Rethinking the role of non-selective beta blockers in patients with cirrhosis and portal hypertension. *World J Hepatol* 2016; 8(24): 1012-1018 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i24/1012.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i24.1012>

### INTRODUCTION

Cirrhosis is among the leading causes of death worldwide and hepatocellular carcinoma and complications of portal hypertension (PH) represent the most frequent causes of death.

PH is characterized by a systemic hyperdynamic

circulation, with increase of cardiac output (CO) and heart rate (HR), and reduction of mean arterial pressure (MAP) and systemic vascular resistances<sup>[1]</sup>. The degree of PH correlates with the severity of hyperdynamic circulation, while the absence of hemodynamic imbalance (*i.e.*, preserved right heart preload) is associated with better prognosis<sup>[2]</sup>.

Ascites, esophageal varices, encephalopathy and/or jaundice are the main features of decompensated cirrhosis. Ascites represents the first clinical sign of decompensation in 30%-50% of patients, being the incidence about 50% within 10 years<sup>[3]</sup>. Refractory ascites occurs in 5% to 10% of cases, leading to a significant shortening in survival<sup>[4]</sup>. Oesophageal varices occur in about 50% of cirrhotic patients<sup>[5]</sup> being the incidence of first variceal bleeding estimated to be about 12%-15% per year, and the mortality of 15%-20% for every episode<sup>[6]</sup>. Varices mainly develop due to increased PH, but Fernandez *et al.*<sup>[7]</sup> reported that their formation was also modulated by active angiogenesis, and not by a simple mechanism of vasodilation.

Moreover, several external factors, such surgery, bacterial infections or bleeding, represent severe trigger factors for derangement of hemodynamic; for instance, infection seemed more frequent in those patients who developed an acute-on-chronic liver failure (32.6% vs 21.8%,  $P < 0.01$ )<sup>[8]</sup>. Phillip *et al.*<sup>[9]</sup> showed that removal of > 5 L of ascites determined a significant reduction of MAP and SVR, which is usually associated with a counterbalancing increase of CO<sup>[10]</sup>. The hemodynamic imbalance after LVP led to an increased risk of renal dysfunction, and subsequently to an increased mortality, according to the well-defined Paracentesis Induced Circulatory Dysfunction (PICD)<sup>[11]</sup>.

Heart dysfunction has been shown in decompensated cirrhosis<sup>[12]</sup>, being caused both by organic (*i.e.*, alcoholic or septic cardiomyopathy) and/or functional [*i.e.*, cirrhotic cardiomyopathy (CM)] factors. CM is mainly due to chronic increase of pro-inflammatory cytokines, impairment of systemic and regional hemodynamic, and beta-adrenergic receptor desensitization, with reversible impairment of systolic contractility, diastolic function and electrophysiological activity<sup>[1,13]</sup>. The impaired CO may also contribute to a decrease in renal perfusion: For instance, Krag *et al.*<sup>[14]</sup> demonstrated that a lower cardiac index was associated with an increased development of hepatorenal syndrome within 3 mo (43% vs 5%,  $P = 0.04$ ). Although it's difficult to determine the prevalence of CM since it's usually masked at rest, it could be an important cause of multi-organ failure and death during stressing conditions, as infection or liver transplantation<sup>[15]</sup>.

## ROLE OF NON-SELECTIVE BETA BLOCKERS IN THE TREATMENT OF PH

### **Non-selective beta blockers and variceal bleeding**

Non-selective beta blockers (NSBB) act reducing portal

flow and PH by decreasing CO (through  $\beta_1$  receptors) and determining splanchnic vasoconstriction (through  $\beta_2$  receptors)<sup>[16]</sup>. In 1981 Lebrec *et al.*<sup>[17]</sup> demonstrated for the first time the effectiveness of NSBB for variceal bleeding; the re-bleeding rate was 4% in the treated group, compared to 50% in the placebo group.

Several randomized studies confirmed that NSBB represent the preferred option in primary prophylaxis against no intervention<sup>[18]</sup> and in preventing re-bleeding in combination with endoscopic band ligation<sup>[19]</sup>. Furthermore, a Cochrane metanalysis<sup>[20]</sup> confirmed that NSBB were as effective as endoscopic band ligation for reducing bleeding related mortality [29/567 (5.1%) vs 37/585 (6.3%); RR = 0.85; 95%CI: 0.53 to 1.39].

However, identification of hemodynamic response to NSBB still remains challenging for the hepatologists. Heebøll *et al.*<sup>[21]</sup> demonstrated that only 51/124 (40%) of patients with cirrhosis who underwent measurement of gradient between portal and hepatic veins (HVPG) presented a significant hemodynamic improvement (reduction greater than 20% or > 12 mmHg) after NSBB use. Moreover, authors did not demonstrate a significant association between improvement of HVPG and change of HR ( $P = 0.8$ ), which is commonly used parameter to tailor propranolol therapy.

Importantly, all the trials often ruled out cirrhotics with decompensated liver disease (*i.e.*, those with refractory ascites) from the analysis.

## NSBBS IN DECOMPENSATED CIRRHOTICS

Serstè *et al.*<sup>[22]</sup> showed for the first time in 2010 that the median survival was extremely reduced in 151 patients with cirrhosis and refractory ascites treated with propranolol (20.0 mo vs 5.0 mo;  $P = 0.00001$ ); other factors associated with higher mortality were Child-Pugh class C, hyponatremia and renal failure. These data raised several concerns amongst hepatologists<sup>[23-25]</sup> about the use of NSBB in cirrhotics with more advanced liver disease.

First, the group receiving NSBB comprises obviously sicker patients, because of higher prevalence of oesophageal varices (77/77 vs 3/74;  $P = 0.001$ ) and higher serum bilirubin (56 mg/dL vs 48 mg/dL,  $P = 0.01$ ). Second, the propranolol dose of 160 mg/d was significantly higher (in about half of the patients) than the mean dose used in the previous RCTs. Third, mortality was extremely higher in the NSBB group (63/77, 85.1%, median survival time was 5 mo), and there was an increased prevalence of sepsis related mortality, which remain difficult to explain<sup>[25]</sup>.

The French group hypothesized that NSBB use can worsen hemodynamic after LVP; thus, reduced survival could be due to an increased incidence of PICD. A cross-over study published in 2011<sup>[26]</sup> including 10 patients with refractory ascites, investigated the incidence of PICD after LVP when patients were taking NSBB and after

drug discontinuation. The authors showed that PICD was extremely decreased after propranolol discontinuation (1/10 vs 8/10;  $P = 0.01$ ). The hypothesis was that propranolol use determined a reduction of CO and consequently an increase of counter-regulatory vasoconstriction systems, as renin angiotensin aldosterone, whose permanent hyper-activation could be associated with poorer renal function and reduced paracentesis-free interval time.

The link between NSBB and hemodynamic impairment was explained with the reduced MAP, which is a known negative prognostic factor for hyperdynamic circulation and progression of liver disease<sup>[27]</sup>. For instance, in the French study by Serstè *et al.*<sup>[22]</sup>, the cohort receiving propranolol did have lower MAP (90 mmHg vs 83 mmHg). Nevertheless, NSBB have been shown not to reduce MAP after acute *i.v.* administration<sup>[28]</sup>, and the detrimental effects which were seen by the authors could have been due to the dose related side effect made by propranolol. CO is not usually reduced by NSBB introduction<sup>[29]</sup>.

The following clinical studies failed to find any association between the use of NSBB and increased risk of deaths in decompensated cirrhotics (Table 1). Leithead *et al.*<sup>[30]</sup> analyzed a subgroup of 117 patients with refractory ascites listed for LT, receiving a median dose of propranolol of 80 mg/d. They demonstrated that NSBB were independently associated with reduced waitlist death (adjusted HR = 0.35,  $P = 0.022$ ), without higher prevalence of sepsis related mortality. Moreover, an equal survival between patients with refractory ascites taking NSBB and patients without NSBB (12/38 vs 8/23;  $P = 0.79$ ) was shown in another smaller single center retrospective analysis<sup>[31]</sup>.

Bossen *et al.*<sup>[32]</sup> not only confirmed similar mid-term mortality between 258 patients with refractory ascites receiving NSBB and a control group of 330 patients (30.8% vs 30.5%; adjusted HR = 1.02, 95%CI: 0.74-1.39) retrospectively evaluated, but also showed that discontinuation of NSBB was associated with an higher mortality (adjusted HR = 5.13, 95%CI: 2.28-11.55).

In addition, new data seemed to confirm the absence of correlation between mortality and NSBB. Pereira *et al.*<sup>[33]</sup> included 163 patients with infection, of whom 104 were on NSBB. Use of NSBB was associated with lower frequency of sepsis (21% vs 42%,  $P = 0.03$ ), being 3-mo survival not different between cohorts (59% vs 63%;  $P = \text{ns}$ ). Mallawaarachchi *et al.*<sup>[34]</sup> showed that 75 patients treated with NSBB (67 with carvedilol and 8 propranolol) presented equal mortality after a median follow-up time of 28.0 mo (60.0% vs 66.7%;  $P = 0.10$ ); in those with moderate or severe ascites, survival was similar in both groups ( $P = 0.67$ ), while it was better in NSBB patients in mild ascites ( $P = 0.02$ ).

In a large multicentric cohort, Bhutta *et al.*<sup>[35]</sup> confirmed that survival was significantly greater in patients on NSBB at admission with a median survival of 58 d compared to 32 d in patients not on NSBB ( $P = 0.033$ ). No difference was found between those who did or did

not discontinue NSBB ( $P = 0.91$ ), being only systolic arterial pressure and acute renal failure independent predictors of death.

Onali *et al.*<sup>[36]</sup> evaluating 316 patients (126 with refractory ascites), showed that those on NSBB ( $n = 128$ , 40.5%) had a higher frequency of previous variceal bleeding (50% vs 21%,  $P < 0.001$ ) and spontaneous bacterial peritonitis (27% vs 17%,  $P = 0.025$ ), but were at lower risk of death (16% vs 32%;  $P = 0.002$ ). At multivariate analysis use of NSBB was associated with reduced mortality (HR = 0.511, 95%CI: 0.3-0.87,  $P = 0.014$ ).

Finally, in a recent study provided on 349 acute-on chronic patients with cirrhosis, Mookerjee *et al.*<sup>[37]</sup> demonstrated a significantly lower short term mortality in patients on NSBB compared to those without NSBB (24% vs 34%,  $P = 0.048$ ). Interestingly, patients on NSBB had less severe progression to the stages of acute-on-chronic liver failure, and those who discontinued NSBB had a higher mortality (37% vs 13%), even if it might be due to an independently higher presence of circulatory dysfunction.

The association between increased mortality and NSBB could be explained with the worsening of an already impaired hemodynamics, especially in those who experience a greater decrease of cardiac function (*i.e.*, of CO) and of MAP. However, in the study by Karagiannakis *et al.*<sup>[15]</sup> in which the decrease of CO (and subsequently of cardiac index) has been correlated with a lower survival, the used cut-off (1.5 L/m per square meter) is not diffusely seen in cirrhotics, even when decompensated<sup>[38]</sup>.

Simultaneous presence of several cofactors, as infection, could contribute to the change of clinical scenario, being patients at higher risk of hemodynamic derangement if NSBB are not withdrawn.

Mandorfer *et al.*<sup>[39]</sup> showed that 245 patients with refractory ascites but without infection, taking NSBB, experienced a significant reduction in hospitalization rate (19.4 d vs 23.9 d per person-year); at multivariate analysis, NSBB treatment correlated with higher transplant-free survival (HR = 0.771; 95%CI: 0.598-0.993;  $P = 0.04$ ). The Authors demonstrated a correlation between mortality and NSBB only in patients experiencing a previous episode of spontaneous bacterial peritonitis (SBP), with a significant difference in length of hospitalization (NSBB: 33.4 d per person-year; 95%CI: 31.9-34.9 vs no-NSBB: 28.8 d per person-year; 95%CI: 27.6-29.9), and impaired transplant-free survival (HR = 1.644; 95%CI: 1.145-2.361). These data may confirm that NSBB could negatively influence hemodynamic status in patients with infection, but not that NSBB represented a trigger for infection.

However, Galbois *et al.*<sup>[40]</sup> showed that cirrhotics admitted to intensive care unit for sepsis or septic shock who were receiving NSBB were not at increased risk of early or mid-term mortality (15/26 vs 26/42,  $P = 0.8$ ; and 21/26 vs 28/42;  $P = 0.27$ , respectively).

In summary, latest studies seem not to confirm correlation between NSBB and mortality. Another meta-

analysis<sup>[41]</sup>, which comprised 23 and 28 RCTs on primary and secondary prophylaxis for variceal bleeding, for a total of 4481 patients included (39.8% with ascites), extensively confirmed the absence of increased mortality for patients on NSBB. In primary prophylaxis, 215/955 patients died for bleeding-unrelated causes, in a proportion not different between those who were or were not on treatment with NSBB (OR = 0.91, 95%CI: 0.73-1.15). Similarly, in secondary prophylaxis RCTs, bleeding-unrelated deaths did not differ between groups (189/1143 vs 225/1208; OR = 0.90, 95%CI: 0.67-1.23). These data were confirmed in the subgroup taking 120 mg/d or more of propranolol (48/374 vs 57/309, OR = 1.01, 95%CI: 0.55-1.84), and in those with severe ascites (124/595 vs 151/627, OR = 0.93, CI: 0.61-1.43).

## SECOND GENERATION OF BETA BLOCKERS: CARVEDILOL

Carvedilol is a NSBB with mild anti- $\alpha$ 1-adrenergic activity. It has been shown to be more effective than propranolol in reducing HVPg due to the  $\alpha$ -1 blockage, which reduces intra-hepatic resistances. Its role was investigated for the first time more than 20 years ago<sup>[42]</sup>, as a potential tool for reducing PH in patients with cirrhosis, with promising results. Since then, several studies demonstrated its effectiveness in terms of HVPg decrease, after acute administration and after chronic treatment<sup>[43]</sup>.

In 2002, Bañares *et al*<sup>[44]</sup> demonstrated that 26

patients receiving carvedilol experienced a greater reduction of HVPg than 25 patients taking propranolol ( $-19\% \pm 2\%$  vs  $-12\% \pm 2\%$ ;  $P < 0.001$ ); the decrease of HVPg was higher in patients with more severe liver disease (Child-Pugh class B and C vs Child-Pugh class A:  $-25\% \pm 2\%$  vs  $-14\% \pm 3\%$  respectively).

Previous studies showed that, in patients with cirrhosis, acute administration of carvedilol could enhance hypotension and effective hypovolemia, reducing renal blood flow and consequently glomerular filtration rate. In the study by Bañares *et al*<sup>[44]</sup>, renal function remained stable (glomerular filtration rate from 90 mL/min  $\pm$  4 mL/min to 84 mL/min  $\pm$  5 mL/min;  $P =$  ns) in both groups, suggesting a potential chronic hemodynamic adjustment in response to arterial hypotension. Furthermore, the authors confirmed that reductions of HR and CO were lower with carvedilol than with propranolol. However, MAP was significantly reduced only in the carvedilol group (91.4 mmHg  $\pm$  2.5 mmHg vs 81.2 mmHg  $\pm$  2.9 mmHg;  $P < 0.05$ ; propranolol: 88.6 mmHg  $\pm$  4.5 mmHg vs 83.8 mmHg  $\pm$  3.1 mmHg;  $P =$  ns). Thus, despite promising data, the use of carvedilol as first choice drug remains controversial<sup>[19]</sup>, especially in those patients with severely impairment of hemodynamic (*i.e.*, refractory ascites), because further reduction of MAP could be detrimental for organ perfusion. In fact in a recent metanalysis<sup>[45]</sup> on 5 studies which analyzed the role of carvedilol in a total of 90 patients, the number of patients achieving a reduction in HVPg to  $\geq 20\%$  was markedly higher with carvedilol (57/94 vs 33/87), but hypotension occurred in one-third

more patients than with propranolol.

## NON-HEMODYNAMIC EFFECTS OF NSBBS IN PH

Several pleiotropic effects of NSBB have been recently demonstrated beyond their hemodynamic role<sup>[46]</sup>.

In 2003 Abrales *et al.*<sup>[47]</sup> compared the incidence of complications due to PH in 28 patients responders to NSBB; after a follow-up of 8 years, they found that the risk of developing ascites ( $P = 0.025$ ), hepatorenal syndrome ( $P = 0.026$ ), and encephalopathy ( $P = 0.024$ ) were significantly lower than in the 45 patients non-responders. Another study of Hernández-Gea *et al.*<sup>[48]</sup> demonstrated that an effective treatment (*i.e.*, significant reduction of HVP) with NSBB for primary prophylaxis was associated with reduced risk of ascites development (19% vs 57% at 3 years,  $P < 0.001$ ).

Since bacterial translocation has been widely considered an important trigger factor for worsening of PH, also for the lack of response of immune system in cirrhosis<sup>[49]</sup>, and since selective bacterial decontamination seems to partly reverse the hemodynamic derangement in cirrhosis<sup>[50]</sup>, several studies tried to investigate whether NSBB could contribute to PH reduction through a modification of the protean interactions between the gut and the liver.

Propranolol seems to play a role in reduction of bacterial translocation, probably increasing bowel motility through a sympatholytic action<sup>[51]</sup>. After the confirmation that intestinal permeability was significantly impaired in cirrhotic than in controls (lactulose/mannitol ratio: 0.026 vs 0.014,  $P = 0.001$ ); we demonstrated that NSBB introduction determined a significant improvement of intestinal permeability, and reduction of hyper-vascularization at confocal microscopy<sup>[52]</sup>. Also Reiberger *et al.*<sup>[53]</sup> showed a reduction of intestinal permeability after introduction of NSBB, and a contemporary reduction of bacterial translocation [LPS-binding protein: -16% ( $P = 0.018$ ); interleukin-6: -41% ( $P < 0.0001$ )]; interestingly, the Authors showed equal effectiveness also in those whose HVP did not significantly reduced after NSBB introduction.

Although a retrospective study on 134 patients with cirrhosis and ascites<sup>[54]</sup> did not show a reduction of SBP during therapy with NSBB (6/33 vs 33/101; OR = 0.46,  $P = 0.17$ ), a meta-analysis performed on 4 studies demonstrated a significant difference (12.1%,  $P < 0.001$ ) in favor of propranolol in preventing SBP<sup>[55]</sup>.

Bacterial translocation is the main trigger factor for infection in cirrhosis, and infection is a known trigger for variceal bleeding<sup>[46]</sup>. Merli *et al.*<sup>[56]</sup> demonstrated that in 140 patients with cirrhosis who experienced infection, those on NSBB showed a trend towards a lower incidence of sepsis (40% vs 57%), septic shock (8% vs 15%), hepatorenal syndrome (14% vs 17%) and mortality (15% vs 40%).

## CONCLUSION AND FUTURE PERSPECTIVES

To date, NSBB remain the treatment of choice for primary and secondary prophylaxis for portal hypertensive bleeding, even though new drugs, as statins<sup>[57]</sup>, or new generation beta blockers, as carvedilol, may increase the rate of hemodynamic response. NSBB use has been associated with several pleiotropic characteristics, *i.e.*, reduction of bacterial translocation, prevention of spontaneous bacterial peritonitis - different from prevention of bleeding, suggesting a pleiotropic role in decompensated cirrhosis. Contrasting data on the use of NSBB in sickest patients with decompensated cirrhosis made their use controversial. A recent survey<sup>[58]</sup> about 629 physicians highlighted the high heterogeneity across centers. For instance, refractory ascites was considered a contraindication to NSBB use for 36% of responders, while for the 61% NSBB have to be withdrawn during HRS, highlighting a general lack of consensus across all the issues of the survey. A window hypothesis for therapy with NSBB in the natural history of cirrhosis was made by Krag *et al.*<sup>[59]</sup>; according to this view, NSBB could play a detrimental role for cirrhotics at the earlier stage (*i.e.*, for pre-primary prophylaxis) and in the "extremely decompensated" phase, in those patients with MAP lower than 80 mmHg, decreased baseline CO of those with concomitant infections<sup>[19]</sup>.

Since infected cirrhotics are those at greater risk of variceal bleeding and HVP has been increased also after the resolution of infection<sup>[38]</sup>, attention should be paid to a potential increase in the risk of portal hypertensive bleeding. In addition, the interplay between propranolol and sepsis has to be further investigated with future larger studies.

## Abstract

### AIM

To assess lactase gene (*LCT*)-13910C>T polymorphisms in Brazilian non-alcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) patients in comparison with healthy controls.

### METHODS

This was a transverse observational clinical study with NAFLD patients who were followed at the Hepatology Outpatient Unit of the Hospital das Clínicas, São Paulo, Brazil. The polymorphism of lactase non-persistence/lactase persistence (*LCT*-13910C>T) was examined by PCR-restriction fragment length polymorphism technique in 102 liver biopsy-proven NAFLD patients (steatosis in 9 and NASH in 93) and compared to those of 501 unrelated healthy volunteers. Anthropometric, clinical, biochemical and liver histology data were analyzed. Continuous variables were compared using the *t* or Mann-Whitney tests, and categorical data were compared with the Fisher's exact test. Univariate logistic regression and

multivariate logistic regression adjusted for gender and age were performed.

## RESULTS

No differences in the *LCT*-13910 genotype frequencies were noted between the NAFLD patients (66.67% of the patients with steatosis were CC, 33.33% were CT, and none were TT; 55.91% of the patients with NASH were CC, 39.78% were CT, and 4.3% were TT;  $P = 0.941$ ) and the healthy controls (59.12% were CC, 35.67% were CT, and 5.21% were TT) or between the steatosis and NASH patients. That is, the distribution of the lactase non-persistence/lactase persistence polymorphism (*LCT*-13910C>T) in the patients with NAFLD was equal to that in the general population. In the NASH patients, the univariate analysis revealed that the lactase non-persistence (low lactase activity or hypolactasia) phenotype was associated with higher insulin levels ( $23.47 \pm 15.94 \mu\text{U/mL}$  *vs*  $15.8 \pm 8.33 \mu\text{U/mL}$ ,  $P = 0.027$ ) and a higher frequency of insulin resistance (91.84% *vs* 72.22%,  $P = 0.02$ ) compared with the lactase persistence phenotype. There were no associations between the *LCT* genotypes and diabetes ( $P = 0.651$ ), dyslipidaemia ( $P = 0.328$ ), hypertension ( $P = 0.507$ ) or liver histology in these patients. Moreover, in the NASH patients, hypolactasia was an independent risk factor for insulin resistance even after adjusting for gender and age [OR = 5.0 (95%CI: 1.35-20;  $P = 0.017$ )].

## CONCLUSION

The *LCT*-13910 genotype distribution in Brazilian NAFLD patients was the same as that of the general population, but hypolactasia increased the risk of insulin resistance in the NASH patients.

**Key words:** Lactose intolerance; Genetic polymorphism; Insulin resistance; Non-alcoholic fatty liver disease; Nonalcoholic steatohepatitis

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Non-alcoholic fatty liver disease (NAFLD) exhibits a close relationship with metabolic syndrome (MetS), but the associations of the lactase non-persistence/lactase persistence genotypes with MetS components are controversial. Therefore, we assessed hypolactasia (*LCT*-13910CC) and lactase persistence genotypes in 102 Brazilian NAFLD patients in comparison with 501 healthy controls, the associations of these polymorphisms were verified with the results of biochemical tests, MetS and severity of liver histology in nonalcoholic steatohepatitis (NASH) patients. No differences in the *LCT*-13910C>T polymorphisms were noted between the NAFLD and controls, but hypolactasia increased the risk of insulin resistance in the NASH patients.

## INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) encompasses a wide spectrum of liver damage that ranges from steatosis to nonalcoholic steatohepatitis (NASH) and advanced fibrosis/cirrhosis in persons without significant alcohol consumption<sup>[1,2]</sup>. NAFLD is currently considered the most common liver disease and is associated to metabolic syndrome (MetS) components, such as obesity and diabetes<sup>[3-5]</sup>. Several studies have correlated the severity of liver injury with increased frequencies of such components, thus making these components important targets in the management of this condition<sup>[1,6-8]</sup>. However, while specific pharmacological therapy are still far from solving all of the issues related to fatty liver disease, the pursuit of high-risk individuals can be a strategy for concentrating efforts on its diagnosis and management.

Milk is the primary energy source for newborns and is rich in lactose. Lactase phlorizin hydrolase in the microvillus membrane of the small intestinal cells digests lactose. However, after 2-12 years of age, a physiological genetically programmed reduction in lactase activity occurs, hypolactasia or lactase non-persistence, which, when accompanied by symptoms, defines lactose intolerance<sup>[9]</sup>. In contrast some populations mainly from Northern Europe present lactase persistence during adulthood<sup>[10]</sup>. The most interesting report published in 2002<sup>[11]</sup> found that the polymorphisms in intron 13 [lactase gene (*LCT*)-13910C>T] and in intron 9 (*LCT*-22018G>A) of the *MCM6* gene conferred lactase persistence in several populations<sup>[9,12-14]</sup>. These genotypes render a person a lactose digester. The lactase-persistence phenotype has a prevalence of 43.4% in Caucasian Brazilians, and there is no difference between genders<sup>[12]</sup>.

Recent studies have raised concerns regarding the possible associations of lactase persistence with the components of MetS. In Europeans those with hypolactasia genotype (*LCT*-13910CC) had lower body mass indices and waist circumferences than those with lactase persistence genotypes<sup>[15,16]</sup>. Likewise, in the Canary Islands, those with lactase persistence genotypes exhibit higher odds ratios for MetS than do subjects with the *LCT*-13910CC genotype<sup>[17]</sup>.

However, other studies have demonstrated that dairy food consumption showed lower susceptibility to type 2 diabetes or worsening of glucose homeostasis indices<sup>[18-20]</sup>. Nicklas *et al*<sup>[21]</sup> applied a questionnaire to a sample of 3452 American adults and reported that diagnosis of diabetes and hypertension were higher in individuals that considered themselves lactose intolerant with lower ingestion of calcium from dairies. Additionally, Samara *et al*<sup>[22]</sup> assessed a French population and

reported that better metabolic profiles in men was associated with more dairies intake.

As noted, the role of milk in MetS is not clearly defined at this moment, and the literature is controversial<sup>[23]</sup>. Moreover, publications regarding the *LCT-13910C>T* polymorphism in patients with NAFLD are scarce. Therefore, the purpose was to assess expression profiles of the *LCT-13910* genotypes in Brazilians with NAFLD compared to those of healthy individuals to investigate whether the *LCT-13910C>T* variant could be a predictor of NASH. An additional goal was to analyze the associations of the lactase-persistence genotype with biochemical tests, components of MetS and the severity of liver histology in NASH patients.

## MATERIALS AND METHODS

### Ethical considerations

The Ethics Committee of the Hospital das Clínicas (number 448520) approved this study that was conducted following the ethical guidelines of the 1975 Declaration of Helsinki.

### Patients and clinical design

This was a transverse study with NAFLD patients who were followed at the Hepatology Outpatient Unit of the Hospital das Clínicas, São Paulo, Brazil. *LCT-13910C>T* polymorphism was investigated in 102 liver biopsy-proven NAFLD patients and 501 unrelated healthy volunteers. All NAFLD patients were previously evaluated for other liver diseases, being excluded viral hepatitis, autoimmune hepatitis, hemochromatosis, Wilson disease and alpha 1-antitrypsin deficiency. MetS components identification followed the recommendations of the Adult Treatment Panel III Report as follows: Triglycerides  $\geq 150$  mg/dL, high-density lipoproteins (HDL)  $< 40$  mg/dL in men and  $< 50$  mg/dL in women, fasting glucose  $\geq 110$  mg/dL,  $\geq 130$  mmHg systolic or  $\geq 85$  mmHg diastolic pressure, and abdominal obesity<sup>[24]</sup>. The study inclusion criteria were patients 18-75 years old with NAFLD diagnoses based on liver histology. Exclusion criteria were any other liver disease, significant alcohol intake ( $> 100$  g/wk), previous exposure to drugs associated with liver steatosis or not accepting to participate in the study.

Liver histology were scored according to the macro- and micro-vacuolar steatosis, the inflammation and the hepatocyte ballooning. Fibrosis pattern and zonal distributions of the analysed variables were also recorded. The slides were classified according to the NASH Clinical Research Network<sup>[25]</sup>. The biochemical investigations included the following: Fasting glucose, plasma insulin, total cholesterol and fractions, triglycerides, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma glutamyl transferase (GGT), which were collected after a 12-h overnight fast and evaluated at the time of the liver biopsy. Homeostatic Model of Assessment (HOMA-IR) was used to evaluate insulin resistance [ $22.5 \times \text{fasting insulin (mU/mL)} \times \text{glucose (mmol/L)}$ ]<sup>[26]</sup>. A HOMA-IR  $\geq 2.5$  was used as the cutoff

point to define insulin resistance<sup>[27,28]</sup>. Retrospective information regarding co-morbidities was also collected.

### Genotyping

Leukocytes were used for genomic DNA extraction (Miller *et al.*<sup>[29]</sup> 1988). The technique for *LCT-13910* genotyping was described elsewhere<sup>[11,30-32]</sup>.

### Statistical analysis

The continuous variables are presented as the means  $\pm$  the standard deviations and were compared using the *t* test (the assumption of normality was verified using the Anderson-Darling test). When appropriate, the Mann-Whitney test was used. The categorical variables are expressed as the percentages (frequencies) of affected individuals and were compared using Fisher's exact test. Univariate logistic regression was performed to evaluate the odds ratios with the respective 95% CIs. Multivariate logistic regression adjusted for gender and age was performed. The best predictive cut-offs for the continuous variables were determined using conditional trees when the traditional cut-offs did not provide interesting information<sup>[33]</sup>. *P* values below 0.05 were considered statistically significant. The R Project for Statistical Computing ver. 3.1.1 (R Core Team, Vienna, Austria, 2014) software package was used for the statistical analyses<sup>[34]</sup>. A statistical review of the study was performed by a biomedical statistician (Márcio Augusto Diniz).

## RESULTS

The anthropometric, clinical, and biochemical characteristics of the patients are provided in Table 1. We evaluated 102 NAFLD patients, including 9 steatosis and 93 with NASH. All of the steatosis patients were women, whereas in the NASH group, 32 patients (34.41%) were men ( $P = 0.04$ ). The NASH patients had higher fasting glucose levels than did the patients with steatosis only ( $123.14 \pm 48.28$  vs  $91.71 \pm 9.2$ , respectively,  $P = 0.033$ ). There were no differences between the groups in terms of age, MetS components, BMI, insulin, HOMA-IR values  $\geq 2.5$ , AST, ALT, GGT, total cholesterol, HDL, LDL or triglycerides (Table 1).

The distributions of alleles and genotypes are presented in Table 2. No differences in *LCT-13910* genotype frequencies were noted between the NAFLD patients (66.67% patients with steatosis were CC, 33.33% were CT and none were TT; 55.91% of those with NASH were CC, 39.78% were CT and 4.3% were TT;  $P = 0.941$ ) and the healthy controls (59.12% were CC, 35.67% CT, 5.21% TT). Likewise, no differences in the *LCT-13910C>T* allele frequencies were noted between the groups (76.95% of the controls, 83.33% of those with steatosis and 75.81% of the NASH patients had the *LCT-13910C* allele;  $P = 0.764$ ). That is, the distribution of the *LCT-13910C>T* polymorphism in the patients with NAFLD was equal to that in the general population.

