital; depending on tumor location, one type may lead to a higher complication rate than another. This also fits for imaging guidance, where some tumors locations are better visualized by a specific method over another. The physician's experience is very important as well. Identification of high-risk subjects (with close follow-up), early diagnosis of known complications and a high level of suspicion are acquired with time and may lead to better outcomes and reduced risk of complications.

Abstract

Fatty liver or nonalcoholic fatty liver disease (NAFLD), a problem of increasing clinical significance and prevalence worldwide, is associated with increased risk for the development of cirrhosis and hepatocellular carcinoma. Although several therapeutic approaches can be used in the context of NAFLD, dietary and physical activities are still the most frequently used strategies. Some pharmacological agents show promising results although no conclusions can be drawn from recent clinical trials. Thyroid hormones [THs; thyroxine (T4) and 3,3′,5-triiodo-L-thyronine (T3)] coordinate a diverse array of physiological events during development and lipid/energy homeostasis and have some potentially therapeutic actions which include inducing weight loss, and lowering plasma cholesterol levels and tissue adiposity. The thyroid hormones exert their physiological effects by binding to specific nuclear receptors [thyroid hormone receptors (TR)] of which the TRβ isoform is liver specific and has been considered a putative target for the treatment of dyslipidemia and fatty liver. In view of this, the aim of the review is (1) to provide an overview of the action of T3 on lipid metabolism with implications for liver steatosis and (2) to provide an update on the current knowledge concerning the administration of TRβ selective thyromimetics (GC-1 and MB07811), as well as of 3,5-diiodo-L-thyronine and its novel functional analogue TRC150094 in animal models of overweight and related disorders including primarily fatty liver.

Core tip: Fatty liver is associated with increased risk for the development of cirrhosis and hepatocellular carcinoma. Thyroid hormones have some potentially therapeutic actions by binding to specific nuclear receptors [thyroid hormone receptors (TR)] of which the TRβ isoform is liver specific and a putative target for the treatment of dyslipidemia and fatty liver. This review provides (1) an overview of the action of T3 on lipid metabolism and (2) an update concerning the administration of TRβ selective thyromimetics (GC-1 and MB07811), as well as of 3,5-diiodo-L-thyronine and its novel functional analogue TRC150094 in animal models of overweight and fatty liver.

INTRODUCTION

The liver plays essential roles in supporting many meta-

bolic processes and is critically involved in facilitating the maintenance of blood-glucose levels and energy homeostasis. Diet-induced obesity - commonly associated with diseases such as type 2 diabetes (T2DM), hypertension, heart failure, or cancer - also leads to fatty liver or steatosis, a histopathological condition characterized by an excess accumulation within hepatocytes of lipids, which are primarily triglycerides (TGs)[1]. Although the primary metabolic abnormalities leading to lipid accumulation within hepatocytes are still not fully understood, a decreased capacity to oxidize fatty acids, an increased delivery and transport of free fatty acids (FFAs) into the liver as well as an augmented hepatic fatty acid synthesis are likely to play significant roles in the pathogenesis of hepatic steatosis[2-4]. Moreover, steatosis is clearly, inextricably linked to modifications of mitochondrial functions[5,6]. Indeed, the mitochondrion plays an important role in the hepatocyte's metabolism because it is the primary site of fatty acid oxidation and oxidative phosphorylation. Multiple enzymes are involved in mitochondrial β-oxidation, and even partial deficiencies of these enzymes may lead to the development of hepatic steatosis[7,8] (Figure 1A). Two broad categories of hepatic steatosis have been recognized: alcoholic fatty liver disease (AFLD) and nonalcoholic fatty liver disease (NAFLD). In particular, NAFLD, commonly associated with insulin resistance (IR) and cardiovascular diseases[9], comprises a morphological spectrum of liver lesions ranging from simple triglyceride accumulation in hepatocytes (hepatic steatosis) to inflammatory and hepatocellular ballooning injury (non-alcoholic steatohepatitis; NASH), which eventually leads to fibrosis and cirrhosis[1]. The exact mechanism underlying the transition from steatosis to steatohepatitis is still unknown. According to the "two-hit" hypothesis[10]: the first hit involves the accumulation of TGs in hepatocytes that causes a vicious cycle of metabolic dysfunction; once the presence of hepatic steatosis is established, progression to steatohepatitis involves a "second hit" with oxidative stress playing a key role. Fatty liver is more susceptible to oxidative injury[1] and lipid peroxidation[11], and the chemical modification of biological molecules may be directly toxic to the cells or may stimulate host-immune response that leads to inflammation, collagen production and further disease progression[12-14].

Therapeutic interventions in NAFLD are mainly based on lifestyle changes, including diet and exercise[15,16]. Currently, there are no approved pharmacological therapies for NAFLD, but because IR is almost universally present in patients with this condition, drugs that increase insulin sensitivity are currently undergoing extensive evaluation and hold promise as therapeutically effective agents[17,18]. Several other agents, such as antioxidants and hepatoprotective compounds, have been evaluated, and the data was inconclusive or demonstrated no effects[16].

Thyroid hormones [THs; thyroxine (T4) and 3,3',5-triiodo-L-thyronine (T3)] exert a multiplicity of effects and are potent regulators of glucose and lipid metabolism and body weight. In particular, they play an important role in

hepatic lipid homeostasis. They exert their physiological effects by binding to specific nuclear receptors, the thyroid hormone receptors (TR) α and β that are widely distributed throughout the body. The β isoform is the major TR expressed in the liver. The beneficial effects of TRβ activation include lowering low-density lipoprotein (LDL) cholesterol, reducing whole body adiposity and weight[19], and increasing the metabolic rate in the liver which could potentially lead to reduced lipid content. However, to date, there is a lack of data available on the specific effects elicited by T3 on liver steatosis. In a recent study, T3 was shown to exert a strong inhibitory effect on the development of steatosis and to cause a rapid regression of fully established steatosis[20].

An excess of thyroid hormone is associated with unwanted effects particularly on the heart (including tachycardia and sudden death) and also on bone and skeletal muscle[21]. Because of these adverse effects of THs, several new TH analogs (generically termed as thyromimetics) have recently been developed to generate effective and safe treatments to counteract obesity and related disorders among which hyperlipidemia and liver steatosis. These either have selective effects on the liver *vs* the heart or bind selectively to TRβ rather than to TRα without cardiac side effects[22]. Such compounds could serve as powerful new tools to address some of the largest medical problems in developed countries-obesity and related disorders[23]. Interestingly, THs also exert non-genomic effects[24] and some are attributable to naturally occurring iodothyronines apart from T4 and T3[25,26]. These THs derivatives are currently being studied to elucidate their potential biological activities and application as anti-hyperlipidemic as well as anti-steatotic agents[22].

This review, including T3 action in the liver and fatty liver, will focus on the current understanding of the actions of thyroid hormone analogues and derivatives in fatty liver in view of the development of potential future therapeutic approaches for the prevention or counteraction of liver steatosis.

ACTIONS OF T3 ON LIPID METABOLISM IN THE LIVER: IMPLICATIONS FOR FATTY LIVER

The pleiotropic effects exerted by T3 includes the maintenance of lipid homeostasis *via* regulation of gene expression in target organs such as liver and adipose tissues. Most T3 effects are mediated by the canonical, or classic, pathway which requires the nuclear T3 receptors[27-29]. Actually, T3 can also signal through non canonical pathways by binding to cytoplasmic or mitochondrial TR isoforms[24]. In mammals, two distinct genes express the TRα and TRβ isoforms. The *TRβ* gene encodes three T3-binding TRβ isoforms (β1, β2, and β3) that share high sequence homology in the DNA and T3-binding domains but differ in length and amino acid sequences in the amino-terminal A/B domain. The *TRα* gene en-

Figure 1 Hepatic lipid partitioning and liver and systemic metabolic damages in nonalcoholic fatty liver disease (A) and a schematic representation of the anti-steatotic effect of 3,3',5-triiodo-L-thyronine (B). A: Hepatic lipid partitioning and liver and systemic metabolic damages in nonalcoholic fatty liver disease. Chronic overnutrition/hyperlipidemic feeding causes fat retention in hepatocytes that, in turn, results in alteration of fat uptake, de novo synthesis (lipogenesis) and oxidation with a significant imbalance of lipid homeostasis. This can subsequently induce insulin-resistance, metabolic syndrome and cardiovascular diseases; B: A schematic representation of the anti-steatotic effect of T3: An update. T3-administration associated adverse effects are also highlighted (for details see the text). T3: 3,3',5-triiodo-L-thyronine; TRs: Thyroid hormone receptor isoforms; FFA: Free fatty acid; TG: Triglyceride; L-FABP: Liver-type fatty acid-binding protein; COX2: Cyclo-oxygenase 2; JNK: c-Jun N-terminal kinases; STAT3: Signal transducer and activator of transcription 3.

codes one T3-high affinity binding TRα1 and two splice variants (TRα2 and TRα3) which differ from TRα1 in length and amino acid sequences in the C-terminal region starting at amino acid 370, and they have no T3-binding activity[30]. While TRα1 is preferentially expressed in the heart, TRβ1 is the major isoform in the liver, kidney and thyroid. However, TRβ2 is predominantly expressed in the brain, adipose tissue and anterior pituitary gland. The liver is an important T3 target tissue[31]. T3 increases the expression of several genes involved in hepatic lipogenesis including fatty acid synthase (FAS), hepatic product

spot 14 (which interacts physically and functionally with the TR to regulate malic enzyme gene expression[32]), acyl-CoA synthetase 5, fatty acid transporter protein, malic enzyme, glucose-6-P dehydrogenase (G6PDH)[33], sterol regulatory element binding protein-1c (SREBP-1c)[34]. T3 also induces genes involved in fatty acid oxidation, such as fatty acid transporter (FAT), fatty acid-binding protein (FABP), lipoprotein lipase (LPL)[33], and carnitine palmitoyltransferase-1alpha (CPT-1α), a key rate-limiting enzyme in mitochondrial fatty acid oxidation. In the liver, many of these genes (*e.g.*, malic enzyme, SREBP-1c, FAS

and CPT-1α) are directly regulated by T3/TR as the thyroid hormone response elements (TREs) have been reported in their promoters[34,35]. Importantly, T3 transcriptional activity also depends on several other factors including the type of TREs located on the promoters of target genes, the developmental- and tissue-dependent expression of TR isoforms, and a number of nuclear coregulatory proteins. TRs bind to TREs not only as homodimers but also as heterodimers with other members of the receptor superfamily, such as retinoic X receptors (RXRs), vitamin D receptor, and all subtypes of the retinoic acid receptors. Heterodimerization with RXR dramatically increases the binding of TRs to TREs, the responsiveness of TR to T3, transcriptional activation[30] and, due to promiscuity of RXR in heterodimerization with many members of the receptor superfamily, allows TR to crosstalk with other receptors. Crosstalk with peroxisome proliferator-activated receptor (PPAR) signaling *via* heterodimerization with RXR by TR is a well-known example[30,36].

Moreover, in the liver, activation of the NAD+-dependent deacetylase sirtuin 1 (SIRT1) facilitates fatty acid oxidation[37]. Indeed, in hepatocytes isolated from mice lacking SIRT1, fatty acid oxidation rates are reduced, and these mice accumulate lipids within the liver[38]. Recently, SIRT1 has been reported to interact directly with TRβ1, contributing to the T3-mediated stimulation of hepatic genes *via* the activation of several factors such as PPARα, estrogen-related receptor α (ERR-α), and peroxisome proliferator-activated receptor γ coactivator (PGC-1α)[39]. In the liver, PGC1-α promotes expression of genes involved in hepatic fatty acid oxidation[40] and drives the expression of genes involved in hepatic gluconeogenesis *via* interactions with HNF4α (hepatic nuclear factor-4) and FoxO1 (forkhead transcription factor)[41,42]. In particular, PGC-1α appears to be another key player in T3-signaling as it is able to coactivate the TRβ[43] and its overexpression enhances the induction T3-mediated of CPT-1α[44] and PDK4 (pyruvate dehydrogenase kinase, isozyme 4)[45,46]. Interestingly, T3 can also signal in a TRβ-independent manner by binding to surface receptor such as integrin αvb3 receptor, thus activating the MAPK/ERK and PI3K/Akt/mTOR-C1 pathways[24]. Recent studies have highlighted that such effects in hepatocytes have the potential to modulate lipogenesis and cholesterologenesis[47].

Normal serum THs levels are essential for the maintenance of a sufficient pool of cholesterol to meet the body's requirements and to regulate the critical steps of cholesterol synthesis, uptake and metabolism[19]. T3 signaling: (1) stimulates 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG CoA) reductase and farnesyl pyrophosphate (FPP), favoring cholesterol synthesis; (2) up-regulates the LDL receptor (LDLR; low density lipoprotein receptor), increasing cholesterol uptake; and (3) stimulates cholesterol 7α-hydroxylase (CYP7A1), enhancing the metabolism of cholesterol into bile acids[48-50].

Although the T3-mediated actions involved in the regulation of serum lipid homeostasis as well as in hepatic fat metabolism are quite well established, the T3-specific effects on NAFLD are still not fully elucidated. A study using a nutritional model of NAFLD [treating rats with high-fat choline-methionine deficient (CMD) diet] revealed that co-feeding T3 (4 mg/kg of diet) with a CMD diet exerts a strong inhibitory effect on the development of steatosis. Indeed, T3 prevents accumulation of TGs by inducing fatty acid oxidation with subsequent impairment of TGs hepatic synthesis/accumulation, and decreases the expression of liver-type fatty acid-binding protein (L-FABP), an abundant protein in the cytosol of hepatocytes that facilitates fatty acid transport and utilization[20]. Furthermore, the same study showed that T3 administration for only 1 wk, following 10 wk on a CMD diet, caused a rapid regression of fully established steatosis by: (1) dramatically reducing liver TGs levels and cyclooxygenase 2 (COX2) expression; (2) down-regulating pathways, such as JNK (c-Jun N-terminal kinase) and STAT3 (signal transducer and activator of transcription 3) pathways, usually activated in inflammatory processes; and (3) reducing the severity of liver injury as determined by serum levels of transaminases (AST and ALT; aspartate aminotransferase and alanine aminotransferase)[20] (Figure 1B).

Of note, T3 is also a potent mitogen that, in the liver, induces Cyclin-D1 expression[51]. Very recently, it has been shown that it exerts hepatocyte mitogenic response by PKA-dependent β-catenin activation, thus eliciting a potent liver regeneration action[52]. This has suggested that T3 can have therapeutic relevance in the treatment of selected cases of hepatic insufficiency.

However, long term treatment with T3, both in animals and humans, can produce several adverse effects including systemic thyrotoxicosis. Thus, extensive research is dedicated to the identification of new effective and safe active molecules (T3-derivatives and analogues) for the treatment of dyslipidemias, NAFLD, obesity and related disorders.

In particular, the development of synthetic thyroid hormone analogues which have tissue-selective hormone actions (*i.e.*, selective thyromimetics) has been pursued.

THYROMIMETICS AND LIVER STEATOSIS

As mentioned previously, many of the T3 actions are tissue-specific and are primarily mediated by a panel of TR isoforms that are expressed in different ratios in various tissues. Thus, there is a rationale to pursue approaches that selectively modulate TRs function, and several agents have been shown to have some β-selective, hepatic selective and/or cardiac sparing activities. The possibility of selectively targeting the TRβ was suggested by the findings that the TRα-forms may preferentially regulate the heart rate, whereas many other actions of T3 are mediated by the TRβ. X-ray crystal structures of the TRα and TRβ ligand-binding domains (LBDs) suggested that a

Figure 2 Chemical structure of thyroid hormones and thyromimetics/analogues with reported anti-steatotic effects.

single amino acid difference in the ligand-binding cavities of the two receptors could affect hydrogen bonding in the receptor region where the ligand's 1-position substituent fits and might be exploited to generate β-selective ligands[53].

The development of a TRβ-selective agonist has prompted a number of studies addressing whether such molecules could be used to trigger the metabolic effects of T3 while preserving the TRα-expressing tissues[54-58]. Essentially, these studies have been encouraging as it has been shown that the use of TRβ-selective agonists can prevent or improve metabolic parameters and/or complications resulting from high-fat feeding, NAFLD[20], or genetic hypercholesterolemia[59,60] with the liver being their major target. Indeed, tissue distribution analyses suggest that these molecules achieve TRβ selectivity by virtue of being concentrated predominantly in liver[55,61]. TRβ activation in the liver also favorably affects plasma cholesterol and lipoprotein levels by multiple mechanisms, which include increasing: (1) LDL clearance through increased expression of LDLR, (2) high-density lipoprotein (HDL) uptake through SR-B1 (scavenger receptor class B type 1); and (3) bile acid synthesis *via* CYP7A1[62].

To exploit the favorable consequences of hepatic TRβ activation, a variety of synthetic TRβ agonists have been prepared and tested on a variety of experimental models[63-73]. Ideally, these selective TRβ agonists, would cause modest increases in the metabolic rate without tachycardia[22]. However, it has been reported that most of thyromimetics could suppress thyroid axis and lower serum T4/T3 levels, especially at high doses.

Here, we will discuss two thyromimetics, namely GC-1[74] and MB07811[57,75,76] (Figure 2), for which these effects are less marked and which, at the same time, elicit anti-steatotic effects. In particular, MB07811, being specifically targeted to the liver, reduces serum T4 levels (-50% in Sprague-Dawley rats) probably by enhancing T4 to T3 conversion through deiodinase 1[53,57]. As far as it concerns GC-1, it has been shown a dose-dependent ability to reduce thyroid-stimulating hormone (TSH) levels, being this action 20-fold less potent than that of T3[55].

GC-1 (or sobetirome) is a halogen-free thyroid hormone agonist[74]. Although the structural changes it contains with respect to the natural hormone T3 (*i.e.*, replacement of the three iodines with methyl and isopro-

Figure 3 A summary of key events and molecular pathways underlying GC-1 (A) and MB07811 (B) anti-steatotic and hypolipidemic effects (for details see the text). TSH: Thyroid-stimulating hormone; T3: 3,3',5-triiodo-L-thyronine; TRβ: Thyroid hormone receptor β isoform; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; FFA: Free fatty acid; TG: Triglyceride; T4: Thyroxine; Apo-C3: Apolipoprotein C3; mGPDH: Mitochondrial glycerol-3-phosphate dehydrogenase; CPT-1α: Carnitine palmitoyltransferase-1α.

pyl groups, replacement of the biaryl-ether linkage with methylene linkage, and replacement of the amino acid side chain with an oxyacetic acid side chain)[77], it binds the TRβ with an affinity that is comparable to that of T3[22]. Functionally, when GC1 is administered to rats undergoing a CMD diet prevents and reverses the hepatic steatosis much like T3[20]. Moreover, similar to T3, GC-1 can reduce liver weight, liver weight/body weight ratio, and serum TGs levels. GC-1 also causes a reduction of CMD-induced TGs accumulation in the liver, with the

disappearance of hepatic TGs being accompanied by a concomitant decrease of lipoperoxidation, and of liver injury as indicated by the significant reduction in AST and ALT levels[20]. These findings made GC-1 an ideal molecule for therapies against fatty liver disease. Interestingly, GC-1 also stimulates energy expenditure[78] and mitochondrial oxidative processes but to a lesser extent compared to T3[79,80] (Figure 3A). Notably, animal studies[55] revealed that treatment with GC-1 also induces a reduction of cholesterol levels similar to that obtained

with equimolar doses of T3 and even higher than that achieved with the most common drugs currently available on the market for the treatment of hypercholesterolemia, such as the inhibitors of HMG CoA reductase (statins)[77]. In doing so, GC-1 regulates key steps in the reverse cholesterol transport pathway[62], increasing the expression of HDL receptor SR-B1 in the liver, stimulating the activity of CYP7A1 and inducing the expression of hepatic ATP-binding cassette proteins G5/G8 (ABCG5/G8), which promote biliary cholesterol secretion. Consequently, treated animals displayed an increased turnover of plasma HDL cholesterol, and an increased amount of fecal excretion of bile acids and cholesterol[70]. Phase 1 clinical studies tested the therapeutic concept of lowering cholesterol and found GC-1 to be generally well tolerated at all doses studied[81,82].

In a recent study, GC-1 has also been shown to be capable of markedly reducing serum cholesterol in mice devoid of functional LDLRs by inducing CYP7A1 expression[60]. These results, having elucidated the possibility that a LDLR-independent mechanism could underlie GC-1 action, potentiated the idea that GC-1 may represent a promising cholesterol-lowering therapeutic with a specific application for the treatment of diseases such as homozygous familial hypercholesterolemia. Currently, there are only limited treatment options for this disorder because most therapeutics are only minimally effective.

Another agent being studied is MB07811 which exhibits increased TR activation in liver relative to other tissues[57]. By using several experimental approaches, MB07811 was shown to have anti-steatotic activity and was able to reduce hepatic triglyceride levels in both normal and metabolically-challenged animal models, including ob/ob mice, Zucker rats, and mice with diet-induced obesity (rodent models of NAFLD)[83]. The main mechanism underlying MB07811 effects appears to be an augmented metabolic rate in the liver and, specifically, an increased rate of mitochondrial β-oxidation. MB07811 increases: (1) the levels of CPT-1α[35] and short and intermediate length acyl-carnitine species in plasma and (2) the liver mitochondrial respiration rates as well as the activity of hepatic mitochondrial glycerol-3-phosphate dehydrogenase (mGPDH), an enzyme which is important for energy production and dissipation. Decreased mRNA levels of apolipoprotein C3 (Apo-C3), an inhibitor of hepatic lipase activity, might also contribute to the activation of fatty acid oxidation pathways. Additionally, MB07811 can also lower both serum cholesterol and triglyceride levels[83,84] (Figure 3B). These data in rodents confirm that MB07811 represents a novel class of liver-targeted TR agonists with beneficial LDL-lowering properties, and suggest that these compounds may provide additional therapeutic benefit to hyperlipidemic patients with concomitant NAFLD[83]. The human Phase 1b clinical trial showed reduced LDL cholesterol and TGs levels in both normolipidemic and hyperlipidemic subjects without severe adverse events[23].

Together, these data demonstrate that selective activation of hepatic TR prevents or reverses fatty liver and reveals a new approach to treat NAFLD based on selectively burning hepatic fat.

Now, the question is whether other molecules such as naturally occurring TH metabolites, even deprived of TR selectivity or characterized by low binding affinity for TRs, can have uses as therapeutic applications.

NATURALLY OCCURRING IODOTHYRONINES AND LIVER STEATOSIS: 3,5-T2

An increasing amount of data indicates that there are at least four natural iodothyronines with significant, but not identical, biological activities, namely T4, T3, rT3 (reverse T3), and 3,5-diiodo-L-thyronine (T2). T2 is particularly intriguing because of its effects on metabolism[22,25,26]. T2 has been estimated, in euthyroid rats, to reach serum concentrations of approximately 5 pM and is present in liver at concentrations of approximately 1.0 fmol/100 mg[85]. In humans, serum T2 levels consistently elevated in disease states, with the mean T2 serum level being 16.2 ± 6.4 pM in healthy subjects, 21.6 ± 4.8 pM in patients with brain tumors and 46.7 ± 48.8 pM in patients with sepsis[86].

T2 measurements are routinely taken using methods based on immunoassays, an approach with high sensitivity but which lacks specificity for many analytes[87,88]. In recent years, mass spectrometry (MS) techniques have drawn attention to the analyses of T4 and T3 because they provide high mass accuracy, structural information, and have the ability to quantify the hormones[89-93]. A recently developed methodology revealed that electrospray ionization tandem mass spectrometry (ESI-MS/MS) can be used for identification and quantification of mixtures of isomers and has been applied to identify and quantify T3 and rT3 isomers as well as T2 isomers[94,95]. Currently, however, intrinsic instrumental limits restrain the application of such approaches as routine tools for biological samples analysis and slow the advancements in understanding T2 metabolism[96,97].

T2 is a product of a currently unknown peripheral enzymatic process most probably utilizing T3 as its precursor[85] and has 50-1000 times lower affinity for TR than T3[98]. Thus, it is unlikely that TR activation represents a central mechanism in its effects on metabolism, at least in physiological conditions. However, more recent studies have reported new data concerning T2 binding to TRβ isoforms in teleosts[99,100]. Specifically, T2 has been shown to bind and transactivate both the human and the long tilapia TRβ1 isoform whereas T3 preferentially binds the short isoform. These results prompted a reevaluation of the mechanisms of action of thyroid hormone metabolites.

Several studies on T2 effects in mammals revealed its ability to stimulate cellular/mitochondrial respiration by pathways with mitochondria and bioenergetic mecha-

nisms being the major targets[26,80,101-103]. Outside the mitochondria, T2 also has effects on carriers, ion-exchangers, and enzymes, and may affect the transcription of some genes, but again the underlying mechanisms appear to be different from those elicited by T3[26].

In 1998, Arnold *et al*[104] identified the Va subunit of the mitochondrial respiratory chain complex cytochrome-*c* oxidase (COX) as a specific binding site for T2 using photoaffinity labeling procedures. T2 binding to the COX complex abolishes the allosteric ATP inhibition of COX which leads to a decrease in the respiratory control ratio of the complex[105] thus rendering the oxidative phosphorylation more inefficient.

The biological and pharmacological importance of T2 has become a topic of considerable interest to researchers during the past few years, and now represents a significant and promising issue in the field of metabolism and THs.

The effects and mechanisms underlining the beneficial actions of T2 have so far been studied with both *in vivo* and *in vitro*[106-108] models. *In vivo* studies from different laboratories have shown that acute or chronic administration of T2 to rats results in significant changes in mitochondrial activities and resting metabolic rate[22,26,109].

A recent study reported an increased basal metabolic rate and decreased body weight also in humans chronically administered with T2 with no deleterious side effects on the thyroid axis or at the cardiac level[110].

Of the currently described *in vivo* stimulatory and beneficial effects of T2, a particular physiological and pharmacological relevance appears to be associated with those effects that we can define as hypolipidemic and anti-steatotic effects which have been described in several animal models[111-114]. Among the methods to study liver metabolism and physiology, the variation in the nutritional status is a widely used approach because of its ability to affect several signaling pathways and regulatory mechanisms[115-118]. High fat feeding (HFD) in animals, in particular, has the advantage to mimic most features of human fat overload and overnutrition and allows the study of obesity and related disorders such as ectopic fat accumulation.

Specifically, the administration of T2 to rats subjected to HFD is able to prevent and reduce the visceral fat accumulation as well as hepatosteatosis, serum levels of triglycerides and cholesterol, and the onset of IR without inducing thyrotoxicosis[111,112,114,119]. Moreover, T2 has been reported to elicit additional beneficial effects on lipid metabolism by reducing LDL-cholesterol in a LDLR independent way in a mouse model of familial hypercholesterolemia[120].

The simultaneous administration of T2 (25 μg/100 g body weight) to rats receiving a HFD for 4 wk can prevent liver steatosis by stimulating hepatic fatty acid oxidation and increasing mitochondrial uncoupling[111]. This leads to a less efficient utilization of lipid substrates, and helps to prevent body-weight gain, hepatic fat accumulation, hypertriglyceridemia and hypercholesterolemia lev-

els without inducing changes in T3 and T4 serum levels or affecting the hypothalamus-pituitary-thyroid (HPT) axis[111,119].

The T2 effects on liver fatty acid oxidation are paralleled by an increased entry of activated fatty acids into the mitochondria *via* activation of the CPT system. This leads to a strong reduction in the fatty acids inside the cell and a strong activation of AMP-activated protein kinase (AMPK), enhancing the cycle of fat uptake and fat burning and the disappearance of lipid droplets (LDs)[111].

Importantly, T2 administration prevents the HDF-induced lipid peroxidation, as well as the increase in H_2O_2 metabolism counteracting both lipid accumulation and oxidative stress associated with increased fat metabolism[121].

In a more recent study, to further investigate how T2 affects lipid and glucose metabolism in HFD rats eliciting beneficial effects on liver, independently of AMPK, the involvement of another important regulator of metabolic balance[122-127], SIRT1, was studied[114]. In HFD rats, T2 was demonstrated to (1) rapidly increase hepatic nuclear SIRT1 activity and (2) through SIRT1-activation, deacetylate PGC-1α and SREBP-1c with a concomitant upregulation of genes involved in mitochondrial biogenesis and downregulation of lipogenic genes[114]. Moreover, the obtained data added new information on the time-latency of the anti-steatotic effect of T2 which within 6 h after administration, rapidly and directly activates hepatic SIRT1 (affecting β-oxidation and mitochondrial biogenesis) and later (4 wk) promotes AMPK phosphorylation/activation thus profoundly modulating liver expression pattern of genes and proteins.

A proteomic study[113] showed that the steatotic effect of HFD, and the anti-steatotic effect of T2-treatment are strictly associated with altered expression levels of several proteins and enzymes involved in key liver metabolic (canonical and non-canonical) pathways across different subcellular compartments (*i.e.*, cytoplasm, mitochondria and nuclei). These pathways included: fatty acid metabolism, ketone-bodies and energy metabolism, amino acid and nitrogen metabolism, the urea cycle and the stress response and protein turnover.

All the analyzed liver subcellular compartments were significantly affected, in terms of protein expression, by both HFD and long-term T2-treatment. However, mitochondria appeared to be a major target for the metabolic and energy adaptations induced by fat-overload, and displayed a significant response, in terms of their proteome, to T2-treatment. These data supported the concept that T2-supplementation while having hypolipidemic and anti-steatosis effects, may provide protection against diet-induced liver damage, possibly by counteracting the alterations in the expression of several cellular proteins, reducing oxidative stress and impairing the mitochondrial respiratory chain[113].

T2 administration to rats is also able to reduce pre-existing hepatic fat accumulation (that had already been induced by feeding with a HFD)[112] by eliciting systemic

and tissue specific effects. In particular, T2, without suppressing TSH, decreases body weight gain, metabolic efficiency and serum levels of cholesterol, triglycerides and ALT. In the liver, T2 increases hepatic mitochondrial oxygen consumption and fatty acid oxidation and activates mitochondrial proton leak reducing mitochondrial oxidative stress[112].

In vitro studies have been performed to address whether the anti-steatotic effect of T2 is due to the direct action of T2 on the liver or if it is a secondary effect due to upstream changes in endocrine or metabolic pathways. Primary cultures of rat hepatocytes overloaded with lipids ("fatty hepatocytes") and then treated with T2 showed a reduction in: (1) lipid content and LD diameter; (2) PPARs expression; and (3) activities of acyl-CoA oxidase (AOX) and antioxidant enzymes. These data support a direct role of T2 in reducing the excess fat in cultured hepatocytes[128]. The putative involvement of TRs in mediating such lipid-lowering effects of T2 has been elucidated using the rat hepatoma FaO cellular model, which is defective for functional TRs[128]. The addition of T2 to lipid-overloaded cells resulted in: (1) reduction in lipid content; (2) downregulation of PPARα, PPARγ, and AOX expression; (3) increase in PPARδ expression; and (4) stimulation of mitochondrial uncoupling[128]. These data demonstrate, for the first time that the *in vitro* lipid-lowering actions of T2 may be not mediated by TRs.

All the utilized approaches, both in animal models and humans, successfully highlighted metabolic actions and potential pharmacological use of T2. Notably, T2, without thyrotoxic side effects, increasing resting metabolic rate, decreasing adiposity and body weight, could be considered an active agent in preparation for treatment of metabolic disorders, such as T2DM, overweight and NAFLD (Figure 4A).

THYROID HORMONE FUNCTIONAL ANALOGUES: TRC150094 (TRC)

T2 research has been recently focused on the discovery and development of T2 functional analogues with therapeutic potentials. In particular, a series of novel substituted pyrazoles were designed and synthesized as T2 analogs with lower affinities toward TRs. Among these molecules, TRC150094 (TRC) has attracted particular attention emerging as a novel thyromimetic and functional T2-analogue linking fat consumption with the pathogenesis of hepatic steatosis. The chemical name for TRC is 3-[4-(7-hydroxy-6-methyl-indan-4-ylmethyl)-3,5-dimethyl-pyrazol-1-yl]-propionic acid, and its chemical structure is shown in Figure 2. TRC was synthesized by the Torrent Research Centre, Torrent Pharmaceuticals Ltd., Ahmedabad, Gujarat, India and has a much lower potency toward both TRα1 and TRβ1 isoforms' activation than T3. Therefore, it is devoid of adverse effects on the heart classically associated with TR hyperactivation [the rank order of potencies for TR (α1/β1) transcriptional activation being T3 > T2 >>TRC[129]].

When screened for its *in vivo* metabolic effects, TRC (injected, at a dose of 0.750 mg/100 g body weight, in rats simultaneously undergoing a HFD for 4 wk) counteracts the hepatic pathological condition observed in HFD rats without any thyrotoxic effects[129]. The anti-steatotic activity of TRC is due to increased rates of mitochondrial fatty acid uptake and oxidation, respiratory chain activity and resting metabolic rate, and to the activation of the CPT system[129,130]. Importantly, TRC significantly increases SIRT1 activity although the SIRT1 protein level remains unaltered. These results strongly suggested that a TRC-induced increase in SIRT1 activity might underlie the increase in fatty acid oxidation and the prevention of liver steatosis observed in the TRC-treated rats[129].

An integrated functional study performed by combining *in vivo* and *ex vivo* metabolic assays with proteomic and bioinformatic analyses showed that TRC administration to rats with pre-existing body fat accumulation significantly altered the expression levels of several proteins and enzymes involved in key liver metabolic pathways, including amino acid, nitrogen, fructose and mannose metabolism, and RXR activation and function[130]. Consistent with the increased oxidation of mitochondrial fatty acids and the unaltered mitochondrial efficiency, numerous mitochondrial enzymes associated with fatty acid oxidation and energy metabolism were increased in livers from HFD-TRC[130].

Oral administration of TRC to obese Zucker rats (obese ZSF1, spontaneously hypertensive fatty rats) decreased hepatic steatosis[131] by inducing a significant increase in mitochondrial respiration as well as an increased fatty acids oxidation. All the above mentioned studies have so far provided the characterization of the pharmacological/metabolic effects of TRC and highlighted its potential utility as a new compound with effectiveness for prevention/amelioration of certain key biochemical parameters altered during feeding on a HFD-regimen and a cluster of multiple cardiovascular risk factors associated with visceral obesity, steatosis and metabolic derangements (Figure 4B). If reproduced in humans, these results could determine whether TRC150094 represents an attractive therapeutic agent for the treatment of overweight dysglycemic patients.

Indeed, clinical trials are currently in progress to translate these effects into approaches for the treatment of human obesity.

THYROID HORMONES AND MITOCHONDRIAL FUNCTIONS

As already stated, mitochondria play a fundamental role in the development, perpetuation and worsening of liver steatosis and NAFLD. Indeed, the generation of NAFLD, apart from involving defects or polymorphisms in mitochondrial DNA, can be an important consequence of damages to the respiratory chain complexes impairing mitochondrial oxidative capacity, particularly critical when fatty acid supply to the hepatocytes is increased as
Figure 4 A summary of key events and molecular pathways underlying T2 (A) and TRC (B) anti-steatotic and hypolipidemic effects (for details see the text). T2: 3,5-diiodo-L-thyronine; TR: Thyroid hormone receptor; COX Va: Cytochrome-*c* oxidase Va subunit; FFA: Free fatty acid; TG: Triglyceride; P-AMPK: Phosphorylated AMP-activated protein kinase; SIRT1: NAD$^+$-dependent deacetylase sirtuin 1; PGC-1α: Peroxisome proliferator-activated receptor γ coactivator; SREBP-1c: Sterol response element binding protein-1c; CPT: Carnitine palmitoyltransferase system; OXPHOS: Oxidative phosphorylation system.

in calorie-rich diets[132].

Mitochondrial bioenergetics deficits may be the consequence of: (1) a progressive decay of oxidative capacity with impairments of β-oxidation; and (2) major changes in the redox balance with increased reactive oxygen species production.

It is widely recognized that mitochondria are central targets for THs actions. Indeed, mitochondria, providing about the 90% of the cellular energy supply, likely may be a major player of the so called calorigenic effects of THs[133]. In particular, T3 stimulates mitochondriogenesis and thereby augments cellular oxidative capacity and induces, at the same time, substantial modifications in mitochondrial inner membrane protein and lipid compositions, activating uncoupling of oxidative phosphorylation[133].

In terms of time latency, two types of effects of T3 on mitochondria have been described: (1) a rapid stimulation of respiration, which is evident within minutes/hours after hormone treatment; (2) a delayed induction

of mitochondrial biogenesis and changes in mitochondrial mass, which occur one to several days after hormone treatment. The first effect is probably due to extranuclear/non-genomic mechanisms; the second one involves both T3-responsive nuclear genes and a direct action of T3 at mitochondrial level[109,133]. In other words, this second effect allows T3 to modulate mitochondria activity in two different ways: direct or indirect. The direct action requires the presence inside the organelles of specific binding sites for the hormone[134-136] while the indirect one possibly requires T3 binding to extramitochondrial sites and the modulation of the expression of either nuclear-encoded mitochondrial proteins or intermediate factors (*e.g.*, nuclear respiratory factors 1 and 2; mitochondrial transcription factor A)[137,138].

T3, by the regulation of these pathways, allows the coordinated expression of both the nuclear and the mitochondrial genome that in turn modulates mitochondrial biogenesis, turnover and bioenergetics.

Although the network of factors and cellular events involved in T3 signaling remains incompletely understood, the so far described mechanisms can justify, at least in part, the above reported hypolipidemic and antisteatotic effects elicited by T3 in NAFLD.

CONCLUSION

Considering the impact of THs on the maintenance of lipid homeostasis but also of their adverse effects in TH excess states, recent efforts to identify effective and safe treatments for the counteraction of metabolic disorders (such as liver steatosis), has led to the development and characterization of thyromimetics. Some of these analogs are undergoing further examinations for possible clinical applications. However, despite their original promise, it is unlikely that any first generation synthetic ligands (*i.e.*, GC-1 and MB07811) which already reached human clinical trials will develop into therapeutics. Thus, attention should be focused on other molecules, such as T2 or TRC which could have therapeutic applications. Indeed, such compounds could serve as powerful new tools to address some of the largest over-nutrition associated medical problems as they are able to reduce, at least in animal models of diet-induced obesity, body adiposity, serum triglycerides and cholesterol. They also preserve glucose homeostasis without thyrotoxic side effects. Notably, the hypolipidemic effect of T2 is associated with a potent ability in both preventing and reducing fatty liver. Increasing evidence supports TH derivatives and analogues as attractive active agents that could be taken into consideration for the establishment of new treatments in the counteraction of metabolic disorders, such as T2DM, obesity and NAFLD, thus clinical trials are desirable.

Abstract

Gastric varices (GVs) are notorious to bleed massively and often difficult to manage with conventional techniques. This mini-review addresses endoscopic management principles for gastric variceal bleeding, including limitations of ligation and sclerotherapy and merits of endoscopic variceal obliteration. The article also discusses how emerging use of endoscopic ultrasound provides optimism of better diagnosis, improved classification, innovative management strategies and confirmatory tool for eradication of GVs.

Core tip: This mini-review addresses endoscopic management principles for gastric variceal bleeding. Endoscopic variceal obliteration (EVO) with tissue adhesives is the currently accepted strategy for controlling bleeding and eradicating gastric varices (GVs). EVO is deemed better than both variceal ligation and sclerotherapy in randomized controlled trials. One unsettled issue with EVO is if routine reinjection is better than reinjection in case of rebleeding. The experience with combination treatments is still premature. For secondary prophylaxis, EVO, transjugular intrahepatic portosystemic shunt or beta-blocker use is recommended. Emerging use of EUS provides optimism of better diagnosis, improved classification, innovative management strategies and confirmatory tool for eradication of GVs.

INTRODUCTION

The natural history of gastric varices (GVs) is less understood than that of esophageal varices (EVs). GVs may be seen in 18%-70% of the patients with portal hypertension (PHT) and are probable source of bleeding in 10%-36% of patients with acute variceal bleeding (AVB)[1-3]. Isolated GVs (IGVs), without EVs, are seen in 5%-12% of patients with PHT[1-3]. They are also commonly seen in patients with non-cirrhotic portal hypertension (NCPHT),

especially with splenic vein thrombosis (SVT). They are more commonly associated with shunts than EVs, most commonly spleno-renal shunt, and their management is quite different from that of EVs.

CLASSIFICATIONS

GVs are commonly classified according to Sarin's classification[4,5] based on location and direction of blood flow: GOV1 (Gastro-Oesophageal Varices) are the most common (74% of all GV) and consist of the esophageal varices extending along the lesser curvature of stomach; GOV2 are the extension of the esophageal varices along the greater curvature near the fundus; IGV1 are isolated gastric varices localized to fundus, without any associated esophageal varices. These arise from spleno-renal or gastro-renal shunts where the feeding vessel arises from the splenic hilum and drains in to left renal vein through gastric cardia/fundus veins. GOV2 and IGV1 are sometimes together called "fundic varices". IGV2 are the isolated gastric varices present elsewhere other than the fundus, which drain in a similar fashion into left renal vein but with multiple tributaries. It is reported that fundal varices (GOV2 and IGV1), though less common than GOV1 varices, are noted to account for 80% of patients with bleeding GV.

Hashizume *et al*[6] proposed an alternate classification of GVs based on endoscopic findings, taking into account their shape (tortuous = F1, nodular = F2, and tumorous = F3), location (anterior = La, posterior = Lp, lesser curvature = Ll, greater curvature = Lg of the cardia, and fundic area = Lf) and color (white = Cw or red = Cr) and further emphasized on presence of glossy, thin-walled focal redness on the varix called as red color spot (RC spot) as a marker of impending bleeding risk[6].

BLEEDING RISK OF GVS

Although GVs are known to bleed less frequently than the EVs, however when they do, they bleed massively and are difficult to achieve primary hemostasis, with a mortality rate of 10%-30%[4,5]. Their chance of re-bleeding is high (35% to 90%) after spontaneous remission and 22%-37% with the glue technique[4,5]. The chance of variceal bleeding is driven by the pressure changes rather than hemostatic forces. The pressures in the GVs are lower than the in the EVs because of their larger size and more frequent presence of the shunts like spleno-renal[7,8]. Despite this, their rupture is more devastating because of the fact that the wall stress increases dramatically even with small rise in the portal pressures due to their larger radius. When there is increase in transmural pressure, the variceal size increases and wall thickness decreases, which leads to rupture[7,8]. The factors which predict hemorrhage in EVs also govern GVs: most importantly the size of the varices (15% in patients with large varices, which are defined as > 10 mm), decompensated cirrhosis and endoscopic presence of the red wale sign. Another factor

implicated in increase in incidence and/or size of fundic varices and possible bleeding is the treatment of EVs by either endoscopic variceal ligation (EVL) or endoscopic sclerotherapy (EST)[9]. The plausible explanation is that after treatment the existing collaterals are not sufficient enough to decompress the portal pressure causing an increased incidence of fundic varices.

GENERAL PRINCIPLES OF MANAGEMENT OF BLEEDING GVS

The preliminary management of bleeding GVs is the same as any other variceal bleeding[1-3]. Fluid resuscitation, airway protection, antibiotic administration for the bacterial peritonitis prophylaxis and use of vasoactive agents like octreotide and acid suppressant agents like proton pump inhibitors form cornerstone of initial management. Cautious administration of the blood products (to achieve a target of hemoglobin level between 7-8 g/dL) is advocated as there is potential risk of increased rebleeding if the portal pressures increase due to repeated transfusions. A schematic of management algorithm of GVs is presented in Figure 1.

Treatment options for acute GV bleeding are varied and include medical, surgical, endoscopic, and endovascular approaches[1-3]. Two general methods exist to deal with bleeding GVs: directly exclude the varices from the porto-systemic system or indirectly decrease the pressure in the varices by decompressing the portal system.

Direct approach
Variceal management by direct endoscopy or endoscopic ultrasound.

Role of endoscopy: Once the patient is deemed stable from airway and circulation standpoint, an esophagogastroduodenoscopy (EGD) should be performed, which might show active bleeding or reveal stigmata of recent bleeding, in addition to qualify type of GVs and concomitant presence of EVs or PHG[1-3].

Several endoscopic techniques have been tested to control acute gastric variceal bleeding with varying successes. However, the universal phenomena is that majority of the methods used in controlling the bleeding EVs are difficult to practice in GVs and are inconsistently successful. These include endoscopic injection sclerotherapy (EIS) and esophageal variceal ligation (EVL). The varying success of these methods may be owing to different physiology and size of GVs which pose technical problems.

GV ligation: The main indications for ligation in management of acute GV bleeding is banding of GOV1 varices, which are extensions of EVs into the stomach along the lesser curvature or as salvage strategy if other modalities are not available[10]. Studies suggest good hemostasis efficacy and comparable re-bleeding rates of GOV1 ligation to EVL of EVs. There is limited role for ligation

Figure 1 Proposed management algorithm for gastric varices. High risk patient: Child Pugh class B or C or endoscopic presence of red wale sign; Low Risk Patient: Child Pugh class A and no endoscopic high-risk features. GV: Gastric varices; EVO: Endoscopic variceal obliteration; EVL: Endoscopic variceal ligation; EIS: Endoscopic injection sclerotherapy; NSBB: Non specific beta blocker; BRTO: Balloon-occluded retrograde transvenous obliteration; TIPS: Trans-jugular intra-hepatic porto-systemic shunt; GOV: Gastro-oesophageal varices; IGV: Isolated gastric varices.

in management of bleeding fundic varices[1-3]. In head-to-head studies, EVL was less effective than endoscopic obturation by injection of cyanoacrylate for hemostasis of large GVs[11], and had higher re-bleeding rates too[12]. Smaller studies have attempted improvisation of ligation methods to increase its success in GV, like using detachable snares and elastic bands or in combination with sclerotherapy, however these experimental techniques are yet to be implemented universally[13,14].

Endoscopic injection sclerotherapy: Fundic varices (IGV1 and IGV2) are wider and have larger volume, needing large quantity of sclerosant which is susceptible to being washed away, potentially leading to systemic (esp. pulmonary) embolization, and may also lead to increased chances of ulceration at injection site. Before the advent of newer techniques, sclerotherapy of GVs using alcohol or tetradecyl sulfate was common and was associated with decent initial hemostasis rates (up to 67%-100%),

however the higher frequency of re-bleeding mainly due to post-procedure ulceration severely limited its long-term success[10]. Furthermore, the risk of complications including fever, retrosternal chest pain, temporary dysphagia and pleural effusions was unacceptably higher with EIS[15]. Overall, the success of EIS is questionable in management of acute GV bleeding[16] and hence is not the preferred method in any of the guidelines.

Endoscopic variceal obturation: Endoscopic variceal obturation (EVO) using tissue adhesives like glue, cyanoacrylate or histoacryl has provided a positive direction to management of fundic varices, which was always a challenge. Cyanoacrylate is a polymer which upon coming in contact with blood polymerises instantly leading to obliteration of varices. It is called "obliteration" and not "eradication" since the varices may be still visible post-treatment.

EVO with N-butyl-2-cyanoacrylate has been the advocated first-line method in managing the gastric varices especially fundic varices[1-3]. Kang *et al*[17] performed EVO with cyanoacrylate in 127 patients with GVs (100 active bleeding and 27 prophylactically) and reported a primary hemostasis rate of 98.4% (1 session-98 patients, 2 sessions-25 patients, ≥ 3 sessions-4 patients), with a recurrent bleeding rate of 18.1 % at 1 year[17]. Several studies have compared EVO head-to-head with EIS or EVL to conclude the favorable outcomes of EVO in terms of initial hemostasis, and lesser re-bleeding and complications[11,12,18-20]. Furthermore, re-bleeding rates after EVO were found to be comparable to transjugular intrahepatic porto-systemic shunt (TIPS) in patients with acute GV bleeding, suggesting this technique may be equally efficacious in secondary prevention and creating opportunity of therapy in patients in who TIPS is contraindicated for encephalopathy reasons[21]. Few studies have advocated using dynamic CT scan prior to EVO to increase the detection of feeding vessels, assessment of direction of blood flow, presence of shunts, in an attempt to increase efficacy and minimize complications of EVO technique[22], although this is not universally practiced.

Although EVO is clearly a superior technique than EIS or EVL for bleeding GVs, it is not free of technical difficulties (para-variceal injection, needle sticking in the varix, intra-peritoneal injection leading to peritonitis and adherence of the glue to the endoscope) or complications (fever, para-variceal injection with mucosal necrosis and bleeding, embolization into the renal vein, IVC, pulmonary or systemic vessels and retro-gastric abscesses)[12,18-20]. However, emerging literature supports preference of distilled water over saline to dilute cyanoacrylate to decrease coagulation and use of standardized techniques of tissue adhesive preparation and delivery to decrease rates of these complications[23]. In case of large gastric varix, it is advised to begin tissue adhesive injection from bottom to dome to minimize risk of bleeding if injected directly at high pressure-high flow dome area. Liu *et al*[24] reported an interesting scenario which devel-

oped when EVO of GVs led to hemorrhage from EVs due to embolism of the glue into the EV thus increasing the pressure. This was not amenable to EV ligation due to presence of foreign body (glue) and was managed with cyanoacrylate injection into EVs to achieve hemostasis and authors rightly cautioned endoscopists to treat EVs in the same setting as EVO of GVs to prevent such a complication[24].

Another major difference between EVO and other endoscopic techniques is that variceal obliteration of the GVs is not quite obvious after cyanoacrylate injection, and hence adequacy of EVO is controversial. Most often GVs are probed with an endoscope and the induration is accepted as a sign of inadequate obliteration with the need to inject more tissue adhesive till it is "hard" to palpate. Improved radiology (use of CT portography)[22] and newer endoscopic techniques have made this EVO adequacy assessment easier, as discussed later in this article. Notably, EVO has recently been shown to be superior to beta blocker therapy for primary prophylaxis of GVs and hence is being advocated[25]. Evidence regarding efficacy of the glue in pregnant females and in children is still emerging and premature, and so is data on newer combination EVO-sclerotherapy modalities[26].

Novel EVO materials: Endoscopists are trying several materials to achieve hemostasis in technically challenging situations, like successful use of hemostatic powder in situation with failed EVO with cyanoacrylate glue and contraindication to TIPS due to dilated cardiomyopathy[27]. Thrombin was used by Yang *et al*[28] and Ramesh *et al*[29] in separate studies to successfully achieve initial hemostasis 100% and 92% patients, with re-bleeding rates of 27% and 0% respectively. Thrombin helps in clotting by converting fibrinogen to fibrin and promotes platelet aggregation as well. Although these studies were limited by their patient size (12 and 13 patients respectively)[28,29], and did not report any untoward thrombo-embolic events, the concern for thrombin leakage into systemic circulation and potentially causing disseminated intravascular coagulation (DIC) or systemic embolization still remains. It is currently not being advocated due to lack of adequate data.

Role of endoscopic ultrasound: It is common knowledge that endoscopic ultrasound (EUS) enables the visualization of esophago-gastric varices and other venous collaterals viz. peri- and para-esophageal collateral veins and perforating veins, in patients with PHT, and can be useful to assess the patency of the portal venous system[30]. There has been an attempt in 1993 to classify gastric varices endosonographically by Boustière *et al*[31], which considered size of GVs and gastric wall abnormalities (Table 1), and inferred that while endoscopy graded EVs better, EUS was a better tool to classify GVs and early signs of portal gastropathy. The other EUS features of portal hypertension, in addition to EVs and GVs, may include dilatation of the azygos vein, splenic vein

Table 1 Endoscopic ultrasound classification of gastric varices: Proposed by Boustiere *et al* in 1993

Endoscopic ultrasound classification of gastric varices	
1: Size of gastric varices	Grade 0 (none)
	Grade 1 (small or non-confluent varies < 5 mm)
	Grade 2 (large or confluent varices ⩾ 5 mm)
2: Abnormalities of gastric wall	Grade 0 (none)
	Grade 1 (thickening and brilliance of the third hyperechogenic layer with or without fine internal anechogenic structures)
	Grade 2 (visible vessels in the third layer which deform the entire wall, with penetrating varices)

and portal vein, increased diameter of the thoracic duct, thickening of gastric mucosa and submucosa, presence of portal hypertensive gastropathy, and the presence of rectal varices[30,32]. In addition, EUS combined with color Doppler imaging enabled visualization of shunts viz. gastro-renal shunt in one report[33]. Furthermore, EUS doppler helps characterize gastric submucosal lesions better than EGDs before proceeding to the biopsy of potential GV.

Role of EUS in risk estimation for GV bleeding is a field of growing interest. EUS probes can be used to measure size of varices (diameter), and furthermore to estimate variceal wall thickness which is deemed as a better predictor of bleeding than varices diameter alone[34]. Intra-variceal pressure measurement may be a better surrogate for risk of bleeding, which can be accomplished by direct variceal puncture which is not practiced because of invasiveness. Although data is slim, there has been an attempt looking at EUS guided EV pressure recording, to better predict risk of bleeding, and it has been shown to have reasonable correlation with hepatic venous pressure gradient (HVPG)[35]. Finally, high risk stigmata like red hematocytic spot can be visualized with EUS[36].

EUS-assisted injection sclerotherapy for both gastric[37] and esophageal varices[38] is effective, achieving high eradication and low recurrence rates in long-term follow-up. In fact the risk of re-bleeding after EUS directed sclerotherapy is reportedly lower than endoscopic technique. Recently additional attention has been diverted towards EUS delivered therapies to control bleeding in acute variceal bleeding patients, using unique agents like adhesive tissue (histoacryl)[39], thrombin[40] and EUS-guided coil injection for gastric[41] and ectopic duodenal varices[42]. Last but not the least, EUS finds its utility in confirmation of adequacy of EVO of gastric varices, eliminating the need for inept endoscope probing assessment and thus increasing overall efficacy of EVO technique[43]. A recent study from Taiwan used miniature ultrasound probe (MUP) sonography in 34 patients who underwent cyanoacrylate EVO therapy for acute GV bleeding, during follow-up endoscopy session to assess adequacy of obturation and reinjection if necessary. The authors demonstrated a significantly greater

free-of-rebleeding rate and trend towards better survival for patients in MUP group compared with conventional endoscopy group[43]. Although these advances bring a sound of promise, EUS probe which has a larger diameter compared to conventional scope, in addition to GV intervention is certainly a high-risk procedure. Using a mini-probe may counter some of this added disadvantage but non-availability of pediatric sizes is still a limitation. Furthermore, future studies need to compare radial and linear EUS scopes in diagnosis and management of varices.

Indirect approach
Decreasing portal pressure - either surgically or percutaneously by establishing a TIPS.

Role of TIPS: Porto-systemic shunts such as TIPS are typically advocated as second-line acute therapy (after endoscopic management) to prevent re-bleeding of varices[1-3]. Although decreasing portal pressure is considered effective in reducing the bleeding rate of EVs, it is inconsistently effective for GVs, which tend to occur and bleed at lower portal pressures[21,44]. Also there is discordance between decreased hepato-portal gradient with TIPS and actual decrease in GV re-bleeding. In addition, TIPS has its own limitations including worsening of encephalopathy or shunt occlusion, which can lead to recurrence of hemorrhage, and surveillance for patency.

Role of advanced radiological procedures: If all endoscopic techniques and TIPS fail or if TIPS is contraindicated, then the next step would be balloon-occluded retrograde transvenous obliteration (BRTO)[1-3], which is a popular technique in Japan, and allowing modulation of flow within the varices. BRTO was popularized and named by Kanagawa *et al*[45] in 1996, this technique optimize the action of the sclerosing agent by inducing stagnation in the gastric varices, thereby allowing maximal sclerosant dwell time to cause endothelial sclerosis and vascular thrombosis. The discussion of technique, advantages and complications of BRTO is beyond the scope of current mini-review, but one of the emerging fronts in management of acute GV bleeding.

CONCLUSION
GVs are notorious to bleed massively and often difficult to manage with conventional techniques. EVO with cyanoacrylate glue injection is currently the most favored for being superior to variceal ligation or sclerotherapy in achieving hemostasis in acute gastric variceal bleeding. Endoscopists must remain cognizant about the possible complications of tissue adhesive injections and strive for standardization of EVO techniques to minimize them. Novel techniques like use of thrombin, coil embolization are under investigation as alternatives to cyanoacrylate aiming for improved outcomes. TIPS and BRTO are advanced radiological procedures available as

salvage techniques in uncontrollable bleeding situations or when patients are not candidates or have failed endoscopic management. The role of EUS in the therapeutic algorithm for GVs is still evolving. EUS is being used to confirm presence, size and location of GVs, to stratify the risk of re-bleeding, as a therapeutic tool to perform sclerotherapy or EVO, and to confirm eradication of GVs after EVO. Emerging use of EUS provides optimism of better diagnosis, improved classification, innovative management strategies and confirmatory tool for eradication of GVs.

Abstract

Liver innervation comprises sympathetic, parasympathetic and peptidergic nerve fibers, organized as either afferent or efferent nerves with different origins and roles. Their anatomy and physiology have been studied in the past 30 years, with different results published over time. Hepatocytes are the main cell population of the liver, making up almost 80% of the total liver volume. The interaction between hepatocytes and nerve fibers is accomplished through a wealth of neurotransmitters and signaling pathways. In this short review, we have taken the task of condensing the most important data related to how the nervous system interacts with the liver and especially with the hepatocyte population, how it influences their metabolism and functions, and how different receptors and transmitters are involved in this complex process.

Key words: Liver innervations; Hepatocytes; Neurotransmitters; Cellular receptors

Core tip: Liver innervation comprises sympathetic, parasympathetic and peptidergic nerve fibers, organized as either afferent or efferent nerves with different origins and roles. Their anatomy and physiology have been studied in the past 30 years, with different results published over time. Hepatocytes are the main cell population of the liver, making up almost 80% of the total liver volume. The interaction between hepatocytes and nerve fibers is accomplished through a wealth of neurotransmitters and signaling pathways.

INTRODUCTION

Innervation of the liver comprises efferent and afferent nerves containing sympathetic, parasympathetic and peptidergic fibers. Sympathetic nerve fibers derive from splanchnic nerves and the parasympathetic counterparts have a vagal origin. Fibers derived from splanchnic, vagus and sometimes the phrenic nerves enter the liver through the hilum, together with the hepatic artery, portal vein and bile duct. Some nerve fibers do not accompany hepatic vessels and enter the liver *via* the small omentum or the hepatic vein. Sympathetic and parasympathetic nerves form two separate plexus but communicate with each other: the anterior plexus placed around the hepatic artery, consisting of nerve fibers with their origin in the celiac ganglion and posterior vagus nerve, and the posterior plexus located around the portal vein and bile duct,

formed by fibers from the celiac ganglion and the right vagus[1]. Nervous fibers which are distributed to the hepatic parenchyma derive from a corresponding nervous plexus and their intrahepatic distribution differ according to species[2,3].

In the human liver, nerve endings are located in the hepatic lobules[4], which consists of hepatocytes and non-parenchymal cells. Unlike hepatocytes, which occupy almost 80% of liver volume and have numerous functions, non-parenchymal liver cells occupy only 6.5% of the liver, although representing 40% of total liver cells[5].

Hepatocytes are arranged as cellular cords with a radial disposition that converges towards the centrilobular vein, being separated by sinusoidal capillaries. Between hepatocyte cell cords and sinusoid capillaries there is an interstitial space, a perisinusoidal called a Disse space. This space is formed by a fine network of reticulin fibers, a support for the sinusoids, non myelinated nerve fibers and mesenchymal type cells[6]. Non-parenchymal cells are located in the liver sinusoidal compartment. The hepatic sinusoidal wall consists of three cell types: sinusoidal endothelial cells (SECs), Kupffer cells (KCs) and hepatic stellate cells (HSCs)[5]. Most nerve endings from intralobular spaces are located in Disse spaces[4,7-12], where they make close contact with HSCs, SECs and hepatocytes[7,8,10].

NERVOUS INFLUX TRANSMISSION MECHANISM INTO HEPATOCYTES

Hepatocytes serve multiple functions, such as synthesis, storage, metabolism and transformation of carbohydrates, amino acids, proteins, lipids, vitamins and detoxification, conjugation and excretion of exo- and endogenous substances. During liver regeneration, hepatocytes initiate cell proliferation, maintain metabolic function of the liver, secrete interleukin-6 (IL-6), proteases, protease inhibitors and hepatocyte growth factor[13].

The liver receives both sympathetic and parasympathetic nerve fibers; however, the innervation that hepatocytes receive varies by species. Thus, in the cat, rabbit, guinea pig liver as well as primate liver, it appears that nerve endings are connected to all hepatocytes, unlike rats and mice in which only hepatic cells in the portal region appear to be in contact with intrahepatic nerve endings[14].

Nerve fiber communication with hepatocytes can be accomplished by several mechanisms (Figure 1): (1) hepatocyte direct innervation mediated by norepinephrine and acetylcholine, neuropeptides [neuropeptide Y, galanine (NPY), vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), *etc*.], purines [adenosine triphosphate or adenosine (ATP)]; (2) signals intercellular transmission using gap type junctions; and (3) sinusoidal capillary cells innervation which interact with hepatocytes through eicosanoids (prostaglandins, leukotrienes), cytokines (necrotic factor, IL-6, IL-1) and other chemical mediators (endothelin, nitric oxide).

Direct innervation of hepatocytes

Nerve transmission to hepatocytes is achieved through neurotransmitters such as norepinephrine and acetylcholine, neuropeptides, such as NPY, galanine, VIP and CGRP, or purine derivatives as ATP and adenosine.

The liver is stimulated by norepinephrine and epinephrine released from intrahepatic nerve endings but also derived through the blood from the adrenal glands. Catecholamines act in the liver on α1-, α2- and β2-adrenergic receptors[15-17]. Norepinephrine is removed from the site of action by intrahepatic nerve ending uptake, being degraded by liver cells and diffused through the vascular bed[1].

Experiments on rat liver have shown that stimulation of the autonomic nerve plexus around the hepatic artery and portal vein causes increased production of glucose and lactate[1], urate and allantoin formation[17], decreased ketogenesis[18], increased ureogenesis and ammonia uptake[19], as well as increased oxygen utilization[20,21]. Also, hepatic nerve stimulation leads to decreased[16,17,20,22,23] and redistributed intrahepatic flow[21], as well as raised noradrenaline levels in the hepatic vein[15-18]. All these effects of hepatic nerves are only possible in the presence of extracellular calcium[22,24].

NPY, galanin, SP, CGRP, VIP and purine derivatives (ATP, adenosine) act as neurotransmitters, both in adrenergic and cholinergic nerve fibers, as well as in the related hepatic nerves. These neurotransmitters are released locally and are involved in regulating hepatic microcirculation. NPY and ATP act as vasoconstrictors, while VIP, CGRP, SP and adenosine produce vasodilation[14].

Some neurotransmitters also have a metabolic function. Thus, sympathetic hepatic nerve stimulation causes the release of noradrenaline but also of galanin[25], suggesting that galanin potentiates the action of norepinephrine to stimulate hepatic glucose production under stress[14].

Yamamoto *et al*[26] revealed the metabolic activity of ATP, which potentiates the action of hepatic sympathetic nerves suppression action on the formation of ketone bodies in the liver, the effect probably being due to ATP interaction with norepinephrine[14].

Intercellular transmission of signals through gap type junctions

Intrahepatic innervation varies by species. In some species, most hepatocytes are not directly innervated but there is an indirect mechanism for transmitting nervous inflow. One such mechanism is the intercellular communication carried out between adjacent hepatocytes *via* specific channels known as gap type junctions (GJ), which allow the passage of ions and small molecules[14].

GJ density is different among species[27]. Thus, hepatic GJ are more numerous in rats and mice compared to rabbits and guinea pigs[14].

GJ are membrane channels that allow intercellular communication between neighboring cells. GJ consists of two hemichannels, one hemichannel belonging to each

Figure 1 Schematic representation of the communication pathways between nerve fibers and hepatocytes. AG: Adrenal gland; IH NE: Intrahepatic nerve endings; ATP: Adenosine triphosphate; NPY: Neuropeptide Y; VIP: Vasoactive intestinal peptide; CGRP: Calcitonin gene-related peptide; IL: Interleukin; NF: Necrotic factor; NO: Nitric oxide; GJ: Gap junction.

of the two adjacent cells. A hemichannel consists of six subunits or connexins. Connexin 32 (Cx32) is the major protein component expressed in murine hepatocytes. Cx32 plays an essential role in signal propagation induced by the norepinephrine released from sympathetic nerve endings in hepatocytes[28].

GJ ensure the transmission of information to neighboring cells, achieving functional integration of hepatocytes, and thus functioning as a body and not as a mere cluster of cells[28].

GJ have an important role in transmitting nervous impulses from sympathetic nerve endings in parenchymal and non-parenchymal cells of the liver, in some species of mammals. There is an inverse relationship between sympathetic nerve fiber density and number of intrahepatic GJ[14]. Research on rat liver, which contains numerous GJ[15,29], showed that sympathetic nerves innervate only a part of parenchymal and non-parenchymal cells of the periportal area[15]. Metabolic and hemodynamic effects of hepatic sympathetic nerves are achieved by $\alpha 1$ receptor stimulation[17,23,30], are abolished by prostanoids synthesis inhibitors, and are mimicked by prostaglandins but not by thromboxanes[31]. Norepinephrine, as well as F2α prostaglandin, stimulates the release of glucose from isolated hepatocytes with increased inositol 1,4,5-triphosphate and glycogen formation[32].

Sending signals through GJ is involved in the metabolic effects of sympathetic nerves[14]. The norepinephrine released from sympathetic nerve endings binds to $\alpha 1$ receptors of parenchymal and non-parenchymal cells. The release of glucose from the proximal parenchymal cells from the periportal region under the action of norepinephrine initiates a signal which propagates through GJ to distal parenchymal cells, which in turn releases glucose. Norepinephrine stimulates contraction of proximal non-parenchymal cells (sphincters), reducing the flow in the sinusoid capillaries. It also causes the release of prostaglandins (PG) into the Disse space. PG, in turn, bind to prostanoid receptors of parenchymal and non-parenchymal cells. PG released from non-parenchymal cells are rapidly degraded in the liver[32] and so do not reach the distal cells. PG increase glucose release in the periportal parenchymal cells and perhaps initiate a signal that propagates to the other cells by GJ. PG stimulate contraction of proximal non-parenchymal cells, thus reducing the flow to sinusoid capillaries[15,33].

Sinusoidal capillary cells innervation
Sinusoidal capillaries are located between the cell cords and have a 9 to 12 micrometers diameter. The sinusoidal capillary wall is discontinuous and is formed out of a basement membrane and a capillary endothelium. Sinusoidal endothelium consists of flattened endothelial cells and phagocytic Kupffer cells in a ratio of 5/3. In addition to these two main types of cells in the sinusoid capillaries, there are also stellate cells and lymphocytes[6]. Capillary walls have an important role in the regulation

of the sinusoidal microcirculation[34,35].

Endothelial cells are flat and have elongated, hyperchromic nuclei and reduced cytoplasm. Junctional complexes are lacking. There are very small spaces of 0.5 micrometers between the cells. The apical membrane of the endothelial cells has transcytoplasmic fenestrations which are small holes arranged in nests with a diameter of 100 nm, with a role in controlling cholesterol, lipoprotein and vitamin A metabolism. In the cytoplasm of endothelial cells, a small number of cell organelles and pinocytosis vesicles were revealed. Endothelial cells produce prostaglandins, endothelin, IL-1 and IL-2[6,13].

Hepatic stellate cells (Ito cells, lipocytes) are located in the Disse space in small niches, among hepatocytes. They are in contact with the liver cells and through their microvilli and cytoplasmic processes have contacts with endothelial cell microvilli[6]. Well developed organelles and lipid droplets were found in the HSC cytoplasm. HSCs store vitamin A, containing factors related to retinoid acid and retinol, and produce extracellular matrix. Under normal conditions, HSCs have a deposit function, while in pathological ones it transforms into myofibroblastic type cells[6,13,36,37].

Research has shown that the distribution of intrahepatic innervation varies by species[29,38-43]. Guinea pig, cat and tupaia have an intralobular innervation similar to the human one[11,12,29,40], in contrast to mice and rats where it differs from the human[39,41-43].

In human liver, nerve endings are located in the Disse space[4,11,12], closely connected to hepatocytes and non-parenchymal cells, particularly HSCs[7,8,10,11].

Non-parenchymal cells are the only ones that can synthesize eicosanoids (prostaglandins, thromboxanes and leukotrienes) from arachidonic acid released from phospholipids by the action of phospholipase A_2 and converted to prostaglandins and thromboxanes *via* the cyclooxygenase path and leukotrienes *via* the lipoxygenase path[1]. Experiments on perfused rat liver have shown that the synthesis and secretion of prostanoids in non-parenchymal liver cells is influenced by a number of physiological stimuli, pathological and chemical. These stimuli also determine an increased release of glucose and lactate, as well as increased vascular resistance in the liver[1]. Of these stimuli, the most important are: extracellular nucleotides[44], nucleosides[45], zymosan[46,47], endotoxins[48], aggregates of immunoglobulins[49], anaphylatoxins[50,51], phorbol esters and calcium ionophores[44]. Norepinephrine and/or other chemical mediators released from nerve endings can stimulate the formation of prostanoids in non-parenchymal liver cells. Prostanoids, in turn, can modulate hepatocyte metabolism[1].

Of eicosanoids, only PG, without thromboxanes and leukotrienes, play a role in the events triggered by nerve stimulation[1].

PG participation in the chain of events initiated by nerve stimuli in the liver depends on hepatocellular receptors for PG. Research conducted so far confirms the existence of these receptors[1].

HSCs are indirectly involved in nerve fiber communication with hepatocytes, through PG. Noradrenaline may lead, by means of α1-adrenergic receptors, to increased synthesis of PG in the HSC, and PG, in turn, stimulate glycogenolysis in the hepatocytes. Unlike KC, producing predominantly PGD_2, HSC secret PGF 2 alpha released in increased amounts compared with PGD_2, as a result of sympathetic stimulation[52].

Intrahepatic nerve fiber terminations, often containing vesicles which contain neurotransmitters like substance P (SP) and vasoactive intestinal peptide (VIP), are closely related to HSC. It is considered that HSC that surround CECS, forming sinusoidal capillary walls, have a role in the contraction and relaxation of sinusoidal walls, thus intervening in the regulation of the sinusoidal microcirculation[4].

HSC contraction is stimulated by a number of substances such as endothelin-1 (ET-1), angiotensin II, norepinephrine, prostaglandin F_2, thromboxane A_2 and thrombin. In contrast, vasoactive substances such as acetylcholine, VIP, nitric oxide (NO), carbon monoxide, prostaglandin E_2 and adrenomedulin produce HSC relaxation[4].

ET-1 produces contraction of HSCs through ET receptor stimulation on autocrine or paracrine pathways. HSC contraction appears to be related to the increase of intracellular Ca^{2+} and inositol phosphate. For the sinusoid microcirculation control role of the HSC, the presence in the HSC cytoplasm of α smooth muscle actin, which is a contractile protein, also stands, such that the contraction of the HSC can be compared with that of smooth muscle cells in the vessel wall structure. On the other hand, prostaglandin E_2, adrenomedulin and other vasoactive substances determine HSC relaxation by increasing intracellular cAMP. In addition, HSC produces NO and inhibits contractility by an autocrine mechanism linked to NO[8].

Of the mentioned vasoactive substances, ET-1 and NO have an important role in the regulation of sinusoidal microcirculation. ET is a peptide consisting of 21 amino acids with a strong vasoconstrictive effect on the smooth muscle fibers. It has three isoforms, ET-1, ET-2 and ET-3[4,53].

Two receptors have been identified for ET: ET_A and ET_B, both belonging to the superfamily of G-protein-coupled receptors[54]. ET_A receptor has a higher affinity for ET-1 and ET-2 than for ET-3, while the ET_B receptor has a similar affinity for all three isoforms of ET. ET_A receptors stimulation increases intracellular cAMP levels, whereas ET_B receptor stimulation leads to inhibition of the adenylate cyclase system[55]. Also, ET_B receptor stimulation activates Ca^{2+}-dependent NOS[56]. Douglas *et al*[57] described two ET_B receptor subtypes: ET_{B1} and ET_{B2}. Stimulation of ET_A and ET_{B1} receptors causes contraction of smooth muscle fibers, while ET_{B2} receptor stimulation causes dilation by increased synthesis of NO[58].

ET-1 receptors from intralobular spaces predominate in the juxtaportal region. About 35% of ET-1 receptors

are located in the HSCs, a smaller number are located in the CECS and KCs[59]. Both ETA and ETB receptors are found in the liver. All cells of the sinusoidal capillary walls have ETB receptors but only HSCs have ETA receptors. Mallat *et al*[60] have identified 20% ETA receptors and 80% ETB receptors on activated HSCs.

NO is synthesized from L-arginine by the NO synthetase path (NOS). Three NOS isoforms have been identified: two are calcium-dependent, one produced by the neurons (nNOS or NOS I) and other by the vascular endothelial cells (eNOS or NOS III), and one calcium-independent isoform, cytokine-induced (iNOS or NOS II). Rat HSCs shrink under ET-1 or SP action and relax, causing vasodilatation, under NO action produced by HSC under the influence of IL-1[4,61].

In normal liver, sinusoidal contraction is inhibited by ETA receptor antagonists[62,63] but, according to some authors, not by ETB receptors antagonists[4,62-64]. Other researchers believe, however, that ETB receptor stimulation results in constriction of sinusoid capillaries[65]. It is possible that this discrepancy between the results obtained by different authors is due to coupling ETB receptors with NOS, which masks the vasoconstrictor effect[63,66].

The various subtypes of endothelin have different effects on hepatic microcirculation. The relationship between NO and endothelin is extremely important in the control of vascular tone[63].

Liu *et al*[58] have shown that ET-1 binding to ETB receptor leads to eNOS activation on the Akt phosphorylation path, thus reducing the phosphorylation of eNOS and NO synthesis. The same researchers highlighted the crucial role of βγ subunits of the G protein in triggering endothelin/NO reactions. The stimuli which regulate the ET expression and vascular sensitivity to ET also adjust the NOS and heme oxygenase-1 activity. Both enzymes catalyze the production of substances which, by guanylate cyclase activation, produce vasodilation[67].

CONCLUSION

Liver innervation is one of the most complex control systems in the human body; therefore, a better understanding of its inner workings is of paramount importance for developing future therapies and procedures for ameliorating the metabolic function of the liver. Being able to manipulate nerve impulses and synaptic mediators can possibly allow direct control over the functions of hepatocytes. Direct acting agents with excellent control over specific liver functions could become a reality, with direct implications for drug therapy, surgery or liver transplant.

Abstract

The use of medicinal plants in treating illnesses has been reported since ancestral times. In the case of hepatic diseases, several species such as *Silybum marianum*, Phyllanthus niruri, and *Panus giganteus* (Berk.) have been shown to ameliorate hepatic lesions. Silymarin is a natural compound derived from the species *Silybum marianum*, which is commonly known as Milk thistle. This plant contains at least seven flavoligands and the flavonoid taxifolin. The hepatoprotective and antioxidant activity of silymarin is caused by its ability to inhibit the free radicals that are produced from the metabolism of toxic substances such as ethanol, acetaminophen, and carbon tetrachloride. The generation of free radicals is known to damage cellular membranes and cause lipoperoxidation. Silymarin enhances hepatic glutathione and may contribute to the antioxidant defense of the liver. It has also been shown that silymarin increases protein synthesis in hepatocytes by stimulating RNA polymerase I activity. A previous study on humans reported that silymarin treatment caused a slight increase in the survival of patients with cirrhotic alcoholism compared with untreated controls.

Core tip: One of the mechanisms of liver damage caused by alcohol is the generation of free radicals formed by the metabolism of this xenobiotic. Silymarin is an antioxidant that protects the liver from the free radical damage produced by alcohol metabolism. Silymarin is the most used natural compound for the treatment of hepatic diseases worldwide due to its antioxidant, anti-inflammatory, and anti-fibrotic activities. Silymarin functions by stabilizing biological membranes and increasing protein synthesis.

INTRODUCTION

The liver is an important organ that has a key role in the

maintenance of homeostasis. The liver is responsible for multiple metabolic functions and physiological processes such as bile production, energy generation, vitamin storage, and the metabolism of carbohydrates, proteins, and lipids. After intestinal absorption is complete the blood is rich in nutrients and xenobiotics. The blood is then transported to the liver *via* the portal vein, which carries multiple toxic substances including ethanol (Et-OH), drugs, pharmaceuticals, and toxins to the liver. As a result, the liver is susceptible to toxicity and damage. Many people have been afflicted with some type of liver lesion. Examples of liver lesions include fatty liver, non-alcoholic steatosis, hepatitis A, B, or C, cirrhosis, and hepatocellular carcinoma (the third leading cause of cancer-related mortality worldwide)[1]. Hepatic diseases are primary causes of morbidity and mortality worldwide. The most recent surveillance report published by the National Institute on Alcohol Abuse and Alcoholism showed that liver cirrhosis was the 12th leading cause of death in the United States[2]. Liver disease is exacerbated by unhealthy lifestyles, obesity, and the excessive consumption of alcohol and drugs[3].

The use of medicinal plants has been reported since ancestral times. In the case of hepatic diseases, several species such as *Silybum marianum*[4], *Phyllanthus niruri*[5], and *Panus giganteus* (Berk.) have been shown to ameliorate hepatic lesions[6].

SILYMARIN

Overview

Flavonoids are polyphenol compounds that are also considered essential nutrients. Their basic chemical structure consists of two benzene rings bound by a three-atom heterocyclic carbon chain. The oxidation of the structure generates several families of flavonoids (flavones, flavonoles, flavanones, anthocyanins, flavanoles, and isoflavones). Chemical modifications of each family can lead to > 5000 individual compounds with different properties[7].

Silybum marianum is the scientific name for Milk thistle or St. Mary's thistle. It is a plant native to the Mediterranean region and belongs to the Asteraceae family. It is characterized by thorny branches and a milky sap, with its oval leaves reaching up to 30 cm. The flowers are bright pink and can measure up to 8 cm in diameter[8]. Milk thistle grows in its wild form in southern Europe, northern Africa, and the Middle East. The plant is cultivated in Hungary, China, and South American countries such as Argentina, Venezuela, and Ecuador. In Mexico, Milk thistle is consumed as a supplementary food[9].

Silymarin is a natural compound that is present in species derived from *Silybum marianum*, which is commonly known as Milk thistle. The plant contains at least seven flavolignans and the flavonoid taxifolin. The most important flavolignans present include silybin, silydianin, and silychristine. Silybin represents between 50% and 70% of the extract from silymarin. The following flavolignan iso-

forms are known (Figure 1): silybin A, silybin B, isosilybin A, and isosilybin B[10]. Silymarin has been used worldwide for many years as a complementary alternative medicine because of the beneficial effects associated with the treatment of hepatic diseases. Silymarin belongs to the Aster family (Asteraceae or Compositae). The mature plant has large brilliant-purple flowers and abundant thorns. The plant grows in places with sufficient sun exposure[11].

The low level of bioavailable flavolignans is known. For example, the level of silymarin absorption is between 20% and 50%. Silybin is the major compound of silymarin and limiting factors such as low solubility in water, low bioavailability, and poor intestinal absorption reduce its efficacy. New soluble silybin-derived biocompounds (silybin bis-hemisuccinate, β-cyclodextrin complex, silybin-*N*-methyl-glucamine, silybin 11-*O*-phosphate, and silybin-phosphatidylcholine) have thus been designed[10]. Chronic inflammation occurs in patients with hepatic damage. Thus, for patients with compensatory cirrhosis, hepatitis C, and non-alcoholic hepatic steatosis, the bioavailability of compounds present in silymarin may be affected, which may also explain the low effectiveness of treatment with flavonoids in these patients[12,13].

Sy-Cordero *et al*[14] isolated four key flavolignans and diastereoisomers (silybin A, silybin B, isosilybin A, and isosilybin B) from *S. marianum* on a gram-scale. These compounds and two other related analogues are present in extremely minute quantities. The compounds were evaluated for their antiproliferative/cytotoxic activity against human prostate cancer cell lines. Silymarin reduces the incidence of certain cancers[15]. Su *et al*[16] used silymarin on nasopharyngeal carcinoma cells (NPC-TW01) and found an increase in Bcl-2 expression and a decrease in the activated caspase-3 or apoptosis-inducing factor (AIF) with low-dose (80 μmol/L) treatment.

The molecular targets of silymarin for cancer prevention have been studied. Milk thistle interferes with the expression of the cell cycle regulators and proteins involved in apoptosis. Thus, it can modulate the balance between cell survival and apoptosis. Lee *et al*[17] reported that silybin inhibited the kinase activity of mitogen-activated protein kinase (MEK)-1/2 and ribosomal S6 kinase (RSK)-2 in melanoma cells. The treatment of melanoma cells with silybin attenuated the phosphorylation of extracellular signal-regulated kinase (ERK)-1/2 and RSK2, which is regulated by the upstream kinases MEK1/2. The blockade of MEK1/2-ERK1/2-RSK2 signaling by silybin resulted in the reduced activation of nuclear factor-kappa B (NF-κB), activator protein-1, and STAT3. These proteins are transcriptional regulators of several proliferative genes in melanomas. Silybin blocks the activation of these transcription factors and induces cell-cycle arrest at the G1 phase, which inhibits melanoma cell growth *in vitro* and *in vivo*. Silymarin suppresses ultraviolet radiation A-induced oxidative stress (OS), which can induce skin damage. Thus, the topical application of silymarin can be a useful strategy for protecting against skin cancer[18].

Silibyn A

Silibyn B

Isosilibyn A

Isosilibyn B

Figure 1 The chemical structure of silybin A, silybin B, isosilybin A, and isosilybin B, the extract of silymarin.

In previous studies, the inherent hepatoprotective and antioxidant activity of silymarin was shown to be caused by its control of free radicals (FR), which are produced by the hepatic metabolism of toxic substances such as Et-OH, acetaminophen (Paracetamol), or carbon tetrachloride. The FR damage cellular membranes and cause lipoperoxidation (LPO)[19]. The cytoprotective effect in liver is also caused by the inhibition of the cyclooxygenase cycle, leukotrienes, and the production of FR in Kupffer cells in mice. These affects reduce inflammation[20], and it has been suggested that silymarin also performs the following functions: protecting against genomic injury, increasing hepatocyte protein synthesis, decreasing the activity of tumor promoters, stabilizing mast cells, chelating iron, and slowing calcium metabolism, among other activities that have been described in the literature[21].

Silymarin has been reported to have antioxidant, immunomodulatory, anti-fibrotic, anti-proliferative, and antiviral properties. It also affects the synthesis of RNA and DNA. Furthermore, silymarin maintains the integrity of the hepatocyte membrane and impedes the entrance of toxic substances or xenobiotics. Due to its phenolic nature, it is capable of donating electrons to stabilize FR and reactive oxygen species (ROS). Silymarin also affects intracellular glutathione, which prevents lipoperoxidation of membranes[22].

Pure compounds extracted from silymarin have been examined in cell lines infected with the hepatitis C virus (HCV). Polyak *et al*[23] showed that silymarin inhibits the replication of an infectious HCV genotype 2a strain (JFH1) in hepatoma cell cultures. The most effective compounds were isosilbin A, taxifolin, and silybinin, and these compounds reduced virus infection. The OS level induced by HCV, the tumor necrosis factor (TNF)-α level, and the transcription factor NF-κB were affected by silbyn A and silbyn B treatment. In general, all of the compounds showed antiviral activity and reduced the OS level caused by HCV infection[24].

The use of a silymarin extract in 72 patients with non-alcoholic hepatic steatosis (non-alcoholic fatty liver disease, NAFLD) on a controlled diet led to significantly reduced levels of alanine aminotransferase (ALT) and aspartame aminotransferase (AST) (AST/ALT < 1). Another parameter evaluated was γ-glutamyl transpeptidase (γ-GT). In NAFLD patients, γ-GT is high because of obesity, hyperinsulinemia, inflammation, and changes in the membrane permeability of the hepatocytes. The level of γ-GT decreased due to the silymarin-mediated inhibition of toxins entering the cells. Additionally, silymarin permits the stabilization of hepatocyte membranes. It also reduced the level of TNF-α, which reduces inflammation. A favorable change in the hepatorenal clearance index was also observed, which suggests a reduction in the accumulation of lipids in the liver. All of these results were visible after 6 mo of treatment[4].

EVIDENCE FROM STUDIES OF SILYMARIN AS A HEPATIC PROTECTOR AGAINST ETHANOL

Silymarin has both hepatoprotective and regenerative actions. The mechanism of action is a reduction of the FR formed by toxins that damage the cell membranes (LPO) and competitive inhibition through hepatocyte external cell membrane modification. Silymarin forms a complex that impedes the entrance of toxins into the interior of liver cells. Additionally, silymarin metabolically stimulates hepatic cells and activates the RNA iosynthesis of ribosomes to stimulate protein formation[25-27]. In a study published by Sandoval *et al*[28], the authors observed a

silymarin protection effect in rat hepatic cells when they used it as a comparison factor to measure liver weight/animal weight % (hepatomegaly). The hepatomegaly was reduced compared to other groups that were administered antioxidant substances. There was no significant difference observed between the silymarin group and the silymarin-alcohol group. This result suggests liver protection by silymarin. Silymarin enhances hepatic glutathione generation by elevating cysteine availability and inducing cysteine synthesis while inhibiting its catabolism to taurine. The regulation of cysteine synthesis may subsequently contribute to the antioxidant defense[29]. Silymarin reduced collagen accumulation by 30% in biliary fibrosis induced in rats[30]. A study in humans reported a slight increase in the survival of patients with cirrhotic alcoholism compared with untreated controls[31]. Silymarin is perhaps the most frequently used natural compound for the treatment of hepatic diseases worldwide due to its antioxidant, anti-inflammatory, and anti-fibrotic activities[32].

Study conducted with guinea pigs (*Cavia porcellus*) examining hepatic fibrosis induced through the administration of Et-OH (4/kg of weight/d) for 90 d revealed a significant reduction of lesion markers such as ALT, AST, and γ-glutamyl after silymarin treatment. The gene expressions of cytochrome 450 2E1 (CYP2E1), TNF-α, transforming growth factor beta-1 (TGF-β1), and nuclear factor kappa-light-chain-enhancer of activated B cells-1 were also reduced. There was also a reduction in FR and reduced markers of fibrosis such as alpha smooth muscle actin, collagen α_1(I), and in the caspase cytotoxicity marker. However, silymarin was less effective than vitamin C in this study. This result indicates that vitamin C is more effective in reducing the markers of damage and the production of ROS during Et-OH-induced lesions[33]. Another study evaluated the hepatoprotective effect by measuring the level of antioxidants and the effect of body weight (*bw*) in rats exposed to Et-OH (1.6 g/kg of *bw* for 4 wk). The results revealed that intoxication by Et-OH influences the *bw* of rats and the levels of thiobarbituric acid reactive substances (TBARS). The activity of the enzymes superoxide dismutase (SOD) and glutathione-*S*-transferase (GST) increased significantly. Conversely, glutathione (GSH), the activity of glutathione reductase (GR), glutathione peroxidase, and catalase (CAT) were reduced by exposure to Et-OH. The rats that received silybin and ascorbic acid had attenuated lesion markers, although the effect was greater in the group that received ascorbic acid than in the group treated with silybin. The study also concluded that stopping alcohol intake favors hepatic regeneration. Thus, it is more effective to take preventive measures than to implement curative treatment[34]. A mouse study examining the antioxidant, immunomodulatory activity and vascular function of mice showed a significant increase in OS levels in animals that received ethanol (1.6 g/kg per *bw*/d during 12 wk). Ethanol increased the production of TBARS, nitrite levels, and the activity of GST. Ethanol also significantly diminished the content of GSH and the activity of SOD,

CAT, GPX, and GR. Mice that received Et-OH plus silymarin (250 mg/kg of *bw*/d for 12 wk) normalized the altered parameters. In addition, the silymarin-treated mice had reduced levels of interleukin-10 (IL-10), TNF-α, interferon (IFN), IFN-γ, vascular endothelial growth factor-A, and TGF-1β. The treatment also reduced the levels of IL-4 in the blood. The results of silymarin treatment were similar to mice that received vitamin C treatment[35].

The use of Sylubim β-cyclodextrin has been studied in non-insulin-dependent patients with diabetes and alcoholic hepatopathy. Treatment with a 135-mg/d dose did not influence insulin secretion but did significantly reduce the glucose ($P < 0.03$) and serum levels of triglycerides ($P < 0.01$) compared with the placebo. These results suggest that this treatment improves the response to insulin[36].

Clinical study conducted in 170 cirrhosis patients treated with 140 mg of silymarin three times daily for 41 months showed significant improvement, especially in the subgroups with alcoholic cirrhosis and initial "Child A" hepatic disease[31]. However, the results are controversial. A meta-analysis of 13 randomized clinical assays evaluated the beneficial or detrimental effects of Milk thistle and included patients with alcoholic and/or hepatitis B and C hepatic disease. The authors concluded that according to the data, Milk thistle did not significantly influence the improvement of these diseases. Conversely, it may have negatively affected the pathological condition[37].

CONCLUSION

There is substantial evidence suggesting that silymarin treatment improves hepatic diseases. However, some of the data are contradictory. Therefore, additional molecular studies investigating the mechanisms of action for these compounds are needed. It is known that silymarin does not possess adverse effects at high doses. Thus, it is a natural compound that is widely utilized in traditional medicine and has been investigated in formal scientific studies. Diverse hepatic damage models and ethanol injury have been utilized to study silymarin because ethanol is responsible for many cases of liver damage worldwide. The current data demonstrate that the use of silymarin treatment in alcoholic cirrhosis patients may attenuate the damage. However, silymarin treatment does not affect mortality.

Abstract

AIM: To investigate the potential role of khat in triggering auto immune hepatitis.

METHODS: Patients with a history of khat use and acute hepatitis were identified using the computer database in the hepatology department at the Royal Hallamshire Hospital. They were then assessed for probability of having autoimmune hepatitis using the revised autoimmune hepatitis scoring criteria.