**Table 1** Demographic, clinical and biochemical characteristics of the non-alcoholic fatty liver disease patients

	Steatosis ( <i>n</i> = 9)	NASH ( <i>n</i> = 93)	<i>P</i> value
Age	55.11 ± 10.3	56.51 ± 10.13	0.692
Men/women ( <i>n</i> )	0% (0)/100% (9)	34.41% (32)/65.59% (61)	0.04 <sup>a</sup>
Type 2 diabetes ( <i>n</i> )	33.33% (2)	60.67% (54)	0.224
Dyslipidaemia ( <i>n</i> )	83.33% (5)	79.78% (71)	1
High-blood pressure ( <i>n</i> )	66.67% (4)	64.04% (89)	1
BMI	31.28 ± 5.79	31.25 ± 5.93	0.969
Fasting glucose (mg/dL)	91.71 ± 9.2	123.14 ± 48.28	0.033 <sup>a</sup>
Insulin (μU/mL)	12.44 ± 4.2	19.92 ± 13.29	0.102
HOMA-IR value ≥ 2.5	57.14%	83.53%	0.115
AST (U/L)	25.14 ± 6.89	38.8 ± 37.99	0.159
ALT (U/L)	40 ± 16.74	50.65 ± 54.99	0.934
GGT (U/L)	56.57 ± 59.9	87.36 ± 96.33	0.185
Total cholesterol (mg/dL)	203.29 ± 54.39	195.31 ± 45.71	0.863
HDL (mg/dL)	53 ± 6.58	46.15 ± 13.42	0.067
LDL (mg/dL)	124.14 ± 51.87	114.89 ± 39.74	0.72
Triglycerides (mg/dL)	130.43 ± 59.19	167.25 ± 82.02	0.258

<sup>a</sup>*P* value < 0.05. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BMI: Body mass index; HDL: High-density lipoprotein; HOMA-IR: Homeostatic Model of Assessment; LDL: Low-density lipoprotein; GGT: Gamma glutamyl transferase; NASH: Nonalcoholic steatohepatitis.

Analysis *via* simple logistic regressions of the associations of the *LCT*-13910C>T polymorphisms with the results of the biochemical tests, components of MetS and severity of liver histology in the NAFLD patients (steatosis and NASH groups) did not reveal any associations (data not shown). Subsequently, we evaluated the patients with NASH (Table 3). In this group (*n* = 93), univariate analysis revealed that the hypolactasia phenotype was associated with higher insulin levels (*P* = 0.027) and greater insulin resistance (*P* = 0.02). No associations were noted between the liver histology parameters (*i.e.*, steatosis, inflammation and fibrosis) and the *LCT*-13910 genotype or phenotype. Moreover, no associations were found between the components of MetS or MetS diagnosis (*P* = 1.0) and the *LCT*-13910 genotype or phenotype.

Table 4 illustrates the logistic regression analysis that was adjusted for gender and age and assessed the independent associations of the *LCT*-13910C>T polymorphism with HOMA-IR, BMI ≥ 30, insulin value and MetS in the NASH patients. Hypolactasia phenotype was associated with a 5-fold increase in insulin resistance (95%CI: 1.35-20; *P* = 0.017). The *LCT*-13910CT genotype conferred a 6.25-fold decrease in insulin resistance (95%CI: 0.04-0.64; *P* = 0.009). In this multivariate regression analysis, we no longer observed an association between hypolactasia and insulin level (even when using the cut-off of > 29.8 μU/mL, *P* = 0.197) after adjusting for gender and age. Similarly, the MetS diagnosis and a BMI ≥ 30 were not associated with the *LCT*-13910C>T polymorphism.

## DISCUSSION

### Key findings

In this transverse clinical study, we were unable to find any differences in the *LCT*-13910C>T polymorphism

expression profile between Brazilian NAFLD patients and healthy controls (*P* = 0.941). Moreover, the presence of the T allele was not able to differentiate steatosis from NASH in NAFLD patients (*P* = 0.764). However, in NASH patients, the hypolactasia phenotype (*i.e.*, the *LCT*-13910CC genotype) was associated with insulin resistance, and conversely, the *LCT*-13910CT genotype conferred protection against its occurrence.

The *LCT*-13910C>T polymorphism prevalence varies among different populations across the globe. The lactase-persistence phenotype (*i.e.*, the *LCT*-13910-CT and *LCT*-13910-TT genotypes) can occur at rates as high as 72% and 73.7% in New Zealand and Sweden, respectively<sup>[13,35]</sup>. In Hungary, the prevalence is 35.9%, and in Caucasian Brazilians, the prevalence is 43.4%<sup>[12,36]</sup>. In contrast, in Chinese and Japanese Brazilians, the lactase-persistence phenotype was not found at all in some published studies<sup>[12,37]</sup>. The *LCT* genotype distribution was also the same in NAFLD patients regardless of the presence of NASH or steatosis only.

In a recent European meta-analysis with 31720 individuals, Kettunen *et al.*<sup>[16]</sup> found that the *LCT*-13910CC genotype was associated with a decreased body mass index (BMI), when compared to *LCT*-13910CT/TT. In an analysis of 17374 Finns, it was observed that when the lactase persistent allele was present, BMI was 0.3 kg/m<sup>2</sup> higher, which corresponds to approximately 1 kg<sup>[16]</sup>. These findings were reproduced by Corella *et al.*<sup>[15]</sup> in a Mediterranean population in which *LCT*-13910CC individuals exhibited a lower risk of obesity, lower body weights, lower BMIs and smaller waist circumferences than *LCT*-13910T-allele carriers. Although the association between the *LCT*-13910C>T genotypes and the diagnosis of full-blown MetS was not significant in the overall analysis in the study, a subgroup analysis revealed a significant association in the subjects with a lactose intake higher than 8 g/d<sup>[15]</sup>. In a cross-sectional

work conducted in the Canary Islands, Almon *et al.*<sup>[17]</sup> demonstrated that subjects with the *LCT*-13910CT and *LCT*-13910TT genotypes exhibited higher odds ratio for MetS than subjects with the *LCT*-13910CC genotype. The authors concluded that the T allele might constitute a nutrigenetic factor that increases the susceptibility to MetS development, and this susceptibility was particularly noted in women<sup>[17]</sup>.

Despite the aforementioned studies that have demonstrated correlations of the CC genotype with decreased BMI, a lower risk of obesity, a lower body weight, and smaller waist circumference compared with the CT and TT genotypes<sup>[15,16]</sup> and the even further increased

higher odds ratio for MetS in individuals with the T allele<sup>[17]</sup>, we could not corroborate these findings in our NAFLD population. Studying only the NASH patients in the univariate analysis, we did not find associations between the *LCT*-13910C>T polymorphism and BMI or MetS diagnoses even after adjusting for gender and age in the multivariate analysis. In fact, the patients with NASH and a genetic profile of persistent lactase activity exhibited less insulin resistance than the patients with hypolactasia. These divergences in our findings could be related to differences in the studied populations and possible positive effects of dairy ingestion on the metabolic profiles of these individuals.

**Table 4** Multivariate logistic regression analysis in non-alcoholic steatohepatitis patients

Factor	OR	95%CI	P value
HOMA-IR value $\geq 2.5$

<sup>a</sup>P value < 0.05. HOMA-IR: Homeostatic Model of Assessment; OR: Odds ratio; BMI: Body mass index; MetS: Metabolic syndrome.

Our studied population consisted only of NAFLD patients, among which the prevalences of MetS components are expected to be higher than those of the overall population. Therefore, firm direct comparisons are precluded. However, a recently published Brazilian study demonstrated that in the general population, the lactase non-persistence genotype subjects exhibit higher prevalences of hypertension ( $P = 0.032$ ) and MetS ( $P = 0.01$ ) than lactase-persistence genotype individuals based on univariate analysis<sup>[38]</sup>. Furthermore, multivariate analyses revealed that lactase persistence was associated with a lower risk for MetS after adjusting for gender, age, BMI and physical activity (OR = 0.462;  $P = 0.009$ ). These data are in line with our findings that demonstrated a favourable profile of MetS components and glucose homeostasis in the NASH patients with lactase persistence. Moreover, in a longitudinal French study encompassing 3575 subjects, Lamri *et al.*<sup>[39]</sup> demonstrated that the C allele was associated with a higher frequency of impaired fasting glycaemia and type 2 diabetes. However, Enattah *et al.*<sup>[40]</sup> were unable to demonstrate that lactase persistence polymorphisms were risk factors for type 1 or type 2 diabetes in the Finnish study. Similar to NASH, polycystic ovary syndrome is also frequently associated with metabolic disturbances, including dyslipidaemia, insulin resistance and central obesity, and NASH often coexists in these patients<sup>[41]</sup>. Lerchbaum *et al.*<sup>[42]</sup> demonstrated a significantly higher prevalence of hypolactasia in polycystic ovary syndrome women, which also corroborates our findings.

Ultimately, we believe that dairy consumption appears to modulate the metabolic profiles of these different populations because of the strong association of the *LCT*-13910 genotype with dairies intake and lactose malabsorption<sup>[11,31,39,43]</sup>. Several studies have highlighted the benefits of dairy and dairy components on MetS components<sup>[18-22,44-46]</sup> and cardiovascular health<sup>[47]</sup>. The

benefits of dairy products may be mediated through several mechanisms, including the following<sup>[23,48]</sup>: The insulinotropic role of whey and its beneficial effect on body weight and fat; the favorable effects of amino acids, medium chain fatty acids, calcium and other minerals found in milk and its derivatives; improvements in insulin sensitivity due to medium chain fatty acids; reductions in the absorption of cholesterol and other fats from fermented products; the probiotic bacteria present in these foods and the associated proteins and peptides; and improvements in weight control, blood pressure and plasma lipids due to lactose, citrate, proteins and peptides. Specifically addressing glucose homeostasis, a hypothetical explanation is that milk and dairy consumption may be associated with an enhanced insulinaemic response, decreased glycemic fluctuations, and increased secretion of glucagon-like peptide 1 and glucose-dependent insulinotropic polypeptide<sup>[49]</sup>.

Experimental models also provide some mechanistic explanations that link dairy consumption with lower incidences of insulin resistance and diabetes<sup>[50]</sup>. Milk components such as rumenic acid, vaccenic acid, phytanic acid and its derivative pristanic acid have been demonstrated to improve insulin resistance through PPAR signalling activation in different rat models<sup>[51-54]</sup>. These findings suggest that dairy consumption could have a role in insulin resistance and NASH management.

However, in our study, there was no association between *LCT*-13910 genotype and the severity of liver histology in the NASH patients. The reason for this finding may be that the pathogenesis of NASH involves a complex multiple parallel hits process in which a number of different events may contribute to liver injury<sup>[55]</sup>. Lifestyle and genetic predisposition remain relevant disease determinants. The consumption of high-calorie diets rich in lipids results in weight gain, obesity and insulin resistance. Moreover, a diet high in carbohydrates (mainly fructose) and saturated fatty acids contributes to the production of excess free fatty acids, whose safe disposal is impaired, which results in oxidative stress and NASH<sup>[56]</sup>. Recent data have also demonstrated a potential role of the microbiota in the induction of insulin resistance and the development of NAFLD/NASH<sup>[57-59]</sup>. The major components of the gut microbiota at the phylum level are *Bacteroidetes* and *Firmicutes*<sup>[60]</sup>. It has been demonstrated that *Firmicutes* levels are elevated in obesity and related diseases, whereas *Bacteroidetes* levels are decreased, which leads to an increase in the *Firmicutes/Bacteroidetes* ratio<sup>[61,62]</sup>. Interestingly, it has been shown that lysozyme-rich milk consumption results in a decline in *Firmicutes* levels (mainly *Clostridia* spp.) and in an increase in *Bacteroidetes* levels over time<sup>[63,64]</sup>. Despite the absence of high levels of lysozyme in the milk of dairy animals, these studies highlighted the potential role of milk and its components in the composition of the microbiome in health and disease.

The main limitations of our study are the lack of alimentary reports from the NAFLD patients to quantify the dairy intakes and the absence of ethnic data because

the prevalence of LCT-13910C>T polymorphisms may vary widely, as has been previously demonstrated<sup>[12]</sup>.

In conclusion, we demonstrate that hypolactasia (*i.e.*, the LCT-13910CC genotype) is associated with a higher insulin resistance frequency in NASH patients. However, further studies that include dairy ingestion reports are needed to elucidate the associations of the lactase-persistence phenotype with MetS and NAFLD/NASH in different populations.

## COMMENTS

### Background

Non-alcoholic fatty liver disease (NAFLD) encompasses a wide spectrum of liver damage that ranges from steatosis to nonalcoholic steatohepatitis (NASH) and cirrhosis in persons without significant alcohol consumption and has a close relationship with metabolic syndrome (MetS). The lactase gene (LCT)-13910C>T polymorphism located upstream of the LCT is tightly associated with lactase persistence. The LCT-13910CT and LCT-13910TT genotypes are associated with the lactase-persistence phenotype, *i.e.*, they render a person a lactose digester, whereas the LCT-13910CC genotype is associated with lactose malabsorption.

### Research frontiers

The role of milk in MetS is not currently clearly defined, and the literature is controversial. Moreover, to our knowledge, there are no published data regarding the LCT-13910C>T polymorphism in patients with NAFLD. Therefore, the authors assessed the expression profile of LCT-13910 genotypes in Brazilian patients with NAFLD in comparison with those of healthy controls to investigate whether the LCT-13910C>T variant could be a predictor of NASH. Furthermore, in NASH patients, the authors analyzed the associations of the lactase-persistence genotype with the results of biochemical tests, components of MetS and the severity of liver histology.

### Innovations and breakthroughs

The authors were unable to find any differences in the LCT-13910C>T polymorphism expression profiles between Brazilian NAFLD patients and healthy controls. Moreover, the presence of the T allele was not able to discriminate steatosis from NASH in NAFLD patients. However, in NASH patients, the hypolactasia phenotype (*i.e.*, the LCT-13910CC genotype) was associated with insulin resistance, and conversely, the LCT-13910CT genotype conferred protection against its occurrence.

### Applications

Specific pharmacological therapy for NASH is still lacking, so the pursuit of high-risk individuals can be a strategy for concentrating efforts on its diagnosis and management. Dairy consumption appears to modulate the metabolic profile because hypolactasia was found to be an independent risk factor for insulin resistance in NASH patients. Further studies that include dairy ingestion reports are needed to elucidate the associations of the lactase-persistence phenotype with MetS and NAFLD/NASH in different populations.

### Terminology

NAFLD: Non-alcoholic fatty liver disease, which encompasses a wide spectrum of liver damage that ranges from steatosis to NASH and cirrhosis in persons without significant alcohol consumption. The MetS components include the following: Fasting glucose  $\geq 110$  mg/dL, triglyceride  $\geq 150$  mg/dL, high-density lipoprotein  $< 40$  mg/dL in men or  $< 50$  mg/dL in women,  $\geq 130$  mmHg systolic or  $\geq 85$  mmHg diastolic pressure and abdominal obesity. The LCT-13910CT and LCT-13910TT genotypes are associated with the lactase-persistence phenotype, *i.e.*, these genotypes render a person a lactose digester, whereas the LCT-13910CC genotype is associated with hypolactasia, *i.e.*, lactose malabsorption.

### Peer-review

The paper indicated that among nonalcoholic steatohepatitis patients, hypo-

lactasia is associated with insulin resistance in Brazil. It is a very interesting and well-written paper.

### Abstract

#### AIM

To build a diagnostic non-invasive model for screening of large varices in cirrhotic hepatitis C virus (HCV) patients.

#### METHODS

This study was conducted on 124 post-HCV cirrhotic patients presenting to the clinics of the Endemic Medicine Department at Mansoura University Hospital for evaluation before HCV antiviral therapy: 78 were Child A and 46 were Child B (score  $\leq 8$ ). Inclusion criteria for patients enrolled in this study was presence of cirrhotic HCV (diagnosed by either biopsy or fulfillment of clinical basis). Exclusion criteria consisted of patients with other etiologies of liver cirrhosis, *e.g.*, hepatitis B virus and patients with high MELD score on transplant list. All patients were subjected to full medical record, full basic investigations, endoscopy, and computed tomography

(CT), and then divided into groups with no varices, small varices, or large risky varices. In addition, values of Fibrosis-4 score (FIB-4), aminotransferase-to-platelet ratio index (APRI), and platelet count/splenic diameter ratio (PC/SD) were also calculated.

### RESULTS

Detection of large varices is a multi-factorial process, affected by many variables. Choosing binary logistic regression, dependent factors were either large or small varices while independent factors included CT variables such as coronary vein diameter, portal vein (PV) diameter, lieno-renal shunt and other laboratory non-invasive variables namely FIB-4, APRI, and platelet count/splenic diameter. Receiver operating characteristic (ROC) curve was plotted to determine the accuracy of non-invasive parameters for predicting the presence of large esophageal varices and the area under the ROC curve for each one of these parameters was obtained. A model was established and the best model for prediction of large risky esophageal varices used both PC/SD and PV diameter (75% accuracy), while the logistic model equation was shown to be  $(PV \text{ diameter} \times -0.256) \text{ plus } (PC/SD \times -0.006) \text{ plus } (8.155)$ . Values nearing 2 or more denote large varices.

### CONCLUSION

This model equation has 86.9% sensitivity and 57.1% specificity, and would be of clinical applicability with 75% accuracy.

**Key words:** Diagnostic model; Large varices; Cirrhotic hepatitis C virus; Computed tomography; Noninvasive variceal diagnosis

**Core tip:** Hepatitis C virus infection is a major global health problem, with over 14% of the Egyptian population currently infected. End-stage liver disease with cirrhosis is commonly complicated by potentially life-threatening esophageal varices, which require regular screening by endoscopy. However, this invasive procedure is burdened by patient non-compliance and possible complications, thus prompting the search for alternative non-invasive yet accurate means of diagnosis. This study group aimed to assess the use of computed tomography to evaluate and grade variceal size, and to compare its diagnostic value with other non-invasive predictors of portal hypertension, such as platelet count to splenic diameter ratio, aminotransferase-to-platelet ratio index, and Fibrosis-4 score.

Elalfy H, Elsherbiny W, Abdel Rahman A, Elhammady D, Shaltout SW, Elsamanoudy AZ, El Deek B. Diagnostic non-invasive model of large risky esophageal varices in cirrhotic hepatitis C virus patients. *World J Hepatol* 2016; 8(24): 1028-1037 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i24/1028.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v8.i24.1028>

## INTRODUCTION

Hepatitis C virus (HCV) represents one of the major health problems affronting the medical community today, with chronic HCV infection affecting approximately 130-170 million people globally, or about 2%-3% of the world's population<sup>[1]</sup>. The largest HCV epidemic is currently found in Egypt, with an estimated national prevalence reported to be 14.7%<sup>[2]</sup>. As with any chronic liver disease, the end stage of chronic HCV infection is cirrhosis, ultimately complicated by portal hypertension, an established contributing factor in the evolution of a variety of complications of cirrhosis including ascites, hepatic encephalopathy, and esophageal varices<sup>[3]</sup>.

Portal hypertension generates development of porto-systemic collaterals, giving rise to esophageal varices (OV), most notably gastroesophageal varices because of their enhanced tendency for bleeding<sup>[4]</sup>. Esophageal varices can be found in 60%-80% of cirrhotic patients<sup>[5]</sup>, with variceal hemorrhage presenting as the most devastating complication of cirrhosis. Because of this dramatic course of events, it is imperative to prevent variceal bleeding either with non-selective beta-blockers or endoscopic variceal ligation<sup>[6]</sup>. However, in spite of recent progress, mortality rate due to bleeding from ruptured esophageal varices remains between 10%-20%<sup>[7]</sup>.

Current guidelines advocate screening for esophageal varices in all cirrhotic patients at the time of diagnosis. Lack of detection of esophageal varices at the first endoscopic evaluation warrants repeat endoscopy annually in patients with decompensated liver cirrhosis and every 2-3 years in patients with compensated cirrhosis<sup>[8]</sup>. Although upper endoscopy is regularly performed and conveys a diminished risk of adverse effects<sup>[9]</sup>, repeated endoscopies are associated with several side effects including aspiration, perforation, and bacteremia<sup>[10]</sup>. Furthermore, these recommendations impose a huge burden on medical resources and branch from expert assumption rather than being evidence-based. In addition to the invasive nature of the procedure and lack of patient compliance restricting its use, there is also a cost-ineffectiveness of this policy in lack of actual detection of varices in many of the patients<sup>[11]</sup>. These considerations have spurred several attempts to identify non-invasive clinical, radiological, and biochemical parameters, used either separately or in conjunction, to determine the presence of portal hypertension and esophageal varices.

Perhaps the best predictor of esophageal varices developed to date is the platelet count to splenic diameter ratio, which proposes linking thrombocytopenia to spleen size by considering that diminished platelet count is probably the result of hypersplenism due to splenomegaly caused by portal hypertension<sup>[12]</sup>. Other parameters have attempted to determine the state of liver tissue with good accuracy by evaluating the extent of fibrosis and cirrhosis as a predictive indicator of progression of portal hypertension, these including

aminotransferase-to-platelet ratio index (APRI), Fibro-index, and Fibrosis-4 score (FIB-4)<sup>[13]</sup>.

Several radiological techniques have also been suggested for evaluation of esophageal varices. Doppler ultrasonography has been used for investigating portal and hepatic hemodynamics but its value in assessment of portal hypertension remains obscure. Although several indices for portal hypertension have been commonly used, inaccuracy remains due to fluctuating variations related to both observer and equipment<sup>[14]</sup>.

Computed tomography (CT) has also been proposed as an evaluation tool for esophageal varices<sup>[15]</sup>. Examination of the correlation between CT findings and endoscopy from previous studies has shown better agreement between variceal size and radiological assessment than with endoscopic interpretation<sup>[16]</sup>. In addition, CT was found to be more desirable in initial screening of esophageal varices in comparison to endoscopy when considering patient preference and cost-effectiveness<sup>[17]</sup>.

Therefore, considering these findings, we aimed to evaluate the use of CT in the diagnosis of esophageal varices, differentiating between small and large varices, and assessing its use in grading the size of varices. In addition, we aimed to compare the value of CT in diagnosis of esophageal varices with other non-invasive predictors of portal hypertension including laboratory indices such as platelet count to splenic diameter ratio, APRI, and FIB-4.

The objective of the study was to build a diagnostic non-invasive model for screening of large esophageal varices in cirrhotic HCV patients.

## MATERIALS AND METHODS

### Ethical approval

Informed consent was taken from each patient. The research protocol was approved by the Ethical Committee of Faculty of Medicine, Mansoura University.

### Study design

This comparative cross sectional study included subjects presenting to the Endemic Medicine Department clinic at Mansoura University Hospital for evaluation before HCV antiviral therapy during the period between December 2014 and June 2015. Inclusion criteria for patients enrolled in this study was presence of cirrhotic HCV as diagnosed either by biopsy (F4) or on the basis of clinical evaluation combined with laboratory findings and ultrasonography. Exclusion criteria consisted of patients with other etiologies of liver cirrhosis or those ineligible for the HCV therapy program, *e.g.*, HBV, Child C decompensated patients, and patients with high MELD score on transplant list. Patients with liver cirrhosis were then stratified according to endoscopic findings into groups with either no varices, small varices, or large varices.

The indication for CT imaging in the majority of cases was for evaluation of focal lesions for hepatocellular

carcinoma while the entire laboratory assessment was done as a part of the HCV therapeutic evaluation program.

### Clinical and laboratory workup

All subjects were HCV infected and thus subjected to complete laboratory assessment before antiviral therapy, including complete blood picture, PCR for HCV, alpha fetal protein (AFP), alanine and aspartate transaminases, albumin, bilirubin, INR, creatinine, TSH, as well as abdominal ultrasound and biopsy in selected cases.

Those with findings of F4 on biopsy or showed clinical, laboratory, or ultrasonographic features of cirrhosis were selected for this study, to be then classified into case and control groups.

Cases were patients with post-HCV liver cirrhosis with esophageal varices on endoscopy, divided into two groups with either small or large varices, while the control group was patients with post-HCV liver cirrhosis without varices.

### Gastroscopy for varices evaluation and therapy

Using slight sedation with IV midazolam administered just before the session, patients were stratified by risk of first variceal hemorrhage into either high-risk patients, *i.e.*, those with medium/large varices, or low risk patients, *i.e.*, those with small varices occurring in a Child A or B patient. Trials have shown that patients with medium/large varices can be treated with either non-selective  $\beta$ -blockers (propranolol, nadolol) or esophageal band ligation.

### Calculation of non-invasive parameters (APRI, FIB4, platelet count/splenic diameter)

$APRI = \{[AST \text{ Level (IU/L)}] / [AST \text{ (upper limit of normal) (IU/L)}] \times 100\} / \text{Platelet count (} 10^9/\text{L)}^{[18]}$

$FIB4 = [\text{age (years)} \times AST \text{ (IU/L)}] / [\text{PLT (} \times 10^9/\text{L)}] \times [\sqrt{ALT \text{ (IU/L)}}]^{[19,20]}$

$\text{Platelet count (PC) to spleen diameter (SD) ratio} = \text{PC (N}/\mu\text{L)} / \text{the maximum bipolar diameter of the spleen (mm)}^{[21]}$

These parameters were selected based on the criteria of being simple routine laboratory tests that are also inexpensive.

### Multi-slice detector CT

For all patients, multi-slice detector CT (MDCT) scan of the abdomen and pelvis was performed on a 16-MDCT scanner (Brilliance, Philips) using a tube collimation of 16 mm  $\times$  1.5 mm with overlapping reconstruction at 2 mm slice thickness and 0.8 mm increment.

Examination was carried out using a multiphasic liver protocol starting with non-contrast examination. Arterial phase examination was carried out using bolus tracking technique and post-threshold delay of 12 s. Low osmolar iodinated intravenous contrast [Omnipaque™ (iohexol) 350, GE Healthcare] was injected using a power injector [MEDRAD Vistron CT® Injector, Medrad] administered in a dose of 1.5 mL/kg at a flow rate of 4-5 mL/s. Portal phase examination was carried out 40 s after threshold

and delayed phase examination after 5 min.

Images were reviewed on a dedicated workstation (Extended brilliance work space, Philips) in axial, coronal and sagittal planes. Images were evaluated for the following parameters: Maximum short axis diameter of the largest visible esophageal varix, diameter of coronary vein, diameter of the paraumbilical vein, maximum short axis diameter of the portal vein at the portahepatis, presence of ascites, and maximum height of the spleen. An esophageal varix was defined as an enhancing intramural nodular tubular structure (which may be bulging into the lumen of the esophagus or runs within the inner esophageal mucosa).

### Statistical analysis

Data were statistically analyzed using the Statistical Package for Social Science (SPSS) version 20. The quantitative data were presented in the form of mean and standard deviation. One-way Anova was used to compare between the three groups.  $\chi^2$  test was used to compare the qualitative data. Receiver operating curve (ROC) was done to determine a cut-off point predicting large varices. Logistic regression was done to construct a model for predicting the occurrence of large varices. Significance was considered at *P* value of 0.05.

## RESULTS

### Patient characteristics

A total of 124 patients with hepatic cirrhosis were included in this study. The mean age of the included patients were  $56.52 \pm 5.759$  (range 37-66) years with 26 patients (52%) being males. The etiology of cirrhosis in all included patients was HCV. Most patients (59.7%) had esophageal varices and 50 patients (40.3%) had no varices. According to gastroscopy, among those who had esophageal varices, 28 patients (22.6%) were classified as having small varices and 46 patients (37.1%) had large varices. According to Child-Turcotte-Pugh Classification, 78 patients (62.9%) were classified as class A, proven by liver biopsy and 46 (37.1%) as class B. There were 34 patients with diuretic responsive ascites (27.5%) and 90 patients (72.5%) without ascites. Ten patients (8.06%) had hepatocellular carcinoma less than 3 cm (Table 1).

### Comparison between non-invasive parameters in the studied groups

The values of Fib4 and APRI were significantly higher in cirrhotic patients with large esophageal varices than those in cirrhotic patients without varices or with small esophageal varices (*P* = 0.001). Comparison of values of the PC/SD ratio between groups demonstrated a significant decrease in cirrhotic patients with large esophageal varices in comparison to cirrhotic patients without varices or with small esophageal varices (*P* = 0.001).

Regarding the values of CT parameters, there was a demonstrable difference between groups, as the

cirrhotic patients with esophageal varices had higher values of portal vein diameter (PVD) and splenic vein diameter (SVD) than cirrhotic patients without varices (*P* = 0.012 vs 0.284, respectively). A coronary vein threshold  $\geq 7$  mm as measured by CT was present in 16 of these cirrhotic patients (12.7%), of which 4 patients were without varices, 4 patients had small varices, and 8 patients had large varices (*P* = 0.026). While the measurement of lieno-renal shunt by CT was  $\geq 12$  mm, there were 8 cirrhotic patients (6.45%) without esophageal varices (*P* = 0.006). In addition, CT significantly differentiated between presence and absence of OV. When CT reported that there were no variceal findings in 50 patients (40.3%), 46 of these were actually without varices and 4 patients had esophageal varices; CT indication of varices in 74 patients (59.7%) was confirmed in 70 of these patients who actually had OV (*P* = 0.001) (Table 2).

### Non-invasive prediction of large risky esophageal varices

ROC curve was plotted to determine the accuracy of non-invasive parameters for predicting the presence of large esophageal varices rather than presence of varices and the area under the ROC curve for each one of these parameters was obtained. A FIB-4  $\geq 3.13$  had a sensitivity of 71.7% and a specificity of 50% with an area under the ROC curve of 0.585 (95%CI: 0.442-0.728). The area under the ROC curve for APRI was 0.558 (95%CI: 0.417-0.699). An APRI value of  $\geq 1.083$  had a sensitivity of 63% and specificity of 46.4%. A PC/SD ratio of  $\leq 806.93$  had 75% sensitivity and 47.8% specificity, with the area under the ROC curve being 0.558 (95%CI: 0.417-0.699). In addition, the PVD as measured by CT had a sensitivity of 71.1% and specificity of 37% at cutoff  $\geq 12.5$  mm with an area under the ROC curve of 0.560 (95%CI: 0.425-0.630) (Table 3). ROC curves are demonstrated in Figure 1.

### Model for detecting large risky varices

The detection of large risky esophageal varices on the verge of rupture is a multi-factorial process affected by many variables. Statistically, the research team chose to use binary logistic regression. Dependent factors were either large or small varices while the independent factors measured by CT were coronary vein diameter, PVD and lieno-renal shunt in addition to various laboratory parameters including FIB-4, APRI, and PC/SD. The accuracy of this model was about 62.2%. After removal of insignificant predictors, *i.e.*, APRI, FIB-4, coronary vein diameter, and lieno-renal shunt, the accuracy of the model becomes 75%. If only PC/SD was used, the accuracy was 73%, while use of both PC/SD and PVD raised the accuracy to 75.7% (Tables 4-6).

## DISCUSSION

A major health problem facing the medical community

**Table 1** Patients characteristics *n* (%)

Variables	All patients ( <i>n</i> = 124)	No varices ( <i>n</i> = 50)	Small varices ( <i>n</i> = 28)	Large varices ( <i>n</i> = 46)	<i>P</i> value

mortality rate of 10%-20%<sup>[7]</sup>.

Current guidelines advocate screening for esophageal varices using endoscopy in all cirrhotic patients at the time of diagnosis<sup>[8]</sup>. However, the invasive nature and subsequent complications associated with this maneuver have prompted the search for further accurate and

non-invasive techniques to evaluate the presence of esophageal varices resulting from portal hypertension in these cirrhotic patients.

Founded on the basis that liver fibrosis is the primary factor enhancing hepatic resistance resulting in portal hypertension, use of non-invasive serum markers of liver

fibrosis has shown favorable outcomes when predicting presence of esophageal varices<sup>[21]</sup>. Expected findings from previous studies have demonstrated that scores of FIB-4 and APRI were significantly higher in cirrhotic patients with or without portal hypertension when compared to healthy volunteers or patients with chronic liver disease<sup>[3]</sup>. In our study, significantly higher values of FIB-4 and APRI were also found in cirrhotic patients with large esophageal varices in comparison to those without varices or with small esophageal varices ( $P = 0.001$ ).

Although several studies have previously demonstrated a strong relation between platelet count and splenic diameter with presence of esophageal varices<sup>[22,23]</sup>, the decreased platelet count present in chronic liver disease may be the result of several factors other than portal hypertension, including diminished mean platelet life span, reduced production of thrombopoietin, or myelotoxic effects of hepatitis viruses<sup>[24]</sup>. An additional proposed underlying mechanism of "platelet exhaustion" states that hyperdynamic circulation causes platelet damage during intravascular activation with consequent hypofunction. However, the presence of splenomegaly in patients with cirrhosis is, in all likelihood, derived from vascular derangement mainly resulting from portal hypertension<sup>[25]</sup>.

Consequently, Giannini *et al*<sup>[26]</sup> aimed to chart a new parameter bridging thrombocytopenia to splenomegaly so as to originate a variable that takes into account the diminished platelet count probably due to hypersplenism attributed to portal hypertension. A study performed by Giannini *et al* demonstrated that a PC/SD ratio cutoff

< 909 had a positive predictive value of 96% and negative predictive value of 100%<sup>[26]</sup>. These data have been subsequently confirmed in a number of recent studies<sup>[27-30]</sup>; however, these studies focused mainly on presence of varices as a whole.

In the current study, our main target was detection of large risky varices subject to impending rupture. Comparison of values of PS/SD ratio between studied groups showed significant decrease in cirrhotic patients with large esophageal varices compared to those without varices or with small esophageal varices ( $P = 0.001$ ). These findings are in concordance with several previous studies demonstrating a similar significant correlation between platelet count/splenic size ratio with stages according to Child-Turcotte-Pugh classification, extent of ascites, and size of esophageal varices<sup>[31,32]</sup>.

Findings indicative of portal hypertension can also be commonly detected with use of CT imaging, these including, in addition to splenomegaly and ascites, the presence esophageal varices, augmentation of portal vein, and existence of collateral vessel enlargement<sup>[33]</sup>. Several previous studies have investigated the interconnection between findings from both CT and endoscopy, and have demonstrated an agreement between variceal size and radiologic interpretations rather than between variceal size and endoscopic valuation<sup>[16,34]</sup>. However, CT scanning cannot adequately differentiate between small and large varices nor can it detect red signs on small varices that are also subject to a higher risk of bleeding<sup>[35]</sup>.

Comparison of CT parameters between groups in this study demonstrated evident differences, as cirr-

hotic patients with esophageal varices had higher values for PVD as well as SVD when compared with cirrhotic patients without varices (0.0012 and 0.284 respectively). In addition, CT significantly differentiated between presence and absence of esophageal varices. Interpretation of CT imaging showing no varices in 50 patients (40.2%) proved accurate in 46 of these patients who truly had no varices while only 4 patients indeed had esophageal varices as detected by endoscopy. Furthermore, demonstration of varices by CT in 74 patients (59.7%) was correct in 70 of these patients who had endoscopic evidence of esophageal varices. These results indicate that CT is almost as effective in detection of esophageal varices as endoscopy, hence possibly providing an acceptable substitute to endoscopy in detection of esophageal varices in cirrhotic patients.

To evaluate the efficacy of these non-invasive parameters in detecting presence of large esophageal varices, our study group plotted a ROC curve and the area under the curve was obtained for each individual parameter. FIB-4 score of  $\geq 3.13$  was shown to have a sensitivity of 71.7% and a specificity of 50% with an area under the ROC curve of 0.585 (95%CI: 0.442-0.728), which are higher than those for APRI which at a value of  $\geq 1.083$  had a sensitivity of 63% and a specificity of 46.4%, with the area under the ROC curve being 0.550 (95%CI: 0.442-0.728). In addition, a PC/SD ratio of  $\leq 806.93$  had a sensitivity of 75% and specificity of 47.8%, while PVD measurement by CT had 71.1% sensitivity and 37% specificity at a cutoff of  $\geq 12.5$  mm, with area under the ROC curve of 0.560 (95%CI: 0.425-0.630). These results indicate that use of CT in detection of large esophageal varices offers results comparable to those provided by both FIB-4 and APRI values, as well by evaluation of PC/SD ratio.

Based on these data, we proposed a non-invasive model for the prediction of large esophageal varices in patients with cirrhosis. Being a multi-factorial process, the detection of large varices is affected by many variables. In order to construct a model for the prediction of large esophageal varices, the research team chose binary logistic regression as a statistical means of evaluation. Dependent factors were either large or small varices, while independent factors were coronary vein diameter, PVD, lienorenal shunt, FIB-4, APRI, and PC/SD. The accuracy of this model was shown to be about 62.2%. However, after removal of insignificant factors such as APRI, FIB-4, coronary vein diameter, and lienorenal shunt, accuracy of the model becomes 75%. With use of PC/SD alone, the model accuracy was shown to be 73%, but combined use of both PC/SD and PVD offered an accuracy of 75.7% for prediction of large risky esophageal varices.

In conclusion, endoscopy continues to be the mainstay in diagnosis of esophageal varices, in spite of its invasive nature, unacceptability by a large number of patients, and diverse side effects and complications; however, there remains a need for further non-invasive, effective tools for detection of large esophageal varices

which may be subject to imminent rupture and hemorrhage in patients with cirrhosis. Thus, CT scanning may afford an adequate alternative to endoscopy in diagnosis of esophageal varices in patients afflicted with cirrhosis, as it appears to offer similar diagnostic value for large esophageal varices as other non-invasive parameters, with the added benefit of detection of other pathology of the liver, such as various hepatic lesions or masses, most notably hepatocellular carcinoma. In addition, parameters easily detectable by CT, such as PC/SD and PVD, form the basis for the model proposed by this study group, which provides accuracy of 75% for detection of large risky esophageal varices threatening to rupture in cirrhotic patients.

## COMMENTS

### Background

Chronic hepatitis C virus (HCV) infection currently affects approximately 130-170 million people globally, or about 2%-3% of the world's population, with the largest HCV epidemic currently found in Egypt, affecting about 14.7% of the Egyptian population. The end stage of chronic HCV infection is cirrhosis, often complicated by esophageal varices. While upper gastroscopy remains the gold standard for diagnosis of esophageal varices, several disadvantages of this invasive procedure have prompted the search for non-invasive parameters to determine the presence of esophageal varices.

### Research frontiers

Several parameters have emerged as predictors of esophageal varices including platelet count to splenic diameter ratio, aminotransferase-to-platelet ratio index (APRI), Fibroindex, and Fibrosis-4 score (FIB-4) as well as a number of radiological techniques including Doppler ultrasonography and computed tomography (CT). However, all of these elements are plagued by limitations. The research hotspot is to acknowledge these various parameters and their limitations to help other peers understand the background behind the search for an accurate.

### Innovations and breakthroughs

The search for a non-invasive method to accurately diagnose the presence of esophageal varices has been advancing in recent years. The present study involved a significant number of cirrhotic patients who underwent upper gastroscopy followed by CT imaging in addition to a series of simple inexpensive investigations to determine values for APRI, FIB-4, and platelet count/splenic diameter ratio (PC/SD). Patients undergoing the latter procedures were much more willing to comply when compared to those consenting for endoscopy, giving further support that endoscopy, in spite of its established benefits, remains a costly, uncomfortable procedure for many patients who prefer to avoid this invasive maneuver in any way possible, particularly when other accurate diagnostic tools are readily available.

### Applications

Data from this study suggest that CT scanning may afford an adequate alternative to endoscopy in diagnosis of esophageal varices in cirrhotic patients. In addition, parameters easily detectable by CT, such as PC/SD and portal vein diameter, form the basis for the model proposed by this study group.

### Terminology

Chronic HCV infection is a long-standing infection of the liver with HCV culminating into development of cirrhosis and its associated complications, including portal hypertension and esophageal varices. Esophageal varices are abnormally enlarged veins in the lower part of the esophagus, which may leak or even rupture, possibly causing life-threatening bleeding. Endoscopy continues to be the mainstay in diagnosis of esophageal varices.

### Peer-review

The work is really valuable occult blood in stool is always a diagnostic challenge.

Besides esophageal varices, acute mucosa lesions, venous bleeding caused by portal hypertension in any site of the gastrointestinal tract are equally causes.

## Abstract

### AIM

To evaluate liver resections without Pringle maneuver, *i.e.*, clamping of the portal triad.

### METHODS

Between 9/2002 and 7/2013, 175 consecutive liver resections ( $n = 101$  major anatomical and  $n = 74$  large atypical  $> 5$  cm) without Pringle maneuver were performed in 127 patients (143 surgeries). Accompanying, 37 wedge resections (specimens  $< 5$  cm) and 43 radiofrequency ablations were performed. Preoperative volumetric calculation of the liver remnant preceded all anatomical resections. The liver parenchyma was dissected by water-jet. The median central venous pressure was 4 mmHg (range: 5-14). Data was collected prospectively.

### RESULTS

The median age of patients was 60 years (range: 16-85). Preoperative chemotherapy was used in 70 cases (49.0%). Liver cirrhosis was present in 6.3%, and liver steatosis of  $\geq 10\%$  in 28.0%. Blood loss was median 400 mL (range 50-5000 mL). Perioperative blood transfusions were given in 22/143 procedures (15%). The median weight of anatomically resected liver specimens

was 525 g (range: 51-1850 g). One patient died post-operatively. Biliary leakages ( $n = 5$ ) were treated conservatively. Temporary liver failure occurred in two patients.

# CONCLUSION

Major liver resections without Pringle maneuver are feasible and safe. The avoidance of liver inflow clamping might reduce liver damage and failure, and shorten the hospital stay.

**Key words:** Liver resection; Pringle maneuver; Blood loss

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This retrospective cohort study on 175 consecutive liver resections ( $n = 101$  major anatomical and  $n = 74$  large atypical  $> 5$  cm) shows that major liver resections without Pringle maneuver are feasible and safe. The avoidance of liver inflow clamping might reduce liver damage and failure, and shorten the hospital stay.

Maurer CA, Walensi M, Käser SA, Künzli BM, Lötscher R, Zuse A. Liver resections can be performed safely without Pringle maneuver: A prospective study. *World J Hepatol* 2016; 8(24): 1038-1046 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i24/1038.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i24.1038>

# INTRODUCTION

Massive haemorrhage is a key factor associated with poorer prognosis and outcome of patients undergoing liver resection<sup>[1,2]</sup>. The amount of blood loss correlates with postoperative morbidity and mortality<sup>[3]</sup>. Moreover, blood transfusion is linked to a decrease in cancer free survival<sup>[4]</sup>. Hence, it is a major goal to minimize the blood loss during liver resection. There are three main phases during liver resections when bleeding may occur: The liver mobilisation phase, the parenchymal dissection phase and the revascularization phase<sup>[1]</sup>. Portal triad clamping (PTC), also known as Pringle maneuver<sup>[5]</sup>, is the most widely used technique to reduce bleeding during the parenchymal dissection phase. In addition, vascular clamping can also be applied to control venous backflow<sup>[6,7]</sup>. Thus, total hepatic vascular exclusion can be achieved when combining PTC with clamping of the liver veins or the inferior vena cava cranial and caudad of the liver<sup>[8]</sup>. Further techniques to minimize intraoperative blood loss such as hypoventilation<sup>[9]</sup> and reduction of the central venous pressure (CVP)<sup>[10]</sup> have been developed over the last decades.

Although partial or complete vascular clamping results in reduction of blood loss, there are concerns regarding ischemia/reperfusion (I/R) injury to the liver remnant mediated by cytokines and reactive oxygen species<sup>[11,12]</sup>. Therefore, various attempts have been made to decrease

the I/R-injury associated with prolonged clamping of liver vessels: Use of drugs<sup>[13]</sup>, *in situ* cooling<sup>[14]</sup>, intermittent clamping<sup>[15,16]</sup>, ischemic preconditioning<sup>[17]</sup> and ischemic postconditioning<sup>[18]</sup>. Ischemic preconditioning involves I/R for a short period of time before exposure to prolonged I/R. The molecule nitric oxide plays a critical role in the early<sup>[11,12]</sup> and late phases<sup>[11]</sup> of ischemic preconditioning. Furthermore, during I/R-injury neutrophil and kupffer cell-induced oxidative stress, hepatic circular disturbance as well as inflammatory processes occur. Circular dysfunction is based on sinusoidal endothelial damage<sup>[19]</sup> as well as unbalance of vasoconstrictive and vasodilating transmitters such as endothelin<sup>[20]</sup>, tumor necrosis factor  $\alpha$ <sup>[21]</sup>, and interleukins<sup>[22]</sup>. Other mediators and pathways, *e.g.*, CD39 and purinergic signalling, are believed to play a role in hepatic ischemia and reperfusion injury<sup>[23]</sup>.

Thus, the molecular hepatic system is far better understood today and recent advances in surgical strategies and perioperative care have made liver resections much safer, allowing low mortality and morbidity in experienced hands. However, the question remains whether the risk of resective liver surgery can be further reduced by complete avoidance of any vascular clamping of the liver remnant and hence by minimizing the I/R injury.

The purpose of this retrospective single center data analysis was to assess the feasibility and safety of major liver resections without any Pringle maneuver or its variations. In the second step, we were interested in any differences in outcome between three subgroups: Anatomical resections, atypical resections and the combination of both, *i.e.*, the combination of anatomical and atypical resection.

# MATERIALS AND METHODS

## Study population

From September 2002 through July 2013, a prospective database was established including 175 liver resections [anatomical resections ( $n = 101$ ) and large atypical resections (specimens  $> 5$  cm in at least one diameter,  $n = 74$ )] which were performed at the occasion of 143 consecutive liver surgeries. Twenty-five patients had two stage procedures, 2 patients had 3 or more staged liver resections. The indications for these 143 liver surgeries were liver metastases ( $n = 91$ , from the following primaries: 73 colorectal cancer, 2 ovarian, 5 breast, 1 gallbladder, 1 esophageal, 1 stomach, 1 leiomyosarcoma, 1 melanoma, 2 gastrointestinal stroma tumor, and 4 with unknown primary), hepatocellular carcinoma ( $n = 11$ ), follicular nodular hyperplasia ( $n = 4$ ), liver hemangioma ( $n = 9$ ), carcinoma of the gallbladder ( $n = 4$ ), cholangiolar carcinomas ( $n = 8$ ), liver adenomas ( $n = 4$ ), hepaticolithiasis ( $n = 4$ ), echinococcal cysts ( $n = 5$ ), benign liver cysts ( $n = 2$ ) and one sclerotic steatohepatitis. Patients' characteristics were summarized in Table 1. The extent of hepatectomy was depending on tumor size and localization, severity of liver steatosis and cirrhosis, age, nutritional status, preoperatively determined liver function and preopera-

tive chemotherapy. The various extents of anatomical resections were classified according to Brisbane nomenclature<sup>[24]</sup> and were shown in Table 2.

### Intraoperative anesthesia management

Surgery was generally performed under low central venous pressure (LCVP). Therefore, the patient's internal jugular vein was cannulated using a dual-channel catheter and CVP was continuously measured. Values below 5 mmHg were targeted by limiting the volume of crystalloid infusion (lactated Ringer) and stimulating diuresis with furosemide (10-20 mg *i.v.*). At the same time, mean arterial blood pressure, determined within the radial artery, was maintained above 60 mmHg by intravenous

infusion of norepinephrine (0-10  $\mu$ g/min). During dissection of liver parenchyma intermittent positive pressure ventilation was reduced to an end-expiratory level of zero mmHg to further minimize the CVP.

### Surgical procedures

Following an intravenous antibiotic single shot prophylaxis, either a roof-top or midline abdominal incision without thoracotomy was used in all patients. After exclusion of extrahepatic intraabdominal tumor spread by exploration of the abdominal cavity and the hepatoduodenal ligament, careful visual and bimanual examination of the liver was performed. At least partial mobilization of the liver including dissection of round and falciforme ligament was done in almost all procedures. Inferior hepatic veins were dissected for hemihepatectomies and/or segment 1 resections, and as necessary in other types of resection. Intraoperative ultrasonography of the liver was systematically done to accurately determine the number and location of liver tumors and their relation to hepatic blood vessels and bile ducts. A Tru-Cut<sup>®</sup>-needle (CareFusion Temno needle 14G, 11 cm, distributed by Admedics, Zuchwil, Switzerland) biopsy of grossly normal liver was sent to frozen section to assess the grades of steatosis and cirrhosis.

Blood vessels of the liver were clamped and dissected from the later liver specimen, only. Temporary or intermittent clamping of vascular structures of the liver remnant or of the liver hilum has been strictly avoided in all patients. And, neither ischemic preconditioning nor

ischemic postconditioning has been used in any of the patients. Only twice, an anterior approach according to Launois<sup>[25]</sup> was necessary due to a large tumor mass of the right liver lobe.

In all surgeries, the liver parenchyma was cut by means of water-jet dissection. The hence visualized intrahepatic blood vessels and bile ducts were dissected between ligatures or metal clips, small ones were electro-coagulated. The resection surface was treated punctually by argon plasma coagulation and checked for small bile leaks using white gauzes. The resection surface was then covered by the fibrin-based hemostyptic Tachosil® or Beriplast® (Takeda/Nycomed, Basel, Switzerland). In all patients a silicone drain (EasyFlow®, Teleflex Medical GmbH, Kernen, Germany) without suction was inserted.

### Perioperative assessment of liver function

The liver function was assessed by measurement of indocyanine green (ICG) clearance<sup>[26]</sup>. The dye ICG is metabolized and eliminated by the liver, only. Therefore, their elimination velocity is directly corresponding with the functional capacity of the liver. Plasma disappearance rate (range of normal values from 18%-25%) of ICG and the residual ICG after 15 min (R15, normal range between 0%-10%) were examined pre-, intra- and post-operatively. At the beginning of the series, 6 patients had measurement of galactose elimination capacity (GEC) instead of ICG-clearance. No intra- or postoperative controls of GEC were performed at that time. Additionally, various serum parameters were measured repeatedly, most of them daily.

The volumina of total functional liver and the anticipated functional liver remnant (FLR) were calculated by computed tomography (CT), when a resection volume of more than 40% of the total functional liver volume was anticipated. Twenty percent to 25% of total functional liver volume was regarded as a sufficient FLR in an otherwise healthy and non-steatotic liver, and 30%-40% in a steatotic or chemotherapeutically pretreated liver, respectively. In advance of 8 anatomical liver resections, induction of an atrophy-hypertrophy complex by embolization or ligation of right or left portal vein was regarded necessary. One patient underwent preoperative chemoembolization. Patients with liver cirrhosis Child-Pugh stage B were not considered candidates for surgery, and stage A patients ( $n = 9$ ) had  $\leq 2$  liver segments resected.

### Outcome measures and perioperative management

Intraoperative blood loss was calculated by adding the blood volume in the suction device plus the blood kept in towels. The indications for blood transfusion were determined individually, according to patients' preoperative heart status and haemoglobin. Generally, patients with ASA-scores 1 or 2 did not receive blood transfusions before the haemoglobin decreased below a value of 80 g/L. For patients with coronary heart disease or hemodynamic instability, the administration of blood

transfusion was less restrictive. Blood transfusions referred to the total time of hospital stay.

Postoperatively, patients were closely monitored at the intensive care unit (ICU). The Simplified Acute Physiology Score (SAPS) II was used to assess the severity of illness in intensive care patients<sup>[27]</sup>. The SAPS II predicts the risk of hospital mortality and provides an reliable estimation of the risk of death<sup>[27]</sup>.

Bilirubin content was measured from the silicon drainage tube at days 2 and 4, or daily when the drained fluid was suspicious for bile leak. Bile leakage was defined as suggested by Koch *et al.*<sup>[28]</sup> as bilirubin concentration in the drain fluid at least 3 times the serum bilirubin concentration on or after postoperative day 3; or further as the need for radiologic or operative intervention resulting from biliary collections or biliary peritonitis<sup>[28]</sup>.

Resected specimens were weighed immediately after removal. Specimens of malignant neoplasias were sent to the department of pathology for marking the resection margins with ink before formaline fixation.

Liver cirrhosis was defined as F4 fibrosis according to the METAVIR score<sup>[29]</sup>.

### Statistical analysis

Data in this study are presented as median and range or as mean  $\pm$  standard error of mean. Statistical analysis of data was performed using the GraphPad PRISM6 software (GraphPad Software Inc., San Diego, CA, United States). Comparisons of continuous variables between groups were analyzed using one-way ANOVA analysis for multiple comparisons. Categorical variables were compared by chi-square test ( $\chi^2$  test). Values of  $P < 0.05$  are considered statistically significant.

## RESULTS

Data related to the operative procedure such as operation time, CVP, blood loss and substitution, length of ICU stay, SAPS, and specimen weight is summarized in Table 3. Data are presented as total of the  $n = 143$  liver surgeries and as subgroups according to the types of resection. From the 22 patients needing perioperative blood transfusions, 7 received them intraoperatively, 1 preoperatively and 14 postoperatively.

In patients with provided preoperative volumetry of the liver, *i.e.*, patients with anticipated minimum resected volume of  $\geq 40\%$  of total functional liver volume, the median effectively resected functional volume was 53% (20%-76%). A R0-resection at the liver site could be achieved in 98/114 (86.0%) procedures for malignant liver disease. No local R2-resection did occur.

### Laboratory results

Perioperative increases or decreases of relevant laboratory parameters are shown in Table 4, as total and as subgroups according to the types of resection. Table 5 summarizes the ICG-measurements preoperatively, intraoperatively immediately upon removal of the speci-

<sup>1</sup>Since some patients had simultaneously more than 1 resection, the percentage of the perioperative need for ECs is calculated per number of procedures. P-values were calculated, comparing the variable of interest in between the different resection groups (Anova one-way analysis Kruskal-Wallis);

<sup>2</sup>Continuous variables are expressed as median (range), except presented as mean ± SEM; <sup>3</sup>Denote statistical significance among resections in the group of anatomical, atypical, and combined resections. CVP: Central venous pressure; EC: Erythrocyte concentrate; ECU: Erythrocyte concentrate unit; ICU: Intensive care unit; SAPS: Simplified acute physiology score.

mens and on postoperative day 2, again as total and as subgroups according to the type of resection. All 6 patients with preoperatively measured GEC showed values within the normal range. From further 22 patients, only the preoperative ICG-testing was available and resulted as normal (data not shown).

### Morbidity and mortality

There was one death in our series due to a preoperatively unknown high-grade stenosis at the origin of the superior mesenteric artery with consecutive extended mesenteric infarction in the postoperative course. Hence, in-hospital mortality was 1/143 procedures (0.7%).

The following major procedure-specific complications (9/143 procedures, 6.3%) occurred: 1 hemorrhage on postoperative day 9 after right hemihepatectomy in a patient needing therapeutic dosages of heparin, 5 biliary leakages treated conservatively and 2 temporary liver failures. From the later, one occurred in a patient after right hemihepatectomy who suffered from ischemic colon perforation, fecal peritonitis and multiorgan dysfunction. Another patient with extended left hemihepatectomy including segment 1 and includes hepatic artery and bile duct reconstruction for a Klatskin tumor developed intercurrent portal vein thrombosis with prolonged hepatic insufficiency. Relief was achieved by insertion of a portal stent. Finally, 1 patient with right hemihepatectomy developed postoperative peritonitis from an accidental small bowel leak, needing reintervention and laparostomy. No hepato-renal syndrome did occur.

Overall, the following advanced grades of complications according Dindo *et al.*<sup>[30]</sup> were encountered: 2 patients with grade IIIA, 4 with grade IVB and 1 with grade V complication.

## DISCUSSION

During hepatectomy, portal triad clamping developed by Pringle<sup>[5]</sup> is still commonly applied today as a routine procedure and gold standard to limit haemorrhage worldwide<sup>[18,31-35]</sup>. Clamping of the hepatoduodenal ligament and hence control of the hepatic vascular inflow is thought to reduce blood loss and to avoid blood transfusions<sup>[5]</sup>, both associated with increased perioperative morbidity and mortality<sup>[4,36,37]</sup> as well as impaired long-term outcome<sup>[34]</sup>.

Albeit the huge importance of this topic, only few studies investigated the value of Pringle maneuver in the past. No randomized study using a standard Pringle maneuver could be found in literature. And to our knowledge, only three randomized trials comparing liver resections with or without intermittent Pringle maneuver were performed so far<sup>[38-40]</sup>. The value of the intermittent Pringle maneuver is even more questionable, since these studies report conflicting results. Therefore, a very recent paper from Hoekstra *et al.*<sup>[6]</sup> was entitled "vascular occlusion or not during liver resection: The continuing story".

### Feasibility and safety of liver resections without Pringle maneuver

In the present paper, a consecutive series of major liver resections is reported without any Pringle maneuver during the total operation time in all procedures. Accordingly, a conversion to Pringle maneuver as a salvage clamping was necessary in none of the patients. Furthermore, only a minor number of patients needed perioperative blood transfusions and in-hospital-mortality was minimal with 0.7%. Hence, the feasibility and safety

**Table 4 Perioperative alterations of laboratory parameters, shown as total and as subgroups according to the types of resection**

Serum parameters	Total (n = 143)	Anatomical resections (n = 77)	Atypical resections > 5 cm (n = 50)	Combination of ana-tomical and atypical resections > 5 cm (n = 16)	P-values
	Median $\Delta$ -values <sup>1</sup> (ranges)	Median $\Delta$ -values <sup>1</sup> (ranges)	Median $\Delta$ -values <sup>1</sup> (ranges)	Median $\Delta$ -values <sup>1</sup> (ranges)

<sup>1</sup>Median values and range of data are presented. As sensitive indicator for liver function the retention rate after 15 min (R15) and the plasma disappearance rate (PDR) were evaluated; <sup>2</sup> $\Delta$  values of R15 and PDR were determined by the difference of preoperative and postoperative day 2 values. P values were calculated, comparing the variable of interest in between the different resection group (one-way Anova analysis of variance); <sup>3</sup>Denote statistical significance among resections in the group of anatomical, atypical, and combined resections. ICG: Indocyanine green clearance.

to principally avoid the Pringle maneuver seems to be demonstrated.

### Comparison of blood loss and blood transfusions without Pringle maneuver in the present series vs the literature with Pringle maneuver

In the present series, having used water jet dissection but no Pringle maneuver for all hepatic resections, the median blood loss of 500 mL was comparable with other reported series using a Pringle maneuver<sup>[38,40]</sup>, varying between 370 and 610 mL. Additionally, the percentage of patients who needed perioperative blood transfusions was 15 in this data and again comparable with data from studies having used Pringle maneuver, ranging from 13% to 36%<sup>[35,39,40]</sup>. It is noteworthy that excessive intraoperative blood losses in this series, in one patient up to 5000 mL, were exceptional and resulted all from bleeding from the inferior vena cava or the liver veins that would not have been improved by the use of a Pringle maneuver.

### Conditions facilitating the avoidance of Pringle maneuver

The following points are regarded as crucial if avoidance of Pringle maneuver is intended: Good exposure of the liver, careful planning of the dissection plane(s) on behalf of the preoperative imaging procedures and the intraoperative ultrasound, knowledge of the liver anatomy and its variants, low CVP during parenchyma dissection phase<sup>[38,41,42]</sup> and a completed learning curve in major hepatic surgery<sup>[43]</sup>. Furthermore, various dissection tools such as water jet, harmonic knife, ultrasound, humid bipolar clamp and other devices are thought to facilitate a well controlled parenchyma dissection and avoidance of major blood loss<sup>[43,44]</sup>.

### How to obtain low CVP?

The goal is a CVP below 5 mmHg at the time point of hepatic parenchyma dissection. There is a direct relation between the pressure of the hepatic sinusoidal system with CVP. Bleeding during resection phase is proportional

to the pressure gradient across vascular walls and diameter of injured vessels. Therefore, lowering of the CVP contributes to minimizing the blood loss during dissection phase<sup>[45]</sup>. Besides a close cooperation and communication between surgeon and anesthesiologist, the following measures may support lowering the CVP: Omission of any positive endexpiratory pressure during ventilation, restrictive intravenous fluid administration, forced diuresis, and a liberal use of drugs sustaining arterial blood pressure.

#### **Advantages of liver resections without Pringle maneuver**

The most important advantage of abstaining from Pringle maneuver is the fact that the I/R injury to the liver remnant is almost nihil. This is especially relevant in patients with pre-existing liver damage since the toxic effects of liver ischemia with consecutive liver dysfunction lead to morbidity and mortality<sup>[15]</sup>.

Furthermore, PTC may lead to significant higher systemic vascular resistance combined with decrease in cardiac index as well as increase in mean arterial pressure and, thus, increasing risk of perioperative cardiovascular complications<sup>[16]</sup>.

Although various modifications of Pringle maneuver such as intermittent PTC, ischemic preconditioning and more recently pharmacological preconditioning have been developed to limit these disadvantages<sup>[16,46-48]</sup>, excessive bleeding during reperfusion period partially counterbalances the positive effects regarding minimizing damage of residual liver tissue.

#### **Perioperative monitoring of I/R-injury and liver function**

Ischemia/reperfusion (I/R)-injury is usually monitored by measuring levels of aminotransaminases, bilirubin and prothrombin. The trauma during liver surgery caused by manipulation and parenchyma dissection usually result in a mild to moderate increase of transaminases in the serum (not more than 10-fold normal values), with a quick tendency to recover from postoperative day 1 or 2 on. Such mild increases in liver enzymes are usually not relevant for clinical outcome. However, strong elevation of transaminases (more than 20-fold normal level) with a continuous increase over at least 3 postoperative days may be the result of I/R-injury or decreased blood supply to the liver remnant. Levels of transaminases are well correlating with the ischemic damage<sup>[49]</sup>. I/R-injury may cause postoperative liver failure, mainly in preconditioned patients (*e.g.*, steatosis) with lower tolerance towards ischemia. In the present series without Pringle maneuver, no death occurred due to postoperative liver failure. Only 2 patients experienced temporary liver insufficiency, one due to a septic complication, and another due to postoperative thrombosis of portal vein. It is supposed that these favorable results with regard to postoperative liver failure may be attributed to the maintenance of optimum blood supply to the liver remnant at any time and hence the avoidance of I/R-injury. Accordingly, only moderate increases of transaminases (AST and ALT) in

this series were noticed (Table 4).