RESULTS: Six patients were identified. All of them had presented with acute hepatitis on a background of khat. All were male and five of these patients were of Somali origin, while one patient was from Yemen. The patients were given points on the modified autoimmune hepatitis score which is based on their liver enzymes, autoimmune screen, exclusion of viral hepatitis alcohol and drugs, immunoglobulin levels and liver histology. The patients were given a score of -4 for khat use due to its potential to cause drug induced liver injury. Five of these patients scored between 10 and 15 points, placing them in the probable group for having autoimmune hepatitis. All of these patients were treated with prednisolone and demonstrated a good response to immunosuppression.

CONCLUSION: One possibile cause of hepatotoxicity with khat could be *via* triggering of autoimmune hepatitis in a genetically susceptible individual. Further studies are needed for confirmation.

Key words: Khat; Autoimmune hepatitis; Drug induced liver injury; Acute hepatitis; Herbs

Core tip: Khat causes hepatotoxicity. One possible mechanism could be by inducing autoimmune hepatitis.

INTRODUCTION

Khat (Catha Edulis Celestrasae) is an evergreen shrub native to East Africa and Southern Arabia. It is chewed daily by over 20 million people in these countries. Chewing khat is a popular social habit, particularly in young males, that has spread to Yemeni, Somali and East African communities living in the United Kingdom and United States[1]. The use of khat as a stimulant is increasing primarily due to immigration. The Somali population in the United Kingdom is estimated to be as high as 90000, and

concerns over health and social problems associated with chewing khat have grown due to its potential side effects including hypertension, coronary vasospasm, myocardial infarction, delayed intestinal absorption, and mood disorders, which may result from its sympathomimetic action[2].

Various studies and case reports have suggested that khat is also hepatotoxic, leading to deranged liver enzymes and also histopathological evidence of acute hepatocellular degeneration[3-7]. Recent studies in Somali populations have shown that khat can cause acute severe liver injury in humans due to its hepatotoxic effects[8,9]. Certain drugs that are known to be hepatotoxic cause liver damage by inducing an immunological response leading to a clinical presentation similar to autoimmune hepatitis (AIH). D'Souza *et al*[10] have described atypical presentation of AIH in young Somali men, although any history of khat use was not reported. Our aim was to assess the possible relationship of khat and autoimmune hepatitis in patients presenting with acute hepatitis on a background of khat use.

MATERIALS AND METHODS

The Hepatology database at Sheffield Hospitals was searched for patients referred to the Hepatology department between 2005 and 2010 with liver problems and a history of khat use. All of the patients were tested for hepatitis A, B and C serology, autoimmune profile (including antinuclear antibodies, smooth muscle antibodies and LKM-1 antibodies), ceruloplasmin, alpha-1 antitrypsin, and serum ferritin, and underwent ultrasound scanning of the abdomen, which was normal. This was followed by a percutaneous liver biopsy. Each biopsy was reviewed with particular attention to features of interface hepatitis, lobular necroinflammation and biliary changes. The patients were categorized according to the probability of having autoimmune hepatitis: no evidence (scores < 10), probable (scores of 10-15) or definite (score of more than 15), according to the established international criteria for diagnosis of autoimmune hepatitis[11,12].

All patients were treated with prednisolone (0.5 mg per kilogram per day) initially. Complete response, partial response and no response were defined according to the original and revised international autoimmune hepatitis criteria[11,12].

RESULTS

Acute hepatitis was defined in accordance with the scheme established by the Council for International Organisations of Medical Sciences (CIOMS)[13], and by the USFDA Drug Hepatotoxicities Steering Committee[14]. Eight patients were identified, of which six had presented with acute hepatitis on this basis. All were male and five of these patients were of Somali origin, while one patient was from Yemen. The age range of these patients was 24 to 57 years (mean 42.3 years). All of the patients had

been using khat for several years. There was no history of herbal medication (other than khat) or alcohol use in any patient. All other causes of liver injury were excluded *via* non invasive liver screen. Five of the six patients went on to have a liver biopsy. The patients were scored according to the revised autoimmune hepatitis criteria - (Table 1). They were given -4 for khat use on the scoring system due to its potential hepatotoxicity. Despite this, five out of six patients had a pre treatment score of 10 to 15 which placed them in the probable group for autoimmune hepatitis.

The five patients that were in the probable group had at least a partial response to corticosteroids with a greater than 50% reduction in their ALT after one month of treatment. Only two patients had more than 1 year of follow up, with one showing complete response to treatment. The patient that had scored negative for AIH (< 10) showed the least improvement with prednisolone and continued to have raised liver enzymes after 1 year of treatment. Four out of the six patients were maintained on long term low dose prednisolone while the other two patients were lost to follow up after 1 year. Two patients were commenced on azathioprine with complete response at 1 year follow-up. There was no history of re-exposure to khat.

Five out of six patients met the criteria for probable diagnosis of AIH but none of the patients actually met the criteria for confirmed diagnosis (score > 15). It has been reported previously that Somalian patients with AIH present atypically. It is therefore suggested that the AIH in these patients may have been triggered by khat use.

DISCUSSION

Over 40 khat strains are grown and used in Southern Arabia and East Africa. It is consumed in the form of fresh leaves which may often be contaminated with pesticides. The leaves of khat contain the Pyrrolizidine alkaloids, Cathine, Cathidine, and Cathinone. The pleasure derived from khat chewing is attributed to the euphoric action of Cathinone which is a sympathomimetic amine, with properties similar to amphetamine[15]. Although Cathinone is restricted in the United Kingdom under the Misuse of Drugs Act 1971, khat possession and use are not[1].

The diagnosis of drug induced liver injury (DILI) *vs* AIH triggered by khat is challenging. Various causality methods have been used for herbal induced liver injury and can be broadly divided into retrospective and prospective methods[16-25]. Establishing with any degree of certainty as to whether the liver disease is drug-induced can be very difficult[26]. The issue is further compounded by the relatively rare incidence of DILI, under reporting and potential drug interactions, due to which establishing the identity of the culprit drug may be impossible[27,28]. Furthermore, histology is often unhelpful as it only provides the type and degree of liver injury rather than the

aetiology. The key to causality is to assess the temporal relationship between drug initiation and development of abnormal liver tests and to diligently exclude other causes of liver diseases. This includes liver injury induced by alcohol, viral hepatitis (acute hepatitis A, B, C and E), autoimmune causes, metabolic disorders, biliary obstruction and sepsis.

The diagnosis of AIH alone is based on the characteristic clinical and histological features as well as the absence of other potential causes of hepatitis. The revised criteria for diagnosis of autoimmune hepatitis are considered the current gold standard[11,12]. Drugs can occasionally cause a clinical-serological picture similar to autoimmune hepatitis and may trigger autoimmune hepatitis in patients with an underlying genetic predisposition to autoimmune hepatitis, or the patients may develop AIH as a squeal of the drug itself. In a Swedish study of 23 patients who developed chronic DILI 23.1% were subsequently diagnosed with autoimmune hepatitis, the suspected drugs being ranitidine, enalapril, oestrogen, carbamazepine, and oestriol[29]. In a recent case series,

Peevers *et al*[9] described seven patients presenting with acute hepatitis who had a history of khat use. Two of those patients met the criteria for the diagnosis of probable AIH. It has been reported previously that Somalian patients with AIH present atypically. In a study of Somalian patients with a history of AIH, it was noted that all of the patients were male and scored in the probable group[10]. History of chewing khat was not mentioned in that particular study. However, in our series, all of the patients who presented with acute hepatitis had a history of khat use with five out of six patient meeting the criteria for probable AIH and demonstrating a good clinical response to immunosuppression. We therefore conclude that, in addition to producing DILI, khat may also trigger AIH in patients with a possible genetic pre-disposition.

Recently, Terschke *et al*[30] have validated the use of the CIOMS scale to be used with herbal induced liver injury (HILI) cases. Although the diagnosis of AIH is well founded in these patients, the causality assessment by means of CIOMS is not available. Also, the small number of patients in this series means that our hypoth-

esis of AIH being induced by khat can only be tentative and should be interpreted with caution. Whether these patients benefit from long-term immunosuppression after stopping khat remains unclear. Further studies of similar groups of patients are required to increase our understanding of this phenomenon and its management.

COMMENTS

Background
Khat is widely used in Southern arabia and East Africa. It is also known that autoimmune hepatitis presents atypically in these population as it is more common in males and presents at a younger age.

Research frontiers
Khat is well known to cause liver damage but the mechanism of this remains elusive. Patients in the areas where khat is consumed, present with atypical autoimmune hepatitis - the cause of which is not known.

Innovations and breakthroughs
The authors present an interesting observation of development of autoimmune hepatitis in a group of patients consuming Khat.

Applications
People can treat these group of patients more effectively by understanding the possible mechanisms of liver damage caused by Khat use.

Terminology
Khat (Catha Edulis Celestrasae) is an evergreen shrub native to East Africa and Southern Arabia. It is chewed daily by over 20 million people in these countries for its addictive and euphoric properties.

Peer review
This is an important case-report and the manuscript reads well.

Abstract

Nested stromal-epithelial tumours (NSETs) of the liver have been reported to be extremely unusual primary hepatic neoplasms. To date, few cases have been described in the literature. NSETs have been defined as non-hepatocytic and non-biliary tumours of the liver consisting of nests of epithelial and spindled cells, myofibroblastic stroma and variable intralesional calcification and ossification. Here, we report a case of a young female who underwent liver resection for a large hepatic lesion that proved to be a calcifying NSET on pathological examination. Details about the clinical and histopathological features of the tumour are reported.

Key words: Nested stromal-epithelial tumour; Hepatic tumour; Liver resection; Hepatic mixed tumour; Hepatectomy

Core tip: Rare cases of hepatic nested stromal-epithelial tumours (NSETs), consisting of non-hepatocytic mixed stromal and epithelial neoplasms with associated calcification and ossification, have been previously described. To date, NSETs' behaviour and prognosis are completely unclear. We report the case of a 23-year-old female who underwent liver resection for a large hepatic, calcifying NSET. Details about preoperative imaging and the clinical and histopathological features of this very rare hepatic tumour are reported.

INTRODUCTION

Nested stromal-epithelial tumours (NSETs) of the liver are very rare primary tumours characterised by unexampled clinicopathological features. To date, only isolated cases[1] and small series have been reported in the literature[2-4]. NSETs have been defined as a non-hepatocytic and non-biliary tumour of the liver consisting of nests of epithelial and spindled cells with associated myofibroblastic stroma and variable intralesional calcification and ossification[2]. This rare liver malignancy appears solid on imaging and has been reported to be isolated or occasionally associated with hormone cortisol-related syndrome. Herein, we describe a patient who underwent radical hepatectomy for a large calcifying NSET of the liver.

CASE REPORT

Clinical history

In January 2012, a 23-year-old female was referred to our

unit for recurrent dull abdominal pain associated with abdominal distension and dyspepsia. The patient had a past history of being negative for hepatitis but positive for the consumption of oral contraceptives during the previous 5 years.

On physical examination, a palpable mass in the upper abdomen was revealed. No Cushingoid or other clinical features were evident.

Laboratory tests revealed an altered serum level of aspartate aminotransferase (36 IU/L; normal range: 5-30), alanine aminotransferase (297 IU/L; normal range: 5-35), alkaline phosphatase (62 IU/L; normal range: 4-150) and gamma-glutamyltransferase (285 IU/L; normal range: 6-32). Virological markers for hepatitis B and C yielded negative results. Tumour markers, including carcinoembryonic antigen (CEA) and alpha-fetoprotein (AFP), were negative, whereas the level of carbohydrate antigen 19-9 (CA19-9) was elevated (98 IU/mL; normal value: < 40).

Abdominal computed tomography (CT) revealed a well-circumscribed liver lesion of 16 cm in size involving the left hemiliver, part of the right anterior section (S5-8)[5] and the paracaval portion of the caudate lobe (S1pc). Extensive vascular invasion including the left hepatic vein (LHV) and middle hepatic vein (MHV) at the hepatocaval confluence and the left portal pedicle (LPP) was evident. The lesion appeared solid and heterogeneous, with a rim-like enhancement on the arterial phase and a gradual centripetal enhancement on delayed phases. Multiple intralesional calcifications were also evident.

On magnetic resonance imaging (MRI), the tumour showed hypointensity on T1-weighted images and hyperintensity on both T2- and diffusion-weighted images (DWI), with small central necrotic collections. An inhomogeneous pattern with subcentimetric calcifications showing mostly hypointensity on both T1- and T2-weighted images was depicted. On gadolinium-enhanced images, the lesion showed a heterogeneous enhancement pattern on the arterial phase and washout in the portal and parenchymal phases (Figure 1A). The hepatocyte-specific delayed phase (Primovist, Bayer-Schering, Berlin, Germany) showed a hypointense lesion on T1-weighted images, with well-defined margins and a hyperintense capsule.

The work-up was completed with total-body ^{11}C-choline positron emission tomography (PET), which showed only slight pathological uptake of the tracer into the liver (Figure 1B). Based on these preoperative findings, a percutaneous lesion biopsy was not considered, and the patient was candidated to liver resection with a presumptive diagnosis of fibrolamellar hepatocellular carcinoma (HCC) or hepatocholangiocarcinoma.

At laparotomy, peritoneal carcinomatosis was excluded. During liver exploration, a huge, hard liver tumour entirely occupying the left hemiliver, part of S5-8 and the S1pc was confirmed. On intraoperative ultrasonography (IOUS), no additional lesions were detected, and the tumour showed well-defined margins and a heterogeneous echogenicity, with several intralesional hyperechoic spots due to multiple calcifications. Extensive involvement of the LHV, MHV and LPP was confirmed. Once the intraoperative staging was completed, the patient underwent an extended left hepatectomy with left and middle hepatic vein resection for radical removal of the mass. The specimen weighed 2000 g. Intraoperative blood loss was 100 mL, and the patient did not receive a blood transfusion. The postoperative course was uneventful, and the patient was discharge on the 10th postoperative day. Currently, the patient is alive and disease free 21 mo after surgery.

Pathological features

Grossly, the tumour had well-defined margins, was arranged in yellow lobules with several granular and rasping foci and was 16 cm in size (Figure 2A). On histology, the tumour was composed of well-defined nests of epithelial cells separated by strands of stromal cells and focally admixed with calcifying material (Figure 2B). The epithelial component was represented by polygonal to spindle-shaped cells, devoid of overt cytological atypia; stained positive for CKpool, CK19 and CD56; and stained negative for Hep Par-1 (hepatocyte paraffin 1) and AFP. Scattered nuclei were also immunoreactive for WT1 (Figure 2C). The stromal component stained positive for vimentin and smooth muscle actin. The mitotic index was < 5 mitoses/10 HPFs, and 10%-15% of cells stained positive for Ki67.

Molecular genetic study

Several neoplastic nuclei were positive for the EWS-WT1 fusion transcript (Figure 2D) but negative for the SYT-SSX fusion transcript.

DISCUSSION

Stromal-epithelial tumours are extremely rare conditions of the liver, and very few cases have been previously described[1-4]. The unusual entity defined as an NSET typically displays an arrangement of cellular nests composed of spindled or epithelioid cells surrounded by desmoplastic stroma and associated with variable calcifications or ossifications. To our knowledge, few cases of NSETs have been reported[1-4,6]: of these, only one has been described in Asian descendants[6].

This primary liver lesion represents an unexampled clinicopathological entity with an unclear pathogenesis. However, based on immunohistochemical studies showing an intimate correlation of tumoural cell nests with bile ducts and the expression of specific antigens, as well as the shared expression of CD56 by both components, the origin of this tumour in a hepatic mesenchymal precursor cell with primitive differentiation along the bile duct lineage is strongly suspected[3,4]. The expression of WT1 is also in favour of this hypothesis, as this multifunctional protein is a requisite component of the mesenchymal-to-epithelial transformation during certain processes in organogenesis[7].

Figure 1 Radiological imaging. A: Abdominal magnetic resonance imaging scan showing a 16 cm diameter inhomogeneous and partially calcified (asterisk) mass of the left liver; B: Total-body ^{11}C-choline positron emission tomography showed a slight pathological uptake of the tracer in the peripheral part of the tumour (red arrows).

NSETs predominantly occur in young females and are more frequently located in the right hemiliver. Conversely, in the case described here, the tumour occupied the left hemiliver.

The development of this tumour may occur as an isolated condition or in association with a hormone-related syndrome, such as Cushing syndrome. Heerema-McKenney *et al*[3] reported two cases of NSETs occurring in paediatric patients that were associated with Cushing syndrome due to an elevated adrenocorticotropic hormone (ACTH) level[4]. Additionally, Rod *et al*[8] described a 17-year-old female patient affected by a large hepatic NSET causing mild Cushingoid syndrome secondary to moderate-to-high ACTH secretion. In our experience, Cushing-like symptoms were not evident.

From a clinical standpoint, one of the main differential diagnoses is a mixed epithelial and mesenchymal hepatoblastoma, although very few cases have been reported in adults[9]. However, this tumour shows components of foetal and/or embryonal hepatocyte differentiation and lacks the typical stromal architecture of NSETs. Synovial sarcomas and desmoplastic small round cell tumours (DSRCTs) are other diagnostic possibilities to consider that can be distinguished based on specific histologic features. Indeed, in the current study, the absence of a demonstrable carcinoma component and the SYT-SSX fusion transcript helped to exclude the diagnosis of synovial sarcoma. However, cases of synovial sarcoma with extensive calcification and osteoid formation have been reported[10,11]. In our case, the histologic features

of the NSET were slightly reminiscent of those of DSRCTs[12,13], as both tumours exhibited nests of WT1-positive cells and were positive for the EWS-WT1 fusion transcript. The NSET, however, can be distinguished from DSRCTs by the NSET's typical arrangement of myofibroblastic collars and fibrovascular supporting stroma, which differed from the fibrous stroma of DSRCTs. However, the NSET was not immunoreactive for desmin, whereas the opposite is observed in DSRCTs. In the case reported here, based on preoperative imaging features, a diagnosis of fibrolamellar HCC or eventually mixed hepatocholangiocarcinoma was considered.

Interestingly, the patient had taken oral contraceptive pills (OCPs) during the previous 5 years. As reported for hepatic adenoma[14], a possible role for OCPs in the occurrence of the NSET could be considered. However, no staining for hepatocyte antigens was demonstrated in any tumour cells, which led us to exclude a likely correlation with hepatic adenoma. Furthermore, a lack of progesterone and oestrogen receptors in tumoural cells contributed to doubt about the hypothetical correlation between NSET occurrence and OCP consumption. However, more studies on a larger number of cases are likely needed before a possible correlation can be determined.

NSET prognosis remains an unclear matter, but based on current information, this tumour seems to have low proliferation activity and an indolent course, behaving as a low-grade malignancy featuring unusual extrahepatic spread and a possible presentation since childhood. However, specific tumoural features, a large size and vascular

Figure 2 Pathological features of the reported calcifying nested stromal-epithelial tumor of the liver. A: At gross inspection the lesion shows well defined margins and is arranged in lobules; B: At histology the lesion is characterized by the presence of well defined nests of epithelial cells separated by strand of stromal cells, focally admixed with calcifying deposits (arrow); C: Scattered neoplastic cells stain positive for WT-1 immunostaining; D: Some neoplastic nuclei showed well separated green and orange probes signals (arrow), in keeping with a translocation involving *EWSR1* gene (FISH); some neoplastic nuclei (asterisks) did not show the same break apart pattern.

invasion seem to be associated with a higher probability of recurrence. Brodsky *et al*[15] reported experiences of recurrent NSETs of the liver with lymph node metastasis after partial hepatectomy. Hommann *et al*[16] reported a case of lung metastasis after liver transplantation for an unresectable NSET. Based on these experiences, although the risk of relapse seems negligible, a careful postoperative follow-up is recommended.

To date, the benefit of systemic chemotherapy and the most appropriate regimen to adopt remain poorly defined. In paediatric experience, preliminary results showing a minimal response for an unresectable NSET when a hepatoblastoma and sarcoma protocol regimen was adopted have been reported[3]. However, this topic remains completely unexplored.

Surgery seems to be the pivotal therapeutic approach, remaining the best strategy to guarantee longer survival and a better prognosis[1,3]. Our experience attempts to convey more information about the reliability of the surgical approach in the case of a resectable NSET. In this sense, our clinical experience confirms that liver resection allows the safe attainment of complete tumour clearance, even in advanced disease. Conversely, considering the low tendency of NSETs to relapse and previous unsuccessful experiences, at least for oncological control, liver transplantation generally should not be recommended, at least as a first choice[16]. Liver transplantation would be potentially useful for those patients with unresectable but

not extrahepatic disease.

In conclusion, this report aimed to clarify the clinical history, therapy, imaging pattern and histopathological features of a very rare primary liver tumour that is still poorly characterised. Awareness of hepatic NSET occurrence may help to identify additional cases, enlarging knowledge about NSETs' clinical behaviour and prognostic features and limiting the possibility that these tumours could be misdiagnosed and confused with other aggressive liver malignancies.

COMMENTS

Case characteristics
Symptoms were featured by dull abdominal pain associated with abdominal distension and dyspepsia.

Clinical diagnosis
Palpable mass in the upper abdomen. Cushingoid clinical features can be sometimes detected.

Differential diagnosis
Mixed epithelial and mesenchymal hepatoblastoma, synovial sarcoma and desmoplastic small round cell tumour are the main differential diagnosis. Histologic and immunohistochemical analysis help to distinguish them.

Laboratory diagnosis
Laboratory tests revealed altered serum level of AST, ALT, alkaline phosphatase and gamma glutamyltransferase. Virological markers for hepatitis B and C and tumour markers including carcinoembryonic antigen, alpha-fetoprotein were negative, while, the CA19-9 was elevated.

Imaging diagnosis
Preoperative imaging (Computed tomography, Magnetic resonance imaging

scan) revealed a well-circumscribed liver lesion involving the left hemiliver. The lesion appeared solid and heterogeneous with a rim-like enhancement at contrast phase with multiple intra-lesional calcifications. An extensive vascular invasion was evident.

Pathological diagnosis
Nested stromal-epithelial tumours (NSETs) are a non-hepatocytic and non-biliary tumor of the liver consisting in nests of epithelial and spindled cells with associated myofibroblastic stroma and variable intralesional calcification and ossification.

Treatment
Surgery seems the pivotal therapeutic approach remaining the best strategy to guarantee longer survival and a better prognosis.

Related reports
Heerema-McKenney *et al*, Rod *et al* reported cases of NSETs occurring in pedriatic patients and associated with a Cushing syndrome. Brodsky *et al* reported experiences of recurrent NSET of the liver with lymph-node metastasis after partial hepatectomy. Hommann *et al* reported a case of lung metastasis after liver transplantation for unresectable NSET.

Term explanation
WT1 is a mutifunctional zinc-finger protein involved in mesenchyme-to-epithelium transformation which suggests an origin of NSET in a hepatic mesenchymal precursor cell with primitive differentiation along the bile duct lineage. EWS-WT1 and SYT-SSX fusion transcript are genes can help to distinguish NSETs from other liver malignancy.

Experiences and lessons
NSETs occur predominantly in young female and their development may occur as an isolated condition, otherwise associated with hormone-related syndrome, such as Cushing syndrome. From a clinical standpoint, histologic and immunohistochemical studies are essential to distinguish NSETs from other malignancy because of lack of a typical imaging pattern.

Peer review
In the present study, the authors report a case with a nested stromal-epithelial tumor in the liver, which has been rarely reported worldwide. They fully examined the pathological features of the tumor, by using immunohistochemical analysis. This report has originality, figures are clear, and the discussion is well written.

AIM AND SCOPE

World Journal of Hepatology (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

Abstract

The aetiology of autoimmune hepatitis (AIH) is uncertain but the disease can be triggered in susceptible patients by external factors such as viruses or drugs. AIH usually develops in individuals with a genetic background mainly consisting of some risk alleles of the major histocompatibility complex (HLA). Many drugs have been linked to AIH phenotypes, which sometimes persist after drug discontinuation, suggesting that they awaken latent autoimmunity. At least three clinical scenarios have been proposed that refers to drug-induced autoimmune liver disease (DIAILD): AIH with drug-induced liver injury (DILI); drug induced-AIH (DI-AIH); and immune mediated DILI (IM-DILI). In addition, there are instances showing mixed features of DI-AIH and IM-DILI, as well as DILI cases with positive autoantibodies. Histologically distinguishing DILI from AIH remains a challenge. Even more challenging is the differentiation of AIH from DI-AIH mainly relying in histological features; however, a detailed standardised histologic evaluation of large cohorts of AIH and DI-AIH patients would probably render more subtle features that could be of help in the differential diagnosis between both entities. Growing information on the relationship of drugs and AIH is being available, being drugs like statins and biologic agents more frequently involved in cases of DIAILD. In addition, there is some evidence on the fact that patients diagnosed with DIAILD may have had a previous episode of hepatotoxicity. Further collaborative studies in DIAILD will strengthen the knowledge and understanding of this intriguing and complex disorder which might represent different phenotypes across the spectrum of disease

Core tip: Drug-induced autoimmune liver disease (DIAILD) is a poorly defined and under-reported liver disorder, and, probably, a underestimated liver disease. A small number of drug-induced liver injury (DILI) cases exhibit features typical of autoimmune hepatitis (AIH). To differentiate between true AIH triggered by drugs (DI-AIH) and immune mediated DILI still remains a challenge. Patients diagnosed with DIAILD have frequently had a previous episode of hepatotoxicity. We consider that some basic requirements are needed to be considered before supporting a drug as a trigger of AIH and they should be taken into account by authors, reviewers and editors when cases are published and made available to the scientific community.

INTRODUCTION

The cause and pathogenesis of autoimmune hepatitis (AIH) is unknown[1]. AIH is characterised by the following clinical features: (1) presence of raised aminotransferases with normal or minimal elevations of alkaline phosphatase; (2) association with hypergammalobulinemia and raised immunoglobulin G; (3) female gender preponderance; (4) high titres of a variety of autoantibodies; (5) immunogenetic background; (6) good response to immunosuppressive treatment; and (7) the presence of extrahepatic autoimmune manifestations[2,3]. In liver biopsy specimens, the presence of interface hepatitis is characteristic[3]. In 1999, an international group developed a diagnostic score system[4]; which was later on simplified in 2008[5].

The aetiology of AIH is uncertain, but the disease can be triggered in susceptible persons by an external factor, such as viruses, drugs or herbal remedies[1,2].

Many clinical observations suggest that drugs are potential triggers in some patients[6,7]. Several drugs have been identified to cause AIH that may persist after discontinuation, suggesting that they triggered true autoimmunity. These include oxyphenisatin, nitrofurantoin, minocycline, chlometacin and alpha-methyl dopa[3,8]. Other drugs have been infrequently reported to lead to AIH, making the association less probable. Recently, a growing number of drug-induced autoimmune liver disease (DIAILD) reports meeting the established international criteria[4,5] and showing clinical data (hypergammaglobulinemia, ANA/ASMA), typical liver biopsy findings and HLA-DR status, which allow to establish a causal relationship[6,9-11].

For instance, Björnsson *et al*[12], in a series of 261 patients with AIH, reported 9.2% (24 patients) of patients with drug-induced AIH. A French group[10] searched for a potential causative drug in a consecutive series of 65 patients with AIH, and identified that 12% of the cases were drug-induced, highlighting the frequency of this disorder. In this line, 5 out of 29 (17%) consecutive patients with AIH from Spain were diagnosed with drug-induced AIH[13].

Very recently, Licata *et al*[14] reported 12 patients from a series of 136 drug-induced liver injury (DILI) subjects that were diagnosed as drug-induced AIH (8.8%). All were treated with corticosteroids and remission was achieved after six months in 10 of the cases (83%).

Although no particular drug has been definitively identified as a true aetiological trigger agent for AIH, it is interesting to note that drug-metabolizing enzymes of phase I and phase II are common targets of autoimmunity in idiopathic AIH and viral hepatitis[2].

It is important to distinguish drugs as triggers of a self-perpetuating autoimmune liver disease from immune-mediated drug-induced liver injury (IM-DILI). Immune-mediated DILI nearly always resolves[2,12] or becomes quiescent when drugs are withdrawn. Another possibility is that AIH was quiescent and remains undiagnosed until a drug triggered a new autoimmune process. Thus, to attempt to make a proper diagnosis of the type of immune process affecting the liver is challenging. Björnsson *et al*[12] reported 24 cases of drug-induced AIH (22 minocycline-nitrofurantoin cases, 11/11). Immunosuppressive therapy withdrawal was successful in all the 14 cases in which it was attempted. On the contrary of the AIH cases in this series 65% relapsed upon corticosteroid withdrawal. Heurgué *et al*[10], observed one spontaneous remission, three relapses and four remissions without relapse in 8 patients out of 65 with drug-induced AIH.

In the Spanish DILI Registry, out of 742 DILI cases, 16 were diagnosed as DIAILD[9] and 25% of these cases had another autoimmune associated disease that may require persistent immunosuppressive treatment. Such cases may preclude the therapy to be discontinued and, therefore, one cannot ascertain the course of AIH upon immunosuppressive drug withdrawal. Therefore, to state that relapse after corticosteroid discontinuation might distinguish DIAILD from classical AIH is a very attractive conclusion, but far away from the complex reality of this disorder since in many cases the coexistence of other autoimmune disorders does not allow for stopping immunosuppressive therapy[15,16]. To further complicate the differentiation between AIH and DILI, we must underline the fact that there does not seem to be any specific histological features for either of the processes and the pathological features may show only subtle differences, pointing toward an immune-mediated liver disease versus hepatic toxicity[17].

CLASSIFICATION

There are several possible combinations of DILI and AIH (see Table 1). In 2002 Liu *et al*[2] distinguished 2 types: drugs as a potential triggers of drug-induced AIH (DI-AIH), which supposes a self-perpetuating liver disease, and immune-mediated DILI (IM-DILI), which is an acute or chronic process depending of the duration of the exposure of the liver to the hepatic insult (viruses, herbal remedies, drugs) and disappears or becomes quiescent when the drug is withdrawn[2]. In 2011, Weiler-Normann and Schramm[18] established a classification of DILI and AIH proposing possible connections with suggested diagnoses and clinical characteristics. First, AIH with DILI: The reactivation of a known AIH upon introduction of a new drug is possible, but it is very difficult to demonstrate a causal relationship, as it might be coincidental (chance by association) Often, there is advance fibrosis on histology (see Table 1). Second, DI-AIH, reveals a patient that has not been diagnosed before, or even just the predisposition to AIH that is awakened by DILI. An immune reaction in a genetically predisposed individual may lead to a chronic process, perpetuating the AIH in these patients, with a permanent need for immunosuppression. Usually, they have typical HLA-DR associated with true AIH (Table 1). Third, IM-DILI: acute

Table 1 Classification of drug-induced autoimmune liver disease

AIH with DILI	Patients with known AIH
	AIH quiescent: the drug may be the trigger of a new bout
	AIH under IS or corticosteroids treatment: Reactivation of known AIH upon intro duction of a newdrug (very difficult to demonstrate a causal relationship as it might be coincidental
	Often advanced fibrosis on histology
DI-AIH	Patients with a low grade disease not diagnosed before or predisposition to AIH
	Drug produce an immune reaction that lead to a chronic process:
	Perpetuating the AIH
	Permanent need of IS
	Habitually typical HLA-DR associated
IM-DILI (Autoimmune hypersensitivity)	Fever, eosinophilia, lymphadenopathy, rush
	Indistinguishable from true AIH: Mandatory IS treatment
	Frequently spontaneous remission after drug cessation
	Usually complete response to treatment and sustained remission without relapse
	It is the most frequent drug-induced immune process in the liver attributable to drugs
Mixed autoimmune type	Patients with mixed clinical features of DI-AIH and IM-DILI
	Complete response to IS treatment but with chronic course after withdrawal
	Patients under IS treatment for another autoimmune disease. Withdraw IS drugs is not possible. Remission cannot be evaluated
DILI with positive autoantibodies	Patients with positive autoantibodies
	The probability of developing DIAILD increases in second DILI episodes indepe dently of the causal agent

AIH: Autoimmune hepatitis; DILI: Drug-induced liver injury; IS: Immunosuppressants; IM-DILI: Immunomediated DILI; DIAILD: Drug-induced autoimmune liver disease; HLA: Human leukocyte antigen.

or chronic liver injury (depending of the duration of the exposure to the drug), as has been explained by Liu and Kaplowicz[2], that resolves or becomes quiescent with drug withdrawal. This scenario can be caused by a number of drugs, such as minocycline and nitrofurantoin[2,12]. These individuals may have spontaneous remission of acute hepatitis after drug cessation, or have a hepatocellular or mixed type of liver damage that does not improve after drug-withdrawal. Fever, eosinophilia, lymphadenopathy and rash may be present, but not always. In these situations, which are indistinguishable from true AIH, the immunosuppressive (IS) treatment is mandatory and may be life-saving. Most of these patients do not need IS forever as they usually have a complete response to treatment and a sustained remission without relapse[12,16,18,19]. This type of adverse drug reaction, which can be viewed as autoimmune hypersensitivity, is the most frequent drug-induced immune process in the liver that is attributable to drugs (see Table 1)[2,12].

A second DILI episode (recurrent DILI) involving a different drug is a rare event, but if it happens, AIH or AIH-like DILI is frequent, and reported in up to 40% of cases in the series published from the Spanish DILI Registry[20]. Differentiating IM-DILI from DI-AIH in these cases is very difficult as the clinical presentation may be the same[20].

Nevertheless, we think that a fourth type must be added: mixed autoimmune type. These patients have mixed clinical features that belong to DI-AIH and IM-DILI types. Thus, there are published cases of IM-DILI induced by minocycline which have a complete response to IS treatment, but experience a chronic course after drug withdrawal[15,21,22]. Therefore, the same drug can be DI-AIH or IM-DILI, depending on the clinical charac-

teristics and outcome of the episode. Another possibility is that the patient requires IS treatment for an autoimmune disease, different to AIH, in which case we cannot withdraw IS drugs. In these cases, we cannot differentiate DI-AIH or IM-DILI because the patient needs chronic IS treatment for another autoimmune disease. Therefore, one cannot ascertain the course of AIH upon IS drug withdrawal. For example, chronic uveitis has been associated with AIH[23,24], and may require permanent IS treatment.In the Spanish DILI Registry[25], 16 out of 742 DILI cases, were diagnosed as DIAILD[9]; 25% of these cases had another associated autoimmune disease, which may require persistent IS treatment. In a French series of eight patients[10], 25% of them had another AI associated disease.

Finally, there are patients that present DILI with positive autoantibodies. However, its significance is unknown and requires further studies. In 2002, Ohmoto and Yamamoto studied 64 patients admitted to their hospital with DILI and identified 6 with positive ANA[26]. They found a higher prevalence of associated autoimmune diseases in the ANA positive group such as AIH, rheumatoid arthritis, Hashimoto's disease. The authors suggested that patients with DILI and ANA might also have autoimmune disease and should be followed over the long-term, even if liver function has recovered. On the other hand, Hinrichsen *et al*[27] reported a case of phenprocoumon-induced hepatitis with positive autoantibodies. After the drug was stopped, no clinical or laboratory features of autoimmune liver disease were present.

Recently, the Spanish-Latin American DILI Network has published a series of 73 DILI cases, in which 29% presented positive autoantibodies, mainly ANA. Six cases were DIAILD (AIH DILI) (8%) and 5 cases (7%) had

experienced a second DILI episode[28].

Therefore, this analysis further support that the probability of presenting positive antibodies increases in second DILI episodes, as previously shown by Andrade *et al*[29].

HISTOLOGY

Liver histology shows apoptosis, necrosis and inflammatory infiltrates including mononuclear cells, neutrophils, eosinophils and lymphocytes, or cholestasis and paucity of bile ducts with moderate portal inflammation. Granulomas may also be seen[2]. Distinguishing DILI from AIH is challenging histologically. Recently, Suzuki *et al*[17] showed that while a histologic overlap exists for these pathologies, sufficient differences exist for pathologists and they can use the pattern of injury proposed by Suzuki *et al*[17] to suggest a correct diagnosis. Interface hepatitis, focal necrosis and portal inflammation were present in all of the evaluated cases but were more severe in AIH than in hepatocellular DILI. Portal and intra-acinar plasma cells, rosette formation, and emperipolesis were features that favoured AIH. All Ishak inflammation scores were more severe in AIH than in cholestasic DILI. They did not identify any histologic features differentiating AIH from DIAILD (DI-AIH) in a small subgroup analysis (7 cases), but it might still be possible that detailed standardised histologic evaluation using a larger cohort of DIAILD (DI-AIH) *vs* AIH can identify histologic features that can be helpful in the differential diagnosis. Björnsson *et al*[12], in a recent work, revealed that similar histological grades and stages were present in patients with IM-DILI (DI-AIH) *vs* AIH. However, none of the IM-DILI (DI-AIH) patients had cirrhosis at baseline and it was present in 20% of the AIH patients. Czaja[16], based on the referred work, confirmed that cirrhosis is a rare histologic feature in nitrofurantoin AIH cases at presentation, which may help to distinguish it from classical AIH (0 *vs* 13%). In a recent review of the histological patterns found in cases of DILI[30], it was pointed out that, contrary to minocycline, significant fibrosis and cirrhosis occurs with nitrofurantoin. The French group[10,31] biopsied all of their cases (Minocycline *n* = 3; nitrofurantoin *n* = 2; atorvastatin *n* = 1; fenofibrate *n* = 1; isotretinoin *n* = 1), showing a fibrosis score F3-F4 in 57% *vs* 48% in the DIAILD (AIH-DILI) and AIH groups, respectively. Necroinflammatory activity A3, with Metavir, was revealed in 75% *vs* 65%. They concluded that the 2 groups showed similar histological lesions of fibrosis/cirrhosis. Recently, Licata *et al*[14] studied a series of 12 patients (4 nimesulide, 1 ketoprofen, 3 amoxicillin-calvulanate, 1 ceftriaxone, 1 epigallocatechin gallate and 1 hypericum perforatum -herbal drugs-, and dimethoate-toxic agent). All DIAILD patients were treated with corticosteroids and none developed cirrhosis. Appleyard *et al*[32] published a series of 3 cases, one of which had pre-cirrhosis/cirrhosis at diagnosis. The Spanish Registry of Hepatotoxicity[9] presented a case report of DIAILD that showed cirrhosis in the liver biopsy at presentation. Therefore, the absence of histological cirrhosis at presentation would not help to discern between these two entities.

Ju *et al*[33] have studied the histological features of DILI patients in Korea, with special focus on relevancy of AIH. The study showed that characteristic histologic features of AIH, as interface hepatitis and lymphoplasmocytic infiltrates, were present in up to one third of DILI patients.

FREQUENCY

Recently Czaja[16] stated that the best estimate of the frequency of drug-induced autoimmune-like hepatitis among patients with classical features of AIH is 9%[12]. There are other reports that show higher figures[15]. Heurgué *et al*[10], in France, identified 8 cases (12%) with drug-induced AIH in a consecutive series of 65 patients with AIH, fulfilling all requirements recommended in the review to confirm the diagnosis (Table 2). In Gipuzkoa, Spain, from 1994 to 2009, 29 cases of AIH were diagnosed, 5 of which were considered AIH-DILI, which resulted in a 17% frequency[13]. We believe that these differences in frequencies may be explained by the fact that AIH-DILI is often misdiagnosed.

If we study patients diagnosed with DILI, Licata *et al*[14] reported 8.8% of the patients presenting features of DIAILD (DI-AIH). In the Spanish DILI Registry[9], out of 742 recruited cases, 16 presented DIAILD criteria (2.15%).

Why is there a growing number of case reports?

Indeed, the diagnosis of AIH is often made in the setting of a patient being treated with multiple drugs. If the diagnostic scale points out probable AIH, the possible role of the drug is generally underscored, and immunosuppressive treatment is started. On the other hand, if the AIH scale is not conclusive and/or histology findings are more consistent with DILI, the case is assumed to be a DILI case, particularly if the clinical symptoms resolve after discontinuation of the suspected drug (DIAILD may be a self-limiting process), and the possibility of unmasking AIH by the action of a drug is disregarded. To further complicate the differentiation between AIH and DILI we must underline the fact that there is no specific histological features of either process and the pathological features may show only subtle differences pointing to the immune-mediated liver disease versus hepatic toxicity[17]. These considerations lead us to suggest that DIAILD might be underreported nowadays.

When a patient is admitted to hospital because of acute hepatitis and the drug that is thought to be responsible is identified, treatment is stopped.

If transaminases decreased more than 50% in 1 week to 1 month, and the DILI case fulfils other Council for International Organizations of medical Science (CIOMS) criteria such as a favourable temporal sequence, alternative pharmacological and clinical conditions have been ruled out, dechallenge with the drug is followed by improvement, and rechallenge if present is positive, then the DILI case is probably related to the drug[34,35]. Sponta-

neous recovery supports this possibility and, generally, if autoantibodies have been solicited to the laboratory and are positive, we do not consider the possibility of a drug as a trigger of IM-DILI.

If aminotransferases remain permanently raised, suffer an increase during follow-up, and autoantibodies are positive, AIH is assumed; if the AIH-scale reveals a probable AIH, treatment with IS is begun as soon as possible. There is complete exclusion of the trigger paper of a drug treatment if it is present prior to acute hepatitis, or if the drug is retired but without giving its importance to it; if true, AIH may resolve spontaneously.

New drugs: the growing use of drugs such as statins and biologic agents, which have been related to DILI with autoimmune features, which has prompted an increase in the diagnosis of DIAILD[36-42].

The diagnosis DIAILD represents a challenge to the clinician as there are neither histological, nor clinical features that are pathognomonic of true AIH, and HLA haplotypes do not convincingly distinguish between either entity. Indeed, as previously commented many cases of drug-induced AIH tend to be misdiagnosed as classical AIH cases. The CIOMS scale is unable to distinguish between AIH and DIAILD, as the scale fails to accommodate all relevant information for diagnosing DIAILD. Causality may also be challenged by the lack of spontaneous improvement after drug withdrawal in this form of DILI.

PREDICTION OF AUTOIMMUNE HEPATITIS-RISK FACTORS

Susceptibility

Autoantibodies: Many autoimmune diseases are chronic conditions that progress over the years, and are characterised by the presence of autoantibodies that may precede the overt disease by months or years[43]. In AIH, the hallmark is the presence of circulating autoantibodies. If ANAs are detected in female patients with DILI, the coexistence of an autoimmune disease is possible[26].

***HLA* genes and haplotypes:** Susceptibility to AIH, via a genetic predisposition, has been clearly associated with class II human leukocyte antigen (*HLA*) genes, more specifically to the DRB1 locus[44]. This is the major associated gene locus. Predisposition to AIH type I is associated with HLA-DRB1*0301, DRB3*0101, and DRB1*0401 alleles in European and North-American Caucasoid, encoding the HLA-DR3, DR52 and DR4 molecules, respectively. Czaja *et al*[45] determined in 1993 the following class II HLA associations with AIH: 44% DR3, 32% DR4, 9% DR3-DR4, and 15% other antigens. The study of different geographical areas and ethnic groups revealed different results. In Japan and Argentinean Caucasoid adults, susceptibility was associated with HLA-DRB*1-0405 (DR4): Mexican adults presented DRB1*0404 (DR4), and Caucasoid children and adults from Argentina presented DRB1*1301 (DR13)[45-49]. In Brazil, the haplotype DRB1*1301 is the most frequently

related to type 1-AIH[44]. A secondary association with HLA-DRB1*0301 has been detected in this country[50]. Another haplotype, DRB1*07, seems to produce susceptibility in German and Brazilian populations[51,52]. Type 2 AIH is associated with the haplotypes HLA-DRB1*0301 and HLA-DRB1*07[50]. Recently, Oliveira *et al*[50] searched for additional susceptibility factors in the extended MHC region. They have studied genes located in the MHC class III region, in addition to class I HLA-B and MICA genes, to verify if the specific haplotypes DRB1*1301 or DRB1*0301 could be involved in the susceptibility of paediatric patients in Brazil[53]. The ancestral haplotype comprising *TNFA*-308A, *TNFA*-238G, *LTA*+252G, *LTA*+80C, *NFKBIL1*-63A, *BAT1*-348C, *BAT1*-22C, *HLA-B*08 and *MICA*08 was more common in DRB1*03 positive patients than in controls (40% *vs* 14%), showing a seven-fold increased risk of disease. Finally, a variety of class III haplotypes was also present in HLA-DRB1*13 patients, without a predominant pattern. The most common of the 98 haplotypes present in patients were completely absent in controls. The extended haplotype analysis in this sample of AIH-1 patients highlighted not only the genetic diversity present in the Brazilian population, and was also in accordance with the previously documented microdiversity within the MHC region. The DRB1*1501 allele may protect from disease[46].

Triggers

Triggers may induce AIH. AIH may be induced by drugs[12], herbal remedies[11], different viruses and bacteria[54-58] and vaccines[59,60].

Exposure to all of these potential triggers may produce immune responses that especially target the liver, mainly in predisposed individuals, as we have seen previously; therefore, chronic hepatitis with autoimmune features might develop. If not recognised promptly and the responsible agent is not withdrawn, such responses can evolve to chronic hepatitis (resembling viral hepatitis) - alpha-metil dopa, halothane, hydralazyne, minocycline, nitrofurantoin, and oxyphenisatin - or to a chronic nonsuppurative cholangitis (resembling PBC) - chlorpromazine[1].

Identification of these risk factors might help us to think about this disease and halt treatment with the offending trigger as soon as possible. Withdrawal of the offending agent may lead to a rapid resolution of the process.

Genetic polymorphisms: Several genetic polymorphisms of drug metabolising enzymes, particularly CYP, have been identified, which may produce reactive metabolites[2]. Differences in the metabolism of drugs genetically conditions may produce protein adducts and susceptibility to DI-AIH. The occurrence of more than one case within a family supports the theory that genetic factors are involved[61]. It has been shown that a familiar sensitivity to the toxic effect of the metabolites exists, which may produce an inherited defect in the defence of

the liver from the injury produced by these toxic metabolites[2]. Anti-convulsants and sulphonamides have shown a familiar inheritance of *in vitro* lethal effects against the lymphocytes by their metabolites[62,63].

Sex

In AIH, there is a female sex predominance. Women are affected more frequently than men (sex ratio 3.6:1) and the disease is seen in all ethnic groups and across all age intervals[56]. Björnsson *et al*[12] published 78% (184/237) of females with AIH *vs* 92% in the DI-AIH (20/24); in the nitrofurantoin group the findings were 11/11, with numbers of 10/11 in the minocycline group. In the Spanish DILI Registry, sixteen cases out of the 742 cases (2.15%) of idiosyncratic DILI were identified[9]. There were 10/16 women. Heurgué *et al*[10] reported 8 patients with DI-AIH out of 65 AIH cases diagnosed consecutively. The female/male sex ratio was 87% *vs* 82%, revealing no statistically significant differences. Sugimoto *et al*[11] recently published a series of 7 patients with AIH that developed after a first DILI episode. Six out of the seven affected patients were women. In other smaller series, a female preponderance seems to be the general rule[32]. Czaja *et al*[16] reported that not only does DIAILD (DI-like AIH) occur almost exclusively in women, but that the drug injuries in the liver are more severe than in men[2,12,64,65]. Indeed, female sex has been found to be a risk factor for acute liver failure development after a DILI episode[25].

DILI

Multiple episodes of DILI in the same patient with drugs of similar structure or function as well as unrelated drugs may induce immune-related hepatotoxicity[20]. Between 1994 and 2009, Lucena *et al*[20] identified 9 patients out of 742 in the Spanish DILI Registry (1.21%), with evidence of two distinct DILI episodes produced by different drugs. In each individual, the type of injury was the same

in the two episodes, regardless of the causative drug. Second episodes were associated with features of AIH up to more than 40% (4/9) of cases, making it unclear whether this is drug-induced unmasking of true DI-AIH or IM-DILI (DILI with autoimmune features).

Age

Elderly individuals have an increased risk of drug toxicity[16]. The risk of DILI increases with age for certain drugs, such as those that are implicated in autoimmune-like hepatitis (nitrofurantoin, halothane, and isoniazid).

Association with other autoimmune diseases or induction by biologic agents

Biologic agents: Biologic agents are increasingly being used for rheumatological and systemic autoimmune diseases. The BIOGEAS project[39,40], created by the Spanish Society of Internal medicine, has retrieved more than 800 cases of AI diseases secondary to biological therapies. In this study, 19 cases of AIH have been reported. Statins[36,37] have been reported to induce AI diseases, typically in patients with other AI diseases.

Spontaneously: AI diseases frequently appeared to be associated between them[36,37]. Multiple examples are published in the literature[66].

Drugs

Nowadays, more than 900 drugs, toxins and herbal remedies have been reported to cause liver injury. Recently, it has been reported that at least 24 drugs, probably more, have been associated with AI chronic hepatitis mimicking AIH[67], but more and more new agents are being implicated[67-83]. With the appearance of new statins, biologic agents, and antibiotics, it will be quite normal to see more new agents being reported as being responsible for new drug-induced AIH cases (Table 3).

Elements to be reported when a case of DIAILD is suspected

Some basic requirements are needed to consider a drug as a trigger of AIH. These basic requirements must be debated and consensuated prior to the publication of a suspected new case. The elements that we think that must be included in a suspected DIAILD case before publication are outlined in Table 2.

CONCLUSION

DIAILD is still a poorly defined and under-reported liver disorder and is also a probably underestimated liver disorder. A small number of DILI cases exhibit features typical of AIH. To differentiate between true AIH triggered by drugs (DI-AIH) and IM-DILI still remains a challenge. Patients diagnosed with DIAILD have frequently had a previous episode of hepatotoxicity. The CIOMS scale has a limited value to ascertain causality in DIAILD. Hopefully, the collaborative efforts in DILI research will

Table 3 Drugs and drug-induced autoimmune liver disease

enhance our knowledge of this intriguing hepatic disease. We consider that some basic requirements are needed to be considered before supporting a drug as a trigger of AIH and they should be taken into account by authors, reviewers and editors when cases are published and made available to the scientific community.

Abstract

Non-alcoholic fatty liver disease (NAFLD) is emerging as one of the most common liver diseases, leading to the increasing interest for new therapeutic approaches for its treatment. NAFLD primarily depends on a hypercaloric and/or unbalanced diet leading to overweight and obesity. The liver, in fact, plays a central role in lipid metabolism by importing free fatty acids from the blood and synthesizing, storing, oxidizing and exporting lipids. Furthermore, the liver is the target for the thyroid hormones, thyroxine (T_4) and 3,3',5-triiodo-L-thyronine (T_3), that stimulate the basal metabolic rate and lead to body weight loss. In the last decade, other iodothyronines have been shown to possess biological relevance and play some thyromimetic activities; in particular, 3,5-diiodo-L-thyronine (T_2) gained large interest. The global effect of iodothyronines on liver lipid metabolism results from the balance between direct and indirect actions on the hepatocyte, leading to stimulation of lipid synthesis, oxidation and autophagy. In this review, the results so far obtained on both *in vivo* and *in vitro* models of hepatosteatosis are summarized in order to obtain an updated picture of the lipid-lowering effects of iodothyronines on mammalian liver.

Core tip: This review summarizes the recent insights about the mechanisms underlying the lipid lowering action of iodothyronines. In the last decades, extensive studies investigated the possible use of iodothyronines in the treatment of obesity and dysmetabolic syndromes. Since the pharmacological use of thyroid hormones has found severe limitations because of their thyrotoxic effects, the identification of iodothyronines retaining anti-obesity and hypolipemic efficacies, while being devoid of thyrotoxicity, gained great interest. The review discusses the recent studies employing both *in vivo* and *in vitro* models of hepatosteatosis, with particular attention to the *in vitro* studies demonstrating the direct anti-steatotic effect of iodothyronines.

IODOTHYRONINES AND METABOLISM

Thyroid hormones (THs) secreted by the thyroid gland comprise two main iodothyronines: 3,5,3',5'-tetraiodothyronine (thyroxine or T_4) and 3,5,3'-triiodo-L-thyronine (T_3) (Figure 1). T_4 is the major form secreted by the thyroid and the most abundant TH in circulation, while T_3, the active form, is mainly generated by peripheral deiodination of T_4. T_3 may be further deiodinated to yield different diiodothyronines such as 3,5-diiodo-L-thyronine (T_2) (Figure 1). In the past, T_3 was assumed to be the only active iodothyronine *in vivo*, but recent evidence suggested that other iodothyronines, such as 3',5',3-l-triiodothyronine (rT3) and T_2, may be of biological relevance[1,2].

THs influence a large number of physiological pro-

cesses in vertebrates, including growth, development and differentiation. THs have stimulatory effects on metabolic activity, thus inducing thermogenesis (the so-called calorigenic effect) that represents a major component of the energy expenditure in endotherms. Of particular interest is the effect of THs on lipid metabolism resulting from the balance between stimulation of lipid synthesis and lipid oxidation (Figure 2). The liver represents one of the main target tissues of THs. At the hepatic level, T_3 stimulates cholesterol synthesis and its metabolism into bile acids[3] and cholesterol uptake[4], and it induces lipogenic enzymes, including fatty acid synthase (FAS) and acetyl-CoA-carboxylase[5]. In addition to the lipogenic action, T_3 also leads to a general reduction in the hepatic triglyceride (TAG) content, likely through stimulation of lipolytic pathways[6]. Moreover, it has been suggested that TH-stimulated lipogenesis/lipolysis "futile" cycle may contribute to the calorigenic effect[7].

The metabolic effects of iodothyronines have long been investigated because of their potential use as drugs to treat obesity and lipid metabolism disorders[8]. However, due to the simultaneous undesirable side effects, such as the induction of a thyrotoxic state (tachycardia, muscle wasting, bone loss), the employment of T_3 or T_4 to stimulate body weight loss or treat metabolic syndrome has been limited. At the same time, the development of TH agonists/analogs retaining lipid-lowering and anti-obesity efficacies, while being devoid of thyrotoxic effects, has received great interest as a potential therapeutic advancement. The research of the last years has identified several iodothyronines other than T_3 and T_4 that display some thyromimetic activities. Among them, T_2 assumed a great interest as it mimics several effects of T_3 on energy

metabolism[9-11] without inducing thyrotoxic effects[12]. A single dose of T_2 (25 μg/100 g body wt) stimulated the resting metabolic rate (RMR) of hypothyroid rats and increased the liver oxidative capacity to the same extent as the same dose of T_3[13]. Moreover, T_2 significantly reduced serum triglyceride and cholesterol levels and increased liver oxygen consumption[10].

With regards to the calorigenic effects of THs, several cellular targets have been proposed but none has received universal acceptance. By virtue of their central role in the energy-transduction pathway, mitochondria are natural candidates to mediate the calorigenic activity of iodothyronines[14]. Single injections of T_2 or T_3 into hypothyroid rats stimulated RMR[15], in association with an increase in oxygen consumption[16]. It is widely accepted that iodothyronines may exert two kinds of effects on mitochondria: (1) a rapid stimulation of respiration (within minutes/hours); and (2) a long term effect leading to mitochondrial biogenesis and mitochondrial mass increase. The calorigenic activity of THs has long been ascribed to uncoupling of mitochondrial oxidative phosphorylation, but the mode by which they promote mitochondrial proton leak is still unresolved. Harper et al[17] related the T_3-induced increase in mitochondrial proton leak to an increased permeability of the phospholipid bilayer due to a change in the lipid composition of the inner mitochondrial membrane. On the other hand, T_2, and to a lesser extent T_3, was shown to bind the Va subunit of the cytochrome oxidase complex, thus abolishing the allosteric inhibition due to ATP binding and stimulating enzyme activity[18]. Recently, Yehuda-Shnaidman et al[19] reported that mitochondrial uncoupling by T_3 was transduced both *in vivo* (in rats) and *in vitro* (Jurkat cells) by gating of the

Figure 2 Schematic representation of the mechanisms underlying the control of lipid metabolism by iodothyronines in the hepatic cell: A summary of the possible signaling pathways involved in iodothyronine actions is presented. The classic "receptor-mediated" pathway describes the action of iodothyronines through the thyroid hormone receptors (TR). The "non receptor-mediated" pathway occurs through the interaction of iodothyronines with different cellular targets. FFA: Free fatty acids; LD: Lipid droplet; AOX: Acyl-CoA oxidase; ATGL: Adipose triglyceride lipase; CPT: Carnitine palmitoyl-transferase 1; FAS: fatty acid synthase.

mitochondrial permeability transition pore.

Interestingly, T_2 administration has been demonstrated to be able to stimulate RMR and to also reduce body weight in humans. In a pilot study, two euthyroid subjects were treated with increasing doses of T_2 (from 100 to 900 mcg/d, three times a day for 8 d) and for a further 3 weeks with 3000 mcg/d. A reduction in body weight of -4% was observed without effects at the cardiac level[20].

The pharmacological effects of some derivatives of thyronines called thyronamines have been also investigated. Scanlan et al[21] described the synthesis and biological properties of 3-iodothyronamine (T1AM), a novel thyronamine that was shown to be an endogenous component of biogenic amine extracts from rodents. T1AM has a carbon skeleton identical to that of T_4 and theoretically, it could be produced from T_4 by enzymatic decarboxylation and deiodination (Figure 1). T1AM treatment rapidly induced a hypometabolic state and hypothermia in rodents, with opposite effects compared with those typical of THs.

MECHANISMS OF ACTION OF IODOTHYRONINES

In the past, it was a common notion that TH actions were mediated by specific nuclear thyroid hormone receptors (TRs) acting as ligand-dependent transcription factors binding the "thyroid hormone response elements" (TREs) on the promoter region of thyroid hormone-responsive genes[22]. In the early 1960s, Tata and co-workers provided the first evidence for a "receptor-mediated" mechanism of T_3 action on energy metabolism[23]. In the 1980s, two distinct genes, *THRA* and *THRB*, were iden-

tified in humans and rodents, each encoding a different TR isoform (TRα and TRβ, respectively). The *THRA* gene was originally identified in chicken[24], while *THRB* was cloned from human and rat cDNA libraries[25]. Each isoform shows alternative splice variants (TRα1, TRα2, TRβ1 and TRβ2) with specific and distinct functions and tissue localization.

Although the "receptor-mediated" mechanism accounts for several actions of THs, other effects independent of TRs have been described, suggesting an alternative model for their action. Effects of iodothyronines that are not initiated by binding to TRs are termed 'non-receptor-mediated' mechanisms[26] and could involve a multiplicity of signaling pathways, such as phosphorylation of effector proteins[27], binding to surface receptors[28], Ca^{2+} mobilization[29], alteration of mRNA stability[30], modification of membrane fluidity and permeability[2]. The possibility that TH action was mediated by interactions with membrane surface receptors was confirmed by using cell impermeant agarose-conjugated T_3. The results clearly indicated that both free and conjugated hormones led to activation of extracellular signal-regulated kinase (ERK1/2s)[31] and affected Ca^{2+} homeostasis[32]. Moreover, THs were shown to interact with theαVβ3 integrin receptor triggering the ERK1/2 pathway[33]. Although the "non-receptor mediated" effects are sometimes called "non-genomic", this term is rather confusing as these pathways may also in turn affect gene transcription[34].

In conclusion, it is now widely accepted that TH effects may result from a synergism between "receptor-mediated" and "non-receptor mediated" mechanisms. Moreover, we can distinguish between early and late effects of THs (also called "short-term" and "long-term" effects), the first being evident within minutes or a few

hours, whereas the second occurs over several hours or days[34,35]. However, the latency of a response is not sufficient to discriminate between "receptor-mediated" and "non-receptor" mediated effects.

HEPATIC STEATOSIS: *IN VITRO* AND *IN VIVO* MODELS

With the rapidly growing prevalence of obesity throughout the Western countries, morbidity and mortality related to its complications are on the rise. Severe obesity is generally associated with TAG accumulation in non-adipose tissues like liver, muscle and pancreas and leads to a high risk of co-morbidities, including nonalcoholic fatty liver disease (NAFLD), cardiovascular disease and diabetes (for a review see[36]). NAFLD is a pathological condition associated with over-accumulation of TAGs in the liver and represents the most common of all hepatic disorders and the most frequent cause of chronic liver disease[37,38]. The earliest stage of NAFLD is hepatic steatosis characterized by the deposition of cytoplasmic TAGs as macro- and/or micro-vesicular lipid droplets in more than 5% of hepatocytes. Simple steatosis may progress to nonalcoholic steatohepatitis (NASH), cirrhosis and finally hepatocellular carcinoma[39]. NAFLD is now considered the hepatic manifestation of the metabolic syndrome and has insulin resistance as its hallmark. NAFLD is a syndrome with multifactorial etiology for which there is no effective treatment, although weight loss may halt disease progression and revert histological changes[36].

In hepatocytes, steatosis results from an imbalance between lipid availability (deriving from circulating lipid uptake or *de novo* lipid synthesis) and lipid disposal (through FFA oxidation or TAG secretion)[40]. Typically, the main cause of steatosis is an overflow of free fatty acids (FFAs) into the liver that may eventually trigger lipoperoxidative stress and hepatic injury[39,41]. In the liver, FFAs are stored as TAGs through their esterification with glycerol or, alternatively, catabolized by oxidation to generate adenosine triphosphate (ATP). Excess TAGs are accumulated inside lipid droplets (LDs) that regulate storage and traffic of lipids (for a review see[42]). Typically, LDs are composed of a core of neutral lipids surrounded by phospholipids and proteins of the PAT protein family (acronym referring to the first members identified)[43]. The main PAT proteins are the adipocyte differentiation-related protein (ADRP, also called PLIN2), the oxidative tissue-enriched PAT protein (OXPAT or PLIN5) and the tail-interacting protein (TIP47 or PLIN3)[44]. ADRP expression is increased in rat models of NAFLD and in isolated hepatocytes[45]. PAT proteins are under the control of peroxisome proliferator-activated receptors (PPARs), a subfamily of lipid-activated transcription factors[46] consisting of three members, PPARα, PPARγ and PPARδ, with distinct functional roles[47,48]. In the liver, PPARα enhances lipid catabolism and mobilization[49], PPARδ induces glycolysis/lipogenesis and PPARγ promotes lipid synthesis and LD formation[50]. In summary, PPARα and PPARδ mainly act in energy burning, whereas PPARγ regulates energy storage, although an overlapping in their function has been described[40-51]. Moreover, PAT proteins regulate action of hepatic lipases that mobilize TAGs stored in LDs towards oxidation or secretion[52], in particular, the adipose triglyceride lipase (ATGL) performs the first step in TAG hydrolysis.

In vivo models

Steatosis and steatohepatitis can be modeled in rodents by two main dietary protocols: a methionine and choline deficient (MCD) diet or a high-fat diet (HFD). Different dietary approaches produce different disease severities and work by specific mechanisms[53]. In rodents, a MCD diet quickly induces (2-4 wk) hepatic steatosis (mainly macrovesicular) that may progress to inflammation and fibrosis. MCD diet-induced NASH is reversible by switching to a diet with methionine and choline. Rodents fed MCD diets lose weight (due to the lower caloric intake) and do not show insulin resistance. By contrast, HFD increases body weight, body fat and induces insulin resistance in rodent models. In general, HFD feeding induces only mild steatosis (mainly microvesicular) and does not produce liver fibrosis. The term "HFD" encompasses a wide variety of diet formulas but in all of them about 30%-75% of total calories is derived from saturated fatty acids. This diet closely resembles the pathological and molecular alterations found in humans with NAFLD[53]. It can be emphasized that fatty liver is typically characterized by altered lipid metabolism, increased oxidative stress and abnormal pattern of cytokine production.

In vitro models

Hepatic steatosis in humans is typically associated with excess accumulation of oleic acid, a monounsaturated omega-9 fatty acid which represents the end product of *de novo* fatty acid synthesis. A number of studies using both primary cell cultures[54] and immortalized cell lines[55,56] proposed reliable cell models of hepatosteatosis in which the steatosis severity might be modulated and the TAG content was exactly quantifiable. These *in vitro* models represent a simple experimental system to investigate the mechanisms underlying the steatosis progression and the hepatocyte alterations by excluding the interference from the matrix and other non-hepatocytic cells. Over the past decade, several cellular models of hepatosteatosis have employed palmitate (C16:0) and oleate (C18:1) as exogenous fatty acids since these are common dietary long-chain FFAs and the most abundant FFAs in liver in both normal subjects and patients with NAFLD[57]. The human hepatoma cell line (HepG2) incubated with a mixture of oleate/palmitate (2:1 ratio) was used to study the cellular mechanisms involved in FFA-mediated lipotoxicity[55,58]. The same FFA mixture was used to induce steatosis in primary human hepatocytes[58]. In order to assess the different toxicity of saturated and unsaturated FFAs, primary mice hepatocytes and HepG2 cells were treated with various concentrations (0.05-0.5 mmol/L) of long

chain FFAs with different degrees of saturation; exposure to monounsaturated fatty acids resulted in lipid accumulation without changes in hepatocyte viability; in contrast, saturated fatty acids significantly decreased cell viability[59]. The effect of increasing concentrations of oleate alone (0.1-2.0 mmol/L) was also evaluated in order to clarify the pathophysiological changes associated with NAFLD[60].

LIPID-LOWERING EFFECTS OF IODOTHYRONINES ON *IN VIVO* MODELS OF HEPATOSTEATOSIS

In 1994, a first study reported that a daily intraperitoneal (*ip*) injection of T3 (from 0 to 25 μg/100 g b.w.) to *ob/ob* mice decreased body weight and body fat and increased oxygen consumption and oxidative metabolism[61]. About ten years later, Goglia and coworkers described similar effects for T2[10]. They showed that a daily ip injection of T2 (25 μg/100 g b.w.) to rats simultaneously receiving HFD reduced both adiposity (about -50%) and body weight gain (about -13%) when compared with rats receiving HFD alone. Moreover, T2 administration resulted in an almost complete disappearance of fat accumulation in the liver, a reduction in serum TAG and cholesterol levels (-52% and -18%, respectively), and a stimulation (about +42%) of FFA oxidation rate without inducing thyrotoxicity [10]. The effects of T2 on liver metabolism seemed to involve mitochondria, even although peroxisomes are the main site for fat oxidation. In fact, long chain FFAs enter mitochondria through the activity of carnitine palmitoyl-transferase 1 (CPT1) that was stimulated by HFD and further increased by T2 [10].

Interestingly, dietary administration of T3 was also able to both prevent and reverse hepatic steatosis in rats[62]. In fact, concurrent dietary administration of T3 and MCD diet resulted in prevention of fatty liver and decrease in lipid peroxidation in rats fed a MCD diet for 10 weeks and then co-fed T3 for 1 week. Similar effects were observed using the potent TR selective agonist GC-1[62].

The hepatic effects of T2 administration to HFD rats were investigated in more detail by Grasselli *et al*[63,64]. HFD feeding resulted in hepatic lipid accumulation under the form of numerous LDs, a condition resembling the microvesicular steatosis typical of NAFLD. Fat accumulation was associated with increased transcription of PPARα, a regulator for a number of genes involved in FFA catabolism, and of ATGL, a lipase mobilizing fat from LDs, together with a stimulation of anti-oxidant agents such as catalase and metallothioneins, in line with the increased production of reactive oxygen species (ROS) from mitochondria and peroxisomes as a consequence of fat accumulation[65]. In the liver of HFD rats, concomitant T2 administration was able to prevent lipid accumulation, but also oxidative stress conditions associated with the diet[63]. Moreover, T2 prevented the HFD-induced up-regulation of both PPARα and ATGL and stimulated - (AOX) expression, indicating a stimulation of peroxisomal FFA oxidation[64].

In addition to the above described reports demonstrating the ability of T2 to prevent liver steatosis when administered simultaneously to HFD, other studies demonstrated that T2 was also able to reverse hepatic steatosis after its induction through long term HFD and these effects were associated with a stimulation of mitochondrial uncoupling and a reduction in mitochondrial oxidative stress[66].

A recent paper investigated the changes in the rat liver proteome induced by T2 treatment. The proteomic approach allowed identification of which proteins were differentially expressed in the liver of HFD rats as a function of T2 treatment[67]. Upon T2 administration, the rat liver proteome resembled that typical of a non-steatotic condition. In particular, high-fat feeding led to changes in the expressions of enzymes involved in a multiplicity of pathways (*i.e.*, lipid metabolism, antioxidant defense, respiratory chain, oxidative metabolism). Mitochondria, in particular, appeared as the major target for the metabolic/energy adaptations induced by lipid overload in the liver and showed the more marked changes in terms of proteome as a response to T2 treatment. In mitochondria from HFD rats, enhanced activities of complexes I and V and reduced activities of complexes II and IV were detected, even although the protein levels for all the complexes were increased. T2-treatment stimulated complexes I and II and normalized complex IV activity. On this basis, the authors suggest that the T2-induced enhancement of oxidative capacity may actually be based on a stimulation of the individual respiratory chain complexes (I , II and IV)[67].

LIPID LOWERING EFFECTS OF IODOTHYRONINES ON *IN VITRO* MODELS OF HEPATOSTEATOSIS

The above described *in vivo* studies could not distinguish between the direct antisteatosic effects of THs on the liver and their secondary effects due to upstream changes in endocrine or metabolic pathways. The employment of isolated hepatocytes allowed overcoming these problems.

Grasselli *et al*[51] assessed *in vitro* the direct effects of T2 and T3 (10^{-7}-10^{-5} mol/L doses for 24 h) using primary cultures of rat hepatocytes overloaded of lipids ("steatotic" hepatocytes) by exposure to the classical oleate/palmitate (2:1 ratio) mixture. The use of supraphysiological doses of iodothyronines depends on both their rapid metabolism *in vitro* and on their binding to the high concentration (1%) of albumin present in the culture medium. In accordance with reports showing altered expression of PPARs in murine models developing fatty livers[47], isolated "steatotic" hepatocytes exhibited increased expression of both PPAR-γ and PPAR-δ, as well as of ADRP, a PPAR-regulated PAT protein. As in liver of HFD rats[64], also in isolated "steatotic" hepatocytes an increased activity of AOX, the enzyme catalyzing peroxisomal β-oxidation, as well as of SOD and catalase, two antioxidant enzymes protecting cells from the higher ROS production associ-

ated with FFA catabolism, was described. A reduction in the number and average sizes of LDs was observed after treatment with T2 or T3, suggesting that iodothyronines lead to dispersion/fragmentation of LDs, thus making the stored TAGs more accessible to enzymes acting on catabolism/secretion of FFAs. Moreover, both T2 and T3 were able to reduce the FFA-induced up-regulation of PPARγ and PPARδ, the stimulation of AOX, SOD and catalase activities. These results clearly indicate the lipid-lowering effect of iodothyronines mainly depends on a direct action on the hepatic cell[51].

The use of primary rat hepatocytes allowed verification that the lipid-lowering effect of iodothyronines was a direct action on the hepatocyte but the involvement of thyroid hormone receptors in mediating this action remained to be elucidated. To this end, the same experiments were repeated using the FaO rat hepatoma cell line defective for functional TRs. FaO cells were exposed to the classical oleate/palmitate (2:1) mixture and then treated with T2 or T3 for 24 h (10^{-7}-10^{-5} mol/L doses). In FaO cells, TAG accumulation was associated with an increase in number and size of LDs and in PPARγ mRNA expression. The addition of T2 or T3 to "steatotic" cells reduced both the TAG content and the number and size of LDs and down-regulated expression of PPARα and PPARγ. Moreover, iodothyronines stimulated the fuel-induced O2 consumption. Since iodothyronines prevented the ADP-induced transient stimulation of O2 consumption, this indicated a mitochondrial uncoupling action. In conclusion, this study demonstrated that the lipid-lowering actions of both T2 and T3 on the hepatocyte occur *via* "non-receptor-mediated" mechanisms and involve a short-term action by stimulation of mitochondrial O2 consumption[68].

IODOTHYRONINES AND AUTOPHAGY OF LIPID DROPLETS

Despite the advances in the understanding of the effects of THs on cellular metabolism, little is known about the mechanisms by which THs regulate energy consumption within the cell. This is particularly true for the events involved in the delivery of FFAs to mitochondria, a necessary step in converting stored intracellular triglyceride fuel into ATP.

Autophagy is a stress-induced catabolic process involving lysosome fusion that is conserved in almost all eukaryotes. Autophagy of lipid droplets, termed "lipophagy", has been shown to be a major pathway of lipid mobilization in hepatocytes[69] and its inhibition has been linked to development of fatty liver and insulin resistance[70]. The regulation of autophagy also appears to be important in the context of metabolic diseases, such as obesity. In a recent paper, Sinha *et al*[71] showed that T3 induced both lipophagy in cultured liver cell lines and hepatic autophagy in the mouse liver. The authors observed that the T3-stimulated autophagy of LDs depends on the presence of functional TRs and occurred before any

stimulation of hepatic lipases or oxidation enzyme[71]. Moreover, in animals with impaired autophagy, the effect of THs on FFA oxidation was abolished. Therefore, they propose that T3 may increase the delivery of FFAs to mitochondria for β-oxidation through induction of autophagy of LDs. In this light, T3 or its analogs, through their proautophagic action, may be useful in the treatment or prevention of NAFLD and its associated complications.

CONCLUSION

In the last decades, extensive studies investigated the possible use of iodothyronines as pharmacological tools in the treatment of obesity, hyperlipidemia and dysmetabolic syndromes. The possible pharmacological use of the thyroid hormones T3 or T4 to stimulate body weight loss has found severe limitations because of the thyrotoxic effects associated with their long-term administration. For this reason, the identification of TH agonists/analogs retaining anti-obesity and hypolipemic efficacies, while being devoid of thyrotoxic effects, would represent a potential therapeutic advance.

Recent *in vivo* and *in vitro* studies have accumulated evidence on the lipid-lowering action of iodothyronines in the liver (Figure 2). The first studies showed that systemic administration of iodothyronines to rats receiving HFD resulted in a significant reduction in body weight gain and in the serum levels of triglycerides and cholesterol. At the organ level, the effects on the liver were very interesting, where iodothyronines could lower the excess lipid accumulation associated with HFD. These studies prosecuted by investigating the mechanisms of iodothyronine action. The development of *in vitro* models of hepatosteatosis using both primary cultures of rat hepatocytes and rat hepatoma cell lines allowed demonstration that the lipid lowering effects of iodothyronines depend on a direct interaction with the hepatic cell and is not mediated by thyroid hormone receptors. In conclusion, all the data summarized in this review clearly indicates that T2 is able to reduce the lipid content of "steatotic hepatocytes", thus supporting the possible utilization of T2 as a pharmacological tool in the treatment of dysmetabolic syndromes, such as NAFLD, and also in the light of its lack of thyrotoxic effects.

Although a preliminary study on humans has been published, clinical trials are needed to translate these effects to the treatment of human obesity. If reproduced in humans, these results may offer an interesting perspective on the possible pharmacological approaches to the above mentioned lifestyle-related dysfunctions.

Abstract

Patients with primary sclerosing cholangitis (PSC) complicated by inflammatory bowel disease (IBD) represent a distinct subset of patients with unique characteristics, which have serious clinical implications. The aim of this literature review was to shed light to the obscure clinical and molecular aspects of the two diseases combined utilizing current data available and putting issues of diagnosis and treatment into perspective. The prevalence of IBD, mainly ulcerative colitis in PSC patients is estimated to be 21%-80%, dependent on screening programs and nationality. PSC-associated colitis is likely to be extensive, characterized by rectal sparing, backwash ileitis, and generally mild symptoms. It is also more likely to progress to colorectal malignancy, making it imperative for clinicians to maintain a high level of suspicion when tackling PSC patients. There is no optimal surveillance strategy but current guidelines advocate that colonoscopy is necessary at the time of PSC diagnosis with annual endoscopic follow-up. Random biopsies have been criticized and a shift towards targeted biopsies using chromoendoscopy, laser endomicroscopy and narrow-band imaging has been noted. Techniques directed towards genetic mutations instead of histological abnormalities hold promise for easier, more accurate diagnosis of dysplastic lesions. Chemopreventive measures against colorectal cancer have been sought in these patients. Ursodeoxycholic acid seemed promising at first but subsequent studies yielded conflicting results showing anticarcinogenic effects in low doses (8-15 mg/kg per day) and carcinogenic properties in high doses (15-30 mg/kg per day).

Core tip: Combination of primary sclerosing cholangitis (PSC) and inflammatory bowel disease (IBD) has recently arisen as a challenging research field. Recent data highlight the specific clinical and genetic traits that differentiate PSC-IBD from the two diseases individually. We reviewed the literature on colorectal neoplastic susceptibility in this subset of patients and the underlying pathogenetic mechanisms. We also emphasize the technological advances that have provided novel diagnostic tools for more accurate detection of dysplastic lesions. Finally, we present current guidelines on follow-up as well as all evidence available as to whether ursodeoxycholic acid should be used prophylactically against colorectal cancer.

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic progressive disease characterized by inflammation and fibrosis of

medium size and large ducts in the intrahepatic and extrahepatic biliary tree[1,2]. This disorder results in multifocal intrahepatic and extrahepatic biliary strictures, leading to cholestasis, liver cirrhosis, portal hypertension, and ultimately, premature death from liver failure. It was first reported in the German literature in 1867 by Hoffman, but was described in more detail in the 1920s by two French surgeons, Delbet and Lafourcade. The term sclerosing cholangitis was first used in 1954 by Castleman and later by Schwartz and Dale in their review article[3]. Its etiology remains largely unknown, although it is strongly believed that autoimmunity is the main culprit. The differential diagnosis of PSC includes congenital diseases (*e.g.*, Caroli disease and choledochal cysts) and secondary cholangiopathy, as observed in patients with collagen vascular diseases (*e.g.*, systemic lupus erythematosus, rheumatoid arthritis, and systemic sclerosis) and in those with infiltrative diseases (*e.g.*, mediastinal fibrosis, Riedel thyroiditis, eosinophilic cholangitis, and histiocytosis X). Parasitic, fungal, viral or bacterial infections or recurrent cholangitis itself, especially in patients who are immunocompromised, can cause multifocal liver abscesses that lead to a PSC-like appearance of the bile duct. This disease is associated with many cancers including cholangiocarcinoma, gallbladder cancer, hepatocellular carcinoma and colorectal cancer (CRC), thus establishing a link between chronic inflammation and carcinogenesis.

THE PSC-INFLAMMATORY BOWEL DISEASE INTERPLAY

The overwhelming majority of PSC cases have underlying inflammatory bowel disease (IBD). IBD is defined as a chronic condition characterized by immune-mediated inflammation of the gastrointestinal system. The prevalence ranges from 21% to 80%, with the higher rates seen in settings where screening programs are more intense and rectal and sigmoid biopsies are routinely obtained. A geographical variation also exists, with northern European and American societies exhibiting higher rates of PSC-IBD than southern regions and Asia. About 85%-90% of patients with PSC and IBD are comprised of ulcerative colitis (UC) patients and the remainder involves patients with Crohn's colitis or Crohn's ileocolitis[4]. The association of PSC and Crohn's disease (CD) was first described by Atkinson and Carroll in 1964[5]. A year later, Smith and Loe described an association between PSC and UC[6]. Conversely, it has been estimated that PSC occurs in about 5% of UC patients and 3% of CD patients[7].

IBD may be diagnosed at any time during the course of PSC. Until recently, the diagnosis of IBD more frequently preceded that of PSC, even by several years[8-11]. Nowadays, there has been a shift in the timing of diagnosis of IBD and PSC. PSC is most commonly diagnosed first, or at least there is a concomitant diagnosis of the two diseases. It is intriguing that *de novo* IBD may present after liver transplantation for PSC[12], and PSC may present several years after proctocolectomy for IBD. The altered trend in diagnostic timing can be attributed to two factors. First, the advent of noninvasive imaging techniques such as magnetic resonance cholangiography has enabled early diagnosis of pathological liver biochemistry. Second, the increasing awareness among physicians of the PSC-IBD association has led to early routine endoscopic screening in patients diagnosed with PSC, even in the absence of symptomatic colitis. A study comparing the interval from PSC to IBD diagnosis in 1993-1997 and 2003-2007 showed a decrease from 9 to 7 mo respectively[13].

The genetic factors for PSC development are still poorly understood. There is an obvious geographic clustering with high prevalence in northern countries compared to Southern Europe and Asia. It has been shown that first-degree relatives of PSC patients have a disease prevalence of 0.7%, representing a nearly 100-fold increased risk of developing PSC compared to that in the general population[14]. In siblings the prevalence even reaches 1.5%[15]. Taken together, these epidemiologic data and heritability studies have revealed a strong genetic background for PSC. Genome-wide association studies have shed some light on the subcellular maze of PSC and its overlap with IBD. Human leucocyte antigen (HLA) and non-HLA haplotypes have been identified. The HLA-A1 allele[16], HLA-C7[17], major histocompatibility complex class I chain-related A (MICA)*002 and 008/5.1 alleles[18,19], as well as the tumor necrosis factor (TNF)α promoter -308 A allele[20] were identified as risk loci for PSC susceptibility. Data from five different European countries (United Kingdom, Italy, Norway, Spain and Sweden) demonstrate that PSC is positively associated with three different HLA class II haplotypes: DRB1*03, DQA1*0501, DQB1*02 (which confers the highest relative risk for PSC development); DRB1*15, DQA1*0102, DQB1*0602; and the DRB1*13, DQA1*0103, DQB1*0603[21]. However, non-HLA associations have also been confirmed. Of note, MMEL1 and TNFRS14 on chromosome 1p36 encoding a membrane metalloendopeptidase-like protein of unknown function and a receptor for cytokines and membrane-bound ligands, respectively, have been identified as risk loci for PSC[22]. The risk of PSC has also been associated with the *FUT2* gene encoding fucosyltransferase[22], which is an enzyme that regulates expression of the ABO blood group antigens on the surface of epithelial cells. To date, there is scarcity of molecular evidence regarding the shared susceptibility loci between PSC and IBD. A Scandinavian study comparing PSC with UC patients showed distinct HLA associations[23]. No significant differences were noted between PSC patients with concurrent UC and PSC patients without IBD. This study provides genetic evidence that UC in PSC patients follows a distinct course and demonstrates phenotypic uniqueness compared with UC in isolation. More recently, *REL*, *IL-2* and *CARD9* have been identified as genetic links between the two diseases[24].

Taking into consideration its associations with HLA haplotypes, autoimmune diseases and the presence of IBD in the majority of PSC patients, immunopathoge-

Table 1 Characteristics of inflammatory bowel disease associated with primary sclerosing cholangitis
Extensive colitis (with right-sided predominance)
Rectal sparing
Backwash ileitis
Mild or quiescent course
Increased risk of colorectal cancer
Increased risk of pouchitis in patients undergoing proctocolectomy with
Ileal pouch anal anastomosis
Increased risk of peristomal varices in patients undergoing
proctocolectomy with ileostomy

netic mechanisms have been sought in PSC pathogenesis. In this regard, two theories have been proposed: the leaky gut hypothesis and the gut lymphocyte homing hypothesis. According to the leaky gut hypothesis, bacteria or bacterial products enter the portal-venous system due to the increased intestinal permeability resulting from inflammation, and translocate to the liver. Bacteria trigger the release of cytokines by Kupffer cells and macrophages in the liver and lead to periductal fibrosis[8]. The gut lymphocyte homing hypothesis supports the notion that T lymphocytes primed in the inflamed gut may persist as long-lived memory cells, undergo enterohepatic circulation, and trigger portal inflammation in PSC *via* aberrantly expressed adhesion molecules in the liver and gut[25].

IBD IN PSC: A UNIQUE PHENOTYPIC EXPRESSION

There are many clinical and endoscopic features that differentiate patients with IBD and concomitant PSC and those with IBD in isolation (Table 1). Loftus *et al*[10] compared 71 patients with PSC who had IBD with a matched group of 142 patients with UC. Among the PSC patients, 86% had UC, 7% had CD, and 7% had indeterminate colitis. The PSC patients more frequently had pancolitis (87% *vs* 54%), rectal sparing (52% *vs* 6%), and backwash ileitis (51% *vs* 7%) than the control group. It is now commonly believed that the colitis associated with PSC is frequently extensive and characterized by rectal sparing and backwash ileitis[26,27]. These special traits impede the definitive classification of IBD. For instance, the presence of rectal sparing or ileitis may be misinterpreted for CD or indeterminate colitis, rather than UC. In addition, PSC-associated colitis runs a milder, quiescent course, sometimes with absent clinical manifestations, thus delaying diagnosis[28]. Another intriguing trait in PSC-IBD patients is the higher rate of colorectal neoplasia, which tends to be proximal, is diagnosed at a later stage and has a worse prognosis. The colorectal neoplastic potential in these patients will be discussed later.

Of note, PSC patients who have an ileal pouch anal anastomosis (IPAA) after colectomy have an increased risk of pouchitis compared to patients with UC without PSC[29,30]. The underlying mechanism for this complica-

tion remains obscure. There is also one report suggesting that patients with PSC and IPAA run an increased risk of development of dysplasia in the ileal pouch mucosa compared with UC patients without PSC, and that these patients consequently should be under intensive surveillance[31]. However, more studies are required to substantiate these claims. Interestingly, it has been suggested that PSC-IBD patients undergoing proctocolectomy with ileostomy develop peristomal varices more frequently than IBD patients without evidence of hepatobiliary disease[32]. Bleeding from these often is recurrent and is challenging to treat. This complication can be controlled with a portosystemic shunt or transjugular intrahepatic portosystemic shunt, but liver transplantation may be considered.

PSC in patients with IBD does not seem to run a different course when compared to patients without IBD. Nevertheless, one study has demonstrated that PSC in patients with concomitant IBD has a predilection for men, is more likely to manifest itself for the first time with abnormal liver biochemistry, and has intrahepatic and extrahepatic biliary tree strictures[33]. Proctocolectomy, as a surgical treatment for UC, has no effect on liver function tests, histology or survival of patients with PSC[34].

COLORECTAL NEOPLASTIC POTENTIAL IN PSC-IBD PATIENTS

The increased occurrence of CRC in IBD patients has been well documented since 1925, when it was first described by Crohn and Rosenberg[35]. The cancer risk involves both UC and CD[36-39], and has been linked with prolonged duration and extent of disease, associated PSC and active inflammation[40,41]. Data on the relative risk of CRC in IBD are not in agreement in different studies. The cumulative risk varies from 1.4% after 18 years[42] to 34% after 25 years from onset of disease[43]. Some studies even advocate that the risk is not increased at all[44].

Recent investigations have unveiled another relationship, that of PSC-IBD patients and CRC. The concept that PSC is associated with an increased risk of colorectal neoplasia in patients with UC was proposed by Broomé *et al*[45] in 1992. In a study of 17 patients with UC who were found to have dysplasia, carcinoma, and/or DNA aneuploidy, 28% had coexistent PSC. This led to the hypothesis that PSC is an independent risk factor for the development of colorectal neoplasia in patients with existing UC. There has been a wealth of studies since then reporting the connection of PSC-IBD and CRC, particularly highlighting the compounding neoplastic risk when the two disorders coexist as opposed to patients with IBD alone[46-53] (Table 2). Soetikno *et al*[54] performed a meta-analysis of 11 studies and described an odds ratio (OR) of 4.79 (95%CI: 2.89-5.76) when comparing patients with UC and PSC to UC patients without PSC. However, two studies (both from the Mayo Clinic but using different groups of patients) have yielded contradictory results rejecting the hy-

Table 2 Summary of studies evaluating primary sclerosing cholangitis as a risk factor for colorectal neoplasia in chronic ulcerative colitis

Ref.	UC case group (No)	Centre	End point (No)	Matched controls	Colectomy rate	Is PSC a risk factor?

CRC: Colorectal cancer; CRN: Colorectal neoplasia; Dys: Dysplasia; PSC: Primary sclerosing cholangitis.

pothesis that there is an increased risk for CRC in PSC-IBD patients[52,53]. In general, the increased neoplastic potential in PSC-IBD patients could be ascribed to late diagnosis due to the subclinical course of colitis and the conservative treatment of mild flare-ups as opposed to colectomy, thereby increasing the duration and extent of colitis.

CRCs associated with PSC display a number of characteristics. They appear to have a more proximal localization with up to 76% right-sided distribution. A full colonoscopy is therefore mandatory for surveillance purposes. CRCs in this subset of patients are diagnosed at a more advanced stage and tend to be fatal. In a recent study, PSC patients with IBD and CRC were found to be younger at onset of IBD than patients who had IBD and CRC without PSC (19 *vs* 29 years; *P* = 0.04). The time interval from onset of colitis until diagnosis of CRC was, however, similar in the two groups (17 *vs* 20 years; *P* = 0.02)[55].

PATHOGENETIC MECHANISMS OF CRC IN PSC

The mechanisms underlying the pathogenesis of CRC in IBD patients have been rigorously investigated and many differences in comparison with sporadic CRC have been addressed[56,57]. Even though IBD-CRC usually follows a dysplasia-cancer pattern, as in sporadic cancer, molecular and genetic events seem to occur in an unconventional sequence. Alterations to the *p53* tumor suppressor gene occur earlier in colitis-related CRC[58], whereas adenomatous polyposis coli (*APC*) gene alteration is usually a later event[59]. The reverse applies to sporadic CRC. It is also noteworthy that p53 mutations can be present in nondysplastic mucosa in IBD-CRC, but only in dysplastic areas in sporadic cancer[60]. Another noteworthy difference is that low-grade dysplasia is often in flat lesions in CRC-IBD, which are difficult to detect endoscopically, whereas such dysplasia occurs within raised polyps in sporadic cancer. The role of microsatellite instability, hypermethylation, chromosomal instability, interleukin (IL)-23/IL-17 signaling and E-cadherin (CDH1) has been addressed in studies but is not yet fully understood[61-64]. Polymorphisms of the mismatch repair genes *MLH1* and *MSH2*

have been incriminated for the pathogenesis of IBD and related malignancy[65,66].

The direct impact of PSC on colorectal carcinogenesis has not yet been delineated. Another theory highlights the significance of the cholestasis-associated secondary bile salt pool in the colon[67]. Bile acids such as deoxycholic acid and lithocholic acid (LCA) are thought to contribute to tumorigenesis through disruption of the balance between colorectal crypt cell proliferation, differentiation and apoptosis[68-71]. Mucosa in carcinoma displayed an increased frequency of bile acid receptors compared with normal tissue[72]. A higher fecal bile acid concentration was found in patients with UC who developed neoplasia compared with those without UC[73]. Folate deficiency has also been implicated in the pathogenesis of CRC in IBD patients. Folate deficiency arises from sulfasalazine use to treat UC, which is a competitive inhibitor of folate absorption. Folate supplementation was associated with a 62% reduction in the incidence of neoplasia in patients with pancolonic UC compared with placebo[74]. This theory, however, contradicts epidemiological reports according to which maintenance therapy in UC reduces risk of carcinogenesis[75].