Additional serum markers that are thought to have stronger validity and more sensitive indication for liver failure and prognosis are increased bilirubin and ammonia as well as decreased prothrombin levels<sup>[50]</sup>. No serious changes in these parameters were observed with the exception of the 2 mentioned patients with severe complications.

#### **Comparison of anatomical vs atypical resection**

As expected, no significant difference in perioperative and laboratory parameters was observed between the group of anatomical resections vs the group of atypical resections, with two exceptions: Operation time was significantly shorter and prothrombin time was significantly less reduced in the atypically resected group when compared to the group with anatomical resections. Especially, blood loss, blood transfusions and the length of stay in the ICU were similar in both groups.

#### **Limitations of the study**

Data of this study originates from a single center. However, it is a consecutive series with prospective data recording. Large atypical liver resections were also included in this study although they would not belong to major liver resections per definition. However, with view on the study aim, we considered the inclusion of atypical liver resections of at least 5 cm diameter as appropriate, since atypical resections may be accompanied by technical difficulties and inadvertent blood loss similar to segment oriented liver resections.

In conclusion, the data of this study suggests that major liver resections may be performed safely without Pringle maneuver. The low morbidity and mortality rate might be due to minimizing the postoperative liver failure rate by avoidance of the I/R injury to the liver. Anatomical and large atypical liver resections may attempted to be performed without portal triad clamping.

## **ACKNOWLEDGMENTS**

The authors thank the co-workers of the department of anesthesia and intensive care unit for the appreciated help in optimizing the intra- and post-operative management for the patients undergoing liver surgery.

## **COMMENTS**

### **Background**

The role of Pringle maneuver in liver resection is under debate.

### **Research frontiers**

Different techniques of Pringle maneuver have been compared.

### **Innovations and breakthroughs**

The present study shows that major liver resections may be performed safely without Pringle maneuver.

### **Applications**

Major liver resections can be done avoiding Pringle maneuver.

## Peer-review

This study suggests that major liver resections may be performed safely without Pringle maneuver.

# World Journal of *Hepatology*

*World J Hepatol* 2016 September 8; 8(25): 1047-1092

## Editorial Board

2014-2017

The *World Journal of Hepatology* Editorial Board consists of 474 members, representing a team of worldwide experts in hepatology. They are from 52 countries, including Algeria (1), Argentina (6), Armenia (1), Australia (2), Austria (4), Bangladesh (2), Belgium (3), Botswana (2), Brazil (13), Bulgaria (2), Canada (3), Chile (1), China (97), Czech Republic (1), Denmark (2), Egypt (12), France (6), Germany (20), Greece (11), Hungary (5), India (15), Indonesia (3), Iran (4), Israel (1), Italy (54), Japan (35), Jordan (1), Malaysia (2), Mexico (3), Moldova (1), Netherlands (3), Nigeria (1), Pakistan (1), Philippines (2), Poland (1), Portugal (2), Qatar (1), Romania (6), Russia (2), Saudi Arabia (4), Singapore (1), South Korea (12), Spain (20), Sri Lanka (1), Sudan (1), Sweden (1), Switzerland (1), Thailand (4), Turkey (21), Ukraine (3), United Kingdom (18), and United States (55).

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Dr. Chih-Wen Lin, MD, Lecturer, Division of Gastroenterology and Hepatology, Department of Medicine, E-DA Hospital/ I-SHOU University, Kaohsiung 82445, Taiwan

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Advanced liver cirrhosis is usually accompanied by portal hypertension. Long-term portal hypertension results in various vascular alterations. The systemic hemodynamic state in patients with cirrhosis is termed a hyperdynamic state. This peculiar hemodynamic state is characterized by an expanded blood volume, high cardiac output, and low total peripheral resistance. Vascular alterations do not disappear even long after liver transplantation (LT), and recipients with cirrhosis exhibit a persistent systemic hyperdynamic state even after LT. Stability of optimal systemic hemodynamics is indispensable for adequate portal venous flow (PVF) and successful LT, and reliable parameters for optimal systemic hemodynamics and adequate PVF are required. Even a subtle disorder in systemic hemodynamics is precisely indicated by the balance between cardiac output and blood volume. The indocyanine green (ICG) kinetics reflect the patient's functional hepatocytes and effective PVF, and PVF is a major determinant of the ICG elimination

constant (*k*ICG) in the well-preserved allograft. The *k*ICG value is useful to set the optimal PVF during living-donor LT and to evaluate adequate PVF after LT. Perioperative management has a large influence on the postoperative course and outcome; therefore, key points and unexpected pitfalls for intensive management are herein summarized. Transplant physicians should fully understand the peculiar systemic hemodynamic behavior in LT recipients with cirrhosis and recognize the critical importance of PVF after LT.

**Key words:** Liver cirrhosis; Portal hypertension; Liver transplantation; Indocyanine green; Hyperdynamic

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** In patients with advanced cirrhosis who undergo liver transplantation (LT), perioperative management greatly influences the postoperative course and outcome. This review covers key points and unexpected pitfalls of intensive management in these patients. A peculiar systemic hemodynamic state (hyperdynamic state) persists in recipients with cirrhosis even after LT, and stability of optimal systemic hemodynamics is important for adequate portal venous flow (PVF) and successful LT. Reliable parameters for optimal systemic hemodynamics (a balance between cardiac output and blood volume) and adequate PVF (indocyanine clearance) during and after LT are herein described. Transplant physicians should fully understand these peculiar hemodynamic phenomena.

Systemic hemodynamics in advanced cirrhosis: Concerns during perioperative period of liver transplantation. *World J Hepatol* 2016; 8(25): 1047-1060 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i25/1047.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i25.1047>

## INTRODUCTION

Advanced liver cirrhosis (LC) is usually accompanied by portal hypertension (PH). Long-term PH results in various vascular alterations, such as venous dilatation, endothelial damage, collateral pathway formation, and shunt development<sup>[1-3]</sup>. Some pathognomonic findings (e.g., varices, splanchnic congestion, intractable ascites, hepatic encephalopathy, and hepatorenal syndrome) are directly related to PH<sup>[3,4]</sup>, and the pathophysiology of PH involves a complex of humoral and neural mechanisms<sup>[3]</sup>. These mechanisms determine hemodynamic changes and lead to a peculiar systemic circulation pattern<sup>[3]</sup>. The clinical implications of these peculiar systemic hemo-

dynamics in patients with LC have been described as a hyperdynamic state (so-called "hyperdynamic syndrome")<sup>[3]</sup>. Specific manifestations that have been described include high cardiac output (CO), a large blood volume (BV), low total peripheral resistance (TPR), hyponatremic electrolyte abnormalities, and a lower potassium level due to secondary aldosteronism<sup>[5]</sup>.

Here, we reviewed the peculiar systemic hemodynamics in patients with advanced LC. We focused particularly on the systemic hemodynamic phenomena in liver transplantation (LT) recipients with LC because such LT recipients usually have long-term PH due to advanced LC. Adequate portal venous flow (PVF) to acquire satisfactory graft function is attributed to continuous optimal systemic hemodynamic stability beginning immediately after LT<sup>[1,2]</sup>. Therefore, we herein review the optimal state of the systemic hemodynamics after LT for excellent outcomes and discuss key points and unexpected pitfalls in the perioperative intensive managements of recipients with LC. We also demonstrate the usefulness of indocyanine green (ICG) during and after LT to estimate optimal systemic hemodynamics and adequate PVF.

## SYSTEMIC HEMODYNAMICS IN PATIENTS WITH ADVANCED LC

The systemic hemodynamic state in patients with LC has been characterized as hyperdynamic<sup>[3,6,7]</sup>. Cirrhotic hemodynamics are characterized as hyperdynamic by a high CO, large BV, low TPR, mildly tachycardic heart rate (HR), and low or normal mean arterial pressure (MAP)<sup>[1-4,6,8-10]</sup>. Parameters of peripheral resistance, such as TPR, clearly reflect various vascular alterations<sup>[1-3,9,11,12]</sup>.

## NONINVASIVE METHODOLOGY FOR REAL-TIME ASSESSMENT OF SYSTEMIC HEMODYNAMIC STATE

The ICG dye dilution curve can be used to measure hemodynamic parameters<sup>[13,14]</sup>. The currently available noninvasive method for measuring systemic hemodynamic parameters is pulse dye densitometry (PDD). Its basic principles have been described in detail elsewhere<sup>[13-16]</sup>. This noninvasive method is more reliable than invasive methods<sup>[13-15]</sup> and is suitable for clinical use because of its simplicity for bedside use, real-time presentation of results, and cost-effectiveness<sup>[15-17]</sup>.

The principles of BV measurement using radioactive isotopes have already been established<sup>[18-20]</sup>. However, these techniques are associated with potential biohazards due to the use of radioactive indicators and require complex management. Indeed, these invasive methods using radioactive isotopes are completely unsuitable for BV monitoring during the perioperative period<sup>[14,15]</sup>. BV measurement by noninvasive PDD is considerably correlated with BV measurement by radioactive isotope

**Figure 1 Vascular alterations in advanced liver cirrhosis.** Collaterals along the round ligament are removed with native liver (red line). Collaterals developed around the native liver are also ligated (red line). methods<sup>[21-23]</sup>; it is thus advantageous for real-time evaluation of BV<sup>[1,15]</sup>.

## SYSTEMIC HEMODYNAMIC BEHAVIOR AFTER LT

Adult LT recipients often develop peculiar hemodynamics due to advanced LC<sup>[1,2]</sup> (Figure 1). Mainly in the 1990s, various researchers focused on systemic hemodynamics after LT<sup>[8,9,11,12,24-28]</sup>. Controversial opinions exist regarding these systemic hemodynamic behaviors after LT. While several investigators found persistence of hyperdynamic state<sup>[8,11,24-26]</sup>, others insisted on a decrease toward normal ranges<sup>[12,27,28]</sup>. This discrepancy is believed to be due to the peculiarity of cirrhotic hemodynamics<sup>[9,11]</sup>.

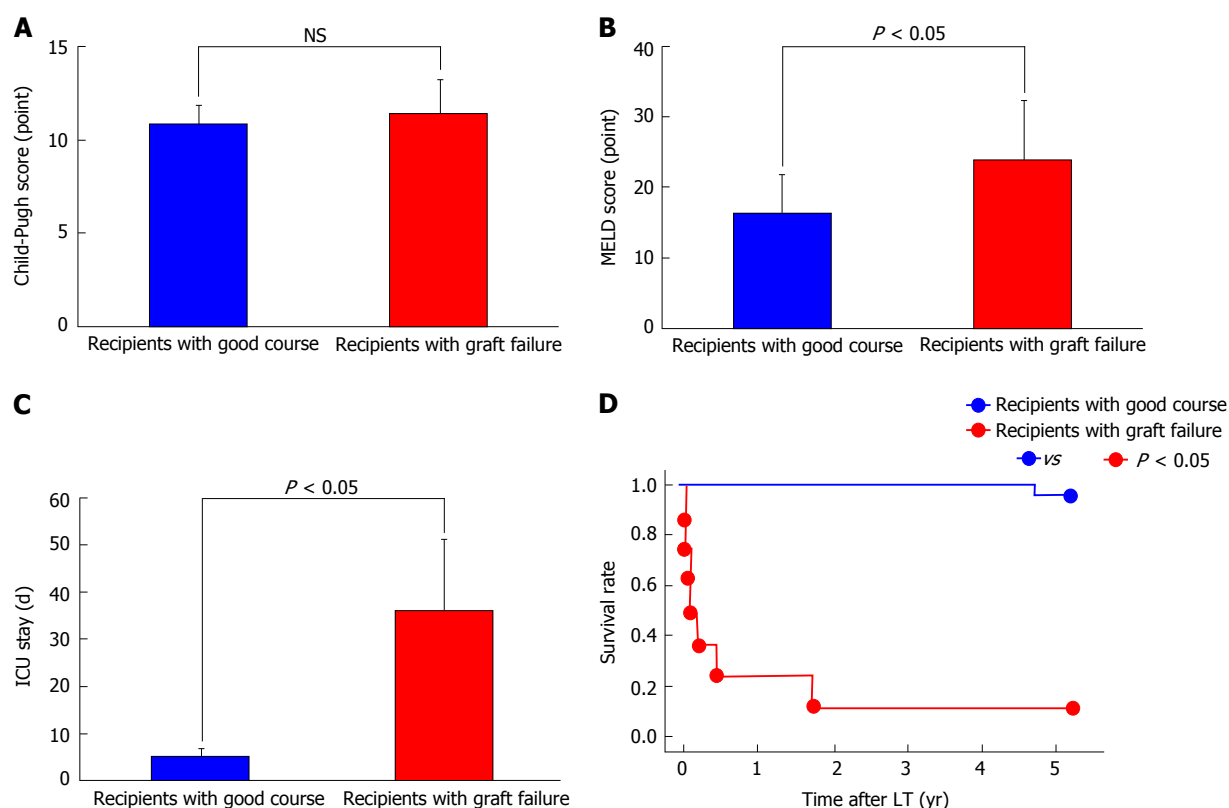

According to studies of TPR in recipients with LC, vascular alterations including venous dilatation and the development of collateral vessels and shunts do not disappear within the first month after LT<sup>[1,2]</sup>. These vascular alterations remain on imaging studies even several years after LT<sup>[29,30]</sup>. Various alterations in systemic hemodynamics in recipients with LC should be maintained despite restoration of the liver function and portal venous pressure (PVP) after LT<sup>[8,11,24-26]</sup>, and most systemic parameters are very slowly restored to the normal range after LT<sup>[9,11]</sup> (Figure 2).

**Figure 2 Intentional modulation of portal venous pressure during living-donor liver transplantation.** Splenectomy is chosen to reduce PVP (red dotted line). Ligations (red lines) of vessels (GCV, IMV, and GCT), collaterals (along LCV and around the native liver) and shunt (SRS) prevent a steal of PVF, and thereafter, PVF will increase (yellow arrow). ## ACTUAL CHANGES IN SYSTEMIC AND SPLANCHNIC HEMODYNAMIC PARAMETERS AFTER LT

Hemodynamic and splanchnic systemic parameters were analyzed in 35 adult recipients who underwent living-donor LT (LDLT). All patients had advanced LC based on imaging studies and histopathological assessments. ABO blood groups were identical or compatible. Combinations of lymphoid cross-matches were all negative. The CO, CI, BV, central blood volume (CBV), and HR were measured with a PDD apparatus. The TPR was measured simultaneously with the PDD examination; calculation of the TPR has been described in detail elsewhere<sup>[2,9]</sup>. Splanchnic circulatory parameters were simultaneously assessed using Doppler ultrasound. Measurements of splanchnic parameters including PVF has been described in detail elsewhere<sup>[2]</sup>. Measurements were performed before LDLT and from 1 to 14 d after LDLT. Measurements were repeated every 12 h until 72 h after LDLT. To establish the normal ranges of each parameter, the variables were investigated in 16 healthy individuals (live donors before LDLT). Our 35 recipients were retrospectively classified into 2 groups based on graft functions that corresponded to outcomes<sup>[31,32]</sup>.

**Figure 3** Pre-transplant factors and post-transplant course. A: Child-Pugh score; B: MELD score; C: Duration of ICU stay; D: Survival rate. ICU: Intensive care unit; LT: Liver transplantation; MELD: Model for end-stage liver disease; NS: Not significant.

Twenty-seven recipients had good clinical courses after LDLT, although eight recipients developed graft failure. No significant differences were found in the Child-Pugh score (Figure 3A), graft-to-recipient weight ratio (GRWR), operative time, or intraoperative blood loss between the two groups; however, significant differences were found in the Model for End-Stage Liver Disease score (Figure 3B), duration of intensive care unit stay (Figure 3C), and survival rate (Figure 3D). In addition, in the patients who survived, the above-mentioned parameters were measured 3 mo after LDLT. All protocols used in the present study were approved by our institutional review board (approved No. C-297) and were based on the ethical guidelines of the Helsinki Declaration. Informed consent was obtained from all patients before enrollment. For individually, temporally, and repeatedly measured data, differences in the changes over time after LDLT between the two groups were analyzed by repeated-measures analysis of variance. Differences in unpaired discontinuous data between the two groups were analyzed by the Mann-Whitney *U* test. Survival rates were calculated by the Kaplan-Meier method, and the log-rank test was used for between-group comparisons of recipient survival. Values of  $P < 0.05$  were considered statistically significant.

There were no significant differences in the absolute CO (Figure 4A), CI, BV (Figure 4B), CBV (Figure 4C), or MAP between the two groups, although the absolute HR showed differences (Figure 4D). There were also

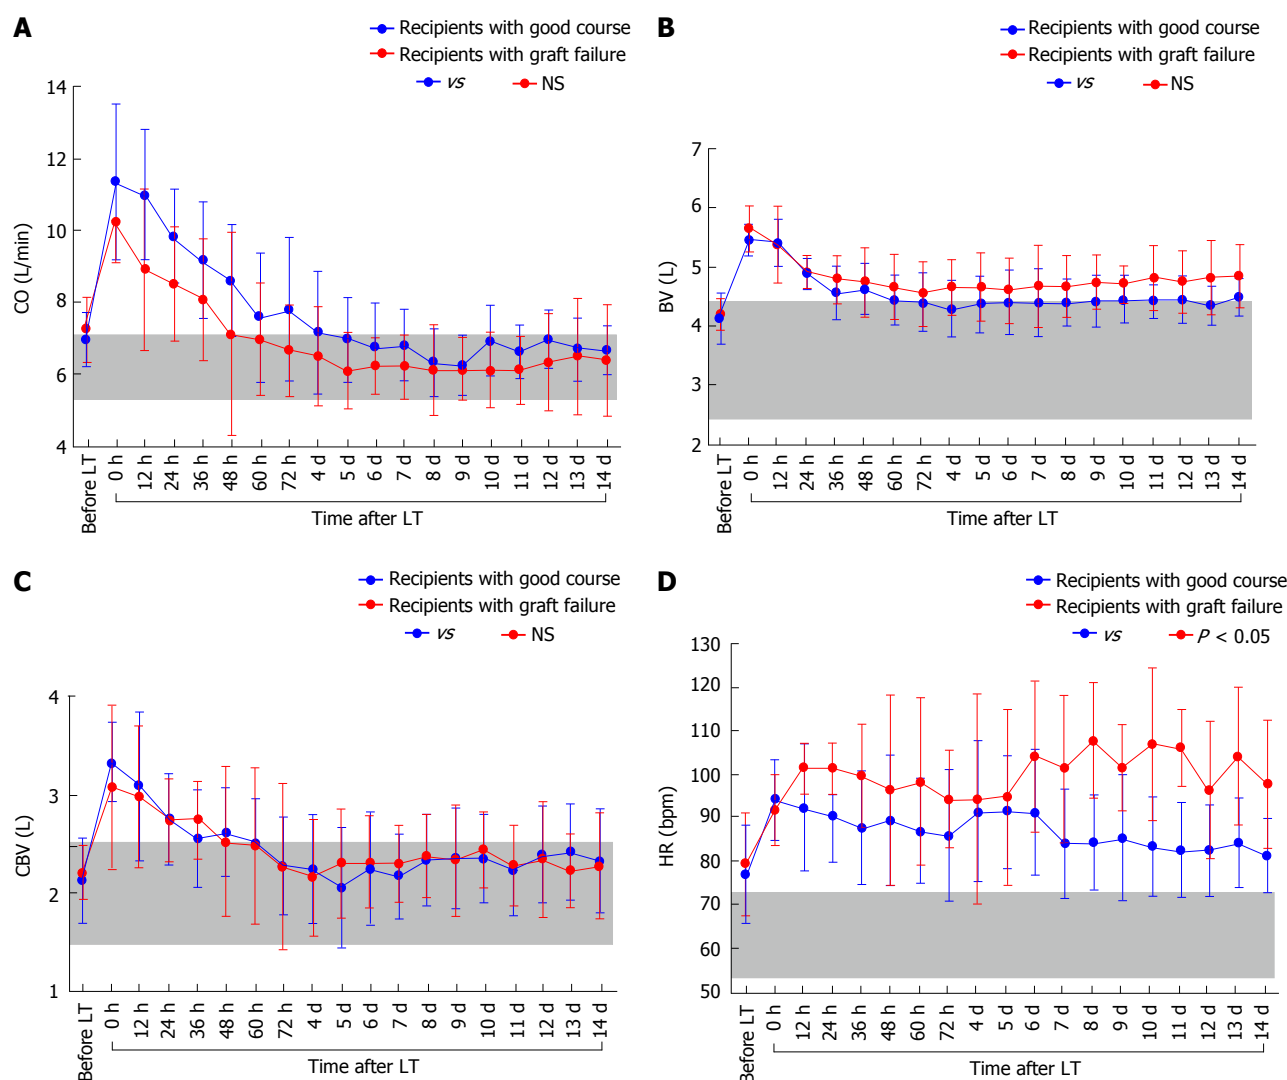

no significant differences in the absolute TPR, which closely reflected vascular alterations (Figure 5A). The balance between CO and BV (*i.e.*, CO/BV) clearly showed significant differences between the groups (Figure 5B). There were significant differences in the PVF velocity (Figure 6A) and PVF volume (Figure 6B) between the groups, although the variables for hepatic arterial flow showed no differences. There were also significant differences in the ICG elimination constant ( $k_{ICG}$ ), which mainly reflects PVF in the early postoperative period<sup>[1,2,32]</sup>.

The CBV reflects the greater circulatory system, and some researchers have suggested that this greater circulation in patients with LC may be slightly lower than that in healthy individuals<sup>[33]</sup>, although the total BV is significantly higher in patients with LC. Our data also demonstrated no remarkable differences in the greater circulation itself between patients with LC and healthy individuals.

The absolute CO, BV, CBV, HR, TPR, and  $k_{ICG}$  in LT recipients who were still alive 3 mo after LDLT are summarized in Figure 7. Our data support the previous opinion that cirrhotic vascular alterations still remain long after LT<sup>[29,30]</sup>.

## OPTIMAL HEMODYNAMIC STATE IN RECIPIENTS WITH LC AFTER LT

As described above, recipients with LC exhibit a persistent systemic hyperdynamic state even after LT<sup>[1,2,8,11,24-26]</sup>.

**Figure 4** Actual changes in systemic hemodynamic parameters. A: CO; B: BV; C: CBV; D: HR. Gray zones represent normal ranges. BV: Blood volume; CBV: Central blood volume; CO: Cardiac output; HR: Heart rate; LT: Liver transplantation; NS: Not significant.

Stability of characteristic systemic hyperdynamic parameters after LT is necessary for successful LT in recipients with LC<sup>[1,2]</sup>. Because recipients with LC exhibit these peculiar systemic hyperdynamics even after LT<sup>[8,9,11,24-26]</sup>, an accurate real-time evaluation is necessary to ensure appropriate intensive management after LT<sup>[1,2,15,32]</sup>. The optimal systemic hemodynamics needed for excellent outcomes and the precise parameters for the most appropriate clinical strategy remain unclear<sup>[1,32]</sup> because the absolute values themselves, such as CO, CI, BV, CBV, and MAP, are not necessarily satisfactory for the detection of the subtle instabilities of these patients' peculiar hyperdynamic state<sup>[1,2]</sup>.

## CONCEPT OF CO STANDARDIZATION AGAINST BV

Several investigators have used CO and/or CI to assess hemodynamics after LT<sup>[8,11,12,25]</sup>. Use of the CI, an index that concisely standardizes CO against the body surface area, has been popularized as a standardized CO value

for better assessment. Similar to CO, BV is also one of the most important factors affecting cardiac preload<sup>[14,34]</sup>. Intrinsically, preload is a concept that represents the blood load in the left ventricle and considers the left ventricle as the center of blood ejection<sup>[1,15]</sup>. Therefore, the left ventricular end-diastolic volume becomes a quantitative parameter<sup>[1,15]</sup>. The preload usually replaces actual clinical assessment with parameters representing pressures such as the pulmonary capillary wedge pressure and central venous pressure<sup>[14,35]</sup>. The central venous pressure can be a useful indicator of the filling status of the right ventricle; it is especially useful when followed over time and combined with a measurement of cardiac output<sup>[36]</sup>. Pressure-expressing parameters including the pulmonary capillary wedge pressure and central venous pressure are mainly provided by the CO and BV<sup>[35]</sup>. Therefore, although pressure-expressing parameters do not necessarily reflect the left ventricular end-diastolic volume<sup>[14,15]</sup>, pressure-expressing parameters that reduce the precision of assessment of the systemic hemodynamics have been paradoxically used to judge

**Figure 5 Actual changes in systemic hemodynamic parameters.** A: TPR; B: CO/BV. Gray zones represent normal ranges. BV: Blood volume; CO: Cardiac output; LT: Liver transplantation; NS: Not significant; TPR: Total peripheral resistance.

distinct factors that represent the amount of BV and strength of CO clinically because BV monitoring has been impossible in the past<sup>[14,15]</sup>. It is necessary to standardize CO against BV, but not against the body surface area, for precise evaluation of preload<sup>[1]</sup>. Currently, the PDD guarantees noninvasive vigilance of the balance between CO and BV as an index for precise assessment of the systemic hemodynamic state<sup>[1,15]</sup>. The CO/BV ratio is a reliable indicator of the optimal systemic hemodynamic state after LT<sup>[1,2]</sup>. Preload focuses on the balance between CO and BV, and cirrhotic systemic hemodynamics are characterized by a high CO and large BV<sup>[6-9,12,24-26,35]</sup>. Real-time assessment of CO and BV by making the best use of noninvasive PDD may become an effective strategy for evaluating the systemic hemodynamic state in LT recipients with LC.

## IMPACT OF SYSTEMIC HEMODYNAMIC STATE ON PVF AFTER LT

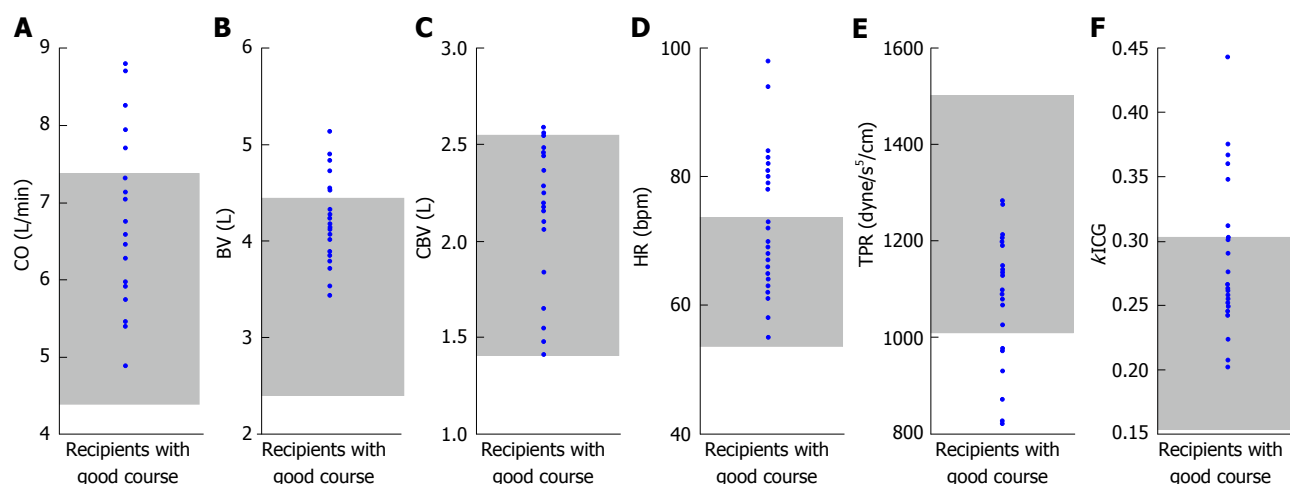

Postoperatively, LT recipients with LC show a clear tendency toward PVF overflow compared with healthy individuals<sup>[2]</sup>. The systemic hemodynamics impact the local graft circulation after LT<sup>[1,2]</sup>, and even a subtle systemic

**Figure 6 Actual changes in portal venous flow and indocyanine green elimination constant.** A: PVF velocity; B: PVF volume; C: kICG. Gray zones represent normal ranges. ICG: Indocyanine green; kICG: Indocyanine green elimination constant; LT: Liver transplantation; PVF: Portal venous flow.

hyperdynamic disorder strongly affects the splanchnic circulation. An imbalance between CO and BV decreases the PVF, which results in critical outcomes<sup>[1,2]</sup>. In brief, an optimal balance between CO and BV guarantees adequate PVF after LT<sup>[1,2]</sup>. Interestingly, subtle disorders in the optimal systemic hyperdynamic state more easily influence the PVF than the hepatic arterial flow<sup>[2]</sup>. Vascular alterations secondary to PH develop in the vessels that originally flow into the portal vein under normal PVP. Such alterations are one cause of a large BV<sup>[2]</sup>. The

**Figure 7 Systemic hemodynamic parameters 3 mo after liver transplantation.** A-F: CO, BV, CBV, HR, TPR, and *k*ICG in patients who survived are shown. Gray zones represent normal ranges. BV: Blood volume; CBV: Central blood volume; CO: Cardiac output; HR: Heart rate; ICG: Indocyanine green; *k*ICG: Indocyanine green elimination constant; LT: Liver transplantation; TPR: Total peripheral resistance.

intestine and spleen become a pool for the large BV<sup>[37]</sup>. Postoperative imbalance between the greater CO and larger BV cause stagnation of the tributary blood flow in the dilated veins and collateral pathways, resulting in a decrease in PVF<sup>[2]</sup>. Transplant physicians should never forget that the systemic hyperdynamic state persists in recipients with LC even after LT<sup>[1,2,8,11,24-26]</sup> and that this peculiar systemic hemodynamic stability is indispensable for adequate PVF after LT<sup>[1,2]</sup>.

Actual images of Doppler ultrasound in cases without stability of systemic hemodynamic state (*i.e.*, an imbalance of CO and BV in the lower TPR) are shown in Figure 8. The PVF should be detected as a stationary wave. However, in a case of unstable systemic hyperdynamic state, the waveform of PVF may seem to be undulant. Moreover, HA waveform may blend into the background of a decreased PVF.

## INTENTIONAL MODULATION OF PVP DURING LDLT

Partial liver grafting is inevitable in the LDLT setting, and the allograft size from the live donor is therefore insufficient. Intentional modulation of the PVP to  $\leq 15$  mmHg is a simple and sure strategy during LDLT<sup>[38-42]</sup>. Detailed surgical procedures for intentional modulation of PVP have been described elsewhere<sup>[40,41]</sup>. Paradoxically, the acceptable minimum GRWR of  $< 0.7$  is possible at graft selection<sup>[40]</sup> because intentional PVP modulation during LDLT will prevent small-for-size syndrome after LDLT<sup>[38-42]</sup>. Although intentional PVP control seems to overcome an GRWR of  $< 0.7$ , these grafts still cause critical problems when evaluated retrospectively<sup>[40]</sup>. Selection of a graft with an GRWR of  $\geq 0.8$  and establishment of a target PVP of  $\leq 15$  mmHg during LDLT are considered keys for successful LDLT<sup>[40]</sup>. Optimal PVF is required for successful LDLT<sup>[2,43]</sup>. Ligation of collaterals and shunts often require an advanced surgical technique because these vessels are always abnormal<sup>[41,42]</sup>.