SURVEILLANCE RECOMMENDATIONS

Periodic surveillance colonoscopy is the milestone of cancer prevention in IBD[76,77]. PSC in combination with IBD further enhances the risk for CRC as described above and necessitates increased alertness. That along with the fact that IBD in PSC patients usually follows an asymptomatic, subclinical course raises the need for routine colonoscopy at the time of PSC diagnosis, which should be repeated on an annual basis[78]. However, a recent study by Imam *et al*[79] showed a low risk of colonic neoplasia in young patients with a combined diagnosis of PSC and IBD, with an estimated prevalence of 1.3% and an incidence of 0.4% per year. This finding raises the question whether annual surveillance is unnecessary in this selected group of patients.

Three categories of dysplasia have been identified according to the IBD Dysplasia Morphology Study Group[80]: (1) negative for dysplasia; (2) indefinite for dysplasia; and (3) positive for dysplasia, which is further subdivided into low-grade dysplasia (LGD) and high-grade

dysplasia (HGD). Each of these categories necessitates a different approach. A finding of indefinite dysplasia dictates a repeat colonoscopy in 3-6 mo. The management of LGD is debatable with no clear evidence of optimal approach. St Mark's Hospital[81] demonstrated a 54% cumulative probability of LGD progressing to HGD or CRC. Mayo Clinic reported a 33% 5-year progression[82], while other studies described an even lower rate[83,84]. Thus, in the case of LGD different options should be discussed with patients and informed consent for conservative or operative management should be obtained. Patients with multifocal flat LGD in one screening or unifocal LGD in more than one screening should prompt prophylactic total proctocolectomy. HGD, however, needs unquestionable referral for total proctocolectomy due to the increased risk of concurrent or subsequent malignancy[85].

There has been increased skepticism in the medical community about the random biopsies used for surveillance purposes. New methods enable targeted biopsies to be obtained from identifiable lesions. Chromoendoscopy, confocal laser endomicroscopy and narrow-band imaging (NBI) are new promising techniques that are likely to replace old-fashioned random biopsies that have proven their inadequacy in many studies[86,87]. Chromoendoscopy uses the application of indigo carmine or methylene blue to stain dysplastic areas on the colonic mucosa. Hurlstone *et al*[88] examined 700 patients in a prospective case-control trial and diagnosed 69 dysplastic lesions with chromoendoscopy and only 24 with random biopsies ($P < 0.001$)[88]. Confocal laser endomicroscopy enables the histological visualization of the mucosa in real time. It is easily inferred that this technique requires specialized training for histological interpretation. A randomized controlled trial was conducted by Kiesslich *et al*[89] showing an increase of 4.75 times in yield of neoplasia when using endomicroscopy ($P = 0.005$). NBI uses optical fibers to enable a clear visualization of vessels, pit pattern and soft tissue structures. A study showed that NBI cannot be recommended as a chromoendoscopy substitute because it detected fewer lesions than chromoendoscopy in chronic colitis, although most were not dysplastic[90].

Newer techniques that target genetic alterations rather than histological abnormalities have been proposed to increase detection efficacy. Deletions and point mutations of tumor-suppressor genes such as *p53*, *Rb*, *APC*, *mcc* and the Sialosyl-Tn antigen have been found in dysplastic lesions and could be a useful tool for early diagnosis[91,92]. DNA evaluation by flow cytometry could reveal aneuploidy and predict suspicious areas likely to progress to CRC. The main drawback is that aneuploidy is not always a prerequisite for cancer occurrence and its presence does not always lead to malignancy.

CHEMOPREVENTION

Many studies have investigated the potential protective effects of different drug agents against malignancy in patients with UC. Pinczowski *et al*[93] was the first to report

that CRC risk is diminished by therapy with 5-aminosalicylic acid (5-ASA) in 1994. Ever since, studies have failed to demonstrate a clear relationship between 5-ASA therapy and CRC, rendering its potential protective effect presumptive rather than definitive. Azathioprine and mercaptopurine have not been shown to have a beneficial effect with regards to CRC in IBD[85]. Likewise, research has yielded inconclusive results regarding the use of corticosteroids, nonsteroidal anti-inflammatory drugs or folates for chemopreventive purposes.

Ursodeoxycholic acid (UDCA) is a drug commonly used in PSC patients due to its safe profile and favorable effects on the biochemical parameters of the disease. *In vitro* and animal studies have revealed a chemoprophylactic effect of UDCA. UDCA appears to arrest proliferation of colon cancer cell lines *in vitro*[94]. CRC induced by N-methylnitrosourea[95] and azoxymethane[96,97] in rats appeared to respond to UDCA therapy with a decrease in size. UDCA also decreased fecal concentrations of deoxycholic acid in animals, suggesting a potential protective effect through control of bile acid concentration in colon[98]. Several molecular mechanisms have been proposed to explain the chemoprophylactic effect of UDCA, including downregulation of cyclo-oxygenase-2 expression[97], prevention of carcinogen-induced changes in protein kinase C isoforms[99], suppression of epidermal growth factor receptor[100], cell cycle modulation by inhibiting the expression of cyclin D1 and promoting that of E-cadherin[101], and stabilization of mitochondrial membranes against damaging free radicals[102]. These results triggered a number of investigations in humans in order to shed light on the real effect of UDCA. Two studies have confirmed the protective effect of the drug. Tung *et al*[103] conducted a retrospective review of 59 patients showing a reduced OR of 0.18 (95%CI: 0.05-0.61) of colonic dysplasia after ursodiol use. Pardi *et al*[104] also performed a randomized placebo controlled study evaluating the effect of UDCA in the subgroup of UC patients with concomitant PSC. Patients who received a low dose of UDCA (13-15 mg/kg per day) showed a relative risk of 0.26 for developing CRC or dysplasia. Wolf *et al*[105] showed in a retrospective study of 120 patients that there was no reduction of CRC or dysplasia in the UDCA group. A hallmark study by Eaton *et al*[106] has recently reversed the long-standing conviction that UDCA has a place in CRC prevention in PSC-IBD patients. Using high doses of UDCA (28-30 mg/kg per day), they showed an increased risk of CRC in the UDCA group. The majority of patients developed colorectal neoplasia after > 2 years of use. This association remained significant after adjusting for smoking history and UC duration. High-dose UDCA also resulted in an increased risk of liver transplantation and/or death[107]. The discrepancy between different studies can be attributed to their inherent limitations and their failure to adjust for confounding factors such as age at onset of colitis, extent of colitis, family history of CRC, cigarette smoking, use of other drugs such as 5-ASA and folate, and use of the same criteria for dysplasia classification.

There has been speculation with regard to mechanisms underlying the toxic and carcinogenic UDCA properties. The most prevalent theory implicates the alteration of colonic bile acid milieu when high doses are used. An increase in serum UDCA and LCA levels in the treatment group has been reported[108]. That combined with results from *in vitro* studies stating that bile acids stimulate cell invasion in a dose-dependent fashion and reduce apoptosis could possibly provide a plausible explanation of the differing effects when low and high UDCA doses are used[109-111]. It is therefore prudent to recommend UDCA chemoprevention only to a high-risk subset of patients, including those with a personal or family history of CRC, and those with long-standing extensive colitis. This rationale has been incorporated to recent European guidelines[112].

In conclusion, PSC-IBD patients represent an important public health concern. Significant steps have been made towards the elucidation of the pathogenetic mechanisms underlying this complex disease. HLA and non-HLA susceptibility genes have been thoroughly studied and proven their association with PSC-IBD. Further investigations are warranted to reveal PSC- and IBD-specific genes and clarify their real impact on the disease. Genome-wide association studies could be invaluable in this direction but are severely undermined by the rarity of the disease and therefore the limited number of PSC patients that can be recruited. In terms of diagnosis, biomarkers currently in use are liver function tests and histology. A couple of new methods have been introduced to facilitate the evaluation of PSC patients. Fibroscan and a breath test assessing the elasticity and metabolic capacity of the liver respectively have paved the way for rapid, non-invasive diagnosis. Their diagnostic accuracy in PSC, however, remains under scrutiny.

CRC is a well-established risk for PSC-IBD patients. Aggressive colonoscopic surveillance is therefore imperative, even in those who have undergone liver transplantation[113]. In an attempt to relieve the socioeconomic and medical burden that PSC-IBD poses, many studies have explored potential pharmaceutical agents that may retard disease progression and protect against colorectal neoplasia. Antibiotics, immunomodulators, UDCA and antifibrotic agents have attracted the attention of researchers but their full potential has not yet been unraveled. Recent meta-analyses have demonstrated that UDCA in low to medium doses seems to have a chemoprophylactic effect, whereas high doses are carcinogenic[114,115]. Further investigations are required to test the efficacy of existing drug agents and promote the development of new ones. Understanding and harnessing molecular events seems a pivotal step towards this direction.

Abstract

The prevalence of obesity and related conditions like non-alcoholic fatty liver disease (NAFLD) is increasing worldwide and therapeutic options are limited. Alternative treatment options are therefore intensively sought after. An interesting candidate is the natural polyphenol resveratrol (RSV) that activates adenosinmonophosphate-activated protein kinase (AMPK) and silent information regulation-2 homolog 1 (SIRT1). In addition, RSV has known anti-oxidant and anti-inflammatory effects. Here, we review the current evidence for RSV-mediated effects on NAFLD and address the different aspects of NAFLD and non-alcoholic steatohepatitis (NASH) pathogenesis with respect to free fatty acid (FFA) flux from adipose tissue, hepatic *de novo* lipogenesis, inadequate FFA β-oxidation and additional intra- and extrahepatic inflammatory and oxidant hits. We review the *in vivo* evidence from animal studies and clinical trials. The abundance of animal studies reports a decrease in hepatic triglyceride accumulation, liver weight and a general improvement in histological fatty liver changes, along with a reduction in circulating insulin, glucose and lipid levels. Some studies document AMPK or SIRT1 activation, and modulation of relevant markers of hepatic lipogenesis, inflammation and oxidation status. However, AMPK/SIRT1-independent actions are also likely. Clinical trials are scarce and have primarily been performed with a focus on overweight/obese participants without a focus on NAFLD/NASH and histological liver changes. Future clinical studies with appropriate design are needed to clarify the true impact of RSV treatment in NAFLD/NASH patients.

Key words: Non-alcoholic fatty liver disease; Non-alcoholic steatohepatitis; Steatosis; Resveratrol; AMP-activated protein kinase; Silent information regulation-2 homolog 1; Anti-oxidants; Anti-inflammatory agents; Animal studies; Clinical trial

Core tip: The prevalence of obesity and related conditions like non-alcoholic fatty liver disease (NAFLD) is increasing. Therapeutic options are limited and alternative treatment options are sought after. An interesting candidate is resveratrol (RSV), a known AMP-activated protein kinase and silent information regulation-2 homolog 1 activator with anti-oxidant and anti-inflammatory properties. Here, we review the current evidence

for RSV-mediated effects and address the different aspects of NAFLD and non-alcoholic steatohepatitis pathogenesis. We review the *in vivo* evidence from animal studies and clinical trials. Uniformly, animal studies report a decrease in hepatic triglyceride accumulation and improvements in histological fatty liver changes, whereas results from the few clinical trials are equivocal.

INTRODUCTION

The prevalence of obesity is increasing worldwide and consequently related conditions like non-alcoholic fatty liver disease (NAFLD) have increased. NAFLD now affects up to one-third of adults and a growing number of children in developed countries[1-3]. Early stages of NAFLD involve pathological accumulation of triglyceride (TG) in the liver, a fairly benign condition. However, some individuals elicit an inflammatory response that can progress to cirrhosis, cirrhosis complications and an increased risk of liver cancer[4]. NAFLD is now the third leading cause of liver transplantation in the United States[5]. Thus, NAFLD and especially the subtype non-alcoholic steatohepatitis (NASH) are thought to become a major health issue in the United States and throughout the world[6].

Therapeutic options are limited and include weight loss, which is hard to obtain and sustain[7], bariatric surgery, Vitamin E and glitazone treatment, especially the latter with a risk of significant side effects[8-11]. Alternative treatment options are therefore warranted and intensively sought after[12-15].

A potential new therapeutic option is the polyphenol resveratrol (RSV). RSV is found in a number of plants, although in low concentrations. It is known as an activator of AMP-activated protein kinase (AMPK) and silent information regulation 2 homolog 1 (SIRT1), thereby mimicking a condition of caloric restriction *in vivo*. In addition, RSV has anti-oxidant and anti-inflammatory properties. All of these effects could in theory be beneficial for the treatment of NAFLD and a number of experimental and clinical studies have been performed.

The aim of the present review is to provide a comprehensive description of the rationale for RSV treatment for NAFLD and to review the present evidence from RSV intervention in experimental and clinical NAFLD studies.

RSV ACTIONS

RSV is primarily recognized as an AMPK and SIRT1 activator[16-18]. AMPK and SIRT1 are both central in the metabolism of many different cell types, rendering RSV with pleiotropic effects in various tissues. To date, studies have been unable to determine if RSV activates AMPK, SIRT1 or both, directly or indirectly[19], a matter of ongoing debate[20]. Regardless, the effects of the enzymes are closely interdependent. Recently, Park *et al*[21] proposed a mechanism involving a direct RSV-mediated inhibition of cAMP-specific phosphodiesterases and identified the cAMP effector protein Epac1 as a key mediator, which may lead to activation of first AMPK[21] and then SIRT1 through the up-regulation of NAD$^{+[20]}$. Furthermore, RSV may also act independently of AMPK/SIRT1; however, the mechanisms are not clarified.

Through the activation of AMPK, SIRT1 and alternative routes including anti-inflammatory and anti-oxidant actions, RSV may inhibit the development or progression of steatosis and steatohepatitis. Former attempts to use the AMPK activator metformin in the treatment of NAFLD have largely been abandoned because clinical studies showed no effect on histological NASH changes, despite a general decrease in hepatic steatosis and transaminase levels[22-24].

AMPK

The AMPK pathway regulates energy homeostasis, both intracellularly and at the whole-body level. Through the action of upstream kinases, AMPK responds to changes in the AMP/ATP ratio and thus serves as an intracellular sensor of energy levels, *e.g.*, in the situation of fasting, calorie restriction or accelerated ATP consumption[25].

AMPK activation in the liver shuts down anabolic processes like cholesterol and TG biosynthesis by reducing the activities of, *e.g.*, sterol regulatory element-binding protein-1c (SREBP-1c) and fatty acid synthase (FAS). AMPK activation also promotes catabolic processes, *e.g.*, fatty acid (FA) β-oxidation by inactivation of acetyl-CoA carboxylase (ACC) and promotion of carnitine palmitoyltransferase-1 (CPT-1) activity[26-28]. *In vivo*, it has been shown that chronic AMPK activation limits TG accumulation in both high-fat and control diet fed rats[29]. These AMPK-mediated effects have been shown in *in vitro* and *in vivo* studies, using RSV as an AMPK activator[28]. As an example, RSV treatment of HepG2 cells in high glucose media dose-dependently attenuated enhanced FAS expression, increased ACC activity and elevated TG accumulation[30].

In adipose tissue, the AMPK effects are similar, impairing lipolysis and promoting mitochondrial β-oxidation, thereby decreasing the level of circulating FFAs and the FFA load on the liver[26]. Both hepatic and peripheral insulin sensitivity is augmented.

SIRT1

SIRT1 is a member of the sirtuin family and a NAD$^+$-dependent deacetylase that acts as a master metabolic sensor of NAD$^+$. Thus, it adapts gene expression and metabolic activity in response to the intracellular energy state. SIRT1 is mainly found in the nucleus, where it functions

as a transcriptional repressor through histone, transcription factor, co-factor and enzyme deacetylation[31]. Following the SIRT1 metabolic effects, the molecule is thought to link calorie restriction and healthy aging and/ or longevity. A number of studies have confirmed this *in vivo* and *in vitro*[32-34], while few have disputed it[35].

In the liver, SIRT1 is implicated in the control of energy metabolism through deacetylation and activation of especially peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α) and the lipid-sensing transcription factor peroxisome proliferator-activated receptor (PPARα), resulting in increased FA β-oxidation[36]. PGC-1α stimulates mitochondrial biogenesis, thereby increasing the mitochondrial content in hepatocytes[37]. In unison with AMPK, SIRT1 deacetylates and regulates SREBP-1c and liver X receptor (LXR), which govern lipid and cholesterol metabolism[38-41]. Adenovirus-mediated overexpression of SIRT1 specifically in mouse liver has been shown to reduce liver fat by downregulation of SREBP-1c and FAS and up-regulation of expression of genes that control FA β-oxidation[42].

SIRT1 is an inhibitor of inflammation, repressing especially NF-κB transcription and activation as shown in liver and adipose tissue[31,36,43]. Anti-inflammatory effects of RSV have also been demonstrated in *in vitro* and *in vivo* studies, however, better documented in adipose tissue[44-48] than in hepatic cells or tissue[18,49-52].

Targeting SIRT1 activation for treatment of NAFLD has been suggested[53] as SIRT1 expression is decreased in dietary NAFLD models and NAFLD patients[54-56] and moderate SIRT1 overexpression protects mice from developing NAFLD[57].

NAFLD PATHOGENESIS

The pathogenesis of NAFLD and NASH is far from clarified and especially the factors that drive disease progression towards a more progressive, inflammatory phenotype are not fully characterized. Recently, a "multiple parallel hit hypothesis" has been proposed by Tilg and Moschen. Here, TG accumulation is viewed as an "innocent bystander", while a number of different parallel hits lead to NASH development[58]. Thus, it appears that there are 3 types of NAFLD patients: the "Good Fat Storer" (the NAFLD patient with a benign course); "the Bad Fat Storer" (the patient who develops immediate NASH); and the "Unfortunate Good Fat Storer" (the NAFLD patient that experiences additional hits and becomes a NASH patient)[59]. Only the latter two may require pharmacological treatment however, bearing in mind that NAFLD may be an independent risk factor for type 2 diabetes[60,61].

STEATOSIS

Hepatic steatosis occurs most often in the setting of obesity and metabolic syndrome and is the result of lipid overload, primarily with increased free fatty acid (FFA)

flux and TG accumulation. Several mechanisms are involved[58,62] and some may be targeted directly or indirectly by RSV treatment. An illustration of the proposed RVS effects on NAFLD pathogenesis is shown in Figure 1.

Increased FFA supply due to increased lipolysis from adipose tissue

Insulin resistance (IR) results in increased lipolysis of TG in adipose tissue, resulting in elevated levels of circulating FFAs. Hepatic uptake of both diet- and lipolysis-derived FFAs is unregulated with limitless hepatocyte uptake *via* fatty acid transporters (*e.g.*, CD36). The bulk of hepatic TG (two-thirds) is derived from circulating FFA from lipolysis[62]. RSV may decrease lipolysis in adipose tissue through improvement of peripheral insulin sensitivity, as documented in several studies[63,64]. Furthermore, RSV may favorably modulate the expression of fatty acid transporters[65-67].

Overnutrition

Dietary fat contributes approximately 15% to the overall FFA load on the liver[62]. Increased fat intake increases circulating FFA, whereas elevated carbohydrate intake, especially in the form of fructose, increases *de novo* lipogenesis[68].

Increased de novo hepatic lipogenesis from dietary carbohydrates and amino acids

Normally, *de novo* synthesis accounts for 5% of hepatic fat content. However, in subjects with NASH, up to 25% of the hepatic fat content may be caused by *de novo* lipogenesis[62]. The process is regulated independently by insulin and glucose. In the postprandial and in the IR state, insulin stimulates the transcription factor SREBP-1c that promotes transcription of all genes involved in lipogenesis, among them ACC, FAS and peroxisome proliferator-activated receptor (PPARγ)[69,70]. Glucose stimulates lipogenesis through stimulation of the transcription factor carbohydrate response element binding protein (ChREBP)[71]. An upstream activator of both SREBP-1c and ChREBP is LXR, which is a transcription factor governing lipid and cholesterol metabolism[72,73].

Results from *in vitro* and *in vivo* studies show that RSV inhibits hepatic lipogenesis by AMPK/SIRT1-mediated inhibition of SREBP-1c, ACC and FAS activity[27,28,37,44,74].

Inadequate fatty acid oxidation

Under normal physiological conditions, the mitochondria handle FFA by β-oxidation. Inadequate β-oxidation may be involved in NAFLD development due to the increased FFA flux through the liver[62,68] and both de- and increased β-oxidation rates are reported[75]. Regardless, SREBP-1c inhibits FA oxidation by indirect inhibition of CPT-1.

RSV may increase FA β-oxidation by stimulating mitochondrial biogenesis through PGC-1α activation[37], increasing mitochondrial number[37,76], increasing uncoupling protein 2 expression[76] and by increasing CPT-1 expression and activity[27,77].

Figure 1 Proposed resveratrol effects on nonalcoholic fatty liver disease pathogenesis, AMP-activated protein kinase and silent information regulation-2 homolog 1 dependent and non-dependent mechanisms. Evidence of *in vivo* effect demonstrated especially a RSV-mediated inhibition of adipose tissue lipolysis, inhibition of hepatic de novo lipogenesis and an increase in FA β-oxidation. ACC: Acetyl-CoA carboxylase; CPT-1: Carnitine palmitoyltransferase-1; FAS: Fatty acid synthase; FFA: Free fatty acids; NAFLD: Non-alcoholic fatty liver disease; PGC-1α: Peroxisome proliferator-activated receptor gamma coactivator 1 α; PPARγ/α: Peroxisome proliferator-activated receptor γ/α; ROS: Reactive oxygen species; SREBP-1c: Sterol regulatory element-binding protein-1c; TG: Triglyceride; TGF-1β: Tumor growth factor 1β.

STEATOHEPATITIS

Hepatic inflammation is the hallmark of NASH and the inflammation is driven by several inflammatory hits that may include both intra- and extrahepatic factors[58].

Among the intrahepatic factors are the excess cholesterol, FFA and lipotoxic intermediates, which elicit a number of damaging effects, collectively named "lipotoxicity"[78]. This is recently reviewed in comprehensive reviews[78,79]. Converging the harmful factors is the NF-κB pathway in immune cells, hepatocytes and hepatic stellate cells (HSC), resulting in an inflammatory, profibrogenetic and pro-apoptotic hepatic environment. NF-κB activation enhances transcription of pro-inflammatory cytokines[80,81], with increased hepatic transcription of interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α) and the TNFα receptor, as shown in NASH patients[82]. Kupffer cells and damaged hepatocytes release, *e.g.*, transforming growth factor 1β (TGF-1β) that acts on quiescent HSC, inducing an activated state and thereby fibrosis. In addition, extracellular molecules, endotoxins, such as lipopolysaccharide (LPS) (*via* toll-like receptor 4), TNFα, IL-1, IL-6 and reactive oxygen species, can induce NF-κB-mediated activation of the HSCs.

The anti-inflammatory effects of RSV are also documented in the liver. Animal studies have shown reduced hepatic macrophage infiltration[51] and TNFα levels[49,52,83],

as well as inhibition of the NF-κB pathway[50,52,83]. Only one study has focused on NASH-like fibrosis[52], probably due to the lack of appropriate animal models. However, other hepatic fibrosis models have shown RSV-mediated mitigating effects on markers of hepatic fibrosis[84-87] and HSC activation[86,88,89].

A number of studies report endoplasmatic reticulum stress, lipid peroxidation and oxidative stress as causative or early events in NASH pathogenesis[90-93]. RSV is a known anti-oxidant compound and has been shown to lower hepatic oxidative stress in rodent diabetes and NAFLD models[49,51,94-98]. One potential mechanism is interference in the Keap1/Nrf2 pathway, leading to up-regulation of anti-oxidant enzymes[99,100].

The extrahepatic inflammatory factors include dietary factors (*e.g.*, trans-fatty acids and fructose), gut-derived factors (*e.g.*, microbiota composition and bacterial byproducts) and adipose tissue-derived factors (*e.g.*, hypoadiponectinemia, adipo and cytokines, namely leptin, resistin, IL-6, TNF-α and monocyte chemotactic protein-1 (MCP-1)), that induce a state of whole-body low-grade inflammation in obesity[101]. Several lines of evidence document the anti-inflammatory effects of RSV in adipose tissue, especially by inhibiting NF-κB activation[46,102,103], lowering IL-6 levels[47,104] and macrophage infiltration[103], and modulating circulating cytokines and adipokines[45,50,103,105]. RSV-mediated reduction of LPS-

induced liver pathology and oxidative stress has also been reported[106,107].

In summary, RSV has AMPK/SIRT1 activating, anti-inflammatory and anti-oxidant effects that may act in unison, combating the different hits in the pathogenesis of NAFLD and NASH development.

RESVERATROL *IN VIVO*

Animal studies of RSV effects on NAFLD are numerous and span a wide variety of models, intervention periods and RSV doses. The studies can be divided into low-dose [RSV doses 7-45 mg/kg bodyweight (BW) daily] and high-dose studies (RSV 45-300 mg/kg BW daily). Some of the studies have hepatic steatosis as the primary end-point, others as secondary. The RSV treatment is generally started from the beginning of the study and therefore most of the studies concentrate on the preventive effect of RSV and not the therapeutic effect. Almost uniformly, the studies report beneficial effects of RSV treatment on NAFLD pathology. In addition, RSV treatment in experimental models generally reduce circulating insulin and glucose levels[18,37,45,46,50-52,63,105,108-110] and, in some instances, weight[50,52,110-113], circulating transaminases[44,52,77,110] and lipids[45,50,65,96,108,111,112].

In Table 1 we present a list of published RSV animal studies with hepatic histological NAFLD/NASH data.

MOUSE STUDIES

In 2006, Baur *et al*[37] published a much-cited study on the effect of RSV on the health and survival of mice on a high-fat diet (HFD). HFD and low-dose RSV (10 mg/d) were fed to the mice from senescence to death. Besides increased survival and a number of beneficial metabolic effects, the study showed RSV-mediated hepatic AMPK activation, ACC inhibition, decreased FAS transcription and increased mitochondrial number. RSV also decreased liver weight and the degree of steatosis. This study triggered a number of other mouse studies, often using C57BL/6J diet-induced obese (DIO) mice.

Regarding NAFLD data, the studies report a decrease in hepatic TG[45,50,65,96,111,114] and/or cholesterol accumulation[45,108,111-113] and liver weight[37,65,112], along with improvement in histological fatty liver changes[37,46,51,52,65,96,108,111,113-115]. Only a few studies report NASH changes in the histological specimens. Ahn *et al*[65] and Li *et al*[52] find that RSV supplementation represses development of histological steatosis and steatohepatitis and also fibrosis in the latter study. Tauriainen *et al*[115] find that high-dose RSV represses steatosis and hepatocyte ballooning in a model with minimal hepatic inflammation.

Although tested in a few studies, only two mouse studies are able to verify RSV-mediated AMPK activation in liver tissue[105,114]. Also, no subsequent mouse studies have investigated hepatic PGC-1α deacetylation as a marker of SIRT1 activation. However, other markers of AMPK/SIRT1 activation have been documented in several mouse studies, among them inhibition of FAS expression

and activation[65,109,111], inhibition of ACC activation[97,114], augmentation of FA β-oxidation[111], inhibition of PPARγ and SREBP-1c expression and stimulation of PPARα expression[52,65]. In mouse models, RSV treatment inhibits NF-κB activation[50,52] and lowers hepatic expression of inflammation markers[52]. Furthermore, oxidative stress is alleviated by RSV treatment in a number of mouse models[51,52,97].

In a long-term study of high-dose RSV treatment alone and in combination with another polyphenolic compound, namely quercetin, transcriptomic and metabonomic data demonstrated that combination therapy results in a significant restoration of gene sets in functional pathways of glucose and lipid metabolism (glycolysis and FA β-oxidation), inflammation/immunity, liver function and the cardiovascular system, which were altered by HFD feeding[108].

Also, in mutant Werner syndrome mice (showing premature signs of aging, *e.g.*, fatty liver), RSV treatment reversed liver steatosis and lipid peroxidation[109]. Microarray and biological enrichment analyses on liver tissues suggested that RSV mainly decreases lipogenesis and increases genes involved in the insulin signaling pathway and glutathione metabolism. The authors also observed a lower prevalence of hepatocellular carcinoma, however, an increase in lymphomas and other solid tumors was observed.

RAT AND HAMSTER STUDIES

Numerous different rat models of NAFLD report on RSV effects on NAFLD relevant endpoints, along with a single hamster study. Similar to the mouse studies, the conclusions are positive overall. The studies show a decrease in liver weight[67,74,77], hepatic TG[27,44,66,67,74,76,77] and/or cholesterol accumulation[66,67], and histological fatty liver[49,66,67,74,76,77].

The first to describe RSV effects on NAFLD in rats was Shang *et al*[74], using a HFD rat model in which the HFD was started 6 wk prior to the high-dose RSV treatment (100 mg/kg BW daily). This study therefore focused on the therapeutic effects of RSV. Besides alleviating NAFLD changes, it demonstrated that high-dose RSV treatment promotes phosphorylation and activation of AMPK and suppresses expression of FAS and SREBP-1c. This is backed by a recent study in which the HFD was added to a high amount of sucrose. Alberdi *et al*[27] found that low-dose RSV treatment for 6 wk activates AMPK and PGC-1α, increases CPT-1 and decreases ACC activities with no change in the mRNA expression of SREBP-1c, PPARα, SIRT1 and PGC-1α. Yet, not all rat studies find AMPK activation either. At variance, our group found no increase in AMPK phosphorylation or expression of related genes in spite of improvement in fatty liver changes, along with an increase in the hepatic mitochondrial content[76].

Obese Zucker rats have been used in low-dose RSV studies[44,77], with a reduction in hepatic lipid content and alanine aminotransferase levels, along with activation of

Table 1 Rodent resveratrol studies with histological liver data

Ref.	Focus	Model	RSV dose	RSV exposure (wk)	Histology/ LW	TG/CH content	Liver AMPK activation	Suggested RSV actions/mechanisms
Baur *et al*[37] (2006)	Longevity	Middle-aged DIO mice	22.4 mg/kg BW = 0.04% in diet	27	+/+	ND	+	Elevated PGC-1α deacetylation as marker of enzymatic SIRT1 activity. Phosphorylation of ACC
Ahn *et al*[65] (2008)	NAFLD/NASH	DIO mice (1% CH in diet)	1.25 g/kg diet	8	+/+ Decrease in NASH	+/-	ND	Reduced hepatic expression of FAS, PPARγ, CD36. Increased PPARα expression
Kang *et al*[46] (2010)	Insulin signaling	DIO mice	30 mg/kg BW	2	+/ND	ND	-	Increased Akt phosphorylation, improving insulin signaling
Labbé *et al*[109] (2011)	NAFLD, metabolic profile, longevity	Werner syndrome mice	0.04% RSV in diet	Life-long (≤ 22.5 mo)	+/ND	ND	-	Decreased FAS expression Decreased HCC prevalence
Tauriainen *et al*[115] (2011)	Obesity, NAFLD	DIO mice	2 or 4 g/kg diet	15	+/ND	ND	ND	Increased SIRT1 expression in liver tissue. High-dose most effective
Cho *et al*[111] (2012)	NAFLD	DIO mice (1% CH in diet)	7 mg/kg BW or 30 mg/kg BW	10	+/ND	+/+	ND	Suppressed FAS activity. Activation of FA β-oxidation in liver. The lower dose is more efficient than the higher dose
Zhou *et al*[108] (2012)	Overall transcriptomic and metabolic profiling	DIO mice	0.04% or 0.02% RSV + quercetin 0.02%	26	+/ND	-/+	ND	Modulation of inflammation and FA β-oxidation. Combination with quercetin was more effective than RSV alone
Jeon *et al*[51] (2012)	Cognitive deficit	DIO mice	200 mg/kg BW	20	+/ND	ND	ND	Attenuation of hepatic lipid peroxidation and macrophage infiltration
Shiozaki *et al*[97] (2012)	Longevity	SAMP10 mice	0.04% RSV	20	+/ND	ND	ND	Inhibition of ACC. Improved mitochondrial number, redox status and activity
Gao *et al*[114] (2013)	NAFLD	T0901317-treated mice	200 mg/kg BW	< 1	+/+	+/ND	+	Inhibition of ACC. Unchanged expression SREBP-1c and related genes
Li *et al*[52] (2013)	NAFLD	HFS mice	50 mg/kg BW	3	+/ND Decrease in NASH	ND	ND	Inhibition of NF-κB-induced inflammation and MDA-induced oxidative stress. Protection against NASH fibrosis
Bujanda *et al*[49] (2008)	NAFLD	Fasting/ feeding special diet, rats	10 mg daily	4	+/-	ND	ND	Hepatic TNF-α decrease. Improved oxidant/antioxidant markers (MDA, NOS, SOD, *e.g.*, catalase)
Shang *et al*[74] (2008)	NAFLD	HFD rats	100 mg/kg BW	10	+/+	+/-	+	Suppressed *SREBP-1c* and *FAS* gene expression
Poulsen *et al*[76] (2012)	NAFLD	HFD rats	100 mg daily	8	+/-	+/ND	-	Increased UCP2 expression Increased mitochondrial number
Gomez-Zorita *et al*[103] (2012)	NAFLD	Obese Zucker rats	15 mg/kg BW or 45 mg/kg BW	6	+/+	+/?	ND	Increased CPT-1α and ACO No effect on activity of lipogenic enzymes

AMPK and increased CPT-1 activity, which is important for the rate of FA β-oxidation. Resveratrol treatment also improved the inflammatory status of visceral adipose tissue[44] and reduced liver oxidative stress[77]. Here, the ef-

fect on lipogenetic enzyme activity was equivocal.

Similar results on inflammatory and oxidative status was found by Bujanda *et al*[49] in a model in which cycles of fasting and feeding with a high carbohydrate-fat free diet induced steatosis. Low dose RSV for 4 wk lowered hepatic TNFα levels and reduced markers of lipid peroxidation and hepatic oxidative stress.

To our knowledge, only one study reports no RSV effect on hepatic lipid levels. Andersen *et al*[116] used a dietary rat model and high-dose RSV treatment for 8 wk, yet found no decrease in liver TG, FFA or cholesterol content. Also, they found no effect on liver SIRT1 protein expression.

Taken together, the current evidence shows that RSV prevents NAFLD-like hepatic steatosis in rodent NAFLD models. This may be caused by inhibition of adipose tissue lipolysis, inhibition of hepatic *de novo* lipogenesis and an increase in FA β-oxidation. A graphic illustration of the proposed RVS effects on NAFLD pathology is shown in Figure 1. Development of steatohepatitis may be attenuated by an inhibition of adipose tissue and hepatic inflammation and reduction of oxidative stress. However, few studies have used appropriate animal NASH models and there is only one study documenting an alleviating effect on NASH fibrosis. RSV could exert some of these effects through AMPK activation but AMPK activation is not found in all studies. Also, hepatic SIRT1 activation has not been verified in an experimental NAFLD model. Studies focusing on the therapeutic effect as opposed to the preventive effect of RSV on NAFLD and especially NASH are few but warranted.

OTHER ANIMAL MODELS

In a porcine model of metabolic syndrome, Burgess *et al*[110] found that high-dose RSV treatment had mitigating effects on insulin resistance and transaminase levels. Oil red O staining showed a decrease in hepatic lipid accumulation. However, a HE stain found no difference in histology between the control, HFD and HFD with RSV groups, signifying that steatosis was not sufficiently induced in this model.

CLINICAL TRIALS

So far, only a few clinical RSV trials on efficacy outcomes have been concluded and none of these studies have focused on fatty liver disease *per se*. Two studies on obese but otherwise healthy male participants report liver data. In the study by Timmers *et al*[117], 11 participants received a daily dose of 150 mg RSV or placebo for 30 days in a double-blind, cross-over design. Results suggest a number of beneficial metabolic effects, among these a reduction of liver transaminases and liver fat by magnetic resonance (MR) spectroscopy. In another study, 24 participants received a dose of 1.5 g RSV or placebo daily for 4 wk[118] and there was no effect on liver fat content (MR spectroscopy) or transaminase levels. This is consistent with another study in 45 non-obese postmenopausal women receiving a dose of 75 mg for 12 wk where no effect on liver fat (MR spectroscopy) or any other physiological parameter could be demonstrated[119].

Future clinical studies should focus on patients with biopsy verified NAFLD and NASH to determine any efficacy of RSV treatment in this setting.

CONCLUSION

So far, clinical studies of RSV effects on steatosis are scarce and the overall positive effects seen in rodent studies are still missing. None of the studies have included verified NAFLD patients or histological data and the studies differ significantly in the RSV dose used. New clinical studies should focus on the RSV effects in patients rather than healthy or near-healthy individuals[120], in this case, histologically verified NAFLD/NASH patients. In this setting, the focus should be on the therapeutic effects of RSV and not its preventive effects, as reported in the majority of animal studies.

Abstract

Non-alcoholic fatty liver disease (NAFLD) is the leading cause of liver disease in the Western world and is closely associated with metabolic syndrome, which includes hypertension, central obesity, dyslipidemia and insulin resistance. NAFLD includes a wide spectrum of liver alterations, ranging from simple hepatic steatosis to variable degrees of fibrosis, cirrhosis and even hepatocellular carcinoma. Although the etiology and progression of the disorder remain poorly understood, insulin resistance is considered to play a pivotal role in the pathogenesis. Insulin sensitizers such as biguanides, thiazolidinediones (TZDs), glucagon-like peptide-1 receptor agonists and dipeptidyl peptidase 4 inhibitors have been studied as therapeutic approaches for NAFLD in recent years. Metformin improves insulin sensitivity and serum alanine transaminase and aspartate transaminase (ALT/AST) levels in the majority of subjects; however, it has no significant effect on liver histology. TZDs improve insulin sensitivity, serum ALT/AST levels and histology in some cases, but there are some concerns about the safety of long-term therapy. Selection of appropriate patients for avoiding side effects and the treatment of underlying disease are the main points. These drugs are the best choice for the treatment of NAFLD in patients with type 2 DM who are also candidates for treatment with an insulin sensitizer. The present review provides an overview of insulin sensitizers in the treatment of NAFLD.

Core tip: Non-alcoholic fatty liver disease (NAFLD) is increasing significantly due to the obesity epidemic. Insulin resistance, mainly caused by obesity, plays a primary role in NAFLD pathogenesis. Medications that improve insulin sensitivity are theorized to be useful in the treatment of NAFLD. Therefore, recent studies have explored the role of insulin sensitizers to improve biochemical and histological features of NAFLD.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) was first described by Ludwig *et al*[1] as a liver disease that mimicked alcoholic hepatitis in histopathological features, but without a history of excessive drinking. A recent definition of NAFLD consists of evidence of hepatic steatosis either by imaging or by histology and no secondary hepatic fat accumulation from causes such as alcohol consumption, hereditary disorders and steatogenic medication[2]. The

Figure 1 The relationship between obesity, insulin resistance and hepatic steatosis. VLDL: Very low-density lipoprotein; TG: Triglyceride.

spectrum of the disease reaches from simple hepatic steatosis to lobular inflammation (non-alcoholic steatohepatitis or NASH), fibrosis, cirrhosis and hepatocellular carcinoma[3,4]. It is the most common cause of chronic liver disease in all industrialized regions of the world[5-7].

BACKGROUND

The estimated prevalence of NAFLD varies in a wide range depending on the population studied and methods used for diagnosis. The disease has been reported in up to 10%-15% of normal weight individuals and 90% of obese persons[8-10]. The prevalence of NAFLD in patients with type 2 diabetes mellitus and hyperlipidemia is approximately 70% and 50%, respectively[11]. Ageing, male gender and ethnicity, such as being Hispanic, are associated factors that increase the prevalence of NAFLD. Elevated liver enzymes, histopathology of liver biopsy and imaging techniques such as ultrasound and magnetic resonance spectroscopy are different methods used for definition.

Previous studies have shown that 40% of patients with NAFLD may go on to develop NASH. The most common cause of cryptogenic cirrhosis is NASH and it progresses to advanced fibrosis in 32% to 37% of patients[12]. The patients with advanced fibrosis and cirrhosis also have higher risk of hepatocellular carcinoma[13-15]. Patients with NAFLD and NASH have increased cardiovascular mortality as well as liver-related mortality[16-18]. This is due to increased pericardial fat, increased carotid intima thickness and abnormal electrocardiogram changes[19-21]. Ramilli *et al*[22] showed that the prevalence of carotid plaques was close to 60% in patients with NAFLD, while it was 38% in patients without NAFLD.

Type 2 DM, obesity and the associated insulin re-

sistance have been shown as independent factors for fibrosis progression[23]. Although a lot of risk factors have been defined, the major underlying mechanisms of the disease progression have not been clearly understood. The pathogenesis of NAFLD is closely related to obesity that leads to insulin resistance and significant metabolic alterations in liver occur in the setting of insulin resistance[24] (Figure 1). The prevailing hypothesis for explaining the pathway and involved mechanisms is the so-called two hit model[25,26]. At the first hit, hepatic steatosis develops due to insulin resistance and liver fat accumulation induced by excessive free fatty acid production, increased fatty acid oxidation and decreased hepatic triglyceride export. Following this step, the second hit includes increased oxidative stress which is characterized by excessive reactive oxygen species (ROS) in the liver. Progression from NAFLD to NASH is promoted by ROS through lipid peroxidation, cytochrome P450 activation and pro-inflammatory cytokine production[27]. Considering the complexity and unexpected progression of the disease, environmental and genetic factors are approved as contributors of a third hit.

Insulin resistance is the most specific metabolic risk and pathophysiological feature of NAFLD, with most patients having insulin resistance. In diabetic patients, a correlation between the severity of insulin resistance and grade of hepatic steatosis has also been shown[28]. On the basis of these data, studies of NAFLD treatment are mostly focused on improving insulin resistance and a pharmacological approach targeting improving insulin resistance are the more promising therapeutic candidates among categories that include antioxidants, lipid-lowering agents and anti-obesity drugs.

INSULIN-SENSITIZING MEDICATIONS

Metformin

Metformin was first used in medical practice in the 1950s and has been considered the first-line treatment of type 2 diabetes after receiving approval by the United States Food and Drug Administration (FDA) in 1994. Metformin belongs to a class of insulin-sensitizer drugs and acts through reducing hepatic glucose output, increasing insulin-stimulated glucose uptake in peripheral tissue and stimulating fatty acid oxidation in adipose tissue[29]. Adenosine monophosphate-activated protein kinase is the main player in mediating metformin effects.

Animal studies demonstrated that metformin reverses aminotransferase abnormalities, steatosis and inflammation in mouse models of NAFLD and NASH[30,31]. During last decade, many clinical trials have evaluated the useful effects of metformin on patients with NAFLD and NASH[32-41] (Table 1). Only a few of these studies were randomized and the results are conflicting.

The first nonrandomized study was carried out by Marchesini in 2001 and it included 20 biopsy proven NASH patients. For 4 mo the patients were treated with 1.5 g/d metformin and they observed a decrease in ami-

notransferase levels[32]. The limitation of the study was the lack of histological evaluation and a control group. In 2004, Uygun *et al*[34] conducted the first randomized control trial comparing dietary modification to dietary modification plus metformin for six months. Aminotransferase levels and insulin sensitivity improved in the metformin treated group but there was no significant differences in necroinflammatory activity or fibrosis between groups. Bugianesi *et al*[35] presented an open label trial consisting of 110 patients who were randomized to receive either metformin 2 g/d (55 patients), vitamin E 800 IU/d (28 patients) or dietary-induced weight loss (27) patients for 12 mo. Liver transaminase levels were significantly decreased in the metformin group and there was also a histological improvement in hepatic steatosis, inflammation and fibrosis in the subset of 17 patients taking metformin. Haukeland *et al*[39] demonstrated that treatment with metformin for 6 mo was no better than placebo in terms of improvement in liver histology in patients with NAFLD. Another recent randomized control trial showed that metformin only transiently improved aminotransferase levels in patients with NASH[41]. A meta-analysis including five randomized controlled trials (RCT) concluded that metformin did not improve steatosis, lobular inflammation, hepatocellular ballooning and fibrosis in patients with NASH[42]. These results were independent of drug dose, treatment duration or diabetic state. Therewithal, a recent guideline indicates that metformin has no significant effect on liver histology and therefore it is not recommended as a specific treatment for liver disease in adults with NASH[2]. The largest RCT, "The Treatment of NAFLD in Children" (TONIC), investigated the effects of metformin in a pediatric population. The results of this study demonstrated that metformin was not associated with improvement in histology and reduction in serum alanine transaminase (ALT) levels[43]. On the basis of all these data, the AASLD guideline for the diagnosis and treatment of NAFLD concluded that metformin has no significant effect on liver histology and is not recommended as a specific treatment of NASH.

A position statement on NAFLD/NASH based on an EASL special conference has not recommended metformin for specific liver-directed therapy of NASH[44].

Some studies demonstrated that high insulin and IGF levels have important roles in hepatic fibrosis and hepatocellular carcinoma[45,46]. An inverse association between cancer risk and long term metformin therapy has been found in previous studies. A recent meta-analysis showed that metformin was associated with an estimated 62% reduction in the risk of liver cancer among patients with type 2 diabetes[47]. Chen *et al*[48] demonstrated that each incremental year increase in metformin use results in 7% reduction in the risk of hepatocellular cancer. While the main anti-tumor effect of metformin is not clear in reducing lipogenesis and lipogenic expression, inhibition of hepatocyte proliferation and induction cell cycle arrest at G_0/G_1 phase *via* adenosine monophosphate (AMP)-activated protein kinase, reduction endogenous reactive oxygen species are possible estimated mechanisms.

In summary, metformin improves insulin sensitivity and serum ALT and aspartate transaminase levels in the majority of subjects; however, it has no significant effect on liver histology. The precise dose and duration of treatment is unknown and the beneficial effects on serum ALT only continued during treatment. Metformin has no apparent increase in the risk of lactic acidosis[49] and unlike the thiazolidinediones, it is not encumbered by weight gain or potential hepatotoxicity. According to current data, it cannot be suggested for the specific treatment of NAFLD or NASH but can be given in patients with both NAFLD/NASH and type 2 DM.

Thiazolidinediones

Thiazolidinediones (TZDs) are a class of oral antidiabetic drugs that induce a nuclear transcription factor, peroxisome proliferator activated receptor-γ (PPAR-γ), by binding selective ligands[50]. PPAR-γ is predominantly expressed in adipose tissue and leads to decreased hepatic fat content and improves glycemic control with insulin sensitivity. TZDs also increase plasma adiponectin levels,

activate AMP-activated protein kinase and induce fatty acid stimulation[51].

A lot of human and animal studies have investigated the effect of TZDs on liver enzymes and histology to date. In rat models, pioglitazone and rosiglitazone prevented activation of hepatic stellate cells *in vitro* and improved hepatic steatosis and fibrosis *in vivo*[52].

The first human study was conducted by Caldwell in 2001[53]. Troglitazone was studied in 10 patients who had biopsy-proven NASH and the results were associated with improved aminotransferase levels. There was no change in histology and the drug was withdrawn from clinical use due to severe idiosyncratic hepatotoxicity. Neuschwander-Tetri *et al*[54] showed that rosiglitazone (4 mg twice daily for 48 wk) significantly decreased liver enzymes and improved steatosis, ballooning and inflammation scores in 30 patients who had biopsy-proven NASH. In addition to no change in fibrosis, the liver enzymes levels reverted to pretreatment values 6 mo after withdrawal of the drug. Clinical trials evaluating the effect of thiazolidinediones on patients with NAFLD and NASH are summarized in Table 2[53-61]. Omer *et al*[60] conducted an open label RCT including biopsy-proven NAFLD individuals to compare rosiglitazone with metformin. After 12 mo treatment, study results reported that rosiglitazone was more effective in metabolic control and histological improvement but fibrosis did not change significantly.

An early study with pioglitazone in 18 patients who had biopsy-proven NASH resulted in a decrease in aminotransferase levels with histological improvement[55]. The first double-blind, placebo-controlled trial using pioglitazone compared with placebo included 55 patients with NASH for 6 mo[57]. Insulin sensitivity, serum ALT levels, steatosis and necroinflammation, except fibrosis, were significantly ameliorated in the pioglitazone group.

In the largest trial completed to date for evaluation of the role of pioglitazone, 247 subjects with biopsy proven NASH were randomized to vitamin E, pioglitazone or placebo for 96 wk[61]. Compared with placebo, both agents, pioglitazone and vitamin E, were associated with reductions in liver steatosis, lobular inflammation, hepatocellular ballooning and improvement in insulin resistance and serum aminotransferase levels. However, there was no improvement in fibrosis scores in the pioglitazone treated group. The "Fatty Liver Improvement with Rosiglitazone Therapy" (FLIRT) trial compared rosiglitazone with placebo in 63 patients[59]. Rosiglitazone improved serum aminotransferase levels, insulin sensitivity and hepatic steatosis. The two year extended trial (FLIRT2) demonstrated that improvement in liver enzyme levels continued but there was no further improvement in liver histology[62].

A meta-analysis including six trials demonstrated reduction in steatosis and hepatocyte ballooning but no improvement in inflammation or fibrosis compared with control[63]. In contrast to this study, Mahady *et al*[64] found improvement in inflammation and fibrosis in addition to reduction in steatosis and hepatocyte ballooning in a meta-analysis including seven randomized trials.

The largest meta-analysis that included 11 RCTs (862 participants, 38% diabetic) showed that TZDs improve steatosis, hepatocellular ballooning and necroinflammation, delay fibrosis progression and ameliorate hepatic, muscle and adipose tissue insulin resistance with more consistent cardiovascular benefits with pioglitazone[42].

Although the results of studies suggest some benefits from TZDs, a major problem also emerges: safety of long-term therapy and adverse effects. The use of rosiglitazone has been highly restricted in the United States and prohibited in Europe due to the increased risk of coronary events. On the other hand, pioglitazone is associated with adverse events such as bladder cancer, bone loss, weight gain, painful swollen legs and congestive heart failure. After evaluation of the overall results, it would be a good choice to use TZDs for the treatment of NAFLD only in patients with type 2 DM who are also candidates

for treatment with a TZD. The AASLD guideline recommended that pioglitazone can be used to treat only patients with biopsy-proven NASH; however, it also raised the concern about its long term safety and efficacy in patients with NASH[2]. The guideline also stressed that most of the clinical studies had been done in non-diabetic patients and thus the effect of TZDs on NASH of diabetic patients was not established. The position statement of a special EASL conference has recommended that pharmacological therapy of NASH could be a 1-2 year course of therapy with glitazone[44].

Dipeptidyl peptidase 4 inhibitors

Dipeptidyl peptidase 4 (DPP4) inhibitors are a new class of drugs and include sitagliptin, vildagliptin and saxagliptin. DPP4 is a membrane associated peptidase with a widespread organ distribution and deactivates a variety of bioactive peptides such as glucagon like peptide-1 (GLP-1). Inactivation of GLP-1 causes glucose intolerance, diabetes mellitus and hepatic steatosis. In a study including 31 NASH patients, Balaban *et al*[65] reported that serum DPP-4 levels were higher in patients with NASH compared to controls. Furthermore, the serum DPP-4 activity and staining intensity in liver were correlated with histopathological grade of NASH and hepatosteatosis.

In rat models, DPP-4 inhibitors improve hepatic steatosis by increasing insulin sensitivity and decreasing hepatic triglyceride levels[66,67]. To date, there is no published controlled trial with these agents in humans.

GLP-1, a hormone excreted by intestinal L cells, regulates blood glucose by stimulation of glucose-dependent insulin release. GLP-1 has a direct effect on hepatocytes by inducing genes responsible for fatty acid oxidation and insulin sensitivity[68]. GLP-1 analogs (exenatide, liraglutide) have been approved by the FDA for treatment of patients with type 2 diabetes mellitus. Ding *et al*[69] demonstrated that exenatide improves insulin sensitivity and reduces hepatosteatosis in rats with fatty liver. In another animal study liraglutide treatment reduced hepatic steatosis[70]. A case series including 8 patients with type 2 diabetes and biopsy-proven NAFLD showed that exenatide improves serum liver enzyme levels but has no effect on histopathology[71]. A recent meta-analysis including 4442 patients indicated that liraglutide decreased aminotransferase levels and that this effect was dose-dependent[72]. However, controlled studies are needed to show the efficacy of GLP-1 analogs in NAFLD and NASH treatment.

CONCLUSION

NAFLD is a complex, multifactorial and major public health problem with an increasing prevalence worldwide. Insulin resistance is very common in this disease and the goal of the therapy should include improving insulin sensitivity. Insulin sensitizing agents could be convenient drugs to reach this target. Metformin has been accepted to have no significant effect on liver histology and is not recommended as a specific treatment for liver disease in

adults with NAFLD. TZDs have been most extensively evaluated in published trials to date and they have modest effects on liver histology. The long term safety and efficacy of TZDs in patients with NAFLD is lacking. Selection of appropriate patients to avoid side effects and treatment of the underlying disease causing insulin resistance, such as obesity, are crucial main points. NAFLD patients with metabolic syndrome and obesity are likely to be the best candidates to be treated with TZDs. According to current data, unfortunately insulin sensitizers do not satisfy expectations for the treatment of NAFLD. Future RCTs with adequate size and duration are still needed to assess the clinical outcomes in patients with NAFLD.

Abstract

Liver injuries are repaired by fibrosis and regeneration. The cause of fibrosis and diminished regeneration, especially in liver cirrhosis, is still unknown. Epithelial-mesenchymal transition (EMT) has been found to be associated with liver fibrosis. The possibility that EMT could contribute to hepatic fibrogenesis reinforced the concept that activated hepatic stellate cells are not the only key players in the hepatic fibrogenic process and that other cell types, either hepatic or bone marrow-derived cells could contribute to this process. Following an initial enthusiasm for the discovery of this novel pathway in fibrogenesis, more recent research has started to cast serious doubts upon the real relevance of this phenomenon in human fibrogenetic disorders. The debate on the authenticity of EMT or on its contribution to the fibrogenic process has become very animated. The overall result is a general confusion on the meaning and on the definition of several key aspects. The aim of this article is to describe how EMT participates to hepatic fibrosis and discuss the evidence of supporting this possibility in order to reach reasonable and useful conclusions.

Core tip: The cause of fibrosis and diminished regeneration, especially in liver cirrhosis, is still unknown. Epithelial-mesenchymal transition (EMT) has been found to be associated with liver fibrosis. The possibility that EMT could contribute to hepatic fibrogenesis reinforced the concept that activated hepatic stellate cells are not the only key players in the hepatic fibrogenic process. The aim of this article is to describe how EMT participates to hepatic fibrosis and discuss the evidence of supporting this possibility in order to reach reasonable and useful conclusions.

INTRODUCTION

Chronic liver damage can be triggered by different mechanisms (*e.g.*, viral hepatitis, metabolic liver diseases, or chronic alcohol consumption)[1] and are accompanied by changes in several key biochemical pathways involved in hepatic tissue homeostasis. One of the most important alterations is hepatic fibrosis, which is characterized by deposition of extracellular matrix (ECM) components around the sinusoidal layer in the space of Disse, together with molecular reorganization of the matrix components resulting in an altered composition[2].

Fibrosis is comparable with a wound-healing response

Figure 1 Mechanisms of hepatic fibrogenesis. A: The proposed sources of hepatic myofibroblasts: Resident cells (hepatic stellate cells and portal fibroblasts); bone marrow-derived mesenchymal cells, and EMT from hepatocytes and cholangiocytes. Different insults initiate inflammation and then cause hepatocyte stellate cells activation and hepatocyte and biliary cell damage, necrosis and EMT. Continuous insults will shift those EMT-like cells to complete EMT cells and finally myofibroblasts, the main producer of extracellular matrix, which may be one of the main causes of an early loss of regenerative capacity. A similar process also occurs in biliary cells. Some cytokines play an important role to affect the adjacent cells and promote EMTs, such as TGF-β1 (B); B: Schematic presentation of the major intracellular signal transduction pathways of TGF-β1 in liver fibrosis. TGF-β1 is a chief inducer of the EMT process, and p-Smad2/3, p38 MAPK and ILK function as mediators of the intracellular signaling pathway. TGF-β1 signals via heteromeric transmembrane complexes of type I and type II receptors that are endowed with intrinsic serine/threonine kinase activity (ALK activin receptor-like kinase). Upon type-II-mediated phosphorylation of the type I receptor, the activated type I receptor initiates intracellular signalling by phosphorylating receptor regulated-Smad2 and Smad3. Activated Smads form heteromeric complexes with Smad4 and these complexes accumulate in the nucleus where they mediate transcriptional responses. p-Smad2/3: Phosphorylated-Smad2/3; MAPK: Mitogen-activated protein kinase; GSK-3β: Glycogen synthase kinase-3β; ILK: Integrin-linked kinase; TCF/LEF-1 complex: T cell factor/lymphoid enhancer-binding factor-1 complex; EMT: Epithelial-mesenchymal transition; TGF: Transforming growth factor.

being out of control. Repair mechanisms aim at the replacement of injured cells. However, contrary to the pure regeneration of tissue in fibroplasia, connective tissue substitutes normal parenchyma[3]. The ultimate result is organ failure. In the liver, the final common pathway is cirrhosis, characterized by accumulation of ECM. In human beings liver fibrosis is associated with dysregulated growth of hepatocytes and results in the formation of regenerative nodules, dysplastic nodules, and hepatocellular carcinomas[4]. At present, no therapeutic concepts have been developed to treat and reverse fibrosis[5].

Striking increases in our understanding of the pathogenesis of liver fibrosis include the identification of the main cellular effectors, key cytokines regulating the EMT process, and determinants of ECM turnover[3].

FIBROGENESIS OF HEPATIC STELLATE CELLS, MYOFIBROBLASTS AND HEPATOCYTES IN LIVER CIRRHOSIS

Recent work regarding liver fibrosis centers on the myofibroblast as a pivotal cell type due to its contractile nature and synthesis repertoire[6]. The sources of myofibroblasts

are still matters of discussion. Undisputedly, a "myofibroblast" phenotype is observed with hepatic stellate cell (HSC) after exposure to profibrogenic cytokines[3].

Liver myofibroblasts stand for a wide repertoire of functions that emphasize the dynamic nature of the wound-healing response, including synthesis of fibrillar collagens, contractile and migratory activities, secretion of chemotactic and vasoactive factors, and the secretion of matrix metalloproteinases (MMPs) and tissue inhibitor of metalloproteinases (TIMPs)[3]. The origin of myofibroblasts in the injured liver is now under scrutiny, although evidence hints at HSCs as a major source[3]. Myofibroblasts can be derived from local mesenchymal cells recruited from the bone marrow or could derive from other cellular sources by EMT, a physiologic process in embryogenesis and of relevance for cancerous cell transformation[7] (Figure 1A).

Studies with animals and human tissue indicate that bone marrow stem cells infiltrate the liver and contribute to the myofibroblast population after damage. This may occur directly or through an intermediary cell, such as quiescent HSCs or CD45+ fibrocytes[8,9]. Several studies have indicated that bone marrow-derived mesenchymal stem cells could be a source of multi-lineage cells for

various organs. They have the capacity to differentiate into hepatocytes, biliary epithelial cells, sinusoidal endothelial cells and even Kupffer cells in the presence of a suitable hepatic microenvironment[10,11]. There is growing evidence to suggest that bone marrow-derived stem cells are recruited during both progression and regression of liver fibrosis[8,12-16].

Most studies in the past decade have focused on HSCs and analyzed characteristic features like plasticity and transdifferentiation to myofibroblasts, a phenotype that can be readily recapitulated in tissue culture[3]. Current concepts envision activated HSCs as a crucial profibrogenic source, while the majority of hepatocytes are believed to undergo necrosis or apoptosis, thereby providing space for proliferating cells. Besides the resident hepatic cells, infiltrating neutrophils, macrophages, T and B cells, and eosinophils participate in the inflammatory response and may perpetuate the damage, whereby activated macrophages and neutrophils clean up tissue debris, dead cells, and invading organisms[17].

HSCs are located in the space of Disse of hepatic sinusoids between hepatocytes and sinusoidal endothelial cells[1] as liver-specific pericytes interposed by sparse connective tissue and closely adhering to sinusoidal endothelial cells[18]. They also directly face hepatocytes and maintain a quiescent phenotype with the main function to store vitamin A[19]. During liver injury, HSCs lose their vitamin A content[20] and undergo activation triggered by exposure to cytokines and growth factors, such as platelet-derived growth factor (PDGF) and transforming growth factor (TGF)-β1, which derive from activated Kupffer cells and damaged hepatocytes. During activation, HSCs transform into a myofibroblast-like phenotype[21-23] losing their typical star-shape[20], characterized by the expression of α-smooth muscle actin (SMA)[24], by the production of ECM and matrix degrading enzymes, such as MMPs[21-23] and TIMPs[25,26]. Activated HSCs are thought to migrate from the sinusoids into necrotic areas and produce a variety of ECM[19].

Some authors[27] have proposed that HSC could be transitional cells derived from epithelial cells that have undergone partial EMT[28] or even a particular type of oval cell/hepatocyte precursor[29]. This hypothesis was based, at least in part, on the finding of an adult subpopulation of primary rat HSC expressing the progenitor cell marker CD133 and differentiating into either myofibroblasts or hepatocytes when cultured under different *in vitro* conditions[30].

Another source of myofibroblast may be portal fibroblasts that are described in fibrotic diseases with a portal component (*e.g.*, viral hepatitis and autoimmune conditions)[31]. In coherence with experimental data on hepatocytes, TGF-β1 is required for myofibroblast transdifferentiation of this cell type[32]. The portal connective tissue in healthy liver is surrounded by quiescent portal fibroblasts, which constitute a second population of liver cells implicated in portal fibrosis[33]. Derived from small portal vessels, they express markers distinct from HSC (*e.g.*, elastin)[32]. Proliferation of biliary cells is often accompanied

by proliferation of portal fibroblasts, which form onion-like configurations around biliary structures and acquire a myofibroblast phenotype, and are thus implied in the early deposition of ECM in portal zones[34]. It is generally believed that substantial signaling from biliary epithelial cells leads to portal fibroblast activation, although the key factors remain to be identified[20]. In complex studies employing the "lineage tracing" methodological approach have documented, in different animal models of liver fibrogenesis, that some hepatocytes or cholangiocytes acquire "mesenchymal markers" implicated in cell motility and survival, but are not involved in active fibrillar ECM deposition and, therefore, cannot be considered profibrogenic cells[35].

Dooley *et al*[3] have provided *in vitro* and *in vivo* evidence that profibrogenic TGF-β1 functions during liver damage are directed toward hepatocytes. A TGF-β1-induced gene expression profiling of hepatocytes indicates a minor role of apoptosis and induction of fibrogenesis- and EMT-related genes. While the definite occurrence of EMT in this cell type *in vivo* needs further investigation (*e.g.*, by double-transgenic animals expressing fluorescent proteins under the control of hepatocyte- and myofibroblast-specific promoters), their results suggest that hepatocytes and TGF-β1 signaling in this cell type play a prominent role for fibrogenesis. In patients with chronic hepatitis B virus (HBV) infection, the activation of the TGF-β1 pathway was also shown by the accumulation of phosphorylated Smad2 in hepatocyte nuclei. Furthermore, the induction of Snail, a transcription factor known to repress E-cadherin expression, and the co-expression of type I collagen and transferrin in HBV livers, indicated that hepatocyte EMT was a feature of human liver fibrosis[36]. Therefore, the hepatocytes may be a contributor to hepatic fibrosis, especially when they are chronically injured[4].

TGF-β/SMAD AND NON-SMAD SIGNALLING PATHWAY IN LIVER FIBROSIS

TGF-β1 is recognized as a major profibrogenic cytokine and is a potent inducer of HSC proliferation and collagen production[37]. Furthermore, TGF-β1 expression is also associated with morphologic alterations like EMT in fetal[38] and adult hepatocytes[39], and changes in survival signaling pathways[40].

TGF-β1 binds to TGF-β1 receptor type Ⅱ (TbR-Ⅱ), and it recruits the TGF-β1 receptor type I (TbR-I)[41]. TbR-I subsequently phosphorylates Smad2 and Smad3, which form hetero-oligomers with Smad4. They translocate from the cytoplasm to the nucleus, where they regulate transcription of target genes[42] (Figure 1B). R-Smad signaling is limited by the inhibitory effects of inhibitory Smad6 and 7[3].

Dysregulated TGF-β1 signaling is implicated in multiple developmental disorders and various human diseases, including cancer and autoimmune illnesses[43]. Its

over-expression is linked to liver fibrosis in diverse animal models[44] and in human patients with chronic liver diseases[45]. TGF-β1 crucially regulates ECM deposition by controlling the expression of ECM network components such as fibrillar collagens and fibronectin, ECM-degrading protease inhibitors, such as plasminogen activator inhibitor (PAI)-1 and TIMPs. Its activity is strongly induced during chronic liver damage with links between TGF-β1 and connective tissue growth factor in the HSC activation process[46], which in turn acquire myofibroblastic features and produce ECM proteins.

Epithelial cell transdifferentiation comprises alterations in cellular morphology characterized by changes in cell polarity and loss of adhesion protein expression[3]. TGF-β1 can initiate and maintain this process in a variety of biological systems and pathophysiological contexts by activating major signaling pathways and transcriptional regulators integrated in extensive cellular networks[47]. In MDCKII cells, claudin-1, claudin-2, occludin and E-cadherin disappear within 72 h of exposure to TGF-β1. It is suggested that this expression loss occurs through a Smad-independent mechanism, involving mitogen-activated protein kinase kinase and phosphatidylinositol 3-kinase pathways with expression of Snail. On the other hand, a complete loss of E-cadherin and transition to the mesenchymal phenotype additionally requires Smad signaling, which results in formation of β-catenin/lymphoid enhancer factor-1 complexes that induce EMT[48]. Participation of TGF-β1 in the regulation of Notch signaling has been reported previously at the onset of EMT in epithelial cells from mammary gland, kidney tubules, and epidermis[49]. A set of the previously mentioned genes and others described to be involved in EMT, including Snail and Notch2, were identified as TGF-β1 target genes in hepatocytes. Some studies[39,50] have suggested on hepatocyte plasticity showing up-regulation of α1(I) collagen mRNA expression and type I collagen deposition in mouse hepatocytes and α (alpha) mouse liver 12 cells as a result of Smad2/3/4-dependent induction of Snail-1.

EMT IN HEPATIC FIBROGENESIS

EMT is a process that is normally evident in embryonic stages of development and recently has been investigated as a mechanism of cancer cell migration and metastasis[51,52]. A classification of EMT has been recently proposed to distinguish between these different types of EMT[53]. It is characterized by the loss of epithelial characteristics (E-cadherin) and the acquisition of a mesenchymal phenotype (vimentin and fibronectin)[54,55]. According to the functional consequences and biological context, EMT is divided into three subtypes[53,55,56]: Type I EMT occurs during embryogenesis, in which it produces motile cells but does not lead to ECM deposition or intravascular invasion. Type II EMT induces a morphogenetic change during organ fibrosis or wound healing, which is associated with ECM production and muscle-like characteristics. Type III EMT is involved in carcinoma-metastatic transition.

Evidence of EMT in fibrosis was first demonstrated in the kidney. *In vitro*, adult renal tubular epithelial cells were shown to undergo EMT[57,58]. Thereafter, induction of renal fibrosis in mice by unilateral ureteral obstruction (UUO) showed that epithelial marker expression (*i.e.*, E-cadherin) was lost in tubular epithelial cells, while the mesenchymal marker α-SMA expression was increased[59]. A cell tracing method later established that mice submitted to UUO display EMT-derived fibroblasts that contribute to the fibroblastic population[60].

Because the liver is an organ prone to fibrosis and because the origin of fibroblastic cells in fibrotic liver is still debated, the possibility that liver epithelial cells participate to fibrosis by EMT is appealing. Such hypothesis was strengthened by the observation that HSC lines express E-cadherin, while hepatic epithelial progenitor cells are positive for α-SMA[61]. Kaimori *et al*[39] then demonstrated that freshly isolated hepatocytes were able to convert to mesenchymal cells *in vitro*. Hepatocyte EMT, characterized by a decrease in E-cadherin expression and concomitant acquisition of mesenchymal markers (vimentin and type I collagen), was observed when cells were incubated with the profibrogenic cytokine, TGF-β1[39]. Zeisberg and co-workers were the first to report *in vivo* evidence for hepatocyte EMT[50]. They demonstrated that hepatocyte EMT was observed in CCl4 induced liver fibrosis by developing transgenic mice specifically expressing a molecular tag in hepatocytes (*i.e.*, β-galactosidase). In these mice challenged with CCl4, 45% of the cells expressing the mesenchymal marker fibroblast-specific protein-1 (FSP-1) were also positive for β-galactosidase expression. Furthermore, the inhibition of the TGF-β1 pathway limited the extent of liver fibrosis in the CCl4-injected mice[50]. *In vitro* TGF-β1 treatment induced higher vimentin expression in cirrhotic liver-derived hepatocytes than in normal liver-derived hepatocytes[4]. Taken together, these results suggest that hepatocyte EMT is triggered by TGF-β1 and contributes to liver fibrosis. Some studies have proposed that EMT leads to myofibroblast accumulation through a two-stage process. In the first stage, epithelial cells adopt a mesenchymal phenotype, whereas in the second stage these mesenchymal cells further transition to myofibroblasts as part of what has been termed an epithelial-to-myofibroblast transition (EMyT)[62-64].

Substantial experimental evidence supports the occurrence of EMT in embryonic development and tumor metastasis, processes in which the motility phenotype of the transitioned cells is essential[56,65,66]. For tissue fibrosis, however, there are conflicting data on whether or not EMT occurs[67]. Many studies of EMT in fibrosis have failed to define EMT rigorously or to differentiate between the transition to a mesenchymal (EMT) *vs* a myofibroblast (EMyT) phenotype. Type I collagen expression is the most direct measure of fibrogenesis, and the literature suggests that α-SMA-positive cells are the primary effectors of fibrogenesis[55,62,68,69]. Nevertheless, surrogate fibroblast markers have often been used to identify EMT, most notably FSP-1, despite some data suggesting that it is nonspecific[68,70,71].

Mendez *et al*[72] examined the expression of four different mesenchymal markers, including FSP-1, vimentin, α-SMA, and procollagen I . Their lack of colocalization with yellow fluorescent protein (YFP) in the setting of fibrosis supports the conclusion that in these models EMT does not contribute to fibrosis. The complete absence of its colocalization with YFP in their study suggests that liver epithelial cells do not transition to either mesenchymal cells or myofibroblasts in the mouse models examined.

The hypothesis of hepatocyte EMT contributing to liver fibrosis has been also challenged by a cell lineage strategy in mice[67]. A lineage tracing study in which β-galactosidase was expressed under the control of the hepatocyte marker albumin in transgenic mice expressing a collagen marker provided strong evidence against hepatocyte EMT in the CCl4 model of fibrosis[73]. Triple transgenic mice with permanent cell labeling were produced to track hepatocyte-derived cells and type I collagen-expressing cells. Hepatocytes isolated from these triple transgenic mice were able to undergo EMT in culture when incubated with TGF-β1. However, in mice challenged by CCl4, no cells exhibited a double labeling specific for both hepatocytes and collagen expressing cells[73]. These observations also suggest that hepatocytes may not undergo EMT *in vivo*, while the observed transition *in vitro* might be an experimental artifact.

EMT IN CHOLANGIOCYTES

The assumption that liver epithelial cells undergo EMT in liver fibrosis cannot however be ruled out for biliary epithelial cells. Indeed, biliary epithelial cell EMT could represent a cellular mechanism supporting histological observations[70]. For instance, primary biliary cirrhosis (PBC), a prototypical biliary-type liver disease, is characterized by both the loss of biliary epithelial cells and the concomitant development of periportal fibrosis.

The bile duct basement membranes undergo degradation in fibrogenic liver diseases and that cholangiocytes, the other major hepatic epithelial cell type, assume fibroblast-like, non-cuboidal shapes. Therefore, it became obvious that the next step was to investigate whether or not biliary cells could undergo EMT in chronic liver disease[27]. It is well established that proliferating cholangiocytes within the so-called "ductular reaction" (*i.e.*, "reactive cholangiocytes"), detectable in all types of chronic liver disease, express a variety of pro-fibrogenic growth factors and cytokines and are likely to contribute to fibrosis and inflammation by promoting activation, proliferation, and collagen synthesis in the surrounding pro-fibrogenic cells[74-80]. Nevertheless, the possibility of a direct contribution of cholangiocytes to fibrosis *via* EMT was suggested by Omenetti and his colleagues[81] showing *in vitro* a complete EMT in an immature cholangiocyte cell line treated with activated HSC conditioned medium.

Biliary epithelial cell EMT was confirmed by another study analyzing liver of patients with PBC, primary sclerosing cholangitis or alcoholic liver disease. Irrespective of the underlying etiology, biliary epithelial cells from ducts associated with the ductular reaction were positive for FSP-1 and vimentin[82]. In biliary atresia, a disease defined by a destructive inflammatory obliterative cholangiopathy with portal tract fibrosis and ductular proliferation[83], biliary epithelial cells were shown to express FSP-1 and vimentin, while hepatocytes were not. Moreover, the authors of this study show that the expression of mesenchymal markers in biliary epithelial cells is observed in all liver disease with a ductular proliferation component[84]. The common bile duct ligation (BDL) is an experimental liver fibrosis model that induces strong ductular reaction. In mice submitted to BDL, biliary epithelial cells undergo EMT as shown by α-SMA and type I collagen expression[85].

Evidence of cholangiocyte EMT was recently challenged with the lineage-tracing methodology previously used for the investigation of hepatocyte EMT[27]. Along these lines, Scholten and the colleagues[86] employed the Cre-Lox technology for lineage tracing and studied several mouse strains expressing Cre under cholangiocyte-, HSC-, or FSP-1-specific promoters in two established models of liver fibrosis, *i.e.*, chronic CCl4 intoxication and common BDL. In this case the fundamental experiment was tracing the fate of cells expressing K19, a bile ductular cell-specific marker, after permanent genetic Cre-mediated labeling of cholangiocytes. The key result of this study was that, although myofibroblast markers were often found in the close proximity of the K19+ progeny of cholangiocytes, the two signals never overlapped in either CCl4 or BDL fibrosis. Based on these and other observations reported in the paper, the authors concluded that cholangiocyte EMT does not occur in their experimental models.

It may be that in human livers EMT occurs in cirrhosis, a state not well modeled in rodents, and may require a florid ductular reaction, which is also poorly mimicked by rodent models. Alternatively, this discrepancy may reflect the limitations of immunohistochemistry-based lineage-tracing methodology[67]. Future work should focus on better understanding the direct contribution of dysfunctional epithelial cells to liver fibrosis, as well as determining the mechanistic relationships between fibrogenesis and the progenitor cell activation characteristic of the ductular reaction. This will ultimately require the development of animal models of biliary fibrosis that better reflect human disease[67].

SPECIFIC CELLULAR MARKERS IN EMT

The most widely used marker identifying myofibroblasts is the cytoskeletal protein α-SMA that is a part of the contractile machinery and is involved in cell motility[27]. In adult normal tissue, α-SMA expression is mostly restricted to vascular smooth muscle cells, but in most chronic inflammatory and fibrogenic disease states, it is often found in myofibroblasts of different derivation, and this expression is interpreted as an active involvement of these cells in fibrogenesis (*i.e.*, "activated myofibroblast").

Table 1 Useful biomarkers for identifying epithelial-mesenchymal transition

Biomarkers	Myofibroblast	Hepatic stellate cell	Hepatocyte	Cholangiocyte
α-SMA[1]	+	+	-	-
Vimentin[1]	+	+	-	-
Desmin[1]	+	+	-	-
ICAM-1	+	+	-	-
Collagen type IV	+	+	-	-
Fibronectin	+	+	-	-

Albumin	-	-	+	-
Slug[1]	+	?	-	-
Twist[1]	+	?	-	-
Snail[1]	+	?	-	-

[1]Previously proven markers associated with epithelial-mesenchymal transition. α-SMA: α-smooth muscle actin; ICAM-1: Intercellular adhesion molecule-1; IL-6: Interleukin-6; NCAM: Neural cell adhesion molecule; FSP-1: Fibroblast-specific protein-1.

Accordingly, α-SMA cannot be a good lineage marker since its expression is activated by disease states and, in addition, does not denote function. Regardless of this, there is supportive evidence that epithelial cells express intermediate filaments such as α-SMA and vimentin following tissue injury[4,87].

A multitude of studies have shown that epithelial cells, including hepatocytes, when cultured *in vitro* retain epithelial features including polarity and specific protein expression (*i.e.*, albumin for hepatocytes), but when chronically stimulated with TGF-β1 or serum factors acquire a pattern of gene expression that is somehow typical of myofibroblasts *in vivo* and in the mesenchyme during development[39,88-91]. These genes are often represented by Slug, Twist, Snail, α-SMA, vimentin, desmin, FSP-1, and discoidin domain receptor tyrosine kinase 2. Some of these markers have been used to identify epithelial cells that are in the midst of undergoing an EMT associated with chronic inflammation. These cells continue to exhibit epithelial-specific morphology and molecular markers, such as cytokeratin and E-cadherin, but often show the concomitant expression of the FSP-1 and α-SMA. These aspects have been proposed to represent the intermediate stages of EMT, when epithelial markers continue to be expressed but new mesenchymal markers have already been acquired, and, overall, these observations have led to the notion of the so-called "partial EMT"[53].

Previous work has demonstrated in a model of fetal hepatocytes that TGF-β1 treatment induces EMT-like morphologic changes in 50%-60% of the hepatocyte population, whereas the remaining hepatocytes undergo apoptosis[38,40]. This means that EMT can be elicited by several oncogenic pathways (Src, Ras, integrin, Wnt/β-catenin and Notch)[27,92]. In particular, Ras-MAPK has been shown to activate two related transcription factors known as Snail and Slug[93]. Both of these proteins are transcriptional repressors of E-cadherin and their expression induces EMT.

Chronic liver damage leads to fibrotic degeneration of parenchyma, characterized by the formation of fibrotic septa. Except for HSCs, portal myofibroblasts can produce collagen in the liver[94]. Although both cell types show similar expression patterns of intercellular adhesion molecule-1, desmin, vimentin, collagen type IV, fibronectin, and α-SMA, several differences between them have also been observed[94]. For instance, cultured portal myofibroblasts are positive for fibulin-2 and interleukin-6 mRNA, whereas CD95L, α2-macroglobulin, P100, and reelin are exclusively expressed by activated HSCs[94-100]. In addition, neural cell adhesion molecule, synaptophysin, neurotrophin, neural growth factor, αB-crystallin, and tyrosine kinases are markers that distinguish HSCs from portal myofibroblasts[99,101]. Experiments using these markers have shown that myofibroblastic cells in fibrotic septa strongly resemble portal myofibroblasts, that they may originate and migrate from the portal tract, and that they are different from sinusoidal HSCs[19].

Uyama *et al*[19] found that fascin is present in intralobular sinusoidal areas, but not in the periportal areas or fibrotic septa of the human liver. In addition, the localization of fascin in the sinusoidal area is similar to that of vimentin. They concluded that fascin was localized in human HSCs, but not in (myo)fibroblasts of the periportal area or fibrotic septa.

Evidence favoring biliary EMT comes largely from immunohistochemical studies of fibrotic human and rodent livers that identified cholangiocytes coexpressing epithelial markers (especially the cholangiocyte marker K19) and mesenchymal markers (*i.e.*, FSP-1, vimentin, and HSP47)[64]. Table 1 shows the summary of useful biomarkers for identifying EMT.

CONCLUSION

The pathogenesis of liver fibrosis is now better understood than ever before. It is increasingly recognized that the fibrogenic cells in the liver are heterogenous in both their formation and their behaviour.

EMT is an established process in embryo development and plays an important role in liver fibrosis. Discussions now arise on the involvement of EMT in organ

fibrosis. The possibility that EMT could contribute to hepatic fibrogenesis in chronic liver diseases reinforced the concept that activated HSCs are not the only key players in the hepatic fibrogenic process and that other cell types, either hepatic or extrahepatic (bone marrow-derived cells and circulating fibrocytes) could contribute to this process. The presence of cells expressing both epithelial and mesenchymal markers suggests that EMT is a feature of liver fibrosis, however the ability of these cells to produce ECM *in vivo* has not yet been documented.

Therefore, the knowledge relative to the interpretation of what is defined as EMT in chronic fibrogenic disorders of the liver represents a scientific treasure that has prompted discussion, animated debates and has ultimately provided further maturity in this field of research. Definitely, there is now need for a more insightful analysis of the real pathophysiological meaning of these observations beyond their morphologic and biological features. Nevertheless, the future holds great promise for EMT as a viable therapeutic target.

EMT research in the next few years promises to be exciting, as new mouse models and molecular probes are identified to address the identities of the EMT-inducing microenvironmental signals, the nature of the cellular response of such signals and signaling machinery within epithelial cells.

Future research will surely be required on uncovering the origin of all fibrogenic cells within the liver and the molecular similarities and differences among the EMT programs.

Abstract

One of the most common complications of childhood obesity is the non-alcoholic fatty liver disease (NAFLD), which is the most common form of liver disease in children. NAFLD is defined by hepatic fat infiltration > 5% hepatocytes, as assessed by liver biopsy, in the absence of excessive alcohol intake, viral, autoimmune and drug-induced liver disease. It encompasses a wide spectrum of liver diseases ranging from simple steatosis to non-alcoholic steatohepatitis, which, in turn, can evolve into cirrhosis and end stage liver disease. Obesity and insulin resistance are the main risk factors for pediatric NAFLD. In fact, NAFLD is strongly associated with the clinical features of insulin resistance especially the metabolic syndrome, prediabetes and type 2 diabetes mellitus (T2D). In particular, it has been clearly shown in obese youth that the prevalence of metabolic syndrome, pre-diabetes and type 2 diabetes increases with NAFLD severity progression. Evidence that not all of the obese patients develop NAFLD suggests that the disease progression is likely to depend on complex interplay between environmental factors and genetic predisposition. Recently, a non-synonymous SNP (rs738409), characterized by a C to G substitution encoding an isoleucine to methionine substitution at the amino acid position 148 in the patatin like phospholipase containing domain 3 gene (*PNPLA3*), has been associated with hepatic steatosis in a multi-ethnic cohort of adults as well as in children. Another important polymorphisms that acts with *PNPLA3* to convey susceptibility to fatty liver in obese youths is the rs1260326 polymorphism in the glucokinase regulatory protein. The pharmacological approach in NAFLD children poorly adherent to or being unresponsive/partially responsive to lifestyle changes, is aimed at acting upon specific targets involved in the pathogenesis. There are some therapeutic approaches that are being studied in children. This article reviews the current knowledge regarding the pediatric fatty liver disease, the new insights and the future directions.

Core tip: The prevalence of hepatic steatosis is increased in the last three decades concomitantly with the increased prevalence of pediatric obesity. Non-alcoholic fatty liver disease (NAFLD) is the most common form of liver disease in children. The *PNPLA3* rs738409 and the glucokinase regulatory protein rs1260326 are the strongest variants associated with fatty liver in paediatrics. Important risk factors are obesity, insulin resistence, gender, ethnicity and excessive dietetic intake of n-6 polyunsatured fatty acids and fructose. New pharmacological approaches are object of study, in NAFLD children poorly adherent to or being unrespon-

sive/partially responsive to lifestyle changes.

INTRODUCTION

In the last three decades with the increased prevalence of childhood obesity, there has been an increase also of the obesity complications in paediatrics. One of the most common complications of childhood obesity is the non-alcoholic fatty liver disease (NAFLD), which is the most common form of liver disease in children[1].

NAFLD is defined by hepatic fat infiltration > 5% hepatocytes, as assessed by liver biopsy, in the absence of excessive alcohol intake, viral, autoimmune and drug-induced liver disease[2,3]. It encompasses a wide spectrum of liver diseases ranging from simple steatosis to non-alcoholic steatohepatitis (NASH), which, in turn, can evolve into cirrhosis and end stage liver disease[3,4].

The prevalence of NAFLD has more than doubled over the past 20 years. According to a landmark study by Schwimmer *et al*[1] based on autoptic data obtained in 1138 children and adolescents of the San Diego county (CA), its prevalence in the general pediatric population is estimated to be nearly 13%, while among obese and overweight children and, particularly, adolescents it rises up to 46%[1]. Nevertheless, other studies report quite a wide range of steatosis prevalence, likely due to the different diagnostic methods used. In fact, although liver histology is important for NAFLD evaluation, performing biopsies is not always indispensable from a clinical point of view; therefore, surrogate markers are often used in epidemiological and clinical studies. One of the marker most commonly used is liver aminotransferase [aspartate aminotransferase, and alanine aminotransferase (ALT)] evaluation. Children with NAFLD typically have elevated liver enzymes values[5], which is why elevated serum levels of liver enzymes, even though may misrepresent the entity of intrahepatic damage, are used as a non-invasive test to screen for pediatric NAFLD[6].

RISK FACTORS FOR THE DEVELOPMENT OF PEDIATRIC NAFLD

Obesity and insulin resistance are the main risk factors for pediatric NAFLD[1,7,8]. In fact, NAFLD is strongly associated with the clinical features of insulin resistance especially the metabolic syndrome (MS), prediabetes and type 2 diabetes mellitus (T2D)[9-11]. In particular, it has been clearly shown in obese youth that the prevalence of metabolic syndrome, pre-diabetes and type 2 diabetes increases with progression of NAFLD severity[12].

This picture is strongly contributed by pubertal insulin resistance, a physiologic state characterized by an increased insulin resistance during the adolescence and resolving at the end of the pubertal development and probably consequent to the increase in growth hormone action during this stage of life[8,13]. In fact, although obesity is the most important cause of NAFLD among obese and adolescents, it is important to note that a transient insulin resistant state occurs during puberty[14], and that this state worsens the insulin resistance present in obese children in turn accelerating the progression to MS and type 2 diabetes. In healthy individuals this phenomenon is balanced by an increased insulin secretion by the beta cell, but in obese individuals the co-occurrence of obesity and puberty represents the perfect storm causing such a high degree of insulin resistance that the beta cell is not always able to produce enough insulin to maintain the glycemic control[15-17].

Two other critical risk factors for NAFLD development are represented by the gender and the ethnic background. In fact, NAFLD is more common in boys than in girls[15] with a male to female ratio of 2:1. This has been explained by the liver-protective role of estrogens, as well as by the potentially negative role of androgens in aggravating NASH[18,19]. The beneficial effects of estrogens on liver could be mediated by the beneficial effect on insulin action. Studies showed that insulin sensitivity is greater in premenopausal women compared with age-matched men, and metabolic-related cardiovascular diseases and type 2 diabetes are less frequent in premenopausal women[20,21]. Also, estrogens deficiency leads to increased fat mass and body weight in postmenopausal women, which has been associated with increased intraabdominal fat[22]. Moreover, Camporez *et al*[23] showed that, in mice, endogenous estrogens are important to protect against high-fat diet induced skeletal muscle insulin resistance, whereas E2 treatment in estrogen-deprived mice increased insulin sensitivity in both liver and skeletal muscle. Also, the estrogens effect is important in turn preventing diet-induced ectopic lipid deposition and hepatic and muscle insulin resistance.

The risk linked to the ethnic background has been investigated in large multiethnic populations. A cornerstone article by Browning *et al*[15] described for the first time that the prevalence of NAFLD is the highest in the American Hispanic population (45%) and the lowest among African Americans (24%), with the Caucasians showing an intermediate prevalence (33%). Ethnic differences could possibly be due to different degree of insulin resistance, and of visceral adiposity at equivalent body mass index, but may also be a result of genetics as well as socio-economic factors, including type of diet, exercise choice and living location[24].

The accumulation of fat, as triacylglycerol (TAG), in the hepatocyte is the fingerprint of fatty liver. The TAG accumulated in the liver mostly derive from adipose tissue lipolysis (60%) and hepatic de novo lipogenesis (26%) whereas only a small amount directly derives from the diet as chylomicron remnants (14%)[25]. A large body of

Figure 1 **Risk factors for non-alcoholic fatty liver disease development.** In this figure, all risk factors for non-alcoholic fatty liver disease (NAFLD) are summarized. We divided the risk factors in modifiable and not modifiable. Among not modifiable risk factors we listed *PNPLA3* rs738409, but as underlined in the text, the weight loss can modify the capacity of *PNPLA3* polymorphism to lead to hepatic steatosis. *PNPLA3*: Patatin like phospholipase 3 gene; *GCKR*: Glucokinase regulatory protein; *FDFT1*: Farnesyl-diphosphate farnesyltransferase 1; *NCAN*: Neurocan; *PPP1R3B*: Protein phosphatase 1 regulatory subunit 3B; *LYPLAL1*: Lysophospholipase-like 1; *GC*: Group-specific component; *LCP1*: Lymphocyte cytosolic protein-1; *LPPR4*: Lipid phosphate phosphatise-related protein type 4; *SLC38A8*: Solute carrier family 38 member 8; *APOC3*: Apolipoprotein C3 gene; *SAMM50*: Sorting and assembly machinery component; *PARVB*: Parvin beta.

evidence suggests that not only the amount, but also the quality of dietary fat plays a role in NAFLD development[26]. In particular, recently published literature provides clues that the dietary imbalance between omega-6 (n-6) and omega-3 (n-3) polyunsatured fatty acids (PUFAs) leads to development of an adverse cardiovascular and metabolic profile, thus contributing to the pathogenesis of NAFLD[27]. N-6 and n-3 are essential fatty acids; this means that they are not synthesized by human body. N-6 species are mainly represented by linoleic acid while n-3 are represented by alpha-linolenic acid, mainly found in plants and limited sets of seeds and nuts[28]. N-6 is readily converted by the body into other species such as omega-9 and so incorporated into triglycerides, or converted into arachidonic acid, which is the parent molecule of the main regulators of the inflammatory response including prostaglandins (ciclooxigenase pathway), leukotrienes (lipoxygenase pathway) and tromboxane[28]. It has been demonstrated that individuals with NAFLD have a lower dietary intake of n-3 PUFAs than healthy controls[29] and an increased n-6/n-3 PUFA ratio consumed in the diet[29,30]. Consistent with these data, lipidomic studies have shown that the intrahepatic fat in subjects with steatohepatitis is composed by an excess n-6 PUFA[31]. In particular, studying the three groups of subjects-NAFLD, NASH and healthy controls- it has been observed a progressive increase in the n-6/n-3 ratio from controls to NASH subjects[31].