However, intentional setting of the PVF during LDLT is effective not only to trigger liver regeneration after LT, but also to prevent steal of PVF after LDLT.

## STRATEGIC VALUE OF ICG KINETICS DURING LT

ICG is widely used for analysis of liver functions because it is exclusively eliminated by the liver without involvement of the enterohepatic circulation and does not accumulate in the body<sup>[44]</sup>. Asialoglycoprotein receptors on hepatocytes are characteristic of functional liver cells<sup>[45]</sup>, and liver scintigraphy using <sup>99m</sup>Tc-galactosyl human serum albumin has been used as a reliable method of assessment of the hepatic functional reserve in hepatectomy and graft parenchymal function after LT<sup>[46-48]</sup>. There is a correlation between ICG clearance and the hepatic uptake ratio assayed by liver scintigraphy<sup>[45,46]</sup>.

ICG kinetics reflect the functional hepatocytes (cell volume) and effective PVF (clearance)<sup>[31,49-52]</sup>, and PVF is a major determinant of *k*ICG in the normal liver<sup>[32,34,49,51,53]</sup>. The PVF has a large influence on liver regeneration after LT<sup>[32,43]</sup>, and reversible damage to hepatocytes begins immediately after graft recirculation<sup>[32,38,39,43]</sup>. Some researchers have focused on ICG kinetics as a liver function test after LT<sup>[31,32]</sup>, and *k*ICG values can predict clinical outcomes in the early postoperative period after LDLT by closely reflecting the influence of systemic dynamics on the splanchnic circulation<sup>[32]</sup>.

Hepatocytes are well preserved in LDLT because the cold storage time (CIT) is shorter. The *k*ICG reflects the optimum PVF value during LT and in the early postoperative period<sup>[41,42]</sup>. Hence, a division by graft weight is a simple resolution to ensure that the *k*ICG reflects only the PVF based on the advantage of well-preserved hepatocytes during LDLT<sup>[41,42]</sup>. Intentional PVP modulation based on real-time PVP monitoring and the confirmation of an optimal *k*ICG/graft weight value reflecting the PVF are useful procedures used by transplant surgeons

**Figure 8 Decreased portal venous flow due to unstable systemic hyperdynamic state (A and B).** Even a subtle instability of systemic hyperdynamic state (i.e., an imbalance of CO and BV in the lower TPR) results in a decreased PVF. During the PVF measurement by Doppler ultrasound, HA waveform (Red line) blends into the background of a decreased PVF (purple lines). BV: Blood volume; CO: Cardiac output; HA: Hepatic artery; PVF: Portal venous flow; TPR: Total peripheral resistance.

during LDLT<sup>[41,42]</sup>. Actually, in some cases, the *k*ICG value did not change even with intentional controls to decrease or increase the PVP<sup>[41]</sup>. In other cases, the *k*ICG values improved with an increased PVP by ligation of portosystemic collaterals or a decrease in the PVP by splenectomy<sup>[41]</sup>. Thus, these factors seemed to show some discrepancies in some cases<sup>[41,42]</sup>. The relationship between PVP and PVF remains unclear<sup>[42]</sup>. The usefulness of ICG kinetics during LT was first described in 2012<sup>[41]</sup>. Simultaneous fulfillment of a final PVP of  $\leq 15$  mmHg and a final *k*ICG of  $> 4 \times 10^{-4}/g \times$  the graft weight (g) is a sure strategy for achieving the optimal PVF during LDLT<sup>[41]</sup>. Thereafter, the cut-off level of the final *k*ICG/graft weight was demonstrated as  $3.1175 \times 10^{-4}/g$ <sup>[42]</sup>. The final *k*ICG/graft weight during LT has potential as an accurate parameter for the optimal PVF and as a reliable predictor of the postoperative course and outcome after LT<sup>[41,42]</sup>.

## KEY POINTS AND UNEXPECTED PITFALLS IN PERIOPERATIVE MANAGEMENT OF LT RECIPIENTS WITH ADVANCED LC

Liver allografts are at risk of problems such as cold

ischemia/warm reperfusion injury, acute rejection, disease recurrence and hepatic blood flow disorders<sup>[32]</sup>. Transplant physicians should consider many factors simultaneously.

Eventration of the diaphragm because of intractable ascites, or easily broken ribs, often disrupts ventilation<sup>[54]</sup>. Vascular alteration due to long-term PH causes endothelial injury and permeant breakdown and subsequently results in large amounts of ascites, pleural effusion, and gastric fluid<sup>[55]</sup>. The electrolyte composition of these third-space fluids may not be similar to that of the extracellular fluid, and the electrolyte composition of third-space fluids should be checked once if the quantity is large<sup>[56]</sup>. Replenishment for third-space loss should be performed using not Ringer's solution but bicarbonated Ringer's solution<sup>[57-59]</sup> if the electrolyte composition is similar to that of the extracellular fluid and if the third-space loss is quantitatively large.

Careless management techniques, such as rapid increases or decreases of transfusions and medications, are detrimental<sup>[60,61]</sup>. Effects of increases or decreases of transfusions are usually reflected on a day-to-day basis because of the peculiar cirrhotic hemodynamics<sup>[55,60,61]</sup>, and a roller-coaster management technique that repeatedly changes within a single day will trigger poor clinical courses with unexpected complications<sup>[60,61]</sup>. All transfusion management plans should be handled with great caution, and transplant physicians should very carefully evaluate the effects of increases or decreases of transfusions<sup>[60,62]</sup>. A response time lag due to endothelial injury and permeant breakdown should be considered in LC recipients with long-term PH<sup>[63-65]</sup>. Adequate hydration is also required; dehydration should be avoided because of these patients' peculiar hemodynamics. Even temporal dehydration causes unexpected thrombosis, renal failure, and impaired drug metabolism<sup>[60-62]</sup>. Plans to stay within stable systemic hemodynamics (e.g., noradrenaline to maintain CO and well-hydration with human atrial natriuretic peptide) should be considered. Tachycardia may lower the CO. A lower CO that is insufficient to circulate the larger BV decreases the PVF, and a lower PVF results in a poor outcome. As described above, vascular alterations cause the large BV in these patients<sup>[2]</sup>, and the intestine and spleen become pools for the large BV<sup>[37]</sup>. Even a subtle imbalance between the greater CO and larger BV induced by roller-coaster management triggers a decrease in the PVF<sup>[2,60,61]</sup>.

Long-term PH causes splanchnic congestion and intractable ascites. Splanchnic congestion results in breakdown of the enteric barrier<sup>[66]</sup>, and portal venous gas and/or abdominal compartment syndrome may be temporally observed<sup>[66-68]</sup>. Induction of drugs with fibrolytic activity (not heparin, but urokinase and warfarin) should be initiated without hesitation based on the endothelial damage in patients with LC, although heparin induction may be effective from the viewpoint of thromboprophylaxis<sup>[69]</sup>. Notably, long-term biliary drainage may cause coagulopathy due to impaired absorption of vitamins<sup>[70]</sup>. Massive ascites is usually intractable due to endothelial injury and

permeant breakdown, and systemic arterial pressure may be effected even by body motion<sup>[63-65]</sup>. Diuretics (e.g., furosemide and potassium-conserving diuretics) and a water-clearance mediator (e.g., tolvaptan) are available<sup>[71]</sup>. Hemodynamic disorders such as hepatic venous obstruction and portal thrombosis may develop if no response is observed after diuretic induction<sup>[72]</sup>.

The most frequent cause of morbidity and mortality after LT is not immunological rejection but infection-related complications<sup>[73-75]</sup>. Some infections are usually intractable in patients with LC, including bacterial cholangitis<sup>[76]</sup>, spontaneous bacterial peritonitis<sup>[77]</sup>, spontaneous bacterial empyema<sup>[78]</sup>, viral infection<sup>[79]</sup>, aspergillosis<sup>[80]</sup>, and *Pneumocystis jirovecii* pneumonia (formerly known as *Pneumocystis carinii* pneumonia)<sup>[81]</sup>. Because the postoperative risk of complications is associated with the pretransplant conditions<sup>[82,83]</sup>, these infections should be ruled-out and/or treated beforehand. Even a subtle infection will trigger severe complications after LT<sup>[73-75,83,84]</sup>. Evaluation of LT candidates should be carefully performed<sup>[83,85,86]</sup>; pretransplant infections may greatly impair the clinical course and outcomes after LT<sup>[83,87,88]</sup>. Transplant physicians should never forget that intentional pretransplant control of infections, including bacterial, viral, and fungal infections, has a large influence on allograft function and survival<sup>[89,90]</sup>. Uncontrolled infections will have catastrophic effects<sup>[83,87,88]</sup>, and any infections should therefore be treated before LT.

Glycemic control also has an influence on the clinical course after LT<sup>[91]</sup>. Good glycolytic activity and glycemic control in the perioperative period will help to ensure adequate liver regeneration<sup>[92,93]</sup>.

## DISTINCTION BETWEEN HEPATOPULMONARY SYNDROME AND PORTOPULMONARY HYPERTENSION

Hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPHTN) are cardiopulmonary complications<sup>[3,94-97]</sup> that are frequently seen in patients with LC<sup>[54,94-98]</sup>. Both conditions result from a lack of hepatic clearance of vasoactive substances produced in the splanchnic territory<sup>[95]</sup>. These substances mainly cause subsequent pulmonary vascular remodeling. In previous studies, some degree of vasoconstriction in patients with PPHTN resulted in pulmonary arterial hypertension (PAH) and right ventricular dysfunction<sup>[54,98]</sup>. The current definition of PPHTN includes secondary PAH due to portosystemic shunts<sup>[98]</sup>. In patients with HPS, these vasoactive mediators cause intrapulmonary shunts with hypoxemia<sup>[97]</sup>. The HPS is accompanied by abnormal pulmonary gas exchange and evidence of intrapulmonary vascular dilatation that results in a right-to-left intrapulmonary shunt<sup>[98]</sup>. These entities are both clinically and pathophysiologically distinct<sup>[3,94,95]</sup>, and PPHTN and HPS should be considered as different pathological states<sup>[98]</sup>. HPS is characterized by abnormal pulmonary vasodilation and right-to-left shunting that result in gas

exchange abnormalities<sup>[3,54,94,95,97,98]</sup>, whereas PPHTN is caused by pulmonary artery vasoconstriction that leads to hemodynamic failure<sup>[3,94-96]</sup>. Both HPS and PPHTN are associated with significantly increased morbidity and mortality<sup>[3,94,95,97]</sup>, although these patients are commonly asymptomatic. All candidates for LT should be actively screened for the presence of these two complications<sup>[54,94,95,97,98]</sup>.

Although LT results in the disappearance of HPS within 1 year<sup>[95,99]</sup>, the effect of LT on PPHTN is highly unpredictable<sup>[54,95,98-101]</sup>. PPHTN with PAH has historically been a contraindication for LT<sup>[54,98-100]</sup>. However, the diagnosis and treatment of PPHTN have advanced during the past two decades<sup>[54]</sup>. Assessment of patients' preoperative reactivity and response to pharmacological therapies for moderate-to-severe PPHTN is important to ensure excellent survival rates after LT<sup>[102]</sup>. Prostaglandin *I*<sub>2</sub> has drastically improved outcomes<sup>[103]</sup> and is currently considered a key drug in the control of PPHTN<sup>[103]</sup>. Modern strategies in managing HPS and PPHTN rely on a thorough screening and grading of the disease severity to tailor the appropriate therapy and select only the patients who will benefit from LT<sup>[54,95,97-101]</sup>. Hemodynamic and respiratory modifications in the perioperative period must be avoided through continuation of the preoperatively initiated drugs, appropriate intraoperative monitoring, and proper hemodynamic and respiratory therapies<sup>[54,95,98,99]</sup>. The most reliable monitoring factor for PPHTN with PAH during the perioperative period is the mean pulmonary arterial pressure<sup>[54,98]</sup>, though supplemental oxygen and monitoring of oxygen saturation during the perioperative period are adequate for monitoring of HPS<sup>[97,104,105]</sup>.

## COAGULOPATHY AND ENDOTHELIAL INJURY

The systemic hyperdynamic state causes vessel dilation and collateral development, and the venous endothelium becomes damaged<sup>[4,65]</sup>. An intact endothelial barrier is important, especially in critical situations such as sepsis and thrombotic microangiopathy<sup>[106,107]</sup>. High mobility group box 1 (HMGB1) is an evolutionarily conserved nuclear protein that is passively released by almost all cells during cellular necrosis and is actively secreted from activated macrophages, monocytes, and endothelial cells<sup>[108]</sup>. Once secreted into the extracellular space, HMGB1 serves as a dangerous signal that stimulates inflammatory reactions<sup>[108]</sup>. Thrombomodulin (TM) is an endothelial anticoagulant cofactor that promotes thrombin-mediated formation of activated protein C<sup>[109]</sup>. TM plays an anti-inflammatory role through inactivation of HMGB1<sup>[109,110]</sup>. Recombinant human soluble TM (rTM) has recently become available<sup>[111]</sup>, and this novel drug is effective for sepsis<sup>[110]</sup>. Thrombotic microangiopathy and a positive lymphoid cross-match combination will result in poor outcomes after LT, especially in adult recipients<sup>[112,113]</sup>. Intrahepatic and vascular conditions pathophysiologically overlap. Pathophysiologically, rTM

is effective for sepsis and thrombotic microangiopathy in LT recipients<sup>[107,111]</sup>, although there are no reports of its usefulness for ABO incompatibility in patients undergoing LT. Vascular alterations including endothelial injury still remain even after LT. Based on our experience, the dose of rTM should be reduced to two-thirds of the regular dose in LT recipients with LC, although one-half of the regular dose loses any effects.

## MEDICAL ECONOMY

Insurance systems are different in each country<sup>[114,115]</sup>, and every country has its own limitations of medical resources<sup>[116]</sup>. Hence, transplant physicians should always consider a cost-benefit analysis if they want to continue an effective LT program<sup>[116,117]</sup>. Dialysis treatment, plasma exchange, blood derivatives, and direct-acting antivirals are very expensive<sup>[62,118,119]</sup>. Notably, attempts to perform blood transfusion and infusion of fraction products are ill-advised because they are very detrimental to the medical economy<sup>[62,116,117,119]</sup>. A shorter intensive care unit (ICU) stay has benefits for patients<sup>[120]</sup>, although expensive and intensive care during the ICU stay is needed for post-transplant management. Longer hospital stay impairs quality of life and spoils social status after hospital discharge<sup>[121,122]</sup>.

## DISCUSSION

It is necessary to standardize CO against BV for precise evaluation of preload<sup>[1]</sup>. Considering that cirrhotic hyperdynamics are consolidated in patients with a large BV and high CO under a low TPR<sup>[3,6,8-10]</sup> and that the concept of preload is focused on the balance between CO and BV<sup>[35]</sup>, we can now use the new concept of the CO/BV ratio by making the best use of available devices that can noninvasively measure BV<sup>[1,2,15]</sup>. The PDD guarantees noninvasive vigilance of the balance between CO and BV as an index for precise assessment of the systemic hemodynamic state in LT recipients with LC<sup>[1]</sup>. The CO/BV ratio expresses the CO per min corresponding to a fraction of the BV, which represents how the heart efficiently ejects the BV that should be circulated<sup>[1,2]</sup>. Interestingly, previous studies revealed no differences in the CO/BV among recipients with LC, recipients without LC, and healthy individuals<sup>[1,2]</sup>. This variable has potential as a reliable clinical marker after LT. Subtle instabilities that do not appear when comparing absolute values themselves are simply indicated by the balance between CO and BV<sup>[1,2]</sup>. It seems reasonable that tachycardia resulted in a lower CO in recipients with poor outcomes (Figure 4D) and that the decreased CO could not circulate the large BV in these recipients (Figure 5B).

In LDLT, the CIT is short and the hepatocytes are well preserved<sup>[41]</sup>. Therefore, division by the graft weight is a simple method that allows the kICG to reflect only the PVF, by taking advantage of the shorter CIT in LDLT<sup>[41]</sup>. Strategic values in ICG kinetics are used to set the optimal PVF during LDLT and to evaluate the optimal

systemic hemodynamics after LT<sup>[1,2,32,41,42]</sup>. ICG kinetics reflects the functional hepatocyte volume and effective PVF<sup>[31,49-52]</sup>. Advanced selection criteria of a graft with an GRWR of  $\geq 0.6$  and establishment of a target PVP of  $\leq 15$  mmHg during LDLT are currently documented for successful LDLT<sup>[123-126]</sup>. This defiant set-up with lower GRWR has advantages for donor pool and safety, although these grafts may cause critical problems<sup>[40]</sup>. ICG kinetics is useful to set-up of adequate PVF during LDLT with lower GRWR. Conversely, in deceased-donor LT, although PVF is a major determinant of kICG in the normal liver<sup>[32,34,49,51,53]</sup>, the kICG value may be affected by damaged hepatocytes due to the longer CIT. The decreased kICG may not indicate only an inadequate PVF in deceased-donor LT because ICG kinetics is dually factorial.

## CONCLUSION

LT recipients with LC exhibit peculiar hemodynamics (*i.e.*, systemic hyperdynamic syndrome and PH). Vascular alterations do not easily disappear despite restorations of PH and liver function in recipients with LC, and PVF impacts liver regeneration after LT<sup>[43]</sup>. Stability of characteristic systemic hyperdynamics is indispensable for adequate PVF and successful LT<sup>[1,2]</sup>. Even a subtle disorder of the systemic hyperdynamics dictates PVF<sup>[1,2]</sup>. ICG kinetics is useful to set an adequate PVF during LDLT and evaluate the optimal systemic hemodynamics after LT<sup>[1,2,32,41,42]</sup>. Perioperative management has a large influence on the postoperative course and outcome. Transplant physicians should fully understand the peculiarities of cirrhotic hemodynamics. We hope that this review will be informative for transplant physicians.

### Abstract

Hepatitis B virus X protein (HBx) plays an important role in the development of hepatocellular carcinoma (HCC). In addition, hepatoma upregulated protein (HURP) is a cellular oncogene that is upregulated in a majority of HCC cases. We highlight here recent findings demonstrating a link between HBx, HURP and anti-apoptosis effects observed in cisplatin-treated HCC cells. We observed that Hep3B cells overexpressing HBx display increased HURP mRNA and protein levels, and show resistance to cisplatin-induced apoptosis. Knockdown of HURP in HBx-expressing cells reverses this effect, and sensitizes cells to cisplatin. The anti-apoptotic effect of HBx requires activation of the p38/MAPK pathway as well as expression of SATB1, survivin and HURP. Furthermore, silencing of HURP using short-hairpin RNA promotes accumulation of p53 and reduces cell proliferation in SK-Hep-1 cells (p53<sup>+/+</sup>), whereas these effects are not observed in p53-mutant Mahlavu cells. Similarly, HURP silencing does not affect the proliferation of H1299 lung carcinoma cells or Hep3B HCC cells which lack p53. Silencing of HURP sensitizes SK-Hep-1 cells to cisplatin. While HURP overexpression promotes p53 ubiquitination and degradation by the proteasome, HURP silencing reverses these effects. Inoculation of SK-Hep-1 cancer cells in which HURP has been silenced produces smaller tumors than control in nude mice. Besides, gankyrin, a positive regulator of the E3 ubiquitin ligase MDM2, is upregulated following HURP expression, and silencing of gankyrin reduces HURP-mediated downregulation of p53. In addition, we observed a positive correlation between HURP and gankyrin protein levels in HCC patients ( $r^2 = 0.778$ ;  $n = 9$ ). These findings suggest a role for the viral protein HBx and the host protein HURP in preventing p53-mediated apoptosis during cancer progression and establishment of chemoresistance.

**Core tip:** Hepatitis B virus X protein (HBx) plays a critical role in the development of hepatocellular carcinoma (HCC). Hepatoma upregulated protein (HURP) is an oncogene that is upregulated in a majority of HCC cases. However, the role of these proteins in the response of HCC cells to chemotherapeutic drugs remains unclear. We show here that the HBx/SATB1/HURP axis plays a critical role in down-regulating p53 and upregulating anti-apoptotic proteins *in vitro* and *in vivo*. We discuss the regulation of this novel pathway and its implications in resistance of HCC cells to chemotherapy.

## INTRODUCTION

Chronic hepatitis B virus (HBV) infection represents an important risk factor for the development of hepatocellular carcinoma (HCC)<sup>[1-3]</sup>. The hepatitis B virus X protein (HBx) is produced by HBV and is required for viral replication in host cells<sup>[4,5]</sup>. HBx interferes with a variety of cellular functions in host cells. It forms a heterodimeric complex with the host protein HBx interacting protein, and this interaction dysregulates centrosome dynamics and chromosomal stability<sup>[6]</sup>. HBx also interacts with the tumor suppressor p53 and modulates cellular apoptosis in the presence of various stimuli<sup>[7-9]</sup>. A recent study indicates that HBx binds to the DNA-repair protein damaged DNA binding protein 1 (DDB1), and redirects the CUL4-DDB1 E3 complex, a protein complex with ubiquitin ligase activity that is involved in regulating DNA replication and repair, transcription and signal transduction in host cells<sup>[10]</sup>.

Recent studies suggest that HBx plays a role in HCC pathogenesis<sup>[11-14]</sup>. However, the effect of HBx on apoptosis remains incompletely understood as some authors have reported pro-apoptotic<sup>[15-19]</sup> as well as anti-apoptotic effects<sup>[8,20-23]</sup>. Importantly, experiments performed in laboratory animals indicate that the HBx protein may induce resistance to the anti-cancer drug cisplatin in hepatoma cells<sup>[16]</sup>. Here, I present recent experimental evidence highlighting a prominent pathway used by HBx to upregulate hepatoma upregulated protein (HURP) and avoid apoptosis in HCC cells.

## HURP AS A MARKER IN HCC

HURP was initially shown to be overexpressed in HCC

based on a bioinformatics analysis of sequence tags expressed in the human liver<sup>[24]</sup>. Also known as discs large homolog 7 or disks large-associated protein 5<sup>[25,26]</sup>, HURP was previously thought to represent a stem cell marker as this protein is not detected in fully differentiated cells<sup>[27]</sup>. Previous reports indicate that HURP overexpression in differentiated cells blocks apoptosis and increases cell growth in response to serum starvation<sup>[24,28]</sup>. HURP also appears to regulate the cell cycle and act specifically during mitosis. More specifically, HURP represents a kinetochore protein that stabilizes microtubules in the vicinity of chromosomes<sup>[29-31]</sup>. That is, HURP is associated with the mitotic spindle where it helps to determine spindle bipolarity and participates in the growth of microtubules toward chromosomes during mitosis. Furthermore, HURP forms a Ran-dependent complex<sup>[29]</sup>, and is a target of the serine/threonine kinase aurora-A, which possesses oncogenic properties<sup>[28]</sup>. Aurora-A thus phosphorylates HURP and this process may represent a cellular mechanism that controls mitotic spindle assembly and functions<sup>[32]</sup>. Therefore, HURP is implicated in stem cell functions<sup>[25-27]</sup> and carcinogenesis in cancer cells of human origins<sup>[24,28]</sup>. Analysis of gene expression showed that HURP represents a marker of cancer prognosis that can be used to distinguish between benign and malignant adrenocortical tumors<sup>[33,34]</sup>. In addition, HURP undergoes proteolysis following phosphorylation by Cdk1-cyclin B and recognition by the Fbx7-associated SCF complex that functions as an E3 ubiquitin ligase<sup>[35]</sup>. These results indicate that HURP is involved in control of the cell cycle, specifically during mitosis, suggesting that this protein may regulate apoptosis and be involved in tumor development. However, the role of HURP in HCC and apoptosis, and how this protein is regulated is incompletely understood.

## HBx UPREGULATES HURP EXPRESSION IN HCC CELLS

Given that the viral protein HBx plays a critical role in the development of HCC and HURP is upregulated in a majority of HCC cases, we examined the possible link between HBx, HURP, and cisplatin resistance in HCC cells. Hep3B cells expressing HBx showed not only elevated HURP mRNA and protein levels but also resistance to apoptosis induced by cisplatin. HURP silencing in cells expressing HBx reversed this process and enhanced sensitization of Hep3B cells to apoptosis. Notably, HBx overexpression induced SATB1, a global gene regulator that is upregulated in breast cancer. However, the role of SATB1 in the regulation of cell survival is unclear. We found that the anti-apoptotic effect of HBx requires p38/MAPK pathway activation in Hep3B cells. HBx also induced the expression of the anti-apoptotic protein survivin in an HURP-dependent manner<sup>[36]</sup>. We observed that the HBx produces anti-apoptotic effects in HCC cells, a process that may lead to chemoresistance. Enhanced chemoresistance of HCC cells that express

**Figure 1** Proposed model to explain the link between hepatitis B virus X protein, p38/MAPK, SATB1, hepatoma upregulated protein, and survivin in mediating anti-apoptotic effects during cisplatin treatment. HBx upregulates the anti-apoptotic protein survivin through induction of p38/MAPK and ERK/MAPK pathways. Another less defined ERK/MAPK pathway which may regulate survivin independently of HURP is also shown. HBx: Hepatitis B virus X protein; HURP: Hepatoma upregulated protein.

HBx was associated with increased activity of several proteins, including SATB1, HURP, and survivin. Previous reports indicate that PKC negatively regulates SATB1 transactivation activity<sup>[37]</sup>. Our group showed that SATB1 and the p38/MAPK pathway mediates the anti-apoptotic activity of HBx. Therefore, it appears that HBx upregulates SATB1 and MAPK or HURP transcription. HURP induced survivin expression in HBx-expressing cells. ERK inhibition also inhibited surviving activity<sup>[36,38]</sup>; however, HURP protein levels remained constant in the presence of ERKi, an observation which suggested that HBx may induce survivin *via* another pathway that requires the ERK kinase (Figure 1). Our results may explain, at least in part, the cellular mechanism underlying the anti-apoptotic effect of HBx during the development of HBV-associated HCC. In agreement with our results, previous studies have shown that stable expression of HBx can stimulate PI3-kinase activity and suppress TGF-beta-induced apoptosis in Hep3B cells<sup>[8,22]</sup>.

SATB1, a chromatin organizer, is involved in gene regulation and the formation of chromosome loops, in addition to its role in the organization of transcriptionally poised chromatin<sup>[39]</sup>. SATB1 was initially described as a protein mediator of apoptosis<sup>[40]</sup>. We have shown the role of SATB1 in upregulating surviving and preventing apoptosis during cancer progression and establishment of chemoresistance<sup>[36]</sup>. SATB1 phosphorylation also appears to control interleukin-2 transcription as shown based on results obtained in a T-cell activation model; a similar mechanism may potentially be associated with SATB1 and its gene regulation activity<sup>[37]</sup>. In addition, SATB1 cleavage *via* sumoylation-directed caspase activity appears to regulate gene expression or may lead to clearance of immune cells<sup>[41]</sup>. Furthermore, SATB1 promotes cancer cell metastasis and overexpression of this protein increases resistance to chemotherapeutic drugs in breast cancer cells<sup>[42,43]</sup>. These observations suggest that HBx induces HURP expression by activating the p38/MAPK pathway and SATB1, leading to accumulation of survivin. We conclude that

activation of the HBx/SATB1/HURP axis may increase chemoresistance in hepatic cancer cells.

## HURP/GANKYRIN/p53 AXIS IN REGULATING HCC APOPTOSIS

The tumor suppressor p53 inhibits cancer development by inducing cell cycle arrest and apoptosis<sup>[44,45]</sup>. Some human tumors (10%) are characterized by overexpression of MDM2, an E3 ubiquitin ligase known for its role in the ubiquitination of p53 and its subsequent degradation by the proteasome<sup>[46]</sup>; this phenomenon may account for the development of many cancers, even those in which the *p53* gene is no longer functional<sup>[47]</sup>. We found that overexpressing HURP in HEK293 cells induces p53 ubiquitination and degradation of the protein by the proteasome<sup>[48]</sup>. Conversely, HURP silencing with short-hairpin RNA reverses these processes. Knockdown of HURP promotes p53 accumulation and reduces cell proliferation in SK-Hep-1 cells (p53<sup>+/−</sup>), while Mahlavu cells (p53-mutant) are not affected. HURP silencing showed no effect on cellular proliferation in Hep3B and H1299 cells (lung carcinoma) (both lack p53 activity). In comparison, HURP silencing sensitized SK-Hep-1 cells to cisplatin. HURP overexpression not only reduced exogenous p53 expression in H1299 and Hep3B cells but also reduced sensitivity of these cells to cisplatin. Notably, HURP expression induced HEK293 cell proliferation in an anchorage-independent manner; moreover, injection of SK-Hep-1 cancer cells in which HURP had been silenced produced tumors of smaller size in immunocompromised mice compared to control<sup>[48]</sup>.

The ankyrin-repeat oncoprotein gankyrin<sup>[49]</sup> has also been shown to be upregulated in HCC. Previous work indicated that this protein interacts with the product of retinoblastoma (*Rb*) gene as well as a subunit of the 26S proteasome subunit (S6 ATPase), a process that increases degradation of *Rb*<sup>[50,51]</sup>. Gankyrin is part of the 19S cap of the proteasome. This protein has an ankyrin repeat that forms alpha helices<sup>[51]</sup>. Gankyrin can increase the E3 ubiquitin ligase activity of MDM2, which regulates the degradation of the tumor suppressors *p53* and *Rb*, which are both often mutated in human tumors<sup>[52,53]</sup>. Gankyrin regulates the cell cycle by mediating protein-protein interactions involving CDK4 (a cyclin-dependent kinase). *Rb* may inhibit the activity of gankyrin and lead to inhibition of MDM2-mediated p53 ubiquitination in HCC cells<sup>[54]</sup>. In our study<sup>[48]</sup>, we observed that HURP represents an oncogene that reduces the level of p53 in normal cells and cancerous cells. Gankyrin was upregulated following HURP overexpression, and silencing of gankyrin reduced downregulation of p53 mediated by HURP. Importantly, high HURP levels positively correlated with gankyrin protein levels in HCC patients ( $n = 9$ ;  $r^2 = 0.778$ ).

We propose a mechanism to explain the activity of HURP and its action on gankyrin accumulation in cancer cells (Figure 2). In this model, HURP prevents the ubiqui-

**Figure 2** Simplified model illustrating the oncogenic properties of hepatitis B virus X protein and hepatoma upregulated protein in human liver cancer. In this cycle of gankyrin/MDM2-enhanced p53 degradation, HURP reduces MDM2-mediated ubiquitination of gankyrin, leading to accumulation of gankyrin in both normal and tumorigenic cells. Downstream effects of HURP appear to include malignant cell transformation and prevention of apoptosis induced by chemotherapeutic drug, processes which may in turn lead to the development of a chemoresistant cellular phenotype. HBx: Hepatitis B virus X protein; HURP: Hepatoma upregulated protein.

tion and degradation of gankyrin but in a process that does not involve the disruption of the interaction between MDM2 and gankyrin. Alternatively, HURP may regulate the activity of other deubiquitination enzymes by inducing binding to the gankyrin/MDM2 protein complex (not illustrated in the model shown in Figure 2), which may subsequently inhibit MDM2's effects on gankyrin degradation. More experimental data are needed to determine if HURP affects deubiquitination enzymes which interact with the MDM2/gankyrin protein complex. The degradation of p53 mediated by HURP may therefore be relevant to the development of HCC. Our findings identify a novel pathway for the malignant transformation induced by HURP and involving degradation of p53 and accumulation of gankyrin.