Another dietary risk factor contributing to the development of NAFLD is the fructose. Nowadays, the majority of fructose consumption comes from the added sugars in the beverages more than from the fruit[32]. Strong evidence exists that high in fructose intake results in increased de novo lipogenesis (DNL), dyslipidemia, insulin resistance, and obesity in humans[33]. Stanhope *et al*[33], studying the effect of consumption of glucose- or fructose-sweetened beverages providing 25% of energy requirements for 10

wk in overweight and obese subjects, provided the evidence that the consumption of fructose, instead of glucose, specifically increases DNL, promotes dyslipidemia, decreases insulin sensitivity, and increases visceral adiposity in overweight/obese adults.

Progression from NAFLD to NASH

A recent study demonstrated that NAFLD in children is a progressive disease[34]. In that study the authors showed that 6% of subjects with early onset NAFLD develop cirrhosis and end-stage liver disease with the consequent need of liver transplantation.

The oxidative stress seems to explain the progression to NASH and liver fibrosis. Reactive oxygen species (ROS) can induce hepatocellular injury by the inhibition of the mitochondrial respiratory chain enzymes, the inactivation of glyceraldehyde-3-phosphate dehydrogenase and the inactivation of membrane sodium channels. ROS further cause lipid peroxidation, cytokine production, and induce Fas ligand, contributing to hepatocellular injury and fibrosis[12]. The risk of progression varies by ethnicity, in fact, as recently demonstrated, the African American obese children and adolescents show a lower degree of liver damage than Caucasians and Hispanics, independent of the degree of hepatic fat accumulation and insulin resistance. These data suggest that African Americans are protected from hepatic damage even in presence of high degree of hepatic fat accumulation and insulin resistance[35].

GENETIC PREDISPOSITION

Evidence that not all of the obese patients develop NAFLD suggests that disease progression is likely to depend on complex interplay between environmental factors and genetic predisposition (Figure 1).

Recently, a non-synonymous SNP (rs738409), char-

Table 1 Current and future non-alcoholic fatty liver disease treatment strategies

Present	Under development	
Weight loss	Vitamin E	Pentoxifylline
Physical activity	Metformin	Farnesoid X receptor agonists
Reduced dietary	Probiotics	Toll-like receptors modifiers
sucrose intake	Oral treatment	Glucagon-like peptid-1 receptor
Reduced dietary	with omega 3	agonists resistant to DPP-4
fructose intake		mediated degradation
Reduced dietary		DPP-4 inhibitors
omega 6 intake		
Increased dietary		
omega 3 intake		

DPP-4: Dipeptidyl peptidase-4.

acterized by a C to G substitution encoding an isoleucine to methionine substitution at the amino acid position 148 in the patatin like phospholipase 3 gene (*PNPLA3*), has been associated with hepatic steatosis in a multiethnic cohort of adults[36] as well as in children[37,38]. *PNPLA3* encodes for a triglyceride hydrolase expressed in the liver and adipose tissue[39]. Metabolic studies in transgenic mice revealed that high level expression of PNPLA3[I148M] in the liver, but not in adipose tissue, affected both hepatic triacylglycerol (TAG) synthesis and catabolism. A surprising finding was that the PNPLA3[I148M] transgenic mice have significantly increased fatty acid synthesis and an altered spectrum of TAG-fatty acids in the liver, with no evidence of insulin resistance[40]. It is interesting that PNPLA3[I148M] transgenic mice develop steatosis on a sucrose diet but not on a high-fat diet. Ingestion of sucrose stimulates de novo synthesis of fatty acids[41], whereas most of the hepatic fatty acids in livers of fat-fed mice are derived from circulating non esterified fatty acids (NEFAs). Perhaps PNPLA3 in hepatocytes is exposed preferentially to newly synthesized TAG and is shielded from fatty acids that enter the liver in lipoproteins or are synthesized from circulating NEFAs[40]. Alternatively, PNPLA3 may function specifically under conditions of insulin-stimulated lipid anabolism. The finding that PNPLA3 is virtually absent from livers of fasting animals and is strongly upregulated both transcriptionally[42-45] and post-translationally[39] by carbohydrate refeeding is consistent with the latter hypothesis.

Moreover, purified recombinant PNPLA3 has been found to have 5 enzymatic activities: triacylglycerol, diacylglycerol, and monoacylglycerol hydrolysis[42,46] as well as acyl-CoA thioesterase[42] and lysophosphatidic acid acyltransferase activity[47]. These different activities are not equally affected by the I148M substitution. In vitro assays, the I148M substitution results in a substantial loss of triacylglycerol, monoacylglycerols, and diacylglycerols hydrolytic activity[33]; a modest reduction in acyl-CoA thioesterase activity[33]; and an increase in lysophosphatidic acid acyltransferase activity[47]. None of these activities alone can explain all of the changes in TAG metabolism observed in the *PNPLA3* I148M transgenic mice. Therefore, some of the metabolic changes observed in these animals are likely to be secondary rather than direct consequences of altered *PNPLA3* activity.

The effect of this polymorphism on liver damage seems to be driven by the size of abdominal fat, expressed as waist to height ratio (W/Hr)[38]. More recently it has been demonstrated that weight loss reduce the effect of this polymorphism in obese children[48].

Other findings suggest also that the influence of *PNPLA3* on hepatic fat in obese children and adolescents might be modulated by dietary factors such as n-6/n-3 polynsatured fatty acids (PUFA) intake[49]. Finally, the rs738409 *PNPLA3* polymorphysm is considered, regardless of metabolic profile, a risk factor for liver disease. In fact, in a recent study, in a hepatitis C-infected population, the *PNPLA3* polymorphism influenced the development of liver steatosis[50]. Moreover, it was also demonstrated as a novel genetic marker associated with progressive ALD (alcoholic liver disease)[51].

Another polymorphism that acts along with the *PNPLA3* gene variant to convey susceptibility to fatty liver in obese youths is the rs1260326 polymorphism in the glucokinase regulatory protein (*GCKR*). This polymorphism is associated with hepatic fat accumulation along with large VLDL and triglyceride levels[52].

Speliotes *et al*[53], in addition to *GCKR,* identified variants in novel loci *NCAN* and *LYPLAL1* associated with both increasing computer tomography (CT) hepatic steatosis and histological NAFLD and identified variants in another locus, protein phosphatase 1 regulatory subunit 3B (*PPP1R3B*), associated with CT steatosis but not histologic NAFLD[53]. Recently Kitamoto *et al*[54] found that *PNPLA3, SAMM50* sorting and assembly machinery component (*SAMM50*), parvin beta (*PARVB*) genetic regions was significantly associated with NAFLD in the Japanese population. Adams *et al*[55] showed that SNPs in two genes expressed in liver were associated with NAFLD in adolescents: group-specific component (*GC*) and lymphocyte cytosolic protein-1 (*LCP1*). SNPs in two genes expressed in neurons were also associated with NAFLD: lipid phosphate phosphatise-related protein type 4 (*LPPR4*) and solute carrier family 38 member 8 (*SLC38A8*)[55].

TREATMENTS

Diet and lifestyle changes

The goal of lifestyle interventions is a gradual and controlled weight loss achieved by diet and physical exercise (Table 1). This aim is difficult to achieve and only a small percentage of individuals is able to steadily lose weight and exercise regularly[56]. Weight loss in NAFLD patients improves hepatic insulin sensitivity by reducing hepatic NEFAs supply, improves extra-hepatic insulin sensitivity through better glucose utilization and reduces ROS generation and adipose tissue inflammation[56].

Currently, there are no evidence-based guidelines establishing the optimal intervention. The only effective interventions are physical activity and dietary changes. In fact, reduction in sugar/sucrose and in soft drinks

rich in fructose, most probably not only acts through a reduction in IR and lipogenesis, but also counteracts the recently evidenced hepatic pro-inflammatory/fibrogenetic role of fructose[57]. It should be taken in mind that diet in childhood must be balanced to allow a healthy and harmonic growth, including wellness of bone structures. To intervene on dietary changes does not only mean to reduce the caloric intake, but also the single components of the diet (Table 1). In fact, also diet composition plays an important role in the development of NAFLD, as an increased dietary intake of monounsaturated and poly-unsaturated fatty acids (mainly omega 3 PUFA) has been associated with a reduction of hepatic fat content, representing a reasonable intervention especially in the pediatric population[58].

Pharmacological interventions for NAFLD

The pharmacological approach, in NAFLD children poorly adherent to or being unresponsive/partially responsive to lifestyle changes, is aimed at acting upon specific targets involved in etiopathogenesis (Table 1).

Antioxidants, by reducing oxidative stress, protect susceptible components of biological membranes from lipid peroxidation, and may, therefore, prevent the progression of simple steatosis to NASH. The most studied antioxidant in children with NAFLD is alpha tocopherol (vitamin E) and warrants consideration in obesity-related liver dysfunction for children unable to adhere to low-calorie diets[59]. Sanyal *et al*[60] showed that vitamin E therapy, as compared with placebo, was associated with a significantly higher rate of improvement in NASH (43% *vs* 19%, *P* = 0.001) in adults without diabetes. There was no benefit of pioglitazone over placebo for improvement of NASH but serum alanine and aspartate aminotransferase levels were reduced as well as with vitamin E.

For its pathogenic role, insulin resistance appears as an adequate therapeutic target. Metformin is the only insulin-sensitizing agent evaluated in children.

Lavine *et al*[61] in a more recent large, multicenter, randomised double-bind placebo-controlled trial (TONIC study), evaluated the effect of daily dosing of 800 IU of vitamin E (58 patients), 1000 mg of metformin (57 patients) or placebo (58 patients) for 96 wk of NAFLD course. The patients (aged 8-17 years) with biopsy-confirmed NAFLD and persistently elevated levels of ALT, without diabetes or cirrhosis, were randomly assigned to 1 of 3 groups. At 96 wk neither vitamin E nor metformin was superior to placebo in attaining the primary outcome of sustained reduction in ALT level in pediatric NAFLD; vitamin E and metformin groups, however, showed an improvement in histological hepatocellular ballooning in NAFLD and NASH.

Another, single-arm, open-label, small pilot study on metfotmin (500 mg twice daily for 24 wk), conducted in 10 non-diabetic children with biopsy proven NASH and elevated ALT levels showed reduction of hepatic steatosis, as evaluated with Magnetic Resonance Spectroscopy (MRS) and low serum ALT levels[62].

FUTURE DIRECTIONS

A growing body of evidence[63] shows that the gut microbiota controls obesity and visceral fat storage. Specific variations in gut microbiota in early life may determine a major risk factor of obesity and its complications later in life[64]. Small intestinal bacterial overgrowth (SIBO) (a frequent condition in obese individuals, mainly prompted by slowing of the oro-coecal transit time) may promote NAFLD progression to non-alcoholic steatohepatitis by enhancing intestinal permeability and by favouring absorption of endotoxins with pro-inflammatory and pro-fibrogenetic effects on the liver[65].

Probiotics are live microorganisms which when consumed in adequate amounts, confer an healthy benefit to the host[66]. Gut microbiota manipulation with probiotics in rodents with fatty liver reduces intestinal inflammation and improves the epithelial barrier function[67,68]. Therefore, probiotics could represent a new effective treatment also in NAFLD human patients (Table 1). Loguercio and colleagues have shown that probiotics may reduce NAFLD liver injury and may improve liver function tests[69].

Moreover, recent pharmacological studies in NAFLD animal models and in adult humans focusing on the effect of oral treatment with n-3 fatty acids, demonstrate that they have both anti-inflammatory and insulin sensitizing properties, suggesting a potential role in treatment of NAFLD[70]. In NAFLD children n-3-docosahexaenoic acid (DHA) treatment for 6 months improved ultrasonographic fatty liver and insulin sensitivity[71]. Because this treatment is well tolerated in pediatric population, DHA deserve further studies in the management of children with NAFLD.

A series of other interesting approaches, hitherto explored only in NAFLD animal models or in few pilot studies in adults will possibly become in future the object of study in pediatric population (Table 1), as well: (1) tumor necrosis factor-α (TNF-α) and other adipocytokines produced by adipose tissue are involved in NAFLD progression. Pentoxifylline, a phosphodiesterase inhibitor, exerts immunomodulatory functions by antagonizing the TNF-α pathway. In adults with NASH, pentoxifylline treatment showed good tolerability and could decrease serum ALT levels and improve histological features[72]; (2) the nuclear bile acid receptor, Farnesoid X receptor (FXR), strongly expressed in bowel and liver, is probably involved in NAFLD pathogenesis, by mediating control of lipids and glucose homeostasis, and controlling bacterial flora growth. Altogether, these effects may induce reduction of hepatic inflammation and fibrogenesis, through different mechanisms. Therefore, recently developed FXR agonists have a potential role in the pharmacological therapy of NAFLD/NASH[73]; (3) toll-like receptors (TLRs) are receptors sensing microbial components of gut microbiota. A number of recent evidences suggests the role of SIBO and increased intestinal permeability in NAFLD, by exposing *via* portal vein the liver to an high load of intestinal noxae including lipo-

polysaccharide and other pathogen-associated molecular patterns[74]. Furthermore, TLRs stimulation causes downstream activation of the inflammatory response. Proinflammatory patterns result in production of cytokines and chemokines implicated in progression from simple steatosis to steatohepatitis and fibro-cirrhosis; so therapeutic manipulation of innate immune system through TLRs modifiers, formerly evaluated for autoimmune diseases[75], might be a new potential therapeutic target for pediatric NAFLD, but further studies are necessary; and (4) glucagon-like peptid-1 (GLP-1) is an incretin secreted in response to food intake, allotted to multiple functions, including, the stimulation of glucose-dependent insulin secretion and inhibition of glucagon release. The enzyme dipeptidyl peptidase-4 (DPP-4) rapidly degrades circulating GLP-1 (half-life: 1-2 min). Recent animal model and NAFLD adults studies showed an effective role of GLP-1 receptor agonists resistant to DPP-4 (such as exenatide and liraglutide) or DPP-4 inhibitors (*e.g.*, some gliptins) as a promising new therapy in NAFLD for their ability in modulating fatty acid oxidation, decreasing lipogenesis, and improving hepatic glucose metabolism[76].

CONCLUSION

Non-alcoholic fatty liver disease, because of the rise in the prevalence of childhood obesity, is becoming one of the most important chronic liver disease among children. Evidence that only a sub-group of obese patients develop NAFLD suggests that disease progression is likely to depend on complex interplay between environmental factors and genetic predisposition (Figure 1). Recent researches led us to understand the genetic basis predisposing to NAFLD. Many genes have been identified and many other will be identified and, actually, the most important it appears to be *PNPLA3* gene. Probably, all the genetic polymorphisms implicated in NAFLD development could have a summarizing effect. In fact, if more predisposing NAFLD polymorphisms coexist in the same subject, the risk to develop NAFLD and to develop it more severely could increase. Other important findings are related to the diet. For example, strong evidence exists that high in fructose intake, usually present in beverages, results in increased de novo lipogenesis and then in increased risk of NAFLD. Moreover, also high n-6/n-3 PUFA ratio consumed in the diet could predispose the NAFLD development. All these findings must drive the clinical practice: the diet is the first and important approach for the NAFLD prevention and treatment. In fact, there is the striking evidence that the weight loss can reduce the effect of I148M polymorphisms on determining hepatic steatosis. In addition to weight loss, to reduce the fructose intake trough the beverages and increasing the n-3 fatty acids dietary intake could be also useful in contrasting the NAFLD.

In conclusion, waiting the new approaches, the dear and old diet is always a fundamental and irreplaceable NAFLD therapy.

A thorough review of the updated published reports was carried out and a merge of the various management options, with a special point of view of the author, is stated.

Abstract

Hepatitis B virus (HBV) infection is a global public health problem, with an estimated 350 million people worldwide chronically infected and approximately 500000 who die annually from HBV-related liver diseases. Management of chronic HBV is challenging and waves of guidelines emerge every year. One of the hottest topics and a matter of debate is the management of patients in their early immunotolerant phase of infection. With the lack of evidence, dealing with this particular subset of patients creates a great conflict with opposing views. In this review, the author highlights the pros and cons of these views and proposes a reasonable solution to resolve this dilemma.

Key words: Liver biopsy; Hepatitis B Virus; Immunotolerant phase; Polymerase chain reaction; Nucleotide analogue

Core tip: In this mini review, the author discusses the management dilemma of this peculiar subset of patients suffering from chronic hepatitis B in the immunotolerant phase. As already known, the immunotolerant phase of hepatitis B virus may last for a long period and hence there may be a potential for subtle liver damage.

INTRODUCTION

Hepatitis B virus (HBV) infection is a global public health problem, with an estimated 350 million people chronically infected worldwide. Fifteen to forty percent of these individuals will develop serious sequelae during their lifetime, with greater evolution to cirrhosis or hepatocellular carcinoma (HCC). The estimated 5-year rate of progression from chronic hepatitis B (CHB) to cirrhosis was estimated to be 12%-20% and the 5-year cumulative risk of developing HCC was also estimated to be between 10%-17% in patients with cirrhosis. These figures vary from country to country according to the disease endemicity and prevalence[1-3]. The natural history of CHB is complex and described to run through different immunological phases that may overlap. In its early phases, HBV infection is characterized by minimal liver damage on liver biopsy, a high level of HBV replication and positivity for HBe-antigen (HBeAg). These patients are asymptomatic and have normal levels of serum alanine aminotransferase (ALT). This phase is described as the "immunotolerant phase"[3,4].

Managing these patients creates a great conflict with two opposing views. One view is optimistic, conservative and relies upon the long-term course of benignity of the disease. They adopt the view of "leave the patient alone on close follow up". On the other hand, the other view is

pessimistic and relies upon the great risk of cancer development, even without cirrhosis. This latter view adopts the view of "to treat the patient and why wait". Between these two views, there are no real evidence based guidelines.

In this review, an extensive online research for English reviews and articles that tackle this subject by using the key words "immunotolerant", "HBV" and "management" was carried out. The author highlights the pros and cons of all views regarding the management strategies of this subject and makes a reasonable proposed solution for this dilemma.

IMMUNOTOLERANT PHASE: CHARACTERISTICS AND IMMUNOLOGICAL INSIGHT

The natural history of HBV infection is perplexing and its net result is an interplay between the viral replication and the host immune response. After primary infection, an immunotolerant phase characterized by a very high rate of viral replication but without liver injury takes place. The mechanism of this tolerance is not yet fully understood[5]. These patients are infected early in life through vertical or early horizontal infection. Such infection most often occurs in areas with high rates of endemic infection, low rates of maternal screening, and lack of widely available neonatal prophylaxis with HBV vaccine and hepatitis B immunoglobulin[6,7].

It is believed that before birth, HBeAg acts as a "tolerogen viral protein" in the fetus, and thus virus specific T-cells undergo deletion. This phase lasts from weeks to years, depending on the age at acquisition. After years/decades, this tolerance is somehow ruptured and the immune attack against infected hepatocytes to clear them begins, causing liver damage. During this "immune clearance phase", ALT levels increase and HBV DNA levels begin to decrease. Immune attacks of infected hepatocytes result in HBeAg seroconversion and this seroconversion is usually associated with sustained remission of liver disease. Selection pressures for the virus come from either competition between viral variants, which are different in their replicative efficiency, and the host immune activity[8-10].

It was found that the majority of young children who presented in the immunotolerant phase have either minimal chronic hepatitis or, more commonly, non-specific reactive hepatitis, in spite of persistently normal ALT activity[11-13].

Wang *et al*[14] studied seven patients (age range between 7-25 years) by follow up for at least 17 years with serial sampling for ALT activity and viral load. They concluded that the interplay between viral replication and host immunity explains the pattern of HBV dynamics within the host during the early stages of infection. That is, without immune selection, competition between peers increases the viral load and decreases the nucleotide diversity; in contrast, host immunity accelerates viral evolu-

tion and decreases copy numbers but increases diversity. The fully infected liver can yield between 10^9 to 10^{10} viruses per milliliter of serum, a level of production that would be expected to persist if infection were benign and the host were truly immunotolerant. Virus titers in adolescent and young adult carriers in the immunotolerant phase of infection tend to be lower, ranging from 10^7 to 10^9 copies per milliliter[15,16]. Some studies explain the declining of virus titers during the time in the immunotolerant phase by a low but persistent immune destruction of infected cells by the cytotoxic T-cell, leading to an adaptive immune response over time[14].

IMMUNOTOLERANT PHASE: MANAGEMENT OPTIONS AND DEBATES

Of particular concern is the fact that until now there is no drug therapy that is actually effective in achieving a sustained response against HBV in the immunotolerant phase[17].

The currently approved treatment options for chronic HBV infection are interferon and nucleoside analogues (NA). Interferon acts primarily as an immunomodulatory agent, while NAs have essentially antiviral effects. According to current consensus and guideline statements, treatment candidates are patients with active liver disease characterized by persistently elevated ALT levels and detectable HBV DNA (10^5 copy/mL) by most commercial assays, irrespective of their HBeAg/Ab status. These statements also concluded that HBeAg-negative inactive carriers do not need any treatment because of the absence of viral replication and liver injury. Also, patients in the immunotolerant phase should be followed up without treatment[18,19].

However, and in the light of the Risk Evaluation of Viremia Elevation and Associated Liver Disease study, a baseline high HBV DNA level was associated with a significant risk of hepatocellular carcinoma[20]. These results led to the debate on whether a HBV infected person with normal liver enzymes, unremarkable liver histology, but with a detectable level of HBV DNA (high or low regardless the cutoff), should be treated with antiviral drugs or not[20,21].

As a rule, most of the current guidelines recommend that patients with moderate/severe inflammation or bridging fibrosis/cirrhosis must be treated. Also, they recommend liver biopsy for the grey zone of patients who do not meet the typical criteria, have a detectable level of HBV DNA and/or fluctuating or persistently elevated ALT. The presence of significant inflammation or bridging fibrosis/cirrhosis is an indication for treatment[22,23].

Hence, and in the light of the previous statements, we can assume that there are two options regarding the management of the immunotolerant phase; the "why wait" view and the "close follow up" view.

The "why wait" view adopts the option to treat all patients with a persistently high level of viral replication regardless of the phase of infection and relying only on the presence of detectable DNA levels. They rely on the

high risk of cancer/cirrhosis development, considering the infection as not totally benign[24]. Therefore, earlier treatment intervention may be beneficial in preventing disease progression. A recently published study aimed to break this tolerance in children by treating a group of HBV-infected children in the immunotolerant phase with lamivudine and interferon and comparing them to an untreated group. They reported a cure rate in more than one-fifth of the studied cohort, a figure that is still primitive and not high[25].

On the opposing side, another strong option exists and adopts the view of "wait and observe". This view relies on some evidence. The first is the evidence of the benign long term course of the immunotolerant phase[26]. The second is the pooled results of poor response to antiviral therapy in this unique phase, which hardly reaches 19%[27]. The third is the proved emerging resistance on long term therapy[28]. The last is a heavy cost burden of treatment.

Wong *et al*[29] studied the risk of liver fibrosis progression in HBeAg-positive patients at different phases by recruiting two hundred and forty-seven HBeAg-positive patients without advanced fibrosis at baseline. They found that liver fibrosis progression is uncommon in HBeAg-positive patients and hence their results enforce the follow-up strategy.

As is known, the degree of fibrosis or inflammation on liver biopsy cannot be predicted by the level of HBV-DNA and ALT is also considered an imperfect surrogate marker for liver disease[30]. Therefore, without evidence of normal liver histology, the definition of immunotolerant disease depends mainly on the persistence of a normal ALT level as a major determinant. Nevertheless and unfortunately, the definition of a "normal" ALT level has been redefined several times and was subjected to a strong debate. The study of Prati *et al*[31] modified the normal upper limit for ALT to be 30 IU/mL for men and 19 IU/mL for women. Re-introducing these relatively low figures will endorse many more patients under the umbrella of raised ALT levels.

The most appropriate way to make this miss clear cut is to perform a liver biopsy. However, there are still some unanswered questions; *e.g.*, what is the optimal timing of liver biopsy during the natural history of this phase, how many times and at what intervals should it be done, which drug is the best to start with, *etc.*

The use of therapeutic vaccines may also help to break the tolerance. In spite of its preliminary application, the published results of the study of Buchmann *et al*[32] carry a great hope for a wide future applicability. They evaluated the potential use of a novel vaccine formulation, comprising particulate hepatitis B surface and core antigen and the saponin-based adjuvant, for its ability to stimulate T and B cell responses in C57BL/6 mice. Their results were promising and future intense research in this subject is deemed to be mandatory.

CONCLUSION

The immunotolerant phase of chronic HBV is a chal-

lenging problem, with an increasing awareness of its occurrence, especially in endemic areas. More intense studies are required for a better delineation of the pathogenesis and whether it is better is to break the tolerance or to wait for the natural clearance. Until then, the most suitable solution is to perform liver biopsy to stand on solid ground in choosing the best option, to wait or to interfere.

Abstract

AIM: To elucidate the effects of melatonin on cisplatin-induced hepatocellular carcinoma (HepG2) cell death and to identify potential cross-talk pathways.

METHODS: Hepatocellular carcinoma HepG2 cells were treated with melatonin and/or cisplatin for 24 to 48 h. Cell viability and the 50% cytotoxic concentration (CC_{50}) were calculated by MTT assays. The effects and intracellular events induced by the selected concentrations of melatonin (1 mmol/L) and cisplatin (20 µmol/L) were investigated. Cell death and survival detection were primarily evaluated using a fluorescence microscope to assess 4',6 diamideno-2-phenylindol DNA staining and acridine orange lysosome staining and then further analyzed with immunocytochemistry using an anti-LC3 antibody. The potential molecular responses mediated by melatonin against cisplatin after the combined treatment were investigated by reverse transcription-polymerase chains reaction and Western blot analyses of the genes and proteins associated with cell survival and death. A cell cycle analysis was performed using a flow cytometry assay.

RESULTS: Melatonin had a concentration-dependent effect on HepG2 cell viability. At 1 mmol/L, melatonin significantly increased the cell viability percentage and decreased reactive oxygen species production due to cisplatin. Melatonin reduced cisplatin-induced cell death, decreasing phosphorylated p53 apoptotic protein, cleaved caspase 3 and Bax levels but increasing anti-apoptotic *Bcl-2* gene and protein expression. When combined with cisplatin, melatonin induced S phase (DNA synthesis) cell cycle arrest and promoted autophagic events in HepG2 cells. Melatonin also had a concentration-dependent effect on Beclin-1 and its autophagic regulator mammalian target of rapamycin (mTOR) as well as the DNA excision repair cross complementary 1 (ERCC1) protein. The expression levels of these proteins were altered in HepG2 cells during cisplatin or melatonin treatment alone. In the combination treatment, melatonin reversed the effects of cisplatin by suppressing the over-expression of mTOR and ERCC 1 and enhancing the expression levels of Beclin-1 and microtubule-associated protein-light chain3-Ⅱ, leading to intracellular autophagosome progression.

CONCLUSION: Melatonin attenuated cisplatin-induced cell death in HepG2 cells *via* a counter-balance between the roles of apoptotic- and autophagy-related proteins.

Core tip: Melatonin has anti-oxidative stress and anti-

proliferative effects on cisplatin-treated hepatocellular carcinoma cells through a counter-balance between the roles of apoptosis and autophagy proteins. Melatonin also reduced cisplatin-induced DNA damage by decreasing the activation of excision repair cross complementary 1 in the DNA repair system. Thus, co-treatment with melatonin to ameliorate cisplatin adverse effects might be beneficial for Hepatocellular carcinoma therapy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the leading causes of human death worldwide. Aberrant gene expression and mutations induced by any genotoxic agents that can cause DNA damage contribute to its development. Effective treatment for HCC is not yet available because all anticancer strategies have limitations associated with the tumor grade and stage of the disease. For example, chemotherapy is limited by the side effects of cytotoxic drugs that also kill normal cells and by the long-term side effects of these drugs, which are carcinogenic and can cause secondary cancers[1]. Moreover, the mechanisms controlling the responses of pro-oncogenes and tumor suppressor genes in the effected cells are not well defined. In cancer research, the human hepatocellular carcinoma (HepG2) cell line has been used as a model system for studies of hepatocarcinogenesis because it is a permanent cell line derived from a well-differentiated hepatocellular carcinoma patient. The HepG2 cell line has also been used as an in vitro model for studying liver metabolism and in drug targeting assays[2].

To date, several anticancer drugs have been used clinically. Cisplatin, a platinum-based drug that has a known molecular mechanism of action, is a drug of choice that has been widely chosen for the treatment of solid cancers[3,4]. Cisplatin platinum can form complexes with DNA, inducing DNA adducts and damage[5]. Once produced, the complex mediates a series of intracellular responses that lead to apoptosis and also activates the DNA repair system, which is capable of inducing recovery of the damaged DNA and participates in the restoration of normal cell systems. However, if the damage is too extensive, the repair mechanism fails, and the cell undergoing apoptosis dies[6]. Through this pathway, cisplatin has no selective effects on cancers or normal cells. When receiving chemotherapy with cisplatin, some individuals respond by showing excessive side effects, and some cancers develop resistance to cisplatin by mechanisms that are only partially known. To improve chemothera-

peutic efficiency, investigators have emphasized the need to search for new drugs. An example would be to study the potency of cisplatin at low concentrations, which can protect against hepatotoxicity, and to study drug resistance mechanisms to identify a new drug to replace cisplatin.

Melatonin is a hormone that is produced in the pineal gland and has several normal physiological functions in the human body. Its known properties include circadian rhythm regulation[7], sleep induction[8], immunemodulation[9], neuroprotection[10], bone differentiation[11], and anti-microbial[12] and anti-oxidative effects[13]. Previous investigations have demonstrated that melatonin also possesses anti-proliferative effects, especially in cell lines derived from various malignancies such as lymphoma[14], prostate cancer[15], melanoma[16] and hepatocellular carcinoma[17]. Although most of the biological effects of melatonin are produced through the activation of melatonin receptors, some are due to its status as a powerful antioxidant that plays roles in the protection of nuclear and mitochondrial DNA[18]. The anti-proliferative effect of the human osteosarcoma cell line MG-63 was shown to be activated by melatonin if the concentration of melatonin reached an optimal value, which was a high concentration of 4-10 mol/L[19]. Further data have suggested that melatonin could be used as an adjuvant to increase responses to anticancer drugs and to ameliorate their side effects[20-22]. However, the effectiveness of melatonin as an adjuvant of chemotherapy most likely differs among cancer types, and the mechanisms of the action of melatonin are still unclear. Due to the selective effects of melatonin, the current oncology research aiming to enhance the apoptosis effect of cisplatin combined with melatonin has extended to alternative pathways in treated cells.

It is well accepted that cells under oxidative stress or exposed to DNA damage, hypoxia, nutrient deprivation, and intracellular pathogens can survive through an autophagy pathway[23]. This pathway involves the lysosomal degradation of cytoplasmic organelles or cytosolic components, allowing cells to eliminate damaged or harmful components and also to recycle the released amino acids and energy to maintain cellular homeostasis[24]. In mammalian cells, the pathway is regulated through a serine/threonine protein kinase called mammalian target of rapamycin (mTOR)[25]. Normally, mTOR is activated under nutrient-rich conditions and inhibits autophagy[26]. However, under stress conditions, mTOR plays a role in autophagy activation *via* an effector Beclin-1 that initiates core nucleation for autophagy formation[27]. Under the normal condition, Beclin-1 is inhibited by an interaction with the Bcl-2/Bcl-xL complex, but when p53 binds to Bcl-2, it frees Beclin-1, leading to autophagy[28]. In addition to losing collaborative proto-oncogenes and tumor-suppressor genes during DNA damage, the cells expressed several efficient DNA repair systems, such as the nucleotide excision repair (NER) pathway, to prevent cancer formation[29]. NER can eradicate a broad spectrum

of DNA damage lesions through the action of a specific endonuclease enzyme named excision repair cross complementary 1 (ERCC1), which functions at the incision step of the NER pathway. ERCC1 cleaves damaged DNA at upstream sites, leading to DNA re-synthesis and ligation to return the damaged DNA to its native state and configuration[30]. Therefore, increased or decreased levels of ERCC1 expression should indicate efficiency of the DNA repair system.

In this study, we hypothesized that autophagy is an important pathway that plays roles in the outcome of cell death or survival in HepG2 cell during cisplatin and melatonin chemotherapy. We explored the expression of genes and proteins that regulate autophagy processes and lead to cell death and also identified the possible mechanism or cross-talk pathways mediated by melatonin and cisplatin.

MATERIALS AND METHODS

Cell culture

A HepG2 cell line was purchased from the American Type Culture Collection (Rockville, MD, United States). The cells were cultured at 37 ℃ in a humidified 5% CO_2 incubator and maintained in DMEM supplemented with 10% (v/v) fetal bovine serum, 1% (v/v) non-essential amino acids, 1% (v/v) sodium pyruvate, and 100 Units/mL penicillin-streptomycin were purchased from Thermo Fisher Scientific (Waltham, MA, United States).

Cell viability assay

HepG2 cells were seeded onto 96-well plates (2×10^4 cells/well) for 24 h and then treated with 0.5-5.0 mmol/L melatonin (Merck, Frankfurter , Germany), 2.5-80.0 µmol/L cisplatin (Sigma Aldrich, St. Louis, MO, United States), or the combination of both for 24 and 48 h. In the combination treatment, the selected concentration was based on the minimal concentration that induced the anti-proliferative effect of melatonin and the most tolerable concentration that induced the cytotoxic effect of cisplatin. Cell viability was measured using an MTT colorimetric assay; MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) was purchased from Sigma Aldrich (St. Louis, MO, United States), a working solution was added to each well and incubated at 37 ℃ for 2 h. The optical density of each well was measured using a microplate reader at 570 nm and the reference wavelength of 690 nm. Cell viability was calculated as the percentage of viable cells in the drug-treated group versus the untreated control group. The concentration of the compound that decreased cell viability by 50% cytotoxic concentrations (CC50) was calculated. Each experiment was performed in triplicate, and each result was presented as the mean ± SE.

Measurement of intracellular reactive oxygen species production

HepG2 cells were seeded onto 96-well black, flat, clear-bottom plates (2×10^4 cells/well). After treatment, the intracellular levels of ROS were measured by staining the treated and untreated cells with 50 µmol/L 2',7'-dichlorodihydrofluorescein diacetate (DCFH-DA) that was purchased from Sigma Aldrich (St. Louis, MO, United States) after incubation in the dark at 37 ℃ for 30 min. The fluorescence intensity was quantified by the relative percentage of untreated cells using a fluorescence microplate reader and used 500 µmol/L H_2O_2-treated cells as the positive control. Each experiment was performed in triplicate, and each result was presented as the mean ± SE.

4',6 diamideno-2-phenylindol DNA stain and acridine orange lysosome stain

HepG2 cells were seeded onto 24-well plates (2×10^4 cells/well) for 24 h and then treated with 1 mmol/L melatonin, 20 µmol/L cisplatin, or both for 24 and 48 h.

DNA stain: Treated cells were fixed with cold methanol, air dried, and stained with 4'-6-diamidino-2-phenylindole, (DAPI) (Boehringer, Ingelheim, Germany) at 37 ℃ for 30 min. The primary signs of apoptosis induction, namely, chromatin condensation, fragmented DNA, and/or apoptotic body formation, were evaluated under an inverted fluorescent microscope.

Acridine orange stain: Treated cells were stained with 5 µg/mL acridine orange (Sigma Aldrich, St. Louis, MO, United States) in serum-free medium at 37 ℃ for 15 min. The cells were examined under an inverted fluorescence microscope. Positive acidic vacuoles or stained lysosomes were observed as orange or red foci in the cytoplasm, and DNA bound-acridine orange was detected as a green signal.

Immunocytochemistry

To determine an autophagic event, treated cells grown on coverslips were fixed in 4% paraformaldehyde for 5 min, permeabilized with methanol, and blocked with 3% bovine serum albumin in phosphate buffer saline (PBS) for 1 h at room temperature. The cells were then incubated with an indicator of autophagy, an anti-LC3 antibody was purchased from Cell Signaling Technology (Danvers, MA, United States) and was diluted 1:400 in PBS, overnight at 4 ℃. After incubation, the cells were washed with PBS and incubated with an Alexa Fluor 555-conjugated secondary antibody (Cell Signaling Technology, Danvers, MA, United States) for 2 h at room temperature, washed with PBS, and counter-stained with DAPI. The immunofluorescently labeled cells were visualized under a confocal laser-scanning microscope (Olympus, Tokyo, Japan).

Semi-quantitative analysis (RT-PCR) of genes controlling apoptosis and autophagy

HepG2 cells were seeded onto 6-well plates (4×10^5 cells/well). After treatment with 1 mM melatonin, 20 µmol/L cisplatin, or both for 24 h, total RNA was extracted with TRI Reagent (Molecular Research Center Inc; Cincinnati, OH, United States). cDNAs were synthesized by RevertAid™ M-MuLV Reverse Transcriptase and amplified by polymerase chain reaction (PCR) with

specific primer pairs, as indicated in Table 1, using a High Fidelity PCR kit (Thermo Fisher Scientific, Waltham, MA, United States). The PCR cycles were adjusted accordingly to primer annealing. The PCR products were analyzed by 1.5% agarose gel electrophoresis and gel staining with ethidium bromide for 30 min. The gels were photographed using gel documentation (UVP Bioimaging System, United States). The experiments were performed in triplicate, and the relative band densities of cDNA from the treated cells were compared to the untreated cells.

Western blot analysis of proteins associated with apoptosis and autophagy

The treated cells were lysed in RIPA buffer (25 mmol/L Tris-HCl pH 7.6, 150 mmol/L NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% sodium dodecyl sulfate (SDS), and protease inhibitor cocktail were purchased from Merck (Frankfurter, Germany) on ice for 30 min. The samples were then centrifuged at 24000 *g* at 4 ℃ for 15 min. The cell lysates were collected, and the total protein concentrations were determined by a BCA assay (Merck, Frankfurter, Germany). Equal amounts of protein (30 μg) from each sample were separated by 8%-15% SDS-polyacrylamide gel electrophoresis at 100 V and transferred onto nitrocellulose membranes (GE Healthcare, Buckinghamshire, United Kingdom). The membranes were blocked with 3% w/v bovine serum albumin (Sigma Aldrich, St. Louis, MO, United States) in Tris-buffered saline containing 0.1% Tween-20 for 2 h at room temperature. Then, the membranes were incubated with a 1:1000 dilution of primary antibodies against Bax (Santa Cruz, CA, United States), p53, phospho-p53, Bcl-2, pro-caspase3, cleaved-caspase3, p-mTOR, ERCC1, Beclin-1 or LC3 (Cell Signaling Technology, Danvers, MA, United States) overnight at 4 ℃, followed by two extensive washings with TBST. The membranes were incubated with a 1:2000 dilution of horseradish peroxidase-conjugated secondary antibody for 2 h. The specific bands corresponding to the investigated proteins were visualized using enhanced chemiluminescence (ECL reagents, GE

Healthcare, Buckinghamshire, United Kingdom). The signal intensities were determined by densitometry using Image-J software (National Institutes of Health, Bethesda, MD, United States). After stripping off the first probe, each membrane was re-probed with a β-actin antibody (Santa Cruz, CA, United States) to confirm the equal loading of protein in each experiment. The levels of protein expression were presented in relation to β-actin.

Flow cytometry analysis of DNA synthesis and cell cycle activity

HepG2 cells were seeded onto 6-well plates (4×10^5 cells/well). After treatment with 1 mmol/L melatonin, 20 μmol/L cisplatin, or a combination of both for 24 h, the cells were trypsinized, centrifuged, washed twice with cold PBS, and fixed overnight with 70% ethanol at -20 ℃. The cells were resuspended in staining buffer containing 50 μg/mL propidium iodide (Merck, Frankfurter, Germany), 3.8 mmol/L sodium citrate, and 50 μg/mL RNase A (Sigma Aldrich, St. Louis, MO, United States) and incubated in the dark at 37 ℃ for 30 min. The stained cell suspensions were processed for flow cytometry analysis to determine the amount of DNA at different phases of the cell cycle using a FACScanto apparatus (BD Pharmingen, San Diego, CA, United States) with the loaded software. A total of 30000 cells from each sample were collected for evaluation of each data file.

Statistical analysis

All experiments were performed in triplicate ($n = 3$). Data are presented as the mean ± SE for each group, and these were compared for significant differences using a one-way analysis of variance test, followed by a post-hoc analysis (Tukey's multiple comparison test) using Prism 5 (GraphPad Software Inc; San Diego, CA, United States).

RESULTS

Effect of melatonin and cisplatin on HepG2 cell viability

As shown in Figure 1, melatonin (concentration 0.5-5 mmol/L) and cisplatin (concentration 2.5-80 μmol/L) reduced the viability of HepG2 cells in a time-concentration dependent manner. The 50% CC_{50} of melatonin were 6.25 mmol/L and 3.74 mmol/L and of cisplatin were 38.53 μmol/L and 17.53 μmol/L, at 24 h and 48 h, respectively. The concentrations of melatonin and cisplatin used in the combination treatment were selected from the minimal anti-proliferative effect of melatonin, which significantly decreased percent cell viability, and the most tolerable cytotoxic effect of cisplatin, which induced cell death at a rate below 50%. Therefore, 1 mmol/L melatonin was used in combination with 20 and 30 μmol/L cisplatin for 48 h. Melatonin increased the viability of HepG2 cells compared with cisplatin treatment alone. The combined treatment significantly reduced cell viability compared with the control and significantly increased cell viability compared with the cisplatin treatment alone

Figure 1 Effect of melatonin and cisplatin on cell viability analyzed using an MTT assay. Hepatocellular carcinoma (HepG2) cells were treated with various concentrations of melatonin and cisplatin for 24 h and 48 h. Both melatonin and cisplatin reduced the percent viability of HepG2 cells in a time and concentration-dependent manner ($P < 0.001$). The experiments were performed in triplicate, and the results are presented as the means ± SE.

Figure 2 Effect of the combined treatment of melatonin and cisplatin on cell viability. Hepatocellular carcinoma cells were treated with melatonin (1 mmol/L) and/or cisplatin (20 and 30 μmol/L) for 48 h and then analyzed by an MTT assay. Melatonin reduced the cisplatin cytotoxic effect at 20 μmol/L cisplatin. The results are presented as the mean ± SE. ([c]$P < 0.001$ compared with the control group, [d]$P < 0.05$, [f]$P < 0.001$ compared with cisplatin-treated group).

(Figure 2).

Potential mechanisms and pathways of the melatonin-mediated attenuation of cisplatin-induced cell death

Anti-ROS production: To determine whether melatonin reduced the ROS production due to cisplatin, the biochemical basis of intracellular ROS was explored using a fluorescein-labeled dye, DCFH-DA. The results showed significantly increased intracellular ROS in cisplatin-treated cells. However, the combined treatment with melatonin (1 mmol/L) reduced the intracellular ROS level (Figure 3).

Reduction of cellular damage and apoptosis formation: The combined effect of melatonin and cisplatin

Figure 3 Melatonin reduced cisplatin-induced intracellular reactive oxygen species levels. Hepatocellular carcinoma cells were treated with melatonin (1 mmol/L) and/or cisplatin (20 μmol/L) for 24 h. The results are presented as the means ± SE. ([c]$P < 0.001$ compared with the control group, [d]$P < 0.05$ compared with the cisplatin-treated group).

was evaluated in unstained in HepG2 cells under an inverted light microscope (Figure 4A) and in HepG2 cells stained with DAPI under a fluorescence microscope (Figure 4B). Melatonin treatment resulted in no morphological changes and the absence of apoptotic nuclei. Cisplatin treatment induced intense morphological changes, with cell shrinkage and typical apoptotic nuclear features, such as nuclear condensation and apoptotic bodies. The combined melatonin and cisplatin treatment revealed unchanged cell morphology and a reduction of apoptotic bodies.

Regulation of apoptosis *vs* anti-apoptosis genes and protein expression: To determine apoptotic events in cells, the expression of the genes and proteins involved in apoptosis were analyzed. As shown in Figure 5, Western blotting results indicated that melatonin (1 mmol/L) had no significant effect on proteins associated with apoptosis (p53, p-p53, pro-caspase3 and cleaved-caspase3), whereas cisplatin significantly increased p53 and p-p53 levels.

Figure 4 Histological changes. Hepatocellular carcinoma cells were treated with melatonin (1 mmol/L) and/or cisplatin (20 μmol/L) for 48 h. The cells were stained with DAPI for fragmented DNA (apoptotic bodies) and observed under an inverted microscope. A: Morphological changes showing vacuoles in the cytoplasm of cisplatin-treated cells (scale bar = 50 μm); B: DAPI staining showing nuclear condensation and apoptotic bodies (white arrows) in cisplatin-treated cells. The combined treatment showed less apoptotic effects (scale bar = 100 μm).

Gene and protein expression analyses of pro-apoptosis Bax and anti-apoptosis Bcl-2 levels revealed slight decreases in the Bax/Bcl-2 ratio with melatonin treatment while resulting in a significantly increased Bax/Bcl-2 ratio with cisplatin treatment. In the combined treatment, melatonin significantly ameliorated the pro-apoptotic effects of cisplatin.

Cell cycle regulation: To determine the effects of the treatments on HepG2 cell cycle control, DNA accumulation was measured by flow cytometry at different phases of the cell cycle. The phases of cell cycle arrest were determined at G_0/G_1 by melatonin and at $subG_0$, G_0/G_1, and S by cisplatin. In the combined treatment, melatonin reduced cisplatin cell cycle arrest at the $subG_0$ through G_0/G_1 phases but significantly increased cell cycle arrest at the S phase (Figure 6).

Autophagy regulation: The combined effect of melatonin and cisplatin in HepG2-treated cells was evaluated for lysosomal staining with acridine orange dye and observation under an inverted microscope to measure fluorescence. Both melatonin and cisplatin caused slight increases in the acidic lysosomal compartments; an increase in acridine orange intensity was highly apparent in the combined treatment (Figure 7A). In the immunofluorescence assay with the anti-LC3 antibody, melatonin and cisplatin treatment alone induced minor autophagy events in HepG2 cells compared with the control. However, the combination of melatonin and cisplatin treatment significantly enhanced autophagy, as indicated by the fluorescence intensity of LC3 scattered throughout the cytoplasm (Figure 7B).

Alteration of autophagy regulators and the DNA repair system: To explore the potential pathways of melatonin and cisplatin effects on autophagy regulation and DNA repair process in HepG2-treated cells, the relationship between the proteins Beclin-1, mTOR and ERCC1 were analyzed. Melatonin (0.5 and 1 mmol/L) increased Beclin-1, p-mTOR, and ERCC1 in a concentration-dependent manner (Figure 8). Conversely, cisplatin (10 and 20 μmol/L) decreased Beclin-1, p-mTOR, and ERCC1 in a concentration-dependent manner. At the selected concentrations (1 mmol/L melatonin and 20 μmol/L cisplatin), melatonin significantly increased p-mTOR and ERCC1 from the basal levels, whereas cisplatin decreased Beclin-1 and increased p-mTOR and ERCC1 from the basal levels.

Evaluation of the autophagy process in melatonin- and cisplatin-treated HepG2 cells showed changes in Beclin-1 (an initiator of autophagy) and LC3-Ⅱ (a mature marker of autophagy). Melatonin (1 mmol/L) treatment alone slightly increased both Beclin-1 and LC3-Ⅱ, but cisplatin (20 μmol/L) treatment alone decreased Beclin-1 and slightly increased LC3-Ⅱ (Figure 9). The combined treatment showed that melatonin prevented cisplatin from affecting the level of Beclin-1 but significantly increased the effect of cisplatin on the LC3-Ⅱ level.

The analysis of mTOR and ERCC1 mRNA and protein expression in the treated HepG2 cells revealed that melatonin (1 mmol/L) or cisplatin (20 μmol/L) treatment alone significantly increased p-mTOR and ERCC1 from the basal levels. However, the combined treatment resulted in the suppression of both p-mTOR and ERCC1 compared with the basal cellular levels (Figure 10). (See a schematic overview of the results in Figure 11)

DISCUSSION

Cisplatin chemotherapy has been used to kill several solid cancer cells with satisfactory results. However, due to

Figure 5 Reverse transcription-polymerase chain reaction and Western blot analyses of apoptosis regulators in treated hepatocellular carcinoma cells. Melatonin had minor effects on all apoptosis markers, whereas cisplatin significantly increased apoptosis via the activation of p53 and caspase3 and the Bax/Bcl-2 ratio. Melatonin reduced cisplatin effects in the combined treatment. ([a]$P < 0.05$, [c]$P < 0.001$ compared with the control group, [d]$P < 0.05$, [e]$P < 0.01$ compared with the cisplatin-treated group).

Figure 6 Effects of melatonin and cisplatin on the cell cycle, as evaluated using flow cytometric analysis. Hepatocellular carcinoma (HepG2) cells were treated with melatonin (1 mmol/L) and/or cisplatin (20 μmol/L) for 24 h. Melatonin induced DNA accumulation in the HepG2 cells at the G_0/G_1 phase, whereas cisplatin affected cell cycle arrest at the sub-G_0, G_0/G_1, and S phases. In the combined treatment, melatonin decreased the cisplatin effect on cell cycle arrest at the sub-G_0 through G_0/G_1 phases but significantly increased S phase cell cycle arrest.

Figure 7 Autophagic detection by acridine orange staining and immunofluorescence. Hepatocellular carcinoma (HepG2) cells were treated with 1 mmol/L melatonin and/or 20 μmol/L cisplatin for 24 h and evaluated for autophagy formation. The experiments were performed in triplicate, and representative micrographs are shown. A: Acridine orange staining showed lysosomal (red or orange) staining in the cells of all treatments. The increased acidic lysosomes in the combination treatment suggests potential lysosomal activation (scale bar = 20 μm); B: Confocal immunofluorescence micrographs of representative treated-HepG2 cells immuno-labeled with the anti-LC3 antibody (scale bar = 10 μm). Melatonin and cisplatin treatment alone induced some fluorescent immunoreactivity in the cytoplasm, but the combined treatment induced intense immunoreactivity.

its efficient cytotoxic effects, cisplatin produces adverse drug effects and chemo-resistance. Therefore, adjuvant therapy with melatonin has been proposed, and extensive studies were performed, with variable outcomes[22]. In the

Figure 8 Analysis of autophagy and DNA repair-related proteins. Hepatocellular carcinoma cells were treated with various concentrations of melatonin and cisplatin. At the selected concentrations, 1 mmol/L melatonin and 20 μmol/L cisplatin have a similar effect by significantly increasing p-mTOR and ERCC 1 from the basal levels. However, the effect on Beclin-1 was the opposite, with melatonin increasing Beclin-1 and cisplatin decreasing Beclin-1 from the basal level. The results are presented as the mean ± SE. ([a]$P < 0.05$, [b]$P < 0.01$, [c]$P < 0.001$ compared with the control group). ERCC1: Excision repair cross complementary-1.

Figure 9 Alteration of autophagy-forming proteins. Hepatocellular carcinoma cells were treated with melatonin and/or cisplatin for 24 h. Melatonin slightly increased Beclin-1 and LC3-Ⅱ, whereas cisplatin significantly decreased Beclin-1 and slightly increased LC3-Ⅱ. Melatonin inhibited the cisplatin effect on Beclin-1 but increased LC3-Ⅱ in the combined treatment. ([c]$P < 0.001$ compared with the control group, [f]$P < 0.001$ compared with the cisplatin-treated group).

present study, we set out to determine whether melatonin could mediate a protective effect against cisplatin-induced apoptosis using HepG2 cells and attempted to identify the potential molecular pathways of melatonin action. The results demonstrated that the overall effect of this adjuvant in chemotherapy depends on a number of melatonin effects on cells. When melatonin was combined with cisplatin in the HepG2 cell line, the expression of the apoptosis mediators phosphorylated p53, cleaved caspase 3, and Bax decreased, whereas anti-apoptotic Bcl-2 increased. These biochemical results correlated well with decreases in the intracellular ROS level and the recovery of cell morphology. The results indicated the anti-

oxidative stress property of melatonin, which directly scavenges reactive oxygen species induced by cisplatin anticancer drugs[31,32], thus reducing adverse cisplatin drug effects in hepatocytes.

In addition to the extended results from the alteration of the anti-apoptotic Bcl-2 level, we found that melatonin decreased the expression ratio of Bax/Bcl-2, which was affected by cisplatin. Thus, an apoptosis event in the combined treatment was switched to cell survival. The expression of p53 protein was also subjected to a switch by the melatonin and cisplatin combination, suggesting a direct effect of both on the cell cycle. The pro-death effect of cisplatin, which was mostly mediated by p53, indicated

Figure 10 RT-PCR and Western blot analyses of autophagy regulators. Both melatonin and cisplatin increased p-mTOR and ERCC 1 levels in the HepG2 cells, but the combined treatment resulted in the suppression of both proteins. ([b]$P < 0.01$, [c]$P < 0.001$ compared with the control group, [e]$P < 0.01$, [f]$P < 0.001$ compared with the cisplatin-treated group). ERCC1: Excision repair cross complementary-1.

Figure 11 Schematic overview of the major findings in the combination group.

that the cell cycle specificity of cisplatin in HepG2 cells

affected G_0/G_1 phase. In the combined treatment, the cell

cycle arrest was changed to the S and G₂/M phases. Therefore, melatonin must have increased the cisplatin effect on cell cycle arrest through inhibition at the S (DNA synthesis) and M (mitosis) phases. These are considered the most anti-proliferative (oncostatic) effects of melatonin. However, the cell cycle arrest by melatonin in the treated cells could also be mediated by other cell cycle control proteins, such as the calcium/calmodulin pathway[33] and autophagy regulation pathway. Both pathways are related to the anti-proliferation of cells and pro-survival.

In our study, DNA damage may have been induced in HepG2 cells by the cisplatin genotoxic chemical and ROS by-products of cell metabolism[34]. The subsequent response reactions include the activation of a DNA damage checkpoint, which arrests cell cycle progression and leads to apoptosis[35]. We demonstrated that there was a survival switch from cisplatin-induced apoptosis to autophagy in the combination treatment with melatonin. The indicators included acridine orange staining, an immunohistochemistry assay for autophagy, and the measurement of mRNA and proteins associated with autophagy [*i.e.*, mTOR, Beclin-1, and chain3-Ⅱ (LC3-Ⅱ)]. Compared with cisplatin treatment alone, the combination treatment showed a high intensity of positive fluorescence staining in the lysosomal compartment of the cell, suggesting increased autophagy activity. Cisplatin acted on p53 and Bcl-2 to induce apoptosis, but in the combined treatment, Bcl-2 was decreased to an extent lower than the basal level. This could occur through reduced binding between the Bcl-2/Bcl-xL complex and Beclin-1, followed by a release of Beclin-1 to initiate autophagy formation. Thus, the combined treatment could change apoptosis to autophagy.

The basal levels of Beclin-1 and mTOR, major regulators of autophagy, were evaluated in HepG2 cells. Cisplatin treatment alone up-regulated mTOR and down-regulated Beclin-1 expression compared with the basal levels, thus decreasing autophagy and promoting the apoptosis pathway. Melatonin treatment alone up-regulated both mTOR and Beclin-1 expression compared with the basal levels, and this up-regulation by melatonin played a significant role in the survival of HepG2 cells. In the combined treatment, melatonin caused autophagy through the final formation of the autophagosome and was shown by an increased microtubule-associated protein-light LC3-Ⅱ level via the up-regulation of p-mTOR and Beclin-1. This changed the apoptotic signal caused by cisplatin. Overall, melatonin attenuated cisplatin-induced HepG2 cell death by inducing an autophagy survival signal[36].

A novel autophagy regulation mediated by melatonin was identified in this study. Both melatonin and cisplatin exhibited concentration-dependent effects on mTOR, Beclin-1, and DNA ERCC1. ERCC1 is a marker of DNA repair, whereby ERCC1 is the rate-limiting enzyme in the NER system, a pathway known to remove cisplatin lesions from DNA[37]. The analysis of protein expression in this study revealed that increases in ERCC1 from the basal levels in HepG2 cells by each

treatment were associated with an increase in mTOR expression, suggesting a tight relationship between DNA repair and autophagy. We also found that both mTOR and ERCC1 were significantly decreased by melatonin induction in the co-treatment group compared with the cisplatin-treated group. However, the only slight reduction in ERCC1 in our assay using rapamycin as an inhibitor of mTOR demonstrated that the melatonin effect on ERCC1 was not directly to the mTOR activation pathway (data not included). Therefore, melatonin reduced cisplatin-induced DNA damage, resulting in decreased activation of the DNA repair capacity and might be involved in transcriptional regulation or an epigenetic mechanism. As previously shown, p-p53 is a transcription factor for apoptotic gene expression and also plays a role in DNA repair via the subsequent up-regulation of genes in the NER pathway[38-40]. AP-1 is a transcription factor for autophagy and ERCC1 regulation in DNA damage pathways[41]. In the combined treatment, melatonin and cisplatin may encounter transcription inactivation. That is, after cisplatin treatment, DNA damage occurs, and ERCC1 is induced. An increased level and activation of mTOR induced by melatonin counter-balances the role of p-p53 in the DNA damage and repair process induced by cisplatin. This finding is the first report that melatonin can activate ERCC1 in a concentration-dependent manner.

Interestingly, significant decreases in both mTOR and ERCC1 compared with the basal levels were identified in the combined treatment, suggesting a positive response of the cells. The expression level of ERCC1 has been previously suggested to be a prognostic marker of cancers, and ERCC1 over-expression has been associated with to cisplatin resistance[42]. In our research, ERCC1 decreased compared with the cisplatin-treated group, indicating an improvement in cancer prognosis.

In conclusion, melatonin exerted an oncostatic effect on cisplatin-treated hepatocellular carcinoma cells via a counter-balance between the roles of apoptosis-related p53 and Bcl-2 and autophagy proteins. The alteration of Beclin-1, mTOR, and ERCC1 levels determined the pro-death and pro-survival effects of treatment in this cancer cell line. Therefore, during cisplatin treatment of hepatocellular carcinoma, the administration of a high dose of melatonin as an adjuvant in cancer therapy should ameliorate the adverse effects of cisplatin.

ACKNOWLEDGMENTS

COMMENTS

Background

Liver cancer is one of the major causes of death in humans worldwide due to

the limitation of drugs for treatment. Frequently, chemotherapy with platinum-based cisplatin is provided during the late stage of the disease. This drug causes excessive side effects and sometimes induces cancer drug resistance.

Research frontiers

Melatonin is a hormone produced in our body to maintain several normal physiological functions, which may be altered during the course of cancer. To reduce cisplatin side effects and still maintain the drug's efficacy, we treated human hepatocellular carcinoma (HepG2) cells with cisplatin and a high concentration of melatonin. The results showed that melatonin could reduce the oxidative stress effects of cisplatin by altering the stages of cell cycle arrest and apoptosis mediators such as p53. Melatonin switched cisplatin-induced apoptosis in HepG2 cell to autophagy-induced survival via Bcl-2, Beclin-1 and mTOR. In addition, melatonin reduced cisplatin-induced DNA damage by decreasing the activation of excision repair cross complementary-1 (ERCC1) in the DNA repair system.

Innovations and breakthroughs

Melatonin can activate DNA ERCC1 in a concentration-dependent manner. An analysis of protein expression in this study revealed that increases in ERCC1 from the basal levels in HepG2 cells by each treatment were associated with an increase in mTOR expression, suggesting a tight relationship between DNA repair and autophagy. In the combined treatment, melatonin and cisplatin may result in transcriptional inactivation between mTOR and ERCC1.

Applications

During cisplatin treatment of hepatocellular carcinoma, the administration of melatonin as an adjuvant in cancer therapy should ameliorate the adverse cisplatin effects while maintaining the drug's efficacy.

Terminology

ERCC1 is the rate-limiting endonuclease in the nucleotide excision repair (NER) pathway, which is the major pathway for removing cisplatin from the DNA strand. ERCC1 is a good predictive biomarker for cancer treatment with cisplatin. ERCC1-negative tumor patients were associated with a higher survival rate than ERCC1-positive tumor patients treated with adjuvant platinum-based regimens.

Peer review

This study has a good structure and is easy to read despite many abbreviations, even for inexperienced readers in this field. It is a very important and up-to-date subject. The work is interesting, technically correct, and well written and describes an important role for melatonin as an adjuvant to cisplatin, a therapy known to cause severe toxicity in the body. The studies were well-designed, clearly presented, highly mechanistic, and demonstrated novel pathways regulated by melatonin to improve health outcomes associated with hepatic cancer and cisplatin-induced hepatotoxicity. This study will open up new research areas in this field. The authors used myriad techniques and approaches to tackle this deadly disease.

Abstract

AIM: To propose an alternative model of hepatic encephalopathy (HE) in mice, resembling the human features of the disease.

METHODS: Mice received two consecutive intraperitoneal injections of thioacetamide (TAA) at low dosage (300 mg/kg). Liver injury was assessed by serum transaminase levels (ALT) and liver histology (hematoxylin and eosin). Neutrophil infiltration was estimated by confocal liver intravital microscopy. Coagulopathy was evaluated using prolonged prothrombin and partial thromboplastin time. Hemodynamic parameters were measured through tail cuff. Ammonia levels were quantified in serum and brain samples. Electroencephalography (EEG) and psychomotor activity score were performed to show brain function. Brain edema was evaluated using magnetic resonance imaging.

RESULTS: Mice submitted to the TAA regime developed massive liver injury, as shown by elevation of serum ALT levels and a high degree of liver necrosis. An intense hepatic neutrophil accumulation occurred in response to TAA-induced liver injury. This led to mice mortality and weight loss, which was associated with severe coagulopathy. Furthermore, TAA-treated mice presented with increased serum and cerebral levels of ammonia, in parallel with alterations in EEG spectrum and discrete brain edema, as shown by magnetic resonance imaging. In agreement with this, neuropsychomotor abnormalities ensued 36 h after TAA, fulfilling several HE features observed in humans. In this context of liver injury and neurological dysfunction, we observed lung inflammation and alterations in blood pressure and heart rate that were indicative of multiple organ dysfunction syndrome.

CONCLUSION: In summary, we describe a new murine model of hepatic encephalopathy comprising multiple features of the disease in humans, which may provide new insights for treatment.

Core tip: The study of hepatic encephalopathy is crucial for development of new therapies but has been dampened by the absence of murine models resembling the disease in patients. We showed that sequential thioacetamide injections cause extensive liver injury in mice, leading to increased ammonia levels, electroencephalography alterations and brain edema. In line with this, mice presented with poor psychomotor activity and survival rate. Liver injury and brain function impairment by thioacetamide resulted in systemic alterations such as coagulopathy, hemodynamic instability and lung inflammation, consistent with multiple organ failure. Therefore, this alternative model may provide tools for new therapeutic insights for hepatic encephalopathy.

INTRODUCTION

Acute liver failure (ALF) is a rare but severe clinical syndrome. It is typically characterized by jaundice, coagulopathy and encephalopathy resulting from sudden hepatic dysfunction without preexisting liver disease[1]. Drug-induced liver injury (DILI) is the main cause of ALF in the United States and Europe[2], whereas in developing countries viral hepatitis is the most important etiology. Although liver injuries may result from a wide range of situations, drug overdose may become the most important etiology of ALF worldwide in a few years[2] as life expectancy increases and the medicalization of the older population tends to increase[3]. Moreover, the worldwide cause of ALF tends towards DILI due to increasing public health measures (*e.g.*, vaccination)[1], making it an emergent widespread problem. ALF has a high mortality rate of approximately 30% due to multiple organ dysfunction, hepatic encephalopathy and sepsis. Unfortunately, therapeutic options are very limited since liver transplantation is the only definitive therapy available. Besides that, patients are kept under clinical management and supportive care until spontaneous liver recovery[1,4].

Hepatic encephalopathy (HE) is one of the major complications in ALF because of rapid brain edema, intracranial hypertension and cerebral herniation[5]. Clinically, HE is a neuropsychiatric syndrome that comprises a wide range of signs and symptoms from subtle altered mental status to stupor and coma[6]. The severity of HE has prognostic implications since patient outcome worsens as HE progresses. There is a chance of 65%-70% of spontaneous liver recovery in mild HE and less than 20% in severe HE[7]. Moreover, patients with ALF who manifest increased intracranial pressure during the course of illness are more likely to develop sepsis[8]. Hence, understanding HE pathophysiology is crucial for development of new and specific therapies that would slow down its progression and increase chances of better outcomes.

In this sense, a murine model that reproduces features of HE in humans would be key to improve our understanding in HE pathophysiology and may also be useful for drug testing and development. Here, we propose an alternative murine model of HE using sequential systemic thioacetamide (TAA) injections in a lower dosage instead of a single higher dose administration.

MATERIALS AND METHODS

TAA induced liver failure and hepatic encephalopathy

Female C57BL/6 mice and Lysm-eGFP (eGFP-expressing neutrophils) had free access to food and water. TAA-induced liver injury protocol was based on two consecutive days of treatment with thioacetamide (300 mg/kg) administered intraperitoneally. Treated groups received the first dose in time zero and an additional dose after 24 h. Controls received vehicle following the same chronogram. Mice were sacrificed after 24 or 48 h and liver, lung, blood and brain samples were collected for further analysis. All mice received glucose replacement (12/12 h; 5%; *s.c.*) and glycemia was monitored (12/12 h) with commercially available reactive strips and a glucometer (Accu-Chek, Performa). Body temperature was maintained at 37 ℃ by a thermal pad. Psychomotor activity was graded following an adapted clinical score, in which 0 = normal behavior; 1 = mild lethargy; 2 = decreased motor activity, poor gesture control, diminished pain perception; 3 = Severe ataxia, no spontaneous righting reflex; 4 = no righting reflex, no reaction to pain stimuli; and 5 = death[9]. All procedures were approved by Animal Care and Use Committee in UFMG (CEBIO n°051/2011). The investigation conformed to the standards of Guide for the Care and Use of Laboratory Animals (National Institutes of Health publication 85-23, 1996 revision). In a separate set of experiments, the liver was imaged using confocal intravital microscopy as described previously[10]. Lysm-eGFP mice received propidium iodide (200 μL of a 100 μmol/L stock solution; *i.v*) prior to the surgical procedure in order to visualize necrotic cells.

Serum and cerebral ammonia determination

Immediately after decapitation, the brain was rapidly removed from the cranial cavity and fast-frozen in liquid nitrogen. Subsequently, brain samples were macerated using a pestle in perchloric acid (ice-cold; 1mol/L) and centrifuged at 10000 *g* for 10 min at 4 ℃. The supernatant was collected for immediate dosage. Also, blood

samples were centrifuged for 7 min (7000 *g*) and plasma was collected. Ammonia concentration was estimated using Ammonia Assay kit (Sigma, United States) following manufacturer instructions.

Alanine aminotransferase

The alanine aminotransferase enzyme is present in the cytoplasm of hepatocytes and is highly specific for the liver. The measurement of serum alanine aminotransferase (ALT) is a gold-standard marker of liver damage. To determine the activity of ALT, blood samples were centrifuged and the serum was collected and dosed using a kinetic kit (Bioclin, Brazil).

Hemodynamic measurements using tail cuff method

Mean arterial pressure (MAP) and heart rate (HR) were evaluated by a volume pressure recording sensor and an occlusion tail-cuff, which measures mice blood pressure and HR noninvasively (Kent Scientific Corporation, Torrington, CT, United States)[11]. Mice were acclimated to the restraint and tail cuff inflation for two days before the beginning of the experiments. The restraint platform was maintained at 36-38 ℃. In each session, mice were placed in an acrylic box restraint, and the tail was inserted into a compression cuff that measured the blood pressure 10 times. Following the measurement cycle, the average of these values was considered for each mouse. MAP and HR were evaluated at 0, 24 and 48 h after TAA administration.

Procedures for electroencephalography recording

Surgery procedures: Mice (*n* = 8) were anesthetized using a mixture of ketamine (100 mg/kg) and xylazine (10 mg/kg). Prophylactic treatment with antibiotics (enrofloxacin; 10 mg/kg; *s.c.*) was done in order to prevent post-surgical infections. The animals were submitted to surgery for electroencephalography (EEG) electrode implantation in the right and left parietal cortices. The electrodes for superficial EEG recordings were made with surgical screws (Fine Science Tools; model 19010-00; Foster City, CA, United States) previously soldered to Teflon-coated stainless-steel wires (A&M Systems; model 7916; Carlsborg, WA, United States) and introduced bilaterally in the parietal bones. A reference electrode, also made with surgical screws, was inserted in the nasal bone. All the electrodes were soldered to a common pin connector and anchored to the cranium with dental acrylic. Following surgery, animals were allowed to recover for at least 4 days before EEG recordings.

Experimental protocol: Mice were injected with thioacetamide in the same regime (*n* = 5) or saline (*n* = 3). Each mouse was recorded in three consecutive days, namely: day 1, before drug injection; days 2 and 3, after first and second drug injections, respectively. Mice were recorded for a period of 10 min each day. Bioelectrical activity was recorded with a video-EEG recording system (8:00-11:00 am). The EEG signal from both parietal cortices was amplified (1000 × gain) and filtered (1 Hz High

pass, 500 Hz Low pass) by a signal conditioner (Aisha4 - Kananda® Ltda). Data were sampled at 1 kHz (12 bit DI-148U A/D converter - DATAQ® Instruments) and recorded in a computer hard disk for offline analyses. Spectral analysis and 3D rendering of EEG spectrum were done using MatLab® scripts.

Magnetic resonance imaging: Acquisition and analysis

MR image experiments were acquired using 4.7T NMR system (Oxford Systems) controlled by a UNITY Inova-200 imaging console (Varian). The imaging protocol consisted of coronal T2-weighted (TR = 3000 ms, TE = 50 ms) spin echo multislice scans, 16 contiguous 1 mm thick slices. Mice (*n*= 12) were anesthetized with halothane (4% induction, 1.5% maintenance) and oxygen (1.5 l/min) delivered by a facemask in a head holder to minimize artifact movements. Animals anesthetized for the duration of an imaging experiment (50 min) recovered with no apparent difficulty and could be used for subsequent imaging studies. Each mouse was imaged in three consecutive days, namely: day 1, before drug injection; days 2 and 3, after first and second drug injections, respectively. Brain masks, based on the anatomical scans, were done using a tablet driver (Bamboo Tablet Driver, V5.2.5 WIN, WACOM Technology Corporation, United States) and MeVisLab software (MeVis Medical Solutions AG, Fraunhofer). Additionally, densitometry analysis was done using MatLab® scripts and repeated measures. ANOVA was used to compare densitometry values on different days.

Statistical analysis

Statistical analyzes were performed using one-way ANOVA (Tukey's post test) and Student's *t* test. *P* values less than 0.05 were considered statistically significant. All data are presented as mean ± SE.

RESULTS

Repeated TAA injections caused neuropsychomotor changes, brain edema and hyperammonemia, with EEG spectrum suggestive of metabolic encephalopathy

As shown in Figure 1A, around 30% of mice treated with a single dose of TAA died after 24 h and more than 40% succumbed due to a second TAA administration. Also, a progressive increase in neurological score (reflecting a decreased neuropsychomotor activity) was observed (Figure 1B) and, probably due to such reduced mobility, TAA-treated mice presented with a significant weight loss in comparison to controls throughout the experiment (Figure 1C). In addition, TAA treatment caused serum hyperammonemia after 24 h (Figure 1D), which was also detected in the brain in later timepoints (48 h; Figure 1E). Taking into account the edematogenic effects of cerebral ammonia accumulation, we imaged mice brains using magnetic resonance (MR) to investigate potential morphological alterations, including suggestive areas of fluid accumulation. MR revealed a discrete but diffuse brain edema in TAA-treated mice, which was not observed in

Figure 1 Thioacetamide treatment triggered neuropsychomotor changes, diffuse brain edema and hyperammonemia, with electroencephalography spectrum compatible with of encephalopathy. A: Survival rate following repeated TAA injections (arrows); B: Neurological score was assessed through all experimental procedure. Neuropsychomotor deficit increases as higher is the score average, with 1 = normal and 5 = death; C: Mice treated with TAA also presented with significant weight loss in comparison to controls; D, E: Serum ammonemia was detected following 24 h of TAA injection, while brain ammonia concentration increased gradually, reaching significant higher values after 48 h (E); F: In agreement, MRI from TAA-treated mice brains showed discrete, but diffuse edema as pointed by arrow heads. G, H: EEG analysis revealed that while controls had coincident EEG records during the experimental protocol (G), brain waves spectrum of TAA-treated mice (H) was compatible with metabolic encephalopathy; I: 3D rendering of 60 minutes EEG record (Z axis) plotted comparing energy (in Y axis) with frequency (X axis). Note the increase in higher frequencies waves (theta and alpha; 4-8 and 8-13 Hz, respectively) with a concomitant increase of lower frequency ones (mainly delta; up to 4 Hz). Best case results were depicted here; *N* = 8 for each group; J: Total EEG energy was also reduced in TAA-treated group. aIndicates statistical significance in comparison to controls and bin comparison to 24 h group. *P* < 0.05, analysis of variance (Tukey's post test). *N* ≥ 5 for each group. TAA: Thioacetamide; EEG: Electroencephalography.

controls (Figure 1F). Increased fluid accumulation was more evident following 48 h of TAA treatment; however, such a feature was not prominent. In fact, no significant differences were observed in brain densitometry during analysis of MRI images (data not shown), suggesting that a mild brain edema was occurring in this model. To further dissect the neurological effects of TAA poisoning, we submitted mice to daily EEG registration throughout the experimental protocol. Analysis of the EEG spectrum revealed that while untreated mice had coincident EEG records during all experimental protocol (Figure 1G), TAA administration caused a progressive decrease in higher frequencies waves (*theta* and *alpha*; 4-8 and 8-13 Hz, respectively) with a concomitant increase of lower frequency ones (mainly *delta*; up to 4 Hz; Figure 1H-I). Such an EEG profile, with concentration of energy mainly in *delta* waves region and significant reduction in total energy (Figure 1J), confirmed that repeated TAA administration led to a diffuse brain lesion and metabolic encephalopathy.

Severe liver necrosis and inflammation triggered metabolic encephalopathy, coagulopathy and remote lung injury

It is well established that impaired liver function caused by extensive hepatocyte death leads to a general deficiency in metabolism, including ammonia depuration and synthesis of coagulation cascade factors[3]. Liver intravital microscopy revealed a marked increase in necrotic cells (stained by propidium iodide; in red) following TAA exposure (Figure 2A), which was also confirmed by histology analysis (Figure 2B). Also, we observed an exuberant neutrophil accumulation in liver necrotic areas, which increased throughout TAA intoxication process (Figure 2A; eGFP-expressing cells). Macroscopically, livers from TAA treated mice displayed extensive areas of necrosis (Figure 2C), which became more obvious after repeated TAA administration (48 h). Significantly higher serum levels of alanine aminotransferase (ALT) also indicated massive liver injury, which was sustained during the whole experimental period (Figure 2D). In fact, a complete lack of hemostatic function also confirmed hepatotoxicity and organ failure, suggesting that synthesis of liver-derived coagulation factors was seriously impaired. While controls had normal hemostatic parameters (MAP and HR), TAA-treated mice had a prolonged (undetermined) prothrombin and partial thromboplastin time (Figure 2E, F). Moreover, while control mice had normal hemodynamic parameters, the TAA-treated group had a significant drop in MAP (approximately 35%) with concomitant tachycardia, suggesting that mice might be evolving to a hemodynamic shock (Figure 2G, H). In this direction, we hypothesized that in our model TAA might also cause multiple organ failure and remote injury.

We have previously shown that necrosis-derived products may reach systemic circulation and trigger remote inflammatory responses in organs including the lungs[12]. Here, we evaluated the potential of TAA in induction of lung inflammation. Histopathological analysis showed that TAA-induced liver injury also caused pulmonary injury. After 24 h, lungs from mice had increased cellularity in lung parenchyma, alveolar edema and hemorrhage in comparison to controls (Figure 1I; arrows). Those observations were found to be more pronounced after 48 h, showing increased tissue damage, alveolar hemorrhage and lung architecture disruption, suggesting that lethality induced by TAA can also be due to exacerbation of lung inflammatory response in this model.

DISCUSSION

The hepatotoxic ability of TAA is well described in the literature and this drug has been extensively used in rat models of ALF and HE in sequential repeated dose administration[9,13-16]. Once in circulation, TAA is absorbed and bioactivated by hepatocytes. This metabolite will finally modify aminolipids and proteins, causing cell damage and death[17]. In mice, acute TAA poisoning causes centrilobular necrosis and an increase in plasma transaminases and bilirubin. We have shown that following two daily TAA injections, mice developed a massive and progressive liver damage and failure, with hyperammonemia in serum and brain, with discrete signals of cerebral edema.

Hyperammonemia is a hallmark of HE pathophysiology. In patients with ALF, the arterial ammonia level is directly related to severity of HE and development of intracranial hypertension[18]. Also, persistent hyperammonemia seems to be more important than a transient increase in the ammonia level regarding the occurrence of intracranial hypertension[19]. Most studies in mice used a single dose of a hepatotoxic drug which caused a briefer period of illness[20-22]. To supersede this, we developed a novel protocol using a lower TAA dose (300 mg/kg) and repeated administration (2 daily doses), trying to mimic a more realistic scenario closer to severe HE. We found that under these conditions, mice progressively presented with neuropsychomotor deficiencies (as assessed by neurological score)[23], which was accompanied by persistent liver injury and failure. Interestingly, serum ammonia concentration peaked after the first TAA administration, decreasing at 48 h. However, cerebral ammonia gradually increased throughout the experimental protocol, reaching significantly higher levels 48 h after TAA, suggesting that probably excessive serum levels of ammonia might be transferred to the brain due to deficient liver ammonia clearance. The mechanisms responsible for ammonia-mediated encephalopathy and brain edema are still under debate; however, it is accepted that increased blood-derived ammonia intensifies glutamine synthesis via amidation of glutamate, generating a hyperosmotic environment within brain cells (mainly astrocytes)[24]. Consequently, cerebral liquid accumulation leads to intracranial hypertension, herniation and coma. In agreement with this, magnetic resonance imaging from mice treated with TAA revealed a discrete, but crescent-shaped and diffuse

Figure 2 Thioacetamide caused severe liver necrosis and inflammation, which may explain mice metabolic encephalopathy, coagulopathy and remote lung injury. A: Liver intravital microscopy showing crescent number of necrotic cells (in red, propidium iodide) with concomitant neutrophil infiltration (in green, Lysm-eGFP mice); B: Liver sections stained by hematoxylin and eosin (4 × increase). Arrows indicate necrotic areas; C, D: Liver macroscopic analysis confirmed extensive and diffuse necrosis, which is also reflected by elevated serum transaminase activity (D); E, F: Liver failure was confirmed by prolonged prothrombin and partial thromboplastin times; G, H: Also, significant drop in mean arterial pressure (MAP; G) and increased heart rate (H), as assessed by tail cuff method, suggested that TAA-treated mice also evolved to hemodynamic shock; I: After TAA treatment hours, lungs from mice had increased cellularity in lung parenchyma, alveolar edema and hemorrhage in comparison to controls (arrows, 4 x increase) aIndicates statistical significance in comparison to controls. [a]$P < 0.05$, ANOVA (Tukey's post test). N ≥ 5 for each group. TAA: Thioacetamide.

brain edema[25]. In addition, through analysis of the EEG spectrum we found diffuse a brain lesion compatible with metabolic encephalopathy[26], suggesting that our DILI model reproduces some of the main clinical manifestations of HE[27]. In conjunct, our data suggest that this model may be suitable for further studies involving ALF,

hyperammonemia and brain edema.

We also investigated the mechanisms involved in liver damage triggered by TAA in mice. Intravital microscopy revealed that large areas of liver necrosis were infiltrated by neutrophils and such sterile inflammation has been described as a key factor for injury amplification[12]. Furthermore, we also observed repercussions in hemodynamic functions and inflammatory infiltration in the lungs. In this sense, the innate immune response triggered by necrosis-derived products may add to direct TAA-mediated hepatotoxicity to establish not only ALF, but also remote organ injury. Accordingly, TAA-treated mice displayed a severe impairment in hemostatic function compatible with an end-stage liver failure, with coagulopathy, hypovolemic shock and possible multiple organ failure. Thus, these factors should be also evaluated in future studies primarily dedicated to the liver or central nervous system.

In conclusion, we have shown that repeated lower doses of TAA might constitute as a novel murine model of HE and ALF, which reproduce several features of human disease. Also, we provided read-outs for disease grade and severity that comprise behavioral changes, brain edema and ammonemia, hemodynamic parameters and inflammatory response.

ACKNOWLEDGMENTS

COMMENTS

Background
Acute liver failure (ALF) is a rare but severe clinical syndrome. ALF is the result of massive liver injury, which can be caused mostly by drugs or viruses. During the disease, patients may suffer hepatic encephalopathy, multiple organ dysfunction and sepsis, leading to a high mortality rate. The incidence of ALF is increasing worldwide and liver transplantation and supportive medical care are the only therapies available for ALF.

Research frontiers
Hepatic encephalopathy (HE) is one of the major complications in ALF because of rapidly progressing brain edema and hypertension. Hence, understanding HE pathophysiology is crucial for development of new and specific therapies that would slow down its progression and increase chances of better outcomes. In this sense, a murine model that reproduces most features of HE in humans would be key to improve our understanding of HE pathophysiology and may also be useful for drug testing and development.

Innovations and breakthroughs
This study provided a new model to study hepatic encephalopathy and acute liver failure in mice. In this model, mice are treated twice with a low dose thioacetamide, causing extensive liver injury and characteristic complications of human HE, including high ammonia levels, altered electroencephalography (EEG), brain edema and poor neuropsychomotor function. In addition, mice presented with a systemic response similar to multiple organ failure syndrome, where lung inflammation, coagulopathy and hemodynamic alterations were observed.

Applications
This is a new model to study ALF and HE in mice, the most used animal model. Also, this is the first animal model to present such similar symptoms to the human disease, making it a more useful research tool for this biomedical area.

Terminology
The most important terms in this article are: ALF, HE and thioacetamide.

Peer review
The authors describe a murine model of acute hepatic failure to study hepatic encephalopathy by sequential administration of thioacetamide intraperitoneally. The hypothesis is convenient, the methodology for acute hepatic failure was suitable, the evaluation of hepatic encephalopathy was convenient and sophisticated, the results were interesting and the discussion appropriate.

Abstract

AIM: To investigate the hepatic hemodynamics in the Budd-Chiari syndrome (BCS) using per-rectal portal scintigraphy (PRPS) and liver angioscintigraphy (LAS).

METHODS: Fourteen consecutive patients with BCS were evaluated by PRPS between 2003 and 2012. Ten of them underwent LAS and liver scan (LS) with Tc-99m colloid. Eleven patients had clinical manifestations and three were asymptomatic, incidentally diagnosed at PRPS. The control group included 15 healthy subjects. We used new parameters at PRPS, the liver transit time of portal inflow and the blood circulation time between the right heart and liver. PRPS offered information on the hepatic areas missing venous outflow or portal inflow, length and extent of the lesions, open portosystemic shunts (PSS), involvement of the caudate lobe (CL) as an intrahepatic shunt and flow reversal in the splenic vein. LAS was useful in the differential diagnosis between the BCS and portal obstructions, highlighting the hepatic artery buffer response and reversed portal flow. LS offered complementary data, especially on the CL.

RESULTS: We described three hemodynamic categories of the BCS with several subtypes and stages, based on the finding that perfusion changes depend on the initial number and succession in time of the hepatic veins (HVs) obstructions. Obstruction of one hepatic vein (HV) did not cause opening of PSS. The BCS debuted by common obstruction of two HVs had different hemodynamic aspects in acute and chronic stages after subsequent obstruction of the third HV. In chronic stages, obstruction of two HVs resulted in opening of PSS. The BCS, determined by thrombosis of the terminal part of the inferior vena cava, presented in the acute stage with open PSS with low speed flow. At least several weeks are required in the obstructions of two or three HVs for the spontaneous opening of dynamically efficient PSS. The CL seems to have only a transient important role of intrahepatic shunt in several types of the BCS.

CONCLUSION: Dynamic nuclear medicine investigations assess the extent and length of hepatic venous obstructions, open collaterals, areas without portal inflow, hemodynamic function of the CL and reverse venous flow.

Core tip: Per-rectal portal scintigraphy (PRPS) and liver angioscintigraphy (LAS) are reliable investigations of the liver hemodynamics in the Budd-Chiari syndrome (BCS). Diagnosis of the number, length and succession in time of hepatic vein obstructions allows identification

of hemodynamic varieties and stages of the BCS. Our new PRPS parameters, liver transit time and right heart to liver time, are used to diagnose obstructed hepatic veins, areas missing venous outflow or portal inflow, open collaterals, reverse splenic vein flow and hemodynamic role of the caudate lobe. LAS is useful in the differential diagnosis with portal occlusions, highlighting arterial-venous shunts and reverse portal flow.

INTRODUCTION

The Budd-Chiari syndrome (BCS) is determined by hepatic venous obstruction localized from the small hepatic veins (HVs) to the terminal part of the inferior vena cava (IVC), resulting in increased sinusoidal pressure, hepatic congestion and portal hypertension (PHT)[1]. The natural outcome is poor in many cases, with a three year survival rate of about 10%[2,3]. Clinical manifestations are extremely varied and include ascites, jaundice, hepatomegaly, splenomegaly, collateral veins and upper right abdominal quadrant pain[4]. Ascites fluid has a characteristic high protein concentration (> 2.5 g/dL).

A widely accepted classification is based on etiology, site of obstruction, manifestations and duration of the disease[5]. Primary BCS is produced by thrombosis, its sequels or web obstruction[6]. Secondary forms are determined by malignant or parasitic obstruction of the lumen or by extrinsic compression, commonly produced by tumors[7]. The site involved by the obstruction and the affected HVs are commonly diagnosed through non-invasive imaging [ultrasound (US), magnetic resonance imaging (MRI), computed tomography (CT)] or by using venography[8].

Clinical approach accounts for the severity of disease (fulminant/non-fulminant) and its duration (acute, subacute or chronic). Subacute forms show signs or symptoms for less than six months and no evidence of liver cirrhosis. Chronic evolution is characterized by onset over six months, with evidence of PHT and cirrhosis[9]. However, the severity of liver damage may be inconsistent with apparent symptomatology. Recent clinical onset may be discordant with advanced liver fibrosis, suggesting a long course without clinical symptoms. Asymptomatic disease (10%-15% of cases) is usually associated with the obstruction of only one HV but also with spontaneous development of dynamically efficient intrahepatic collaterals and extrahepatic portosystemic shunts (PSS), incidentally diagnosed by imaging at surgery or necropsy[10]. For the patients with acute clinical onset but with advanced histological damage, a recent hepatic venous obstruction added to older obstructions of other

HVs has to be suspected. In acute forms, the liver area without physiological outflow is hypertrophied and PHT occurs. Because of the higher pressure (35 mmHg) in the hepatic artery (HA) than in the portal vein (PV) branches (3-6 mmHg), the portal flow may be reversed.

Chronic alterations include parenchyma atrophy and extended fibrosis, gaining a cirrhotic appearance and considerably reducing both portal and arterial inflow. Splenomegaly is found in a third of patients[11].

Thrombosis is the usual cause for the occlusion of large HVs, while the obstructions of the IVC or of the small HVs are rarely thrombotic[12].

The anatomical varieties of the HVs have to be accounted for, both for the diagnosis and surgical treatment. A common opening into the IVC of the left hepatic vein (LHV) and middle hepatic vein (MHV) was reported in around 55%-60% of cases[13]. Other varieties, such as a common trunk of the MHV and right hepatic vein (RHV), separate opening of the three HVs into the IVC or the existence of an accessory RHV, were identified in various percentages[14-16]. The caudate lobe (CL) hemodynamic status is important as it may be an anastomosis between the obstructed HVs and the IVC. CL hypertrophy is described in 65%-75% of cases, with good sensitivity but not specificity[17]. A caliber of the CL vein higher than 3 mm is considered diagnostic for the BCS[18].

US usually demonstrates altered HVs and hypertrophy of the CL[19]. Duplex Doppler sonography is widely used, offering a good assessment of the blood flow through the HVs[20,21]. Color Doppler sonography allows a more reliable identification of abnormalities of the HVs than conventional sonography and detects collateral vessels not visible with other techniques. The lack of flow signals in the HVs, intrahepatic and extrahepatic collaterals, together with reverse, slow or turbulent portal flow, are characteristic findings. US techniques should be the first line investigations, due to a low cost and a diagnostic sensitivity of more than 75%. There are, however, cases where the occlusion of HVs is difficult to demonstrate by US, even by color Doppler imaging[22].

CT scans offer a good assessment of thrombosis of the HVs or IVC, global liver enlargement, abnormalities of liver structure, size and direction of the venous flow. The contrast-enhanced helical CT allows a good dynamic visualization of HVs[23]. MRI provides useful images of the hepatic venous outflow and thrombosis of HVs, as second line investigations together with CT[24,25]. It can be difficult to diagnose spontaneous intrahepatic anastomoses and prominent azygos and hemiazygos veins (especially in IVC thrombosis) on MRI[26]. The liver biopsy has limited value due to the inhomogeneous distribution of liver lesions in the BCS[27].

Per-rectal portal scintigraphy (PRPS) was used over the last decades to investigate PHT and PSS in chronic liver disease (CLD) by evaluating a per-rectal portal shunt index[28,29]. Detailed information may be acquired about liver hemodynamics by using the parameters introduced by us in the interpretation of PRPS dynamic curves - liver transit time (LTT) and right heart to liver

time (RHLT)[30].