## CONCLUSION

Our observations suggest that HBx induces HURP expression via the p38/MAPK pathway and SATB1 activity. This process leads to accumulation survivin, which possesses anti-apoptotic properties. Our results also identify a novel cellular pathway in which the oncogenic protein HURP induces cancer transformation by inducing p53 degradation and gankyrin accumulation. The processes of cell survival and apoptosis have been shown to be regulated by differential activation of p53 target genes<sup>[55]</sup>. For instance, CAS may bind to p53 on chromatin and this process may induce expression of a set of genes that facilitate apoptosis<sup>[56]</sup>. In contrast, interaction between the zinc-finger protein Hzf and p53 activates expression of growth-arrest genes and promotes cell survival<sup>[56,57]</sup>. HURP-mediated p53 degradation thus appears to be relevant for the development of HCC. In conclusion, recent advances regarding the oncogenic proteins HBx and HURP as described here offer new strategies to defeat human

liver cancer.

## Abstract

### AIM

To analyze the association of the *CD36* polymorphism (rs1761667) with dietary intake and liver fibrosis (LF) in chronic hepatitis C (CHC) patients.

### METHODS

In this study, 73 patients with CHC were recruited. The *CD36* genotype (G > A) was determined by a TaqMan real-time PCR system. Dietary assessment was carried out using a three-day food record to register the daily intake of macronutrients. Serum lipids and liver enzymes were measured by a dry chemistry assay. LF evaluated by transient elastography (Fibroscan®)

and APRI score was classified as mild LF (F1-F2) and advanced LF (F3-F4).

## RESULTS

Overall, the *CD36* genotypic frequencies were AA (30.1%), AG (54.8%), and GG (15.1%), whereas the allelic A and G frequencies were 57.5% and 42.5%, respectively. CHC patients who were carriers of the *CD36* AA genotype had a higher intake of calories attributable to total fat and saturated fatty acids than those with the non-AA genotypes. Additionally, aspartate aminotransferase (AST) serum values were higher in AA genotype carriers compared to non-AA carriers (91.7 IU/L vs 69.8 IU/L,  $P = 0.02$ ). Moreover, the AA genotype was associated with an increase of 30.23 IU/L of AST ( $\beta = 30.23$ , 95%CI: 9.0-51.46,  $P = 0.006$ ). Likewise, the AA genotype was associated with advanced LF compared to the AG (OR = 3.60, 95%CI: 1.16-11.15,  $P = 0.02$ ) or AG + GG genotypes (OR = 3.52, 95%CI: 1.18-10.45,  $P = 0.02$ ).

## CONCLUSION

This study suggests that the *CD36* (rs1761667) AA genotype is associated with higher fat intake and more instances of advanced LF in CHC patients.

**Key words:** Hepatitis C virus infection; *CD36* receptor; Lipids; Liver fibrosis; Mexico

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** In this study, chronically infected hepatitis C patients who were carriers of the AA genotype of the *CD36* receptor polymorphism (rs1761667) showed a higher risk of advanced liver fibrosis compared to patients with an AG/GG genotype. This liver damage was associated with the consumption of a hepatopathogenic diet, high-calories and excessive intake of total and saturated fat, typical of the population of West Mexico. Thus, preventive nutritional intervention strategies based on the *CD36* genotype may be a useful tool to avoid further liver damage due to alterations in liver lipid metabolism and inflammation in patients with chronic hepatitis C infection.

## INTRODUCTION

The hepatitis C virus (HCV) is a hepatotropic human RNA virus, member of the *Flaviviridae* family<sup>[1]</sup>. Globally, it is estimated that nearly 170 million individuals are infected with HCV, causing yearly 350000 deaths<sup>[2]</sup>. Liver cirrhosis

causes a high burden of liver disease in Mexico, and HCV infection represents one of its primary etiologies<sup>[3,4]</sup>. Approximately two million Mexican individuals are infected with HCV<sup>[5,6]</sup> and up to 64% of patients with acute HCV infection fail to undergo spontaneous viral clearance<sup>[7]</sup>. Thus, chronically infected patients may be at risk of liver fibrosis (LF), cirrhosis, and hepatocellular carcinoma during a period of 20 to 30 years<sup>[4,8]</sup>.

Regardless of etiology, the pathogenesis of LF is influenced both by genetic and environmental factors<sup>[9,10]</sup>. High-fat diets, which have a significant content of saturated fatty acids (SFA), have been associated with the pathological processes known to be involved in liver fibrogenesis, including steatosis, inflammation, and insulin resistance<sup>[11-13]</sup>. Recently, we reported that in West Mexico, the general population and patients with liver disease consume an excessive amount of red meat, fried foods, sausages, and pastry products<sup>[14]</sup>. Consequently, these dietary trends have increased the proportional intake of calories, total fat, and SFA, which could eventually lead to liver damage in individuals that consume this type of hepatopathogenic diet.

In addition to the textural, olfactory, neural and hormonal mechanisms involved in food intake, taste perception is considered a critical determinant of dietary preferences<sup>[15,16]</sup>. There is growing evidence of the existence of a new taste modality related to fat preference<sup>[17]</sup>. Experimental studies suggest that the lingual cluster of differentiation 36 (*CD36*) receptor regulates the motivation for fatty food consumption in rodents<sup>[18,19]</sup>. This effect is carried out through the cellular capture of long-chain fatty acids by the *CD36* receptors on the taste buds<sup>[20]</sup>; subsequently, lipid signals are transduced into the gustatory nervous pathway<sup>[21]</sup>. Therefore, genetic variations that lead to changes in the expression of *CD36* could explain the interindividual differences in fat linking<sup>[15]</sup>. *CD36* protein levels are modulated by several single nucleotide polymorphisms (SNPs) in the *CD36* gene on chromosome 7<sup>[22,23]</sup>. One SNP consists of a nucleotide substitution of guanine for adenine in the *CD36* gene promoter sequence (-31118G > A, rs1761667)<sup>[24]</sup>. This SNP has been associated with a significant reduction in the *CD36* expression in several tissues<sup>[25,26]</sup>.

Recently, we reported an association between *CD36* with a higher intake of fat portions and high serum cholesterol among the general population of West Mexico<sup>[27]</sup>. However, its role in dietary intake and HCV-related liver damage is currently unknown. Therefore, this study aimed to analyze the association of the rs1761667 *CD36* polymorphism with dietary intake and LF in patients chronically infected with hepatitis C.

## MATERIALS AND METHODS

### Study design

In this retrospective study, 73 chronic hepatitis C (CHC) patients were recruited at the Department of Molecular Biology in Medicine from January 2012 to December 2014. Chronic HCV infection was defined as a positive

anti-HCV test result (ELISA Third-Generation, AxSYM, Abbott Laboratories, Illinois, United States) and the presence of serum HCV RNA for more than six months (COBAS® AmpliPrep/COBAS® Taqman® HCV Test; Roche Diagnostics, Pleasanton, CA, United States)<sup>[28,29]</sup>. Duration of infection (years) was estimated by the self-reported date of exposure to any known risk factor for HCV infection including the history of surgeries, blood transfusions, hemodialysis, acupuncture, injection drug use and tattooing<sup>[30]</sup>. Patients co-infected with the hepatitis B virus or human immunodeficiency virus, as well as alcohol abusers were excluded. Based on the pattern of alcohol intake in West Mexico, alcohol abusers were defined as those individuals that consumed more than two drinks per occasion, as previously described<sup>[31]</sup>. None of the CHC patients in the study group had received antiviral treatment for HCV infection.

### **Viral genotyping**

A VERSANT HCV Genotype 2.0 line probe assay was used to determine the HCV genotypes (Innogenetics, Ghent, Belgium).

### **Body mass index measurement**

An electrical bioimpedance apparatus was used to assess body mass index (BMI, kg/m<sup>2</sup>) (INBODY 3.0, Analyzer Body Composition, Biospace, South Korea).

### **Dietary assessment**

A three-day food record (two weekdays and one weekend day) was used as a tool to assess the patient's dietary intake, which has been previously used for our population<sup>[27,32-34]</sup>. This methodology provides accurate data concerning intake of food and nutrients<sup>[35]</sup>. Briefly, each subject was instructed on how to register the type, amount, and mode of preparation of all foods using food models<sup>[32]</sup>. The food records were coded by a qualified dietitian using a specialized software (Nutrikal VO®, Mexico). This program calculated the total amount of calories, fat, protein, and carbohydrates as well as the daily intake of food group servings such as sugars, meat, fruits, vegetables, fats, milk, legumes, and cereals. Dietary data were averaged over the three-day food records and were compared with the recommended dietary intakes based on the Mexican System of Food and Equivalents<sup>[36,37]</sup>.

### **Biochemical tests**

Serum was obtained from 10 mL blood samples after a 12-h overnight fast. Biochemical tests included glucose, alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), total cholesterol (TC), triglycerides (TG) and high-density lipoprotein cholesterol (HDL-c). The Friedewald formula was selected to estimate low-density lipoprotein cholesterol (LDL-c)<sup>[38]</sup>. The concentration of very low-density lipoprotein cholesterol (VLDL-c) was calculated as Total Cholesterol - (LDL-c + HDL-c). All biochemical tests were performed using a dry chemistry assay on a Vitros

250 Analyzer (Ortho-Clinical Diagnostics, Johnson and Johnson Co, Rochester, NY).

### **Liver fibrosis evaluation**

Liver stiffness (fibrosis) was evaluated by transient elastography (TE) (FibroScan® Echosens, Paris, France). The average value of ten successful readings expressed in kilopascals (kPa) was used as an indicator of LF according to the following classification: F1 (< 7 kPa), F1-F2 (7 kPa-8.49 kPa), F2 (8.5 kPa-9.49 kPa), F3 (9.5 kPa-12.49 kPa) and F3-F4 (12.5 kPa-14.49 kPa) and F4 (> 14.5 kPa)<sup>[39]</sup>. For this study, patients in either the F1 or F2 stages were classified as having mild LF and those in the F3 or F4 stages were classified as having advanced LF<sup>[40]</sup>. This classification was corroborated by calculating the aspartate aminotransferase-to-platelet ratio index (APRI score), as previously described<sup>[41]</sup>.

### **CD36 genotyping**

Leukocyte genomic DNA was extracted by a modified salting-out method<sup>[42]</sup>. The rs1761667 *CD36* polymorphism was detected by an allelic discrimination assay (TaqMan, Applied Biosystems, ID C\_8314999\_10; Foster City, CA, United States) in a 96-well format (StepOnePlus thermocycler (Applied Biosystems, Foster City, CA, United States) as previously described<sup>[27,34]</sup>.

### **Statistical analysis**

The sample size was estimated by a formula for the comparison of proportions<sup>[43]</sup> resulting in a statistical power of 80% ( $\beta = 0.20$ ) with a reliability of 95% ( $\alpha = 0.05$ ) based on the rs1761667 *CD36* allelic frequency in our population<sup>[24,27]</sup>. Quantitative variables were expressed as mean  $\pm$  SD and analyzed by one-way ANOVA adjusted for age, gender, and BMI. Subsequently, post hoc tests were run (Bonferroni's test and Dunnett's T3 test). Finally, to quantify the effect of the *CD36* genotypes on quantitative variables, linear regression was performed. The Hardy-Weinberg equilibrium (HWE) and qualitative variables were evaluated by the  $\chi^2$  test. The association of the *CD36* genotypes with LF was assessed by odds ratio (OR) as well as logistic regression tests considering a confidence interval (CI) of 95%. A *P*-value of < 0.05 was considered significant. Statistical analyses were performed using Arlequin (version 3.1), Epi Info™ 7 (CDC, Atlanta, GA) and SPSS Statistics, Version 20.0 (IBM Corp, Armonk, NY). All statistical analyses were reviewed and approved by an expert biomedical statistician.

### **Ethical guidelines**

This study was in compliance with the ethical guidelines defined by the Declaration of Helsinki 2013 and was approved by the Institutional Board Review (CI-01913). All patients who agreed to enter this study signed a written informed consent.

## **RESULTS**

In this study, the genotypic frequencies were AA (30.1%),

**Table 1** Demographical and clinical characteristics of the chronic hepatitis C patients classified by cluster of differentiation 36 genotype

Variable	<i>CD36</i> genotype			<i>P</i> -value
	AA	AG	GG	
No. of patients, <i>n</i> (%)	22 (30.1)	40 (54.8)	11 (15.1)	---
Age (yr)	48.1 ± 11.7	51.4 ± 11.1	53.7 ± 15.3	0.38
Gender (F/M)	(12/10)	(21/19)	(7/4)	0.68
BMI (kg/m <sup>2</sup> )	26.6 ± 4.1	24.9 ± 4.2	24.4 ± 3.1	0.52
Duration of infection (yr)	26.9 ± 10.1	25.2 ± 8.1	25.4 ± 7.4	0.62
HCV genotype 1, <i>n</i> (%)	15 (68.2)	27 (67.5)	8 (72.7)	0.40
HCV genotype 2, <i>n</i> (%)	5 (22.7)	9 (22.5)	3 (27.3)	
HCV genotype 3, <i>n</i> (%)	2 (9.1)	4 (10)	0 (0)	

Quantitative values are expressed as mean ± SD. Frequencies are expressed as percentage. CHC: Chronic hepatitis C; F/M: Female/male; BMI: Body mass index; HCV: Hepatitis C virus; *CD36*: Cluster of differentiation 36.

AG (54.8%), and GG (15.1%), whereas the allelic A and G frequencies were 57.5% and 42.5%, respectively. These genotypes were concordant with the HWE ( $P = 0.50$ ). In Table 1, the demographical and clinical characteristics of the CHC patients by *CD36* genotype are shown. No significant differences for the variables of age, gender, BMI, years of infection, and HCV genotypes between *CD36* genotypes were found. Only the CHC patients who were carriers of the AA genotype were overweight according to the WHO classification (BMI = 26.6 kg/m<sup>2</sup>). HCV genotype 1 was the most frequent with 68.4% of the total cases, followed by HCV genotype 2 (23.3%) and HCV genotype 3 (8.2%).

The daily dietary intake of the CHC patients classified by *CD36* genotype is shown in Table 2. CHC patients who were carriers of the *CD36* AA genotype had a higher caloric intake relative to total fat, and SFA than those with the AG and GG genotypes. No differences in protein and CH intakes between *CD36* genotypes were observed. Subsequently, the daily intake of several food groups classified by *CD36* genotype is shown in Table 3. Fats were the only food group associated with the *CD36* genotype. The lipid and liver profiles of the CHC patients by *CD36* genotype are shown in Table 4. CHC patients with the *CD36* AA genotype had more elevated serum levels of AST than the AG genotype carriers (91.7 IU/L vs 69.8 IU/L,  $P = 0.02$ ). Furthermore, an increase of 30.23 IU/L of AST was attributed to the AA genotype when compared with the AG genotype ( $\beta = 30.23$ , 95%CI: 9.0–51.46,  $P = 0.006$ ). No differences for ALT and GGT were observed (Table 4).

According to the categories of LF established in this study, 47.9% of the CHC patients had mild fibrosis, whereas 52.1% presented advanced fibrosis (Table 5). Among the CHC patients, the kPa values and APRI score were higher in those with advanced fibrosis compared to those with mild fibrosis (22.7 kPa vs 6.5 kPa,  $P < 0.001$  and 1.78 vs 0.81,  $P < 0.001$ , respectively). CHC patients with advanced fibrosis had a higher frequency of the *CD36* AA genotype than those with mild fibrosis (42.1% vs 17.1%,  $P = 0.002$ ), respectively (Table 6). Additionally, patients who were AA genotype carriers had

a higher risk for advanced fibrosis than those with the AG genotype (OR = 3.60, 95%CI: 1.16–11.15,  $P = 0.02$ ) and AG + GG genotypes (OR = 3.51 95%CI: 1.18–10.45,  $P = 0.02$ ). A logistic regression test was used to corroborate this association (OR = 2.23 95%CI: 1.03–4.81,  $P = 0.041$ ).

## DISCUSSION

Genetic polymorphisms in fat taste perception may partially explain the interindividual variability in fat intake<sup>[15]</sup> and their association with the risk of developing chronic diseases<sup>[15,44]</sup>. Over recent years, it has been proposed that the *CD36* receptor is an oral fat sensor that may influence an individual's preference for high-fat foods<sup>[15–18]</sup>. Specifically, it has been shown that the *CD36* AA genotype decreases fat taste perception<sup>[45–48]</sup>. In this study, the frequency of *CD36* AA genotype was 30.1%. In regards to food consumption, despite that the three-day food record may not be representative of the long-term food variety, the amount of fat intake represented over 30% of the total daily calories. It has been documented that the prolonged ingestion of high-fat diets increases the risk for metabolic disorders<sup>[49]</sup>. These data were consistent with previous results found in overweight patients from the general population of West Mexico<sup>[27]</sup>.

The association of high-fat diets with LF has been well documented in animal models<sup>[11–13]</sup> as well as in humans in different populations<sup>[50,51]</sup>. In this study, among the *CD36* AA genotype carriers, more cases of advanced LF were detected. This disease stage is characterized by steatosis and persistent inflammation<sup>[4]</sup>. Also, they exhibited significantly higher levels of AST, which is a better predictor of progression of LF than ALT or GGT<sup>[52]</sup>. Furthermore, two validated non-invasive methods (TE and APRI score) were used to evaluate LF<sup>[41,53]</sup>. Since no differences in demographic and viral characteristics between *CD36* genotypes were found, the likelihood of HCV-related LF seems to be enhanced because of the higher consumption of fat portions observed among the *CD36* AA genotype carriers.

The immunological mechanisms that regulate LF progression during HCV infection have been extensively studied<sup>[54–56]</sup>. However, alterations in lipid and lipoprotein metabolism have been reported to play a key role<sup>[9]</sup>, considering that chronic HCV infection is characterized by hypocholesterolemia and reduced levels of LDL-c, TG and apolipoprotein B (apoB)<sup>[57]</sup>. Recently, a novel interaction of the *CD36* receptor in liver VLDL-c metabolism has been proposed<sup>[58]</sup>. Findings in a further study, concurring with this hypothesis, have demonstrated that *CD36* deletion can reduce VLDL output and liver fat in obese mice<sup>[59]</sup>. This finding was related to the enhanced production of the series-2 liver prostaglandins, which have been shown to suppress VLDL output and increase the hepatocyte triglyceride content in an inflammatory condition-dependent manner<sup>[60]</sup>. Thus, it is plausible that the AA genotype carriers may have a lower expression of the *CD36* receptor that could contribute to liver steatosis and consequently to fibrosis similar to the effects of

a *CD36* deletion. Nonetheless, further investigation is required to elucidate the correlation between the *CD36* genotype and liver steatosis and clarify its interaction with other key molecules involved in this metabolic alteration, such as the microsomal triglyceride transfer protein (MTTP), apolipoprotein E and apoB<sup>[61,62]</sup>.

Concerning the nutritional management of liver disease,

**Table 5** Kilopascals and aspartate aminotransferase to platelet ratio index score values by the severity of liver fibrosis among chronic hepatitis C patients

Variable	Mild fibrosis	Advanced fibrosis	<i>P</i> -value
No. of patients, <i>n</i> (%)	35 (47.9)	38 (52.1)	-
kPa	6.5 ± 1.7	22.7 ± 13.4	< 0.001

including HCV infection, the majority of international guidelines focus on the reduction of total fat and SFA intake<sup>[51,63]</sup> without taking into account the nutrigenetics and food cultures of individual populations. We advocate shifting towards a genome-based nutrition approach as a preventive and intervention strategy for chronic diseases given the fact that, worldwide, human populations differ<sup>[64]</sup>. Specifically, in the case of Mexico and most of Latin America, the people in these regions are genetically an admixture of Amerindian, Caucasian, and African ancestries with a heterogeneous inter-regional distribution<sup>[65,66]</sup>. Furthermore, 70% of the Mexican general population is overweight or obese due to the consumption of an obesogenic and hepatopatogenic diet that was previously described<sup>[4,14,64]</sup>. Thus, based on the gene-environmental interactions that currently prevail in the Mexican population, specific preventive strategies are crucial to diminish the progression of liver damage caused by alterations in lipid metabolism and inflammation.

In this study, the frequency of the *CD36* AA genotype (30.1%) was comparable to the pattern of distribution (28.4%) observed in non-diabetic individuals of Caucasian origin<sup>[24]</sup>. These findings are consistent with the high Caucasian ancestry that prevails among Mexican-Mestizos and HCV patients that have been previously reported<sup>[7]</sup>, whereas different frequencies have been reported elsewhere<sup>[67-69]</sup>. Thus, we consider that the detection of the *CD36* genotype, as well as other nutrient-interacting genes<sup>[31-34]</sup> could be used as auxiliary tools to predict the adherence to dietary regimens and for the implementation of genome-based intervention

**Table 6 Association of the cluster of differentiation 36 genotype with the severity of liver fibrosis among chronic hepatitis C patients**

CD36 genotype	Mild fibrosis n (%)	Advanced fibrosis n (%)	Genotype comparison	Odds ratio (95%CI)	P-value

AG	23 (65.7)	17 (44.7)	AA vs AG	3.60 (1.16-11.15)	0.02
GG	6 (17.1)	5 (13.2)	AA vs AG/GG	3.51 (1.18-10.45)	0.02

CD36: Cluster of differentiation 36.

strategies<sup>[64]</sup> aimed at reducing fat intake and dyslipidemia in our population<sup>[27]</sup>.

In conclusion, the AA genotype of the rs1761667 CD36 polymorphism was associated with higher fat intake and more instances of advanced LF in CHC patients. However, further genomic studies are needed to analyze the role of the CD36 polymorphism on liver disease in other populations within Mexico and worldwide.

## COMMENTS

### Background

Regardless of etiology, liver fibrosis (LF) pathogenesis is influenced by genetic and environmental factors, such as dietary intake. Diets that are high in saturated fatty acids have been associated with the pathological processes involved in liver fibrogenesis, including steatosis, inflammation, and insulin resistance. There is growing evidence that suggest that the lingual cluster of differentiation 36 (CD36) receptor regulates the motivation for fatty food consumption. Therefore, genetic variations in CD36 expression could explain the global heterogeneity of fat linking and its association with chronic diseases. This study aimed to analyze the association of the CD36 polymorphism (rs1761667) with dietary fat intake and LF in chronically infected hepatitis C patients.

### Research frontiers

The results of this study contribute to the understanding of the specific gene-environmental interactions that occur among a population with an admixture genome. The role of CD36 genetic variation on hepatitis C virus (HCV)-related liver disease or other chronic diseases in distinct populations worldwide requires further studies.

### Innovations and breakthroughs

In this study, the authors provide evidence regarding the effect of the CD36 (AA) risk genotype on the consumption of a high-fat diet and its association with LF in HCV patients.

### Applications

The detection of the CD36 genotype together with other nutrient-sensing genes could be useful for the implementation of genome-based intervention strategies aimed at reducing fat intake and dyslipidemia in chronic hepatitis C patients.

### Peer-review

The authors of this paper evaluated the dietary fat intake and the degree of LF in patients chronically infected with hepatitis C based on the CD36 genotypes. The results suggest that the risk AA genotype of the CD36 polymorphism was associated with higher dietary fat intake and more instances of advanced LF in chronic hepatitis C patients.

### Abstract

#### AIM

To propose several alternatives treatment of type 1 hepatorenal syndrome (HRS-1) what is the most severe expression of circulatory dysfunction on patients with portal hypertension.

#### METHODS

A group of eleven gastroenterologists and nephrologists performed a structured analysis of available literature. Each expert was designated to review and answer a question. They generated draft statements for evaluation by all the experts. Additional input was obtained from medical community. In order to reach consensus, a modified three-round Delphi technique method was used. According to United States

Preventive Services Task Force criteria, the quality of the evidence and level of recommendation supporting each statement was graded.

## RESULTS

Nine questions were formulated. The available evidence was evaluated considering its quality, number of patients included in the studies and the consistency of its results. The generated questions were answered by the expert panel with a high level of agreement. Thus, a therapeutic algorithm was generated. The role of terlipressin and norepinephrine was confirmed as the pharmacologic treatment of choice. On the other hand the use of the combination of octreotide, midodrine and albumin without vasoconstrictors was discouraged. The role of several other options was also evaluated and the available evidence was explored and discussed. Liver transplantation is considered the definitive treatment for HRS-1. The present consensus is an important effort that intends to organize the available strategies based on the available evidence in the literature, the quality of the evidence and the benefits, adverse effects and availability of the therapeutic tools described.

## CONCLUSION

Based on the available evidence the expert panel was able to discriminate the most appropriate therapeutic alternatives for the treatment of HRS-1.

**Key words:** Hepatorenal syndrome; Delphi; Consensus; Evidence-based medicine; Treatment

**Core tip:** The available evidence for the treatment of type 1 hepatorenal syndrome (HRS-1) was evaluated. The role of terlipressin and norepinephrine was confirmed as the pharmacologic treatment of choice. On the other hand the use of the combination of octreotide, midodrine and albumin without vasoconstrictors was discouraged. The role of several other options was also evaluated and the available evidence was explored and discussed. Liver transplantation is considered the definitive treatment for HRS-1 and the necessary conditions to optimize the recovery of renal function was also discussed.

Therapeutic alternatives for the treatment of type 1 hepatorenal syndrome: A Delphi technique-based consensus. *World J Hepatol* 2016; 8(25): 1075-1086 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i25/1075.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i25.1075>

## INTRODUCTION

Hepatorenal syndrome (HRS) is a severe disease strictly

related to the presence of portal hypertension (PHT). The cumulative probability of HRS in patients with cirrhosis and ascites was initially reported as 18% at one year and 39% at five years<sup>[1]</sup>. More recently and employing the Ascites Club criteria, the incidence of HRS was estimated as 7.1% in a cohort that was followed for  $41 \pm 3$  mo<sup>[2]</sup>. Table 1 depicts the diagnostic criteria proposed by the Ascites Club for the diagnosis of HRS<sup>[3]</sup>. These criteria are the result of a consensus based on clinical knowledge of the condition, and at this time, there are no biochemical tests clinically available for the diagnosis of HRS. Two types of HRS have been defined by the Ascites Club. Type 2 (HRS-2) is a slowly progressive disease, clinically expressed as refractory ascites with an average median survival of approximately six months. In contrast, type 1 HRS (HRS-1) is a catastrophic disease characterized by a rapid decrease in glomerular filtration rate<sup>[3]</sup>, and it is considered the most extreme expression of circulatory dysfunction secondary to PHT. Its diagnosis requires the exclusion of intrinsic renal disease, hypovolemia, shock and exposure to nephrotoxic drugs. It has a very poor prognosis with a mean survival of only two weeks without treatment<sup>[4]</sup>. Thus, HRS-1, is considered one of the most severe complications of cirrhosis and PHT, and it represents a therapeutic challenge for hepatologists.

Several alternatives have been proposed for the treatment of HRS-1. Although liver transplantation (LT) appears to be the logical definitive treatment for this condition, other interventions are needed while the patient is on the waitlist, sometimes for several weeks before LT. Moreover, for a myriad of reasons, some patients cannot be considered appropriate candidates for LT. Hence, LT it is not a proper alternative for every patient, and other therapeutic alternatives must be considered.

Recently, the Chilean Gastroenterology Society provided a consensus for the treatment of HRS-1. The aim of this article is to show the results of the consensus and to suggest a therapeutic approach based on the best available evidence.

## MATERIALS AND METHODS

### Participants and literature search

The consensus organizing committee [under the sponsorship of the Chilean Society of Gastroenterology (<http://sociedadgastro.cl>)] assembled a group of adult gastroenterologists and nephrologists with expertise in the management of advanced liver disease patients and evidence-based medicine. The panel generated a list of questions relevant for the treatment of HRS-1. To address these questions, two members of the panel (JCC and JPA) performed separate searches in PubMed®, retrieving reports published in English or Spanish through June 2014. The search results were distributed. Simultaneously, each individual panelist contributed additional data and abstracts presented at meetings. Each expert was designated to review and answer a question. They generated draft statements for evaluation by all the experts; the answers were to

**Table 1** Criteria for the diagnosis of hepatorenal syndrome

<b>HRS</b>	
Presence of cirrhosis and ascites	
Serum creatinine > 1.5 mg/dL (or 133 micromoles/L)	
No improvement of serum creatinine (decrease equal to or less than 1.5 mg/dL) after at least 48 h of diuretic withdrawal and volume expansion with albumin (recommended dose: 1 g/kg per day up to a maximum of 100 g of albumin/day)	
Absence of shock	
No current or recent treatment with nephrotoxic drugs	
Absence of parenchymal kidney disease as indicated by proteinuria > 500 mg/d, microhematuria (> 50 RBCs/high power field, and/or abnormal renal ultrasound scanning)	
<b>HRS-1</b>	
Rapidly progressive renal failure defined by a doubling of the initial serum creatinine to a level greater than 2.5 mg/dL or 220 $\mu$ mol/L in less than 2 wk	
Although it may appear spontaneously, HRS-1 often develops with a precipitating event, particularly spontaneous bacterial peritonitis	
HRS-1 occurs in the setting of an acute deterioration of circulatory function (arterial hypotension and activation of the endogenous vasoconstrictor systems) and is frequently associated to rapid impairment in liver function and encephalopathy	
<b>HRS-2</b>	
Characterized by a moderate renal failure (serum creatinine greater than 1.5 mg/dL) which follows a steady or slowly progressive course. It appears spontaneously in most cases	
HRS-2 is frequently associated with refractory ascites. Survival of patients with HRS-2 is shorter than that of patients with ascites but without renal failure	

HRS: Hepatorenal syndrome; HRS-2: Type-2 HRS; HRS-1: Type-1 HRS.

**Table 2** Levels of evidence according to the study design

Level of evidence	Description
Type I	Evidence obtained at least from one well-designed, randomized, controlled <sup>1</sup> trial or from a systematic review of randomized clinical studies
Type II	II -1 evidence obtained from non-randomized, prospective, controlled <sup>1</sup> studies II -2 evidence obtained from cohort observational studies <sup>2</sup> or case-control studies, preferably multi-centric II -3 evidence obtained from case series
Type III	Opinion of authorities on the subject matter based on expertise, expert committees, case reports, pathophysiological studies or basic science studies

<sup>1</sup>A controlled study is a study where the intervention is managed by the researcher; <sup>2</sup>An observational study is a study where the intervention is not controlled by the researcher.

be supported through a review of the literature. The quality of the evidence (Table 2) and the level of recommendation (Table 3) were graded following the United States Preventive Services Task Force criteria<sup>[5,6]</sup>.

### Consensus methodology

Initially, each expert wrote a draft recommendation statement and sent to organizing committee for evaluation and distribution among the entire panel. A 1 to 5 Likert scale (where 1 means "totally disagree" and 5 "totally agree") was used to measure agreement. To reach a final consensus a modified three-round Delphi technique method was used as described by Arab *et al.*<sup>[7]</sup>.