Liver angioscintigraphy (LAS) evaluates the contribution of arterial inflow to the total liver perfusion. It is especially useful in the differential diagnosis between the BCS and obstructions of the portal branches. Liver areas missing portal inflow have compensatory increased arterial inflow due to the hepatic artery buffer response (HABR)[31] and a characteristic pattern at LAS, with abrupt arterial entry and a flattened portal segment.

Liver scan (LS) with Tc-99m labeled colloid performed after LAS may show changes in radiotracer capture by liver, spleen and spine. Increased radioactivity on the CL area is considered a characteristic finding in the BCS[32].

The aim of this study is to underline the diagnostic possibilities in the BCS of the PRPS and LAS, with auxiliary use of the LS. The goals are assessment of liver areas missing venous drainage, length and order of the appearance of lesions, arterial and portal perfusion changes, existence of dynamically efficient collaterals and of supplementary drainage through the CL.

MATERIALS AND METHODS

We evaluated 14 consecutive patients with the BCS between 2003 and 2012, 9 females and 5 males, between 20 and 63 years old. Eleven patients had clinically manifested BCS and 3 were asymptomatic, incidentally identified at PRPS among over 400 patients explored for chronic liver disease (CLD) staging. The control group included 15 healthy subjects from the laboratory casework, 7 men and 8 women, between 19 and 67 years old. All 14 patients with BCS underwent PRPS. LAS and LS were performed in 10 of them. Anonymity of the patients was respected. All persons gave their informed consent prior to the investigations, accepting inclusion in research studies. The study was realized as part of routine clinical practice.

All the investigations were performed by using a single photon emission computed tomography (SPECT) Orbiter Siemens gamma-camera with high resolution, low-energy, parallel collimator, connected to a Power Macintosh computer, using ICON dedicated software. We used Tc-99m sodium pertechnetate, eluted from Drygen generators (General Electric, Amersham, United Kindom) and Fyton colloid (Institute of Isotopes, Budapest, Hungary).

PRPS was performed using the method developed by Shiomi *et al*[33]. A solution containing 2 mL (296-370 MBq/8-10 mCi) of Tc-99m sodium pertechnetate was instilled at PRPS into the upper part of the rectum through a Nelaton tube, followed by 15 mL of air under pressure. Serial scintigrams were recorded every 2 s for 5 min. Radioactivity curves were built thereafter by computer on liver and heart areas to analyze the dynamics of the radiotracer absorbed from the rectum. The patients were told to fast from the evening preceding the test. Two enemas were performed in each patient, the first the previous evening and the the second one 2 h prior to the PRPS. The patients were placed in a supine position, with

the camera detector in the anterior view, including in the field the liver and heart areas.

LTT and RHLT allow detailed assessment of liver hemodynamics in the BCS. These time parameters can be assessed for particular hepatic areas or for the whole liver. The portal inflow is missing in those areas where the tracer arrives (through the HA) with a delay equal to RHLT after entering into the right heart (RH). LTT increased between 25-40 s shows a higher resistance opposed to the portal inflow. Values over 50 s of the time interval between the entering of tracer into the liver and its arrival to the RH may occur in the acute stage of the BCS produced by obstruction of the terminal part of the IVC. This high delay is determined by the slow flow through the PSS open to the superior vena cava. LTT between 15-23 s reflects a decrease of the resistance opposed by the liver to the portal inflow due to the enlargement of intrahepatic small size shunts between terminal portal branches and small HVs. Open extrahepatic PSS of high flow are emphasized at PRPS by arrival of the portal tracer to the RH before entering into the liver. PRPS also detects alterations of portal and arterial perfusion in the liver areas which maintain their physiological venous outflow, highlighting the changes determined by the redistribution of flow from the affected areas.

The arterial upward inflexion (AUI) of the PRPS curve on a liver area is placed at a time interval equal to RHLT after the moment when the tracer entered into the RH. The beginning of the AUI segment on our figures is noted HA, marking the arrival of tracer to the liver through the HA. The moments when the portal tracer enters into the different areas of the liver are noted as Co, Lo, Mo and Ro. The entering of tracer into the RH is noted as Ho. The slope of the AUI gives information about the amplitude of arterial inflow. The portal segment of the PRPS curve (before the AUI) offers information about the portal inflow and the dynamic resistance encountered. Summed images at PRPS resulting from the overlapping of all the sequential images may highlight the normal aspect, increased accumulation or low quantity of tracer in a liver area. The presence of the spleen on the summed image highlights reverse flow in the splenic vein.

LAS was performed by rapid bolus injection of 8 to 15 mCi (300-450 MBq) of Tc-99m labeled colloid in a volume smaller than 0.5 mL, followed by computer dynamic recording of sequential images during 1 min at a 1 s rate. The detector's area included the heart, liver and kidneys. Six patients underwent LAS in the posterior-anterior view (P-A) and four in the anterior-posterior view (A-P). Patients were asked to fast 12 h before the LAS. Dynamic time-radioactivity curves for the liver, spleen and left or right kidney were built by computer. The moment of the peak of the kidney curve corresponds on the liver curve to the upward inflection point when the portal inflow of tracer adds to the arterial inflow. The interval of 8 s on the liver curve before the kidney curve's peak corresponds to the arterial segment, while the 8 s interval after the peak represents the portal segment[34].

Figure 1 Budd-Chiari syndrome with obstruction of the middle hepatic vein. A: Per-rectal portal scintigraphy; B: Liver angioscintigraphy; C: Liver scan.

The shape of the LAS curve built on a liver area may highlight amplitude changes of the arterial flow, a higher resistance opposed to the blood flow or open arterial-venous shunts. Hepatic perfusion index (HPI) calculated at LAS is used to estimate the ratio between the arterial inflow and total liver perfusion[35]. HPI > 45% on an area of the right liver lobe (RLL) without tumors diagnoses a decrease in portal inflow, with reactive increase in the arterial flow determined by the HABR[36]. HPI > 100% emphasizes reverse flow in the portal vein. HPI can be accounted for the RLL only, as the left liver lobe (LLL) normally has an increased arterial inflow.

LS images were acquired beginning at least 15 min after the LAS, based on the same administration of Tc-99m labeled colloid. P-A, A-P and right lateral (RL) views were used. Time consuming SPECT was not considered to bring significantly more information on hemodynamic status than planar LS and was not performed.

RESULTS

We highlighted three hemodynamic categories of the BCS using PRPS and LAS: (1) BCS debuted by obstruction of one HV: asymptomatic, incidentally diagnosed and old obstruction of one HV followed by recent obstruction of the other two HVs; (2) BCS started by obstruction of two HVs: old obstruction of two HVs, followed by recent obstruction of the third HV, and old obstruction of two HVs, also followed by old obstruction of the third HV; and (3) BCS with acute onset due to simultaneous obstruction of all three HVs caused by obstruction of the terminal part of the IVC.

BCS with one obstructed HV, asymptomatic, incidentally diagnosed

We had three cases of asymptomatic BCS in our study, two with obstruction of the MHV and one with obstruc-

Figure 2 Per-rectal portal scintigraphy in Budd-Chiari syndrome with obstruction of the middle hepatic vein. A: Curve on the territory drained by the middle hepatic vein; B: Caudate lobe curve; C: Left lobe curve; D: Curve on the territory drained by the right hepatic vein; E: Heart curve.

tion of the RHV. All three were incidentally identified at PRPS.

The case presented in Figures 1 and 2 had MHV obstruction. The patient was a 36-year-old male, known to have chronic alcoholic hepatitis. US described inhomogeneous liver with regenerative nodules and dilated portal branches.

Summed image at PRPS (Figure 1A) reveals a decreased amount of radiotracer in the medial part of the RLL. The dynamic PRPS curves built on the RLL show highly different slopes on the medial and lateral segments. The arrival of portal tracer to the medial area was delayed about 30 s after the entrance into the lateral segments. Initial segment of the PRPS curve built on the medial area of the RLL has a slow slope, denoting moderately increased resistance opposed to the portal inflow (Figure 2A). The PRPS curve built on the lateral part of the RLL has an increased slope, showing a rise of its portal inflow (Figure 2D). The dynamic curve built on the CL has a low initial slope, indicating that the portal flow blocked due to the obstruction of the MHV was not drained through the CL. The LLL has a simultaneous entry of tracer as the CL and as the lateral area of the RLL, with a normal initial slope of the PRPS curve.

LTT is prolonged to 30 s, most likely due to the subjacent CLD, with increased resistance opposed to the portal inflow. The LS images confirm the diagnosis of alcoholic CLD, showing splenomegaly and hypertrophy of the LLL, with a normal aspect of the spine. Normal LS aspect of the medial area of the RLL suggests a subacute stage of the BCS, without cirrhotic changes of the affected parenchyma. PSS were not open, as the tracer arrived at the RH by passing through the liver. The LAS curve on the medial segments of the RLL is significant for arterial-venous shunts. The differential diagnosis accounted for the value of LTT and missing of the HABR, excluding a portal branch obstruction.

BCS with old obstruction of one HV and recent obstruction of the other two HVs

The patient presented in Figures 3 and 4 was a 32-year-old male, without a previous diagnosis of CLD. The patient complained of flatulence, vomiting and severe abdominal pain which had started several weeks earlier. US highlighted ascites and venous dilations. No blood flow in the HVs and no portal thrombosis were observed at the US, while numerous intrahepatic arterial-venous and venous-venous collaterals were described. Esophageal varices and gastric injuries were not seen on endoscopy.

The summed image at PRPS presents a sharply increased radioactivity on the CL area (Figure 3A). The LLL only has arterial inflow, receiving tracer after the RH with a delay equal to RHLT (Figure 4B). This suggests an old obstruction of the LHV, with chronic alteration of perfusion of the LLL. The clinical onset in this case resulted from a recent obstruction of the RHV and MHV, while the LHV had been obstructed for a long time. The PRPS curve on the RLL has low slopes on

Figure 3 Budd-Chiari syndrome with old obstruction of the left hepatic vein and recent obstruction of the middle and right hepatic veins. A: Per-rectal portal scintigraphy; B: Liver angioscintigraphy; C: Liver scan.

the initial portal segment and on the AUI, showing that its portal and arterial inflows were decreased. The differential diagnosis excluded portal obstruction, accounting for small arterial inflow of the two liver lobes and missing the HABR.

Arrival of tracer to the RH at 30 s after entering into the CL shows that PSS were not open due to the earlier obstruction of one HV and the recent obstruction of the other two HVs (Figure 4). The tracer was detected in the RLL about 12 s after the CL, a slow portal inflow to the RLL being maintained.

Altered flow of the RLL was highlighted at the LAS (Figure 3B). After a short initial interval of about 1 s with normal arterial input, the LAS curve flattens on the rest of the arterial segment and has a low slope on the portal segment. The flattened curve on the RLL highlights the higher dynamic resistance encountered by the arterial inflow.

The ASH curve of the CL has an initial abrupt and high segment, due to the increased arterial inflow, followed by a flat portal segment and then by fluctuations of amplitude suggesting arterial-venous shunts (Figure 3B). The CL has a very high entering of portal tracer at the PRPS (Figure 4A). LTT on the CL is increased to 30 s due to the dynamic resistance opposed by the supplementary arterial and portal flows redirected from the RLL and LLL. The high amplitude of the PRPS curve on the CL was determined by the increased and slowed portal inflow. LS (Figure 3C) revealed increased radioactivity in the CL, inhomogeneous liver parenchyma and slightly increased radioactivity in the spleen.

The perfusion changes in the LLL and RLL suggest a subacute stage of the BCS. We underline that the old obstruction of the LLL together with more recent occlusion of the other two HVs did not open PSS. The arterial and portal blood flow of the whole liver was drained to the IVC through the CL.

Figure 4 Per-rectal portal scintigraphy in Budd-Chiari syndrome with old obstruction of the left hepatic vein and recent obstruction of the middle and right hepatic veins. A: Caudate lobe curve; B: Left lobe curve; C: Right lobe curve; D: Heart curve.

BCS started by the common obstruction of two HVs, also followed by old obstruction of the third HV

The scintigraphy investigations in a patient with BCS with an old obstruction of the MHV and RHV and subsequent but also old obstruction of the LHV are presented in Figures 5 and 6. This 20 year old woman, a user of an oral contraceptive, was hospitalized with an impaired general condition and abdominal pain. The first symptoms appeared two and a half years earlier when the BCS was diagnosed. US at admission showed abundant ascites and PV dilation to 15 mm. Doppler US could not detect flow in the HVs.

The RLL received tracer at PRPS at a time interval equal to RHLT after the RH, emphasizing that the portal inflow was missing and the blood supply of the RLL came from the HA only (Figures 6C, D).

The tracer entered the LLL and the CL (Figure 6A, B) at about 25 s after reaching the RH, showing that their perfusion was mainly (but not completely) arterial. The

initial low slopes of the CL and LLL curves were caused by increased resistance opposed to the portal inflow. The high slope of the AUI on the CL and LLL curves was determined by the large quantity of tracer that arrived through the HA. The slope of the AUI is smaller on the RLL than on the LLL and CL curves with about 50% (Figure 6C). Due to the older impairment of the RLL, its arterial perfusion per unit of area became lower than for the LLL and CL.

PSS were open, allowing the tracer absorbed from rectum to arrive faster to the RH than to the liver. The presence of the IVC on the summed PRPS image suggests the existence of open per-rectal PSS.

The ASH curve on the CL has a steep and biphasic entrance during the arterial segment. The portal phase has a drop in amplitude and subsequent fluctuations (Figure 5B). Increased arterial perfusion and existence of arterial-venous shunts are highlighted in the CL. The high arterial inflow suggests that the CL maintained part of its role of intrahepatic shunt to the IVC for the arterial inflow redirected from the rest of the liver. The ASH curve on the RLL shows increased arterial perfusion and reverse portal flow, with HPI = 115%.

The CL is visible on the LS, contrasting to the low colloid capture in the RLL (Figure 5C). The normal LS aspect of the spine and spleen argues against alcoholic or viral cirrhosis.

BCS with old obstruction of two HVs followed by recent obstruction of the third HV

We encountered one case of the BCS syndrome with old RHV and MHV obstruction and very recent occlusion of the LHV. One of these patients was a 32-year-old woman, an oral contraceptive user, with ascites in high quantity, increasing abdominal girth and without viral or alcoholic cirrhosis.

The time interval at PRPS (Figure 7) between the dynamic curves built on the heart and on the whole liver is equal to RHLT, showing that both the LLL and RLL missed portal inflow and the extrahepatic PSS of high flow were open. The high initial slope of the PRPS curve on the heart confirms that the PSS were hemodynamically efficient.

The highly increased radioactivity in the congested LLL on the summed PRPS image suggests that its deprivation of physiological venous drainage was very recent, while the obstruction of the MHV and RHV was old. The CL cannot be specifically distinguished on the PRPS summed image or by building dynamic curves on its area, therefore not playing a specific hemodynamic role. The image of the spleen on the summed PRPS image suggests inversion of flow in the splenic vein, while presence of the IVC suggests open per-rectal shunts.

BCS with acute onset by simultaneous obstruction of all three HVs (occlusion of terminal portion of the IVC)

Two of the BCS patients in our study had fulminant symptoms. US and CT scans argued for obstruction of

Figure 5 Budd-Chiari syndrome with old obstruction of the middle and right hepatic veins also followed by old obstruction of the left hepatic vein. A: Per-rectal portal scintigraphy; B: Liver angioscintigraphy; C: Liver scan.

the terminal portion of the IVC in both of them. The data shown in Figure 8 belong to a 39-year-old woman with myeloproliferative disease, admitted for recently appeared severe pain in the upper right abdominal quadrant, with vomiting and encephalopathy signs. US and CT scans showed abundant ascites and significant dilation of the HVs.

PRPS highlights a sharp increase of the transit time of the tracer from entering into the liver to reaching the RH, up to values over 50 s. The amount of tracer passing through the heart during the first 30 s after its arrival was very low, with a flattened PRPS cardiac curve. The normal slope of the PRPS curves built on the liver lobes

show that the dynamic resistance encountered by the portal flow was not significantly increased. The very late arrival to the RH of a small quantity of tracer was determined by the slow transit through the PSS open to the superior vena cava. PRPS highlights the completely blocked venous outflow on the physiological pathway between the liver and the RH, involving all the HVs. The slow flow through the PSS suggested that the obstruction of the terminal portion of the IVC had been recently installed.

DISCUSSION

We propose a new method to assess the liver hemodynamics

Figure 6 Per-rectal portal scintigraphy in Budd-Chiari syndrome with old obstruction of the middle and right hepatic veins also followed by old obstruction of the left hepatic vein. A: Caudate lobe curve; B: Left lobe curve; C: Right lobe curve; D: Heart curve.

in the BCS by performing the PRPS and LAS, with auxiliary use of the LS. PRPS is the main investigation, based on the parameters introduced by us, LTT and RHLT, offering information about the portal and arterial flows and the effects of the venous outflow obstruction.

The liver areas missing portal inflow with only arterial perfusion are highlighted at PRPS based on the time interval equal to RHLT between the origins of cardiac and liver curves. The increased arterial perfusion of a liver area causes a high slope of the AUI at PRPS and HPI > 45% at LAS. In old obstructions of the HVs, PRPS shows decreased portal and arterial flows of the parenchyma without venous outflow. In recent obstructions of the HVs, PRPS detects small or inverted portal flow, increased arterial inflow and accumulation of radioactivity on the summed image in the affected area. A high quanti-

ty of radiotracer appears on the summed PRPS image in the CL of the patients with recent common occlusion of two HVs. Inverted flow in the splenic vein is suggested by a visible spleen on the summed PRPS image.

ASH is useful in the differential diagnosis between the BCS and portal obstructions and also in highlighting arterial-venous shunts and increased resistance opposed to the arterial flow. Reverse portal flow is emphasized by HPI > 100%. LS was performed after ASH, showing increased radioactivity in the CL in particular types of BCS. LS aspect of the liver lobes, spleen and spine is useful when viral or alcoholic CLD is suspected.

Several hemodynamic varieties and stages of the BCS were described by using PRPS and LAS. Liver perfusion status is closely related to the initial number of obstructed HVs and to the lengths of occlusions. The category of the BCS debuted by obstruction of one HV included the patients actually affected by one obstructed HV and the patients affected by an old obstruction of one HV followed by recent obstruction of the other two HVs. For the BCS started by obstruction of two HVs we found different perfusion patterns in acute and chronic stages after the obstruction of the third HV. The BCS with acute onset due to the simultaneous obstruction of all the three HVs is commonly caused by obstruction of the terminal part of the IVC and specifically presents in the acute stage highly prolonged LTT at PRPS. Different hemodynamic patterns of the liver flows related to various types of hepatic venous occlusions underline the autonomous regulation of the perfusion of the two liver lobes.

It is important to know in all the varieties and stages of the BCS if PSS are open. PRPS highlighted that PSS were not open in patients with occlusion of one HV. The CL did not play a significant hemodynamic role in the subacute stage of such patients, suggesting that the blood flow redirected from the area without physiological venous outflow was drained through the unaffected HVs. PSS were not open even in the acute stage after common obstruction of two HVs following an old obstruction of the other HV.

Open PSS were emphasized in our cases with old obstruction of two HVs. This finding suggests that the outflow of two HVs is too high to be redirected in chronic stages only through the unaffected HV and through the CL, with having to leave the liver through extrahepatic PSS.

In acute stages after the occlusion of terminal part of the IVC, the PSS draining the blood to the superior vena cava allowed only a low speed flow. Our data suggest that spontaneous effective drainage through PSS requires at least several weeks to open after the obstruction of two or three HVs.

Hypertrophy of the CL is currently underlined in the diagnosis of the BCS. However, the hemodynamic role of the CL looks to be unimportant or transient in several varieties and stages of the BCS. The CL was not involved as an intrahepatic shunt in asymptomatic pa-

Figure 7 Per-rectal portal scintigraphy of a patient with Budd-Chiari syndrome with old obstruction of the middle and right hepatic veins and recent obstruction of the left hepatic vein.

Figure 8 Per-rectal portal scintigraphy in Budd-Chiari syndrome with obstruction of the terminal part of the inferior vena cava. A: Left lobe curve; B: Right lobe curve; C: Heart curve.

tients with obstruction of one HV and in IVC obstructions. In the patients with chronic obstruction of two HVs, the CL had a reduced role of a hemodynamic shunt for part of the arterial flow redistributed from affected areas, presenting arterial-venous collaterals. The CL was highly active in the subacute stage after the obstruction of two HVs following an old occlusion of the third HV. Our study suggests that the CL usually plays an efficient hemodynamic role of intrahepatic shunt to the IVC in

acute or subacute stages and in particular varieties of the BCS. The importance in each case of the caliber and morphology of the CL venous drainage for its functioning as hemodynamic shunt has also to be accounted for.

Due to the rarity of the disease, we did not explore several other theoretical varieties of the BCS so our classification will have to be detailed. Common obstruction of the LHV and MHV, acute stage after the debut of the BCS by obstruction of one or two HVs, and chronic stage after the occlusion of the terminal part of the IVC may bring more information about the opening of PSS and the role of the CL in draining the redirected flows.

To conclude, PRPS associated with LAS are able to play a useful role as second line investigations in the BCS, adding important data to the US, CT or MRI findings. These scintigraphic procedures have reliable costs, are non-invasive and easily reproducible. The accuracy of the method, however, is dependent on the operator's expertise.

ACKNOWLEDGMENTS

COMMENTS

Background

Impaired liver perfusion in the Budd-Chiari syndrome is determined by the obstruction of the hepatic blood outflow. Portal and arterial altered flows may be properly explored by combined use of two nuclear medicine dynamic investigations, per-rectal portal scintigraphy and liver angioscintigraphy. Radioisotope techniques allow a more precise diagnosis in different types and stages of the Budd-Chiari syndrome and highlight the changes of perfusion patterns during evolution of the disease.

Research frontiers

Scintigraphy investigations proposed by us to explore the Budd-Chiari syndrome highlight open portosystemic shunts, liver areas without portal inflow, hemodynamic involvement of the caudate lobe, inverted flow in the splenic or

portal vein and length of the obstructions of the hepatic veins or the terminal portion of the inferior vena cava. The authors described three hemodynamic categories of the Budd-Chiari syndrome with several subtypes and stages, based on the finding that perfusion changes depend on the initial number and succession in time of the hepatic veins obstructions.

Related publications

The authors previously described the use of dynamic nuclear medicine investigations to evaluate portal hypertension and portosystemic shunts in chronic liver disease. Clinical applications of the liver angioscintigraphy are commonly related to hepatic tumors evaluation.

Innovations and breakthroughs

The authors introduced a new method of interpretation for the per-rectal portal scintigraphy by proposing two new parameters, the transit time of the portal inflow through the liver and the transit time of the blood from the right heart to the liver. These time parameters allow an accurate description of hepatic hemodynamic changes determined by venous obstructions. The authors used liver angioscintigraphy in the differential diagnosis between the Budd-Chiari syndrome and portal obstructions, highlighting the absence of the hepatic artery buffer response in the Budd-Chiari syndrome. The authors showed that portosystemic shunts are not open after the obstruction of one hepatic vein, while at least several weeks are required in the obstructions of two or three hepatic veins for the spontaneous opening of dynamically efficient portosystemic shunts.

Applications

The hemodynamic data offered by per-rectal portal scintigraphy and angioscintigraphy of the liver are especially important for surgery and TIPS mounting. Diagnosis of the number, length and succession in time of hepatic veins obstructions allow identification of hemodynamic varieties and stages of the Budd-Chiari syndrome and support an adequate therapeutic approach.

Terminology

Per-rectal portal scintigraphy is a dynamic procedure performed by instillation into the rectum of a small quantity of radioactive tracer followed by recording its dynamics through the portal vein, liver and heart areas. Liver angioscintigraphy is performed by rapid antecubital intravenous bolus injection of a small quantity of radiotracer followed by recording its entrance into the liver through the hepatic artery and portal vein, allowing the assessment of an arterial to total liver perfusion (arterial plus portal) ratio. The Budd-Chiari syndrome is a vascular liver disease determined by hepatic venous obstruction localized from the small hepatic veins to the terminal part of the inferior vena cava, resulting in increased sinusoidal pressure, hepatic congestion and portal hypertension.

Peer review

This is a well thought and comprehensive manuscript on the relevance of using PRPS and liver angioscintigraphy techniques to investigate the liver hemodynamics in Budd-Chiari syndrome. The manuscript provides useful and interesting information. It also has potential for clinical application.

ABOUT COVER   Editorial Board Member of *World Journal of Hepatology*, Jen-Jung Pan, MD, PhD, Assistant Professor, Division of Gastroenterology, Hepatology and Nutrition, Department of Internal Medicine, The University of Texas Health Science Center at Houston, Houston, TX 77030, United States

AIM AND SCOPE   *World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

   WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

   We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING   *World Journal of Hepatology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

Abstract

Obesity is a global epidemic contributing to an increasing prevalence of obesity-related systemic disorders, including nonalcoholic fatty liver disease. The rising prevalence of nonalcoholic steatohepatitis (NASH) will in the near future lead to end-stage liver disease in a large cohort of patients with NASH-related cirrhosis and NASH is predicted to be a leading indication for liver transplantation in the coming decade. However, the prevalence of obesity and the progression of hepatic histological damage associated with NASH exhibit significant ethnic disparities. Despite a significantly lower body mass index and lower rates of obesity compared to other ethnic groups, Asians continue to demonstrate a significant prevalence of hypertension, diabetes, metabolic syndrome and NASH. Ethnic disparities in central adiposity and visceral fat distribution have been hypothesized to contribute to these ethnic disparities. The current review focuses on the epidemiology of obesity and NASH among Asian populations.

Core tip: Non-alcoholic fatty liver disease (NAFLD) is rapidly becoming a major contributor of chronic liver disease worldwide. The increasing prevalence of NAFLD among Asians reflects both an increasing awareness and diagnosis and the increasing risk of obesity and obesity-related diseases among this population. Ethnic disparities in the impact of weight gain on the development of obesity-related diseases is especially important for Asian populations, who have greater rates of central obesity and visceral deposition of fat and therefore are at greater risk of obesity-related diseases, such as NAFLD, at a lower body mass index.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) spans a spectrum of liver diseases that ranges from simple steatosis of the liver to progressive inflammation and fibrosis, resulting in non-alcoholic steatosis (NASH) and cirrhosis[1]. While the definition of NAFLD relies heavily on the clinical exclusion of significant alcoholic liver disease as well as other concomitant chronic liver diseases that can mimic similar histopathological features, one of the major hallmark features of NAFLD is the consistent association with type 2 diabetes mellitus, hypertension, hyperlipidemia and obesity[1-5]. The rising epidemic of obesity and obesity-related diseases in many post-industrialized countries has been accompanied by a concurrent rise in

the prevalence of NAFLD. These emerging trends along with our better understanding of the pathophysiology of NAFLD clearly highlight the important role of obesity and obesity-related diseases in the increasing prevalence of NAFLD.

Several studies have reported the alarming increase in obesity and metabolic syndrome in western countries[6-12]. One recent large population-based study in the United States, utilizing data from the National Health and Nutrition Examination Surveys from 2009-2010 (NHANES), reported obesity rates of 35.5% among men and 35.8% among women[7]. Furthermore, population based studies utilizing United States census based data have demonstrated a concurrent rise in the prevalence of obesity-related diseases, such as hypertension and diabetes mellitus[13-18]. Among the same population, several studies have reported an increasing prevalence of NAFLD, suggesting that the rising rates of NAFLD are a consequence of the rising rates of obesity and metabolic syndrome in these populations. In fact, a recent study by Charlton *et al*[19] estimates that the rising prevalence of NAFLD in the United States population will soon lead to large cohorts of patients with decompensated cirrhosis from NASH and that NASH will soon become the leading indication for liver transplantation in the United States.

However, the epidemiology of obesity and obesity-related diseases demonstrates significant ethnic disparities. For example, several studies among both western and eastern cohorts demonstrate that Asians as a group consistently have a much lower body mass index (BMI) compared to other ethnic groups[20-23]. The relatively lower BMI is not protective in Asians. The rates of hypertension and diabetes mellitus, while somewhat lower, still continue to demonstrate rising trends among Asians[20]. In addition, cohort studies have demonstrated that despite having significantly lower BMI than other ethnic groups, Asians have a surprisingly high prevalence of NAFLD[24]. While not entirely elucidated, one emerging theory for this discrepancy between BMI and NAFLD prevalence may result from ethnic differences in the distribution of body fat, with more central adiposity and visceral fat deposition reported among individuals of Asian ethnicity[25-29]. Nevertheless, the increasing prevalence of obesity, metabolic syndrome and NAFLD among the Asian population will contribute to a large burden of chronic disease. The current paper reviews the concerning rise in obesity and NAFLD, with a focus on Asian populations.

OBESITY DISPARITIES

The global obesity epidemic has been associated with the increasing burden of obesity-related diseases such as coronary artery diseases, hypertension and diabetes mellitus[9-12]. In addition, a link has been established between obesity and NAFLD such that obesity increases the risk of progression of hepatic inflammation and fibrosis leading to NASH-related cirrhosis. However, one emerging theme in the study of obesity is the ethnic disparities in the prevalence of obesity as well as the impact of weight gain on the overall risk of obesity-related diseases.

Several studies have reported ethnic disparities in the prevalence of obesity, with higher obesity rates in minority groups such as blacks and Hispanics[20,30-34]. However, Asians as a group generally have a lower BMI and lower prevalence of obesity compared to other ethnic groups[20-23]. Despite lower obesity prevalence, higher rates of metabolic syndrome have been reported in Asians compared to other ethnic groups at similar BMI levels[20]. These findings demonstrate that BMI thresholds for defining overweight and obesity should not be applied uniformly to all ethnic cohorts.

Current BMI categories set forth by the United States Centers for Disease Control and Prevention (BMI > 25 kg/m^2 as overweight and BMI > 30 kg/m^2 as obese) were intended to predict an individual's risk of developing diseases associated with overweight and obese categories[35]. Two large population-based longitudinal studies, the San Antonio Heart Study and the Insulin Resistance Atherosclerosis Study, demonstrated a strong association of BMI with the risk of metabolic syndrome. Obese individuals (BMI > 30 kg/m^2) were three to eight times more likely to develop metabolic syndrome compared to individuals with BMI < 25 kg/m^2[31,36]. In addition, the association of obesity and metabolic syndrome with development of complications such as cardiovascular disease and diabetes mellitus is well established[37-40]. However, similar to ethnic disparities in the prevalence of obesity, the correlation of BMI with obesity-related diseases is not uniform across all ethnicities. For example, using data from NHANES, Palaniappan *et al*[30] demonstrated that fasting insulin levels, a marker of insulin sensitivity and risk of diabetes, was 19%-26% higher in blacks and 17-22% higher in Hispanics when compared to non-Hispanic whites with similar BMI. This disparity was also noted among Asians, with one study demonstrating significantly higher rates of metabolic syndrome in Asians compared to other ethnic groups with similar BMI. For example, Palaniappan *et al*[20] demonstrated that the predicted prevalence of metabolic syndrome in non-Hispanic white women aged 55 years with BMI 25 kg/m^2 was 12% compared to 30% in Asians with similar demographics and BMI. Furthermore, compared to white men with BMI 25 kg/m^2, comparable prevalence of metabolic syndrome was seen in Asian men with BMI 19.9 kg/m^2.

Using data from the California Department of Public Health and the United States Centers for Disease Control and Prevention, our group performed an in-depth analysis of ethnic disparities in obesity and obesity-related diseases with a focus on Asian populations. From 1985 to 2011, Asians as a group had the lowest BMI and lowest obesity prevalence (Asians: 22.6 ± 3.3 kg/m^2 in 1985-1990 to 24.4 ± 4.3 kg/m^2 in 2006-2011; non-Hispanic whites: 24.2 ± 4.1 kg/m^2 in 1985-1990 to 26.7 ± 5.5 kg/m^2 in 2006-2011; blacks: 25.4 ± 4.5 kg/m^2 in 1985-1990 to 29.0

Figure 1 Trends in body mass index over time stratified by ethnicity, 1985-2011, California behavioral risk factor survey database.

$\pm$ 6.9 kg/m^2 in 2006-2011; Hispanics: 25.0 $\pm$ 4.1 kg/m^2 in 1985-1990 to 28.3 $\pm$ 5.8 kg/m^2 in 2006-2011) (Figure 1). Despite lower overall BMI, Asians had comparable or even higher rates of hypertension and diabetes mellitus compared to other ethnic groups. To evaluate whether weight gain as measured by BMI affected ethnic groups similarly, we created a multivariate logistic regression model to assess the effect of each one unit increase in BMI on the risk of hypertension or diabetes mellitus (Table 1). In our cohort model, each one unit increase in BMI was associated with 15% increased risk of hypertension in Asians, compared with 11% increase among non-Hispanic whites and 8% increase among blacks and Hispanics. When evaluating the impact of weight gain on the risk of diabetes mellitus, each one unit BMI was associated with 15% increased risk of diabetes mellitus among Asians, compared to 11% increase among non-Hispanic whites, 7% increase among blacks and 8% increase among Hispanics. These data suggest that despite having lower BMI, weight gain as measured by BMI disproportionately affects Asians to a greater degree. Furthermore, similar risks of hypertension and diabetes mellitus among non-Hispanic whites and blacks were seen in Asians at significantly lower BMI. For example, risks of hypertension among Asians with BMI > 22 kg/m^2 were similar to non-Hispanic whites with BMI > 27 kg/m^2 and blacks with BMI > 28 kg/m^2 (Figure 2). While many theories have been proposed to explain these disparities, ethnic differences in body fat distribution may be a major contributing factor. Previous studies evaluating the correlation of BMI with percentage body fat demonstrated that blacks generally have more lean mass and less fat mass compared to whites. In contrast, Asians have more central adiposity and visceral fat distribution, which carries a greater risk of developing cardiovascular and metabolic diseases[25-29].

Acknowledging these disparities, several studies have suggested that current thresholds for defining obesity and overweight in Asians may not accurately reflect the risk of developing obesity-related diseases and BMI thresholds should be lowered for Asian cohorts[41,42]. In 2000, the World Health Organization Western Pacific Regional

Office proposed a lower cutoff of BMI > 25 kg/m^2 for obesity in Asian populations[43]. Several Asian countries have begun to adopt this modified BMI categorization[44-46]. Additional studies have attempted to incorporate additional anthropometric tools to better stratify the risk of metabolic diseases among Asians. Using a cross sectional population-based survey study of 2947 patients in China, Shao *et al*[47] demonstrated that waist-height ratio was significantly better at predicting risk of metabolic syndrome than BMI or waist circumference alone. Liu *et al*[48] performed a similar evaluation among a cross sectional cohort of 772 Chinese patients. BMI, waist circumference and waist-hip ratio were found to have similar predictive power for risk of metabolic diseases, such as hypertension, diabetes mellitus and dyslipidemia. While solely relying on BMI to predict risk of obesity-related diseases such as NAFLD has several limitations, these additional complementary anthropometric tools may improve risk stratification.

DISPARATE ASSOCIATION OF NAFLD AND BMI

While studies in western populations clearly indicate that NASH will be a leading cause of chronic liver disease, less is known about the epidemiology of NAFLD among Asian populations. Recent community-based studies from Asian countries, including Japan, China, Taiwan, and Korea, indicate that the overall NAFLD prevalence reaches as high as 45% with year-specific analyses, demonstrating a continued rise in NAFLD prevalence with time[49-55]. Additional studies from the Asia-Pacific region demonstrated similar trends of NAFLD prevalence in India, Malaysia, Singapore and Indonesia[56-62]. Wong *et al*[63] performed a large cross-sectional study in Hong Kong to assess the community prevalence of NAFLD using proton nuclear magnetic resonance (p-NMR) spectroscopy. A total of 922 patients randomly selected from the Hong Kong census database without chronic liver disease completed a full clinical assessment. Among this cohort, p-NMR was utilized to measure intrahepatic triglyceride content with a cutoff of 5% used to distinguish patients with and without fatty liver disease. Transient elastography was also utilized to assess for hepatic fibrosis with a cutoff of 9.6 kPa to define advanced fibrosis. Overall, the cohort was 42.2% men and average BMI was 22.8 $\pm$ 3.5 kg/m^2. A total of 264 patients (26.8%) met the cutoff for diagnosis of fatty liver disease. Average BMI among the fatty liver disease cohort was 25.3 $\pm$ 3.4 kg/m^2 and among the non-fatty liver disease cohort was 21.8 $\pm$ 3.0 kg/m^2. Prevalence of advanced fibrosis was 3.7% (*n* = 8) and 1.3% (*n* = 7) among fatty liver and non-fatty liver cohorts, respectively. A similar study was performed in Shanghai that included 3175 adults that assessed for prevalence of metabolic syndrome using criteria from the National Cholesterol Education Program - Adult Treatment Panel Ⅲ and for fatty liver with ultrasonography[64]. Overall, 22.9% and 20.8% of individuals had metabolic

Table 1 Increased odds of hypertension and diabetes associated with one unit increase in body mass index						
	Hypertension			Diabetes		
	OR	95%CI	*P* value	OR	95%CI	*P* value

Hispanic	1.08	1.07-1.09	< 0.001	1.08	1.07-1.09	< 0.001

Figure 2 Odds of (A) hypertension and (B) diabetes by ethnicity and body mass index categories.

syndrome and fatty liver, respectively. The risk for fatty liver was increased among patients with abdominal obesity (waist circumference > 90 cm in men and > 80 cm in women: 32.8-fold increase), diabetes mellitus (31.6-fold increase), dyslipidemia (22.6-fold increase) and hypertension (22.3-fold). Patients that met the diagnostic threshold for metabolic syndrome had a nearly 40 times increased risk for fatty liver. When stratified by BMI, those with fatty liver disease and BMI < 25 kg/m^2 had 36.1% prevalence of metabolic syndrome. Furthermore, the presence of fatty liver disease was found to have the best positive predictive value and attributable risk percentage in detecting risk factor clustering for metabolic syndrome.

Variations in fat distribution have been implicated as one potential reason for disparate associations between BMI and NAFLD prevalence among Asian populations. It has been previously reported that the percent body fat as well as fat distribution differs significantly among Asian and non-Asian populations, such that greater central and visceral adiposity is commonly seen in Asians[25-29]. It has also been implied that as a result of this disparate distribution of fat, excessive amounts of visceral adipose tissue may occur in Asians not overweight or obese using BMI cutoffs. Greater central adiposity distribution is associated with higher risks of cardiovascular disease and metabolic syndrome[65-67]. Furthermore, ideal body weight may be different among different ethnicities and different world regions, such that while an individual does not meet BMI threshold for obesity, he may be significantly heavier than ideal body weight, and this translates into increased risk of insulin resistance and metabolic syndrome[68-70]. For example, Chang *et al*[68] performed a prospective South Korean study of 15,347 men to assess ultrasound-based diagnosis of fatty liver disease. Even among men with BMI 18.5-22.9, mild weight gains

of 0.6 to 2.3 kg were associated with 38%-73% increase in the risk for fatty liver disease. This phenomena, termed "metabolically obese", namely the increased risk of insulin resistance, metabolic syndrome and NAFLD despite normal or lean BMI, has been more commonly seen in Asian populations[68-70].

Another potential theory that may partially contribute to the rising prevalence of NAFLD among Asian populations centers on the role of diet. Carbohydrates in the form of rice are a central component of the Asian diet. However, significant amounts of carbohydrates in the diet can lead to accumulation of triglycerides within the liver, which is mediated by glucose stimulated activation of the liver transcription factor, carbohydrate responsive element-binding protein (ChREBP). This process over time leads to significant hepatic steatosis and eventual progression of disease towards NASH[71-73]. However, the impact of ChREBP on hepatic steatosis among individuals with significant carbohydrate exposure may not necessarily correlate with development of insulin resistance. A recent study by Benhamed *et al*[74] evaluated ChREBP over expressing mice fed a standard diet, demonstrating that despite having increased expression of genes involved in lipogenesis/fatty acid esterification and resultant hepatic steatosis, the mice remained insulin sensitive. In addition, ChREBP over expressing mice fed a high-fat diet also showed normal insulin levels and improved insulin signaling and glucose tolerance compared with controls, despite having greater hepatic steatosis.

NATURAL HISTORY OF NAFLD IN ASIANS

The progression of inflammation and fibrosis in patients

with NAFLD is not believed to differ significantly by ethnicity. However, some earlier studies have suggested that NAFLD may be less severe with slower progression among Asian populations[75,76]. This hypothesis is complicated by several potential confounding factors. NAFLD is a relatively more recent phenomenon in Asian countries and the expected progression of disease leading to cirrhosis may occur over the next several decades. Thus, the emergence of fatty liver disease observed in the recent era in Asian populations probably lags behind western populations by several decades and the impact of large cohorts of patients with chronic liver disease and cirrhosis from NASH is expected to flood our health care system in the coming years. Another potential contributing factor is the increasing awareness and subsequent diagnosis of NAFLD among these Asian Pacific regions. Furthermore, the previously reported disparate association between BMI and metabolic syndrome that results from ethnic disparities in central adiposity and visceral fat distribution may alter the natural history of NAFLD among this population.

Despite these potential caveats, it is generally agreed that the progression of disease among patients with simple steatosis is slow compared with other diseases, such as hepatitis C virus (HCV), whereas patients with histological evidence of NASH can progress more rapidly towards advanced fibrosis and cirrhosis[1,2,77]. Long-term longitudinal studies have demonstrated increased mortality among patients with both NAFLD and NASH when compared to controls without underlying liver disease[78-86]. Interestingly, the most common cause of death among patients with NAFLD and NASH was cardiovascular diseases, reflecting the close correlations of NAFLD with metabolic syndrome and cardiovascular disease outcomes. However, simple steatosis is not always benign and progression of disease, while slow, can occur. In a single centered Hong Kong cohort, Wong *et al*[87] conducted a prospective longitudinal study of 52 patients with biopsy proven NAFLD. Among patients with simple steatosis on histology at baseline (n = 13), 15% had normal histology, 23% still had simple steatosis and 62% had evidence of histological progression towards NASH at 36 mo. While the small sample size may limit the generalization of these findings, this study raises awareness of the dynamic nature of steatosis and that simple steatosis is not necessarily benign and may warrant closer follow up.

However, progression of NAFLD to NASH-related cirrhosis is clearly associated with increased risks of hepatic decompensation and liver-related mortality[88-91]. Hui *et al*[88] performed a prospective longitudinal cohort study of 23 patients with clinically/pathologically confirmed NASH-related cirrhosis compared with 46 age and gender matched HCV-related cirrhosis patients. Over a median follow up of 60 mo (range 5-177 mo), 9/23 NASH-related cirrhosis patients developed hepatic decompensation (8 with ascites or encephalopathy, 1 with variceal bleeding). The overall survival at 1, 3, and

10 years was 95%, 90% and 84%, respectively. After multivariate regression modeling, there was no significant survival difference between the NASH-related cirrhosis and HCV-related cirrhosis cohorts. A larger United States study compared 152 patients with NASH-related cirrhosis to 150 matched patients with HCV-related cirrhosis[89]. Over 10 years of follow up, NASH patients had significantly lower mortality compared to HCV patients but this mortality difference was primarily seen in patients with Child Pugh Turcotte (CPT) class A cirrhosis. Among patients with CPT class A cirrhosis, NASH patients had significantly lower rates of hepatic decompensation, development of ascites and hepatocellular carcinoma (HCC). Similar findings were reported in a large multi-center international study of 247 patients with advanced fibrosis or cirrhosis secondary to NASH compared to 264 chronic HCV patients with similar stages of fibrosis[91]. Among the NASH cohort, there were 19.4% liver-related complications and 13.4% deaths or liver transplantation over a mean follow up of 85.6 mo. Among the HCV cohort, there were 16.7% liver-related complications and 9.4% deaths or liver transplantations over a mean follow up of 74.9 mo. After adjusting for differences in baseline characteristics, cumulative incidence of liver-related complications was significantly lower in the NASH group compared to the HCV group. However, the incidence of cardiovascular events and overall mortality was not significantly different between NASH and HCV cohorts. The results of these studies indicate that while progression of NAFLD towards NASH cirrhosis is clearly associated with increased risks of hepatic decompensation and mortality, these increased risks may not be as high as that seen among the cohort of chronic HCV cirrhosis patients.

NAFLD AND HCC

While the risks of HCC from chronic liver disease secondary to hepatitis B and HCV are better defined, the risk of HCC among patients with NASH is less well known. NASH-related HCC occurs primarily in the setting of hepatic cirrhosis[1,92-95]. A large retrospective cohort study from South Korea evaluated 329 patients with fatty liver disease associated HCC and demonstrated an increase in NAFLD-related HCC from 3.8% in 2001-2005 to 12.2% in 2006-2010[96]. A United States based study evaluated 195 NASH-cirrhosis patients from 2003-2007 with serial abdominal computed tomography and serum alpha-fetoprotein every 6 mo with a median follow up of 3.2 years[97]. Among this cohort for NASH-related cirrhosis patients, 12.8% (n = 25) developed HCC with an annual cumulative HCC incidence of 2.6%. Several additional studies, both in western and Asia-Pacific regions, report on the progression of NASH-related cirrhosis towards HCC but this rate of progression is significantly lower than that seen among patients with cirrhosis secondary to chronic HCV. Yasui *et al*[98] prospectively evaluated 412 NAFLD patients from 1990 to 2006. Among this cohort,

Table 2 Etiology of liver disease among liver transplantation recipients in the United States, 1992-2012, United Network for Organ Sharing database *n* (%)

Liver disease etiology	Pre-MELD (1992-2002)	Post-MELD (2003-2007)	Post-MELD (2008-2012)
Acute liver failure	2390 (7.9)	1639 (6.9)	1285 (5.1)
Chronic HCV	9248 (30.7)	7970 (33.5)	7803 (31.2)
Chronic HBV	1419 (4.7)	802 (3.4)	604 (2.4)
HCC	466 (1.6)	1714 (7.2)	3423 (13.7)
ALD	5027 (16.7)	3704 (15.6)	3636 (14.6)
ALD + HCV	2495 (8.3)	1845 (7.8)	1529 (6.1)
NASH	8 (0.1)	796 (3.3)	2162 (8.7)
AIH	1277 (4.2)	715 (3.0)	693 (2.8)
Cryptogenic	3460 (11.5)	2115 (8.9)	1634 (6.5)
PBC	1992 (6.6)	1009 (4.2)	795 (3.2)
PSC	1648 (5.5)	1 (4.3)	922 (3.7)
Metabolic	729 (2.4)	478 (2.0)	491 (2.0)

Metabolic includes Wilson disease, alpha-1 antitrypsin disease and hemochromatosis. MELD: Model for end stage liver disease; HCV: Hepatitis C virus; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; ALD: Alcoholic liver disease; NASH: Non-alcoholic steatohepatitis; AIH: Autoimmune hepatitis; PBC: Primary biliary cirrhosis; PSC: Primary sclerosing cholangitis.

68 patients with NASH-related cirrhosis were compared with 69 age and sex matched HCV-related cirrhosis patient controls to determine HCC risk. Overall, the 5-year cumulative HCC rate was 11.3% for NASH patients and 30.5% for HCV patients. This lower HCC risk among NASH-related cirrhosis patients compared with HCV-related cirrhosis patients was confirmed in additional studies.

While the majority of NASH-related HCC occurs in patients with cirrhosis, several studies have reported HCC development among non-cirrhotic NASH patients, with one Japanese study reporting rates of non-cirrhotic NASH-related HCC ranging from 10%-75% of cases[97-101]. The exact etiology for this non-cirrhotic pathway towards HCC is unclear. However, studies have demonstrated that obesity and diabetes mellitus, both of which are closely associated with NAFLD, are independently associated with increased risk of HCC among patients with chronic liver disease[102-104]. Furthermore, Welzel *et al*[105] utilized the National Cancer Institute's Surveillance, Epidemiology and End Results-Medicare database to evaluate the impact of metabolic syndrome on overall HCC risk among the general United States population. Among a cohort of 3649 HCC cases and 195953 comparison cohort, metabolic syndrome (as defined by National Cholesterol Education Program Adult Treatment Panel III criteria) was associated with a significantly increased risk of HCC (OR = 2.13, 95%CI: 1.96-2.13, $P < 0.0001$).

The implications of these findings on HCC screening among NAFLD patients are a major public health issue. While more studies evaluating the long-term HCC risk among patients with NASH-related cirrhosis are needed, it is reasonable to implement standard HCC screening programs in this cohort as one would for patients with cirrhosis from other chronic liver disease etiologies.

However, as with other chronic liver disease etiologies, only a fraction of NASH-related cirrhosis patients will develop HCC and the ability to better define the cohort of patients from those who will not develop HCC will be especially important in the management of this group of patients. More studies are needed to investigate risk factors for HCC development among this cohort that will allow a more targeted approach towards risk stratifications and earlier detection and treatment of HCC. However, the increasingly reported cases of HCC among non-cirrhotic NAFLD patients introduce an unexpected component to the commonly accepted pathogenesis of HCC. Clearly, these patients do not carry the same HCC risk as those patients with non-cirrhotic hepatitis B infection. However, what distinguishes those patients with non-cirrhotic NAFLD that develop HCC from those that do not? What are the important risk factors that should be incorporated into risk stratification models? How should HCC screening programs be implemented among this cohort? More studies are needed to better understand the risk factors associated with HCC development among NASH patients with and without cirrhosis.

NAFLD AND LIVER TRANSPLANTATION

The increasing prevalence of patients with NASH who develop cirrhosis and decompensated liver disease will undoubtedly lead to a major increase in the number of patients on the waiting list for liver transplantation. Several studies have already predicted that as a result of the obesity epidemic, the rising rates of NASH will become a leading indication for liver transplantation (Table 2)[19,106-108]. A recent study by Charlton *et al*[19] retrospectively evaluated liver transplantations in the United States from 2001-2009 utilizing a national liver transplantation database. This study demonstrated a significant increase in the proportion of patients undergoing liver transplantation for NASH from 1.2% in 2001 to 9.7% in 2009, making NASH the third leading indication for liver transplantation. Furthermore, the trajectory of increasing prevalence of NASH among liver transplantation recipients indicates that it will soon become the leading indication for liver transplantation. It has also been suggested that our current estimation of NASH prevalence is an underestimation, as many patients with cirrhosis secondary to cryptogenic cirrhosis may in fact be more accurately categorized as NASH. This hypothesis is supported by evidence demonstrating that cryptogenic cirrhosis patients share many similar characteristics to NASH patients, including risk factors associated with metabolic syndrome, and many patients with cryptogenic cirrhosis can in fact be more accurately categorized as NASH[109-113]. Furthermore, the outcomes associated with cryptogenic cirrhosis are also similar to those seen among patients with NASH[110-113]. Clearly, the rising prevalence of obesity and NASH patients who develop decompensated liver disease will soon become a significant cohort impacting the liver transplantation waiting list.

In Asia-Pacific regions, viral hepatitis and hepatocellular carcinoma are the leading indications for liver transplantation. Furthermore, unlike western countries, living donor liver transplantations play a more significant role in liver transplantation surgeries[114-116]. With the continued rising prevalence of NAFLD and NASH in this region, NASH may soon become a leading contributor of end stage liver disease and need for liver transplantation in the Asia-Pacific regions.

CONCLUSION

The global obesity epidemic is associated with the increasing prevalence of metabolic syndrome and NAFLD. This phenomenon will contribute to an increasingly large cohort of patients that will develop NASH-related cirrhosis, decompensated liver disease and HCC. The emergence of this cohort is on the horizon and will introduce a significant disease burden in the field of liver transplantation. However, there are significant ethnic disparities in the prevalence and association of obesity with development of NASH. Furthermore, it is not clear if the risk factors associated with development of NASH and progression to cirrhosis and HCC vary by ethnicity. Our current focus on Asian populations clearly indicate that despite having lower average BMI, Asians as a group still maintain significant risks of metabolic syndrome and NAFLD, resulting primarily from the disparately higher central adiposity and visceral fat distribution seen in this cohort. This may further contribute to relatively increased risk of NASH development. More studies are needed to identify factors that influence the ethnicity-dependent rate of hepatic histological damage and the risk of HCC in NASH patients.

Abstract

Due to the worldwide epidemic of obesity, nonalcoholic fatty liver disease (NAFLD) has become the most common cause of elevated liver enzymes. NAFLD represents a spectrum of liver injury ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) which may progress to advanced fibrosis and cirrhosis. Individuals with NAFLD, especially those with metabolic syndrome, have higher overall mortality, cardiovascular mortality, and liver-related mortality compared with the general population. According to the population-based studies, NAFLD and NASH are more prevalent in males and in Hispanics. Both the gender and racial ethnic differences in NAFLD and NASH are likely attributed to interaction between environmental, behavioral, and genetic factors. Using genome-wide association studies, several genetic variants have been identified to be associated with NAFLD/NASH. However, these variants account for only a small amount of variation in hepatic steatosis among ethnic groups and may serve as modifiers of the natural history of NAFLD. Alternatively, these variants may not be the causative variants but simply markers representing a larger body of genetic variations. In this article, we provide a concise review of the gender and racial differences in the prevalence of NAFLD and NASH in adults. We also discuss the possible mechanisms for these disparities.

Core tip: According to the population-based studies, nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) are more prevalent in males and in Hispanics. Both the gender and racial ethnic differences in NAFLD and NASH are likely attributed to interaction between environmental, behavioral, and genetic factors. In this article, we provide a concise review of the gender and racial differences in the prevalence of NAFLD and NASH in adults. We also discuss the possible mechanisms for these disparities.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is highly associated with obesity and insulin resistance (IR) and represents a spectrum of liver injury ranging from simple steatosis with a more benign course to nonalcoholic steatohepatitis (NASH) which may progress to advanced fibrosis and cirrhosis[1,2]. According to the National Health and Nutrition Examination Survey (NHANES), 33.8% and 23.7% of the United States (US) adults are obese and have metabolic syndrome, respectively[3,4]. Due to the worldwide epidemic of obesity, NAFLD has become the most common cause of elevated liver enzymes with

prevalence rates ranging from 2.8% to 46%[5,6]. Individuals with NAFLD and NASH, especially those with metabolic syndrome, have higher overall mortality, cardiovascular mortality, and liver-related mortality compared with the general population[7-9]. Liver cirrhosis secondary to NAFLD is now the second most common indication for liver transplantation in obese patients[10].

Among different racial and ethnic populations in the US, Hispanics (predominantly of Mexican origin) are at particular risk for NAFLD and tend to have a more aggressive disease course[11-20]. Hispanics accounted for nearly 50% of the US population growth from 2000 to 2010 and are projected to reach 30% of the US population within the next three decades[21]. Given the increasing prevalence and the expected growth in the Hispanic population, NAFLD poses a huge threat to the US health care system.

In this article, we provide a concise review of the gender and racial differences in the prevalence of NAFLD and NASH in adults. We also discuss the possible mechanisms for the racial/ethnic disparities, with a special focus on the Hispanics.

PREVALENCE OF NAFLD IN GENERAL POPULATIONS

The prevalence of NAFLD varies depending on the study population and the diagnostic tool used to determine the condition. The prevalence rates of NAFLD in the US based on population-based studies are summarized in Table 1. Most of these studies were based on the third NHANES (1988-1994) data. Defined as elevated alanine aminotransferase (ALT) and/or aspartate aminotransferase (AST), NAFLD was prevalent in 2.8%-5.4% of the US population[11,12,22]. From 1999 to 2002, the prevalence of NAFLD in the US further increased to 8.1%[15]. The differences of the prevalence between the two periods could be due to differences in assay methodology. Serum specimens were initially frozen after collection and then thawed prior to assay during the earlier period (1988-1994) whereas sera were only refrigerated before testing during the later time (1999-2002). Freezing

serum specimens to -20 ℃ has been shown to lead to a 46% loss of ALT activity, whereas refrigerating serum specimens to 4 ℃ only led to a 6% loss[23]. Therefore, more individuals could have been falsely stratified as having normal liver enzymes and hence lower prevalence of NAFLD in the earlier period. On the other hand, true differences may exist as there was an increase in the prevalence of predictors for elevated ALT such as higher body mass index (BMI) and waist circumference between the periods 1988-1994 and 1999-2002[15]. Nevertheless, studies relying on elevated liver enzymes probably underestimate the true prevalence of NAFLD as normal ALT level provides little diagnostic or prognostic value when assessing persons for NAFLD. In the Dallas Heart Study, 79% of the subjects with hepatic steatosis had normal ALT levels (defined as ALT ≤ 40 U/L for men and ≤ 31 U/L for women)[13].

Using ultrasonography as the diagnostic tool for NAFLD, recent studies reported prevalence rates of 18.8%-30.2% in the US (Table 1)[17-20]. Ultrasonography has been used in two studies to assess the prevalence of hepatic steatosis in non-US populations. The first study performed 25 years ago reported that fatty liver was found in 14% of the population in Okinawa, Japan[24]. The second study reported that NAFLD was present in 20% of the residents who live in Northern Italy (the Dionysos study)[25]. The lower prevalence of hepatic steatosis found in the Japanese study likely reflects the low frequency or absence of obese or diabetic subjects in the study cohort[13]. Despite being more sensitive than liver enzymes for the detection of NAFLD, ultrasonography has its own limitation due to a low sensitivity for detection of mild hepatic steatosis (less than 30%)[26]. Therefore, ultrasonography also likely underestimates the true prevalence of NAFLD in general populations. Using a more sensitive magnetic resonance spectroscopy technique for measuring fat content, 31% of the participants in the Dallas Heart Study had hepatic steatosis, defined as hepatic triglyceride content greater than 5.5%[13].

NAFLD occurs in non-obese and non-overweight (defined as BMI < 25 kg/m^2) persons as well. Based on the third NHANES data, 7% of the lean individuals have

NAFLD compared to 28% of the overweight-obese population[17]. In the Dionysos study, hepatic steatosis on ultrasound was present in 16% of the non-obese participants[27]. In a Japanese study, ultrasonographic fatty liver was found in 11.2% of non-obese persons during voluntary health check-up[28].

PREVALENCE OF NASH IN GENERAL POPULATIONS

Liver biopsy is the current suboptimal standard for the diagnosis and staging of NASH, but invasiveness and cost preclude its use as a screening tool in general populations[29]. The population prevalence of NASH has therefore been difficult to establish since it is unethical to biopsy asymptomatic persons in the community. Among 351 apparently nonalcoholic patients, a Canadian autopsy study from the late 1980s found that NASH was present in 2.7% of lean patients and in 18.5% of markedly obese patients[30]. More recently, two Asian studies reported similar prevalence of NASH in 1.1%-2.2% of living donors before liver transplantation[31,32]. Based on the third NHANES data, 2.6% of the US population have NASH defined as the presence of moderate-severe hepatic steatosis by ultrasound and elevated aminotransferases in the presence of type 2 diabetes or IR[17].

GENDER DIFFERENCE IN THE PREVALENCE OF NAFLD

Some old studies reported that women were at higher risk for NAFLD, but these studies were not population based and were subject to potential ascertainment bias[11]. Based on the third NHANES data, most of the studies reported that NAFLD is significantly more prevalent in men than in women (Table 2). However after dichotomizing individuals into lean and overweight-obese groups, Younossi *et al*[17] reported that the lean NAFLD cohort was more commonly female. Using data from 698 patients from the well characterized NASH Clinical Research Network (CRN), patients with biopsy proven NASH were more likely to be female than male in a roughly 2:1 ratio; possibly reflecting a higher disease burden in women or, alternatively, sex differences among those pursuing and receiving healthcare[33]. Together, these findings highlight uncertainties regarding the influence of gender on NAFLD.

A number of mechanisms may contribute to gender differences in the prevalence of NAFLD.

The role of IR, which is closely associated with NAFLD[1,2], remains controversial. Ruhl *et al*[11] reported that NAFLD was more prevalent in men than in women (4.3% *vs* 1.6%, respectively), a finding essentially explained by the higher waist-to-hip circumference (WHR) ratio in men. WHR is correlated with visceral adipose tissue (VAT) and visceral adiposity is associated with both peripheral and hepatic IR[34,35]. In another study using the same database but different cohort size, Clark *et al*[12] also reported that men have higher prevalence of NAFLD than women (5.7% *vs* 4.6%, respectively), although there was no significant difference in either gender in IR as calculated by homeostasis model assessment (HOMA) or exercise level. Moreover, in the Dallas Heart Study, non-Hispanic white men had an approximately 2-fold higher prevalence of hepatic steatosis than white women. Differences in body weight or insulin sensitivity measured by HOMA did not explain these sex differences.

Alcohol use is another possible explanation for gender differences in NAFLD. In the Dallas Heart Study, white men who reported moderate ethanol intake had a significantly higher prevalence of hepatic steatosis than female counterparts (42% *vs* 20%, $P = 0.03$). In fact, moderate alcohol intake was associated with an decrease in the prevalence of hepatic steatosis in women[13]. Similarly, Schneider *et al*[19] reported that non-Hispanic white men, who were more likely to be self-defined as "low current drinkers" (men ⩽ 2 drinks/d; women ⩽ 1 drink/d), had a significantly higher prevalence of NAFLD than non-Hispanic white women (15% *vs* 10.1%, respectively), even after adjusting for BMI and waist circumference. Finally, in adult members of the Kaiser Permanente Medical Care Program in California, NAFLD was 3.5 times more common in Asian men than in Asian women ($P = 0.016$). There was no significant difference in BMI (> 28 kg/m^2), diabetes mellitus, dyslipidemia, or current alcohol use between Asian men and women, but 68% of Asian men were previous drinkers, compared with 17% of Asian

women ($P < 0.02$)[14]. Together, these studies suggest an effect of alcohol consumption on gender differences in the prevalence of NAFLD. Whether differences in hepatic metabolism of alcohol between men and women also contribute to the gender difference in not fully defined[19].

Other factors, including lifestyle and sex hormone may also influence the gender difference in the prevalence of NAFLD. In one study, individuals with NAFLD had similar degrees of IR and obesity to those without, but males with NAFLD consumed more non-diet soda on a weekly basis (54.4% *vs* 34%, $P = 0.037$)[16]. Another recent study showed that prevalence of NAFLD was similar in pre- and intrapubertal boys and higher in the postpubertal groups (51.2%), whereas in girls NAFLD was most common in the intrapubertal group (25.2%) and lower in the postpubertal group (12.2%)[36].

RACIAL/ETHNIC DIFFERENCES IN NAFLD AND NASH

Despite using different diagnostic tools, US population-based studies all found that Hispanics have the highest and non-Hispanic blacks have the lowest prevalence of NAFLD (Table 1). Echoing the racial/ethnic differences in the NAFLD prevalence, Younossi *et al*[17] recently reported that NASH was independently associated with being Hispanic [odds ratio (OR), 1.72; 95%CI: 1.28-2.33] and inversely associated with being African-American (OR, 0.52; 95%CI: 0.34-0.78). Each of these studies is limited by the fact that NASH was diagnosed by imaging and/or biochemical criteria rather than by histology.

Single center studies show that ethnicity may also influence NAFLD histology. For instance, African Americans were found to have less steatosis than whites. Asians and Hispanics showed higher grades of ballooning and Mallory bodies, respectively, than whites and other ethnicities combined[37]. Williams *et al*[16] also reported a significantly higher prevalence of NASH in Hispanics than Caucasians (19.4% *vs* 9.7%, $P = 0.03$) although comparison of demographics such as BMI between different ethnic groups were not available in this study. However, Kallwitz *et al*[38] found no significant differences in hepatic steatosis, NASH, or liver fibrosis ($\geqslant$ F2) between morbidly obese Hispanic and non-Hispanic white patients receiving bariatric surgery. Similar to the other reports, morbidly obese African American patients had a lower rate of NAFLD, NASH and less fibrosis than non-Hispanic whites and Hispanics. Moreover, in a NASH CRN study consisting mainly of Caucasian subjects (82%), subjects of Hispanic ethnicity overall had lower fibrosis scores and less advanced fibrosis[33]. Finally, in an analysis restricted to 3082 individuals with normal weight (BMI 18.5-24.9 kg/m^2), Schneider *et al*[19] found no significant racial differences in the fully adjusted logistic regression model for NAFLD; however, Mexican Americans remained significantly more likely to have NAFLD with elevated aminotransferases (OR, 3.4; 95%CI: 1.29-7.18). This finding was confirmed in a prospective study where

overweight or obese Hispanics and Caucasians had similar hepatic or adipose tissue IR and severity of NASH by histology when matched for major clinical variables, in particular for total body fat[39]. These findings suggest that a component of the higher prevalence of NAFLD and NASH observed in Hispanics may be attributed to differences in the frequency of major clinical variables such as components of metabolic syndrome or diabetes that influence the development of NAFLD.

MECHANISMS FOR THE RACIAL/ETHNIC DIFFERENCES IN NAFLD AND NASH

A number of potential factors have been implicated in racial and ethnic differences in NAFLD. These include differences in lifestyle, IR, distribution of adiposity and genetics. These factors are not mutually exclusive and may occur and act in concert.

Lifestyle
According to the "two hit" theory, steatohepatitis development requires a double hit, the first producing steatosis, and the second a source of oxidative stress capable of initiating significant lipid peroxidation[40]. Dietary habits may promote steatohepatitis directly by modulating hepatic triglyceride accumulation and antioxidant metabolism as well as indirectly by affecting insulin sensitivity and postprandial triglyceride metabolism[41]. Several studies have reported that different racial and ethnic groups have substantial differences in their diet. In an early US population-based study (1987 National Health Interview Survey), Hispanics reported higher energy and carbohydrate intakes and a lower percentage of energy from fat than blacks or whites (35.6%, 38.4%, and 38.7% of energy from fat for Hispanics, blacks, and whites, respectively). Whites had lower cholesterol intake than the other two groups, and blacks had a higher intake of sweets[42]. According to the San Antonio heart study published almost 20 years ago, when data were pooled across socioeconomic groups, Mexican Americans consumed more carbohydrate, saturated fat, and cholesterol, and less linoleic acid than Anglo Americans. However, there were no ethnic differences in total fat, saturated fat, or carbohydrate consumption when compared within a given socioeconomic status[43]. Data from the Stanford Five-City Project showed that low educated white adults consumed significantly more fat as measured by percentage of calories from total fat (37.7% *vs* 33.3%) and saturated fat (13.7% *vs* 11.8%), and consumed significantly less dietary carbohydrate (45.5% *vs* 49.7%) and fiber (17.1 g *vs* 26 g) than Hispanic adults. Interestingly, a graded relationship was found between acculturation and dietary measures, where more acculturated Hispanics (English-speaking) were intermediate between less acculturated Hispanics (Spanish-speaking) and whites in their dietary intake[44].

Common theme in these studies is that Hispanics consume more carbohydrates than other ethnic groups.

The role of excess carbohydrate intake in NASH has been shown in at least two other studies[45,46]. In the first study of a small series of Japanese adults, individuals with histology proven NASH had a higher intake of simple carbohydrates than those with simple steatosis[44]. In the second study from the NASH CRN, Hispanics with NASH had higher carbohydrate intake compared to non-Hispanic whites with NASH[45]. In addition to high carbohydrate diet, NASH is also associated with a low intake of zinc and lower ratio of intake of polyunsaturated fatty acid to saturated fatty acid[44].

Analysis of the NASH CRN data further showed that patients with NAFLD ate at fast-food restaurants ($\geq$ 1 per week) more often (70.9% *vs* 60.5%, *P* = 0.049) and exercised ($\geq$ 30 min per week) less frequently (56.3% *vs* 68.9%, *P* = 0.02) than their non-NAFLD counterparts. However, racial differences in these two measures was not studied[16]. A recent study based on the NHANES data reported that sedentary individuals had a significantly higher prevalence of NAFLD independent of other risk factors[18]. In a small series of 37 patients, Krasnoff *et al*[47] reported that patients with NAFLD of differing histological severity have suboptimal cardiorespiratory fitness, muscle strength, body composition, and physical activity participation. These findings establish the association between physical inactivity and NAFLD and support the current recommendation of regular exercise for patients with the condition.

IR

Several US and non-US population-based studies have shown that NAFLD is highly associated with central obesity, IR, and components of metabolic syndrome (high triglyceride, low high-density-lipoprotein cholesterol, hyperglycemia, and hypertension)[11-13,15,18,22,25,48]. NAFLD has therefore been suggested to be a hepatic feature of the metabolic syndrome[49]. However, Smits *et al*[20] recently challenged this popular notion. In their study, NAFLD was strongly related to the different components of the metabolic syndrome. However, adding hepatic steatosis to a mathematical model containing the traditional components of the metabolic syndrome did not improve goodness of fit and if anything resulted in a decrease in model fit. They thus concluded that NAFLD is not an independent additional component or manifestation of the metabolic syndrome.

In addition to being a lipid storage compartment, adipose tissue is also an endocrine organ[50]. Adipose tissue IR plays key role in the development of metabolic and histological abnormalities of obese patients with NAFLD. Liver steatosis was rare in metabolically healthy obese subjects with normal adipose tissue insulin sensitivity. Compared to patients without steatosis, patients with NAFLD were insulin resistant at the level of adipose tissue, liver, and skeletal muscle. Metabolic parameters, hepatic IR, and liver fibrosis but not necroinflammation deteriorated as adipose tissue IR worsened[51]. The coincident occurrence of hepatic steatosis and IR has led to the

hypothesis that excess triglyceride in liver causes IR[52]. This notion was challenged by a recent study by Lomonaco *et al*[39]. In that study, liver fat was slightly, but not significantly, higher in Hispanic than Caucasian patients. This slightly higher liver fat content was not associated with worse hepatic or adipose tissue IR[39].

As shown in Table 1, Hispanics have a higher prevalence and blacks have a lower prevalence of NAFLD than whites. According to the data from the third NHANES, both black and Mexican American women had higher cardiovascular disease risk factors such as hypertension, physical inactivity, higher BMI and diabetes than white women of comparable socioeconomic status[53]. While the higher prevalence of hepatic steatosis in Hispanics can be explained by the high prevalence of obesity and IR in this population, the lower prevalence of hepatic steatosis in blacks cannot be explained by the same reason. In the Insulin Resistance Atherosclerosis Study, African Americans were more insulin resistant than Hispanics. Hispanics however had higher prevalence of NAFLD than African Americans (24% *vs* 10%)[54]. Therefore an IR paradox may exist[55]. It has been hypothesized that differences in NAFLD and NASH by race may result from differences in the distribution of adiposity (*e.g.*, subcutaneous *vs* visceral) or differences in triglycerides because blacks have relatively less VAT and lower triglycerides than Hispanics[19,56]. In addition, African Americans may be more resistant to both the accretion of triglyceride in the abdominal visceral compartment (adipose tissue and liver) and hypertriglyceridemia associated with IR[55].

Distribution of adiposity

Several studies have reported racial differences in the distribution of adiposity, especially in women. In a small study of age- and weight-matched healthy women (8 black and 10 white), black women had 23% less VAT as measured by computed tomography (CT) than white women. In addition, black women had significantly lower plasma glucose and triglycerides and significantly higher plasma high-density-lipoprotein cholesterol[57]. Based on the Dallas Heart Study data, blacks had less intraperitoneal fat as measured by magnetic resonance imaging and more lower extremity fat than their Hispanic and Caucasian counterparts, despite controlling for age and total adiposity. In that study, the prevalence of IR was similar between blacks and Hispanics who had the highest levels of intraperitoneal fat and liver fat. Furthermore, insulin levels and HOMA values were the highest and serum triglyceride levels were lowest among blacks after controlling for intraperitoneal fat[55]. In a prospective study of healthy sedentary women, Casas *et al*[58] found that Hispanic women had greater total adiposity than white women, which was primarily the result of higher percentage fat and fat mass in the trunk. Within the trunk region, abdominal and subscapular skinfold thicknesses were 30%-40% significantly greater in the Hispanic women. Total fat-free mass was slightly but significantly lower in the Hispanic women primarily due to a smaller fat-free

mass in the trunk region. In a study involving healthy subjects, Asians despite of having lower BMI had more upper-body subcutaneous fat as measured by dual-photon absorptiometry than did whites. The magnitude of differences between the two races was greater in females than in males[59]. A later study with a smaller cohort reported that Asian American premenopausal women had higher VAT than European American women, after adjusting for age and total body fat. There was a significant age by race interaction such that race differences in VAT were more evident over the age of 30 years. No differences in VAT could be detected between Asian American and European American men, even after adjusting for potential covariates[60]. Visceral adiposity has been reported to be associated with both peripheral and hepatic IR, independent of gender, in diabetic patients[35]. Visceral fat has also been shown as an important site for interleukin-6 secretion and provides a potential mechanistic link between visceral fat and systemic inflammation in people with abdominal obesity[61]. Inflammatory activation within metabolic tissues such as white adipose tissue, liver, and skeletal muscle potentiates IR and metabolic disease[62].

Together, these results support that differences in distribution of adiposity may influence racial differences in the prevalence of NAFLD and NASH.

Genetic variations

Caldwell *et al*[63] previously proposed that obesity and IR are often "essential but not sufficient" in the development of NAFLD given the variable prevalence of steatosis in different ancestry groups. They further suggested a genetic basis for the variable presence of steatosis in the metabolic syndrome. Possible mechanisms to explain this variation include differences in hepatic fatty acid-binding protein (influencing fatty acid import to the liver), in the activity of microsomal triglyceride transfer protein (influencing *de novo* fat synthesis), or in other compensatory mechanisms that are active in insulin-resistant patients without steatosis. The findings of familial clustering of NAFLD and NASH suggest a hereditary component for the conditions. Struben *et al*[64] retrospectively examined 8 index patients who had either NASH with or without cirrhosis or cryptogenic cirrhosis and 10 of their relatives from 8 kindreds. They found that co-existence of NASH and/or cryptogenic cirrhosis in 7 of 8 kindreds studied. Willner *et al*[65] reviewed 90 patients with NASH and found that 16 (18%) of the patients came from 9 families with NASH. Two generations were involved in 6 families and siblings were involved in the other 3 families. Notably, cirrhosis was observed in 7 of these 9 families. A small case series from Japan reported 3 families each with 2 members with biopsy-proven NASH[66]. By studying overweight children with and without biopsy-proven NAFLD and their families, Schwimmer *et al*[67] reported that fatty liver was significantly more common in siblings (59% *vs* 17%) and parents (78% *vs* 37%) of children with NAFLD than those without NAFLD. In addition to genetic basis, sharing common environmental factors

and/or lifestyles could be alternative explanations for the familial nature of NAFLD and NASH.

In the landmark study from the Dallas Heart Study, Romeo *et al*[68] first reported that the rs738409[G] allele in patatin-like phospholipase domain-containing 3 (*PNPLA3*) gene was strongly associated with hepatic fat content even after adjustment for BMI, diabetes status, ethanol use, as well as ancestry. The variant is a cytosine to guanine substitution that changes codon 148 from isoleucine to methionine (I148M). Hepatic fat content was more than twofold higher in the G allele homozygotes than in noncarriers. The frequencies of the G allele were concordant with the relative prevalence of NAFLD in the three ancestry groups; the highest frequency of allele was in Hispanics (0.49), with lower frequencies observed in European Americans (0.23) and African Americans (0.17). In the Dallas Heart Study, rs738409(G) was significantly associated with ALT and AST levels only in Hispanics. Interestingly, rs738409(G) was not associated with BMI or indices of insulin sensitivity such as fasting plasma glucose and insulin concentrations or HOMA. Furthermore, *PNPLA3* genotype was not associated with concentrations of triglyceride, total cholesterol, high-density-lipoprotein cholesterol or low-density-lipoprotein cholesterol. Another variant of the *PNPLA3* [rs6006460(T), encoding S453I] was found to be associated with lower hepatic fat in African Americans. Regression analysis indicated that these two sequence variations accounted for 72% of the observed ancestry-related differences in hepatic fat content in the Dallas Heart Study.

Similar to the Dallas Heart Study, Wagenknecht *et al*[69] also found a higher frequency of *PNPLA3* rs738409(G) in Hispanics in a large US minority cohort (843 Hispanic Americans and 371 African Americans) study. The G allele was two times more common in Hispanic Americans than in African Americans (40% *vs* 19%), consistent with the greater prevalence of NAFLD in Hispanic Americans (24% *vs* 9%). The G allele was also associated with elevated ALT and AST but not metabolic phenotypes in both Hispanic- and African Americans. However, unlike the Dallas Heart Study, the *PNPLA3* genotype could only explain 4.4% of variation in liver fat content in Hispanic Americans and 5.6% in African Americans. Even with adjustment for the *PNPLA3* variation, a significant ethnic disparity in liver fat content persisted. It was therefore suggested that *PNPLA3* does not explain the unusually high prevalence of NAFLD in Hispanic Americans.

The *PNPLA3* genotype is associated with hepatic fat content and aminotransferase in non-US populations as well. In a Finnish study, 291 individuals were genotyped and had liver fat measured by magnetic resonance spectroscopy. The G allele was associated with increased liver fat content and AST independently of age, sex, and BMI. *PNPLA3* expression in the liver was positively related to obesity and to liver fat content in persons who were not morbidly obese (BMI < 40 kg/m^2)[70]. In another study, 678 obese (mean BMI = 41 kg/m^2) Italians were genotyped for the *PNPLA3* variant. It was found that ALT

and AST were significantly higher in carriers of the G allele; 50% of the individuals homozygous for the G allele had elevated ALT (> 40 U/L) compared with 25% of the carriers of two C alleles, whereas 30% of the heterozygotes had elevated ALT. Glucose tolerance and insulin sensitivity were similar in all three genotypes[71]. In a Latin American study, 172 Argentinians with NAFLD defined by ultrasonographic steatosis and 94 controls were genotyped. Similar to the previous reports, rs738409[G] was significantly associated with NAFLD, independent of age, sex, BMI, and HOMA index. Patients with CC genotype had a lower histologic steatosis score (14.9% ± 3.9%) in comparison with the CG genotype (26.3% ± 3.5%) and GG genotype (33.3% ± 4%) (*P* < 0.005). Similar to the previous US minority cohort study[69], the *PNPLA3* genotype could only account for a small amount (5.3%) of the total variation in hepatic steatosis[72].

The *PNPLA3* genotype exerts a strong influence not only on liver fat accumulation but also on the susceptibility of a more aggressive disease course. A recent meta-analysis of 16 studies concluded that the GG homozygotes had 3.24-fold greater risk of higher necroinflammatory scores and 3.2-fold greater risk of developing fibrosis when compared with the CC homozygotes (data from 1739 and 2251 individuals, respectively). NASH was more frequently observed in the GG than the CC homozygotes (OR, 3.488; 95%CI: 1.859-6.454; data from 2124 patients). In the meta-analysis, a negative correlation between the male proportion in the studied population and the effect of rs738409 on liver fat content was observed, suggesting that a sexual dimorphism might be involved in the effect of the single nucleotide polymorphism (SNP) on NAFLD development. The rs738409 GG genotype versus CC genotype was associated with a 28% increase in ALT levels. The *PNPLA3* rs738409 was therefore proposed as a strong modifier of the natural history of NAFLD[73].

In addition to *PNPLA3*, the Genetics in Obesity-related Liver Disease (GOLD) Consortium studied 7176 individuals of European ancestry and identified genetic variants in or near three novel loci [neurocan gene *NCAN* (rs2228603), glucokinase regulatory protein gene *GCKR* (rs780094), and lysophospholipase-like 1 gene *LYPLAL1* (s12137855)] that were associated with both increasing CT hepatic steatosis and histologic NAFLD. The genetic variant in or near glycogen binding subunit of protein phosphatase 1 gene *PPP1R3B* (rs4240624) was associated with CT steatosis but not histologic NAFLD. Variants at these 5 loci exhibited distinct patterns of association with serum lipids, as well as glycemic and anthropometric traits. Specifically variants in or near *NCAN*, *GCKR*, and *PPP1R3B* associated with altered serum lipid levels, whereas those in or near *LYPLAL1* and *PNPLA3* did not. Variants near *GCKR* and *PPP1R3B* also affected glycemic traits. These findings suggest development of hepatic steatosis, NASH/fibrosis, or abnormalities in metabolic traits are probably influenced by different metabolic pathways and may provide new insights that into

how obesity can lead to metabolic complications in some but not all individuals[74]. The observed genetic variants in European ancestry individuals were recently characterized in a multi-cohort study of African- (*n* = 3124) and Hispanic Americans (*n* = 849)[75]. In that study, variants in or near *PNPLA3*, *NCAN*, *GCKR*, *PPP1R3B* in African Americans and *PNPLA3* and *PPP1R3B* in Hispanic Americans were significantly associated with CT hepatic steatosis. *LYPLAL1* was not significantly associated with hepatic steatosis in either African- or Hispanic Americans despite comparable allele frequencies. The association of *NCAN* with hepatic steatosis was in an opposite direction in Hispanic Americans, suggesting it would have a small protective effect in this population. The allele frequency and effect size of each variant varied across ancestries. For example, the effect size of *PNPLA3* rs738409 was similar across the ancestries and the frequency of the G allele was higher in Hispanics. The effect size of *PPP1R3B* rs4240624 was twice in European ancestry individuals than other ancestries, whereas its frequency was roughly the same across the three ethnic groups. *GCKR* rs780094 had the same effect across ancestries but its frequency in African Americans was half of that in European ancestry individuals and Hispanic Americans, which were about equal[75].

Finally, in a recent multi-ethnic (*n* = 4804) study from the third NHANES, Hernaez *et al*[76] attempted to replicate the findings of the GOLD Consortium. Similar to the previous report by Palmer *et al*[75], the G allele of *PNPLA3* rs738409 was more prevalent in Mexican Americans than non-Hispanic whites and blacks. However, the T allele of *GCKR* rs780094 and the A allele of *PPP1R3B* rs4240624 were more common in non-Hispanic whites than the other two ethnic groups. In contrast to the GOLD Consortium, several discrepancies were noted. First of all, the *PNPLA3* variant was associated with hepatic steatosis diagnosed by ultrasonography only among Mexican Americans. Secondly, *NCAN* and *PPP1R3B* regions were associated with hepatic steatosis only in non-Hispanic whites. Thirdly, neither *LYPLAL1* nor *GCKR* were associated with hepatic steatosis in the third NHANES population. Fourthly, *PNPLA3* and *GCKR* were the only variants associated with elevated ALT (> 30 U/L in men and > 19 U/L in women) and the association in non-Hispanic whites only[76]. In an editorial comment, Browning called for the following considerations when interpreting the data of Hernaez *et al*[76]. The true prevalence of fatty liver in the study population might be higher than reported and/or that some individuals might have been mistakenly classified as having NAFLD since ultrasound is not as sensitive or specific for hepatic steatosis as other imaging modalities. In addition, the study appears to be underpowered to examine associations across ethnic/racial groups, especially for SNPs with a low allelic frequency. If underpowered, the analysis would be prone to false-negative results[77].

Variants in other genes such as cytochrome P450 2E1[78] and apolipoprotein C3[79] have been reported to be

implicated in NAFLD. To provide a detailed review of other genetic variants in NAFLD is beyond the scope of this review.

CONCLUSION

According to the population-based studies, NAFLD and NASH are more prevalent in males and in Hispanics. The gender differences in NAFLD and NASH can be probably explained by gender disparities in body fat distribution, lifestyle, and sex hormone metabolism. The racial/ethnic differences in NAFLD and NASH are likely attributed to interaction between environmental, behavioral, and genetic factors. Despite having similar or worse insulin sensitivity, non-Hispanic blacks are less likely to have NAFLD/NASH than non-Hispanic whites and Hispanics. Racial differences in body fat distribution and lipid metabolism may explain the IR paradox. By using genome-wide association study, several SNPs have been identified to be associated with NAFLD/NASH. These genetic variants however only account for a small amount of variation in hepatic steatosis among ethnic groups and may serve as modifiers of the natural history of NAFLD. As suggested by Browning[77], these trait-associated SNPs may not be the causative genetic variants but simply tags representing a larger body of SNPs. Further study is required to define how these variants alter normal physiology and/or identify the functional genetic variant in the haplotype block represented by the SNP[77].

Abstract

Treatment of chronic hepatitis B (CHB) has markedly improved in the last 15 years due to the availability of direct antivirals which greatly increase therapeutic options. Currently, there are two classes of agents licensed for CHB treatment: standard or pegylated interferon alpha (IFN or Peg-IFN) and five nucleoside/nucleotide analogues (NAs). Long-term treatment with NAs is the treatment option most often used in the majority of CHB patients. Entecavir and tenofovir, the most potent NAs with high barrier to resistance, are recommended as first-line monotherapy by all major treatment guidelines and can lead to long-lasting virological suppression, resulting in histological improvement or reversal of advanced fibrosis and reduction in disease progression and liver-related complications. In this review, we focus on current treatment strategies of chronic hepatitis B and discuss the most recent efficacy and safety data from clinical trials and real life clinical practice. Recent findings of response-guided approaches are also discussed.

Key words: Chronic hepatitis; Antiviral therapy; Peg-interferon; Nucleos(t)ide analogues; Antiviral resistance

Core tip: Patients with chronic hepatitis B are a hetero-geneous population and require different management strategies. In clinical practice, several baseline factors, related to the patient, drug, stage of liver disease, comorbidities, lifestyle factors, coinfections and profile of hepatitis B virus infection, should be taken into consideration in order to individually optimize therapy. Surface antigen of the hepatitis B virus quantification is a potential new biomarker for treatment individualization and response-guided therapy. In the last two decades, the availability of potent oral antivirals changed the natural history of chronic hepatitis B; however, the risk of hepatocellular carcinoma (HCC) has not been abolished and thus regular HCC surveillance in high risk patients is required.

INTRODUCTION

Chronic infection with hepatitis B virus (HBV) is a major health problem worldwide, affecting approximately 350 million people, and is the leading cause of chronic liver disease, cirrhosis and hepatocellular carcinoma (HCC), accounting for over 1 million deaths annually[1].

The goal of chronic hepatitis B (CHB) treatment is to prevent or reduce the development of cirrhosis, end-stage liver disease, HCC and, ultimately, liver-related death. Several studies have shown that the risk of disease progression is reduced by means of sustained suppression of viral replication[2-4]. Furthermore, maintaining viral suppression increases the rate of hepatitis B surface antigen (HBsAg) clearance, which is the ideal end-point of antiviral treatment as it is associated with a definite remission of chronic hepatitis B activity and an improved long-term outcome. However, even if HBsAg loss occurs, HBV cannot be completely eradicated by treatment due to the persistence of the so-called covalently closed

Table 1 European Association for the Study of the Liver guidelines compared to other international guidelines

Criteria	EASL 2012[6]	AASLD 2009[7]	APASL 2012[8]
HBV DNA treatment threshold			
HBeAg(+) (IU/mL)	2000	20000	20000
HBeAg(-) (IU/mL)	2000	2000-20000	2000
ALT treatment threshold	> ULN	> 2 × ULN	> 2 × ULN
Liver biopsy	Moderate to severe necroinflammation or fibrosis	Not applicable (consider in certain groups)	

ULN: Upper limits of normal; HBeAg: Hepatitis B e antigen; ALT: Alanine aminotransferase; AASLD: American Association for the Study of Liver Diseases; APASL: Asia Pacific Association for the Study of the Liver; EASL: European Association for the Study of the Liver; HBV: Hepatitis B virus.

circular DNA (cccDNA), the template for viral RNA transcription, in the nucleus of infected hepatocytes[5].

Since the introduction of interferon alpha as an initial antiviral therapy at the end of the 1980s, the treatment of CHB has markedly improved in the last 15 years due to the availability of nucleos(t)ide analogues (NAs), direct antiviral agents which have greatly increased therapeutic options and permitted the achievement of virological response in almost all patients.

In this review, we focus on current treatment strategies of chronic hepatitis B and discuss the most recent long-term NA efficacy and safety data from clinical trials and real life clinical practice.

ANTIVIRAL TREATMENT

Treatment indications

The complex interplay between viral replication and host immune response determines the natural course of chronic HBV infection which can generally be divided into four phases: immune tolerance, immune clearance, low/non replicative and reactivation phases. Liver disease is associated with immunoclearance and reactivation

phases; therefore, immunotolerant and inactive carriers do not require treatment, while antiviral therapy should be reserved for HBsAg carriers with active viral replication and biochemical or histological evidence of liver damage. The criteria for identification of candidates for antiviral therapy, according to current guidelines[6-8] are shown in Table 1.

In clinical practice, however, the decision-making process is more complex as it involves several factors related to the patient (age, sex, genetics), the drug (efficacy, side effects, resistance barrier), the liver disease (fibrosis, type and extent of inflammation), the liver disease cofactors (alcohol use, diabetes, insulin-resistance, obesity), the co-infections (HDV, HCV, HIV) and the profile of HBV infection (HBeAg-status, HBV DNA levels, genotype, viral heterogeneity) (Figure 1).

The assessment of hepatic fibrosis with liver biopsy or non-invasive methods is recommended since it can assist the decision to start antiviral therapy. Treatment is mandatory for patients with severe fibrosis or cirrhosis (F3-F4) and patients with compensated or decompensated cirrhosis and detectable HBV DNA should be considered for treatment, independent of ALT levels.

Table 2 Main advantages and disadvantages of pegylated interferon alpha and nucleos(t)ides analogues in chronic hepatitis B[6]

	Peg-IFN	Nucleos(t)ides analogues
Advantages	Finite duration (usually 48 wk)	Potent antiviral effect
	Higher rates of anti-HBe and anti-HBs seroconversion with 12 mo of therapy	Excellent tolerance, good safety
	Absence of resistance	Oral administration (once daily)
		No contraindication for treatment
Disadvantages	Moderate antiviral effect	Unknown (perhaps indefinite) duration of treatment
	Inferior tolerability	Rare HBsAg loss
	Risk of adverse events	Risk of viral resistance
	Subcutaneous injections	Unknown long-term safety
	Contraindications in specific patient subgroups	

Peg-IFN: Pegylated interferon; HBsAg: Hepatitis B surface antigen.

Therapy is indicated for patients with moderate fibrosis (F2), while in those with mild or no fibrosis (F0-F1), the indication for treatment should be assessed individually, taking into account patient age, comorbidities, presence of liver disease cofactors, HDV/HCV/HIV coinfections, family history of HCC or cirrhosis, and extrahepatic manifestations.

Anti-HBV drugs

At present, there are two classes of agents licensed for the treatment of CHB: standard or pegylated interferon alpha (IFN or Peg-IFN) and five nucleoside/nucleotide analogues.

Standard IFN has been largely replaced by Peg-IFN due to the more convenient administration schedule (once weekly versus a thrice weekly subcutaneous injection), the longer half-life without wide fluctuations in serum concentrations, and a more effective viral suppression. There are two pegylated-IFN formulations: Peg-IFN alpha-2a and Peg-IFN alpha-2b which have demonstrated a similar efficacy in clinical trials, but only the former is globally licensed for treatment of CHB, while Peg-IFN alpha-2b has been approved in only a few countries. Peg-IFN is a cytokine with a dual antiviral and immunomodulatory activity and therefore has the potential for an immune-mediated control of HBV infection, thus providing the opportunity to obtain a sustained virological response after treatment discontinuation, and the possibility of inducing HBsAg loss in patients who achieve and maintain undetectable HBV DNA. IFN-based treatment, however, is often complicated by the occurrence of side effects, such as influenza-like symptoms, fatigue, neutropenia, thrombocytopenia and depression, which sometimes require dose modification and cause premature cessation of treatment[9]. Moreover, Peg-IFN is contraindicated in patients with decompensated HBV-related cirrhosis or autoimmune disease, in patients with uncontrolled severe depression or psychosis, in patients receiving immunosuppressive therapy or chemotherapy, and in female patients during pregnancy[6].

NAs are oral direct antiviral agents which specifically inhibit the viral polymerase/reverse transcriptase, an enzyme with a crucial role in the HBV life cycle. As a result, NAs block the production of new virions and progressively reduce serum HBV DNA to undetectable levels, but they have little or no effect on the cccDNA present in the nucleus of the infected hepatocytes. The persistence of the intrahepatic cccDNA determines the reactivation of HBV replication after interrupting NA treatment, thereby justifying the need for a long-term (potentially life-long) therapy for a sustained viral replication control. After lamivudine (LAM), the first nucleoside analogue approved for the treatment of CHB, another two nucleosides, telbivudine (LdT) and entecavir (ETV), and two nucleotide analogues, adefovir (ADV) and tenofovir (TDF), have gradually become available in recent years. NAs are characterized by a different antiviral potency and drug-resistance pattern, while entecavir and tenofovir are the two most potent analogues with a high barrier to resistance development.

The main advantages and disadvantages of Peg-IFN and NAs for treatment of CHB are shown in Table 2.

Treatment strategies

There are two different therapeutic strategies for both HBeAg-positive and HBeAg-negative CHB patients: short-term or "curative" treatment and long-term or "suppressive" treatment. The first strategy aims to obtain a sustained suppression of viral replication off-treatment by inducing the immune-controlled status of HBV infection which corresponds to the profile of the inactive carrier, that is, normal ALT levels coupled with HBV DNA < 2000 IU/mL and anti-HBe positivity. This strategy is IFN-based (Peg-IFN administered for 48 wk); a finite treatment with NAs is possible only in HBeAg-positive patients. The second strategy aims to obtain a rapid and long-term maintained viral suppression (HBV DNA < 10-15 UI/mL). This strategy is exclusively based on NAs.

First-line monotherapy

Peg-IFN, entecavir or tenofovir are recommended as first-line monotherapy by all major guidelines in patients with CHB or compensated cirrhosis[6-8]. The most favorable candidates for Peg-IFN are those with low HBV DNA levels, high ALT and HBV, genotype A or B rather than C or D, and those without advanced liver disease.

Entecavir or tenofovir are the only therapeutic op-

tions in patients with decompensated liver disease, in those undergoing immunosuppressive treatment or with contraindications, and those unwilling to receive Peg-IFN. As Peg-IFN can achieve a sustained off-therapy response in only a minority of cases and a proportion of patients cannot tolerate or have IFN contraindications or do not wish to be treated with Peg-IFN, long-term treatment with NAs is the most commonly used treatment strategy.

IFN-BASED THERAPY

Published data have demonstrated that in patients with HBeAg-positive CHB, Peg-IFN achieves a more than 30% HBeAg seroconversion rate after one year of treatment[6]. In a registration trial, Peg-IFN alpha-2a provided a sustained immune control which increased post-therapy; in fact, the HBeAg seroconversion rate continued to increase from 27% at the end of treatment to 32% during the six months after discontinuing treatment, and to 42% 1 year post-treatment[10,11]. Moreover, the seroconversion remained stable over time in > 80% of Peg-IFN alpha-2b treated patients, achieving this end-point at the end of therapy[12]. Peg-IFN also determined HBsAg seroconversion in up to 30% of patients with a long-term follow-up[13].

In patients with HBeAg-negative CHB, Peg-IFN alpha-2a demonstrated a sustained immune control (HBV DNA < 2000 IU/mL) in 31% of patients 1 year post-treatment. Among these, 88% maintained this response up to 5 years follow-up and, remarkably, 28% achieved HBsAg clearance 5 years post-treatment[14].

Peg-IFN treatment remains an attractive therapeutic option since it provides higher rates of off-therapy immune control, including HBsAg clearance, when compared to NAs. However, IFN is effective in only a minority of patients (20%-30%), has a poor tolerability and significant costs. Therefore, the improvement of Peg-IFN efficacy is a major challenge. Several attempts have been made to optimize the cost-effectiveness of IFN-based therapy, including combination therapy, longer treatment duration and identification of pre-treatment and on-treatment predictors of response. *De novo* combination therapy with NAs did not improve sustained response in either HBeAg-positive or HBeAg-negative patients[10,15-17]. Regarding duration of therapy, the NEPTUNE study conducted in patients with HBeAg-positive CHB reported that dose and duration are important because the highest sustained response was obtained with 180 μg and 48 wk compared to 90 μg and 24 wk[18]. Recently, an Italian multicenter study demonstrated in 128 HBeAg-negative patients (mean age 45 years, 94% genotype D, 13% with cirrhosis) that extended treatment with Peg-IFN alpha-2a to 96 wk was well-tolerated and improved the rates of sustained virological response (29% *vs* 12%, P = 0.03) in HBeAg-negative genotype D patients when compared to the current standard of care of 48 wk. In addition, 1 year post-treatment, HBsAg clearance (6%) was observed only

in the extended therapy group[19]. Among pre-treatment predictors of response, ALT levels, low baseline HBV DNA and virus genotype were significant predictors[6-8]. When combining data from the two largest clinical trials regarding HBeAg-positive CHB patients[9,20], Buster *et al*[13] found that the best candidates for a sustained response to Peg-IFN were genotype A patients with high levels of ALT (ALT ⩾ 2xULN) or low levels of HBV DNA (< 9 $\log_{10}$ copies/mL), and genotypes B and C patients who have both high levels of ALT and low HBV DNA. Genotype D patients have a low chance of sustained response. However, these factors cannot accurately predict response at the individual level; furthermore, ALT and HBV DNA levels are time-dependent and thus their use in clinical practice is difficult.

To obtain additional insight into the individual patient's probability of achieving response to Peg-IFN, the presence of precore and basal core promoter mutants before treatment has been correlated to the serological and virological response in HBeAg-positive CHB patients. Data from this study demonstrated that the presence of a wild-type virus at baseline was an independent predictor of response to Peg-IFN and can assist in improving patient selection for this treatment option[21].

More recently, the role of IL28B polymorphisms, clearly indicated as a baseline host factor predictor of response in patients with chronic hepatitis C, has also been investigated in CHB patients. Studies in HBeAg-positive patients provided conflicting results[22-24]. The only existing data in HBeAg-negative patients are in 101 subjects treated with either conventional IFN or Peg-IFN alpha 2a for 24 mo and followed for 11 years after treatment. Patients with *IL28B rs12979860* genotype CC were shown to have higher EOT (69% *vs* 45%, P = 0.01) and higher SVR (31% *vs* 13%, P = 0.02) than non-CC patients. Interestingly enough, CC patients had a higher cumulative probability of clearing HBsAg during an observation period of 16 years (38% *vs* 12%, P = 0.039)[25]. Further studies are necessary to define the role of *IL28B* polymorphisms as a baseline factor to improve pre-treatment patient selection.

A promising approach to improve the cost-effectiveness of Peg-IFN therapy is a response-guided treatment based on serum HBsAg kinetics which permits early identification of either responders for whom continuation of treatment to week 48 could be beneficial or non-responders who should discontinue IFN treatment.

Two stopping rules at week 12 have been proposed for HBeAg-positive patients: (1) no HBsAg decline; and (2) HBsAg levels > 20000 IU/mL. The negative predictive value (NPV) for a sustained response ranged from 92% to 100% depending on HBV genotypes; thus, HBV genotype-specific stopping-rules may be considered at week 12. However, at week 24, treatment discontinuation is indicated in all patients with HBsAg > 20000 IU/mL, irrespective of HBV genotype[26,27].

In HBeAg-negative genotype D patients, no HBsAg decline and < 2 log copies/mL HBV DNA decline at

HBeAg-positive	HBeAg-negative (geno D)
Week 12: HBsAg > 20000 IU/mL No decline of HBsAg	**Week 12:** No decline in HBsAg plus < 2 log decline in HBV DNA
95%-100% negative predictive values	

Figure 2 Response-guided therapy using hepatitis B surface antigen levels in pegylated interferon-treated patients: stopping rules[26-29]. HBeAg: Hepatitis B e antigen; HBsAg: Hepatitis B surface antigen.

week 12 has been proposed as a stopping rule and independently validated with a 100% NPV[28,29]. Overall, therapy with Peg-IFN could be discontinued at week 12 in the 20% of primary non-responders, who are therefore candidates for suppressive therapy with NAs (Figure 2).

Recently, it has been demonstrated that, even in HBeAg-negative patients, on-treatment HBsAg kinetics varied according to HBV genotype. In fact, for genotype A, the difference between responders and non-responders was greatest at week 24, while for genotypes B and D, the difference was evident at week 12; there was no significant difference for genotype C over time. Moreover, highly positive predictive values for long-term virological response was obtained by applying end-of-treatment genotype-specific HBsAg level cut-offs[30].

NA-BASED THERAPY

Entecavir and tenofovir are the third-generation NAs recommended as first-line therapy for CHB NA-naïve patients by all international guidelines. In registration trials, both antivirals demonstrated a long-lasting efficacy (viral suppression in more than 95% of patients over 5 years) associated with prevention of developing cirrhosis and, to a greater extent, with fibrosis regression[31-36]. Chang *et al*[31] first documented the histological reversal of cirrhosis in 4 of 10 cases who met the criteria for efficacy analysis while they were in a 3 to 7 year period of virological response to ETV. More robust evidence of cirrhosis reversion has been offered by Marcellin and colleagues who reported the effect of 5 years of viral suppression on histology in liver fibrosis and cirrhosis in 348 patients who had evaluable histology at baseline and at week 240. Of the 96 (28%) patients with cirrhosis (Ishak score ≥ 5) at baseline, 71 (74%) demonstrated a reduction in fibrosis at year 5 and were no longer cirrhotic[34].

Moreover, registration trials reported a minimal risk of drug resistance (1.2% with ETV and 0% with TDF after 6 years) and a favorable safety profile[31-36]. However, as registration trials are conducted under standardized conditions with strict enrolment criteria in well-selected and compliant patients, long-term efficacy and safety of ETV and TDF are still to be confirmed in real life patients who generally have a more complex clinical profile as they are usually older, with a higher prevalence of cirrhosis and comorbidities treated with several concomitant medications.

Efficacy and safety of entecavir in real life practice

In a retrospective/prospective multicenter Italian study, 418 consecutive NA-naïve patients initiating treatment with ETV 0.5 mg/d were studied. In this cohort, patients were older at baseline (median age 58 years), were predominately infected with HBV genotype D (90%), 49% had cirrhosis, approximately 46% had a body mass index over 25 kg/m^2, and 56% had concomitant diseases. Viral suppression was achieved in 99% of patients over 60 mo of therapy, independent of HBeAg status. Only one patient with a partial virological response at week 48 developed resistance at year 3 of treatment, with a cumulative rate of 0.2%. In HBeAg-positive patients, the 5 year cumulative probability of HBeAg seroconversion and HBsAg loss were 55% and 34%, respectively. HCC developed in six non-cirrhotics with a yearly rate of 0.8%. The 204 compensated cirrhotics remained clinically stable, yet 18 developed a HCC, a 5 year cumulative rate of 13% and a yearly rate of 2.6%, making continuous surveillance for liver cancer mandatory[37].

The single center Hong Kong cohort study prospectively included 222 NA-naïve patients (median age 45 years) who demonstrated a 97.4% 5 year cumulative rate of virological response. Only two cases of resistance (corresponding to a 1.2% cumulative resistance rate up to year 5) were reported in this patient cohort[38].

The European network of excellence for Vigilance against Viral Resistance performed a multicenter cohort study with over 10 European referral centers between 2005 and 2010. The study including 243 consecutive NA-naïve patients receiving ETV monotherapy; the cumulative probability of achieving a virological response at week 144 was 90% in HBeAg-positive patients and 99% in HBeAg-negative patients, and the proportion of HBeAg-positive patients with HBeAg loss was 34%[39]. In this cohort, 81% of patients with partial virological response at 48 wk reached a virological response during prolonged ETV monotherapy and no patient developed ETV resistance. When stratifying patients according to their viral load at week 48, 95% of patients with HBV DNA < 1000 IU/mL and 57% of patients with HBV DNA > 1000 IU/mL achieved a virological response without treatment adaptation during the prolonged treatment period beyond week 48. Therefore, the authors concluded that no treatment adaptation is needed in the majority of NA-naïve patients treated with ETV who reach a partial virological response, particularly in those with HBV DNA < 1000 IU/mL at week 48. In addition, data from the Virgil cohort demonstrated that in cirrhotic patients, virological response to ETV is associated with a lower probability of developing a clinical event and disease progression[40].

The safety profile of ETV in real life studies has been largely consistent with those of registration trials as there have been no reports of serious drug-related side effects, discontinuation or renal toxicity[37-41]. One retrospective study identified five cases of lactic acidosis among 16 ETV-treated patients with decompensated liver disease.

Table 3 Cross-resistance data for the most frequent resistant hepatitis B virus variants[43]

HBV variant	LVD	LdT	ETV	ADV	TDF
Wild-type	S	S	S	S	S
M204I/V	R	R	I	S	S
L180M + M204V	R	R	I	S	S
A181T/V	R	R	S	R	I
N236T	S	S	S	R	I
A181T/V + N236T	R	R	S	R	R
L180M + M204V/I ± I179T ± T184G ± S202I/G ± M250I/V	R	R	R	S	S

HBV: Hepatitis B virus; LVD: Lamivudine; LdT: Telbivudine; ETV: Entecavir; ADV: Adefovir; TDF: Tenofovir; S: Sensitive; I: Intermediate/reduced susceptibility; R: Resistant.

These patients all had highly impaired liver function, with model for end-stage liver disease scores of 22 or higher[42]. In two subsequent studies enrolling patients with hepatic decompensation, no cases of lactic acidosis were reported[43,44].

Efficacy of tenofovir in real life practice

In the multicenter European cohort study, 374 consecutive NA-naïve patients receiving tenofovir (245 mg/d) were retrospectively and prospectively followed for a median period of 39 mo. At baseline, median age was 55 years, 35% of patients had cirrhosis, and concomitant diseases were present in 47%[45]. Virological response rates increased over time, reaching 97% at year 4, independent of HBeAg status. Virological breakthrough was reported in 2% of patients, with no potential resistance-associated mutations identified to date. In HBeAg-positive patients, cumulative probability of HBeAg seroconversion at 4 years was 37%. Sixteen patients (17%) cleared HBsAg (11 HBeAg-positive patients), six of whom successfully interrupted tenofovir. Most partial virological responders at week 48 achieved undetectable HBV DNA during additional treatment. Serum creatinine and phosphorus median levels remained unchanged over time. The proportion of patients with an eGFR of < 50 mL/min (as calculated by the Modification of Diet in Renal Disease formula) increased from 2% to 3% (year 4). The TDF dose was reduced in 19 patients (5%) because of a decline in the estimated glomerular filtration rate in 17 and low serum phosphate levels in two. Therapy was discontinued in seven patients (2%) who were switched to ETV. Nine additional patients withdrew from TDF and switched to ETV because of non-renal-related side effects. HCC developed in 10 compensated cirrhotics (4 year cumulative probability: 17%, 4.2%/year) and in six non-cirrhotics (4 year cumulative probability: 4%, 1%/year), while no cirrhotics clinically decompensated[45].

Management of antiviral drug resistance

The management of treatment failure has changed significantly in recent years due to the availability of potent antivirals. An appropriate rescue therapy should be initiated with the most effective antiviral drug without cross-resistance to reduce the risk of selecting multiple drug-resistant viral strains (Table 3)[46]. In the past years, the add-on strategy was the therapeutic approach recommended by guidelines in order to prevent the emergence of multi-drug resistant strains and raising the resistance barrier. However, with the availability of more potent drugs, such as entecavir and tenofovir, there is a trend to recommend a switch to a complementary drug with a high barrier to resistance. Both options are considered in the recent EASL guidelines (Table 4)[6]. The switch strategy does not apply to patients who have been exposed to multiple monotherapies; these patients should be treated with add-on strategies in order to minimize the risk of subsequent treatment failure.

NA treatment discontinuation

In HBeAg-positive patients with documented HBeAg seroconversion, NA-treatment can be discontinued after 6-12 mo consolidation therapy[6-8], although the optimal duration of consolidation treatment is not clearly defined. However, the long-term durability of HBeAg seroconversion induced by NAs is controversial and high relapse rates have been reported, suggesting that long-term continuation of NA-treatment, irrespective of the occurrence of HBeAg seroconversion, appears to be necessary[47].

Overall, the ideal end-point for stopping NA-treatment is HBsAg loss; however, the likelihood of HBsAg clearance is very low in clinical practice[6-8]. Studies are underway to determine if it is possible to successfully combine the potent effects of NAs with Peg-IFN to increase the HBsAg clearance rates and allow more patients to stop therapy. Recent reports propose quantification of serum HBsAg levels together with serum HBV DNA levels for predicting the outcome after treatment discontinuation in individual patients and thus whether therapy can be safely stopped. Petersen and colleagues showed that stopping long-term NA-therapy in HBeAg-negative CHB patients without advanced liver disease might be an option for patients with HBsAg titers < 500 IU/mL since these selected patients developed a high rate of HBsAg loss off-therapy.

CONCLUSION

Chronic hepatitis B remains a serious clinical problem because of its worldwide distribution and potential adverse sequelae. Over the last decades, treatment of CHB has greatly advanced due to the availability of safe and effective drugs and new standards of care and guidelines have been developed. Both Peg-IFN and two NAs, entecavir and tenofovir, can currently be prescribed as first-line monotherapy for CHB.

Peg-IFN treatment is the only short-term treatment strategy which provides significant off-treatment sustained responses, including loss of HBsAg. However, as Peg-IFN is effective in 20%-30% of patients, it should

Table 4 European Association for the Study of the Liver 2012 Guidelines recommendations in resistant patients[6]

Resistance	Action
LAM resistance	Switch to TDF (add ADV if TDF not available)
ADV resistance	If patient was NA naive before ADV: switch to ETV or TDF;
	ETV may be preferred in such patients with high viremia
	If patient had prior LAM resistance: switch to TDF and add a nucleoside analogue
LdT resistance	Switch to or add TDF (add ADV if TDF not available)
ETV resistance	Switch to or add TDF (add ADV if TDF not available)
TDF resistance	TDF resistance not detected to date: add a nucleoside analogue
	Switch to ETV if patient had no prior LAM resistance or add ETV in patients with LAM resistance

LAM: Lamivudine; ADV: Adefovir dipivoxil; TDF: Tenofovir; LdT: Telbivudine; ETV: Entecavir.

be considered only for patients with an elevated possibility of response based on pre-treatment and on-treatment factors. In particular, quantitative serum HBV-DNA and HBsAg levels may be suitable to identify patients early who are unlikely to benefit from Peg-IFN early during the treatment course, thereby avoiding unnecessary therapy. Nevertheless, despite this individualized and response-guided approach, increasing the cost-effectiveness of Peg-IFN therapy remains a clinical challenge. Combining Peg-IFN with NAs appears to be the most appealing approach to increase the efficacy of antiviral therapy and new trials on a combination of Peg-IFN with ETV or TDF are required.

Currently, NAs represent the treatment option most often used in the majority of CHB patients. TDF and ETV suppress HBV replication in most treatment-naïve field practice patients with CHB but fail to prevent HCC development, independent of liver disease severity. NA long-term administration raises several concerns: the patient's commitment to lifelong treatment, adherence, long-term safety, drug resistance in the long-term and costs. Different strategies combining Peg-IFN with ETV or TDF might achieve an antiviral synergy and provide new opportunities to increase HBsAg clearance rates and shorten treatment duration.

Finally, development of new antiviral agents targeting other steps in the HBV replication cycle (viral entry, capsid assembly, viral RNA transcription and epigenetic control of cccDNA) and new immune therapies restoring immune response to HBV remain a major research challenge to improve the efficacy of current antiviral therapy and to achieve HBsAg loss and HBV eradication.

Abstract

Cystic echinococcosis (CE) is a complex, chronic and neglected disease with a worldwide distribution. The liver is the most frequent location of parasitic cysts. In humans, its clinical spectrum ranges from asymptomatic infection to severe, potentially fatal disease. Four approaches exist in the clinical management of CE: surgery, percutaneous techniques and drug treatment for active cysts, and the "watch and wait" approach for inactive cysts. Allocation of patients to these treatments should be based on cyst stage, size and location, available clinical expertise, and comorbidities. However, clinical decision algorithms, efficacy, relapse rates, and costs have never been properly evaluated. This paper reviews recent advances in classification and diagnosis and the currently available evidence for clinical decision-making in cystic echinococcosis of the liver.

Key words: Cystic echinococcosis; Hydatidosis; Clinical management; Diagnosis; Treatment; Surgery; Albendazole; Watch-and-wait; Follow-up; Percutaneous treatment

Core tip: Cystic echinococcosis (CE) is a neglected parasitic disease and echinococcal cysts are mostly located in the liver. Therefore, CE should always be included in the differential diagnosis of cystic lesions of the liver. However, diagnosis and clinical management can be difficult because of the combination of clinical variables (cysts stage, size, presence of complications, available expertise and three different treatments that have never been systematically compared). This review summarizes current knowledge and open issues in this field for those hepatologists who have limited or no experience with this complex condition.

INTRODUCTION

Hepatologists may encounter cystic echinococcosis (CE) in their practice. However, due to its relatively low prevalence in many Western countries, this infection is poorly characterized and its complex management can be difficult for clinicians unfamiliar with this condition. Moreover, hepatic CE should be included in the differential diagnosis of focal liver lesions. In this paper, we summarize the current knowledge on clinical management of hepatic CE to increase hepatologists' awareness of this complex condition.

Figure 1 Life cycle of *Echinococcus granulosus*. Source: www.cdc.gov.

CE, or hydatidosis, is caused by the larval stage (metacestode) of *Echinococcus granulosus* (*E. granulosus*). Its life cycle develops in dogs and other canids, which harbor the adult tapeworm in the intestine, and herbivores (or humans as dead-end occasional host) as intermediate hosts, where the larval metacestode form develops in different organs (Figure 1).

Once eggs are ingested by the intermediate host, the oncosphere (also named exacanth larva), is released from the keratinized embryophore in the stomach and intestine where it penetrates the small intestine wall *via* its hook movements. The oncosphere is then carried *via* portal flow to the liver and other organs where the metacestode implants. Organs may also be reached through the lymphatic system[1]. This process results in primary echinococcosis, while secondary echinococcosis follows the spillage of protoscoleces (tapeworm heads) or small daughter cysts from the original cyst that ruptures following trauma or surgery and their seeding, primarily in the peritoneum for abdominal cysts[2].

The impact of CE on human health is significant, with an estimated 1.2 million people affected and 3.6 million DALYs (Disability Adjusted Life Years) lost globally[3]. Despite the low mortality rate (0.2/100000 population with a case fatality rate of 2.2%) morbidity is high[4]. Moreover, it has a major economic impact with an estimated annual livestock production loss of up to 2190 million US$[5].

Despite these figures, the infection is still under-reported and has received to date much less attention than infections of comparing burden[5]. In humans, its clinical manifestations range from asymptomatic infection to severe, potentially fatal disease.

The liver is the most frequent location of echinococcal cysts, representing approximately 70% of cases[4]. The lungs are the second most common location; however, CE can present in virtually any other organ, although this rarely occurs[1,2].

Echinococcal cysts consist of a periparasitic host tissue (pericyst or adventitia), which surrounds the larval endocyst, and an endocyst itself. The endocyst is composed of an outer, acellular laminated layer and an inner layer, the germinal layer, which gives rise, in fertile cysts, to brood capsules and protoscoleces[6]. Each protoscolex may develop into an adult tapeworm if ingested by a suitable definitive host. The cyst is filled with clear fluid containing molecules of both parasite and host origin, numerous brood capsules, and protoscoleces. Some cysts may also harbor daughter cysts of variable size (Figure 2). The fluid is clear in the early stages (Figure 3A), but can be yellowish and turbid, with fragments of endocyst in advanced stages (*e.g.*, in CE3b cysts) or after months of treatment with albendazole (Figure 3B).

E. granulosus occurs in a broad range of geographic areas and can be found on all continents except Antarctica, and in circumpolar, temperate, subtropical, and tropical zones. Eurasia, Africa, Australia, and South America show the highest prevalence[7]. Within endemic zones, the prevalence varies from sporadic to high, with recent studies showing an higher prevalence among females and with increasing age[8]. Only a few countries can be regarded as free of *E. granulosus* infection[3].

Figure 3 Appearance of cystic fluid. A: Clean and clear cyst fluid from a diagnostic puncture; B: Yellowish and turbid echinococcal fluid in a catheter bag after percutaneous catheterization.

E. granulosus parasites from different hosts show considerable phenotypic variation in terms of morphology, larval growth *in vivo* and *in vitro*, range of host infectivity, and biochemical features. Currently, 10 genotypic strains of *E. granulosus* have been identified (G1-G10), and the impact of these variations on CE epidemiology, pathology and control is being investigated. Genotypes are grouped into 4 species that constitute the *E. granulosus* complex: *E. Granulosus sensu strictu* (G1-G3), *E. equinus* (G4), *E. ortleppi* (G5) and *E. canadensis* (G6-G10). The great majority of *E. granulosus* isolates from humans thus far characterized have been of the sheep genotype (G1)[1,2].

COURSE OF INFECTION

Acute infection in humans has never been documented[9], thus all available data come from experimental studies in animal intermediate hosts. Cavity formation and the development of both germinal and laminated layers of the cyst wall occur 10 to 14 d post infection in the mouse model[10]. Formation of brood capsules and protoscoleces requires a longer time period in sheep, from 10 mo to 4 years[11].

Based on clinical observations using ultrasound (US), the cysts progress from a fluid-filled unilocular cavity to a pseudo-solid, eventually calcified lesion. The sequence of cyst development between these 2 stages is poorly understood[12]. Long-term clinical observation indicates that the early stages are CE1 and CE3a cysts, while final stages are represented by CE4 and CE5, referring to the standardized US classification (see "Imaging" below)[13]. Preliminary observations suggest that cysts that have reached the CE4 stage as a result of treatment may revert to CE3b more often than those reaching the inactive

stage spontaneously; this may occur many years after apparently successful treatment[14] (Junghanss, personal communication). The origin and fate of CE2 and CE3b stages are less clear. CE2 may represent a relapsed CE3a, and CE3b a relapsed CE4, but long-term observations of large cohorts of patients are needed to confirm this hypothesis.

The growth rate of cysts is variable. The average increase in cyst diameter is thought to be 1 cm/year, but data on the natural history of CE are scarce. Cysts may behave differently in different subjects and their growth rate also depends on the surrounding host tissue, with growth rates up to 5 cm/year reported for brain cysts[15-19].

DIAGNOSIS

The presentation of human CE is protean. Patients come to the clinician's attention for a variety of reasons. Potential presentations may be due to the mechanical effect of a large cyst on surrounding tissues, rupture of a cyst causing an acute hypersensitivity reaction, or complications such as biliary obstruction or embolism. The cyst is often asymptomatic and diagnosed accidentally during radiographic examination, surgery, or during evaluation of other clinical diagnoses.

Common symptoms are upper abdominal discomfort and pain and poor appetite. Physical findings are hepatomegaly, presence of an abdominal palpable mass and abdominal distension. Cysts in the liver should be included in the differential diagnosis of several conditions, such as jaundice, colicky pain, portal hypertension, ascites, compression of the inferior vena cava and Budd-Chiari syndrome and can be misdiagnosed as non-parasitic cysts, single or multiple hemangiomas, pyogenic or amebic liver abscess, hematoma, adenoma, adenocarcinoma, hepatocellular carcinoma, metastases, focal or diffuse lymphoma, alveolar echinococcosis, and textiloma[20,21].

As the infection may remain silent for years before the enlarging cysts cause symptoms, the clinical diagnosis of CE is often difficult and requires a combination of physical examination, imaging techniques, in particular

Figure 4 World Health Organization Informal Working Group on Echinococcosis standardised classification of echinococcal cysts. Source: World Health Organization Informal Working Group on Echinococcosis. CE: Cystic echinococcosis; CL: Cystic lesions.

US, and serology; the latter plays a supportive role in diagnosing CE despite the development of sensitive sero-diagnostic tests and the use of different antigen sources.

Imaging

Imaging techniques have revolutionized the diagnosis and clinical management of CE. Gharbi *et al*[22] developed the first US classification for CE in 1981. Other classifications were subsequently produced but were not widely adopted. In 1995, the WHO Informal Working Group developed an international standardized US classification that could be universally applied to replace the plethora of classifications in use.

This classification, published in 2003[23], differs from Gharbi original classification by introducing a cystic lesion (CL) category to include cysts of unclear origin, and by reversing the order of CE types 2 and 3 (Figure 4). The number of cyst types remains unchanged from Gharbi's classification and the types are categorized into active, transitional, and inactive stages. CL cysts are not included as a type of CE, as they require further evaluation before being classified as CE[24]. CE1 and 2 are active, usually fertile cysts containing viable protoscoleces. CE3 are cysts entering a transitional stage where the integrity of the cyst has been compromised either by the host or by chemotherapy. CE4 and CE5 are inactive cysts that have lost their fertility and are degenerating. A more recent amendment to the WHO classification clarifies that calcifications are not limited to CE5 cysts, but may be present to a various extent in all cystic stages and are therefore not indicative of cyst death[25].

Data on long-term follow-up of cysts treated with albendazole and percutaneous treatment provide ground for a further sub-classification of CE3 (transitional) cysts into CE3a (with detached endocyst) and CE3b (predomi-

nantly solid with daughter vesicles). This has important implications for clinical decision-making and prognosis[26]. The sub-classification of CE3 into CE3a and CE3b is supported a recent work using high-field ^{1}H magnetic resonance spectroscopy evaluating the metabolic profile of cysts contents *ex vivo*[27]. This study confirmed findings from optical microscopy that CE3a are equally likely to be viable or non-viable, whereas CE3b are consistently viable. Of note, CE3a and CE3b also respond differently to non-surgical treatments[28,29]. In light of these features, CE3b cysts should be considered as active, while CE3a are the transitional cysts *sensu stricto*.

The same study confirmed the biological activity of CE1 and CE2 and the inactivity of CE4 and CE5. Another study showed how a CE1 brain cyst, in *in vivo* magnetic resonance spectroscopy matched the profile of an active stage before the medical treatment with albendazole (ABZ) and that of an inactive one after ABZ[30]. CE2 and CE3b cysts tend to relapse both after PAIR (puncture, aspiration, injection of a scolecidal agent, and reaspiration) and ABZ[26,28,29], and several studies suggest that a strong Th2 response correlates with susceptibility to disease (active cyst), whereas a Th1 response correlates with protective immunity (inactive cyst), however this is not clear cut[31-36].

Computed tomography (CT), including spiral or multidetector CT, with multiplanar reformations, and magnetic resonance imaging (MRI), with at least a T2-weighted imaging sequence, and if necessary cholangio-pancreatography, have distinct indications: (1) impaired US visualization due to obesity or subdiaphragmatic location of the cyst; (2) disseminated disease; (3) extra-abdominal location; (4) complications (cyst infection, cysto-biliary fistulae); and (5) pre-surgical evaluation and follow-up (Figure 5). Whenever possible, MRI is pre-

Figure 5 Computed tomography and magnetic resonance imaging of hepatic cystic echinococcosis. ferred to CT for pre-treatment assessment[37,38].

Serology

Routine blood tests are not specific for CE, and with liver involvement they can be normal or suggestive of cholestasis with or without hyperbilirubinaemia or raised transaminases or γ-glutamyltransferase (γ-GT)[1,39,40]. Transient elevation of γ-GT and alkaline phosphatase, in association with hyper-transaminasemia and eosinophilia, may indicate cyst rupture in the biliary tree. Despite CE being a helminthic infection, eosinophilia is usually moderate or absent.

Despite the development of sensitive laboratory tests and the use of different antigen sources, serology remains complementary to imaging in the diagnosis of CE. Currently, lipoprotein antigen B (AgB) and Ag5, the major components of cystic fluid, have received the most attention with regard to diagnosis, but purified cyst hydatid fluid is still the most widely used in current assays for immunodiagnosis of CE, which are not standardized[41,42]. In clinical practice, usually two tests are performed (for example ELISA and indirect hemagglutination (IHA), with immunoblotting (IB) as a confirmatory test. IHA and ELISA show sensitivity for hepatic cysts ranging between 85% and 98%[42-46]. The result of a single test is not considered diagnostic, and the two tests are generally run in parallel. IB is performed as a confirmatory test when ELISA and IHA are inconclusive or for the differential diagnosis with other infections, although *E.*

granulosus specific bands may be also be detected in the serum of patients affected by *E. multilocularis* and rarely *T. solium* cysticercosis[47]. False positives result from cross-reactivity, most commonly with other cestode infections (*E. multilocularis, Taenia solium* cysticercosis) and some other parasitoses (schistosomiasis, liver flukes, filariasis), but also from non-infectious diseases such as malignancies and cirrhosis[1,41,48-50].

Serologic testing for CE is hampered by many problems[41-43,45]. These include low sensitivity, partially dependent upon the location of the cysts in the body and the cystic stage, and the inability of serology to clearly distinguish between active and inactive cysts when US is inconclusive[43]. Up to 20% of patients with single hepatic cysts and up to 50% of those with lung cysts may be seronegative at diagnosis, while patients with cysts in other locations are often seronegative. In addition, patients with multiple cysts are generally seropositive. In the case of hepatic cysts, patients with CE1 and CE4-CE5 cysts are often seronegative (30%-58% and 50%-87% respectively), while rates of negativity are lower in the presence of CE2 and CE3 cysts (5%-20%). It is also worth noting that serodiagnostic tests may be persistently positive for > 10 years even after radical surgical removal of the cysts, and are often positive in the presence of inactive cysts[17,51,52]. This may lead inexperienced clinicians to prescribe unnecessary treatment and cause unjustified anxiety to the patient. New antigens are under investigation which promise to have higher diagnostic performances in

these situations[53].

Microscopical examination

When US and serology are inconclusive, a direct analysis of the material obtained by percutaneous aspiration is needed. The procedure must be performed with the assistance of an anesthesiologist because of the very low but nonetheless present risk of anaphylaxis[54]. The presence of protoscoleces or their components or of antigens specific to *E. granulosus* indicates the parasitic nature of the cyst[55].

TREATMENT

There is no standard treatment for hepatic CE. The appropriate treatment depends on individual patient factors, cyst characteristics, the therapeutic resources available, and the physician's preference[56]. Matters are further complicated by the dearth of randomized clinical trials evaluating treatment options, and the ensuing low level of evidence to support one therapeutic modality over another[57,58].

Surgery has long been considered the best, if not the only, option in the treatment of CE. However, in the past two decades, medical treatment, percutaneous procedures, and a "watch and wait" approach have been successfully introduced and have replaced surgery as the treatment of choice in selected cases[59].

Surgery

While surgery is increasingly being replaced by other options in uncomplicated cysts, it maintains a central role in complicated cysts (*i.e.*, rupture, biliary fistula, compression of vital structures, superinfection, hemorrhage), cysts at high risk of rupture, or large cysts with many daughter vesicles that are not suitable for percutaneous treatments.

Surgery can be performed as an open procedure, with either radical or conservative techniques, or laparoscopically. There are still controversies as to the safest and most effective technique, and in which cases it should be applied[57,60,61]. As a rule, perioperative ABZ prophylaxis, from 1 wk prior to surgery until 4 wk postoperatively, is necessary to minimize the risk of secondary echinococcosis from seeding of protoscoleces in the abdominal cavity[59].

Radical surgery aims to remove the entire pericystic membrane and the parasitic contents with or without hepatic resection, and can be performed with either the "open-cyst" or "closed-cyst" method. In conservative procedures, only the parasitic material is removed while part or all of the pericyst is left in place and the residual cavity is managed with different techniques, such as omentoplasty, capitonnage, or external drainage.

A cleavage plan between the inner layer of the host's reaction towards the parasite and the cyst outer layer, or "adventitia", as described by Peng *et al*[62], limits damage to liver parenchyma when dissecting around the cyst and

allows for safer removal. Based on these anatomical considerations, such an operation should be more adequately termed "total cystectomy." Mortality ranges between 0.8% and 6.5%, morbidity between 12% and 84%, and relapse rate between 2% and 30%[39,60,63,64].

It is commonly perceived that the more radical the surgery, the higher the operative risk but the lower the risk of relapses and *vice versa*. However, results of meta-analyses and single center studies indicate that radical surgery is superior to conservative surgery, with lower morbidity (3%-24% *vs* 11%-25%), mortality (1%-1.8% *vs* 2%-5%) and recurrence rates (2%-6.4% *vs* 10.4%-40%)[61,64-66], although the type of surgery was not found to be a predictive factor of post-surgery complications in the study of El Malki *et al*[60]. Other factors associated with surgical outcome are large cyst size, more than 3 hepatic cysts, presence of biliary fistulae, age > 40 years, repeated surgery due to recurrence, capitonnage alone as a measure of residual cavity management, and cyst rupture during surgery[60,61,64,67,68].

Recurrence, both local and as secondary echinococcosis, is associated with spillage during removal of the cyst, incomplete removal of the endocyst, and possibly the presence of unnoticed exophytic cyst development[63,69]. For the latter, intraoperative US has been shown to be an important tool to improve the quality of hepatic surgery[70].

Infection and biliary communication with the cyst (*i.e.*, leakage or rupture with cholestasis) are the most common complications of echinococcal cysts and can occur before or after surgical or percutaneous interventions[71,72]. Cyst diameter is a factor associated with a high risk of biliary-cyst communication in clinically asymptomatic patients. A recent study reported that cyst diameter > 7.5 cm had a specificity and sensitivity for biliary-cyst communication of 73% and 79%, respectively[73]. Thus, surgeons operating on cysts larger than 7.5 cm should be prepared to deal with this complication and should perform preoperative retrograde cholangiopancreatography or MR imaging[73,74].

Several methods have been proposed for the management of cyst-biliary communications. When intrabiliary rupture is diagnosed pre- or intra-operatively, a simple suture of the orifice is sufficient if there are no cystic contents in the biliary tree and the common bile duct has a normal caliber. When cyst contents are found in the biliary tree or the common bile duct has an abnormal caliber, evacuation of the cystic content and a T-tube drainage placement or even a coledochoduodenostomy are needed[71,75]. Alternatively, endoscopic treatment with sphincterotomy and placement of a nasobiliary catheter has been performed[76,77]. Postoperative bile leakage resulting in symptomatic bilomas or high-output biliary fistulae can be managed endoscopically by sphincterotomy with nasobiliary drainage or biliary stenting[78,79].

Surgical interventions other than segmentectomies can result in a number of residual cavities that may be mistaken for recurrences or other conditions[20]. Some groups have evaluated these findings and attempted to

categorize them relative to the type of surgical procedure performed[80].

A recent review on management of post-surgical complications concluded that " the evidence level is low" and that "there are many questions and few answers"[81].

Percutaneous treatments

Percutaneous treatments for abdominal CE were introduced in the mid-1980s, with the adoption of minimally invasive procedures made possible by new imaging tools, particularly CT and US[82-85]. These treatment modalities aim either to destroy the germinal layer with scolecidal agents or to evacuate the entire endocyst.

The most popular method is PAIR[13]. Several modified catheterization techniques are used to evacuate the endocyst, and are generally reserved for cysts which are difficult to drain or tend to relapse after PAIR, such as multivesiculated cysts or cysts with predominantly solid content and daughter cysts[26].

Catheterization techniques are based on the aspiration of the "solid" content of the cyst, the endocyst surrounded by pseudocaseous inflammatory material, through a large-bore catheter or other device. Several variants of these techniques have been proposed, in particular percutaneous evacuation (PEVAC)[86], a modified catheterization technique[87], and dilatable multi-function trocar[88].

Puncture of echinococcal cysts has long been discouraged because of the risk of anaphylactic shock and spillage of the fluid; however, as experience with US-guided interventional techniques has increased since the early 1980s, a growing number of articles have reported its safety in treating abdominal, especially liver, echinococcal cysts. In a recent systematic analysis on percutaneous aspiration of echinococcal cysts, only 2 cases of lethal anaphylaxis (0.04%) and 99 reversible anaphylactic reactions (1.8%) were reported[54]. This study divided the complications related to cyst puncture into major (0.5% of cases with anaphylactic shock and peritoneal liquid seeding, liver or intra-abdominal abscess, sepsis, biliary fistulas) and minor (10%-30% of patients with fever, hypotensive reactions, nausea, vomiting, skin rash, respiratory symptoms). Peritoneal seeding has never been reported, but it is difficult to assess the true rate because many reported series have a short follow-up time. Prophylactic administration of ABZ starting 4 h before the puncture and for at least 30 d after puncture is a cautionary measure that should always accompany PAIR[59].

PAIR is performed with several variants of the standard protocol and is generally successful at inducing permanent solidification of medium-sized CE1 and CE3a cysts[13]. A few reports with long-term follow-up indicate that multivesiculated cysts (*i.e.*, CE2 and CE3b) tend to relapse repeatedly after PAIR[26,29,89,90]. Reported morbidity and mortality range from 8.5%-32% and 0%-1% respectively[89,91-94]. Mean hospital stay is 1-4 d compared to 12 d in case of surgery[89,91,93]. PAIR has also been performed in remote, resource-poor areas using portable US ma-

chines[95]. Overall response rates range from 72%-97%, with relapse rates from 1.6%-5%[89,91,92,94,96]. However, these figures vary greatly when cyst stages are taken into account. Indeed, unilocular CE1 and CE3a cysts respond very well to percutaneous treatment (> 80% response), while multi-vesiculated CE2 and CE3b cysts have a success rate lower than 40%[29,89,90]. Giant CE1 and CE3a cysts of 10 cm or greater, should preferably be treated with a large catheter left in place until the daily drainage is less than 10 mL, on average 3 wk[97].

The experience with catheterization techniques in CE2 and CE3b cysts is more recent and less extensive than that with PAIR, and results from series with long-term follow-up are needed before their efficacy can be determined. Data available for PEVAC in cysts with cysto-biliary fistulas are less than satisfying, given the long hospitalization and catheter times, up to 128 and 55 d, respectively[86]; in these cases PEVAC does not compare favorably with surgery.

The use of percutaneous techniques should be reserved for referral or specialized centers where teams are prepared to deal with possible complications and an anesthesiologist should always be present during the procedure.

Use of scolecidal agents in surgery and percutaneous treatments: Scolecidal agents should be applied only after having excluded the presence of cysto-biliary fistulae, either with intraoperative cystoscopy or evaluating bilirubin content in the cyst fluid. Although chemical sclerosing cholangitis, due to contact of the scolecidal agent with the biliary ducts, has never been reported using PAIR, several reports are present in the literature after surgery[98-100] and damage to the biliary epithelium has been shown in animal models[101,102]. While hypertonic (15%-20%) saline and 95% ethanol are the most widely used scolecidal agents for percutaneous treatments, a range of other compounds have been tested or are being investigated in the attempt to find an agent that does not damage the biliary epithelium[103-106].

Direct intracystic injection of mebendazole (MBZ) has been successfully performed in animals and humans, and ABZ sulfoxide, the active metabolite of ABZ, has been successfully injected in cysts in animals, but not in humans[107-110]. However, little difference has been found in *in vitro* studies between the effect of hypertonic saline and that of ABZ sulfoxide or sulfone[103]. Unfortunately, ABZ sulfoxide is not available as an injectable formulation and this prevents its clinical use.

Chemotherapy

The use of benzimidazole (BZD) carbamates in the treatment of CE was introduced in the 1970s. While both albendazole and MBZ have been proven effective against the larval stage of *E. granulosus*, ABZ is the current treatment of choice due to better absorption[111]. ABZ is administered orally at a dose of 10-15 mg/kg per day generally for 3-6 mo; administration should be continu-

ous without treatment interruptions, in contrast to the recommendation in the 1980s[26,112]. However, the optimal dose and duration of treatment with ABZ have not been formally assessed.

The comparative rarity of CE in many industrialized countries where BZD is available and affordable is such that only a few centers are able to follow sufficient numbers of patients within a reasonable period of time. Thus, most studies are small, and few have adequate controls.

In the largest series published thus far, 848 patients with 929 cysts received 3-6-mo continuous cycles of MBZ or ABZ treatment[113]. Long-term follow-up showed that 74.1% of the cysts developed degenerative changes. These were more frequent in ABZ-treated than in MBZ-treated cysts (82.2% *vs* 56.1%; *P* < 0.001). During follow-up, 104 cysts (22%) had degenerative changes, whereas 163 cysts (25%) relapsed. In other series, reported outcome rates for hepatic cysts are: 28.5%-58% cure/marked improvement, 10%-51% partial response, 13%-37% no change, and 4%-33% worsened[112,114-120]. Relapse rates range from 9%-25%[112,113,116,121], and, although responsive to subsequent treatments, cysts tend to relapse multiple times[28]. Factors associated with treatment outcome include cyst stage, size, and localization. Unilocular (CE1 and CE3a) cysts and small cysts (< 6 cm) respond better and faster to ABZ treatment compared with multivesciculated (CE2 and CE3b) and larger cysts, with a lower relapse rate[28,113,117,120,122], as clearly shown in the systematic review by Stojkovic *et al*[28]. A recent study highlighted the importance of at least 12 mo of follow-up, since it is difficult to predict cyst behavior after treatment[28].

Adverse effects of BMZ include headache (10% of cases), gastrointestinal symptoms (56%), hepatotoxicity, severe leukopenia, neutropenia or thrombocytopenia (< 1%), and alopecia (2%)[59,123]. Increases in aminotransferases (15% cases) may be due to drug-related efficacy or to real drug-related toxicity. Risks observed in laboratory animals include embryotoxicity and teratogenicity. While teratogenicity is theoretical, it is nonetheless good practice to avoid use during pregnancy whenever possible. Thus, the treatment should be delayed until after delivery[124]. Hospitalization is not necessary, but regular follow-up is required with a monthly check of the hemogram and liver enzymes.

If ABZ is not available or not tolerated, MBZ, the first BMZ tested against *Echinococcus*, may be used at a dosage of 40-50 mg/kg body weight, in three divided doses during fat-rich meals. Costs of BMZ and repeated examinations may be prohibitive in countries with limited resources. Praziquantel (PZQ) 40 mg/kg once a week in combination with ABZ seems more effective in killing protoscoleces than ABZ alone[125]. Other clinical studies evaluating this combination are available but they do not clarify whether PZQ has a pharmacological effect in its own right or acts only by enhancing ABZ absorption[126]. The usefulness of PZQ to avoid secondary echinococcosis needs confirmation[127].

Watch and wait

Recent expert opinion recommends that inactive CE4-CE5 cysts that are asymptomatic and uncomplicated should be left untreated and monitored regularly by imaging techniques, using the so-called "watch-and-wait" approach[56,59]. The rationale of leaving uncomplicated, inactive cysts untreated and solely monitored over time follows the observation that up to 20% of cysts become spontaneously inactive without any treatment and such cysts are likely to remain stable over time[18,26,118,120,128-130].

Follow-up

In chronic conditions such as CE, follow-up is crucial in order to evaluate the efficacy of treatment. The follow-up should start with a short interval (every 6 mo for the first 2 years) and continue with a longer interval (once a year), but this needs to be adjusted to the patient's setting. In referral centers, follow-up includes US imaging and serology; for specific patients (*e.g.*, with abdominal gas, obesity, multiple cysts, and so on) it may also include CT or MRI.

Long-term follow-up, generally longer than 5 years, is required to evaluate local recurrences which have been reported up to 10 years after apparently successful treatment[14].

CLINICAL DECISION-MAKING IN HEPATIC CE

CE can be very difficult to treat and even more difficult to cure for a number of reasons. The disease is complex and dynamic, with an evolving phase and quietly growing cysts, followed by an involution process during which the parasite is gradually dying, leaving behind a solidified, often calcified cyst or a scar.

Each successive active cyst stage carries its own risks for serious and even life-threatening complications. This variation during the CE disease process leads to a wide range of treatment modalities with an equally wide range of technological and training backgrounds necessary for implementation and delivery. As a result of all of these issues, no "one size fits all" management approach is available, and a stage-specific approach currently appears to be the best way to manage this condition[26].

Technical and economic difficulties are encountered in countries with limited resources where the patient load is greatest: here CE is defined as a *neglected disease*. Problems in acquiring clinical competence in countries where few patients suffer from the disease are also an obstacle: in these settings CE is an *orphan disease*[26]. Further complicating matters is the fact that CE is a chronically neglected disease. Investment in research is very low compared to what is needed based on estimated burden of disease[5]. The latter is very difficult to gauge because the true incidence is unknown. Acute cases have never been recorded because they are clinically silent and only the prevalence can be assessed, although often with great difficulties due to poor access to healthcare

Figure 6 Schematic representation of the natural history of hepatic cystic echinococcosis and suggested treatments. Solid black arrow indicates natural evolution toward inactivation; black dashed arrows indicate evolution of therapy-unresponsive chronic stages. US images: cyst ultrasound classifications according to World Health Organization Informal Working Group on Echinococcosis[23] (in bold) and Gharbi et al[22]. Gray boxes: suggested stage-specific approach to uncomplicated hepatic CE[59]. ABZ: Albendazole; PAIR: Puncture, aspiration, injection of scolecidal agent, re-aspiration; PC: Permanent catheterization.

and underreporting[3]. The best solution to this problem is likely the setting up of national CE registries modeled on the European Register for Alveolar Echinococcosis. We have recently set up the Italian Register for Cystic Echinococcosis: http://www.iss.it/riec/), and preliminary results of systematic enrolment of CE patients seen in Italian hospitals will be published in the near future. However, such initiatives require resources and funding, both difficult to come by when dealing with a neglected disease[5].

OPEN ISSUES IN STAGE-SPECIFIC APPROACH

Although the evidence base for clinical decision-making is still at the level of expert opinion, clinical management of hepatic CE patients is facilitated by the standardization of US classification, enabling clinicians to identify the most rational option on the basis of cyst stage[26,131]. The stage-specific treatment approach for uncomplicated cysts of the liver can be summarized as follows (Figure 6).

Small (< 5 cm) univesicular CE1 and C3a cysts tend to respond well to ABZ treatment, while larger cysts are treated preferentially with PAIR plus ABZ. Giant cysts (> 10 cm) should be treated with a catheter left in place until the drainage is minimum, usually about 3 wk.

Surgery should be reserved for complicated cysts, including those with rupture or high risk of rupture, fistulization, compression of vital organs or vessels, hemorrhage, or bacterial infection. Surgery is also an option for

cysts poorly responsive to medical or percutaneous treatment when a "watch and wait" approach is not viable because of poor access to healthcare.

Abstract

The aim of this topic highlight is to review relevant evidence regarding the influence of the metabolic syndrome (MS) and its associated liver manifestation, non-alcoholic fatty liver disease (NAFLD), on the development of liver cancer as well as their impact on the results of major liver surgery. MS and NAFLD, whose incidences are significantly increasing in Western countries, are leading to a changing profile of the patients undergoing liver surgery. A MEDLINE search was performed for relevant articles using the key words "metabolic syndrome", "liver resection", "liver transplantation", "non alcoholic fatty liver disease", "non-alcoholic steatohepatitis" and "liver cancer". On one hand, the MS favors the development of primary liver malignancies (hepatocellular carcinoma and cholangiocarcinoma) either through NAFLD liver parenchymal alterations (steatosis, steatohepatitis, fibrosis) or in the absence of significant underlying liver parenchyma changes. Also, the existence of NAFLD may have a specific impact on colorectal liver metastases recurrence. On the other hand, the postoperative period following partial liver resection and liver transplantation is at increased risk of both postoperative complications and mortality. These deleterious effects seem to be related to the existence of liver specific complications but also higher cardio-vascular sensitivity in a setting of MS/NAFLD. Finally, the long-term prognosis after curative surgery joins that of patients operated on with other types of underlying liver diseases. An increased rate of patients with MS/NAFLD referred to hepatobiliary units has to be expected. The higher operative risk observed in this subset of patients will require specific improvements in their perioperative management.

Core tip: The metabolic syndrome (MS) and its hepatic manifestations, non-alcoholic fatty liver disease (NAFLD), are increasingly observed in Western countries. Both MS and NAFLD could favor the development of primary liver malignancies and may also lead to end-stage liver disease. These patients are at higher operative risk because of underestimated postoperative liver related complications but also specific increase in cardio-vascular complications. Specific improvements in the perioperative management of these patients are required in order to improve the operative results.

Cauchy F, Fuks D, Zarzavadjian Le Bian A, Belghiti J, Costi R. Metabolic syndrome and non-alcoholic fatty liver disease in liver surgery: The new scourges? *World J Hepatol* 2014; 6(5): 306-314

INTRODUCTION

The prevalence of the metabolic syndrome (MS) is reaching epidemic levels in Western Europe and Northern America, where it is reported to be as high as 25% in the general population[1]. The MS is a constellation of clinico-biological features closely related to insulin-resistance and includes dyslipidemia, hypertension, glucose intolerance and central obesity[1]. Non-alcoholic fatty liver disease (NAFLD) represents the hepatic manifestation of the MS. NAFLD pathological alterations, which range from simple steatosis to steatohepatitis, may lead to fibrosis and end stage liver disease[2]. As its incidence parallels that of the MS, NAFLD is currently becoming one of the first chronic liver diseases in Western countries and therefore has a major health impact[3]. Also, both MS and NAFLD have been suggested to be directly or indirectly associated with the development of primary liver malignancies[4-7]. For all these reasons, it is likely that more and more of these patients will be referred to hepatobiliary (HPB) and liver transplant units in upcoming years[8].

The increasing prevalence of MS/NAFLD and MS/NAFLD-related liver tumors is not the only issue related to these disorders. Despite numerous advances in the fields of hepatology, perioperative management and liver surgery, the impact of both MS and NAFLD on the postoperative course of patients undergoing liver surgery has long been neglected. As a matter of fact, it is only recently that evidence suggesting a specific and underestimated risk regarding postoperative morbidity and mortality in the setting of liver surgery has been released[8-13]. In that sense, it seems crucial that gastroenterologists and surgeons should be fully aware of the existence of MS and NAFLD as well as their negative impact on the postoperative course in order to optimize the perioperative management of concerned patients and to prevent any avoidable morbidity/mortality.

The objectives of this review are therefore: (1) to provide comprehensive insights regarding the current standards and issues in the diagnosis of both MS and NAFLD; (2) to clarify their respective impact on tumor progression as well as their influence on postoperative outcome; and (3) to discuss the measures which should be undertaken in upcoming years in order to improve the results of surgery.

DEFINITIONS AND ISSUES

Metabolic syndrome

The definition of MS has evolved during the past decade. Current consensual criteria for its diagnosis are summarized in Table 1. These include central (or android) obesity, hypertension, dyslipidemia, with either increased triglycerides level or decreased high density lipoprotein cholesterol level, and glucose intolerance[1]. Even although the presence of at least 3 out of 5 criteria of the consensual definition are required to define the MS[1], both liver histological manifestations and influence on surgical outcomes after liver surgery may occur in patients presenting with individual components of the MS. Indeed, fatty liver disease may also occur in patients with isolated diabetes mellitus (DM)[14], hypertriglyceridemia[15] and obesity[16,17]. Likewise, higher perioperative morbidity or mortality rates after liver resection are reported in patients with only DM[18,19] or overweight/obesity[20,21], whereas our groups found the association of just 2 disorders to be related to poor outcome of surgery[13,22].

Interestingly, most of the medical and surgical studies do not always gather all these consensual criteria but rather use substitutes for convenience. Such substitutes may lead to a certain degree of confusion. For example, it is frequently assumed that patients receiving statin or fenofibrate medication have dyslipidemia[8,11] and that patients receiving antihypertensive therapy have hypertension. However, some of these patients may receive such medications for primary cardiovascular prevention or renal protection. In the same way, central obesity, which reflects visceral adiposity, it is often measured using the BMI and various cut off values are proposed[8,12,13]. Yet, BMI does not allow distinguishing central obesity, which is a metabolic disorder included in the MS, from peripheral obesity. In that sense, circumferential waist appears to be more reliable and should be preferred[23,24]. Finally, the terms hyperglycemia and insulin-resistance are often used indiscriminately, whereas some authors suggest that they should not. Hence, the presence of insulin-resistance should be routinely assessed using the homeostasis model assessment of insulin resistance[25] whenever hyperglycemia is found.

NAFLD

NAFLD has emerged as one of the most frequent forms of chronic liver disease in Western countries[5,6] and should be considered in cases of fatty infiltration exceeding 5% of the liver parenchyma at histology in the absence of previous or ongoing significant alcohol consumption[26]. Although NAFLD is considered the hepatic manifestation of the MS, other conditions, including chronic hepatitis B and C infection[27,28], irinotecan based chemotherapy[29,30] and several other medications, including methotrexate, tamoxifen or amiodarone[31,32], may also lead to fatty liver disease and should be meticulously ruled out. NAFLD, which encompasses a wide spectrum of diseases ranging from simple steatosis to non-alcoholic steatohepatitis (NASH)[26], can progress to cirrhosis and may lead to end-stage liver disease[5,6]. Histological analysis remains the gold standard for the assessment of NAFLD and should be performed by a trained pathologist[33]. Several histological scores might be useful for diagnosis. The most frequently used score is the non-alcoholic liver disease activity score (NAS) proposed by Kleiner *et al*[26], which is a semiquantitative,

Table 1 Diagnostic criteria of the metabolic syndrome

Criteria	Consensual criteria definition[1]	Other non-consensual criteria
Central obesity	Abdominal waist[2]	Different cutoff values of BMI
	> 102 cm (United States) or 94 cm (Europe) in men	$\geqslant 28$ or $\geqslant 28.8$ or $\geqslant 30 \ kg/m^2$
	> 88 cm (United States) or 80 cm (Europe) in women	
Dyslipidemia	Triglycerides $\geqslant 150 \ mg/dL$ (1.7 mmol/L)	Statin or fenofibrate medication[3]
	HDL cholesterol	
	< 40 mg/dL (1.03 mmol/L) in men	
	< 50 mg/dL (1.29 mmol/L) in women	
Hypertension	Blood pressure > 135/85 mmHg	Any antihypertensive therapy[3]
Glucose intolerance	Hyperglycemia	Any diabetes
	Fasting glucose $\geqslant 110 \ mg/dL$,	Any antidiabetic therapy (oral or insulin)
	or type Ⅱ diabetes	

[1]Diagnosis of metabolic syndrome (MS) requires at least 3 out of 5 criteria; [2]Other cut off values have been established for Asians and Latin Americans; [3]These treatments can be taken in account for the diagnosis of MS unless if given in preemptive purpose.

histology-based score system including three parameters, namely steatosis (on a scale of 0-3), lobular inflammation and hepatocellular ballooning (on a scale of 0-2 each) and therefore ranges from 0 to 7. Likewise, Bedossa *et al*[34] recently published a histopathological algorithm and scoring system for evaluation of liver lesions in morbidly obese patients.

NASH

NASH is considered the result of long-lasting inflammation. It is characterized by several histological alterations, including steatosis, lobular inflammation and ballooning, and may also be associated with fibrosis. Even although the diagnosis of NASH was initially suggested for NAS values of 4 or 5[26], there is an ongoing debate regarding the accuracy of NAS in assessing NASH. Interestingly, Brunt *et al*[33] have emphasized that the diagnosis of NASH based on evaluation of patterns as well as individual lesions on liver biopsies did not always correlated with threshold values of the semi quantitative NAS. Moreover, NAS does not include other histological alterations often present in NAFLD, such as microcirculation modifications, which are not routinely reported by pathologists[35]. Thus, rather than being based on the NAS value alone, the differentiation between NASH and no-NASH should rather take into account the pathologist report[33].

Identification of NASH in patients with MS/NAFLD

Since the increasing incidence of both MS and NAFLD in Western populations de facto puts a great amount of patients at risk of developing NASH, any large scale screening policy aimed at obtaining histological diagnosis of NAFLD does not seem reasonable. Furthermore, the accuracy of histology in identifying NASH is suboptimal as both inter-observer variations[36] and discrepancies from one sample to the other within the same parenchyma may occur[37]. In order to increase cost/effectiveness and accuracy of diagnosis, and also to avoid the intrinsic invasiveness of biopsy, there has been significant interest in identifying non-invasive methods of predicting liver histology in patients with suspected NASH. Hence, numerous biological (alanine aminotransferase/aspartate

aminotransferase ratio, FIB-4, analysis of organic compounds in breath)[38] and imaging techniques (magnetic resonance imaging (MRI) for quantification of liver steatosis[39] or magnetic resonance spectroscopy) have been proposed for the detection of underlying parenchymal changes among patients with MS, but none has become the "gold standard". In particular, although MRI has shown high accuracy in detecting steatosis, its effectiveness in evaluating (and possibly ruling out) fibrosis is questionable in the presence of fat[40].

MS/NAFLD INFLUENCE ON CARCINOGENESIS

The association between individual components of the MS, such as diabetes[41] and being overweight[42], and an increased risk of cancer has long been known. More recently, it has been suggested that the MS itself was implicated in carcinogenesis, especially in the liver[4]. Indeed, two recent series have shown that the MS itself was associated with an increased risk of developing of both HCC[3] and intrahepatic cholangiocarcinoma[43]. In particular, HCC incidence in patients with MS is reportedly 2-4 fold higher than in general population[7].

How the MS acts to promote carcinogenesis remains to be fully elucidated. Several genetic mechanisms are supposed to be involved in MS-related carcinogenesis. Firstly, direct oncological effects may play a role in the carcinogenesis by loss of tumor suppression genes, deregulation of IL-6 signal or inhibition of JNK1 phosphorylation[22]. This mechanism is supposed to be at the origin of malignant transformation of liver cell adenoma in men[44]. Secondly, the MS has been reported to be associated with low-grade, chronic systemic inflammation, implying a serum increase of inflammatory cytokines, such as TNF-α and IL-6[5], and a decrease in anti-inflammatory ones, including adipocytokines[45].

Interestingly, most studies focusing on HCC occurring in patients with MS (or arising in a context of NAFLD) have consistently reported that 30%-60% of the patients displayed no feature of severe underlying fibrosis[7,8,22,46]. More surprisingly, almost 20% of the

patients had a normal underlying liver parenchyma after conventional pathological examination. In this setting, HCCs furthermore tended to be isolated and of large size[8,22]. These findings seem to indicate that several different pathways may be implicated in liver carcinogenesis in patients with MS, as suggested by the inconstant presence of various histology alterations.

Although not always present, NASH related cirrhosis may possibly be considered a precancerous lesion as it is associated with a yearly incidence of HCC as high as 2.6%[5], leading to a cumulative 5-year incidence ranging from 7.6%[47] to 11%[48]. In the event of NASH related cirrhosis, both presence and pattern of hepatic iron deposition[49] have been incriminated to further accentuate parenchymal changes, thus promoting liver carcinogenesis.

Virus infection may also play an indirect role in tumor development in patients with MS. In particular, the specific subset of patients with chronic hepatitis C virus (HCV) infection developing an HCC is worth being mentioned. Several authors have emphasized that chronic HCV infection was associated with fatty infiltration of the liver parenchyma in 50%-70% of cases, including massive steatosis and NASH[27,28,50,51]. A non-negligible number of the latter display the so-called "viral steatosis" as a consequence of virus interference with fat metabolism (in the absence of pre-existing metabolic disorders). Thus, in this setting, steatosis itself could be responsible for the occurrence of secondary insulin-resistance and systemic inflammation. Even although the "viral steatosis" has been shown to regress after viral eradication[52], its existence has been incriminated in recurrence of HCV related HCC[53] after curative surgery. However, since steatosis and lobular inflammation may be found in HCV infection regardless of MS/NAFLD, the supposed association between HCC, HCV and NAFLD could be more a statistical artifact than a real oncogenic mechanism. Taken together, the supposed pathway from viral infection to viral steatosis and HCC, as well as the possible mechanisms finally leading to HCC development (fibrosis, inflammation or induced insulin-resistance), still remain to be assessed.

Finally, the association between MS, NAFLD and colorectal liver metastases (CLM) has to be considered. Indeed, whereas several studies on colorectal cancer patients analyzed the impact of 5FU + irinotecan based chemotherapy on the development of steatohepatitis[28,30], it is only recently that studies have focused on the specific oncological influence of both MS and NAFLD on CLM, with various results. On one hand, Hamady *et al*[54] found that liver steatosis was associated with a 1.3 fold risk of local recurrence following liver resection for CLM, regardless of the chemotherapy regimen used. On the other hand, Viganò *et al*[55], studying the impact of chemotherapy-related liver injuries, pathological tumor regression grade and micrometastases on long-term survival, found that higher grade (2-3) steatosis was significantly associated with improved 5 year overall survival compared to lesser steatosis (grade 0-1) after resection of CLM (52.5% *vs* 35.2%, *P* = 0.002). Even although these studies lacked specific histological assessment of NAFLD and precise identification of metabolic disorders, the observed results clearly reflect the growing enthusiasm of surgeons in exploring the impact of NAFLD on the long-term outcomes of patients with CLM.

MS/NAFLD IMPACT ON OUTCOME OF LIVER SURGERY

The impact of individual components of the MS and liver steatosis on the postoperative course following liver resection has been extensively investigated[18,56-60]. Accordingly, it has been established that liver surgery provided poorer results in patients affected by diabetes[18] or obesity[56,57] than in otherwise healthy patients. Similarly, several studies have highlighted that steatosis per se was a risk factor for postoperative complications after major hepatectomy[58-60]. In experimental models, liver fatty infiltration, such as mild or severe steatosis, has been found to be associated with lower regenerative ability following portal vein occlusion, elevated sensitivity to ischemia-reperfusion injury and higher hepatocellular injury after partial liver resection[61]. Nevertheless, it is only recently that surgeons have focused on the results of surgery, liver resection and transplantation in the specific subset of patients with MS or NASH.

Liver resection
Table 2 summarizes the results of recent series analyzing the early outcome of patients undergoing liver resection in a setting of MS/NASH[8-13]. Of these six series, three aimed at assessing the influence of the MS on outcome[8,12,13], whereas the remaining three aimed at evaluating the impact of histological modifications, including NAFLD and NASH[9-11]. The fact that data concerning metabolic disorders (and MS) and liver histology were gathered together in only half of the series[8,11,13] emphasizes the absence of clear understanding of the relationship between MS and MS-related liver disease. In these studies, mortality after liver resection varied from 3% up to 30% and was related to the primarily studied parameter, *i.e.,* MS, NAFLD or NASH. In this setting, it has been recently suggested that MS patients with a NAS > 2[8] or those with an histological diagnosis of NASH[11] had a 2.7-fold higher risk of experiencing liver related but also cardio-respiratory complications than those with normal underlying parenchyma. Hence, it seems that steatohepatitis rather than simple steatosis was a risk factor for postoperative complications[11]. Even if these recent findings may appear to be in opposition with previously published results maintaining a negative impact of steatosis on outcome[58-60], it is likely that the poor assessment of inflammatory changes in the underlying steatosic parenchyma may have biased older series. On the opposite hand, the progressively increasing degree of parenchymal change, damage and inflammation from steatosis to steatohepatitis is nowadays considered as a continuum, which progressively and proportionally increases overall

Table 2 Studies focusing on liver resection in a context of metabolic syndrome, non-alcoholic fatty liver disease and non-alcoholic steatohepatitis

Ref.	Endpoint	Underlying parenchyma	Assessment of metabolic factors	Morbidity			Mortality
				Overall	Liver related	CV and respiratory

postoperative morbidity/mortality.

Intuitively, not only the "quality" but also the "quantity" of liver remnant should be considered. In fact, it has been recently suggested that NASH was independently associated with both higher postoperative liver insufficiency and mortality following right hepatectomy (including extended right hepatectomy)[13], and trisectionectomy[10], although a (usually) "safe" amount of liver parenchyma was left in place. This result clearly emphasizes the worse tolerance to extended resection of fatty and inflammatory livers. This feature may be of particular importance in the case of HCC developing in a MS/NAFLD context, where large lesions often require major resections[8,22].

Considering cardiovascular morbidity/mortality, it has been shown that NASH was an independent riskfactor for the development of coronary artery disease and calcifications regardless of the degree of visceral adiposity[62,63], thus leading to a higher incidence of cardiorespiratory events following liver resection. Possibly, the recently described hemorheological alterations occurring in MS patients, including increased erythrocyte aggregation[64,65], may play a role in ischemic cardiac events.

Liver transplantation

NASH can progress to cirrhosis[2,4] and may lead to end-stage liver disease requiring liver transplantation (LT). During the last decade, the rate of LT performed for NASH related end-stage liver disease has dramatically increased from about 3% in the early 2000s up to 19% in 2011[2]. Currently, non-alcoholic steatohepatitis is the third most common cause of LT in the US and is on pace to become the most common within the next two decades in Western countries[66].

LT in NASH patients has peculiar aspects. Compared with other patients undergoing LT, recipients with NASH tend to be older[67] and obviously have a higher frequency of metabolic disorders[62]. In this setting, procedures significantly last longer and are associated with higher blood loss and longer post-transplantation hospital stay[62]. Accordingly, 30 d mortality after LT in patients with NASH tends to be higher than that for other indications[68]. Several studies have reported increased liver related morbidity rates in NASH patients, such as acute rejection rates[67], but also extra-hepatic complications, including sepsis and renal dysfunction[69]. Similarly to patients undergoing liver resectional surgery, NASH patients also have a higher likelihood of developing cardio-vascular complications after LT[62,67,69]. These events, which mainly occur within the first year after LT, have been reported to be responsible for as high as 50% of the total mortality following LT[62]. The relationship between MS/NASH and cardiovascular morbidity seems more complex than a generic multi-organ vascular disorder due to MS, as suggested by the significantly higher occurrence of cardiovascular events associated with MS whenever NASH is present[70]. In fact, similarly to what has been observed after LR, NASH is nowadays thought to put patients at an even higher risk of cardio-vascular complications, regardless of comorbidities and patient-specific cardiac risk[62]. Here again, it is likely that the degree of inflammation in the underlying liver represents a key factor in the occurrence of increased cardiovascular sensitivity.

Long-term results of LT following transplantation for NASH are encouraging. One, three and five year survivals after LT for NASH range from 84%-87.6%, 75%-82.2% and 70%-76.7%, respectively, and are at least similar to that observed for LT for other traditional indications[2,62,67,68,71]. Even more remarkable, LT for HCC developed in patients with NASH seems to provide excellent long-term outcomes with higher survivals compared with patients transplanted for HCV related HCC[72]. These observations could be the result of less aggressive tumors in NASH patients with lower micro vascular invasion and decreased rates of poorly differentiated lesions[8,72].

LT in patients with NASH related cirrhosis presents peculiar issues, including cirrhosis recurrence, to be discussed separately. Recurrent disease after LT for NASH

related cirrhosis has been reported to occur in as high as 34% of recipients[68,73]. There is little information detailing the occurrence and histological evolution of NAFLD recurrence after LT and the long-term natural history of NAFLD recurrence itself is unclear[74]. Nevertheless, in these patients, recurrence is often associated with the presence of the MS or its individual components[73]. Accordingly, recurrence should be further evaluated in larger studies, with special emphasis on management of MS and secondary prevention strategies[73].

WHICH IMPROVEMENTS SHOULD BE UNDERTAKEN IN UPCOMING YEARS?

Both MS and NAFLD/NASH adversely affect short and long-term results of liver surgery. Considering that the rate of patients presenting with such conditions will keep on increasing in upcoming years, it appears crucial that specific measures should be undertaken in order to improve those unsatisfactory results. Above all, the worse tolerance to extended resection of fatty and inflammatory livers (as a consequence of lower regenerative ability) requires that this issue should be attentively pondered in the preoperative planning of surgical strategy whenever a major resection is needed. Unfortunately, the culture of considering just MS or steatosis (even without liver biopsy confirmation) a potential risk factor for major surgery has not already entered clinical practice, even in specialized environments. Addressing this issue, our group has recently shown that MS patients operated on for HCC less frequently underwent preoperative PVE when they displayed a NAS > 2 without severe fibrosis compared to those with severe underlying fibrosis, suggesting that these latter patients would probably benefit from a better anticipation of their operative risk, especially in cases of planned major LR[8].

In general, preventative measures to reduce MS/NAFLD related morbidity/mortality should include: (1) better characterization of the underlying parenchyma using invasive or non-invasive means knowing that patients with inflammatory fatty liver even without severe fibrosis are at similar operative risk as those with severe underlying fibrosis; (2) targeted perioperative management, including complete preoperative cardio-vascular work-up and intraoperative cardio-vascular and pulmonary monitoring; and, finally (3) specific "NAFLD-tailored" perioperative surgical care, such as parenchymal sparing resections, wide use of liver volume modulation techniques, including portal vein embolization and portal vein ligation, but also targeted medical therapies developed in order to improve the tolerance of LR. Concerning this latter issue, a recent experimental study has highlighted the benefits of omega-3 acids in reducing severe steatosis in a preoperative setting leading to improved liver regeneration and functional recovery following partial hepatectomy[75]. These encouraging preliminary results still require confirmation in a clinical setting but may already

be considered a promising future field of research.

Concerning the relationship between MS/NAFLD and neoplastic disease, several strategies should be developed in order to prevent both occurrence and recurrence of primary liver cancer in MS/NASH patients. Even although it is generally recommended that overweight and obese patients with NAFLD lose 7%-10% of their body weight by dietary modification and exercise over the course of 6-12 mo, the paucity of data makes it difficult to make evidence-based recommendations about dietary modification and exercise to treat NAFLD and NASH[76]. In fact, medical research has mainly focused on reducing NASH in MS patients using medical therapies. Several randomized controlled trials have shown significant downstaging of NASH following the administration of specific medications, including vitamin E and pioglitazone[77-79]. Retrospective studies have shown that the use of biguanides, such as metformin, was associated with HCC risk reduction among diabetic patients[80,81]. Experimentally, metformin has been shown to provide antineoplastic effects through deregulation of the m-TOR pathway[82,83]. Hence, in a context of MS/NAFLD related HCC, metformin would theoretically represent an ideal preventative therapy reducing both incidence of HCC following parenchymal alterations or systemic inflammation and also providing inherent antitumoral properties. Nevertheless, despite the encouraging results of all these medications and the possible future development of others that are even more effective, it should be kept in mind that none have currently been tested in a surgical context. In fact, the prolonged time interval required by medications to obtain relevant effects on liver parenchyma possibly reducing morbidity definitely questions its applicability in a surgical environment prior to (or after) surgery. This consideration gains interest if one considers that the great majority of patients undergoing major liver surgery (LR and LT) presents with cancer or end stage liver disease, needing prompt management. Obviously, any medical/preventative strategy should ideally require a large-scale evaluation in a surgical setting.

CONCLUSION

Both the pro-oncogenic effect on the underlying liver and the rising incidence of MS/NASH imply that an increased number of patients with such conditions referred to HPB units has to be expected. The higher operative risk observed in these patients can be partially explained by both underestimated liver related risk and also high perioperative cardio-vascular and respiratory susceptibility. These unsatisfactory postoperative results will require targeted perioperative management. Such actions are justified by the observed favorable long-term outcomes.

Abstract

New nucleos(t)ide analogues (NAs) with high genetic barrier to hepatitis B virus (HBV) resistance (such as entecavir, tenofovir) have improved the prognosis of patients with HBV decompensated cirrhosis and have prevented HBV recurrence after liver transplantation (LT). NAs are considered the most proper approach for HBV infection in patients under renal replacement therapy but their doses should be adjusted according to the patient's creatinine clearance. In addition, physicians should be aware of the potential nephrotoxicity. However, patients with chronic hepatitis C and decompensated cirrhosis can receive only one therapeutic option before LT, as well as for Hepatitis C virus (HCV) recurrence after LT, which is the combination of subcutaneous Peg-IFN and ribavirin. Generally, therapy for HCV after renal transplantation should be avoided. Although the optimal antiviral therapy for HCV infection has not been established, attention has turned to a new, oral direct acting antiviral treatment which marks a promising strategy in prognosis and in amelioration of these diseases.

Core tip: While nucleos(t)ide analogs (NAs) offer a benign course in patients with hepatitis B virus before and after liver and renal transplantation, there is still scope for improvement. The administration of high genetic barrier NAs such as entecavir or tenofovir pre-transplant and the careful patient selection for hepatitis virus immunoglobulin-free regimens post-transplant contribute to improved medical care and facilitate its provision from a practical standpoint. Concordantly, attention has turned to new treatment strategies regarding hepatitis C virus recurrence after liver and renal transplantation. The addition of oral direct acting antivirals to the existing treatment marks a promising strategy for prognosis amelioration of these patients.

INTRODUCTION

The major breakthrough in the field of transplantation for patients with hepatitis B virus (HBV) and hepatitis C virus (HCV) is the application of nucleos(t)ide analogs (NAs) and direct acting antivirals (DAAs). NAs form the mainstay in the treatment of patients with HBV in the non-transplant setting as well as before and after liver and kidney transplantation. The preliminary data regarding the DAAs application favored its use in treatment of HCV recurrence after liver transplantation (LT) and in HCV renal transplant candidates.

Table 1 Recommendations for the management of hepatitis B and C infection before and after liver or renal transplantation

	Chronic hepatitis B		Chronic hepatitis C	
	Liver transplantation	Kidney transplantation	Liver transplantation	Kidney transplantation
Pre transplant		NAs[1]	Peg IFN ± RBV ± DAAs[3] (depending on genotype and type of DAA)	PegIFN plus very low dose RBV (plus DAAs)[4]
Post transplant	Prophylaxis and treatment		No prophylaxis[2]	
	Short term HBIG plus NA	NAs[1]	Peg IFN ± RBV ± DAAs[3] (depending on genotype and type of DAA)	RBV+ sofosbuvir (?)

[1]Entecavir or tenofovir are the advisable NAs in adjusted doses regarding creatinine clearance; [2]Therapy is indicated in fulminant cholestatic hepatitis and de novo glomerulonephritis; [3]Records for boceprevir, telaprevir and sofosbuvir. Triple combination is preferable in cases of cirrhosis (METAVIR fibrosis stages 3 and 4), cholestatic hepatitis, previous virological failure and in the presence of predictors of poor response; [4]There are only cases for the use of DAAs in renal transplant candidates. HBV: Hepatitis B virus; HCV: Hepatitis C virus; NA: Nucleos(t)ide analog; HBIG: Hepatitis virus immunoglobulin; DAAs: Direct oral acting antivirals; Peg IFN: Peg interferon; RBV: Ribavirin.

In general, the induction of immunosuppressive therapy carries the risk of HBV reactivation, leading to liver graft loss and fatal complications[1,2]. NAs have dramatically improved the clinical course of patients with HBV decompensated cirrhosis, reducing the need for LT, and have further improved the prognosis of HBV transplant patients[3,4]. At present, due to high rates of resistance[3,4], lamivudine is preferable only when short term immunosuppression is scheduled. Entecavir and tenofovir are the first choice NAs because they have very high efficacy and low resistant rates[5,6]. NAs administration implies detailed renal function monitoring. Telbivudine may improve renal function but it has an unfavorable resistance profile[7].

In regards to transplantation in patients with chronic hepatitis C (CHC), improvements in the understanding of the viral cycle have led to development of the first generation DAAs (telaprevir and boceprevir) which belong to HCV NS3/4 protease inhibitors[8,9]. Their addition to the standard of treatment [pegylated interferon (Peg-IFN) and ribavirin (RBV)] has improved the response rates in a small number of liver transplant recipients and in a few cases of renal transplant candidates. When DAAs are used, calcineurin inhibitors doses should be adjusted[10] and the hemoglobin levels should be regularly monitored. The present review focuses on the current treatment of patients with HBV and HCV before and after liver and kidney transplantation.

MANAGEMENT OF PATIENTS WITH HEPATITIS B AND C BEFORE AND AFTER LT

The management of patients with hepatitis B and C listed for LT contains a three step approach. Targeted therapy should start before transplantation and continue after transplantation, becoming more intensive immediately post-transplant when the immunosuppression is higher. Therapy escalation in an early post-transplant stage is imperative mainly for avoidance of HBV recurrence, while routine prophylactic therapy for HCV recurrence is not recommended[11,12] (Table 1).

HBV positive and HCV positive liver transplant candidates

Before transplantation, treatment aims to eliminate viral load, to keep it undetectable at the time of transplantation in order to lower the risk of HBV recurrence and improve the outcome[13,14]. HBV DNA clearance pre-transplant has reduced the rate of HBV recurrence in patients with HBV infection[15]. Similarly, HCV RNA eradication pre-transplant resulted in amelioration of fibrosis and long term survival in patients with HCV infection[13,15-18]. The suppression of HCV viremia in LT candidates and the undetectable HBV DNA at the time of LT are the most important goals for each particular infection.

The current management of patients with cirrhosis and CHB before LT is based on NAs[3,15] and modification of lifestyle, comorbidities and drug interactions[19]. Generally, the institution of NAs has ameliorated the transplant prognostic scores to such a high level that many LT candidates with CHB have delisted[20-22], presenting with great clinical improvement and better survival[23-25]. NA administration as monotherapy or in combination are the current guidelines for LT candidates with HBV decompensated cirrhosis[26-28]. The high genetic barrier antivirals entecavir and tenofovir are recommended as monotherapy. Entecavir has reduced the HBV DNA in patients with decompensated cirrhosis, has improved their underlying liver function up to 70% and has presented with very low resistant rates[22,29-31]. Tenofovir has also been an effective initiation therapy, accounting for high fibrosis resolution over five years administration[32-34] with almost negligible resistance. When administered in patients with decompensated cirrhosis, it led to virological, biochemical and clinical improvement with very good tolerance[35].

Nevertheless, entecavir should not be applied in patients with proven lamivudine-resistance because there are high chances of resistance and treatment failure[30], while tenofovir should be used with caution because of potential tubular injury and osteomalacia[34]. However, recent trials have doubted tenofovir nephrotoxicity after ten years of therapy in large groups of HIV infected patients[36,37] or even the nucleotide nephrotoxicity in LT recipients[38].

Furthermore, it has been hypothesized that an antiviral combination might achieve higher virological response rates and lower resistance rates compared to monotherapy. However, emtricitabine plus tenofovir (200 mg and 300 mg daily respectively) have not been found to have superior antiviral potency compared to entecavir and tenofovir monotherapy[35]. In addition, the higher cost of antiviral combination compared to monotherapies limits its use in clinical practice. In conclusion, all patients on NA therapy should be monitored every three months for virological response and possible virological breakthrough with serum HBV-DNA testing[39,40].

Contrary to LT candidates with CHB, patients with CHC and decompensated cirrhosis have only one therapeutic option before LT. This is the combination of subcutaneous Peg-IFN and RBV, leading to reduced cirrhosis-related complications and improving histological changes[41], but in an unsatisfactory percentage of patients (5%-33% in genotype 1 and 14%-100% in genotypes 2/3)[12,42-45]. IFN-based regimens have also been related to poor tolerability and many side effects[42,44], such as anemia, infections and neuropsychiatric disorders[46], which require either erythropoietin and granulocyte colony-stimulating factors or antibiotics to sustain drug regimen optimal doses[47]. The aim is undetectable HCV RNA or SVR at LT to reduce the frequency of HCV recurrence[13].

HBV positive and HCV positive liver transplant recipients

The primary goal in this step is the prevention of HBsAg appearance in a patient with erased HBV infection (HBV recurrence) and a new HBV DNA finding in a patient with negative HBsAg (virological breakthrough)[48]. The combination of HBV immunoglobulin (HBIG) with high genetic barrier NA (entecavir or tenofovir) for the long term is the most effective prophylactic approach for HBV recurrence prevention[49,50]. However, the high cost of HBIG and the fact that the majority of patients receive a transplant with undetectable or minimal HBV DNA since they have been on NAs before LT led to the use of short term HBIG or HBIG-free regimens in the post-transplant period. In the first case, LT recipients take a combination of HBIG and NA for a short period post-transplant, continuing with NA monotherapy long term[49]. In a group of LT recipients with low risk for HBV recurrence (only 4.5% had detectable HBV DNA at the time of LT), entecavir or tenofovir monoprophylaxis after HBIG discontinuation was similarly effective, with no difference in renal adverse events[38,49].

Regarding the HBIG-free prophylactic regimens, dual NAs such as tenofovir and emtricitabine or tenofovir plus entecavir[51-54] accounted for undetectable HBV DNA after 26 mo treatment post LT, but they did not eliminate cases of recurrence[49,52]. Entecavir and tenofovir should be the first-line options for HBIG-free prophylaxis. It is advisable that entecavir not be used in patients with previous lamivudine resistance who should be preferably treated with tenofovir. Until the optimal HBIG-free prophylactic regimen is determined, the combination of

HBIG (at least for a short period) and one high genetic barrier NA appears to be the most reasonable post-transplant approach[49,55].

Physicians should individualize the therapeutic regimen according to the pre-transplant type of liver disease, the patient's viremic status and the risk of reactivation[56,57]. HBV DNA clearance and HBeAg negativity at the time of LT, fulminant HBV and hepatitis D virus coinfection may allow HBIG reduction or withdrawal strategies[48]. At present, more and more patients maintain HBV DNA undetectable peritransplant so their prognosis has improved[3]. In our clinical setting, we use maintenance therapy with entecavir or tenofovir monoprophylaxis after a short course with low dose HBIG plus entecavir or tenofovir as antiviral prophylaxis against HBV recurrence after LT. Striking techniques such as covalently closed circular DNA (cccDNA) could detect occult HBV (HBV infection with negative HBsAg test) in hepatic and extrahepatic sites early. Nevertheless, Lenci *et al*[58] showed that many patients had a recurrence after cessation of any anti-viral prophylaxis despite negative cccDNA.

Regarding HCV positive liver transplant recipients, recurrence of HCV infection occurs in virtually all patients transplanted for HCV-related liver disease after LT. Additionally, three years post-transplant, decompensation developed in 70% of recipients compared with other immunocompetent groups in which the same proportion was less than 10%[59]. Post-transplant prophylaxis (preemptive) against HCV recurrence is not recommended because randomized trials have not confirmed its superiority regarding treatment when there was recurrence and it was associated with high cost and poor tolerability[11,12,60]. Interferon (IFN) use on the basis of high immunosuppression has not been effective and has been related to sepsis and rejection episodes[13,61]. Indications for antiviral therapy are fibrosing cholestatic hepatitis and significant fibrosis[61] [METAVIR score > F1[62], hepatic venous gradient > 6[63] and liver stiffness > 8.7 kPa[64]], but not fibrosis level > 3 because those patients cannot tolerate therapy[18]. Emphasis should be given to prompt diagnosis of histological evidence of HCV recurrence. Patients with female gender, steatosis of the graft, older donor age[65-67], cytomegalovirus and human herpes virus 6 infection[68] require sustained attention with protocol graft biopsies, regardless of normal liver function tests and good clinical condition. Non-invasive diagnostic methods such as elastography, serum and molecular fibrosis markers should also be used simultaneously[47].

The combination of Peg-IFN with RBV is again the standard of care for HCV recurrence after LT. Likewise, the regimen's efficacy is frustrating because after 72 wk of administration, SVR stabilization was achieved in only 30% of recipients[69-71]. The currently used DAAs, boceprevir and telaprevir, on the top of the old regimen have shown very promising results for the treatment of HCV reinfection in LT recipients with CHC[61]. Five studies[72-76] have demonstrated that the institution of the triple regimen obtained SVR in 50%-89% of LT

Table 2 Safety and efficacy of the combined regimen, interferon, ribavirin and protease inhibitors to treat hepatitis C after liver transplantation

	Boceprevir (*n*)	Telaprevir (*n*)	Complete virological response	Side effects
Coilly *et al*[72]	18	19	58% TVR	Anemia 92%

BOC: Boceprevir; TVR: Telaprevir.

recipients with CHC, mostly with genotype 1, when administered for 12 to 66 wk (Table 2). Serious side effects, fatal events, were recorded in two studies[73]. Although the place of DAAs in the management of LT recipients has not been totally clarified, two reported algorithms[19,61] may guide therapy. According to them, the triple regimen should be applied in cases of cirrhosis (METAVIR fibrosis stages 3 and 4), cholestatic hepatitis, previous virological failure and in the presence of predictors of poor response. Interestingly, sofosbuvir (NS5B inhibitor) combined only with RBV with or without PEG IFN demonstrated strong antiviral potency and disease improvement of CHC recurrence in LT recipients[77]. These are all very promising data but need to be tested in large multicenter prospective trials to become the standard of care.

In line with reducing severity of HCV recurrence after LT, immunosuppression is one of the major factors that accounts for accelerated HCV recurrence. For example, both steroid boluses as well as their very rapid tapering have been associated with aggressive HCV recurrence and graft loss. Interestingly, the long term maintenance immunosuppression with azathioprine, tacrolimus and prednisolone delayed the appearance of histologically proven severe fibrosis, while the sirolimus therapy led to HCV RNA elimination without antiviral treatment[78,79].

MANAGEMENT OF PATIENTS WITH HEPATITIS B AND C BEFORE AND AFTER KIDNEY TRANSPLANTATION

HBV positive and HCV positive renal transplant candidates

Antiviral therapy advances for HBV and HCV infection on renal transplantation (RT) have indicated great benefits in pre-transplantation and post-transplantation management and results[80-83]. However, antiviral therapy for HCV is hardly tolerated by RT candidates, especially if they have comorbidities and dialysis-related complications. It may not be wise for HCV positive patients with congestive heart failure, uncontrolled diabetes and with short life expectancy to receive antiviral therapy[84,85].