The final statements and recommendations were exposed during the XLI Chilean Congress of Gastroenterology and the I Chilean Symposium on HRS-1 treatment in Coquimbo, Chile, in November 2014. The audience of approximately 450 physicians voted in real-time. The approved final recommendations (those with average scores  $\geq 4$  on the Likert scale) are presented below.

### Statistical analysis

Statistical review of the study was performed by a

biomedical statistician. Level of agreement from the Delphi panel was expressed in mean  $\pm$  SD.

## RESULTS

### Are vasoconstrictors effective in the treatment of HRS-1?

**Terlipressin:** Terlipressin is the vasoconstrictor of choice for the treatment of HRS-1, due to the large number of studies (and enrolled subjects) showing its effectiveness and its positive effects on survival. Terlipressin is a synthetic analogue of vasopressin acting through V1 receptors, increasing effective circulating volume, and by means of an increase in resistance in the splanchnic territory (which reduces portal pressure), it allows for the redistribution of the bloodstream, increasing renal perfusion<sup>[8]</sup>. Two important controlled, randomized and multicenter trials showed that terlipressin associated with albumin resulted in an improvement in renal function and could also reverse HRS-1<sup>[9,10]</sup>. A recently published meta-analysis, which included 320 subjects, proved 50% effectiveness with an OR of 7.5<sup>[11]</sup>.

An Italian trial reported on the impact of terlipressin on the survival rate of HRS-1 patients. This randomized

**Table 3** Levels of recommendation according to the available evidence

Recommendation	Description
A	The consensus strongly recommends the mentioned intervention or service. This recommendation is based on high quality evidence, with a benefit that significantly exceeds the risks
B	The consensus recommends the regular clinical use of the mentioned intervention or service. This recommendation is based on moderate quality evidence, with a benefit that exceeds the risks
C	The consensus does not make any positive or negative recommendation regarding the mentioned intervention or service. A categorical recommendation is not provided, because the evidence (of at least moderate quality) does not show a satisfactory risk/benefit relationship. The decision has to be made on a case-by-case basis
D	The consensus makes a negative recommendation against the mentioned intervention or service. The recommendation is based on at least moderate quality evidence, not showing any benefit or where the risk or damage exceeds the benefits of the intervention
I	The consensus concludes that the evidence is insufficient, due to low-quality studies, heterogeneous results or because the risk/benefit balance cannot be determined

trial included 52 subjects and showed a higher and more significant probability of survival in the group treated with terlipressin<sup>[12]</sup>. These findings were confirmed in a recent meta-analysis published by Cochrane, including 6 trials and 309 subjects, in which a statistically significant reduction in the mortality rate was observed in HRS-1 patients treated with terlipressin (RR = 0.76, 95%CI: 0.61-0.95)<sup>[13]</sup>.

For the treatment of HRS-1, it is recommended to start the administration of terlipressin at an initial dose of 0.5-1 mg every 4-6 h as an IV bolus, with the possibility of increasing the dose up to 2 mg every 4-6 h if there is no proper response after 3 d; a proper response is defined as a reduction > 25% from basal plasma creatinine. It is recommended to maintain the administration of terlipressin until creatinine levels decrease to less than 1.5 mg/dL or for a maximum of 14 d<sup>[14]</sup>. Recurrence can occur after discontinuation of the therapy (< 20%)<sup>[15]</sup>, in which case, the recommendation is to repeat a new cycle. The most frequent side effects are abdominal pain, diarrhea, arrhythmia and ischemic complications. The incidence of serious effects requiring suspension of terlipressin is close to 7%<sup>[16]</sup>. The presence of coronary, vascular or peripheral arterial ischemic disease must be considered a contraindication for the use of terlipressin and other systemic vasoconstrictors.

**Recommendation:** Treatment with terlipressin associated with albumin represents the drug therapy of choice in HRS-1 patients, and it is capable of reversing this condition and reducing the associated mortality rate (Evidence Level I, grade of recommendation A, Agreement 5 ± 0).

**Norepinephrine:** Norepinephrine, an adrenergic agonist widely available in critical care units, is regarded as an alternative therapy in association with albumin, and it is effective and safe for the treatment of HRS-1<sup>[17]</sup>. Two randomized trials compared norepinephrine to terlipressin, reporting similar efficacy levels for reversal of HRS-1, as well as a comparable safety profile<sup>[18,19]</sup>. A recent study conducted in India enrolled 46 HRS-1 patients and reported results that confirmed previously published results<sup>[20]</sup>, in addition to a recently published meta-analysis<sup>[21]</sup>. The effects of both drugs on mortality

rates after 30 d and the probability of HRS-1 recurrence were also similar. In this meta-analysis, adverse effects were less common with the use of norepinephrine; however, only four studies were considered<sup>[21]</sup>.

Norepinephrine is used as a continuous intravenous infusion at a 0.5 mg/h initial dose, with the purpose of achieving a > 10 mmHg increase in basal mean blood pressure (MBP). Accordingly, the dose can be adjusted by 0.5 mg/h every 4 h until a maximum dose of 3 mg/h is attained<sup>[20]</sup>.

The significantly reduced cost and broad availability of norepinephrine are attractive<sup>[18,20]</sup>. It must be considered, however, that the number of cases treated with norepinephrine remains low, compared to the number of cases treated with terlipressin.

**Recommendation:** The use of norepinephrine associated with albumin represents an alternative to the use of terlipressin for the treatment of HRS-1; however, the currently available information is not as abundant in comparison to terlipressin (Evidence Level I, grade of recommendation B, Agreement 5 ± 0).

**Octreotide plus midodrine:** The most studied vasoconstrictor used for the treatment of HRS-1 is terlipressin, and it results in complete reversal of the disease and a reduction in the associated mortality rate. However, many studies have assessed the use of other vasoconstrictors, with or without volume expansion agents, with variable results<sup>[22]</sup>. The association of midodrine, a systemic vasoconstrictor acting on alpha-adrenergic receptors, and octeotride, a synthetic analogue of vasopressin that inhibits the release of endogenous vasodilators, has shown a benefit to mortality rates in some small studies<sup>[23,24]</sup>. Regarding reversal, some studies have shown complete response with reduction in creatinine to values less than 1.5 mg/dL; nevertheless, other studies have shown contradictory results<sup>[25]</sup>. These two points were assessed in a meta-analysis published in 2012<sup>[26]</sup> that included 256 subjects from 3 separate observational studies. This meta-analysis showed a reduction in mortality rates at 30 d (OR = 0.33; 95%CI: 0.18-0.60) and 90 d (OR = 0.17; 95%CI: 0.03-0.96) but no conclusive results in terms of HRS-1 reversal; however, a delay in progression was observed, based on

a reduction in creatinine levels that was not statistically significant. It is important to note that, in the cases of the control groups in these three studies, two studies used dopamine, and one study used albumin. This reduction in the progression of renal function would be the mechanism believed to reduce the mortality rate, even without achieving HRS-1 reversal.

A randomized, monocentric trial including 23 subjects compared the association of midodrine and octeotride with noradrenaline<sup>[27]</sup>, with complete response in 73% and 75% of subjects, respectively, without significant differences between the two therapeutic options. However, the small number of subjects included in this study limited the interpretation of the results. In contrast, a recent prospective, randomized trial compared the use of terlipressin plus albumin (27 subjects) with the combination of midodrine/octreotide plus albumin (22 subjects). This study showed a 70.4% response rate in the terlipressin branch vs a 28.6% response rate in the midodrine/octreotide branch. Moreover, the complete response rate was significantly higher in the terlipressin branch [55.5% vs 4.8% in the midodrine/octreotide group ( $P < 0.001$ )], showing low efficacy in terms of complete response in the midodrine/octreotide group<sup>[28]</sup>. These results were consistent with the low reversal rate described in previous studies.

Some studies have suggested that an increase in MBP is necessary for reverting alterations in renal hemodynamics specific to HRS-1; this increase is greater in patients responding to vasoconstrictor treatment compared with non-responding patients, regardless of the vasoconstrictor used. In a joint analysis of 501 patients from 21 studies, Velez *et al.*<sup>[29]</sup> proved a significant correlation between an increase of 10 to 15 mm in MBP and the HRS-1 patient's response to treatment, with improvement in renal function. Other studies have not been able to prove this association. The main limitation of the study by Velez *et al.*<sup>[29]</sup> is that it gathered information from previous studies that were not designed to assess the measured result. Therefore, their study cannot be regarded as having sufficient evidence for issuing a recommendation.

With regard to the safety and efficacy of the use of midodrine and octeotride, these data were assessed in a retrospective study<sup>[30]</sup> including 60 HRS-1 patients, compared to 21 patients treated only with albumin. Midodrine treatment combined with octeotride was not associated with significant adverse effects.

**Recommendation:** Although the midodrine-octeotride combination is a safe treatment with easy administration, its beneficial effects on survival and improvement in renal function have not been consistent across trials. Therefore, we do not recommend its use for the treatment of HRS-1 (Evidence Level I, grade of recommendation B, Agreement  $4.6 \pm 0.5$ ).

**Vasopressin:** Vasopressin has been proposed as a vasoconstrictor for the treatment of HRS-1 in some

countries where no other therapies are available.

A retrospective study<sup>[31]</sup> compared the use of vasopressin alone and in combination with octeotride in HRS-1 patients vs the use of octeotride. This study showed a reduction in creatinine to values  $< 1.5$  mg/dL with the use of vasopressin with or without octeotride vs octeotride alone (42% vs 38% vs 0%, respectively,  $P = 0.001$ ), with an OR of 6.4 as well as an improvement in the survival rate and the possibility of being candidate for LT.

The dose required for achieving this objective has not yet been established. The aforementioned study required a dose of  $0.23 + 0.19$  U/min for a period of 5 to 9 d. In contrast, the use of low doses of vasopressin (1 U/h)<sup>[32]</sup> was effective for the restoration of urine volume in HRS-1 patients and patients with congestive heart failure, without improving the overall prognosis of the patients or their creatinine levels.

The use of vasopressin requires strict monitoring to avoid adverse effects associated with ischemic phenomena.

**Recommendation:** We do not recommend the use of vasopressin for the treatment of HRS-1, due to several adverse effects and the lack of randomized, clinical trials supporting its use (Evidence Level II -2, grade of recommendation I, Agreement  $4.8 \pm 0.3$ ).

### **Efficacy of the use of albumin**

The use of human albumin in cirrhosis is based mainly on its hemodynamic properties, improving oncotic pressure in patients with circulatory disorders, and it is characterized by dilatation of the splanchnic territory, effective hypovolemia and activation of the renin-angiotensin-aldosterone system. In addition, albumin has antioxidant and immunomodulatory functions; albumin also has the capacity to transport and metabolize other substances and has hemostatic and endothelial stabilization effects. In cirrhotic patients, both plasma albumin concentration and its functional properties are diminished, becoming even more severe depending on the level of the patient's renal failure<sup>[33]</sup>.

The aforementioned situation has been the rationale for the use of albumin in decompensated cirrhosis. The main evidence in favor of its use is in the prevention of renal failure, both in the presence of spontaneous bacterial peritonitis and after a large-volume paracentesis.

In HRS-1, circulatory disorders are established at its highest levels, and by definition, these disorders are not reversed by the administration of albumin alone, the use of which is commonly suggested to expand intravascular volume and to improve cases of prerenal failure, thus disregarding the HRS-1 diagnosis in these patients<sup>[3]</sup>.

Vasoconstrictors are the basis of HRS-1 treatment, and in the majority of well-designed, prospective and randomized studies, they have been associated with the use of albumin as a plasma expander and compared to the isolated use of albumin<sup>[9,12]</sup>. In these studies, there has been evidence of a significant difference in favor of combined therapy regarding HRS-1 reversal,

improvement of renal function, MBP and diuresis.

The purpose of a meta-analysis performed by Dobre *et al.*<sup>[11]</sup> was to prove the usefulness of terlipressin with or without albumin, compared with placebo with or without albumin. The study showed that HRS-1 reversal using the first alternative was significantly more common, with an OR of 7.47. Of the six studies included in the meta-analysis, only 1 did not use albumin, and it was the oldest (1998) and had the smallest number of subjects<sup>[11]</sup>, proving that the majority of researchers have considered albumin to be a part of the basic treatment for HRS-1 patients.

Regarding the assumption that albumin provides an additional benefit to the use of vasoconstrictors alone, we only found evidence of an observational study designed to answer this question. Seventy-seven percent of the patients who used terlipressin and albumin experienced a resolution of HRS-1, compared to 25% in the group that used terlipressin alone. In addition, the group of patients treated with terlipressin plus albumin showed significant improvement in MBP and a reduction in the activation of the renin-aldosterone system<sup>[34]</sup>.

Along these same lines, the retrospective study by Moreau *et al.*<sup>[35]</sup> assessing the usefulness of terlipressin in HRS-1 showed that the respondent group used albumin in 79% of cases vs 68% in the non-respondent group, which was not a significant difference.

There is no evidence available that other fluids (such as crystalloids) can have a similar effect to albumin associated with vasoconstrictors. No studies have been designed for this purpose, and no such studies are likely to be performed because the use of crystalloids increases ascites and, therefore, intra-abdominal pressure, which in turn affects renal perfusion and reduces the likelihood of improvement of renal and circulatory failure. An observational study, in which a large-volume paracentesis with reposition of albumin was performed in HRS-1 patients, showed partial improvement of renal function, supporting the hypothesis that a reduction in intra-abdominal pressure could be useful for renal perfusion recovery<sup>[36]</sup>.

**Recommendation:** The use of albumin with vasoconstrictors is the therapy of choice for treating HRS-1. The use of albumin without vasoconstrictors is only recommended in the stage prior to HRS-1 diagnosis to exclude patients with prerenal failure (Evidence Level II-2, grade of recommendation B, Agreement  $4.8 \pm 0.3$ ).

### **Efficacy of the use of a trans-jugular intrahepatic portosystemic shunt**

There is scarce evidence for the use of trans-jugular intrahepatic portosystemic shunt (TIPS) in HRS-1. In a study including 16 patients, 6 with HRS-1 and 10 with HRS-2 and Child-Pugh scores of 7-9, a duplication of creatinine clearance in serum and increased sodium concentration excreted in the urine were observed two weeks after the TIPS procedure. Three of the HRS-1 patients required hemodialysis during the progression of

the disease, and 12 and 18 d after the TIPS procedure, two patients were able to stop hemodialysis. There was an improvement in renal function, even after 6-8 wk. Three of the 16 HRS-1 and HRS-2 patients did not respond, and they died within a 6-wk period<sup>[37]</sup>. A prospective, non-randomized, phase II study included 41 patients with cirrhosis and HRS without indications for transplantation: 21 with HRS-1 and 20 with HRS-2. Thirty-one of these patients (14 type 1 and 17 type 2) received TIPS and were followed for a mean of 24 mo. The use of TIPS in HRS-1 and HRS-2 patients reduced significantly ( $P < 0.001$ ) the hepatic venous pressure gradient and increased creatinine clearance and sodium excretion. Those patients who received TIPS showed higher survival rates than those who did not. There was only one death related to the procedure (3.2%). It is important to note that the HRS-2 patients had a significantly greater benefit and were identified as a variable independently correlated with survival<sup>[38]</sup>. Another uncontrolled study assessed 7 patients with cirrhosis and HRS-1. The TIPS procedure was associated with gradual improvements in the glomerular filtration rate (9 to 27 mL/min) and blood urea nitrogen and creatinine reduction. The majority of patients also showed a reduction in the activity of the renin-angiotensin system and in the sympathetic nervous system, suggesting an improvement in hemodynamic parameters. The average survival after the TIPS procedure was approximately 5 mo, which was longer than the survival rate expected for these patients<sup>[39]</sup>.

Unfortunately, many HRS-1 patients are too sick to undergo a TIPS procedure, mainly because the procedure can present complications such as deterioration of hepatic encephalopathy and liver function (increased bilirubin levels), bleeding and intravenous contrast-induced nephropathy<sup>[40]</sup>. In a study that designed a predictive model for determining the survival rate after a TIPS procedure, patients with HRS-1 due to alcoholic cirrhosis or chronic cholestatic disease showed a 25% mortality rate 90 d after the procedure and a mortality rate of 80% in patients with cirrhosis due to other causes<sup>[41]</sup>.

In general, these results suggest that TIPS could be considered for patients with relatively preserved liver function and as a bridge therapy to LT. However, due to the risks associated with the procedure and the lack of well-designed studies, this procedure should be considered only as a last resource.

**Recommendation:** Due to the lack of evidence, the consensus considers that the use of TIPS shall not be recommended in HRS-1 patients (Evidence Level II-2, grade of recommendation I, Agreement  $4.7 \pm 0.4$ ).

### **Extracorporeal substitution therapies**

#### **Role of renal replacement therapies for the management of acute renal failure associated with HRS-1:**

If there is no response to proven pharmacological strategies, acute renal failure (ARF) in HRS-1 takes an irreversible course unless the patient undergoes LT. At this point, patients develop oliguria, hydrosaline balance

disorders and severe metabolic disorders that can lead to the prescription of renal replacement therapies (RRTs).

For patients who will not undergo LT, the potential benefit of RRT is controversial due to the high morbidity-mortality associated with RRT, basically determined by poor hemodynamic tolerance and/or hemorrhages associated with liver failure complications<sup>[42]</sup>.

For patients who are non-respondent to pharmacological therapy or TIPS, who are waiting for a LT or who are under evaluation to undergo the surgery, the use of RRT is advised as a bridge to LT. In a retrospective study developed by Keller *et al.*<sup>[43]</sup>, the survival rate of patients with HRS-1 was 44% in the group that received RRT vs 10% in the group that did not receive the therapy. However, this higher survival rate could be related to reduced RRT tolerance, which could increase the number of hospitalizations. In a report of 4 patients who received hemodialysis while waiting for LT, Capling *et al.*<sup>[44]</sup> observed an average survival of 236 d (31 to 460 d). All of the patients survived the initial event and were discharged, but 33% of the days gained were then spent in hospitalization due to intercurrent diseases. The most common cause of hospitalization was hepatic encephalopathy; the authors believe that avoiding lactulose during the days when the patient undergoes dialysis, to prevent diarrhea events, might have been a contributing factor<sup>[44]</sup>.

Efficacy, safety and the best RRT modality in HRS-1 patients have not been systematically assessed. Potential advantages of continuous vs intermittent RRT include slower removal of fluids with higher hemodynamic stability and slower control of solute concentrations, which is why many clinicians prefer continuous RRT in patients with hemodynamic instability and in patients with evidence of cerebral edema<sup>[45]</sup>. In two studies, Davenport and Detry proved that continuous RRT was better tolerated than intermittent hemodialysis in patients with liver failure, evidenced by greater cardiovascular stability, gradual correction of hyponatremia and less variation in intracranial pressure<sup>[46,47]</sup>.

**Recommendation:** We recommend the initiation of RRT in patients with HRS-1 refractory to pharmacological therapy who are candidates for LT. In patients with hemodynamic instability and/or evidence of cerebral edema, we recommend the use of other continuous RRTs; We recommend maintaining RRT in patients with HRS-1 who are candidates for LT and who must be temporarily removed from the waiting list because they have developed an intercurrent disease (Evidence Level II-3, grade of recommendation C, Agreement 4.6 ± 0.5).

**Extracorporeal liver support with albumin dialysis (molecular adsorbent recirculating system):** The molecular adsorbent recirculating system (MARS) is an extracorporeal liver support that, by means of recirculating albumin dialysis, helps to remove water-soluble substances, as well as protein-bound substances. The removal function has been shown to reduce

bilirubin, ammonium, urea nitrogen, creatinine, fatty acids and bile salts, which are all substances that, in high concentrations, are related to liver and renal failure. As expected, the effect is temporary, and if there is no improvement in liver function, these parameters change again in the short term<sup>[48,49]</sup>. This system does not improve hepatic synthesis; it is used as a depuration system, comparable to renal hemodialysis. In contrast, some small studies have shown an improvement in the hemodynamics of these patients, with increased blood pressure that had been reduced due to the hyperdynamic circulation characteristic of liver failure. The mechanism of the aforementioned benefit would be depuration and the reduction of substances such as renin, angiotensin and aldosterone, which are responsible for the hemodynamic disorders related to liver failure<sup>[48]</sup>. A recent retrospective, uncontrolled study showed that, of 32 HRS-1 patients receiving MARS therapy for an average of 3.5 ± 1.5 sessions, 13 (40%) experienced an improvement in renal function, but only 9 (28%) showed complete response in the form of renal function recovery. In contrast, of the 15 patients who survived > 28 d, only 9 achieved this stage without transplantation, and of these 9 patients, only 2 showed complete renal response using MARS therapy<sup>[50]</sup>. Therefore, it has been suggested that MARS therapy is capable of improving HRS-1 through the removal of vasodilators; however, this effect would more probably be caused by MARS's hemofiltration function, which is an effect that is similar to conventional hemodiafiltration.

As mentioned, non-treated HRS-1 patients show high mortality rates in the short term. The effect of MARS therapy in this stage is controversial. There have been three studies that have not shown any benefit in terms of survival<sup>[51-53]</sup>, and another two studies, both from the same author, did not show benefits<sup>[49,54]</sup>.

Finally, a recent (2013) multi-center, randomized study<sup>[51]</sup> included patients with acute or chronic liver failure and randomized a total of 189 patients to a group with standard medical therapy plus MARS therapy (95 patients) vs another group using only standard medical therapy (94 patients); this study observed no benefit in survival at 28 d in the MARS group. A sub-analysis of the HRS-1 patients that were included (48 in the MARS group and 47 in the control group) also did not show differences in the survival rates.

**Recommendation:** We do not recommend the use of extracorporeal liver support with albumin dialysis (MARS) for the treatment of HRS-1 (Evidence Level I, grade of recommendation D, Agreement 4.8 ± 0.3).

#### **Efficacy of LT: Survival and renal function**

LT is the therapy of choice for HRS-1 patients because it not only improves renal failure but also improves the underlying diseases, *i.e.*, cirrhosis and PHT. Post-transplantation survival in HRS-1 patients seems to be lower than for transplanted patients without HRS-1; however, survival is considerably higher compared with

that in HRS-1 patients without transplantation. In a retrospective study, the survival of HRS-1 transplanted patients after 1 and 3 years was 80.3% and 76.6%, respectively, and it was 90.7% and 85.3%, respectively, for recipients without HRS-1<sup>[55]</sup>.

Although we can consider that treating HRS-1 with vasoconstrictor agents can improve post-transplant results by improving renal function before the procedure, there is no clear evidence of this effect. In a clinical study, 99 patients were randomized to receive terlipressin or placebo. Of these patients, 35% received LT. Subjects receiving albumin plus terlipressin showed a 100% survival rate among transplanted patients and a 34% survival in non-transplanted patients after 6 mo. In contrast, subjects receiving only albumin showed 94% survival in transplanted patients and only 17% survival in non-transplanted patients after 6 mo. The authors concluded that the use of terlipressin has no impact on post-transplant survival. The sole benefit of the use of terlipressin in patients who will undergo transplantation seems to be the facilitation of the use of calcineurin inhibitors post-transplant, reducing the need for anti-IL2 antibodies<sup>[56]</sup>.

The majority of HRS-1 patients experience an improvement in renal function post-transplant; therefore, there seems to be no advantage in performing double liver and renal transplantation vs single LT. In a Chinese observational study, 32 HRS-1 patients received transplantation, and of these patients, 8 received dialysis, showing that 94% of the patients recovered renal function in an average of 24 d, with 65% survival after 1 year<sup>[57]</sup>. In another observational study with 28 patients, with an average MELD score of  $30 \pm 6$ , only 58% of patients recovered renal function. Four patients died, of whom 3 showed resolution of HRS-1<sup>[58]</sup>. However, patients that did not experience any improvement in renal function post-transplant showed poorer survival rates<sup>[59]</sup>.

In a recent retrospective study, 62 HRS-1 patients received transplantation, with an average basal creatinine of 3.35 mg/dL and an average MELD score of  $35 \pm 1$ . The progression time of HRS-1 before transplantation was 18 d. Eleven patients continued dialysis after the surgery, and 5 patients died. Survival after 1 year in the patients who recovered renal function was 97% vs 60% in the group that did not show any improvement in renal function. After one year, the creatinine levels in the group with HRS-1 resolution were similar to the creatinine levels in the group of transplanted patients without HRS-1. The only factor associated with the non-resolution of HRS-1 after transplantation was the period of time on dialysis pre-transplantation. For each day of dialysis, the patient has a 6% increase in the risk of non-resolution of HRS-1. A patient who is on dialysis for more than 14 d has a 9.2 times greater relative risk of non-resolution of HRS-1<sup>[60]</sup>.

Despite these findings, apart from the duration of dialysis time before transplantation, predictive factors for the improvement of renal function after transplantation have not been clearly established. Patients with ARF

requiring dialysis more than two times per week for more than 4 wk must be assessed for double liver and renal transplantation, considering the risk factors at the time of the surgery, such as hypertension, diabetes and older age<sup>[60,61]</sup>.

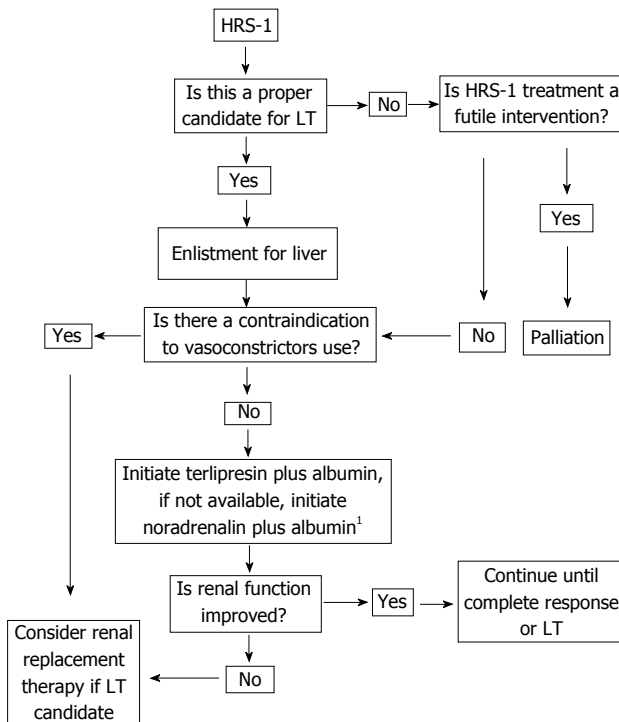

**Recommendation:** LT can be considered the definitive treatment for HRS-1 patients. HRS-1 patients must receive treatment with vasopressors before LT because it could improve the subsequent results. Patients requiring dialysis for long periods of time ( $> 4$  wk) must be considered for combined liver-kidney transplantation (Evidence Level II-2, grade of recommendation B, Agreement  $4.6 \pm 0.5$ ).

## DISCUSSION

LT is considered the treatment of choice for HRS-1<sup>[62]</sup>. It is the only therapy able to reverse this condition completely, resolving circulatory dysfunction and the consequences of cirrhosis and liver failure<sup>[63]</sup>. Thus, survival can be dramatically improved after LT<sup>[55]</sup>. In fact, the 180 d survival rate was 97% in a recent study<sup>[56]</sup>. In another recent study, the one- and three-year survival rates were 80.3% and 76.6%, respectively<sup>[55]</sup>. Interestingly, the impact of pharmacologic treatment on the outcomes after LT was recently evaluated. In the study by Boyer *et al.*<sup>[56]</sup>, the use of terlipressin plus albumin had no impact on post-transplant survival. However, this is not an argument for neglecting the importance of the treatment of HRS-1, especially considering that the time elapsed between enlistment and transplantation could be weeks. In this regard, an effort to recover renal function before LT is advisable. Although it seems to be the most frequent scenario, not every patient recovers renal function after LT. In a very recent study, Wong *et al.*<sup>[64]</sup> evaluated the survival of liver recipients who experienced reversal of HRS-1 after LT, compared to the survival of patients who did not. In this study, 75.8% of the recipients had a reversal of HRS-1 after LT. The one-year survival rate after LT was 97% for patients who had a reversal of HRS-1 and 60% for those who did not<sup>[64]</sup>. Thus, for all of the aforementioned reasons, LT is a desirable approach for HRS-1 patients.

Nonetheless, there are at least two obstacles that render access to LT difficult: (1) the scarcity of liver grafts, which dramatically reduces the likelihood of these patients receiving a transplant as rapidly as they should; and (2) the existence of severe comorbidities or conditions that make LT not plausible. Hence, there is an important role for different therapeutic approaches than could be used as alternatives or "bridges" to LT.

Thus, several therapeutic tools have been evaluated. As expected, the quality of these studies, the efficacy of the interventions, and their availability, costs and adverse effects are, of course, very different. It was the purpose of this panel of experts to determine the treatments with greater efficacy, based on studies with the highest quality available.

**Figure 1 Therapeutic algorithm for the treatment of type 1 hepatorenal syndrome.** <sup>1</sup>Doses must be adjusted according to diuresis or creatinine levels. HRS-1: Type 1 hepatorenal syndrome; LT: Liver transplantation.

Based on the available evidence, the expert panel agrees that the best evidence for the treatment of HRS-1 supports the use of vasoconstrictors as a treatment of the choice, specifically terlipressin, based on a recent systematic review<sup>[13]</sup>. On the other hand, noradrenalin seems to be as effective as terlipressin. In fact, a recent systematic review evaluated the efficacy of noradrenalin compared to terlipressin. Only four studies were included (154 randomized patients). The authors report a similar rate of reversal of HRS-1, 30 d mortality and recurrence. Thus, in this study, its effect on renal function seemed to be completely comparable to that of terlipressin<sup>[21]</sup>, and its use seems to be adequate when terlipressin is not available. Nonetheless, these findings are more difficult to interpret because two studies included patients with HRS-2. In this regard, the expert panel recommends the use of noradrenalin as a second choice if terlipressin is not available. Another strategy based on the use of vasoconstrictors is the combination of octreotide plus midodrine (also in combination with albumin). Very interestingly, a recent study compared the use of terlipressin plus albumin with the combination of octreotide, midodrine and albumin. Notably, the rate of complete response was 55.5% in the terlipressin group and 4.8% in the octreotide-midodrine group ( $P < 0.001$ )<sup>[28]</sup>. Based on these results, the panel of experts did not recommend the use of octreotide plus midodrine for the treatment of HRS-1.

The use of vasopressin was not recommended by the expert panel due to the scarcity and poor quality of the evidence, in addition to the incidence of ischemic side effects<sup>[31]</sup>.

Another issue evaluated by the panel was the use of albumin as a plasma expander. Most of the studies that evaluated the use of vasoconstrictors combined them with albumin. However, Ortega *et al.*<sup>[34]</sup> conducted a prospective, non-randomized study that compared the use of terlipressin with and without albumin. A complete response was observed in 77% of patients receiving albumin and in 25% of those who did not receive albumin. In contrast, there is a lack of evidence suggesting that the apparent benefit of using albumin combined with vasoconstrictors cannot be substituted for another colloid or crystalloids. However, considering that the benefit of vasoconstrictors has been proved in combination with albumin, this panel decided to recommend its use every time that vasoconstrictors are indicated.

The use of a TIPS has been tested in only a few patients; however, there have been no randomized, controlled studies, and it has not been compared to the use of vasoconstrictors. In contrast, the associated adverse effects, mostly hepatic encephalopathy, have made the use of the TIPS procedure difficult. For these reasons, the expert panel does not recommend its use.