HBV and HCV positive candidates for RT should preferably undergo liver biopsy. The transjugular route is preferable since coagulation abnormalities are very common[86]. Fibroscan and other noninvasive techniques are supplementary. The presence of cirrhosis precludes patients from sole RT, while in patients with decompensated cirrhosis combined liver and kidney transplantation is the recommended option[87-90].

HBV positive RT candidates should initiate antiviral therapy when HBV DNA > 2000 IU/mL or HBV DNA ≤ 2000 IU/mL two weeks before RT[39,91,92]. Therapy should be instituted as long as immunosuppressive therapy lasts whatever the HBV DNA level is[2] or for at least the first 2 years when immunosuppressive therapy is most intense[91]. HCV positive RT candidates should receive therapy when there is active viral replication (HCV RNA positive) and a biopsy proven chronic hepatitis[93]. Before transplantation, the goal is the accomplishment of HBV DNA clearance to prevent post-transplant virological relapse and liver-related complications[26,80,94]. The disappearance of viral load is a prerequisite for a HBV or HCV positive patient on hemodialysis to be enrolled in the RT list. Therapy with entecavir, tenofovir or lamivudine on adjusted doses for renal function is included in the current guidelines for prophylaxis of HBV positive RT candidates[26,80,91,94]. The NA optimal regimen has not been pro-

posed yet, so prophylaxis may start before or at the time of RT and continue thereafter[91,92]. Entecavir should be the first line option for avoidance of short term resistance and adefovir nephrotoxicity[91], while tenofovir had better be applied in case of lamivudine resistance.

Guidelines for HCV positive RT candidates recommend treatment with interferon α (α-IFN) in adjusted doses for renal function[93,95], although studies in this population[96,97] have shown the advantage of IFN and RBV to provide persistent SVR. The very severe anemia and heart failure caused by the combinative regimen avert clinicians from using it in clinical practice[97]. However, the addition of very low doses RBV (200-400 mg three times weekly) under thorough monitoring (weekly measure of hemoglobin, application of high erythropoietin doses and iron supplementation) could result in HCV RNA clearance and allow more patients to get on to the list[93]. The preliminary results for five RT candidates with CHC treated with the triple regimen of IFN, RBV and DAAs (four received telaprevir and one boceprevir)[98,99] are very promising. Telaprevir and boceprevir has not required dose adjustment to renal function so far. After 12 to 48 wk of triple therapy, viral load disappeared in 4/5 of patients, while moderate, almost expected side-effects were noted. These were dysgeusia, diarrhea and anemia, leading to the increase of the doses of erythropoietin and the modification of RBV doses.

HBV positive and HCV positive renal transplant recipients

The high doses of immunosuppressants (steroids and anti-CD3 antibody) required to avoid graft rejection post-transplant may be responsible for rapidly progressive liver disease and fibrosing cholestatic hepatitis[100,101]. Initially, HBV positive RT recipients should be under close surveillance and continue the same treatment started before RT. Entecavir is again the therapy of choice. It has been tried in naïve, lamivudine or adefovir resistant RT recipients for 33 mo[102-106], providing excellent results regarding HBV DNA reduction, without aggravation of creatinine clearance, microalbuminuria or allograft rejection. Discontinuation of applied NA is desirable in cases of fibrosing cholestatic hepatitis and resistance, which may occur as hepatic flare and rarely as hepatocellular carcinoma (HCC) and fatal liver decompensation[105,107]. Tenofovir (245 mg daily) adapted to creatinine clearance could be a safe alternative subsequent to resistance[108] on the condition that tubular injury is of great concern. If renal allograft dysfunction is in progress and the HBV positive RT recipient presents with a low viral load, the inception of telbivudine could potentially lead to renal function recovery[20,109-111].

Therapy of HCV after RT should only be considered in RT recipients with fibrosing cholestatic hepatitis or de novo glomerulonephritis[93,112]. α-IFN alone or α-IFN plus RBV post-transplantation are contraindicated because a high percent of irreversible and steroid resistant acute allograft rejection and low efficacy levels have been recorded[113,114]. In our clinical setting, HBV positive and HCV positive RT recipients are screened for liver enzymes, bilirubin and prothrombin time at each visit. Ultrasonography with triplex of splenoportal axis and/or transient elastography is monitored annually. HBV DNA and HCV RNA as well as a-fetoprotein are tested every year. In patients with cirrhosis, endoscopy for detection or monitoring of varices is performed every 1-2 years. All HBV positive and HCV positive RT recipients should avoid alcohol and hepatotoxic drugs. In the case of fever, effective antibiotics are started immediately. Liver biopsy and modulation of antivirals is considered in patients with abnormal liver function and/or increased viral load.

SELECTION OF PATIENTS WHO NEED CLOSE MONITORING

High HBV viral load pre and peritransplant predispose to closer patient surveillance and stronger prophylactic antiviral regimens. This group of patients is more likely to progress to decompensation and to HCC[115]. It is preferable that they be treated with entecavir or tenofovir and often be monitored for signs of decompensation. In a case of severe decompensation, patients receiving antivirals are at higher risk of lactic acidosis so physicians should be vigilant. LT candidates with HCV compensated cirrhosis are more vulnerable to IFN-related hematological toxicities since the splenomegaly caused by portal hypertension magnifies the risk for cytopenias[116]. Therefore, IFN dose modification and close regular monitoring is recommended. Furthermore, therapy in patients with Child-Turcotte-Pugh (CTP) score C (or MELD score > 18) is challenging and should be carried out in dedicated and experienced centers because IFN may cause sepsis and is associated with a low sustained virological response (SVR) rate[61]. Careful monitoring should also be applied to patients with CTP score B. They need individualization of treatment decisions regarding non-genotype 1, high viral load, treatment naïve or relapse from previous antiviral therapies[13].

RT recipients with severe liver disease should receive non aggressive immunosuppressive protocols (cannot always be applied in immunologically high risk patients) and a selected immunosuppressive regimen with minimal or preferably no steroid use. All antivirals should be modified continuously regarding current renal function. Additionally, HBsAg-positive RT recipients with cirrhosis are at risk for hepatic decompensation after isolated RT and therefore they require simultaneous liver and kidney transplantation[86]. In conclusion, we should be on the alert for all HCV positive RT recipients which means screening them regularly for HCC[117], emergence of diabetes, renal thrombotic microangiopathy[118], glomerulonephritis[119,120], renal graft nephropathy[118] and sepsis[121].

SPECIAL TREATMENT CONSIDERATIONS

Generally, entecavir and tenofovir are the preferable an-

Table 3 Prophylactic schemes against hepatitis B virus recurrence after liver and renal transplantation when grafts are from hepatitis B virus positive donors

	Donor	Recipient	Prophylaxis
Liver transplantation	Anti-HBc positive	HBsAg positive	HBIG plus NA
		HBsAg negative	No prophylaxis
		Anti-HBc positive	
		Anti-HBs positive	
		Anti-HBc negative	Long term lamivudine
		Anti-HBs negative	
Kidney transplantation	HBsAg positive	Anti-HBc positive	HBIG plus NA
	Anti-HBc positive	HBsAg negative	No prophylaxis
			Treatment when HBV DNA increases
	HBsAg positive	HBsAg positive	HBIG plus lamivudine
	(HBV DNA negative)	HBsAg negative	Long term lamivudine
		(HBV DNA) negative	

HBV: Hepatitis B virus; NA: Nucleos(t)ide analog; HBIG: Hepatitis virus immunoglobulin.

tiviral treatment for post LT or RT recipients due to its high resistance barrier, the favorable safety profile and the regression of fibrosis with long term application[34,122]. However, entecavir is not advisable for patients with lamivudine resistance and it should be applied carefully in patients with decompensated cirrhosis with MELD score ≥ 22 because cases of lactic acidosis have been recorded with its administration[115]. Tenofovir is the only effective choice practically for patients with resistance to lamivudine or any nucleoside analogue[39] but there are concerns about creatinine clearance decline and acute tubular nephropathy during long term therapy, especially in group of patients with high risk for renal dysfunction over time such as RT and LT recipients[122]. Telbivudine is the only NA with a renal protective effect but its use in the RT and LT setting has still not been tested. Other NA limitations are the indefinite course and the relatively high cost of therapy which complicate patient compliance. Similar concerns exist about the cost and efficacy of HBIG continuation in HBV positive LT recipients. The duration of HBIG prophylaxis in HBV positive LT recipients is controversial and challenging and should be discussed on a case-by-case basis. The access to optimal therapy for HCV positive RT and LT recipients is limited by the low tolerance or contraindication of IFN-based regimens and the lack of experience of the efficacy and safety of first generation DAAs. Newer DAAs (such as sofosbuvir) need further evaluation in this setting.

HBV AND HCV POSITIVE DONORS

Many studies have shown that liver grafts from anti-HBc positive donors can be used safely in: (1) HBsAg negative but anti-HBc/antiHBs positive recipients without antiviral prophylaxis[123]; (2) in HBsAg positive recipients on the condition that dual therapy HBIG and NAs is applied[123]; and (3) anti-HBc and/or antiHBs negative recipients when receiving long term prophylaxis with lamivudine, dual therapy or no prophylaxis[123,124]. Heterogeneity of data exists regarding the use of liver grafts from HBsAg positive donors[125-128].

Similarly, renal grafts from anti-HBc positive donors can be used in HBsAg negative recipients without prophylaxis[129]. It is acceptable practice for renal grafts from HBsAg positive donors to be used in HBsAg positive or HBsAg negative recipients with subsequent long term NA administration with or without HBIG[130,131]. In all cases, serial HBV DNA measurements regardless of normal liver biochemistry are required. In particular, in LT or RT recipients who are not on any antiviral prophylaxis, an increase in viral load indicates NA initiation. On the other hand, when immunosuppression is reduced and complete viral clearance has been achieved, NA interruption could be considered[103] (Table 3).

LT candidates with HCV-related cirrhosis can undergo LT from HCV positive donors if they are not HCV RNA positive because early hepatitis C recurrence may occur[132,133]. Renal grafts from HCV positive donors are acceptable only for HCV positive RT candidates[93]. In this setting, the survival of HCV positive RT recipients increases compared to their survival rates if they remain on hemodialysis[134,135]. Renal grafts from HCV positive donors should not be distributed to HCV negative recipients because many fatal liver complications have been recorded[136,137].

CONCLUSION

Current knowledge on the management of patients with HBV offers effective and safe options for liver or renal transplantation. Individualization and determination of less nephrotoxic and finite duration antiviral treatment will enhance the quality of their treatment and prognosis. Various types of vaccinations (S and pre-S antigen vaccines, DNA vaccination, T cell vaccines) and some monoclonal antibodies (exbivirumab and libivirumab) are promising for preventing HBV recurrence and are being evaluated in clinical trials. Subcutaneous HBIG and hyperimmune anti-HBs plasma may prove to be alternative options with a lower cost and the same efficacy levels. The optimal antiviral therapy has not been established yet for LT or RT candidates with CHC. The DAAs in-

stitution marks a bright new era for treatment approach of these patients. Control randomized studies involving DAAs use in patients with decompensated cirrhosis and in RT candidates and recipients are in high need. Moreover, the optimal use and benefits of granulocyte growth factors and erythropoietin in improving SVR rates should be further researched and become established practice.

Abstract

A new treatment paradigm for hepatitis C is that the treatment must include an existing direct-acting antiviral agent, namely, a protease inhibitor (PI) combined with PEGylated interferon-α and ribavirin. The currently marketed PIs and PIs in clinical trials have different mechanisms of action. The development of new PIs aims for an improved safety profile and higher effectiveness. This article reviews NS3/4A protease inhibitors, focusing on major criteria such as their effectiveness and safety. Specific attention is paid to dosing regimens and adverse event profiles of PIs administered in clinical settings.

Key words: Protease inhibitor; PEGylated interferon-α; Ribavirin; Antiviral treatment; Adverse event; Response-guided therapy; Hepatitis C virus

Core tip: This article reviews NS3/4A protease inhibi-

tors, focusing on major criteria such as effectiveness and safety. Specific attention is paid to dosing regimens and adverse event profiles of protease inhibitor administered in clinical settings.

INTRODUCTION

Since 2011, increased attention has been given to "direct" antiviral agents for chronic hepatitis C (HCV). Combined treatment with PEGylated interferon-α (PEG-IFNα) and ribavirin cannot be considered a standard treatment for type 1 HCV anymore. A new treatment paradigm is that the treatment must include an existing direct-acting antiviral agent (DAA), namely, protease inhibitor (PI) combined with PEG-IFNα and ribavirin.

The currently marketed PIs and PIs in clinical trials (CTs) have different mechanisms of action. The development of new PIs aims for an improved safety profile and higher effectiveness[1]. An ideal combination is an interferon-free therapy with oral once-daily agents that are highly effective and well tolerated, do not interact with the majority of well-known therapeutics, and can be used to treat concomitant disorders. The recent evolution of DAA has included a considerable improvement in their effectiveness since 2011, and in most cases, antiviral treatment (AVT) duration has decreased.

This article reviews NS3/4A protease inhibitors, focusing on major criteria such as effectiveness and safety. Specific attention is paid to the dosing regimens and adverse event (AE) profiles with PIs administered in clinical settings.

PI: Protease inhibitor; PEG-IFNα: PEGylated interferon-α.

GENERAL STATEMENTS

Since 2011, we have seen an increase in the value placed on "direct" antiviral agents for HCV. Most of these agents are at various CT stages, with some already being integrated in routine clinical practice as a treatment standard for type 1 HCV patients (Table 1). In 2011, FDA and EMA approved the first DAA-telaprevir and boceprevir - for HCV treatment in patients infected with type 1 HCV. Randomized CTs have shown that triple therapy is not only significantly more effective for type 1 HCV patients but that it is also the only alternative for patients with previous AVT failure. One should note that in Russia, telaprevir was approved in December 2012 and boceprevir in May 2013.

NS3/4A serine protease inhibitors are divided into two classes. The first generation includes the well-studied telaprevir and boceprevir. By the time their phase III CT was completed, these agents were already acknowledged as new AVT standards for type 1 HCV patients.

NS3/4A protease has a crucial role in the replication cycle of hepatitis C virus. It cleaves polyprotein in four sequential active sites, forming the N-terminal proteins NS4A, NS4B, NS5A and NS5B. Regarding its chemical properties, this enzyme is related to the serine protease group. For instance, it can cleave and inactivate the host proteins Trif and Cardif. Both of these proteins are important in the responses to interferon (IFN) mediated by the receptors TLR3 and RIG-I, respectively[2,3]. Additionally, NS3 is not only a protease but also a component of the replication complex for viral RNA, acting as an RNA-helicase and nucleotide triphosphatase (NTPase). Due to its impressive set of functions, NS3 protease is an attractive target for HCV therapy. The HCV RNA replication cycle and targets for direct-acting antivirals have been thoroughly described in publications by Moradpour and Pawlotsky[4,5]. Clinical trials have studied several promising molecules that inhibit HCV protease.

Table 2 reviews published CT results for ultra-novel NS3/4a PIs, including their efficacy and safety parameters[6].

FIRST-GENERATION NS3/4A PROTEASE INHIBITORS

Telaprevir efficacy

Telaprevir efficacy was studied in phase II and III CTs (Table 3)[6-8].

Table 3 Telaprevir: clinical parameters

RCT	Dose frequency	Duration	SVR	Possible AE
Prove 1	Each 8 h, 6 t/d	24 wk: 12 wk of triple therapy, 12 wk of conventional treatment	61%	Rash, anemia, nausea, diarrhea
Advance	Every 8 h, 6 t/d	24-48 wk: 8-12 wk of viral response-based treatment followed by conventional treatment	69%-75%	Rash, anemia, nausea, diarrhea

Diarrhea	22%	32%-28%	14%	25%-26%	30%

AE: Adverse event.; AVT: Antiviral treatment.

Treatment mode

For telaprevir-based AVT, the following regimens are used: Treatment-naive patients and relapsers: Telaprevir is started from treatment day 1 and is always combined with conventional treatment of PEG-IFN/RBV for 12 wk. If no viremia is present (HCV RNA-negative) at 4 and 12 wk, treatment duration is 24 wk. If viral load is detected (HCV RNA-positive) at 4 or 12 wk, treatment duration is 48 wk. Null responders or partial responders as well as liver cirrhosis patients: The only option for triple therapy is telaprevir for 12 wk, with a total AVT duration of 48 wk. Telaprevir-based regimens have clear algorithms for AVT early discontinuation[9]. Triple therapy must be totally canceled in the following cases: HCV RNA above 1000 IU/mL at 4 and 12 wk on triple therapy; HCV RNA-positive at treatment week 24; Viral breakthrough and/or viral load increase.

The above rules are unambiguous and must be strictly followed because they are evidence-based results that were developed after multicenter randomized CTs. If HCV RNA is present in the titers above, it indicates that the AVT is ineffective when continued treatment has no clinical or cost-effective rationale. Moreover, ongoing treatment might result in resistant strain development, as indicated by phase Ⅱ and Ⅲ CTs showing relapses and no viral response.

Safety

The AE control algorithm is important for telaprevir-based treatment. The safety profile of triple therapy has a higher AE number *vs* conventional treatment, which in the future, may be a limiting factor for first-generation PI use (Table 4).

Triple-therapy AEs have been reviewed in CT results and other recent publications[10]. Therefore, it seems necessary to dwell on some of them because developing AEs might require changes in patient management (PI or AVT discontinuation) or may be difficult to control in clinical settings.

Telaprevir has the following common AEs: rash, anemia and anorectal signs (as shown by the ADVANCED and REALIZE trials).

Telaprevir-based triple therapy increases the anemia rate by 15% to 21% *vs* control. The severe anemia rate is comparable among study arms and results in discontinued treatment in 2%-4% of cases (Table 5).

Anemia development in the compared arms is not a negative prognostic criterion for SVR. Currently, the main method for anemia control is ribavirin dose adjustment. Some experts consider that an Hb below 7.5 g/dL implies complete triple therapy discontinuation. However, the CUPIC study showed that AVT can be continued if erythropoietin and blood transfusions are used[11,12].

Rash is considered a specific AE for telaprevir-based therapy and results in 5%-7% of treatment discontinuation cases. In 50% of cases, rash appears within the first 4 wk of treatment, but rash can develop during the whole course of treatment. In some rare cases, skin signs can be classified as serious AEs.

The rash treatment algorithm depends on its severity (evaluated on the body surface involved). Mild to moderate rash is an indication for antihistamine agents, local steroid ointments and avoiding sunlight. It does not require stopping triple therapy. For severe rash, it is recommended to stop telaprevir, and conventional treatment can be continued with the provision of effective treatment with steroids (locally) and antihistamines. In case of progression and severe skin signs, treatment must be canceled.

Table 5 Boceprevir: clinical parameters

RCT	Dose frequency	Duration	SVR	Possible AE
SPRINT 1	12 pills for 3 intakes	28-wk triple therapy *vs* 4-wk lead-in phase	54%-56%	Metal taste, anemia
		48-wk triple therapy *vs* 4-wk lead-in phase	67%-75%	
SPRINT 2	12 pills for 3 intakes	28-48 wk: "viral response-based treatment"; "lead-in period"; if HCV RNA (-) by week 8 and 24, to stop at week 28; if HCV RNA (+), 20 wk of double therapy	67% And 44% were given abridged AVT	Taste disturbances, anemia, neutropenia

AE: Adverse event; AVT: Antiviral treatment; HCV: Hepatitis C virus.

Figure 2 SVR rate after the lead-in period in patients with F3/4 fibrosis. PR: Conventional therapy (PEGylated interferon-α and ribavirin). BOC RGT: Boceprevir-based, viral response-dependent triple therapy; BOC/PR48: Boceprevir-based triple therapy for 48 wk; the results are from the SPRINT-2 and RESPOND-2 studies.

BOCEPREVIR

Efficacy

Boceprevir's efficacy was studied in phase Ⅱ/Ⅲ CTs (Table 5)[1,6]. Considering a new term, *i.e.*, the lead-in period or lead-in phase, several issues should be discussed. Triple therapy development has provided data on new sensitive response predictors. Assessing the viral load decrease after a 4-wk lead-in can allow for an accurate assessment of a patient's chances to reach SVR (Figure 1): A lead-in period enables researchers to assess conventional treatment tolerance and prognosis if PEG-IFN/RBV is safe to use. RCT results (RESPOND-2 and PROVE-2) show that a lead-in period lowers the viral load before the onset of triple therapy and delineates a patient group that should receive a shorter AVT duration. These diminish the probability of mutant, PI-resistant HCV strain development. If the viral load drops by more than 2 log10, this indicates high patient sensitivity to IFNα and ribavirin, which is a rationale to continue AVT as a standard treatment. However, it seems that the main objective of the lead-in period is to discern the patient groups in which conventional AVT appears to be less effective in a prognostic sense, and triple therapy makes it possible to avoid unjustified treatment costs and a non-mandatory pharmaceutical load when double therapy is continued (Figure 2).

Treatment mode

An important issue is strict compliance with discontinuation rules for triple therapy. For instance, ineffective boceprevir-based triple AVT should stopped in time to prevent the development of boceprevir-resistant HCV

strains. The entire triple therapy should be canceled in the following cases (algorithm for early treatment discontinuation): (1) if the HCV RNA is above IU/mL at week 12 of AVT (triple therapy week 8); (2) if there is no aviremia at week 24 of AVT (triple therapy week 20); and (3) in case of viral breakthrough and/or viral load increase by 1 log10.

Safety

The SPRINT-2 and RESPOND-2 data show that boceprevir use increases the rate of taste disturbances, anemia and neutropenia[6,13] (Table 6).

Second-generation NS3/4A protease inhibitors

The development of second-generation NS3/4A protease inhibitors resulted in some hopes of improving treatment outcomes in type 1 HCV patients. This group of agents has some advantages compared to the 1st-generation NS3/4A protease inhibitors (telaprevir and boceprevir): first, the dosing mode (once a day) and second, a better tolerance profile (fewer adverse events). However, the fact that both groups of agents have both a common viral genotype as their target and similar resistance profiles restrain us from considering 2nd-generation NS3/4A protease inhibitors to be a new class of HCV protease inhibitors. Nevertheless, modern publications still use this term for a range of new therapeutic agents with improved pharmacokinetics. It is possible that after

Agent	Boceprevir

Table 6 Adverse events under triple therapy

AE: Adverse event; AVT: Antiviral treatment.

some CTs are completed, 2nd-generation NS3/4A protease inhibitors will replace the 1st-generation agents when combined with PEG-IFN/RBV, thereby becoming the 1st generation of DAA in regimens of so-called interferon-free HCV treatment.

Simeprevir

Simeprevir (TMC435; Tibotec, Beerse, Belgium; Medivir Pharmaceuticals, Stockholm, Sweden; Janssen, Beerse, Belgium) is one of the 2nd-generation NS3/4A protease inhibitors. Simeprevir has passed phase I to III trials in patients with 1a and 1b HCV genotypes.

Efficacy

Phase I and II trials demonstrated potential antiviral activity for TMC435, as well as its efficacy and tolerability. TMC435's pharmacokinetic properties enable its use in once-a-day dosing[14].

To study TMC435's efficacy and safety, a phase II b trial, PILLAR [Protease Inhibitor TMC435 trial assessing the optimaL dose and duration as once daiLy Antiviral Regimen] (TMC435-C205; NCT00882908), was organized. Conducted in 13 countries in Europe, North America and Australia, it enrolled 368 naive patients with genotype 1 treated with simeprevir combined with PEG-IFN/RBV for 24 or 48 wk. Two doses of simeprevir (75 mg *vs* 150 mg) and treatment durations (12 wk *vs* 24 wk) were compared. The final analysis of the PILLAR study showed that TMC435 given in combination with PEG-IFN/RBV to naive patients with genotype 1 HCV resulted in a SVR rate that significantly exceeded that observed in patients treated with the placebo + PEG-IFN/RBV combination (Figure 3).

In 2 patient arms treated with TMC435 at 75 mg/d, the patient percentage reaching SVR in varied from 75% (12 wk) to 82% (24 wk); with TMC435 at 150 mg/d, this percentage varied from 81% (12 wk) to 86% (24 wk). In the comparison arm, the percentage of placebo-treated patients reaching SVR in 24 wk or less amounted to 65%[15].

A new publication[16] analyzing the PILLAR study

Figure 3 Portion of patients treated either with TMC435 at 75 mg/d or 150 mg/d or with placebo, combined with PEGylated interferon/ribavirin, who reached SVR24 (%) in the PILLAR study[15].

results indicated that SVR determined in 24 wk after planned treatment completion (SVR24) varied in the range of 74.7%-86.1% for all simeprevir arms *vs* 64.9% in the control. All arms treated with simeprevir for 12 or 24 wk showed a significant difference in SVR24 parameters, excluding the arm given 75 mg/d for 24 wk. Rapid virologic response (HCV RNA < 25 IU/mL, undetermined level at treatment week 4) was reached in the SMV-treated arms in 68.0%-75.6% of cases, compared to 5.2% in the placebo-treated controls. The criteria for a shortened treatment course (RGT criteria) were met in 79.2%-86.1% of the SMV-treated patients completing treatment in 24 wk. SVR24 was reached in 85.2%-95.6% of patients in these groups[16].

An international, randomized, double-blinded, controlled phase II b study, ASPIRE (TMC435-C206; NCT00980330), aimed to evaluate the efficacy, tolerability, safety and pharmacokinetics of TMC435 given in combination with PEG-IFN/RBV[17]. ASPIRE enrolled 462 treatment-experienced genotype 1 HCV patients. This arm included partial responders, prior relapsers, and patients with significant fibrosis or cirrhosis (Metavir, F4 stage). Patients were randomized to receive 100 or 150 mg of simeprevir OD or placebo for 12, 24 or 48 wk. The study arms with simeprevir treatment for 12 or 24 wk later continued treatment with PEG-IFN/RBV (control) only up to 48 wk. The SVR rate was significantly higher in all simeprevir-treated arms compared to those treated with PEG-IFN/RBV only. The best results were reached in patients treated with simeprevir 150 mg/d. For instance, SVR in prior relapsers reached 85% *vs* 37% in the control, 75% and 19% in the two subgroups of partial responders, and 51% and 19% in the two subgroups of non-responders[18]. It is important to note that a high SVR24 (31%) was found with simeprevir-based therapy in subgroups of liver cirrhosis patients and those with a previous null response, *i.e.,* those who traditionally are considered difficult to treat.

Viral breakthrough (in 42 of 43 patients) or infection relapse (in 34 of 36 patients) was associated with viral resistance development. Viral breakthrough has been noted in most studies when using protease inhibitors in

combination with conventional treatment[18]. Genotype 1a patients more often have mutation R155 as the only mutation or with other mutations, while genotype 1b patients have mutation D168V[18].

At the moment, 3 Phase Ⅲ clinical studies to study simeprevir's efficacy are known: (1) in treatment-naive HCV patients: QUEST-1 and QUEST-2; (2) in relapsers after previous PEG-IFN/RBV treatment: PROMISE; and (3) in null-responders: ATTAIN.

QUEST-1 enrolled 394 genotype 1 HCV patients with F0-F4 fibrosis (METAVIR scale) stratified by HCV subtype and genotype *IL28B*[19]. Patients were randomized to a simeprevir dose of 150 mg/d or placebo combined with PEG-IFN/RBV for 12 wk followed by PEG-IFN/RBV monotherapy. A treatment duration of 24 or 48 wk in the simeprevir arm and the placebo arm depended on treatment response at wk 4 and 12. If virus was undetected in the blood (HCV RNA < 25 IU/mL) at weeks 4 and 12, the patient met the short treatment criteria (RGT-criteria), and the treatment was finished at week 24. Treatment for 48 wk was recommended for patients who were treated with placebo instead of simeprevir. The majority of simeprevir-treated patients were compliant with the RGT criteria (85%) and completed treatment at week 24. The rapid response rate (RVR) reached 80% in the patients treated with simeprevir in combination with PEG-IFN/RBV and 12% in the patients treated with placebo and PEG-IFN/RBV. Simeprevir combined with PEG-IFN/RBV resulted in HCV elimination in more patients compared to the combination of placebo and PEG-IFN/RBV (80% *vs* 50%, P < 0.001). The relapse rate in the simeprevir/PEG-IFN/RBV arm was less than that in the placebo/PEG-IFN/RBV arm (9% *vs* 21%), as was the percentage of treatment failures (9% *vs* 34%). The QUEST-1 study showed that simeprevir 150 mg/d OD given along with PEG-IFN/RBV provided a high SVR12 rate, making it possible to decrease the treatment duration to 24 wk in a majority of patients (85%).

QUEST-2, a randomized, double-blinded, placebo-controlled study (NCT01290679), enrolled approximately 400 treatment-naive patients with genotype 1 HCV[20]. Patients were stratified according to genotype 1 subtype and host genotype (*IL28B*). They were given simeprevir (150 mg OD) combined with PEG-IFN/RBV (both of PEG-IFN type) or placebo combined with PEG-IFN for 12 wk followed by a PEG-IFN/RBV regimen. A treatment duration of 24 or 48 wk in both patient arms depended on the treatment response at weeks 4 and 12. If virus was undetected in the blood (HCV RNA < 25 IU/mL) at weeks 4 and 12, the patient met the short treatment criteria (RGT-criteria) and the treatment was finished at week 24. Treatment for 48 wk was recommended for patients who were treated with placebo instead of simeprevir. A majority of simeprevir-treated patients complied with the RGT criteria (91%) and completed treatment at 24 wk. The rapid virologic rate (RVR) was 79% in simeprevir/PEG-IFN/RBV patients and 13% in patients treated with placebo/PEG-IFN/RBV. Simeprevir combined with PEG-IFN/RBV provided HCV elimination in more patients than did the combination of placebo with PEG-IFN/RBV (SVR12 rate: 81% *vs* 50%, P < 0.001). The relapse rate in the simeprevir/PEG-IFN/RBV arm was lower than that in the placebo/PEG-IFN/RBV arm (13% *vs* 24%), as was the rate of treatment failure (7% *vs* 32%). The QUEST-2 study showed that simeprevir 150 mg/d OD given along with PEG-IFN/RBV provides a high SVR12 rate, making it possible to decrease the treatment duration to 24 wk in a majority of patients (91%).

The objective of the phase Ⅲ trial PROMISE (TMC435-HPC3007) was to study the efficacy, safety and tolerability of simeprevir combined with PEG-IFN/RBV in patients infected with genotype 1 HCV and treatment failure. The study enrolled 393 prior relapsers after treatment. Approximately 40% of patients had the 1a subtype of the HCV genotype, approximately 75% of them had the unfavorable genotype IL28B, 15% had considerable liver fibrosis (stage F3), and 15% had diagnosed liver cirrhosis (stage F4). Patients were given 150 mg of simeprevir combined with PEG-IFN/RBV for 12 wk, followed by PEG-IFN/RBV only for another 12 wk. At this point, the patients either stopped treatment based on the RGT criteria (no virus in blood at treatment week 4 and 12) or continued PEG-IFN/RBV treatment up to week 48. In the control arm, placebo combined with PEG-IFN/RBV was given for 12 wk; up to week 48, they were given basic treatment, *i.e.,* PEG-IFN/RBV. A total of 77% of the simeprevir-treated patients and 3% of the control group developed rapid treatment response in 4 wk (RVR). At the end of treatment, the responses were very high: 97% in the simeprevir group and 72% in the control. The majority of patients (93%) complied with the RGT criteria (treatment termination at week 24); in this group, 83% of patients reached SVR during the following 12 wk of basic treatment (SVR12). Among the remaining 7% of simeprevir-treated patients who did not comply with the RGT criteria and continued treatment to week 48, SVR12 was reached in only 32%. Among patients with HCV subtype 1a, SVR12 was reached in 70% of the simeprevir-treated group and in 28% of the placebo group; for subtype 1b, these values were 86% and 43%, respectively. The IL28B CC genotype was associated with a better response to simeprevir-based triple therapy *vs* control (SVR12 was 89% *vs* 53%). SVR12 for the CT genotype was 79% *vs* 34%. SVR12 for the TT genotype was 65% *vs* 19%. Regardless of fibrosis severity, the SVR rate in the simeprevir-treated arms was higher than in control. For instance, with fibrosis stage F0-F2 (absent to moderate), the SVR rate was 82%; with significant fibrosis, it was 73%; and with liver cirrhosis, it was 74%. In the control group, SVR reached 41%, 20% and 26%, respectively. Ineffective treatment was noted in 3% of simeprevir-treated patients and in 27% of control patients. Relapse after treatment completion was found in 19% and 48%, respectively. Thus, in case of relapse after conventional therapy with PEG-IFN/RBV in genotype 1 HCV patients, treatment with simeprevir and PEG-IFN/

RBV provided a high cure rate: 79% of patients reached SVR12.

The phase III trial ATTAIN (NCT01485991) is studying the efficacy of simeprevir plus PEG-IFN/RBV and telaprevir plus PEG-IFN/RBV in patients with a failed attempt at HCV eradication after conventional therapy (PEG-IFN/RBV). ATTAIN is projected to be finished in 2014.

Safety

The profile of adverse events recorded in the PILLAR study[15,16] was similar between the group treated with simeprevir and the group with conventional treatment. For instance, comparing patients treated with simeprevir/PEG-IFN/RBV *vs* placebo/PEG-IFN/RBV, an adverse event rate > 10% was recorded for fatigue (42.4% and 48.1%, respectively), flu-like syndrome (31.7% and 37.7%, respectively), itching (31.1% and 45.5%, respectively), headache (46.0% and 51.9%, respectively), nausea (27.8% and 27.3%, respectively), rash (21.0% and 23.4%, respectively), anemia (20.4% and 20.8%, respectively), neutropenia (24.3% and 20.8%, respectively).

The majority of adverse events recorded in patients treated with simeprevir/PEG-IFN/RBV in the ASPIRE study were also observed in patients treated with disease-modifying therapy PEG-IFN/RBV (fatigue, flu-like syndrome, itching, headache, nausea) and were similar to the patient control group[17,18]. Adverse events requiring the discontinuation of at least one of the therapeutics in the study were reported in 4%-10.4% of the patients treated with simeprevir/PEG-IFN/RBV combination compared to 13% of the control group. Serious adverse events (SAEs) were detected at similar rates in patients treated with the combination of simeprevir and disease-modifying therapy (3.8%-11.5%) and in the patients treated with placebo combined with disease-modifying therapy (13%). Anemia developed in 19.0%-22.1% of patients treated with simeprevir + PEG-IFN/RBV and in 20.8% of patients treated with placebo combined with PEG-IFN/RBV. In both arms, anemia did not result in discontinued treatment. Skin rash of any type was reported in 23.4%-30.8% of patients treated with simeprevir + PEG-IFN/RBV and in 20.8% of in patients treated with placebo + PEG-IFN/RBV. Rash resulting in discontinued treatment was noted in only 3 cases (2 patients of the simeprevir + PEG-IFN/RBV arm and 1 patient of the placebo + PEG-IFN/RBV arm). Insignificant, isolated and reversible increase of both bilirubin types (direct and indirect) in blood serum was found in patients treated with simeprevir + PEG-IFN/RBV. Because elevated plasma activity of alanine aminotransferase (ALT) and alkaline phosphatase (ALP) was not associated with the simultaneous elevation of bilirubin, the elevated serum ALT in the majority of patients was interpreted as a developed biochemical response during the treatment.

In the PILLAR and ASPIRE studies, fatigue as a treatment-related adverse event was reported in 63%-65% of treatment-naive and 97% of treated patients[21,22]. In both trials, fatigue severity according to the Fatigue Se-verity Scale increased with treatment duration. However, fatigue disappeared more quickly in treatment-naive simeprevir-treated patients than it did in patients treated with PEG-IFN/RBV only. Considering the follow-up period of 72 wk after treatment completion, these differences were statistically significant ($P < 0.001$).

These trials also showed lower the quality of life in patients according to the health-related quality of life (HRQoL) scale. Treatment-naive simeprevir-treated patients showed a faster quality of life improvement compared to the group treated with PEG-IFN/RBV only[21,22].

Simeprevir was well tolerated by patients enrolled in the QUEST-1, QUEST-2, and PROMISE studies[19-23]. The total AE incidence was similar in the arms treated with simeprevir + PEG-IFN/RBV and placebo + PEG-IFN/RBV.

Discontinued treatment due to adverse events in both arms was found in 3% of patients[19]. The grade 3-4 adverse event rate was 23% in the simeprevir + PEG-IFN/RBV patient arm and 29% in the PEG-IFN/RBV arm. The most common adverse events in the simeprevir and placebo arms were fatigue (40% and 38%, respectively), headache (31% and 37%, respectively), and itching (21% and 11%, respectively). Simeprevir intake was associated with transient moderately elevated bilirubin that was not associated with elevated aminotransferases or alkaline phosphatase. Rash and photosensitivity were slightly more common in patients who were treated with simeprevir compared to the patients receiving placebo (27% *vs* 20% and 4% *vs* 1%, respectively). During the PROMISE study, a shorter treatment duration resulted in lower fatigue intensity and a faster return to normal activity among patients treated with simeprevir and PEG-IFN/RBV.

Summary

Simeprevir seems to be preferable when choosing HCV treatment compared to telaprevir or boceprevir because it is advantageous with regard to dosing regimen (once a day), tolerance and safety (no rash or anemia). All three phase III trials, QUEST-1, QUEST-2, and PROMISE, showed a high infection cure rate (79%-81% SVR12). Importantly, the addition of simeprevir to PEG-IFN/RBV was associated with a higher SVR rate without a significant increase in fatigue severity or decrease in quality of life. Moreover, the shorter-duration antiviral treatment with simeprevir was associated with a higher SVR rate and a shorter period of worsened quality of life.

FALDAPREVIR

Faldaprevir (BI 201335, Boehringer Ingelheim Pharmaceuticals, Ingelheim, Germany) is a 2nd-generation NS3/4A protease inhibitor with once-a-day dosing.

Efficacy

Faldaprevir's efficacy, tolerance and safety were studied

in genotype 1 HCV patients in multiple phase II and III clinical trials (SILEN-C1, SILEN-C2, SILEN-C3, STARTVerso™1).

SILEN-C1 and SILEN-C2 were phase II randomized clinical studies with the objective of examining BI 201335's efficacy and safety in combination with PEG-IFN/RBV in treatment-naive patients[22] and in treatment failures (partial or non-responders)[24] infected with genotype 1 HCV. Both trials studied the effectiveness of a 3-d lead-in phase with PEG-IFN/RBV. The lead-in period was used when studying boceprevir's efficacy in combination with PEG-IFN/RBV in genotype 1 HCV patients[13,25]. This treatment phase was expected to lower the probability of developing HCV resistance during the treatment.

SILEN-C1 enrolled 429 treatment-naive patients infected with genotype 1 HCV[22]. Four study arms were made: for 24 wk, patients were administered a combination of PEG-IFN/RBV with placebo (control group), faldaprevir 120 mg OD with a 3-d PEG-IFN/RBV lead-in (LI) phase, faldaprevir 240 mg OD with LI, or faldaprevir 240 mg OD without LI followed by PEG-IFN/RBV therapy up to the total 24 wk. If a patient taking faldaprevir 240 mg complied with the RGT criteria (HCV RNA < 25 IU/mL at week 4, undetectable viral load at weeks 8-20), the treatment was discontinued at week 24. The rest of the patients continued PEG-IFN/RBV therapy up to week 48. The SVR rate was 56%, 72%, 72% and 84%, respectively, for the four arms. In total, 92% of patients with the RGT in the faldaprevir 240 mg OD arms reached SVR, irrespective of the PEG-IFN/RBV duration, and 82% of patients with genotype 1a treated with faldaprevir 240 mg OD reached SVR, compared to 47% in the placebo group.

SILEN-C2 enrolled 288 patients without liver cirrhosis who were partial or null-responders to previous HCV treatment[24]. All three arms were treated with faldaprevir combined with PEG-IFN/RBV for 48 wk: 240 mg OD with a 3-d PEG-IFN/RBV lead-in, 240 mg OD without LI, or 240 mg BID with LI. Patients treated with faldaprevir 240 mg OD/LI and reaching HCV RNA < 25 IU/mL by week 4 and undetectable HCV at weeks 8-20 were randomized again. Some of them stopped treatment at week 24, and the others continued PEG-IFN/RBV therapy up to week 48. The SVR rate in prior partial responders was 32%, 50% and 42% in the arms given faldaprevir 240 mg OD with LI, faldaprevir 240 mg OD without LI, and 240 mg BID with LI, respectively. The SVR rate in prior null responders was 21%, 35% and 29% in the respective arms. In patients given faldaprevir 240 mg OD with lead-in (LI) and an AVT duration of 24 wk, the percentage of patients with RGT who reached SVR24 was 43%, while in those continuing treatment up to week 48 it was 72% ($P = 0.035$).

Summarizing the results of these two trials, we should note that due to unclear reasons, the patient arms treated with a 3-d lead-in phase (lead-in arms) experienced a treatment effectiveness that was significantly lower, which

was a basis for refusing such management to limit the chances of developing faldaprevir resistance.

SILEN-C3 enrolled 159 treatment-naive patients with genotype 1 HCV. Patients were randomized into two arms: 12 and 24 wk of treatment with 120 mg of BI 201335 OD combined with PEG-IFN/RBV. Liver cirrhosis was found in approximately 12% of patients at treatment onset; 48% of the first arm patients and 37% of the second arm patients had subtype 1a HCV, and 46% and 53%, respectively, had subtype 1b HCV. Both patient arms had a lead-in period of 3 d of PEG-IFN/RBV prior to starting BI 201335 therapy. Patients with an early rapid virologic response (eRVR), meaning unquantifiable HCV RNA at week 4 and undetectable load at weeks 8-18, stopped therapy. The rest of the patients continued treatment with PEG-IFN/RBV only up to week 48. SVR rates were similar for both AVT types (65% *vs* 73%) and in patients with eRVR (82% *vs* 81%).

The STARTVerso™ (placebo-controlled, double blinded, phase III) trial studied the efficacy and safety of faldaprevir combined with PEG-IFN/RBV in 652 patients previously not treated with AVT and with HCV subtypes 1a and 1b, including patients with compensated liver cirrhosis[26]. The patients were divided into three arms: placebo combined with PEG-IFN/RBV for 24 wk, faldaprevir 120 mg OD combined with PEG-IFN/RBV for 12 or 24 wk (RGT arm), and faldaprevir 240 mg OD combined with PEG-IFN/RBV for 12 wk. Patients complying with the RGT criteria (HCV RNA < 25 IU/mL at week 4 and undetectable load at week 8) and treated with faldaprevir combined with PEG-IFN/RBV stopped treatment at week 24. Patients who did not comply with the RGT criteria who were treated with placebo/PEG-IFN/RBV were given PEG-IFN/RBV treatment only up to week 48. The primary endpoint was reaching SVR within 12 wk of the planned treatment completion (SVR12). Patients given faldaprevir OD in combination with PEG-IFN/RBV (120 and 240 mg) reached SVR12 in 79% and 80% of cases, respectively. Compared with these 2 arms, the placebo/PEG-IFN/RBV arm had a SVR12 rate of 52% ($P < 0.0001$). In the RGT arm, early rapid response was seen in 87% and 89% of faldaprevir-treated patients (120 and 240 mg, respectively). Those patients were fully compliant with the criteria for treatment shortening. Treated for 12 wk with faldaprevir and 24 wk with PEG-IFN/RBV alone, 86% and 89% of this patient arm (120 and 240 mg, respectively) reached SVR12. Thus, the STARTVerso™ trial showed that it is possible for a majority of patients (88%) to shorten the treatment to 24 wk with considerable HCV elimination compared to patients treated with PEG-IFN/RBV only for 48 wk.

Safety

All phase II studies of the SILEN-C series reported that the differences in AE patterns and rates were not significant, including rash, photosensitivity, nausea, vomiting and diarrhea. As in the trials of other PIs, faldaprevir for HCV treatment was associated with transitory elevation

of non-conjugated bilirubin. With a faldaprevir OD regimen, significant AEs developed less frequently compared to a BID regimen.

In the phase III trial STARTVerso™[26], all drugs were discontinued in 4% of patients in the placebo arm, 4% in the faldaprevir 120 mg arm, and 5% in the faldaprevir 240 mg arm. Faldaprevir only was discontinued in 1% of patients in the 120 mg arm and 3% in the 240 mg arm. Serious adverse events developed in in 6%, 7% and 7% of patients in the respective study arms. Grade 3 rash (severe) was reported in < 1% in each of the study arms. The rate of Hb drop within first 24 wk (Hb ≤ 8.5 g/dL) was similar in all arms (2%, 3% and 3%, respectively).

Summary
Faldaprevir OD combined with PEG-IFN/RBV provides a high SVR rate in HCV patients along with good tolerance and safety.

DANOPREVIR

Danoprevir (RG7277; Roche, Basle, Switzerland; Inter-Mune Pharmaceuticals, Brisbane, CA, United States) is a 2nd-generation NS3/4A protease inhibitor of macrocyclic origin with the same activity toward HCV genotypes 1, 4 and 6 (*in vitro*)[27,28]. Phase I clinical studies showed the high antiviral activity of danoprevir for genotype 1 HCV. Danoprevir in that category of patients was administered as monotherapy, combined with PEG-IFN/RBV, or combined with a HCV polymerase inhibitor, *i.e.*, mericitabine, in an interferon-free regimen[29-32].

Efficacy
The phase II trial DAUPHINE[33] studied the efficacy of three danoprevir doses (50, 100 and 200 mg) boosted with ritonavir 100 mg taken BID in combination with PEG-IFN/RBV (RGT). Ritonavir addition is known to increase the PI blood concentration, thereby suppressing CYP3A activity. Twelve weeks after treatment completion, the SVR12 rate was 93% in genotype 1 HCV patients treated with danoprevir 200 mg BID combined with PEG-IFN/RBV. Danoprevir 100 mg/d provided a SVR12 rate of 83%, and 50 mg/d 67%. The effectiveness of danoprevir 200 mg BID combined with PEG-IFN/RBV was not affected by HCV genotype subtype (1a *vs* 1b) or *IL28B* genotype (CC *vs* non-CC).

The objective of the randomized, placebo-controlled, parallel-group phase II trial ATLAS (NCT00963885) was to study the efficacy and safety of RGT danoprevir combined with PEG-IFN/RBV for 12 wk compared to PEG-IFN/RBV in naive genotype 1 HCV patients[34]. It was an international study, with sites in North America (31 sites), Europe (8 sites) and Australia (3 sites). Patients who had not previously been treated for HCV (treatment-naïve patients) were randomized into 4 groups. For 12 wk, patients were given danoprevir (300 mg every 8 h, 600 mg every 12 h or 900 mg every 12 h) or placebo in combination with PEG-IFN/RBV. Follow-up treatment

included PEG-IFN/RBV therapy only. Patients with an extended rapid virologic response (eRVR) (RNA < 15 IU/mL for 4-20 wk) stopped treatment at week 24. Patients without eRVR continued PEG-IFN/RBV therapy for 48 wk. The main criterion for assessing efficacy was SVR within 24 wk after treatment completion. The SVR rate was 68% in patients treated with danoprevir 300 mg, 85% in danoprevir 600 mg and 76% in danoprevir 900 mg, compared with 42% in placebo-treated patients. RGT was found in 71 patients given danoprevir 600 mg combined with PEG-IFN/RBV, and SVR was found in 96%.

Safety
In the ATLAS study, serious adverse events were reported for 7%-8% of danoprevir-treated patients and for 19% of placebo-treated patients. Four danoprevir-treated patients had transient ALT elevation. The highest danoprevir dose (900 mg) resulted in grade 4 ALT elevation that, in turn, required therapy discontinuation in the relevant patient arm.

Summary
Danoprevir combined with PEG-IFN/RBV resulted in a high SVR rate in genotype 1 HCV patients. However, high danoprevir doses can result in prominent ALT elevation requiring AVT discontinuation.

ASUNAPREVIR

One of the most considerable achievements in AVT development with PI combinations (if not the most important) is the phase IIa trials with asunaprevir (ASV, BMS-650032, 600 mg; BID) and daclatasvir (DCV, NS5A inhibitor, 60 mg; OD) combined with conventional therapy and a comparison group (with no conventional treatment).

Efficacy
A phase II CT with the above combination, the AI447-011 study, showed its efficacy for one of the most complex HCV-infected patient groups: non-responders with zero prior virologic response (HCV RNA decreased less than 2 $\log_{10}$ by week 12 of conventional therapy). This group appears to be the most complex from the point of view of antiviral regimen selection because null responders should be considered insensitive to IFN-based agents. That study's results show that a combination of direct-acting antivirals is the only therapeutic option for this patient category. The design of the AI447-011 study involved an efficacy comparison in 2 patient arms: Arm 1 was given the combination of ASV + DCV, and arm 2 was given ASV+ DCV + conventional therapy. The treatment duration was 24 wk; one of the important exclusion criteria was liver cirrhosis[35] (Figure 4). The study reported the seemingly unreachable SVR of 90% among null responders under complex therapy (ASV+ DCV + conventional therapy).

Figure 4 Asunaprevir rate (%) after 12- and 24-wk follow-up in the AI447-011 study. ASV: Asunaprevir; DCV: Daclatasvir; PEG-IFN: PEG-IFNPE-Gylated interferon; RBV: Ribavirin.

Figure 5 Undetectable hepatitis C virus RNA rate depending on *IL28B* polymorphism.

Table 7 Effectiveness of combined therapy with asunaprevir *n* (%)		
	Null response (*n* = 21)	Contraindications to IFN-based therapy (*n* = 22)
RVR4	20 (95.2)	15 (68.2)
RVR12	19 (90.5)	14 (63.6)
SVR24	19 (90.5)	14 (63.6)

Data of BMS CT, Suzuki *et al*[36], 2012. IFN: Interferon.

Even more impressive results were shown by Japanese researchers, Suzuki *et al*[36] (2012), who also used an ASV + DCV regimen in null-responders (*n* = 21); their comparison group included patients (*n* = 22) with contraindicated IFN-based therapy (Table 7). Their data showed an SVR of 90.5% in group 1. Additionally, this CT showed the prognostic value of EVR: all EVR patients reached SVR.

The study of the ASV + DCV combination drew the following conclusions: *IL28B* polymorphism appears to lose its SVR predictive value; the majority of patients with aviremia after 2 wk treatment had the CC-genotype, without significant SVR differences in patients with different *IL28B* genotypes (Figure 5).

Safety
The study of the ASV+DCV combination reported relatively more often AEs related to moderate headache, nasopharyngitis exacerbation elevated aminotransferases, and diarrhea. Laboratory AEs were moderate and severe [grade 3-4 (G3-4)] impairments related to elevated transaminase activity. Serious adverse events were found in 6 patients: mild and moderate pyrexia (G2-3), moderate gastroenteritis (in 2 patients); hyperbilirubinemia (G4). In all patients pyrexia disappeared in 4 to 10 d after AVT cancellation. Hyperbilirubinemia and cytolytic syndrome resolved within 4 wk after treatment discontinuation (Table 8). We should note that in the studies of ASV + DCV + conventional therapy combinations, the AE structure showed a prevalence of disorders caused by conventional treatment.

Summary
Asunaprevir-based AVT regimens are highly effective

Table 8 Adverse event structure for asunaprevir				
	Lok *et al*[35] AI447-011		Suzuki *et al*[36]	
	ASV + DCV + conventional therapy (*n* = 10)	ASV + DCV (*n* = 11)	Null response (*n* = 21)	Contraindications to IFN-based therapy (*n* = 22)
Diarrhea	70.0%	72.7%	43%	9%

(above 90%) in the most challenging patient category (null responders); the safety profile of the given AVT regimen was mainly not different from PEG-IFN/RBV.

ABT-450
Agent ABT-450 (AbbVie) is used only in combination with the non-nucleoside inhibitor NS5B (ABT-333), ribavirin and ritonavir. Therefore, ABT-450 efficacy and safety should be considered only a multicomponent "achievement".

Efficacy
The clinical efficacy of an ABT-450-based AVT treatment was published as the results of the AVIATOR study, a phase II a CT, by Poordad *et al*[37] (2013). The genotype 1 patient population mainly included treatment-naive patients (66%, *n* = 33), while partial responders and null responders comprised 34% of the population (*n* = 17). ABT-450 was not used as monotherapy. The dosing of the inhibitor combination depended on the studied population. The given study used a combination of NS5B (ABT-333), ribavirin and ritonavir coupled with various ABT-450 doses for 12 wk. The results showed that ABT-450 was effective at 150 mg OD: the SVR rate

Table 9 AVIATOR, phase Ⅱa study (combination of ABT-450 + ritonavir + ABT-333 + ribavirin)

Study arm	*n*	Genotype	Status	Combination	Duration	Treatment regimen	SVR
Total: group 1 + 2	33	1a/1b (28/5)	Naive	ABT-450 + ritonavir + ABT-333 + ribavirin	12 wk	ABT-450, 250 mg/d or 150 mg/d + ritonavir, 100 mg/d; ABT-333, 400 mg BID; ribavirin, body weight-based	93%-95%

PEG-IFNα: PEGylated interferon-α.

GS-9256

GS-9256 was used only in combination with the non-nucleoside inhibitor tegobuvir (GS-9190). Therefore, GS-9256's efficacy and safety should be considered only in a multicomponent treatment.

Efficacy

Another representative of the PI class, GS-9256 (Gilead) was studied in combination with the non-nucleoside inhibitor tegobuvir (GS-9190) and ribavirin. The combination of 4 agents (GS-9256 + tegobuvir + ribavirin + PEG-IFNα) was used as a comparison group. According to the phase Ⅱ study by Zeuzem *et al*[39] (2010), the SVR rate was comparable in the absence *vs*. the presence of PEG-IFNα: 100% *vs* 94%. The SVR rate of the two-component regimen (only with direct-acting antivirals) amounted to 67% (Table 12).

Safety

Patients taking GS-9256 + tegobuvir 40 mg showed good tolerance, and the majority of AEs were of medium severity. No specific AEs were found. Conversely, the comparison arm (GS-9256 + tegobuvir + ribavirin by weight + PEG-IFNa) developed common AEs typical for PEG-IFN/RBV regimens (Table 13). During the CT period, 2 cases of serious AEs were reported: bursitis (infected) and vasovagal attack, which the investigators interpreted as not related to the studied agent. No laboratory impairments of serious AE (G4) type were found.

Summary

In general, GS-9256 + tegobuvir + ribavirin is highly effective in treatment-naive genotype 1 HCV patients. An analysis of the phase Ⅱ study results indicated a good safety profile for combinations including GS-9256.

amounted to 93%, compared to 95% in the comparison group with ABT-450 250 mg OD (Table 9). The phase Ⅱb study of the combination (2013) showed comparable efficacy in similar study arms: treatment-naive 89% and 96%, null responders 89 and 95%, respectively. It should be noted that the SVR rate for ABT-450-based AVT did not depend on *IL28B* polymorphism (Table 10).

Safety

There were no noted specific AEs from ABT-450-based AVT. The most common were headache, fatigue, nausea (Table 11). However, good tolerance in its totality is related not only to ABT-450 but also to other combination constituents[38]. It is worth mentioning that despite the presence of ribavirin in the combination, anemia was not a frequent AE deserving special attention.

Summary

ABT-450 + ritonavir + ABT-333 + ribavirin in phase Ⅱa and Ⅱb studies was highly effective in HCV patients with the following criteria: genotype 1, both treatment-naive patients and null responders, no liver cirrhosis. At the moment, studies for optimal treatment duration are ongoing. Regarding safety, this combination was well tolerated, and possible AEs were mostly related to asthenia syndrome. Specific AEs were not detected in the studies.

Table 13 Most common adverse event after 4 treatment weeks			
	GS-9256 + tegobuvir	GS-9256 + tegobuvir + ribavirin by weight	GS-9256 + tegobuvir + ribavirin by weight + PEG-IFN[1]

CONCLUSION

The appearance in clinical settings of the first direct-acting antivirals to treat HCV provided improved effectiveness and decreased AVT duration in a majority of genotype 1 patients.

The addition of protease inhibitors has been beneficial for HCV patients. The SVR rate of 40%-50% obtained using conventional treatment was significantly improved (up to 80%) through the addition of telaprevir or boceprevir in triple therapy regimens with the provision that AVT is administered following all main approaches and principles (*e.g.,* accounting for contraindications, potential drug-drug interactions, adherence to AVT regimens depending on initial patient parameters)[10].

Another solid argument for the development of new combined regimens that include direct-acting antivirals is the high rate of hematological AEs, especially ribavirin-induced anemia. When new AVTs for genotype 1 HCV are introduced, most attention should be paid to the regimens, such as by excluding PEG-IFNα to expand the treatment groups and including patients with contraindications to IFN and IFN intolerance.

Our review shows that combinations of direct-acting antivirals can become a novel therapeutic standard not only for patients with contraindicated IFN therapy. PI combinations with other direct-acting antivirals can improve the SVR rates in non-responders with prior partial virologic response and, more importantly, in those with prior null virologic response (Table 14).

When triple therapy appeared, it was the only combination available for null responders. However, the evident barriers were interferon intolerance and issues with concomitant treatment selection to avoid drug interactions. Currently, asunaprevir-based combinations are the treatment of choice for null responders. They have a SVR rate of 90%, and in case of interferon intolerance, patients can be offered antiviral ABT-450-based regimens. In any case, the era of direct-acting antivirals assumes interferon-free therapy. Once, supposedly ideal regimens

Table 14 SVR dependence in null responders for various direct-acting antiviral combinations				
Ref.	*n*	Combination	Duration	SVR
Zeuzem *et al*[39]	37	Telaprevir-based triple therapy	48 wk	33%
Bacon *et al*[25]	58	Boceprevir-based triple therapy	48 wk	52%
Lok *et al*[35]	11	DCV + ASV	24 wk	36%
Lok *et al*[35]	10	DCV + ASV + conventional therapy	24 wk	90%

for HCV treatment implied interferon-free combinations. Now, the emergence of direct-acting antivirals makes it possible to develop optimally dosed treatments and completely exclude clinically significant AEs related to interferon use.

Abstract

AIM: To investigate CYP2E1 IgG4 autoantibody levels and liver biochemical markers in adult patients after anesthesia with desflurane.

METHODS: Forty patients who were > 18 years old and undergoing elective surgery under general anesthesia with desflurane were studied. Alpha-glutathione-S-transferase (αGST) and IgG4 antibodies against CYP2E1 were measured preoperatively and 96 h postoperatively, as well as complete blood count, prothrombin time (PT), activated partial thromboplastin time (aPTT), international normalized ratio (INR), aspartate aminotransferase (SGOT), alanine aminotransferase (SGPT), g-glutamyl-transpeptidase (gGT), alkaline phosphatase, total serum proteins, albumin and bilirubin. A separate group of 8 patients who received regional anesthesia was also studied for calibration of the methodology used for CYP2E1 IgG4 and αGST measurements. Student's t-test and the Mann-Whitney U test were used for comparison of the continuous variables, and Fisher's exact test was used for the categorical variables. All tests were two-tailed, with statistical significance set as $P < 0.05$.

RESULTS: None of the patients developed postoperative liver dysfunction, and all patients were successfully discharged from the hospital. No statistically significant difference was observed regarding liver function tests (SGOT, SGPT, γGT, bilirubin, INR), αGST and CYP2E1 IgG4, before and after exposure to desflurane. After dividing patients into two subgroups based on whether or not they had received general anesthesia in the past, no significant difference in the levels of CYP2E1 IgG4 was observed at baseline or 96 h after desflurane administration ($P = 0.099$ and $P = 0.051$, respectively). Alpha-GST baseline levels and levels after the intervention also did not differ significantly between these two subgroups ($P > 0.1$). The mean αGST differences were statistically elevated in men by 2.15 ng/mL compared to women when adjusted for BMI, duration of anesthesia, number of times anesthesia was administered previously and length of hospital stay. No significant difference was observed between patients who received desflurane and those who received regional anesthesia at any time point.

CONCLUSION: There was no difference in CYP2E1 IgG4 or αGST levels after desflurane exposure; further

research is required to investigate their role in desflurane-induced liver injury.

Core tip: Several case reports of hepatotoxicity following anesthesia with desflurane have been published in the literature, implicating cytochrome P450 2E1-IgG4 autoantibodies. This study investigates the possible changes in CYP2E1 IgG4 autoantibody levels and other biochemical markers of liver injury in 40 adult patients who received anesthesia with desflurane for elective surgery. Samples were obtained before and 96 h after exposure to desflurane, and no significant difference was observed in levels of CYP2E1 IgG4, a-glutamyl-S-transferase, aspartate aminotransferase, alanine aminotransferase, g-glutamyl-transpeptidase or alkaline phosphatase levels, regardless of patients' previous exposure to volatile anesthetics.

INTRODUCTION

Volatile anesthetics, mostly halothane, have been implicated as causative agents of drug-induced liver injury (DILI)[1-5], which has been reported to occur in approximately 1 out of 10000 adult patients receiving general anesthesia with halothane[4,5]. Three main mechanisms have been implicated in the development of hepatotoxicity: (1) a hypersensitivity reaction; (2) the production of hepatotoxic metabolites; and (3) hypoxia[4]. A hypersensitivity reaction is believed to be the most important of these mechanisms, it is also known as idiosyncratic drug-induced hepatitis (IDDIH) and is caused by the production of trifluoroacetylated (TFA) hepatic proteins during the metabolism of halothane by the cytochrome P450 2E1 (CYP2E1)[4]. These proteins act as neoantigens and are responsible for the production of autoantibodies against liver tissue[6-8]. In 1996, it was demonstrated that autoantibodies that react with CYP2E1 were significantly elevated in 45%-70% of patients with halothane hepatitis[7,9], particular including CYP2E1 IgG4 and 58 kDa endoplasmic reticulum protein (ERp58) autoantibodies[10,11].

With the development of newer volatile anesthetics, the risk of developing DILI has decreased, mainly due to the reduced metabolism of newer agents by CYP450 2E1 (20%-30% for halothane, compared to 2% for enflurane, 1% for sevoflurane, 0.2%-0.6% or less for isoflurane and 0.02% for desflurane)[12,13]. Njoku *et al*[14] (1997) demonstrated that desflurane produces lower levels of TFA hepatic proteins, reflecting the decreased metabolism of the agent by CYP2E1. Despite the fact that desflurane seems to have the best safety profile in this regard and is believed to have minimal, if any, hepatotoxic effect, there have been several case reports published implicating desflurane as a causative agent of DILI[11,15-20].

Aspartate aminotransferase (SGOT), alanine aminotransferase (SGPT), g-glutamyl-transpeptidase (gGT), alkaline phosphatase (ALP), albumin, bilirubin and coagulation status are all classical biochemical markers of liver injury, and they have all been reported to change significantly in all published case reports of hepatocellular damage due to desflurane anesthesia[11,15-20]. Additionally, alpha-glutathione S-transferase is believed to be a sensitive marker of hepatocellular injury because it is distributed equally in centrilobular and periportal hepatocytes, in contrast to SGOT/SGPT[21,22]. This distribution is important because liver biopsies of patients with halothane hepatitis have demonstrated that the main histological characteristic of this condition is centrilobular hepatic necrosis[4].

Based on case reports of desflurane hepatotoxicity and the possible mechanisms of DILI in the case of volatile anesthetics, the aim of this study was to investigate the possible production or alteration of CYP2E1 IgG4 autoantibody levels in addition to other biochemical markers of liver injury in patients who received general anesthesia with desflurane.

MATERIALS AND METHODS

The Institutional Review Board and Ethics Committee of "Attikon" University Hospital, where the study was conducted, approved the study, and written informed consent was obtained from all patients. Forty randomly selected adult patients who had received general anesthesia with desflurane for elective surgery between 01/2008 and 07/2011 were included. The exclusion criteria included the following: age < 18 years old; American Society of Anesthesiologists classification > III; history of liver disease of any etiology; history of chronic hepatitis B or C, recent viral disease of unknown etiology; history of exposure to hepatotoxic doses of acetaminophen, nonsteroidal anti-inflammatory drugs or antiepileptic drugs; current treatment with hepatotoxic drugs or immunosuppressants; autoimmune or connective tissue disorders; history of alcohol or illicit drug use; pregnancy; malignancies; intra-abdominal procedures; and operating time of more than 6 h.

Patients' complete medical history and medications were recorded during preoperative assessment. Samples of serum were collected from all patients preoperatively, immediately postoperatively and every 24 h until the 4th postoperative day (96 h after the completion of the surgery). At these time points, complete blood count, prothrombin time (PT), activated partial thromboplastin

time (aPTT), international normalized ratio (INR), aspartate aminotransferase (SGOT), alanine aminotransferase (SGPT), gGT, alkaline phosphatase, total serum proteins, albumin and bilirubin (direct/indirect) were measured. At baseline and 96 h postoperatively, alpha-glutathione-S-transferase (αGST) and IgG4 antibodies against CYP2E1 were measured. A time period of 4 d was selected because the latency period between the exposure and the clinical evidence of liver damage is variable in the current literature on halothane; its approximate value is estimated to be at least 6 d after first exposure and 3 d after multiple exposures[4]. The same applies to the case reports on desflurane-induced hepatotoxicity, in which the period between exposure and clinical presentation varied between 2-17 d[11,15-20]. Therefore, it was assumed that a time period of 4 d would be appropriate to detect early biochemical changes.

Serum was centrifuged at 1000 rounds/min for 10 min and immediately stored at -80 ℃ until the time of measurements. Complete blood count, coagulation status, SGOT, SGPT, gGT, ALP, serum proteins, and bilirubin were measured directly after sampling, according to the standard perioperative protocol.

Anesthesia in all patients was induced using propofol (2-2.5 mg/kg), fentanyl (3 μg/kg) and cis-atracurium (0.2 mg/kg). Maintenance of anesthesia was achieved with desflurane 6% (in an oxygen/air mixture of 50%) to achieve bispectral index values of 40-50, in addition to a remifentanil infusion as required. Intraoperative monitoring of all patients included systemic blood pressure measurement (invasive when needed), continuous ECG, pulse oxymetry, ETCO2 measurement and bispectral index. Postoperative analgesia included intravenous patient-controlled analgesia with morphine (bolus 1 mg, lockout 10 min) and acetaminophen (1 gr three times daily). In cases of minor surgery without significant postoperative pain, only an acetaminophen-codeine combination was administered (500 mg/30 mg), three times daily. Patients were closely monitored by the anesthesiology team for the efficacy of postoperative analgesia, hemodynamics, oxygenation, nausea and vomiting, two times a day, until the 4th postoperative day. All side effects and complications that occurred during that period were recorded.

A separate group of 8 patients who underwent orthopedic procedures under regional anesthesia was also studied to calibrate the methodology of CYP2E1 IgG4 and αGST measurements. All patients received combined spinal-epidural anesthesia using ropivacaine 0.75% combined with fentanyl, as required. The same serum sampling methodology was followed for these patients. Postoperative analgesia included only morphine administered epidurally (initial dose immediately after surgery) and subsequent acetaminophen-codeine administration (as for the general anesthesia patients).

Serum analysis for CYP2E1 IgG4 antibodies
The determination of serum CYP2E1 IgG4 antibody levels was performed according to a previously described

sandwich enzyme-linked immunosorbent assay[21] with slight modifications. Briefly, Immulon 2HB 96-well microtiter plates (ISC BioExpress) were incubated overnight with 0.5 μg/100 μL human CYP2E1 (human CYP2E1 plus P450 reductase plus cytochrome b5 Supersomes (BD Biosciences, Woburn, MA, United States). After washing, plates were incubated with 100 μL serum for 3 h at room temperature and subsequently with 100 μL of a 1:1000 diluted mouse anti-human IgG4 HRP-conjugated second antibody for 2 h at room temperature. The final product was determined by incubation for 20 min with 100 μL of a 1:1 mixture of Color Reagent A (H2O2) and Color Reagent Tetramethylbenzidine (R&D Systems, Minneapolis, United States). The reaction was stopped by the addition of 2 N H2SO4, and the optical density was determined at 450 nm.

Serum analysis for αGST
The determination of serum αGST was performed using a commercially available ELISA according to the manufacturer's instructions (Eagle Biosciences, Inc, Boston, United States).

Statistical analysis
The Shapiro-Wilk test was performed to test for normal distribution of continuous variables. The results are given as the mean ± SD or as the median and interquartile range (IQR) according to normality of continuous variables. All qualitative variables are presented as absolute and relative frequencies. Student's *t* test or its non-parametric equivalent, the Mann-Whitney *U* test, was used for comparison of continuous variables. Fisher's exact test was employed for comparison of categorical variables.

Mean differences in the liver function tests being studied before and after the intervention (general anesthesia) were investigated by the application of multivariate linear regression models. A stepwise backward-forward technique was applied for the selection of the dependent variables.

All tests were two-tailed, and statistical significance was established at 5% ($P < 0.05$). Data were analyzed using Stata ™ (Version 10.1 MP, Stata Corporation, College Station, TX, United States).

RESULTS
Characteristics of study population
Of the 40 patients included in the study, one was excluded due to the diagnosis of malignancy. The demographic characteristics of patients, such as their age, height, weight and body mass index, are presented in Table 1. Previous anesthetic exposure (to general anesthesia), type and duration of anesthesia, and total length of hospital stay after the operation, are also presented in Table 1. All patients remained hemodynamically stable throughout the procedure, without periods of sustained hypotension (of more than 20% below baseline values) or hypoxia that might interfere with liver function. No patient in this

study developed postoperative hepatotoxicity, and all patients were successfully discharged from the hospital.

Comparison of blood test measurements before and after general anaesthesia

No statistically significant difference was observed in the liver function tests (SGOT, SGPT, γGT, bilirubin, INR), αGST or CYP2E1 IgG4 before and after exposure to desflurane. A significant decrease was only observed in the hematocrit, hemoglobin and albumin levels, postoperatively. All data are presented in detail in Table 2.

Multivariate linear regression models were applied using the mean differences of IgG4 and αGST adjusted for gender, BMI, duration of anesthesia, number of times anesthesia was administered previously, and length of hospital stay. A stepwise backward-forward technique was applied for the selection of dependent variables. No significant differences were detected in the mean differences of CYP2E1 IgG4 (before and after general anesthesia) or SGOT, SGPT, γGT, bilirubin and INR (*P* > 0.05). However, significant differences were detected between the mean differences of αGST according to gender, length of hospital stay and duration of general anesthesia. Alpha-glutamyl-S-transferase mean differences were statistically elevated in men by 2.15 ng/mL compared to women when adjusted for BMI, duration of anesthesia, number of times anesthesia was administered previously, and the length of hospital stay. An increase in the duration of anesthesia by one minute was associated with a mean increase in the αGST mean difference of 0.0323 ng/mL. These results are presented in Table 3.

Of the 8 patients who received regional anesthesia, one was excluded due to a malignancy that was diagnosed

after the operation. Four women and 3 men were studied, of median age 70 years old (range 65-70) and ASA Ⅱ and Ⅲ. Three of them had received general anesthesia in the past [median 1.5 (range 1-2)], and 4 had not. Although the number of patients who received regional anesthesia was too small to serve as a control group, we compared the median differences (before and after anesthesia, general or regional) of the liver enzymes (SGOT, SGPT, ALP, γGT, αGST) and CYP2E1 IgG4, using the Mann-Whitney *U* test. There were no significant differences observed for any of the variables studied in this analysis.

Previous anesthetic exposure
Twelve of the patients studied had not received general

anesthesia previously. In this subgroup analysis, mean values for CYP2E1 IgG4 levels, at baseline and after desflurane exposure, were 0.025 (0-0.04) and 0.035 (0-0.07), respectively (*P* = 0.73). Twenty-seven patients had received general anesthesia previously; of these patients, 19 had surgery in childhood. Their CYP2E1 IgG4 levels before and after desflurane exposure were 0.08 (0.02-0.66) and 0.105 (0.03-0.74), respectively (*P* = 0.59). The changes in IgG4 levels after a new exposure to desflurane for patients who had and had not previously received general anesthesia were not significantly different (*P* = 0.79). However, CYP2E1 IgG4 levels in patients who had a medical history of previously receiving general anesthesia compared to those who had not, showed borderline statistical significance 96 h after anaesthesia (with *P* = 0.099 at baseline and *P* = 0.051 96 h post anesthesia) (Table 4, Figure 1). Alpha-GST baseline levels and levels after the intervention did not differ significantly between patients who had previously received general anesthesia and those who had not (*P* > 0.1) (Table 4).

DISCUSSION

Severe postoperative liver injury has been reported as a rare complication after anesthesia with halogenated anesthetics[1-4,14-21,23]. The main mechanism responsible is believed to be the production of trifluoroacetylated proteins through the metabolism of halogenated anesthetics from CYP2E1, which act as neoantigens and induce the production of autoantibodies against liver tissue[14,21]. Although newer volatile anesthetics, desflurane especially, are reported to be safe due to their low metabolism by CYP2E1[14], there are several case reports implicating desflurane as the causative agent of IDDIH[11,15-20]. In some cases, it was assumed that the mechanism might be prior sensitization of patients from previous exposures to halothane or other halogenated volatile anesthetics[16].

Njoku *et al*[14] showed that patients with IDDIH had significantly increased CYP2E1 IgG4 autoantibodies compared to control subjects who had never been exposed to halogenated agents. Similarly, in another study, it was observed that the levels of CYP2E1 autoantibodies were asymptomatically increased in pediatric anesthesiologists compared to general anesthesiologists, due to an in-

creased environmental exposure to volatiles[24]. In another study by the same researchers[21] a comparison was made between the levels of CYP2E1 IgG4 in four separate groups: patients with anesthetic-induced IDDIH, pediatric anesthesiologists, general anesthesiologists and healthy controls; CYP2E1 IgG4 levels were significantly higher in patients who developed IDDIH than in all of the other groups. However, no comparison with our results can be made, because there was no direct quantification of the CYP2E1 IgG subclasses. In case reports of desflurane hepatotoxicity, hepatotoxicity occurred between the 2nd and 17th postoperative day and was related to at least one prior administration of anesthesia[11,15-20]. The problem is that CYP2E1 IgG4 levels were quantified and reported to be elevated in only two of these cases[18,20].

In the present study, no patient developed clinical or biochemical indications of liver injury, and there was no statistically significant increase in CYP2E1 IgG4 96 h after receiving anesthesia with desflurane. The hypothesis that previous exposure to halogenated anesthetics may sensitize patients to desflurane, leading them to develop IDDIH after subsequent desflurane exposure, has been stated by various researchers[14]. A cross-sensitization theory between inhalational anesthetics, in addition to the possibility of "immunological memory" of patients who were sensitized to an antigen, may be possible mechanisms to explain this effect[14]. To investigate this possibility, we also performed a subgroup analysis of patients, according to their previous exposure to halogenated anesthetics. Patients who had previously received general anesthesia were studied for their baseline values of CYP2E1 IgG4 and for their tendency to increase these levels after a new exposure to desflurane. The findings did not demonstrate any differences in the degree of increase of CYP2E1 IgG4 between naïve patients and those who had previously received any type of general anesthesia.

Regarding αGST, a multivariate regression model analysis showed that an increase in the duration of anesthesia by one minute was associated with a mean increase in αGST mean difference of 0.0323 ng/mL. This finding may be related to hepatic blood flow alterations and low-grade centrilobular hypoperfusion associated with

the longer duration of anesthesia[25-27]. This possibility is in accordance with the findings of another study of patients undergoing partial hepatectomy under anesthesia with desflurane versus propofol, where it was found that αGST levels 120 min after hepatic vascular declamping were significantly higher in desflurane patients[25]. Further research is required on this subject to investigate alterations of αGST with respect to liver blood flow and duration of anesthesia.

Limitations of this study include the small sample size of patients and the absence of detailed data regarding previous anesthetic exposure. Although the number of patients who previously received general anesthesia is known, the exact agents used (inhalational or intravenous) are unknown. However, most of the patients received anesthesia in childhood, where the use of inhalational agents is a common practice. Additionally, the lack of a longer period of measurement after anesthesia and the absence of more frequent measurements (*i.e.,* more time points) for CYP2E1 IgG4 and αGST are also limitations because there are cases of patients developing alterations after a longer time.

Our results suggest that there was no statistically significant difference between the levels of CYP2E1 IgG4 autoantibodies before and after anesthesia with desflurane. There was no evidence that the levels of αGST or any of the other biochemical markers of liver function were altered after anesthesia with desflurane and no signs that previous anesthetic exposure might affect these levels.

In conclusion, our findings suggest there are no significant differences between the levels of CYP2E1 IgG4 antibodies and αGST before and 96 h after anesthesia with desflurane and no difference between patients with previous anesthetic exposure versus naïve patients. Further research is required to investigate the actual role of CYP2E1 IgG4 in the pathogenesis of halogenated anesthetic-induced liver injury, especially in patients with multiple anesthetic exposures.

ACKNOWLEDGMENTS

COMMENTS

Background

Volatile anesthetics, mostly halothane, have been implicated as causative agents of Drug Induced Liver Injury (DILI). The most important mechanism for DILI is believed to be a hypersensitivity reaction, which is due to the production of trifluoroacetylated hepatic proteins during metabolism of halothane by the cytochrome P450 2E1 (CYP2E1). With the development of newer volatile anesthetics, the risk of developing DILI has been decreased, due to the minor metabolism of newer agents by the CYP450 2E1 (20%-30% for halothane, in comparison to 0.02% for desflurane). Despite the fact that desflurane seems to have the best safety profile with this regard, and is believed to have minimal, if any, hepatotoxic effect, there have been several case reports published, impli-

cating desflurane as the causative agent of DILI.

Research frontiers

Desflurane is a widely used volatile anesthetic which seems to have the best safety profile regarding liver injury. Despite that, there have been some cases of DILI after desflurane anesthesia and in all of them there was a history of at least one previous general anesthesia. It is very important to identify persons at risk of developing DILI in order to avoid this serious complication. IgG4 CYP2E1 autoantibodies have been implicated in the development of DILI although their specific role is not clear. The measurement of IgG4 CYP2E1 autoantibodies before and after anesthesia with desflurane in patients with and without previous exposure to volatile anesthetics could give some useful information.

Innovations and breakthroughs

In the present study, no patient developed clinical or biochemical indications of liver injury and it was demonstrated that there was no statistically significant increase of CYP2E1 IgG4, 96 h after receiving anesthesia with desflurane. Patients who had previously received general anesthesia were studied as for their baseline values of CYP2E1 IgG4, as well as for their tendency to increase these levels after a new exposure to desflurane. Findings did not demonstrate any significant differences in the degree of increase of CYP2E1 IgG4 between naïve patients and those who had previously received any kind of general anesthesia.

Applications

The study results suggest that desflurane anesthesia is not associated with an increase of IgG4 CYP2E1 autoantibodies and that their role has to be further investigated.

Peer review

Dr. Batistaki C and her colleagues investigated the levels of CYP2E1 IgG4 autoantibody levels and conventional biochemical variables in adult patients before and after anesthesia with desflurane, and found that there was no significant difference in hepatic biochemical variables and CYP2E1 IgG4 levels in patients who received general anesthesia with desflurane. This was an interesting study and the findings also provided them some useful reference in real clinical practice.

SYSTEMATIC REVIEW

Central hepatectomy for centrally located malignant liver tumors: A systematic review

Abstract

AIM: To study whether central hepatectomy (CH) can achieve similar overall patient survival and disease-free survival rates as conventional major hepatectomies or not.

METHODS: A systematic literature search was performed in MEDLINE for articles published from January 1983 to June 2013 to evaluate the evidence for and against CH in the management of central hepatic malignancies and to compare the perioperative variables and outcomes of CH to lobar/extended hemihepatectomy.

RESULTS: A total of 895 patients were included from 21 relevant studies. Most of these patients who underwent CH were a sub-cohort of larger liver resection studies. Only 4 studies directly compared Central *vs* hemi-/extended hepatectomies. The range of operative time for CH was reported to be 115 to 627 min and Pringle's maneuver was used for vascular control in the majority of studies. The mean intraoperative blood loss during CH ranged from 380 to 2450 mL. The reported morbidity rates ranged from 5.1% to 61.1%, the most common surgical complication was bile leakage and the most common cause of mortality was liver failure. Mortality ranged from 0.0% to 7.1% with an overall mortality of 2.3% following CH. The 1-year overall survival (OS) for patients underwent CH for hepatocellular carcinoma ranged from 67% to 94%; with the 3-year and 5-year OS having a reported range of 44% to 66.8%, and 31.7% to 66.8% respectively.

CONCLUSION: Based on current literature, CH is a promising option for anatomical parenchymal-preserving procedure in patients with centrally located liver malignancies; it appears to be safe and comparable in both perioperative, early and long term outcomes when compared to patients undergoing hemi-/extended hepatectomy. More prospective studies are awaited to further define its role.

Key words: Central hepatectomy; Segment orientated liver resection; Mesohepatectomy; Middle hepatic lobectomy; Central bisegmentectomy

Core tip: Central hepatectomy, defined as anatomical segment 4, 5, 8 ± 1 liver resection, is a promising parenchymal-preserving procedure in patients with centrally located liver malignancies. Based on current evidence, it appears to be safe and comparable in both perioperative, early and long term surgical and oncological outcomes when compared to patients undergoing traditional resections such as hemi-/extended hepatectomy.

INTRODUCTION

Surgical resection is the optimal treatment of choice and potential cure for most malignant tumors of the liver if possible[1,2]. With recent improvements in surgical techniques of liver resection, anesthesia and postoperative care, morbidity ranges from 5% to 25% and mortality has improved significantly and has approached zero[3-6]. Centrally located malignancies of the liver such as hepatocellular carcinoma (HCC), Cholangiocarcinoma (CCA) and liver metastases in segments 4, 5, 8 may require extensive resections because of their relationship to major vascular and biliary structures and deep location[7,8]. Traditionally, these centrally located tumors are resected by major resections such as right, left, extended right or extended left hemihepatectomies. Extended or anatomical resections are recommended for oncological reasons; however, these carry a risk of not only significant blood loss, longer operative time but also postoperative liver failure in patients with cirrhosis or poor liver functional reserve or even in patients without cirrhosis[9-11]. Non-anatomical resection is an alternative approach for parenchymal preservation, but it is hindered by intraoperative hemorrhage and betrays oncological principles evident by higher rates of margin positivity and poorer survival outcome[12,13]. With the perpetual lack of donor organs, long waiting time, along with other limitations of liver transplantation, anatomical parenchymal-preserving procedures have an increasing role in treatment of primary and secondary liver malignancies[14].

Central hepatectomy (CH), also known as meso-hepatectomy, was first performed for gallbladder cancer in 1972 and is used to describe the operative procedure to resect segments 4, 5, 8 ± 1 (Figure 1)[15-20]. Other synonymous terms used in the literature include central hepatic resection, middle hepatectomy, middle hepatic lobectomy, central bisegmentectomy and central bisectionectomy[20-27]. Regardless of the technical term used, the principle behind this procedure is the same and was not commonly carried out till more recently. In the Brisbane Terminology of Liver Anatomy and Resections by the International Hepatopancreatobiliary Association (IHPBA) in 2000, there was no definition of this surgical procedure[15,16].

The theoretical risks of CH compared to traditional major liver resections such as extended- or hemihepatectomy are obvious. These include a longer operating time, greater intraoperative blood loss, higher risk of biliary and vascular complications, all mainly attributed to the proximity to the hilar structures and the presence of 2 significant resection planes instead of a single plane. Despite this, previous reports showed that CH is safe and achieves comparable complication rates and overall survival rates as conventional major hepatectomies but harbors the advantages of: (1) preserving liver parenchyma with the aim of decreasing the risk of postoperative liver failure; (2) no proven oncological compromises as long as margins are negative and adequate; and (3) increases the opportunity for future repeat resection, if warranted,

Figure 1 Central hepatectomy-segment orientated resection. Couinaud segments are labeled 2-8; Caudate lobe (Segment 1) is not labelled in this diagram. here) Area shaded blue are the Central segments of 4, 5, 8 which are the segments resected in central hepatectomy (CH). Red rings indicate where the vascular outflow is encountered and ligated during CH.

in cases of recurrent malignancies such as colorectal or neuroendocrine liver metastases[7,8,22,23,25].

The current literature directly comparing patients undergoing extended hemi-hepatectomy and CH is lacking[9,15,17,23,25]. There is only one study in the current literature with more than 100 patients (Table 1)[3,7-9,17-20,22,23,25,27-37]. The aim of this review is to analyze and compare the perioperative, early and long- term results of patients with centrally located liver malignancies, between those treated with CH and those treated with hemi-/extended hepatectomy.

MATERIALS AND METHODS

A systematic literature search was performed in MEDLINE (PubMed) from January 1983 to June 2013 to evaluate the evidence supporting CH as a safe procedure for the management of central hepatic tumors and to compare the perioperative, short and long term results of CH to extended/lobar hemihepatectomy. The search used the following medical subgroup headings (MeSH) terms combined with Boolean operators: mesohepatectomy, central hepatectomy, central liver resection, segmentectomy, bisegmentectomy, central trisegmentectomy, bisectionectomy, segmental liver resection and segment oriented liver resection. References of the identified articles were reviewed to identify additional relevant studies. Only full articles published in the English language reporting a series of more than 10 cases were included in the review and effort was made to exclude studies with significant overlap of the same patient cohorts. The literature search was conducted according to PRISMA (preferred reporting items for systematic reviews and meta-analyses) recommendations(Figure 2)[38]. Definitions and nomenclature for liver resections was based on the 2000 IHPBA Brisbane terminology[15,16]. Namely, resection of segments 5 and 8 was named right anterior sectionectomy, while resection of segments 4a and 4b was named left medial sectionectomy. The procedure of segments 4, 5 and 8 resection has now predominantly been termed

[1]Indicates multiple studies with overlapping study periods from a single institution; [2]Total number calculated after excluding studies with repeat patients; [3]Limited data available as CH patients were a subset of a larger group of patients undergoing various types of hepatic resections. Overall morbidity and mortality was calculated by considering the number of events as a percentage of the total number of patients in included studies. HCC: Hepatocellular carcinoma; CRM: Colorectal metastases; CCA: Cholangiocarcinoma; GBC: Gallbladder carcinoma; IVC: Inferior vena cava; NA: Not available; OS: Overall survival; DFS: Disease-free survival; TACE: Transarterial chemoembolization; CH: Central hepatectomy.

Figure 2 Identification and screening of articles according to preferred reporting items for systematic reviews and meta-analyses recommendations.

central hepatectomy or mesohepatectomy[9,14,17].

When calculating the overall morbidity and mortality, this was calculated as the number of events reported as a percentage of the total number of patients in included studies. In considering individual complications, the number of events or incidences was calculated as a percentage of the total number of complication events in which this data was available. Weighted means were calculated when outcomes were expressed as a mean value.

RESULTS

A literature search on MEDLINE (PubMed) and review of references of relevant articles yielded a total of 90

articles on central hepatectomy after exclusion of irrelevant articles (Figure 2). Of these, 22 articles were published in English and included more than 10 patients. Of these, one study was excluded from analysis because results of these patients were also reported in a later series by the same author[17,39]. Three articles by Chen _et al_[7,18,33] reported on patients undergoing CH at a single institution with overlapping study periods, with the latest 2008 study of 256 patients constituting the largest reported series of CH at a single institution to date. Of the 21 articles included for analysis, 3 studies were comparative studies between 2 different methods of vascular control during CH, 4 studies compared the results of CH _vs_ conventional forms of hepatectomies (hemi- or extended hemihepatectomy), 1 looked at results of CH in patients who had pre-operative transarterial chemo-embolization (TACE) as compared to those who did not have preoperative TACE and 1 compared the outcomes of patients who had huge HCC of 10 cm or greater in size, as to compared to that of HCC measuring 5 to 10 cm[19,33,37]. The remaining papers were descriptive and non-comparative studies. The results of these 21 studies, including number of patients, operative time, method of vascular control, operative blood loss, mortality, morbidity and survival data (where available) are summarized in Table 1. The 4 studies which compared the outcomes of CH _vs_ conventional hepatectomies are summarized in Table 2.

Table 3 Type and frequency of complications reported following central hepatectomy

Type of complication[1]	Number reported (n = 200)	Frequency (%)
Surgical complications		
Bile leakage/biloma	36	18
Intra-abdominal abscess	16	8
Wound infection	7	3.5
Bleeding	4	2
Intestinal perforation	1	0.5
Medical complications		
Pleural effusion/empyema	62	31
Ascites	29	14.5
Pneumonia/pulmonary infection	13	6.5
Pulmonary edema	6	3
Fever	4	2
Upper gastrointestinal bleeding	3	1.5
Urinary tract infection	3	1.5
Transient hepatic dysfunction/ prolonged jaundice	3	1.5
Hepatic necrosis/liver failure	3	1.5
Acute renal failure	2	1
Stroke	1	0.5
Arrhythmia	1	0.5
Deep vein thrombosis	1	0.5
Other (not specified)	4	2

[1]Calculated out of a total of 200 events.

Study characteristics and operative details

A total of 1259 patients from 21 studies were reported after undergoing CH in the literature. However, after excluding studies with potential repeat patients (due to recruitment with significant overlapping study periods at a single institution), a total of 895 unique patients who had CH were obtained. The indication for central hepatectomy was detailed in 14 studies comprising a total of 659 patients. The main indication for CH was HCC, occurring in 565 patients (85.7%), but was also performed in conditions such as centrally-located liver metastases which accounted for 58 cases (most commonly colorectal in origin). Other diagnoses included CCA/ gallbladder carcinoma (25 cases), hepatic sarcoma (1 case), hemangiomas (2 cases) and occasionally for other benign lesions (4 cases).

The range of operative time for CH was reported to be 115 to 627 min, and Pringle's maneuver was used for vascular control in the majority of studies. The mean intraoperative blood loss during CH ranged from 380 to 2450 mL.

Mortality and morbidity

Data on mortality was available in 16 articles with mortality rates ranging from 0.0% to 7.1%. In nearly half of these studies (7 studies) had zero postoperative mortality following CH. A total of 16 deaths in 17 unique studies comprising 689 patients have been reported, giving an overall mortality of 2.3% following CH. The most common cause of death following CH was liver failure. Concomitant contributing factors that have been reported included sepsis, pneumonia, post-operative bleeding,

disseminated intravascular coagulopathy and multi-organ failure. Data on complications following CH were available in 15 studies, with reported morbidity rates ranging from 5.1% to 61.1%. After excluding repeat studies, there were a total of 187 patients reported to have morbidity following CH, out of a total of 680 patients. This gave an overall complication rate of 27.5% (including early and late complications) following CH. A detailed breakdown of the type of complications experienced was available in 13 studies, which accounted for a total of 200 complication events. The most commonly reported surgical complication was bile leakage or biloma formation, which accounted for 18% (36 events) of all complications reported. Bile leakage resolved with conservative treatment in the majority of cases. Other surgical complications reported included wound infection, intra-abdominal abscess, intra-abdominal bleeding/hematoma, and intestinal perforation. Medical complications described following CH included transient hepatic dysfunction/prolonged jaundice/liver failure, ascites, pneumonia/pulmonary infection, pleural effusion/empyema, urinary tract infection, fever, upper gastrointestinal bleeding, renal failure, stroke and deep vein thrombosis (Table 3).

Overall survival

Overall survival (OS) data was available in 8 studies[7,8,17,23,27,31,33,36]. Median survival for HCC treated with CH was reported in 2 studies: this was 34 mo in Hasegawa et al[27] (patient diagnosis included both HCC and colorectal liver metastases) and 51 mo in Hu et al[23] and Hasegawa et al[27] (HCC patients only), Wu et al[17] reported a 6-year OS of 30% (HCC, CCA and other liver metastases); Chen et al[33] reported a 5-year OS of 31.7% in the group of patients with HCC who did not have preoperative TACE, as compared to the group who had TACE prior to CH with a significantly better 5-year OS of 46.2% (P = 0.043). Overall, the CH group for HCC had 1-year OS ranging from 67% to 94%, with 3-year and 5-year OS having a reported range of 44% to 66.8%, and 31.7% to 66.8% respectively.

Disease-free survival

Seven studies reported disease-free survival[7,8,17,23,33,34,36]. The median Disease-free survival (DFS) in Hu et al[23] was 23 mo for HCC. In the remaining HCC studies with DFS data, the range for 1-, 3- and 5-year DFS was 50% to 75%, 28.8% to 46.2% and 15% to 31.8% respectively.

Comparative studies of CH vs hemi-/extended hepatectomies

Of the 21 studies on CH, 4 of these were case-control studies that compared the outcomes following CH vs hemi- or extended hepatectomies at their institutions (Table 2)[8,17,19,23]. A total of 148 patients underwent CH and 243 had hemi- or extended hepatectomies performed for their disease in these 4 studies.

Operative time for CH was shown to be not significantly different from that of extended hepatectomies in

the series by Hu *et al*[23] and Wu *et al*[17], while in 2 studies, Scudamore *et al*[19] and Cheng *et al*[8], patients who underwent CH had significantly shorter operative time (238 and 230 min respectively) as compared to extended hepatectomies (304 and 316 min respectively). The overall weighted mean operative time in these 4 studies for CH was 268 min *vs* 299 min for lobar/extended hemihepatectomy. Also, significantly less blood loss was experienced in CH as compared to extended hepatectomies in Cheng *et al*[8] (500 mL in CH *vs* 750 mL for extended hepatectomies, *P* = 0.004) and in Scudamore *et al*[19] (917 mL *vs* 1628 mL, *P* = 0.009). The overall weighted mean intraoperative blood loss in these 4 studies for CH was 882 mL *vs* 1352 mL for lobar/extended hemihepatectomy.

The morbidity rates between CH and hemi-/extended hepatectomy groups were also not significantly different individually in these studies, with the exception of late complications in Scudamore *et al*[19] which was studied as a subgroup. In study by Scudamore *et al*[19], the rate of late complications in extended hepatectomies (20.9%) was found to be higher than that in CH or lobar hepatectomies (*P* < 0.05). The overall morbidity in our review of CH was comparable: 20.9% (range: 20% to 66.7%) for CH *vs* 38.7% (range: 20% to 66.7%) for the hemi-/extended hepatectomy group. There was no statistically significant difference in mortality of patients who underwent CH and hemi/extended hepatectomy groups in any of the 4 studies. Notably, there was zero mortality in 3 out of 4 CH groups, however, there was mortality in the corresponding control groups (hemi-/extended hepatectomy). The overall mortality in the 2 groups were also similar: 3.4% (range: 0.0% to 7.9%) for CH group *vs* 2.9 % (range: 0.0% to 7.3%) for the hemi-/extended hepatectomy group (Table 2).

DISCUSSION

Advances in imaging technology have contributed to the improvements in the understanding of liver anatomy that is based on functional segmental anatomy and forms the foundation for segment-orientated liver surgery[9,12]. Central hepatectomy removes most or the entire left medial sector (segments 4a and 4b) and all or most part of the right anterior sector (segments 5 and 8) with or without segment 1 (Figure 1). It represents an alternative and attractive option for those patients with limited functional liver reserve especially those with liver cirrhosis or those with chemotherapy associated steatohepatitis, because it removes the tumor-bearing segments in entirety while preserving the rest of the liver without necessarily compromising on recurrence or survival outcome[9,40].

In the presence of a large and/or a deep seated tumor located in the central part of the liver (Couinaud segments 4, 5, 8), the resection is more technically challenging due to its proximity to important hilar structures. Central hepatectomy is more surgically daedalean than the conventional anatomical major liver resection because it has 2 resection planes instead of one, the need

for preservation of the bilateral peripheral segments and its vasculature and the potential need for 2 bilioenteric anastomoses (*e.g.* for perihilar CCA). It involves the resection of liver territory drained by the middle hepatic vein (HV) along 3 lines of transection planes: the right intersectional plane (to the left of the Right HV), the left intersectional plane (falciform ligament) and the coronal transection plane being above the hilum and anterior to the right posterior sectoral pedicle, the root of the middle HV vein is divided at the bottom of the right and left plane of the parenchymal division; as such, it may require longer vascular occlusion time and alternative pedicle clamping may be required (Figure 1)[22,25]. This is especially pertinent in a cirrhotic liver for parenchymal preservation to minimize the risks of post-operative liver failure. Injury or improper division of these important structures during parenchymal division in CH may result in ischemia or necrosis of the residual peripheral liver leading to liver failure and increased mortality[23].

Preoperative evaluation of hepatic functional reserve includes clinical assessment, liver function test, platelet count, coagulation profile and Child-Pugh classification[14]. The Indocyanine Green (ICG[15]) test has been found to be helpful in predicting the safe limit of liver resection along with Computed tomography volumetric evaluation of the adequate remnant liver volume to minimize post-hepatectomy liver failure[14]. For patients with chronic liver cirrhosis being considered for major resection ($\geq$ 3 segments), pre-operative portal vein embolization (PVE) is a reasonable option to hypertrophy the future liver remnant to minimize risk of post-operative liver failure[14]. Ipsilateral PVE is a feasible preoperative strategy facilitating extended or staged resections, however, with centrally located tumors it is often difficult to determine which side of the portal vein should be embolized; in addition, livers with limited functional reserve will also have lower than expected response to PVE, further limiting its role[41].

Does the preservation of an extra 20% to 25% of liver (40% to 60% parenchymal resection by CH *vs* 60% to 85% resection by extended/lobar hemihepatectomies) justify the increased technical demands of CH? Liver surgery has evolved significantly in past decades. Increased cumulative experience in hepatectomy, improved techniques such as different techniques of vascular occlusion(*e.g.*, Pringle's, total vascular occlusion, sequential vascular occlusion) and the liver hanging maneuver, aided by the advent of advanced surgical technology such as the cavitational ultrasonic surgical aspirator (CUSA, Integra LifeSciences Corporation) and various energy devices (*e.g.*, LigaSure™, Covidien Ltd; Aquamantys®, Medtronic Advanced Energy; Harmonic Scalpel™, Ethicon Endo-Surgery, Inc. Johnson and Johnson Medical Ltd) during liver resection, surgical morbidity and mortality rates have declined markedly as compared with historic data[4,14,23,42-47]. Major vessels and bile ducts in the resection plane can be well visualized, skeletonized, and controlled meticulously during division of the liver parenchyma with these de-

vices (CUSA, LigaSure™, Aquamantys®, Harmonic Scalpel™) as an adjunct to traditional methods such as Kelly clamps, surgical clips and staples. The additional routine use of intraoperative ultrasonography further allows the major vessels and intrahepatic bile ducts to be identified and controlled confidently, as a result, minimizing unexpected major blood loss from vessel injury and avoiding major bile duct injuries[48]. In view of the complexity of CH, sequential or alternative hemihepatic vascular control has been advocated by some authors to minimize clamping time *i.e.*, warm ischemic time of the remnant liver. Arkadopoulos and colleagues demonstrated in a recent study looking at CH comparing 16 patients with selective hepatic vascular exclusion (Pringle's maneuver with hepatic vein outflow occlusion) *vs* 20 patients with sequential hemihepatic vascular control, in which they demonstrated that patients with sequential vascular control received fewer blood transfusions, had less intraoperative blood loss, shorter liver warm ischemic time and lower postoperative transaminitis[35]. Chen *et al*[18] had similar results when they compared 2 cohorts of patients (*n* = 58 *vs* 60) undergoing CH: they demonstrated that utilizing Pringle's maneuver with IVC occlusion resulted in less blood loss, lower transfusion requirements and less liver damage than Pringle's maneuver alone. In the hands of experienced hepatobiliary surgeons, operative times were also not increased during these procedures, as seen in our review (Table 2: 256 min in CH group *vs* 305 min in the lobar/extended hepatectomy group). Application of a modified Belghiti's liver hanging maneuver (Double liver hanging maneuver) has also been described to help guide the transection planes for CH[44,49]. These newer techniques make central hepatectomy a feasible and safe procedure, especially in experienced hands[9,23,42,50]. More recently, central hepatectomy has also been reported to be performed *via* minimally invasive techniques (laparoscopic or robotic approach)[51-54].

There are 2 main techniques for performing CH. The first involves ligation and division of the central pedicles supplying segment 4, 5 and 8 of the liver segments during liver parenchyma transection under a Pringle's maneuver, while the second involves extrahepatic individual ligation and division of the vessels supplying the segments 4, 5, and 8 prior to parenchyma transection of the liver with or without temporary total hepatic inflow/outflow occlusion[54,55].

Stratopoulos *et al*[9] in 2007 performed a literature review of major series of central hepatectomies. That review encompassed studies published till 2006, and this current review expands on those studies and includes more recent publications on this topic. The surgical mortality rate reported in this earlier review was between 0% and 6.25%. Our review revealed similar mortality rates of 0% to 7.1 % with an overall mortality rate of 2.3%. Consistent with our review, Stratopoulos *et al*[9]'s review reported that the most common cause of perioperative death was liver failure followed by hemorrhage. In our review, the most common surgical complication was bile leak/biloma. Postoperative early morbidity rates were as high as 61% contributed in most part by surgical events such as bile leakage/biliary fistula, hemorrhage/intra-abdominal hematoma, wound infection, intra-abdominal abscess and intestinal perforation as well as medical complications such as liver failure/dysfunction leading to ascites and hepatic encephalopathy, pulmonary infection/pleural effusion/empyema, urinary tract infection, sepsis, upper gastrointestinal bleeding, renal failure, stroke and deep vein thrombosis.

Biliary leakage is one of the most frequently reported intra-abdominal complications after liver resection[30,45,56-58]. The rate of bile leakage in the literature after liver resection has been reported to range from 0% to 11%[23,46,47,59-61]. In hepatectomy without bilioenteric anastomosis, the principal causes of bile leakage are bile oozing from the transected liver surface and intraoperative biliary injury. There are reports that identified central hepatectomy as an independent risk factor for bile leakage because of the presence of two transection planes and exposure of the hepatic hilum[30,56]. In the 4 comparative studies comparing CH *vs* lobar or extended hemihepatectomies, there were no statistically significant differences in bile leak.

In previous reports, CH has been associated with a higher risk of bleeding than conventional major resections[17,32]. Our review revealed that median intraoperative blood loss during CH ranged from 380 to 2450 mL, which is comparable in large liver resection series with major conventional resections[3,4,62].

Most of the patients with reported survival data in this review underwent CH for diagnosis of HCC. The 1-year OS for these patients ranged from 67% to 94%, with 3-year and 5-year OS having a reported range of 44% to 66.8%, and 31.7% to 66.8% respectively. This is comparable to the results from a recent review of survival outcomes looking at 17 studies with more than a total 13000 patients with HCC treated by liver resection, they reported a 1- year survival rate ranging from 67% to 97%, a 3- year survival rate ranging from 34% to 84% and a 5-year survival rate of 17 to 72% was reported[14,63]. A recent study on CH for HCC by Jeng *et al*[40] reported that even with narrow margins (< 5 mm) after CH, there was no negative impact on recurrence and overall survival. Conversely, Nagino *et al*[64] recently commented in a review of over three decades of their experience in the evolution of surgical treatment for perihilar CCA; they reported that limited resections such a CH for perihilar CCA decreased significantly from almost 30% to less than 3% over almost 4 decades with a corresponding improved survival due to more R$_0$ resections from extended resections. The role of CH for central HCC and perihilar CCA remains to be defined.

Because of the breadth of the current review and the limited available literature of CH as a procedure, the types of studies and the highly descriptive nature of much of the data reviewed, no assessment of the grade quality of individual studies or presence of bias and con-

founders were performed in this review. These studies have inherent selection biases and there is a degree of publication bias as well that is not avoidable due to the retrospective nature of these studies. In addition, because of the lack of high-level evidence and prospective or randomized studies, no objective grading was performed for any specific intervention. The oncological outcomes of HCC in these studies of CH are generalized and not conclusive when compared to HCC undergoing conventional resections due to the lack of detailed clinical and pathological data and risk factors in these studies that determines prognosis and provide strong valid comparison. The literature search was limited to English-language studies within the defined search period and included more recent papers in the past decade that remain highly relevant today. The review nonetheless serves as an updated collection and summary of the cumulative experiences in this relatively novel procedure and approach to segment-orientated liver resection.

Further high-quality and prospective studies with large sample sizes or randomized controlled trials to ascertain the utility and feasibility of central hepatectomy would be important in defining its role in the treatment of centrally-located liver tumors.

In conclusion, this review shows that central hepatectomy can achieve similar overall patient survival and disease-free survival rates as conventional major hepatectomies. Our findings suggest that central hepatectomy may be considered an acceptable procedure for treatment of centrally located malignances and may be the procedure of choice in patients with compromised liver function. It has the advantages of preserving parenchyma and seemingly without oncological compromise however, validation of CH as an oncologically safe procedure requires further prospective studies.

COMMENTS

Background
Central hepatectomy (CH) has similar perioperative outcomes with lobar and extended liver resections and achieves similar overall patient survival and disease-free survival rates as conventional major hepatectomies. Current evidence suggests that CH may be considered an acceptable procedure for treatment of centrally located malignances and may be the procedure of choice in patients with compromised liver function.

Research frontiers
More prospective studies including randomized controlled trials need to be conducted to validate the procedure as an oncologically equivalent and safe operation, specific to different cancer such as hepatocellular carcinoma and colorectal liver metastases, when compared to standard, traditional hepatectomy

Innovations and breakthroughs
Improved surgical and anesthesia experience and better technology has improved the morbidity and mortality of major liver resection and paved the way for safe parenchymal preserving surgery especially in patients with limited liver reserve.

Applications
CH may be applicable in selected patients with central tumors where parenchymal preserving surgery is indicated or preferred.

Terminology
CH also known as mesohepatectomy or central liver resection is used to describe the operative procedure for anatomical liver resection of segments 4, 5,

8 ± 1.

Peer review
In the present manuscript the authors performed a meta-analysis to evaluate the implication of CH for the management of central hepatic malignancies and to compare the perioperative, short and long term results of CH to lobar/extended hemihepatectomy. The authors concluded that CH is a promising option for anatomical parenchymal preserving procedure in patients with centrally located liver malignancies; it is safe and comparable in both perioperative, early and long term outcomes when compared to patients undergoing hemi-/extended hepatectomy.

Abstract

An eleven-year-old clinically dysmorphic and developmentally retarded male child presenting with complaints of 5 episodes of recurrent cholestatic jaundice since 3 years of age was evaluated. Imaging revealed features consistent with congenital extrahepatic portocaval shunt (Abernethy type 1b), multiple regenerative liver nodules and intrahepatic biliary radical dilatation. The presence of ductal paucity and trisomy 8 were confirmed on liver biopsy and karyotyping. The explanation for unusual and previously unreported features in the present case has been proposed.

Key words: Congenital extrahepatic portocaval shunt; Ductal paucity; Warkany syndrome; Trisomy 8

Core tip: This study highlights the association between the congenital extrahepatic portocaval shunt with hepatic ductal paucity and trisomy 8 for the first time in the world literature. Although the exact pathophysiology remains uncertain, plausible explanations are proposed.

INTRODUCTION

An eleven-year-old male child was admitted with recurrent episodes of cholestatic jaundice since age three. Each episode was associated with fever, pruritus and clay colored stool, lasting for 10-15 d. There was no history of variceal bleeding, respiratory difficulty, altered sensorium, abdominal distension, oliguria, loose stool, blood in stool, rash, joint pains or any other autoimmune phenomena.

CASE REPORT

The patient was born preterm at 8.5 mo gestation and had indirect hyperbilirubinemia without kernicterus, and was managed with phototherapy. The antenatal period was uneventful. Developmentally, his motor development coincided with his chronological age, but mental age lagged by 5 years.

On examination, his vital parameters were stable. Anthropometry revealed severe malnutrition. There was no pallor, icterus, clubbing, cyanosis, edema, or any peripheral symptoms of chronic liver disease. Dysmorphic features were present and included triangular facies, deep set eyes, antimongoloid slant, bulbous upturned nose tip, mal-aligned upper teeth, retrognathia, camptodactyly, single crease on little finger, multiple finger webs and

deep plantar furrows (Figure 1). Ophthalmological examination revealed clear lens with normal cornea, iris and fundus. Orthopedic assessment revealed pectus carinatum and elbow contractures with restriction of extension movements. The spine was normal. Abdominal examination revealed no organomegaly or free fluid. Neurological examination was normal with preservation of higher mental, motor and sensory functions. Cardiovascular and respiratory systems were normal.

Laboratory parameters revealed conjugated hyperbilirubinemia with elevated liver enzymes. Synthetic function markers (albumin and prothrombin time) and lipid profile were normal. Serology for hepatitis A, B and C viral infection was negative (Table 1). Doppler ultrasonography (USG) of the abdomen revealed coarse liver with anomalous drainage of the extra-hepatic portal vein (PV) into the inferior vena cava (IVC) with non-visualization of intra-hepatic PV radicles. These findings were confirmed on contrast-enhanced computerized tomography

(CT) (Figure 2A), magnetic resonance imaging (MRI) and cholangiopancreaticography (MRCP). Imaging also revealed bilateral nephromegaly and dilatation of intrahepatic biliary radicles (IHBRD, left > right), without evidence of stricture, beading, mass or calculi in the biliary tree (Figure 2B). On MRI, numerous nodules were seen in both liver lobes which were hyper-intense on T1 and showed variable signal on T2 (Figure 2C). These imaging features were consistent with congenital extrahepatic portocaval shunt (CEPS or Abernethy type 1b), multiple regenerative liver nodules and IHBRD.

Subsequent evaluation revealed fasting hypoglycemia and hyperammonemia. Arterial blood gas analysis showed high alveolar-arterial gradient with hypoxemia on room air. Echocardiography showed structurally normal heart with severe shunting on injection of saline contrast, thus suggesting moderate hepatopulmonary syndrome (HPS). Alpha-fetoprotein concentration was normal. Esophagogastroduodenoscopy revealed no varices. A skeletal

A: Reconstructed 3-D images of contrast-enhanced computerized tomography (CECT) scan showing congenital extrahepatic portosystemic shunt with drainage of the portal vein (arrowhead) into the inferior vena cava-splenic and superior mesenteric veins are shown by vertical and horizontal arrows, respectively; B: Magnetic resonance cholangiopancreaticography images showing dilatation of bilobar intrahepatic biliary radicles (arrow); C: T1-weighted axial images on MR showing well defined, round, hyper-intense lesions in both liver lobes (arrows); D: Reconstructed 3-D CECT images of lumbar spine showing spina bifida at L1 and L2 levels; E, F: Liver biopsy specimen showing preserved acinar architecture; portal tract showing prominent hepatic arteriole (arrowhead) with absence of portal venule and bile ductules (E, hematoxylin and eosin stain, × 400) with periportal fibrosis (F, Masson-trichrome stain, × 40).

survey revealed spina bifida (Figure 2D). Brain imaging was normal. Karyotyping showed mosaic trisomy of chromosome 8. Liver biopsy revealed maintained acinar architecture with mild cholestasis; portal tracts showed total absence of PV profiles, ductal paucity (bile duct: portal tract ratio of 0.3), conspicuous hepatic arteries and periportal fibrosis (Figure 2E and F).

The child was started on sodium benzoate, uncooked cornstarch diet and pentoxiphylline. His fasting hypoglycemia, hyperammonemia and hypoglycemia got corrected after one month of follow-up. He had another episode of jaundice with fever four months later which was managed conservatively. The patient's family was counselled regarding the prognosis including the possible need for liver transplantation (LTx).

DISCUSSION

Congenital extrahepatic portosystemic shunts (CEPS), or Abernethy malformation, is a rare congenital anomaly characterized by shunting of portal venous blood to the systemic circulation. On the basis of the presence of the PV and its intrahepatic radicles and the type of shunt, these malformations were classified by Morgan and Superina as (1) Type 1 (85%), with complete diversion of portal venous blood into the systemic circulation and total absence of intrahepatic PV branches; this was further subclassified as Type 1a, where splenic (SV) and superior mesenteric veins drain separately into the IVC, and Type 1b, when these veins drain after the formation of a short PV trunk, which drains into the IVC in an end-to-side fashion; and (2) Type 2, with intact PV and the presence of a side-to-side portocaval shunt[1]. A recent review suggested a classification based on anatomical site of origin and termination, type of communication with the systemic vein and number of communications[2]. CEPS are known to be associated with various congenital anomalies, particularly cardiovascular, gastrointestinal, genitourinary, skeletal and neurological, and genetic syndromes (Turner's and Goldenhar's)[3]. Our case was Type 1b CEPS without any other major structural malformations, except dysmorphism and spina bifida. He also had nephromegaly with structurally normal kidneys on imaging.

Clinical manifestations in CEPS occur either due to direct entry of intestinal blood and toxins into the systemic circulation or due to long-standing deprivation of PV blood supply with subsequent effects on liver regeneration and metabolism; some features are secondary to associated congenital abnormalities. As per recent reviews, the median age at presentation is 3.7 years with common modes being hypoxemia secondary to HPS or portopulmonary hypertension (26%-34%),

galactosemia (raised blood and urinary concentrations of galactose without enzyme deficiency) (26%), hepatic encephalopathy (HE) or hyperammonemia (9%-34%), neonatal cholestasis (13%) and incidental detection on imaging (9%-21%). Less common presentations are liver dysfunction, hypoglycemia, hepatocellular carcinoma and gastrointestinal bleeding[2,4]. Our patient developed growth failure, hyperammonemia, hypoglycemia, HPS (low partial pressure of oxygen and high alveolar to arterial oxygen gradient on room air) as well as recurrent jaundice (Table 1).

Focal hepatic lesions are common (35%-50%) in CEPS. As the liver is deprived of hepatotrophic factors such as insulin and glucagon, it undergoes atrophy with concomitant regeneration. Regenerative changes manifest as focal nodular hyperplasia, nodular regenerative hyperplasia, hepatocellular adenoma, and rarely cirrhosis, hepatocellular carcinoma and hepatoblastoma[2-4]. Our case had multiple regenerative nodules on imaging with normal AFP.

The diagnosis is established with USG Doppler and CT/MR angiography. Liver biopsy is needed for classification and subsequent management, as well as to establish the nature of the focal lesions. Liver histology in CEPS usually show absence or hypoplastic PVs, thickened hepatic arteries, minimal or moderate portal fibrosis, proliferation of thin vascular, capillary, or lymphatic structures in portal and periportal regions, and occasionally focal ductular proliferation[2]. Our case showed the absence of PV with prominent hepatic arteries and F2 fibrosis on Metavir staging. In addition, our case had ductal paucity, a finding which has not been previously described in CEPS.

Trisomy 8 or Warkany syndrome is a rare disorder. The majority of cases are mosaic as complete trisomy is usually lethal in fetal life. Deep plantar furrow is pathognomonic. Patients also have corneal clouding, strabismus, low set or abnormally shaped ears, bulbous nose tip, cleft palate, camptodactyly, clinodactyly, deep palmar furrow, anomalies related to the skeletal, cardiovascular and urogenital system, and mild to moderate mental retardation[5,6]. Most of these findings were present in our case, and to the best of our knowledge this is the first report of an association between CEPS and trisomy 8.

The presence of recurrent jaundice with bile ductal paucity and IHBRD were unusual features in our case. Recurrent jaundice in CEPS has been described in the literature, but no explanation has been provided[7]. During embryogenesis, PV plays a crucial role in the formation and remodeling of the ductal plate. Conversely, lack of remodeling is frequently associated with abnormalities in the ramification pattern of PV. Thus, both ductal plate malformation (DPM) and PV abnormalities may be interrelated. DPM is also associated with Caroli's syndrome and thus may also explain IHBRD seen in our case[8]. Another possible explanation is a pressure effect on the biliary system by the prominent dilated hepatic artery leading to recurrent cholangitis and ductal paucity secondary to chronic biliary obstruction. Another genetic defect, Alagille's syndrome, associated with mutations in Jagged1 or NOTCH2 genes, is also associated with ductal paucity and dysmorphic features, but our child didn't have other phenotypic features to suggest the disorder[9].

An algorithm for the management of CEPS has been suggested depending on the type of abnormality, symptoms and the presence of liver tumor[2]. Acceptable therapeutic options include LTx in type 1 and shunt occlusion (radiological or interventional) in type 2 cases. Common indications for LTx include HE or hyperammonemia (38%), pulmonary complications (32%) and tumor (15%)[4]. Authors have also proposed shunt occlusion for type 1 cases, presuming that the miniature hepatopetal vessels may enlarge after the procedure[2]. Our patient had moderate subclinical HPS, hyperammonemia and hypoglycemia along with total absence of PV radicles on liver histology, thus mandating LTx.

We describe a case of CEPS type 1b with trisomy 8 with an unusual presentation manifesting as recurrent jaundice, cholangitis and ductal paucity. We discuss the possible cause of recurrent jaundice and ductal paucity in CEPS.

COMMENTS

Case characteristics
Recurrent episodes of cholestatic jaundice, dysmorphism, developmental delay.

Laboratory diagnosis
Conjugated hyperbilirubinemia with elevated liver enzymes, hypoglycemia, hyperammonemia, and hypoxemia with high alveolar-arterial gradient.

Imaging diagnosis
Congenital extrahepatic portocaval shunt (Abernethy Type 1b), multiple regenerative liver nodules and dilatation of intrahepatic biliary radicles.

Pathological diagnosis
Ductal paucity, conspicuous hepatic arteries and periportal fibrosis.

Treatment
Anti-hyperammonemia measures, uncooked cornstarch diet and pentoxiphylline.

Related reports
This is the first report highlighting the association between congenital malformation of portocaval shunt and trisomy 8. The cause of the unusual and previously unreported features in our case such as recurrent jaundice with bile ductal paucity and IHBRD remains unknown.

Term explanation
Congenital extrahepatic portosystemic shunts (CEPS), or Abernethy malformation is a congenital anomaly characterized by shunting of the portal venous blood to the systemic circulation.

Experiences and lessons
CEPS should be considered in the differential diagnosis of a child presenting with developmental delay and liver dysfunction. A simple bedside Doppler ultrasound by an experienced radiologist can help in the identification of this rare anomaly.

Peer review
Article reports the association between a very rare but known congenital malformation of portocaval shunt with not yet reported hepatic ductal paucity and trisomy 8 and also highlights vascular anomalies as one of the causes of recurrent cholestatic jaundice.

AIM AND SCOPE

World Journal of Hepatology (*World J Hepatol*, WJH, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJH covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Hepatology is now indexed in PubMed Central, PubMed, Digital Object Identifier, Directory of Open Access Journals, and Scopus.

Abstract

Variceal bleeding is a life threatening situation with mortality rates of at least 20%. Prophylactic treatment with non-selective beta blockers (NSBBs) is recommended for patients with small varices that have not bled but with increased risk for bleeding. The recommended treatment strategies on primary prevention of variceal bleeding in patients with medium and large-sized varices are NSBBs or endoscopic band ligation. Nitrates, shunt surgery and sclerotherapy are not recommended in this setting. In this review, the most recent data on prevention of esophageal variceal bleeding are presented. Available data derived from randomized-controlled trials suggest both treatment strategies, and according to Baveno V consensus in portal hypertension "the choice of treatment should be based on local resources and expertise, patient preference and characteristics, side-effects and contra-indications".

Key words: Cirrhosis; Portal hypertension; Esophageal varices; Primary prevention; β-Blockers; Endoscopic band ligation

Core tip: The significance of primary prevention of bleeding from esophageal varices in patients with liver cirrhosis is major, considering the high mortality rates that accompany the acute bleeding episode. Current management guidelines suggest the use of either non-selective beta-blockers or endoscopic band ligation with same efficacy between them. In this review, we summarize data from randomized clinical trials or prospective studies together with meta-analytical data, when applicable, to present the most updated recommendations on primary prevention of esophageal variceal bleeding.

INTRODUCTION

Bleeding from esophagogastric varices is a life-threatening condition with an incidence of 5%-15% in patients with liver cirrhosis and mortality rates of at least 20%[1,2], despite improvements in the management of these patients. The term pre-primary prophylaxis is used to define the prevention of development and growth of varices. The term primary prophylaxis refers to the prevention of the first variceal bleeding in patients with liver cirrhosis and consists of two main treatment strategies, non-selective beta blockers (NSBBs) aiming to reduce hepatic venous pressure gradient (HVPG) below 12 mmHg or by 20% from baseline levels, and endoscopic band ligation (EBL) performed until variceal eradication[3].

In this review, we discuss the most recent data on primary prevention of variceal bleeding using data from randomized controlled trials (RCTs), prospective studies or meta-analyses focusing mainly on probability of bleeding, mortality and adverse events. We searched MEDLINE

database, Scopus, and ISI Web of Knowledge search system using the textwords "esophageal varices", or "primary prevention of variceal bleeding", or "management of varices" and major Gastroenterology and Liver meetings.

DIAGNOSIS OF VARICES

The esophagogastroduodenoscopy (EGD) is the gold standard for the diagnosis of esophageal varices and should be performed every 2-3 years in patients with compensated cirrhosis and no varices at initial endoscopy, and every 1-2 years in patients with small varices[4]. In patients with decompensated cirrhosis, EGD should be performed yearly[4]. There is a great interest in identifying non-invasive factors to diagnose esophageal varices but currently there is no evidence that their predictive accuracy is equal to that of EGD. Such factors include platelet count, spleen size, portal vein diameter, Child-Pugh score, presence of ascites, albumin levels and transient elastography[5].

In a recent prospective study[6], spleen stiffness (SS) and liver stiffness (LS) were measured by transient elastography in 200 patients with liver cirrhosis of whom 124 (71%) had esophageal varices. There was a significant difference in median LS ($P = 0.001$), SS ($P = 0.001$), LS-spleen diameter to platelet ratio score (LSPS) ($P = 0.001$), and platelet count to spleen diameter ratio (PSR) ($P = 0.001$) between patients with and without esophageal varices. LS $\geq$ 27.3 kPa had a sensitivity of 91%, specificity of 72%, and a diagnostic accuracy of 86% in predicting esophageal varices. LSPS $\geq$ 3.09 had sensitivity and specificity of 89% and 76%, respectively, and a PSR cut-off value of 909 or less had sensitivity of 64%, specificity of 76%, and diagnostic accuracy of 68% in predicting esophageal varices. SS $\geq$ 40.8 kPa had a sensitivity of 94%, specificity of 76%, and diagnostic accuracy of 86% for predicting esophageal varices. SS was significantly higher in patients who had large varices (56 *vs* 49 kPa, $P = 0.001$) and variceal bleeding (58 *vs* 50.2 kPa, $P = 0.001$).

Capsule endoscopy (CE) has been shown to be an accurate prognostic method for diagnosis of esophageal varices but there is no consensus to recommend its use in this setting. In a meta-analysis of 9 studies including 631 patients[7], the pooled sensitivity and specificity of PILL-CAM ESO capsule was 83% and 85%, respectively with positive and negative likelihood ratios of 4.09 and 0.25, respectively. In a recent, prospective study[8], the overall diagnostic yield of CE for esophageal varices was 72% (51 of 71 esophageal varices detected by EGD). The diagnostic yield was significantly greater for F2/F3 esophageal varices than for F1 (87% *vs* 61%, $P = 0.03$) and for varices located at locus superior or locus medialis than those located at locus inferior (85% *vs* 55%, $P = 0.01$). The diagnostic accuracy of CE for gastric varices was low (1 of 29 gastric varices detected by EGD), whereas for portal hypertensive gastropathy was 69% (24 of 35). EGD is superior to CE in grading of esophageal varices because capsule lacks air insufflation.

RISK OF FIRST VARICEAL BLEEDING EPISODE

The major predictive factors of first variceal bleeding episode are the size of varices, the severity of liver dysfunction and the endoscopic presence of red wale marks[9]. However, the combination of these, fails to predict all episodes of bleeding. Thus, new and more accurate predictive factors are needed to predict the first bleeding episode considering the importance to identify the cohort of patients who are mostly in need for prophylactic therapy. A significant factor associated with rupture of varices is an HVPG higher than 12 mmHg[10], considering that a high HVPG relates directly to a high variceal wall tension. Goulis *et al*[11] have proposed that, in patients with large varices and a high wall tension, the release of endotoxin into the systemic circulation during episodes of bacterial infection results in a further increase in portal pressure through the induction of endothelin and possibly vasoconstrictive cyclo-oxygenase products. Furthermore, endotoxin-induced nitric oxide and prostacyclin could inhibit platelet aggregation, thus resulting in variceal rupture. Patients with cirrhosis and bacterial infection demonstrate a heparin effect using heparinase I-modified thromboelastography and have anti-Xa activity[12,13]. A heparin effect was reported immediately after the bleeding episode in patients with liver cirrhosis suggesting a possible association with continued variceal bleeding or early rebleeding[14].

PRE-PRIMARY PROPHYLAXIS

The rate of development of varices in patients with cirrhosis and no varices at initial endoscopy is 8% per year[4] and the strongest predictor for their development is a HVPG higher than 10 mmHg[4]. In a large RCT[15] of 213 patients with cirrhosis and portal hypertension (minimal HVPG of 6 mmHg), the effect of NSBBs (timolol) on the development of esophageal varices or the occurrence of variceal bleeding was assessed (timolol-group, $n = 108$; placebo-group, $n = 105$). During follow-up (mean 54.9 mo), no significant difference was observed between the timolol-group and the placebo-group, regarding development of varices (39% *vs* 40%, respectively; $P = 0.89$). Serious adverse events were more common in the timolol group (18% *vs* 6%, $P = 0.006$). However, the development of varices was less frequent in patients with a baseline HVPG lower than 10 mmHg and in those with a decrease of HVPG $\geq$ 10% at one year. Thus, NSBBs reduce portal pressure; however, they seem to have no effect on the development of varices. According to current evidence, the use of NSBBs in patients with cirrhosis and no varices is not recommended for the prevention of their development[4]. Treatment of the underlying liver disease may decrease portal hypertension and prevent its clinical complications, according to the recent Baveno consensus[3].

Development of large varices in patients with small

varices at initial endoscopy occurs at a rate of 8% per year[4]. The factors associated to the growth of small varices are decompensated liver cirrhosis (Child-Pugh class B or C), alcoholic etiology of cirrhosis and the presence of red wale marks at initial endoscopy[4]. The efficacy of NSBBs on preventing the progression of small to large varices is debated[16,17]. In a randomized double-blind controlled trial[16] aiming to evaluate propranolol in the prevention of the development of large varices in patients with cirrhosis and small or no varices, 102 patients were randomized to receive propranolol (160 mg/d) and 104 to receive a placebo. The proportion of patients with large varices was 31% in the propranolol group and 14% in the placebo group (*P* < 0.05), at 2 years. However, one third of patients were lost to follow-up after 2 years. In a placebo-controlled trial[17], 161 patients with cirrhosis and small esophageal varices were randomized to nadolol (*n* = 83) or placebo (*n* = 78). The dose of nadolol was adjusted to decrease heart rate by 25%. During follow-up (mean: 36 mo), 9 and 29 patients from nadolol and placebo group respectively, developed large varices. At the end of follow-up, the cumulative risk was 20% *vs* 51% (*P* < 0.001). In addition, the cumulative probability of variceal bleeding was lower in the nadolol group (*P* = 0.02), but there was no difference in survival between groups (*P* = 0.33). Treatment withdrawal because of adverse effects was higher in the nadolol group (*P* = 0.01).

According to current treatment guidelines[4], in patients with cirrhosis and small varices that have not bled but with increased risk of bleeding, NSBBs are recommended. In cases of low risk for variceal bleeding, NSBBs can be used, although their long-term benefit has not been well established[4].

PRIMARY PREVENTION OF VARICEAL BLEEDING

Both shunt surgery and sclerotherapy have been abandoned for primary prevention, mainly because of the high incidence of complications[18-21]. According to Baveno V consensus[3], the current treatment strategies for medium/large-sized varices are NSBBs or EBL, which are both effective in decreasing rates of bleeding and mortality. NSBBs are splachnic vasoconstrictors which reduce portal pressure and increase portal resistance through a decrease in portal venous inflow[4]. Endoscopic treatments have no effect on portal circulation as they act locally by obliteration of varices.

NSBBs vs no intervention
Nine randomized clinical trials enrolling 966 patients compared NSBBs with a non-active treatment[22]. The incidence of bleeding was significantly reduced (OR = 0.54, 95%CI: 0.39-0.74), particularly in patients with medium-sized or large varices or in patients with varices and HVPG higher than 12 mmHg. The number needed to treat (NNT) to prevent one bleeding episode was 11. However, only a trend towards reduced mortality was observed (OR = 0.75, 95%CI: 0.57-1.06). In another meta-analysis[23] which analyzed data from four randomized trials (286 patients received b-blockers-propranolol in 203 and nadolol in 83-and 303 patients received placebo), the mean percentage of patients without upper gastrointestinal bleeding after two years was 78% ± 3% in the treatment group and 65% ± 3% in the placebo group (*P* = 0.002), whereas the 2-year survival rate was 71% ± 3% and 68% ± 3%, respectively (*P* = 0.34). The efficacy of b-blockers in the prevention of bleeding or bleeding-related mortality was the same, independently of the cause and severity of cirrhosis, ascites and size of varices. However, when propranolol is discontinued, the risk of variceal hemorrhage returns to what would be expected in an untreated population[24].

The hemodynamic response to treatment with b-blockers is considered appropriate when HVPG is decreased below 12 mmHg or by ≥ 20% of baseline values, 1-3 mo after initiation of treatment. The acute hemodynamic response to b-blockers (20 min after administration of propranolol) was shown useful to predict the long-term risk of first bleeding by reducing HVPG ≥ 10% from baseline values[25,26].

In a recent study[27], patients with esophageal varices with HVPG measurement before and during propranolol treatment were included. HVPG responders were kept on propranolol (PROP group), and non-responders were treated with carvedilol (CARV group). HVPG responders were 36% (37/104), whereas 56% (38/67) non-responders achieved hemodynamic response with carvedilol (the remaining patients were treated with EBL). Carvedilol achieved a greater decrease in HVPG compared to propranolol (-19% ± 10% *vs* -12% ± 11%, respectively, *P* < 0.001). During a 2-year follow-up, bleeding rates were 11%, 5% and 25% for PROP, CARV and EBL, respectively (*P* = 0.0429). Hemodynamic responders showed lower mortality compared to the EBL group patients (PROP 14%/CARV 11% *vs* EBL 31%, *P* = 0.0455). Thus, it seems that carvedilol is more efficient than propranolol to decrease HVPG and it was recently suggested that it might be the beta blocker of choice for portal hypertension[28].

NSBBs have also the potential to protect against spontaneous bacterial peritonitis (SBP) in cirrhotic patients, considering that infection is a risk factor for variceal bleeding[11]. In a meta-analysis of three RCTs and three retrospective studies[29] (including 644 patients, 257 treated with propranolol and 387 receiving no treatment), b-blockers were evaluated against no treatment for the prevention of SBP. There was a statistically significant difference of 12.1% (95%CI: 5.5-18.8; *P* < 0.001) favoring propranolol. The NNT to prevent an additional episode of SBP was 8. In addition, NSBBs can protect against bleeding from portal hypertensive gastropathy by reducing cardiac output and inducing splachnic arterial vasoconstriction[30], whereas endoscopic treatments have no effects on portal inflow or resistance.

However, there are safety issues on the use of NSBBs in patients with cirrhosis and refractory ascites[31,32]. In a

self-control cross-over study[32], 10 patients with cirrhosis and refractory ascites treated with beta-blockers were evaluated regarding the development of paracentesis-induced circulatory dysfunction (PCID defined as an increase in plasma renin concentrations 1 wk after paracentesis). Patients underwent two clinical and biological assessments: first while receiving NSBBs and second after NSBBs discontinuation. Eight patients (80%) treated with NBBs developed PCID whereas only one patient developed PCID after beta-blocker discontinuation. Thus, a RCT comparing EBL and NSBBs in patients with refractory ascites is needed to determine the use of EBL as preferred prophylactic treatment in this subgroup of patients.

EBL vs no intervention

EBL has substituted sclerotherapy and it is the endoscopic procedure of choice in primary prevention. Meta-analysis of eight RCTs[33] showed that EBL is superior to no intervention in reducing both the risk of first variceal bleeding (OR = 0.3, 95%CI: 0.17-0.53) and mortality (OR = 0.42, 95%CI: 0.3-0.6). However, there are safety issues concerning EBL in primary prophylaxis. In a trial by Triantos *et al*[33], EBL *vs* no treatment was compared in cirrhotics with intolerance or contraindications to b-blockers. The trial had to stop prematurely due to increased bleeding. Sixty percent of the bleeding was probably iatrogenic and the authors suggested that EBL might be as harmful as sclerotherapy regarding primary prevention. However, in a prospective cohort study[34], patients with contraindications, intolerance or not responding to beta-blockers who were treated with EBL achieved protection from variceal bleeding comparable to that of good responders to beta-blockers. Furthermore, in another RCT[35,36], which compared EBL (*n* = 75) with propranolol (*n* = 77) for primary prophylaxis in cirrhotic patients with varices > 5 mm, 5 patients (6.7%) bled from ligation ulcers and the treatment-related mortality was 2.6% (*n* = 2/5).

EBL vs NSBBs

A recent meta-analysis[37] included 19 RCTS with 1504 patients (731 treated with EBL and 773 with NSBBs-propranolol in 17 trials, nadolol in one and carvedilol in one). In total, 24% (*n* = 176) randomized to EBL *vs* 23% (*n* = 177) randomized to NSBBs died and meta-analysis showed no difference in mortality between the two treatment groups (RR = 1.09, 95%CI: 0.92-1.30). Upper gastrointestinal bleeding was diagnosed for 14% (*n* = 103) with EBL and 20% (*n* = 158) with NSBBs. EBL appeared to be superior to NSBBs for this outcome (RR = 0.68, 95%CI: 0.52-0.90). EBL also had lower rate of variceal bleeding compared to NSBBs [13% (75/590) *vs* 19% (113/611), RR = 0.66, 95%CI: 0.45-0.96]. However, when analysis included trials with adequate randomization or full papers, EBL showed no superiority to NSBBs for gastrointestinal or variceal bleeding. No difference was seen between the two interventions regarding bleeding-related mortality [5.1% (29/567) *vs* 6.3% (37/585); RR =

0.85, 95%CI: 0.53-1.39]. Treatment with NSBBs was associated with dizziness, hypotension, impotence, lethargy, and peripheral edema, whereas EBL was associated with clinically important bleeding and retrosternal pain.

Combined treatment strategies

Gheorghe *et al*[38] randomly assigned 72 patients with high-risk esophageal varices listed for liver transplantation to combined treatment of EBL plus propranolol or propranolol monotherapy. During a mean follow-up of 8 mo, bleeding occurred in 6% patients in the combination group and 31% in the monotherapy group (*P* = 0.03), with 96% and 69% actuarial probability of bleeding-free survival after follow-up, respectively (*P* = 0.04). The authors suggested that combined treatment was superior to propranolol monotherapy regarding both bleeding and bleeding-related mortality. On the contrary, Lo *et al*[39] found no differences in upper gastrointestinal bleeding [26% (*n* = 18) *vs* 18% (*n* = 13), *P* = not significant], variceal bleeding [14% (*n* = 10) *vs* 13% (*n* = 9), *P* = not significant], and mortality [22.9% (*n* = 16) in both treatment groups] between patients treated with EBL combined with nadolol (*n* = 70) and nadolol alone (*n* = 70). Patients in the combination group showed a higher rate of adverse events than in nadolol monotherapy (68% *vs* 40%, *P* = 0.06). Two episodes of variceal bleeding were induced by EBL.

One RCT[40] of 144 patients (11.8% non-cirrhotic portal hypertension), has compared EBL combined with propranolol with EBL monotherapy. In this trial, the probability of bleeding, overall mortality and bleeding-related mortality were comparable between groups. Therefore, according to current evidence, combination treatment of EBL and NSBBs is not recommended for primary prevention.

Isosorbide mononitrate

Isosorbide mononitrate (IsMn) decreases portal pressure by lowering the intra-hepatic resistance through vasodilation and has been evaluated in cirrhosis considering the large number of patients with contraindications or intolerance to b-blockers[41]. The evidence concerning the use of IsMn for primary prevention of variceal bleeding is debatable[42,43]. In a recent meta-analysis[44] the effect of IsMn in primary prevention of variceal bleeding was assessed, comparing IsMn alone *vs* placebo or beta-blockers or EBL and IsMn plus beta-blockers *vs* beta-blockers or EBL. No differences in mortality were observed between IsMn and beta-blockers *vs* β-blockers (49/277 *vs* 50/275; RR = 0.95; 95%CI: 0.68-1.32), or EBL (6/31 *vs* 8/30; RR = 0.73; 95%CI: 0.29-1.84). IsMn increased the risk of bleeding compared to placebo (RR = 2.34; 95%CI: 1.10-4.97) or EBL (RR = 4.33; 95%CI: 1.57-11.92). There were no apparent differences between bleeding rates of patients randomized to IsMn alone or with beta-blockers *vs* beta-blockers or EBL. Meta-analyses of variceal bleeding found a negative effect of IsMn compared to EBL (RR = 3.31; 95%CI: 1.01-10.84), but no apparent dif-

Table 1 Summary on primary prevention of esophageal variceal bleeding			
		Management	Goal of treatment
Cirrhosis		Diagnostic endoscopy for the presence of varices	
No varices		Endoscopic surveillance	Surveillance for development of varices (every 2-3 yr in compensated cirrhosis/yearly in cases of decompensation)
Small varices	Low risk of bleeding	Endoscopic surveillance Or NSBBs	Surveillance for progression of varices (every 1-2 yr in compensated cirrhosis/yearly in cases of decompensation)
	Increased risk of bleeding[1]	NSBBs	Decrease in HVPG of at least 20% from baseline or $\leqslant$ to 12 mmHg or resting heart rate of about 55 to 60 beats/min
Medium-large varices		NSBBs Or EBL[2]	NSBBs: Decrease in HVPG of at least 20% from baseline or $\leqslant$ to 12 mmHg or resting heart rate of about 55 to 60 beats/min EBL: Variceal obliteration

[1]Child-Pugh B/C cirrhosis or red signs at initial endoscopy; [2]The choice of treatment should be based on local resources and expertise, patient preference and characteristics, side effects, and contra-indications. NSBBs: Non-selective beta blockers; EBL: Endoscopic band ligation; HVPG: Hepatic venous pressure gradient.

ference in variceal bleeding for the remaining treatment comparisons was observed. No effects on bleeding-related mortality were seen for any of the treatment comparisons assessed. Combination of IsMn and beta-blockers increased the risk of adverse events, compared to beta-blockers monotherapy (RR = 1.65, 95%CI: 1.25-2.17), as well as the number of treatment withdrawal (RR = 2.60, 95%CI: 1.55-4.38). Consequently, current evidence does not support the use of nitrates in primary prevention of variceal bleeding.

CONCLUSION

Baveno V[3] recommends both EBL and NSBBs for the prevention of first variceal bleeding (Table 1); however, there is a controversy on which one should be the first choice. Both therapies are equally effective and have no survival difference. Thus, other issues should be considered in order to determine the best therapeutic approach. Prophylactic treatment should have few adverse events, be easy to administer and inexpensive. EBL can cause fatal iatrogenic bleeding, is accompanied by increased expense, needs specialized staff and cannot prevent bleeding from portal hypertensive gastropathy. NSBBs could probably be the first choice in primary prevention, whereas EBL could be reserved for patients with contra-indications, not response, intolerance to NSBBs or lack of compliance to life-time use of drugs. The potent benefit of EBL on patients with refractory ascites should be further investigated.

Lastly, there are issues on the primary prevention of variceal bleeding that require further study including the use of carvedilol, the advancement in ligation devices with better endoscopic field of view and the evaluation of novel therapeutic agents.

Abstract

Cytomegalovirus (CMV) is one of the most common viral pathogens causing clinical disease in liver transplant recipients, and contributing to substantial morbidity and occasional mortality. CMV causes febrile illness often accompanied by bone marrow suppression, and in some cases, invades tissues including the transplanted liver allograft. In addition, CMV has been significantly associated with an increased predisposition to acute and chronic allograft rejection, accelerated hepatitis C recurrence, and other opportunistic infections, as well as reduced overall patient and allograft survival. To negate the adverse effects of CMV infection on transplant outcome, its prevention, whether through antiviral prophylaxis or preemptive therapy, is an essential component to the management of liver transplant recipients. Two recently updated guidelines have suggested that antiviral prophylaxis or preemptive therapy are similarly effective in preventing CMV disease in modest-risk CMV-seropositive liver transplant recipients, while antiviral prophylaxis is the preferred strategy over preemptive therapy for the prevention of CMV disease in high-risk recipients [CMV-seronegative recipients of liver allografts from CMV-seropositive donors (D+/R-)]. However, antiviral prophylaxis has only delayed the onset of CMV disease in many CMV D+/R- liver transplant recipients, and such occurrence of late-onset CMV disease was significantly associated with increased all-cause and infection-related mortality after liver transplantation. Therefore, a search for better strategies for prevention, such as prolonged duration of antiviral prophylaxis, a hybrid approach (antiviral prophylaxis followed by preemptive therapy), or the use of immunologic measures to guide antiviral prophylaxis has been suggested to prevent late-onset CMV disease. The standard treatment of CMV disease consists of intravenous ganciclovir or oral valganciclovir, and if feasible, reduction in pharmacologic immunosuppression. In one clinical trial, oral valganciclovir was as effective as intravenous ganciclovir for the treatment of mild to moderate CMV disease in solid organ (including liver) transplant recipients. The aim of this article is to provide a state-of-the art review of the epidemiology, diagnosis, prevention, and treatment of CMV infection and disease after liver transplantation.

Key words: Cytomegalovirus; Outcome; Hepatitis; Transplantation; Valganciclovir; Prophylaxis; Treatment

Core tip: This paper summarizes the current state in the management of cytomegalovirus disease after liver transplantation, including a review of recently updated guidelines for diagnosis, prevention and treatment.

INTRODUCTION

Cytomegalovirus (CMV) is the single most common viral pathogen that influences the outcome of liver transplantation[1,2]. CMV is a ubiquitous herpes virus that, depending on the population studied, infects 50%-100% of humans[1,2]. Primary CMV infection in immune competent individuals presents most commonly as an asymptomatic illness or less commonly as a benign infectious mononucleosis-like syndrome. When CMV infection occurs in individuals with compromised immunity, such as liver transplant recipients, clinical disease with high morbidity may develop and, occasionally, may lead to death if untreated[1,2].

Primary infection results in viral latency in various cells, and ensures the persistence of the virus throughout the life of the host[1,2]. Such characteristic plays an important role in how liver recipients develop CMV infection. First, cellular sites of viral latency become reservoirs for reactivation during periods of inflammation (such as allograft rejection and critical illness). And second, cellular sites of viral latency serve as vehicles for transmission to susceptible hosts (*i.e.*, during blood transfusions and transplantation of liver allografts latently infected with CMV)[1-5].

CLINICAL IMPACT OF CMV ON LIVER TRANSPLANTATION

Direct CMV effects

The classic illness caused by CMV after liver transplantation is manifested most commonly as fever and bone marrow suppression (most commonly, leukopenia and neutropenia, termed CMV syndrome). CMV syndrome accounts for over 60% of CMV diseases after liver transplantation. Less commonly, CMV infection may clinically manifest as tissue-invasive disease (which may involve any organ system) (Table 1)[1]. The most common organ system involved is the gastrointestinal tract (in the form of CMV gastritis, esophagitis, enteritis, and colitis). Gastrointestinal CMV disease accounts for over 70% of tissue-invasive CMV disease cases in liver and other solid organ transplant recipients[6]. The transplanted liver allograft is also predisposed to develop tissue-invasion by CMV (*i.e.*, CMV hepatitis), and this is often manifested with symptoms that may be clinically indistinguishable from acute rejection[7].

CMV disease among liver recipients who are not receiving antiviral prophylaxis occur most commonly during the first 3 mo after transplantation[8]. Overall, it is estimated that 18%-29% of all liver transplant recipients will develop CMV disease in the absence of prevention strategy (Table 2)[4,5,9-11]. However, this incidence varies depending upon donor and recipient CMV serologic status; it may be as high as 44%-65% in CMV D+/R-, or as low as 1%-2% among CMV D-/R- patients (who may still acquire the virus from natural transmission or through blood transfusion). The incidence is between

Table 1 Direct and indirect clinical effects of cytomegalovirus after liver transplantation

Direct effects	Indirect effects
CMV syndrome	Acute allograft rejection
Fever	Chronic allograft rejection
Myelosuppression	Vanishing bile duct syndrome
Malaise	Chronic ductopenic rejection
Tissue-invasive CMV disease[1]	Hepatitis C virus recurrence
Gastrointestinal disease	Allograft hepatitis, fibrosis
(colitis, esophagitis, gastritis,	Allograft failure
enteritis)	Opportunistic and other infections
Hepatitis	Fungal superinfection
Pneumonitis	Nocardiosis
CNS disease	Bacterial superinfection
Retinitis	Epstein-Barr virus and PTLD
Mortality	HHV-6 and HHV-7 infections
	Vascular thrombosis
	New onset diabetes mellitus
	Mortality

[1]Any organ system may be affected by cytomegalovirus (CMV). Data adapted from Ref. [104]. PTLD: Post-transplant lymphoproliferative disease; HHV: Human herpes virus.

Table 2 Estimated incidence of cytomegalovirus disease during the first 12 mo after liver transplantation

	Use of anti-CMV prophylaxis for 3-6 mo	
	Yes[1]	No
CMV D+/R-	12%-30%	44%-65%
CMV D+/R+	2.70%	18.20%
CMV D-/R+	3.90%	7.90%
CMV D-/R-	0%	1%-2%
All patients	4.80%	18%-29%

[1]Most cases occur as delayed-onset cytomegalovirus (CMV) disease. CMV disease occurs rarely during prophylaxis with oral valganciclovir. Data adapted from Ref. [4,5,92,104]. D: Donor; R: Recipient.

8%-19% among CMV-seropositive (CMV R+) liver transplant recipients[4,9,11].

The incidence of CMV disease is markedly reduced in liver transplant recipients who received 3 mo of valganciclovir or oral ganciclovir prophylaxis. The CMV disease incidence rates are 12%-30% in CMV D+/R-, and < 10% of CMV R+ liver transplant recipients who received 3 mo of antiviral prophylaxis[3,4,9,11-13]. The onset of disease in these patients occurs during first 3-6 mo after completing antiviral prophylaxis; hence, the term late-onset CMV disease[3]. To reduce the incidence of late onset CMV disease, there have been efforts to prolong prophylaxis to 6 mo in CMV D+/R- liver recipients. There is limited data available on the incidence of late-onset CMV disease after 6 mo of prophylaxis, although this is estimated to be further reduced by half (*e.g.*, about 15% of CMV D+/R- liver recipients).

Indirect CMV effects

CMV has a variety of indirect effects that are believed to be mediated by the ability of the virus to modulate the immune system (Table 1)[1,2]. CMV is a potent up-regu-

Table 3 Actors associated with increased risk of cytomegalovirus disease after liver transplantation

CMV D+/R- > CMV R+
Allograft rejection
High viral replication
Mycophenolate mofetil
Anti-thymocyte globulin
Alemtuzumab
Human herpesvirus-6
Human herpesvirus-7
Renal insufficiency
Deficiency in CMV-specific CD4+ T cells
Deficiency in CMV-specific CD8+ T cells
Toll-like receptor gene polymorphism
Mannose binding lectin deficiency
Chemokine and cytokine defects (IL-10, MCP-1, CCR5)
Expression of immune evasion genes
Programmed cell death 1 expression
Others[1]

[1]Others include re-transplantation, volume of blood transfusion, sepsis and other factors associated with high tumor necrosis factor-α secretion. D: Donor; R: Recipient; IL-10: Interleukin-10; MCP-1: Monocyte chemotactic protein-1; CCR5: Chemokine (C-C motif) receptor 5; CMV: Cytomegalovirus.

lator of alloantigens, which increases the risk of acute rejection and chronic allograft dysfunction[14]. CMV has been associated with vanishing bile duct syndrome and ductopenic rejection that leads to chronic cholestasis and allograft failure[15-17]. A higher incidence of vascular and hepatic artery thrombosis has been reported in liver recipients with CMV disease, and this effect is postulated to result from infection of the vascular endothelial cells[18,19].

The immunomodulatory effects of CMV may account for a higher predisposition to develop opportunistic infections due to fungi, other viruses, and bacteria[20,21]. CMV-infected transplant recipients are more likely to develop Epstein-Barr virus-associated post-transplant lymphoproliferative disorders, or develop co-infections with other viruses such as human herpesvirus (HHV)-6 and HHV-7[20-22]. Co-infection with HHV-6 and HHV-7 is significantly associated with an increased predisposition to CMV disease[23-25]. Similarly, there is a significant association between CMV and hepatitis C virus (HCV) recurrence after liver transplantation[26-31], and this is clinically manifested as a more accelerated clinical course of HCV recurrence[29,31]. A recent retrospective study of 347 HCV-infected liver recipients observed that CMV infection increased by 1.5 times the risk of allograft fibrosis, while CMV disease increased by 3.4 times the risk of allograft inflammation[32]. A significant association between CMV infection and metabolic disease such as post-transplant diabetes mellitus has been reported. In a recent study of 169 non-diabetic liver recipients, CMV infection was a significant risk factor for development of new-onset diabetes after transplantation[33].

Impact on mortality
Through direct, indirect and possibly immunomodulatory mechanisms, CMV is associated with higher risk of death after liver transplantation[20,34,35]. The use of intravenous (IV) and oral ganciclovir has reduced the incidence of CMV disease and the risk of death due to CMV[20,36-38]. Despite these improvements in CMV prevention with use of antiviral drugs, late-onset CMV disease continues to occur, particularly among CMV D+/R- liver transplant recipients. Notably, late-onset CMV disease remains significantly associated with increased risk of mortality after liver transplantation[35]. In an analysis of 437 liver transplant recipients, CMV disease occurred in 37 patients (8.5%) and its occurrence was independently associated with a 5-fold increased risk of all-cause mortality, and 11-fold increased risk of infection-related mortality[35].

RISK FACTORS FOR CMV DISEASE AFTER LIVER TRANSPLANTATION

Lack of pre-existing CMV-specific humoral immunity
The most important risk factor for CMV disease after liver transplantation is a lack of effective CMV-specific immunity. In the clinical setting, this is best measured by serology to detect immunoglobulin G against CMV. Specifically, CMV D+/R- patients are at highest risk of CMV disease[4,20], while CMV R+ patients have modest and CMV D-/R- have the lowest risk of CMV disease after liver transplantation (Table 3).

Drug-induced suppression of immune function
Drug-induced immunosuppression impairs the ability of liver recipients to mount an effective immune response against CMV, thereby predisposing to higher risk of CMV disease[4,20]. Immune dysfunction is particularly intense with the use of lymphocyte-depleting drugs, as either induction or rejection therapy[39,40]. When alemtuzumab, an anti-CD52 lymphocytic antibody, is used for short-course induction therapy, the risk of CMV disease is not significantly increased[41,42]. However, when alemtuzumab is used as treatment for rejection, the risk of CMV disease is higher suggesting that rejection per se also increases the risk[42]. Basiliximab and daclizumab are associated with lower risk of CMV disease compared to anti-thymocyte globulin[43].

The combined effects of drugs for maintenance immunosuppression have been associated with CMV disease[1,2,20], although specific agents such as mycophenolate mofetil, when used at high doses has also been implicated to increase the risk[44,45]. In contrast, some of the newer immunosuppressive drugs such as sirolimus and everolimus [mammalian target of rapamycin (mTOR) inhibitor] have been associated with lower risk of CMV disease[46,47]. These observations have generated special interest in the use of the mTOR agents for patients at high risk of CMV disease.

Defects in innate immunity
Inherent defects in innate immunity, such as mutations

in innate immunity-associated genes, increase the risk of CMV disease (Table 3). In a pilot study in 92 liver recipients with chronic HCV, the R753Q single nucleotide polymorphism (SNP) in the Toll-like receptor 2 (*TLR2*) gene was associated with a higher CMV replication and higher incidence of CMV disease. TLR2 is a pattern recognition receptor that senses the presence of CMV and signals the immune cells to produce antiviral peptides and cytokines; the R753Q SNP impairs this immunologic cascade[48]. A larger study of 737 liver recipients confirmed that TLR2 R753Q SNP was significantly and independently associated with CMV disease after liver transplantation, especially for tissue-invasive disease[49].

The lectin pathway of complement activation is also important in the innate immune response to CMV. Mannose binding lectin levels or mutation in its gene has been assessed as prognostic indicators of CMV disease after transplantation[50]. In a study of 295 liver recipients, whose donors were also genotyped for SNPs in mannose-binding lectin (MBL2), Ficolin-2 (FCN2) and MBL-associated serine protease genes, the risk of CMV infection was 2.77 fold higher with the gene profile of the donor and 4.57 fold higher for the combined MBL2 and FCN2 donor-recipient mismatch profile. These results were independent from donor-recipient CMV serostatus[51].

Other immune measures, such as programmed death-1 expression[52] have also been assessed for their association with CMV infection. In one study, programmed death-1 receptor up-regulation was significantly associated with incipient and overt CMV disease and with CMV viremia[52].

Lack of CMV-specific cell-mediated immunity
Cell-mediated immunity are the most essential components to the control of CMV after liver transplantation[40]. Hence, measuring CMV-specific cell-mediated immunity is a promising strategy in CMV management after transplantation[53]. In one study, secretion of interferon-γ by CD8[+] T cells during *in vitro* stimulation with CMV peptides was associated with a lower incidence of CMV disease in solid organ transplant recipients (including liver recipients)[54]. A variety of CMV-specific T-cell assays are currently being developed including QuantiFERON-CMV assay, ELISpot assay, and intracellular cytokine staining for IFN-γ using flow cytometry. The principle of these assays relies on the detection of cytokine (most commonly interferon-γ) production following *in vitro* stimulation with CMV antigens[55]. Recently, QuantiFERON-CMV assay was studied in a multi-center study that enrolled 124 high-risk (D+/R-) solid-organ transplant (including liver) recipients. Twenty five percent of patients had positive result, 65.3% had a negative result, and 9.7% had an indeterminate result. At 12 mo follow-up, patients with a positive QuantiFERON-CMV assay had a significantly lower risk of CMV disease (6.4%) compared to those with negative (22.2%) and indeterminate result (58.3%). The assay provides a positive and negative predictive values for protection from CMV disease of 0.90 (95%CI: 0.74-0.98)

and 0.27 (95%CI: 0.18-0.37), respectively[53,56]. Collectively, these studies indicate that immune monitoring of CMV-specific T-cell responses may have a potential to predict individuals at increased risk of CMV disease, and may be useful in guiding the use of prophylaxis.

Allograft rejection
Allograft rejection can trigger CMV reactivation after transplantation[13]. The cytokines released during acute rejection, particularly tumor necrosis factor-α[57], could transactivate CMV from latency[58,59]. Subsequent therapy for allograft rejection (intensified immunosuppression with the use of high doses of steroids or lymphocyte-depleting drugs) enhances viral replication by impairing the generation of an effective CMV-specific cell-mediated immunity[60]. In a bidirectional relationship, CMV increases the risk of allograft rejection[61].

Virus-to-virus interactions
Interactions among reactivated viruses have been proposed to enhance the risk of CMV disease after liver transplantation[22,23,27-31]. HHV-6 increases the risk of CMV disease after liver transplantation[22,23,25]. Likewise, HCV-infected liver transplant patients have a higher incidence of CMV disease[62], although the data in the era of valganciclovir prophylaxis has refuted this observation[26].

Viral burden and other factors
The risk of CMV disease after liver transplantation is associated, in direct proportion, with viral burden and the degree of CMV replication[9,24,63,64]. Other factors associated with CMV disease after liver transplantation include cold ischemia time, bacterial and fungal infections and sepsis, the amount of blood loss, fulminant hepatic failure as the indication for liver transplantation, age, female gender, and renal insufficiency[2,3,20,65].

PREVENTION OF CMV DISEASE AFTER LIVER TRANSPLANTATION

There are two major strategies for CMV disease prevention after liver transplantation: (1) preemptive therapy; and (2) antiviral prophylaxis. For preemptive therapy, patients are monitored for evidence of CMV replication by sensitive assays, most commonly using quantitative nucleic acid amplification tests by PCR and less commonly by detection of pp65 antigenemia, and upon the detection of asymptomatic CMV replication, antiviral therapy is administered preemptively to prevent progression to symptomatic clinical disease. In contrast, antiviral prophylaxis entails the administration of antiviral drugs such as valganciclovir to all patients at risk of CMV disease after liver transplantation[20]. Both of these strategies are similarly effective in preventing CMV disease after liver transplantation[4,5,66-69]. However, there has not been a large prospective well-controlled randomized trial directly comparing preemptive therapy and prophylaxis in liver

Figure 1 Suggested algorithm for preemptive therapy. Figure adapted from Ref. [62].

transplant recipients. In a retrospective study comparing the two approaches in liver transplant recipients, antiviral prophylaxis was more effective in prevention of CMV disease in high risk D+/R-, but there were no differences in acute rejection, opportunistic infections, or rate of mortality[40,70]. Another retrospective study reported the incidence of CMV viremia was 4.9% and 50.0% ($P < 0.001$) at 3 mo in the antiviral prophylaxis and preemptive therapy groups, respectively, but the rates were expectedly reversed, at 24.6% and 8.3% ($P = 0.026$), respectively at 6 mo; the reversal of the rates during the latter period accounts for the higher rates of late onset CMV disease with antiviral prophylaxis[71]. An NIH-sponsored prospective study is being conducted in six transplant centers in the United States to compare the efficacy and safety of antiviral prophylaxis *vs* preemptive therapy in CMV D+/R- liver transplant recipients.

According to the recently updated American Society of Transplantation (AST) and The Transplantation Society (TTS) guidelines, preemptive therapy may be an option in CMV D+/R- liver transplant recipients, however, many authorities prefer to use antiviral prophylaxis in this high-risk population and reserve preemptive therapy for lower-risk populations[39,72]. The main reason for this preference for antiviral prophylaxis is the rapidity of CMV replication in CMV D+/R- liver recipients, which may escape detection with once weekly CMV surveillance. Indeed, antiviral prophylaxis has been used by the majority of American and European transplant

centers in preventing primary CMV disease in high-risk CMV D+/R- liver transplant recipients[73,74]. Moreover, primary antiviral prophylaxis has the added benefit of reduction in bacterial and fungal opportunistic infections and mortality[34,35,37,75].

Preemptive therapy

The basic principle of preemptive therapy is to detect the presence of early CMV replication prior to the onset of clinical symptoms, so that antiviral therapy is administered early in order to prevent the progression of asymptomatic infection to clinical disease[64,66,67,69,76]. An example of a preemptive algorithm is shown in Figure 1. Preemptive therapy has the potential advantage of targeting therapy to the highest risk patients and thereby decreasing drug costs and toxicity. The success of this approach relies on several aspects including: (1) the optimal laboratory test and frequency and duration of monitoring; (2) selection of the appropriate population for preemptive therapy; and (3) choosing the type, dose and duration of an antiviral drug.

The two laboratory methods used for CMV surveillance for preemptive therapy are pp65 antigenemia assay and nucleic acid testing (NAT). During the past decade, clinical laboratories have been moving towards preference for NAT over antigenemia, mainly for assay sensitivities, performance and logistics. The pp65 antigenemia assay, a semi-quantitative assay based on detection of CMV pp65 antigen in infected leukocytes, has comparable sensitivity to CMV NAT[77], but it needs to be processed within 6-8 h of blood collection, it requires a large sample volume, it has subjective interpretation of results, and is labor-intensive. Accordingly, quantitative NAT is now the preferred method for detecting CMV after transplantation[78]. The assay has a better precision and faster turnaround time[79]. Because of its quantitative ability, the assay can distinguish between active viral replication (typically with high-level viremia) from latent virus (low-level viremia if using highly sensitive tests)[78]. In the past, NAT lacked standardization, and this prevented the generation of widely applicable viral load thresholds for various clinical applications. In 2011, CMV viral load standardization was made possible with the release of the World Health Organization (WHO) calibrator standard. A recent study applied this assay in the plasma samples of 267 solid organ (including liver) transplant recipients. This study demonstrated that patients with pretreatment CMV DNA of less than 18200 [4.3 log (10)] IU/mL have 1.5 fold higher chance for CMV disease resolution. Likewise, CMV suppression to less than 137 [2.1 log (10)] IU/mL is predictive of clinical response to antiviral treatment[80].

The optimal interval and duration of monitoring for preemptive therapy is still unknown, but guidelines recommend once weekly CMV NAT for 12 wk after liver transplantation. If a patient shows viremia above a defined threshold during the surveillance period, antiviral therapy (with oral valganciclovir or intravenous ganciclovir) should be initiated and continued until CMV

Table 4 Currently available antiviral drugs for cytomegalovirus prophylaxis and treatment in liver transplant recipients

Drug	Route	Usual adult prophylaxis dose	Usual adult treatment dose	Comments on use and major toxicity
Ganciclovir	Intravenous	5 mg/kg once daily	5 mg/kg twice daily	Intravenous access; leukopenia
Ganciclovir	Oral	1 g three times daily	Not applicable	Low oral bioavailability; high pill burden
Valganciclovir	Oral	900 mg once daily	900 mg twice daily	Ease of administration; leukopenia
Foscarnet	Intravenous	Not recommended	60 mg/kg every 8 h (or 90 mg/kg every 12 h)	Second-line drug Intravenous access; nephrotoxicity
Cidofovir	Intravenous	Not recommended	5 mg/kg once weekly × 2 then every 2 wk thereafter	Third-line drug Intravenous access; nephrotoxicity

viremia is no longer detectable[55,72]. Several studies have reported the success of IV ganciclovir or oral valganciclovir for preemptive treatment of CMV infection in liver transplant recipients, including high-risk CMV D+/R- patients[68,76]. However, some studies have indicated that preemptive therapy may not be completely effective in CMV D+/R- liver recipients since the replication kinetics of CMV in immune-deficient individuals is so rapid[63] that it may escape detection with once weekly surveillance[9,58,66]. Indeed, in our clinical experience, nearly 25% of CMV D+/R- liver recipients who developed CMV disease were not identified early despite weekly CMV PCR assay[9,58,66]. Accordingly, the recently updated AST and TTS guidelines prefer antiviral prophylaxis in CMV D+/R- liver recipients. In contrast, preemptive therapy is recommended for preventing CMV disease in CMV-seropositive liver recipients[55,72].

Clinical trials have demonstrated the efficacy of preemptive therapy in CMV disease prevention[66-68,76]. Three meta-analyses that collectively analyzed data from prospective clinical trials demonstrated the benefits of preemptive therapy in preventing CMV disease[35,36,68]. When conducted properly, preemptive therapy, with the use of IV ganciclovir or oral valganciclovir resulted in the reduction of CMV disease by about 70%[37,38,75]. Moreover, preemptive therapy is much less likely associated with late onset CMV disease (unlike in antiviral prophylaxis, as discussed below)[66,67]. Currently, valganciclovir is the most commonly used drug for preemptive therapy[73], and in one non-controlled study, it was demonstrated to be as effective in terms of clinical and virologic response, when compared to IV ganciclovir)[66,67]. In addition, preemptive therapy may be beneficial in reducing the indirect effects of CMV, although to a much lesser degree compared to antiviral prophylaxis. In one study, the incidence of major opportunistic infections, bacteremia, bacterial infection, HCV recurrence, and rejection were not significantly different between liver transplant patients who received preemptive therapy and those who did not have CMV reactivation[81].

Antiviral prophylaxis

Antiviral prophylaxis is highly effective in preventing the direct effects, and there is increasing evidence that it reduces the indirect effects of CMV after liver transplantation[4,5,37,38,75]. Compared to placebo or no treatment, patients who received antiviral prophylaxis had lower incidence of CMV disease (58%-80% reduction) and CMV infection (about 40% reduction)[75]. In one meta-analysis, a 25% reduction in the incidence of acute allograft rejection was observed[37]. In two studies, a reduction in all-cause mortality was observed[37,75], mainly due to a decline in CMV-related death[75]. A reduction in the incidence of other herpes viruses, bacterial, and protozoan infections were also observed[37]. Because of these additional benefits, liver transplant centers prefer the use of antiviral prophylaxis over preemptive therapy in the prevention of CMV disease, particularly in CMV D+/R- liver transplant recipients[73]. Table 4 shows the currently available antiviral drugs for CMV prophylaxis and treatment in liver transplant recipients.

Valganciclovir vs ganciclovir prophylaxis

Ganciclovir-based regimen is more effective than acyclovir or immunoglobulins in reducing the incidence of CMV disease after liver transplantation. In one study, the administration of IV ganciclovir for 90-100 d reduced the incidence of CMV disease in CMV D+/R- liver transplant recipients to 5.4% (compared to 40% in patients who received less than 7 wk of prophylaxis)[44]. Oral ganciclovir, administered at 1000 mg PO three times daily, was compared to placebo, and there was a significant reduction in the 6-mo incidence of CMV infection (51.5% *vs* 24.5%, $P < 0.001$), and CMV disease (19% *vs* 5%, $P < 0.001$) in liver transplant recipients[4], including CMV D+/R- patients (44% *vs* 15%, $P = 0.02$) and patients who received antilymphocyte antibodies (33% *vs* 5%; $P = 0.002$)[4]. Among CMV R+ liver transplant recipients, oral ganciclovir for 12 wk reduced the incidence of CMV disease to 1% (compared to 7% in patients who received acyclovir)[82]. Oral ganciclovir, however, is poorly absorbed, and its oral administration results in low systemic ganciclovir levels[83].

Valganciclovir provides systemic ganciclovir levels that are comparable to IV ganciclovir[83,84]. Pharmacokinetic studies indicate that a 900 mg dose of valganciclovir achieves a similar daily area under the concentration time curve (AUC_{24}) as an IV dose of 5 mg/kg of ganciclovir[83]. The role of valganciclovir in the prevention of CMV disease after liver transplantation was evaluated in a multicenter randomized non-inferiority clinical trial that compared it with oral ganciclovir in a cohort of 364 CMV D+/R- solid organ (including liver) transplant recipients (Figure 2). Among all solid organ transplant

Figure 2 Time to the onset of cytomegalovirus disease in solid organ transplant recipients who received three mo of oral ganciclovir or valganciclovir prophylaxis. Data obtained from the study by Paya *et al*[5].

recipients, the 6-mo incidence of CMV disease was 12% and 15% in the valganciclovir and oral ganciclovir groups, respectively. Follow-up at one year, demonstrated that the incidence of protocol-defined CMV disease in all patients was 17% and 18% with valganciclovir and oral ganciclovir, respectively[5].

However, in a subgroup analysis of the 177 liver transplant recipients, the incidence of CMV disease was 19% in the valganciclovir group as opposed to only 12% in the ganciclovir group. There was also a higher incidence of tissue-invasive CMV disease in the valganciclovir group[5]. As a result of these findings, valganciclovir did not gain approval from the United States food and drug administration (US-FDA) for prophylaxis against CMV disease after liver transplantation. A recent meta-analysis of 5 controlled clinical studies, including 380 liver transplant recipients who received valganciclovir (450 or 900 mg daily) prophylaxis, showed the overall CMV disease rate was 12%, and the rate among D+/R-patients was 20%. The risk of CMV disease with valganciclovir was 1.8-fold higher than oral ganciclovir. For CMV D+/R- patients, the risk of CMV disease was 2-fold higher than oral ganciclovir. The risk of CMV disease remained significant with valganciclovir 900-mg daily dose, but not with the 450 mg dose. The risk of leukopenia with valganciclovir was 1.9-fold higher than those using oral ganciclovir[85]. Despite these findings, and even if not FDA-approved for this indication, valganciclovir remains as the most widely used drug for CMV prophylaxis after liver transplantation[73].

Maribavir prophylaxis

Maribavir, an investigational oral benzimidazole riboside with *in vitro* activity against CMV, was compared to oral ganciclovir, for prophylaxis in 303 high-risk liver transplant recipients. In this randomized, double blind, multicenter controlled trial, maribavir was less effective than oral ganciclovir for the prevention of CMV disease. Significantly fewer patients who received oral ganciclovir prophylaxis had confirmed CMV disease or CMV infection compared to maribavir at 100 d (20% *vs* 60%, *P* < 0.0001) and at 6 mo (53% *vs* 72%, *P* = 0.0053) after liver transplantation. Because of this finding (and the results of the bone marrow transplant trial), the clinical development of maribavir for CMV management is on hold[86].

CMV immunoglobulin

A combination of anti-CMV drugs and CMV immunoglobulin has been used in a clinical practice for prophylaxis. A pooled analysis of previous studies revealed a combination regimen may reduce severe CMV disease and mortality in solid organ transplant recipients; however the finding has been debated[87,88].

Late-onset CMV disease

In many high-risk CMV D+/R- individuals, the use of antiviral prophylaxis for 100 d has only delayed the onset of CMV disease to 3-6 mo after liver transplantation[3,5,13]. In our analysis of 67 CMV D+/R- liver transplant recipients who received 3 mo of oral ganciclovir and valganciclovir prophylaxis, the two-year incidence of CMV disease was 29%, and was similar between the two drugs (22% *vs* 28%, *P* = 0.63)[3]. The most common presentation of late-onset CMV disease was CMV syndrome, with fever and bone marrow suppression[3]. In less than half of the patients, CMV manifested as tissue-invasive disease, and frequently affected the gastrointestinal tract[3]. Factors such as age[3], female gender[3,89], renal dysfunction[77], and allograft rejection[13] predisposed to the development of late-onset primary CMV disease. Late-onset CMV disease appears to be clinically less severe, although it is associated with significant mortality after liver transplantation[35].

Because of the negative effect of late-onset CMV disease on overall outcome, a better method for CMV prevention is needed among CMV D+/R- liver transplant recipients. The recently updated AST and TTS guidelines suggest that the duration of antiviral prophylaxis may be prolonged from the standard 3 mo to 6 mo in CMV D+/R- liver transplant recipients[41,81]. This recommendation is based on the trial that investigated the approach in CMV high-risk D+/R- "kidney" transplant recipients. In the Improved Protection Against Cytomegalovirus in Transplantation study, the incidence of CMV disease was significantly lower in the 200 d *vs* 100 d of prophylaxis at the end of 1 year (16.1% *vs* 36.8%, *P* < 0.0001) and the result was persistent up to 2 years after transplantation (21.3% *vs* 38.7%, *P* < 0.001)[90,91]. In a retrospective study on 203 liver transplant recipients who received valganciclovir 900 mg daily for 3 to 6 mo, the overall incidence of CMV disease was 14%. The incidence was highest in D+/R- (26%) compared to 16% in D+/R+ group and 7% in D-/R+ group[92]. However, it is emphasized that 6 mo of antiviral prophylaxis has not yet been studied prospectively in the liver transplant recipients, and that valganciclovir is not FDA-approved for the prevention of CMV disease after liver transplantation. In addition, there are theoretical concerns about ganciclovir resistance and drug toxicity particularly with leukopenia with prolonged prophylaxis, although these were not demonstrated in the clinical trial. The cost of prophylaxis will need to be evaluated with the use of prolonged prophylaxis.

In summary, the duration of prophylaxis in D+/R- liver transplant recipients should generally be between

3 and 6 mo. For seropositive patients with either donor seropositive or seronegative, a majority of the experts suggested that 3 mo of prophylaxis is sufficient[55].

Hybrid approach

A new strategy has been utilized in some transplant centers to prevent late-onset CMV disease is hybrid strategy in which preemptive monitoring is initiated after completing prophylaxis. A retrospective study of 199 liver transplant recipients [including 23 (11%) high-risk D+/ R- patients] who received 3 mo of valganciclovir prophylaxis and were monitored by CMV antigenemia after prophylaxis (twice a month up to month 6, and monthly until one year). The results were modest at best[93], possibly due to difficult and non-standardized logistics of this approach[94].

TREATMENT OF CMV DISEASE AFTER LIVER TRANSPLANTATION

The first line treatment of CMV disease after liver transplantation is IV ganciclovir or valganciclovir[62,76,93]. In contrast, oral ganciclovir should not be used for the treatment of CMV disease because of its poor bioavailability[20]. In addition, the degree of pharmacologic immunosuppression should be reduced if possible[20].

In a multi-center non-inferiority trial, 321 solid organ (including liver) transplant recipients with non-severe CMV disease were randomized to valganciclovir (900 mg twice daily) or IV ganciclovir (5 mg/kg twice daily) for a fixed 21-d course, followed by valganciclovir (900 mg once daily) maintenance treatment for 4 wk; the proportion of patients with viral eradication at 21 and 49 d were comparable in the IV ganciclovir and valganciclovir groups[93]. The overall time to viral eradication was 21 d with valganciclovir and 19 d with IV ganciclovir. The calculated viral decay was 11.5 d with valganciclovir and 10.4 d with IV ganciclovir. Likewise, clinical resolution was not different between the two groups. It was noted that patients enrolled into this trial were mostly CMV-seropositive, the majority were kidney recipients (although there were good number of liver transplant recipients), and patients with severe CMV disease were excluded. Despite these limitations, this pivotal trial now supports the use of valganciclovir for oral treatment of CMV disease, at least in selected transplant patients[93]. IV ganciclovir is preferable to valganciclovir in patients with severe or life-threatening disease, or in patients who may have a problem with gastrointestinal absorption of oral drug. In many instances, valganciclovir is used as a step-down treatment when the clinical symptoms have resolved after an initial induction treatment with IV ganciclovir.

The duration of treatment of CMV disease should be individualized[62,77]. The persistence of the virus at the end of therapy (by PCR or pp65 antigenemia) is associated with a higher risk of clinical relapse[78]. In the recent study that evaluated the role of viral load using a WHO standard calibrated assay, the degree of viral load at the time of CMV disease diagnosis and the presence or absence of viral load at the end of treatment were significantly associated with CMV disease resolution. It is now generally accepted that multiple (at least two) weekly negative CMV PCR results should be obtained before antiviral therapy is discontinued. Although this may be true for non-tissue invasive CMV syndromes, the utility of such an approach may not necessarily apply to some tissue-invasive disease, which may manifest as "compartmentalized disease"[20].

Treatment of compartmentalized CMV disease

Compartmentalized CMV disease refers to clinical syndromes wherein the virus is detected in the affected tissues but is minimally detectable or undetectable in the blood[20]. In the current era, gastrointestinal CMV disease constitutes the vast majority of tissue-invasive cases[3,8,20], and in a number of cases, especially in CMV R+ patients, this type of CMV disease is "compartmentalized". In a retrospective study, the sensitivity of pp65 antigenemia assay (defined as detection of ≥ 1 positive cells/2×10^5 leukocytes) for diagnosis of CMV gastrointestinal disease was only 54%[79]. Such a clinical presentation is reminiscent of CMV retinitis, a very rare manifestation of tissue-invasive CMV disease after transplantation, that is often not accompanied by viremia[75,80]. This dilemma brings to the forefront the limitation of viral load monitoring in assessing duration of treatment. In our clinical practice, it is not uncommon to have negative blood PCR assay even when there remains histologic evidence of tissue invasion. Accordingly, it has been suggested to perform colonoscopy or upper endoscopy to document clearance of gastrointestinal CMV disease prior to discontinuation of therapy. However, our retrospective review of this practice suggests that this should not be generalized to all patients with gastrointestinal CMV disease. We observed that relapse of gastrointestinal CMV disease was significantly associated with extensive involvement of gastrointestinal tract at the time of diagnosis[81]. In contrast, CMV serologic conversion, degree of viral load, treatment duration, maintenance therapy, and endoscopic findings at the end of therapy were not significantly predictive of CMV relapse. Our experience indicates that endoscopic evidence of resolution of gastrointestinal disease may not be necessary in mild to moderate disease as long as sufficient therapy is provided[81].

Treatment of ganciclovir-resistant CMV disease

Ganciclovir-resistant CMV is now emerging as an important complication of prolonged antiviral drug use after transplantation[2,20,44]. Currently, ganciclovir-resistant CMV is very rarely seen in liver transplant recipients (while it is relatively more common after kidney-pancreas and lung transplantation). The estimated incidence of ganciclovir-resistant CMV after liver transplantation is < 0.5%[95,96]. Several studies have identified risk factors for ganciclovir-resistant CMV[2,20,44], including CMV D+/R- status, high levels of viral replication, potent

immunosuppressive therapy, and suboptimal ganciclovir levels. The vast majority of drug-resistant cases involve the selection of viral strains with UL97 (kinase) mutation[2,20,44,83,84]. UL97 mutation generally confers resistance to ganciclovir, although in some cases, a concomitant UL54 mutation (CMV DNA polymerase) is also observed, in which case, cross-resistance with cidofovir and/or foscarnet is likely.

Drug-resistant CMV is associated with significant morbidity and mortality, and there is a very limited number of antiviral drugs (which are often toxic) available for treatment[82]. Drug-resistant CMV should be suspected when viral load or antigenemia rises or does not decline to undetectable levels despite IV ganciclovir treatment. In our retrospective study of 225 CMV D+/R- solid organ transplant recipients who received 3 mo of valganciclovir prophylaxis, CMV disease occurred in 65 patients (29%), including four (8%) caused by drug-resistant CMV, judged by the failure of the viral load to decline to undetectable levels while on IV ganciclovir treatment. The diagnosis is confirmed by genetic analysis to demonstrate mutational changes in UL97 and UL54 genes encoding for kinase and polymerase, respectively[40,82]. In patients where foscarnet or cidofovir was used, nephrotoxicity was a major and common adverse effect[85].

Other potential drugs for treatment of multi-drug resistant CMV include the off-label use of CMV Immunoglobulin (Cytogam®), adoptive infusions of CMV-specific T cells, leflunomide (an immunosuppressive drug), and artesunate (anti-malaria drug), although data supporting their use are only anecdotal[20,86]. Leflunomide acts at the stage of viral capsid assembly, not DNA replication, and therefore there is a potential use against ganciclovir-resistant strains. A single center retrospective study including 15 solid organ transplant recipients (but not including liver recipients) with drug-resistant[20,86], CMV infection treated with leflunomide monotherapy or in combination with other drugs showed some potential utility. At least half of patients (53%) had long-term responses in terms of control of CMV viremia and recurrences. The common side effects from this medication included diarrhea, anemia, and hepatic dysfunction[97].

Maribavir has also been used for treatment of drug-resistant CMV[98]. Anecdotal use in a small case series of 9 solid organ transplant recipients infected with resistant CMV showed the individual changes varied from a rapid decrease in viral load ($n = 4$) to no response ($n = 3$) with some late response slowly decreasing CMV viremia ($n = 3$)[99]. It has been used as salvage therapy at a higher dose (400 mg twice daily) for drug-resistant CMV infection, with mixed results including success in treating lower initial viral loads[97]. A new phase II trial of maribavir for salvage treatment of refractory and resistant CMV infection was launched in 2012 (ClinicalTrials.gov ID: NCT01611974).

Other investigational drugs being developed for CMV management are CMX001 and AIC246 (Letermovir). CMX001 is an orally bioavailable derivative of cidofovir with lipid acyclic nucleotide converted intracellularly to the active antiviral to avoid the high renal concentrations and nephrotoxicity[100]. It has demonstrated *in vitro* activity against CMV. It has successfully completed phase II clinical development for the prevention of CMV infection. There is an ongoing open-label, expanded-access study, CMX001-350 (ClinicalTrials.gov ID: NCT01143181), to provide access to CMX001 for patients who had no other treatment options[101]. Optimal dosing has yet to be determined, and diarrhea is a dose-limiting adverse effect. Letermovir (AIC246) is a small-molecular-weight compound with both *in vitro* and *in vivo* anti-CMV activity. It has distinct mechanism which acts late in the CMV replication cycle *via* a mechanism by not involving polymerase. Due to a lack of a human counterpart of the viral terminase complex, target-related toxicities are not expected. It also does not affect human blood precursor cells, and thus may allow the generation and expansion of CMV specific immunity during treatment. Theoretically, this may result in a lower rate of relapse after treatment of CMV infection or disease. Antiviral efficacy of letermovir was reported in phase II prophylaxis studies in HSCT recipients[102]. The successful use of letermovir in decreasing viral load has been reported in one case report of lung transplant recipient with drug-resistant CMV disease[103].

CONCLUSION