The MARS has also been tested as an alternative for the treatment of HRS-1. However, its benefits have not been consistently demonstrated. In fact, in a recent randomized, controlled trial, MARS was employed for patients with acute or chronic liver disease, including 95 patients with HRS-1. No benefit on survival was demonstrated<sup>[51]</sup>. Hence, the panel of experts does not recommend its use.

RRT use is considered controversial in cirrhotic patients with HRS-1 when LT is not considered an option because of the morbidity and mortality associated with the procedure and with liver failure<sup>[42]</sup>. Although the literature is scarce in this topic, RRT seems to prolong short term survival<sup>[43]</sup>, potentially improving the probability of receiving a liver graft. Thus, although disputable, the expert panel decided to recommend the use of RRT only in those patients listed for LT.

The present consensus is an important effort that intends to organize the available strategies based on the available evidence in the literature, the quality of the evidence and the benefits, adverse effects and availability of the therapeutic tools described. This attempt has been synthesized in the algorithm described in Figure 1. We hope that it will be a useful tool for guiding the management of HRS-1 patients.

## COMMENTS

### Background

Hepatorenal syndrome (HRS) is a severe condition strictly related to the presence of portal hypertension and ascites. It has a very poor prognosis with a mean survival that only reaches two weeks. Several therapeutics alternatives have been evaluated. Based on the best available evidence the authors attempt to define the best therapeutic choice considering its availability and the clinical characteristics of each patient.

### Research frontiers

Although several therapeutic alternatives have been proposed the quality of the

evidence is heterogeneous and it can be difficult to discriminate the best option on each circumstance. A careful evaluation of the evidence is necessary to make appropriate recommendations.

### Innovations and breakthroughs

This is the first published consensus about the treatment of HRS. A significant effort has been made to evaluate the quality of the available literature to generate appropriate recommendations.

### Applications

The information included on this consensus will be a valuable tool to determine the best therapeutic option for HRS based on the best available evidence, the availability of each intervention and the particular condition of the patient.

### Terminology

Delphi-technique method was used to reach consensus. A panel of experts voted on a 1 to 5 Likert scale (where 1 means "totally disagree" and 5 "totally agree"). Approved recommendations (those with average score  $\geq 4$  on the Likert scale) are presented; Level of evidence: The quality of the evidence is classified in three types. Thus, type I is obtained from well design, randomized trials or systematic reviews. Type II is obtained from studies of lower quality (*i.e.*, non-randomized trials, case-control studies or case series). Type III is obtained from opinion of authorities on the subject matter based on expertise, expert committees, case reports, pathophysiological studies or basic science studies; Levels of recommendation are classified in five categories (A, B, C, D, I) where A corresponds to the stronger recommendation to support a determined intervention and I classifies situations where the evidence is insufficient to generate a recommendation (see Table 3 on the manuscript).

### Peer-review

The study is well organized and properly processed. The conclusion is reasonable.

### Abstract

#### AIM

To evaluate all the references about primary gallbladder hidatidosis looking for best treatment evidence.

#### METHODS

Search: 1966-2015 in MEDLINE, Cochrane Library, SciELO, and Tripdatabase. Key words: "gallbladder hydatid disease" and "gallbladder hydatid cyst". We found 124 papers in our searches but only 14 papers including 16 cases were about hydatid cyst of the gallbladder (GBHC).

#### RESULTS

Eight cases of GBHC were women and seven men. One not mentioned. Median age was 48.3 years. The most frequent clinical symptom was abdominal pain (94%) usually in the right upper quadrant. Ultrasound was performed in ten patients (62.5%) but in most cases a combination of several techniques was performed. The location of the cysts was intravesicular in five patients. Five patients presented GBHC and liver hydatid cysts. Two patients presented cholelithiasis and one choledocholithiasis. The most frequent surgical technique was cholecystectomy by laparotomy (81.25%). Simultaneous surgery of liver cysts was carried out in five cases. Eleven patients did not present postoperative complications, but one died. The mean hospital stay was seven days. No recurrence of GBHC was recorded.

#### CONCLUSION

In GBHC, the most frequent symptom is right hypochondrium pain (evidence level V). Best diagnostic methods are ultrasound and computed tomography (level V, grade D). Suggested treatment is open cholecystectomy and postoperative albendazole (level V, grade D) obtaining good clinical results and none relapses.

**Key words:** Hydatid cyst; Gallbladder; Cholecystectomy; Review; Hydatidosis

Hydatid cyst of the gallbladder: A systematic review of the literature. *World J Hepatol* 2016; 8(25): 1087-1092 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i25/1087.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i25.1087>

## INTRODUCTION

Hydatid disease is a zoonotic infection found all over the world, which is caused by the larval stage of parasites of the *Echinococcus* species. *Echinococcus granulosus* is the most frequent (95% of cases); other species such as *Echinococcus multilocularis* are rare (5%). Hydatid disease is endemic in cattle-raising regions like the Mediterranean countries, Africa, South America, Middle East, Australia and New Zealand<sup>[1,2]</sup>.

*Echinococcus granulosus* lives in the intestine of dogs and other wild canines, which are the definitive hosts. Humans are accidentally infected *via* the fecal-oral route. Larval embryos pass through the intestinal wall and reach the liver through the portal system. Subsequently, through the liver and lungs, parasites reach the arterial circulation and may spread through the rest of the organs<sup>[1-3]</sup>. The larvae can remain and develop into hydatid cyst anywhere in the body, but liver (70%) and lungs (20%) are the most commonly affected sites.

Primary hydatid cyst of the gallbladder (GBHC) is an exceptional location for hydatidosis, and its pathogenesis is not completely clear. While the literature on liver hydatid disease is abundant, references to the primary involvement of the gallbladder are limited to clinical cases and so it is difficult to reach meaningful conclusions<sup>[3-16]</sup>. In this paper we present a systematic review of the literature on GBHC published to date.

## MATERIALS AND METHODS

### Search strategy

We introduced the following keywords in the MEDLINE (PubMed), Tripdatabase, SciELO and Cochrane Library databases: "gallbladder hydatid disease (GHD)" and "gallbladder hydatid cyst (GHC)" without restrictions on publication date or author until 31 December 2015<sup>[17]</sup>. The first selection of papers was made after reading title and abstract, and in case of doubt, after reading the full text. A flowchart is shown in Figure 1.

Our results were as follows: (1) zero results in SciELO; (2) 2 results for both searches (GHD and GHC) in the Cochrane Library: Neither met the inclusion criteria; (3) 21 results for GHD and 17 for GHC in Tripdatabase. After

Figure 1 Search flowchart.

review, none were found to be related to the topic; and (4) 137 results for GHD and 138 for GHC in MEDLINE. Since the overlap between search results was 99%, we used the latter search with 138 results; of them, only 14 (10.14%) met the selection criteria for this study.

These 14 papers included 16 clinical cases covering a wide range of clinical, diagnostic and therapeutic aspects of GBHC. These characteristics are summarized in Tables 1-4.

In the next step, to assess the quality of the selected studies we used the rating scale described by Manterola *et al.*<sup>[18]</sup>, which assesses each publication individually depending on the type of study, the size of the sample and whether it is justified, and the methodology used. A mean score of all the selected studies is produced ranging from 6 to 36 points, with a quality cut-off score of 18 points. The mean score in our review was 10.3; however, due to the rarity of GBHC and the few studies of this issue published, we selected all the papers available.

We also carried out a qualitative analysis of the selected papers and their conclusions, based on the classical levels of evidence and grades of recommendation proposed in Cook *et al.*<sup>[19]</sup> and Sackett<sup>[20]</sup>.

## RESULTS

Eight cases of GBHC were women and seven men. The sex of one patient was not specified. Median age was 48.3 years (range: 27-76). The most frequent clinical manifestation was abdominal pain (15/16) (94%) (Table 1), in the right upper quadrant in 13 patients) (81.25%), in the epigastrium in four (25%), (three of whom combined upper quadrant pain in right hypochondrium and epigastric pain), and finally diffuse abdominal pain in two (12.5%). In one case, no data on abdominal pain were included (6.25%). Three patients presented vomiting and two had nausea; no information on nausea or vomiting was reported in the rest of patients. Three patients had fever, four were fever-free, and no data on fever were available for the remaining nine patients. Four patients had jaundice, five did not, and no data were available in seven cases. As regards past medical history, two patients had been previously diagnosed with hydatid disease and one had had hepatitis.

On physical examination (Table 1), four patients presented abdominal tenderness, three hepatomegaly,

CT: Computed tomography; MRI: magnetic resonance imaging; *E. granulosus*: *Echinococcus granulosus*.

two abdominal distension, and one a palpable mass. Serological information was available in only five cases (Table 2). Levels of alkaline phosphatase and bilirubin were high in four patients, normal in one, and no information was recorded for the other eleven. In the cases in which they were specified, alkaline phosphatase levels were between 140 and 465 IU/L and bilirubin between 5.6 and 10.2 mg/dL. *Echinococcus* serology was performed in four cases, being positive in three and negative in one.

Image diagnostic methods are described in Table 2. Abdominal ultrasound (US) was performed in ten patients (62.5%), abdominal computed tomography (CT) in nine (56.25%), and magnetic resonance imaging (MRI) in three (18.75%). In most cases a combination of several techniques was performed: US + CT + MRI in three cases, US + TC in three others; so four cases underwent US alone and three CT alone. The location of the cysts was intravesicular in five patients. Five patients presented

ERCP: Endoscopic retrograde cholangiopancreatography.

GBHC and liver hydatid cysts. Two patients presented cholelithiasis and one choledocholithiasis.

The data on therapeutic management are displayed in Table 3. One patient received preoperative albendazole for two weeks, but no data on the other fifteen were available. The most frequent surgical technique was cholecystectomy by laparotomy (81.25%), performed in 13 patients; laparoscopic cholecystectomy was performed in two cases (12.5%), in one of them a previous endoscopic retrograde cholangiopancreatography (ERCP) was done and received a biliary stent; in the last patient, cholecystectomy was not performed, only ERCP and biliary stenting (6.25%). Cholecystectomies were total in 14 cases (93.3%) and subtotal in the patient treated preoperatively with albendazole (6.7%). Simultaneous surgery of liver hydatid cysts was carried out in five cases: Cystopericystectomy in three cases, enucleation in one, and in the other the surgical technique was not specified except for the fact that access was made by thoracotomy. Eleven patients did not present postoperative complications: One presented fever, atelectasis

and pleural effusion, and another multiple organ failure and death. No data regarding postoperative outcome were recorded in three cases. The pathological examination (Table 4) was performed in nine patients. In three, the presence of *Echinococcus granulosus* was confirmed microscopically.

The mean hospital stay was seven days (range: 1-12 d). Seven patients were treated postoperatively with varying doses of albendazole. In nine cases follow-up after the postoperative period was recorded, for a mean period of 38 mo (range: 1-120 mo); no recurrence of GBHC was recorded.

## DISCUSSION

Hydatidosis is a disease caused by the larva of the genus *Echinococcus*, within which *Echinococcus granulosus* is the most common species. Although cases have been diagnosed all over the world as a result of increased intercontinental migration, areas in which the incidence is significantly higher include the Mediterranean Sea,

Africa, South America, Middle East, Australia and New Zealand. Hydatid disease is prevalent in pastoral areas where cattle and dogs are in close contact. Dogs are the definitive hosts; they excrete eggs in their feces, and humans become intermediate hosts through accidental fecal-oral infection<sup>[2,21]</sup>.

The reviews of Dziri *et al*<sup>[21,22]</sup> and Gomez I Gavara *et al*<sup>[1]</sup> concluded that many questions about liver hydatidosis still lack evidence-based answers. In 2016, PAIR or surgery, systematic or selective preoperative ERCP, the best surgical approach (conservative or radical), type of technique (laparoscopic or laparotomy), and the use of albendazole all remain topics for debate<sup>[1,21,22]</sup>.

GBHC is an extremely rare entity, even in places where hydatid disease is endemic. Primary involvement is even less common. It is essential to differentiate primary GBHC from secondary invasion of the gallbladder caused by daughter vesicles of primary liver hydatid disease. GBHC can be located within the vesicle or on its outer surface. GBHC pathogenesis is not very well documented; one of the most accepted hypotheses is infestation through the bile duct, although this explanation is unconvincing in cases of superficial cysts, and also often requires prior hepatic involvement. Larval spread through the lymphatic system after intestinal absorption is possible and may explain the intraluminal cysts. Other routes, such as contamination of gallbladder after surgery for hepatic hydatid cyst, should also be considered<sup>[3]</sup>.

In this evidence-based systematic review we have attempted to answer questions about the symptoms, diagnosis and treatment of GBHC. The main limitation is the lack of published series; all the reviewed papers are clinical cases, and so we are unable to reach an acceptable level of evidence. The most common symptom in GBHC is pain in the right upper quadrant<sup>[4-10,12-16]</sup>. Suspicion of GBHC is established by ultrasound and/or CT<sup>[3-13,15]</sup>. The involvement of the gallbladder is usually an incidental

finding in patients being examined for liver hydatid cysts<sup>[4-6,8,10-12,14-16]</sup>. The most common therapeutic approach is cholecystectomy by laparotomy and postoperative albendazole<sup>[4-12,14-16]</sup>. Few cases present postoperative complications, and the recurrence of hydatid disease is practically zero<sup>[3-12,15]</sup>.

In conclusion, three main conclusions can be drawn regarding the clinical diagnosis and treatment of GBHC: (1) the most common clinical finding is right upper quadrant pain with a very low level of evidence (level V, grade D recommendation); (2) the most useful diagnostic methods are diagnostic ultrasound and CT with a very low level of evidence (level V, grade D recommendation); and (3) the recommended treatment is cholecystectomy by laparotomy plus albendazole in the postoperative period. This strategy achieves good results: There is no postoperative recurrence in the subsequent months of follow-up, with a very low level of evidence (level V, grade D recommendation). To our knowledge, this is the first literature review that focuses on the clinical, diagnostic and therapeutic aspects of GBHC. The lack of published cases on the topic and the fact that all the papers included deal with clinical cases impeded us from achieving a higher level of evidence in the results. More studies are needed, especially randomized controlled trials, in order to reach meaningful conclusions.

## COMMENTS

### Background

Primary gallbladder hidatidosis is an unfrequent disease. No systematic reviews have been done before.

### Research frontiers

Obtaining best clinical evidence to treat primary gallbladder hydatidosis.

### Applications

Future cases and publications will have a systematic review to treat these

patients.

### Peer-review

Hydatid disease of the gallbladder is very rare, from this point of view this systematic review has some interest.

# World Journal of *Hepatology*

*World J Hepatol* 2016 September 18; 8(26): 1093-1118

## Editorial Board

2014-2017

The *World Journal of Hepatology* Editorial Board consists of 474 members, representing a team of worldwide experts in hepatology. They are from 52 countries, including Algeria (1), Argentina (6), Armenia (1), Australia (2), Austria (4), Bangladesh (2), Belgium (3), Botswana (2), Brazil (13), Bulgaria (2), Canada (3), Chile (1), China (97), Czech Republic (1), Denmark (2), Egypt (12), France (6), Germany (20), Greece (11), Hungary (5), India (15), Indonesia (3), Iran (4), Israel (1), Italy (54), Japan (35), Jordan (1), Malaysia (2), Mexico (3), Moldova (1), Netherlands (3), Nigeria (1), Pakistan (1), Philippines (2), Poland (1), Portugal (2), Qatar (1), Romania (6), Russia (2), Saudi Arabia (4), Singapore (1), South Korea (12), Spain (20), Sri Lanka (1), Sudan (1), Sweden (1), Switzerland (1), Thailand (4), Turkey (21), Ukraine (3), United Kingdom (18), and United States (55).

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Cholangiocarcinoma (CCA) is a relatively rare malignancy of the intra- or extra-hepatic bile ducts that is classified according to its anatomical localization as intrahepatic, perihilar or distal. Overall, CCA has a dismal prognosis due to typical presentation at an advanced irresectable stage, lack of effective non-surgical treatments, and a high rate of disease recurrence. CCA frequently arises on a background of chronic liver inflammation and cholestasis. Chronic inflammation is accompanied by enhanced cell turnover with generation of additional inflammatory stimuli, and a microenvironment rich in pro-inflammatory mediators and proliferative factors that enable accumulation of mutations, transformation and expansion of mutated cells. A recent study by Boulter *et al* implicates the Wnt signaling cascade in cholangiocarcinogenesis. Wnt ligands Wnt7B and Wnt10A were found to be highly overexpressed in human CCA tissue. Wnt7B protein was present throughout the tumor stroma, and often co-localized with a subset of CD68<sup>+</sup> macrophages. To address in a direct manner whether Wnt signaling is engaged in development of CCA, Boulter *et al* explored the Wnt signaling pathway in an experimental model that recapitulates the multi-stage progression of human CCA. Wnt ligands found to be elevated in human CCA were also upregulated during the course of CCA development following thioacetamide treatment. Wnt10a increased during the (pre-cancerous) regenerative phase, while Wnt7b induction paralleled tumor growth. Along with upregulation of target genes, the findings demonstrate that the canonical Wnt pathway is progressively activated during cholangio-carcinogenesis. Macrophage depletion, eliminating a major source of Wnt7b, prevented activation of the canonical Wnt cascade, and resulted in reduced number and volume of tumors in this model. Moreover, specific inhibitors of the canonical Wnt pathway (ICG-001 and C-59) caused reduction of tumor area and number, in xenograft and thioacetamide models of CCA. The aggregated findings show that experimental, and presumably human CCA, is a Wnt-driven tumor. Modulation of Wnt signaling, alone or in combination with surgical

or chemotherapy approaches, holds promise in the management of this fatal malignancy.

**Core tip:** Cholangiocarcinoma (CCA) is a relatively rare malignancy of the intra- or extra-hepatic bile ducts with dismal prognosis. CCA frequently arises on a background of chronic liver inflammation and cholestasis, which creates a microenvironment rich in pro-inflammatory mediators and proliferative factors that enable accumulation of mutations, transformation and expansion of mutated cells. A recent elaborate study by Boulter *et al* (*J Clin Invest* 125:1269) has provided novel insights into the molecular pathogenesis of CCA. Involvement of the Wnt signaling pathway in cholangiocarcinogenesis, and effect of Wnt inhibitors on CCA development *in vivo* are discussed in this Editorial.

Noll ATR, Cramer T, Olde Damink SWM, Schaap FG. Cholangiocarcinoma, gone without the Wnt? *World J Hepatol* 2016; 8(26): 1093-1096 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i26/1093.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i26.1093>

## INTRODUCTION

Cholangiocarcinoma (CCA) is a relatively rare malignancy of the intra- or extrahepatic bile ducts that is classified according to its anatomical localization as intrahepatic, perihilar or distal<sup>[1,2]</sup>. CCA accounts for 10%-20% of the primary liver malignancies, with perihilar (50%-67%) and distal extrahepatic tumors (27%-42%) comprising the majority of CCA cases<sup>[1]</sup>. Tumor biology (*e.g.*, growth pattern, mutation spectrum) and clinical presentation, management and outcomes are different for the three CCA types. Overall, CCA has a dismal prognosis due to typical presentation at an advanced irresectable stage, lack of non-surgical potentially curative treatments, and a high rate of disease recurrence. The five-year survival rate is 5%-10%.

Our understanding of the molecular pathogenesis of CCA is limited. CCA frequently arises on a background of chronic liver inflammation and cholestasis, as reflected by risk factors of cholangiocarcinogenesis (*e.g.*, liver cirrhosis, viral hepatitis, hepatolithiasis, liver fluke infestation, primary sclerosing cholangitis). Chronic inflammation is accompanied by enhanced cell turnover with generation of additional inflammatory stimuli, and a microenvironment rich in pro-inflammatory mediators and proliferative factors that enable accumulation of mutations, transformation and expansion of mutated cells<sup>[3,4]</sup>. Cholestasis may contribute to cholangiocarcinogenesis through effects of (conjugated)

bile salts on proliferation and invasion of cholangiocytes<sup>[5,6]</sup>.

The overall incidence of CCA has increased over the past decades and this is attributed to a global rise in the incidence of intrahepatic CCA. Liver transplantation is generally not considered for treatment of CCA due to frequent tumor recurrence and poor five-year survival rates after liver transplantation for intrahepatic CCA. Hence, resection is the only potentially curative treatment of CCA. The majority of patients with CCA, however, do not qualify for surgery and have to resort to palliative therapies. Molecular-targeted therapies hold potential for personalized treatment of malignancies including CCA<sup>[7]</sup>. A recent study by Boulter *et al*<sup>[8]</sup> implicates the Wnt signaling cascade in cholangiocarcinogenesis. Importantly, specific inhibitors of this pathway prevented tumor development in animal models of CCA.

## THE WNT SIGNALING CASCADE

Wnt signaling is initiated by binding of membrane-bound Wnt ligand to a transmembrane receptor of the Frizzled family, and can operate in autocrine and paracrine modes<sup>[9-11]</sup>. Wnt ligands are a family of secreted glycoproteins that have undergone a lipid modification (Cys-palmitoylation) that is essential for biological activity. The Frizzled family are G-protein coupled receptors that, alone or in conjunction with co-receptors (*e.g.*, Lrp5/6), serve as binding sites for Wnt ligands. Canonical Wnt signaling results in a transcriptional response in which the transcription factor  $\beta$ -catenin plays a central role, whereas non-canonical Wnt signaling cascades control the cytoskeletal structure or intracellular  $\text{Ca}^{2+}$  content through  $\beta$ -catenin-independent non-genomic actions. The canonical Wnt signaling pathway is the focus of the studies of Boulter *et al*<sup>[8]</sup>. In the absence of Wnt signaling,  $\beta$ -catenin is targeted for proteasomal degradation by a multi-protein complex. Formation of this degradation complex is abrogated by activation of Wnt signaling, resulting in cytoplasmic accumulation and subsequent nuclear translocation of  $\beta$ -catenin. There,  $\beta$ -catenin acts in concert with other transcription factors (*e.g.*, TCF/LEF family members) to activate expression of target genes including cell cycle-related genes (*e.g.*, *CCND2*, *CDKN2A*).

Wnt signaling was identified through its role in carcinogenesis<sup>[10]</sup>, but not surprisingly found to participate in normal development and adult tissue homeostasis as well. Mutations in downstream components of the Wnt signaling pathway have been identified in various types of human cancers<sup>[11,12]</sup>. For example, adenomatous polyposis coli (APC), a tumor suppressor that is part of the  $\beta$ -catenin degradation complex, is frequently mutated in colorectal and gastric cancers. Mutations in  $\beta$ -catenin that enhance protein stability, exemplifying a gain-of-function mutation, have been found in hepatocellular carcinoma<sup>[11]</sup>. Hepatic adenomas that are positive for  $\beta$ -catenin have a high risk for malignant conversion and are typically resected, whereas other adenoma types are generally left untreated<sup>[13]</sup>. Targeting of the Wnt

pathway is being explored as treatment of Wnt-driven malignancies<sup>[14]</sup>.

## WNT SIGNALING IN CCA

By analyzing tumoral and matched unaffected liver tissue of patients with intrahepatic or perihilar CCA, Boulter *et al.*<sup>[8]</sup> demonstrate that Wnt ligands Wnt7B and Wnt10A are highly overexpressed in tumor tissue. Wnt7B protein was present throughout the tumor stroma, often co-localizing with a subset of CD68<sup>+</sup> macrophages. Moreover, tumors displayed elevated levels of transcripts of known  $\beta$ -catenin targets (*e.g.*, *CCND2*, *CDKN2A*, *BIRC5*), and cancerous biliary epithelium showed increased immunohistochemical positivity for a number of  $\beta$ -catenin targets. These findings suggest that canonical Wnt signaling is activated in human CCA.

To address in a direct manner whether Wnt signaling is engaged in development of CCA, this pathway was further explored in an experimental model that recapitulates the multi-stage progression (*i.e.*, chronic cholangiocyte damage, inflammation, biliary repair/regeneration, tumorigenesis) of human CCA. For this purpose, rats were treated with thioacetamide (TAA) and sacrificed at pre-cancerous (0-16 wk of treatment) and cancerous (20-26 wk of treatment) stages. Mirroring end-stage CCA in humans, strong nuclear  $\beta$ -catenin staining was observed in cancerous epithelium. In the pre-cancerous stage, regenerating ductules showed a membranous staining pattern. Wnt ligands found to be elevated in human CCA were also upregulated during the course of CCA development following TAA treatment. Wnt10a increased during the (pre-cancerous) regenerative phase, while Wnt7b induction paralleled tumor growth. Along with upregulation of target genes, above findings demonstrate that the canonical Wnt pathway is progressively activated during cholangiocarcinogenesis.

Through an elegant set of experiments Boulter *et al.*<sup>[8]</sup> demonstrate that Wnt7B in tumor stroma is largely derived from recruited bone marrow-derived macrophages rather than from resident Kupffer cells, and that these cells play a key role in CCA progression. The role of macrophages in CCA growth was initially assessed in mice xenografted with three different human CCA cell lines. Groups of mice with established palpable subcutaneous tumors received vehicle or treatments to deplete phagocytic macrophages or prevent differentiation of monocytes into macrophages. Xenograft characteristics were determined after a further growth period of 3 wk. Loss of macrophages by either of the two strategies, resulted in reduced number of CD68<sup>+</sup> macrophages and decreased Wnt7b expression in all xenografts. In two out of three xenografted CCA cell lines (*i.e.*, CC-LP-1 and SNU-1079, derived from intrahepatic CCA) this was accompanied by decreased expression of (human) proliferative genes, increased apoptosis and lowered tumor burden. The lack of functional consequences, despite loss

of Wnt signal, in xenografts derived from the third cell line (*i.e.*, WITT-1) may relate to its different origin (distal extrahepatic CCA) and/or distinct growth requirements. As a model more representative in terms of tumor micro-environment (stroma) and disease progression, Boulter *et al.*<sup>[8]</sup> then studied the consequences of macrophage depletion (liposomal clodronate) in TAA-induced CCA. Strikingly, macrophage ablation prevented activation of the canonical Wnt cascade (loss of tumoral Wnt7B signal) and resulted in reduced number and volume of tumors.

The aggregated findings show that experimental, and presumably human CCA, is a Wnt-driven tumor. Since general macrophage depletion is not feasible in clinical practice, Boulter *et al.*<sup>[8]</sup> explored the impact of specific inhibitors of the canonical Wnt pathway in the xenograft- and TAA-model of CCA. For this, they chose two targets that were elevated in human CCA, namely *CTBP1* and *PORCN*. CTBP1 interacts with  $\beta$ -catenin to drive expression of growth-stimulating Wnt target genes, and their interaction can be targeted by ICG-001<sup>[15]</sup>. As mentioned above, Wnt ligands require palmitoylation for biological activity and this lipid modification can be prevented by the PORCN inhibitor C-59<sup>[16,17]</sup>. Both ICG-001 and C-59 were effective in reducing *in vitro* growth of five human CCA cell lines with presumed autocrine activation of canonical Wnt signaling (constitutive Wnt7B and  $\beta$ -catenin expression). Similar to macrophage ablation, ICG-001 and C-59 reduced tumor volume and mass in two CCA cell lines of intrahepatic origin when xenografted in mice, but did not affect WITT-1 xenograft growth. The reliance on Wnt signaling for proliferation and survival of CCA cells was confirmed in TAA-induced CCA, with ICG-001 and C-59 causing reduction of tumor area and number. Importantly, neither treatment affected body weight or caused liver test abnormalities, side effects observed with use of earlier generation Wnt inhibitors<sup>[14]</sup>.

## PERSPECTIVE

The work of Boulter *et al.*<sup>[8]</sup> demonstrates that the canonical Wnt pathway is activated in intrahepatic and perihilar CCA. Inhibition of canonical Wnt signaling, either by depleting the macrophage source of Wnt ligand or *via* pharmacological blockage, reduces CCA formation in a rat model that closely resembles human CCA. This is achieved through stimulation of apoptosis and reduced cell cycle entry. Thus, Wnt signaling is important for proliferation and survival of CCA cells in the TAA-model. It remains to be determined whether human CCA growth/progression is Wnt-dependent, and hence amenable to targeting by Wnt pathway inhibitors. More detailed insight into the interaction of Wnt signaling with the complex cellular surrounding, and its integration with other cellular signaling cascades, is warranted. Time will tell if systemic or CCA-directed Wnt inhibition, alone or in combination with surgical or chemotherapy approaches, will improve clinical outcomes of this fatal malignancy.

## Abstract

### AIM

To evaluate the potential benefits and risks of the use of epidural anaesthesia within an enhanced recovery protocol in this specific subpopulation.

### METHODS

A retrospective review was conducted, including all cirrhotic patients who underwent open liver resection between January 2013 and December 2015 at Bologna University Hospital. Patients with an abnormal coagulation profile contraindicating the placement of an epidural catheter were excluded from the analysis. The control group was composed by patients refusing epidural anaesthesia.

### RESULTS

Of the 183 cirrhotic patients undergoing open liver resections, 57 had contraindications to the placement of an epidural catheter; of the remaining 126, 86 patients received general anaesthesia and 40 combined anaesthesia. The two groups presented homogeneous characteristics. Intraoperatively the metabolic data did not differ between the two groups, whilst the epidural group had a lower mean arterial pressure ( $P = 0.041$ ) and received more colloid infusions ( $P = 0.007$ ). Postoperative liver and kidney function did not differ significantly.

Length of mechanical ventilation ( $P = 0.003$ ) and hospital stay ( $P = 0.032$ ) were significantly lower in the epidural group. No complications related to the epidural catheter placement or removal was recorded.

## CONCLUSION

The use of Epidural Anaesthesia within a fast track protocol for cirrhotic patients undergoing liver resections had a positive impact on the patient's outcomes and comfort as demonstrated by a significantly lower length of mechanical ventilation and hospital stay in the epidural group. The technique appears to be safely manageable in this fragile population even though these results need confirmation in larger studies.

**Key words:** Anesthesia; Postoperative care; Analgesia; Epidural; Postoperative; Liver cirrhosis; Liver function tests; Complication

## INTRODUCTION

Fast track surgery or Enhanced Recovery after Surgery (ERAS®) programmes have been first described in the 1990s in the field of colo-rectal surgery<sup>[1]</sup>. These programmes entail a number of evidence based actions aimed at reducing unnecessary perioperative stress and inflammation, and restoring as quickly as possible the normal preoperative physiology. Since their first introduction ERAS programmes are being implemented in different surgical specialties, and in more recent

times also in the field of liver surgery<sup>[2-6]</sup>. A recent meta-analysis<sup>[7]</sup> evaluating five randomized controlled trials, has consolidated the evidence indicating that ERAS applied to liver resection surgery has a positive impact on post-operative complications and length of hospital stay.

The use of epidural anesthesia and analgesia is a vital part of any enhanced recovery program, mostly because it blunts the neuroendocrine response to surgical stress and allows better postoperative pain control and faster mobilization. Epidural analgesia has been widely applied in the field of open liver surgery with very positive results in terms of reduction in pain scores<sup>[8]</sup>. However cirrhotic patients undergoing liver resection represent a special subpopulation with a high risk of developing perioperative complications. In these patients the preoperative liver function, and the future remnant liver volume, are critical factors in determining perioperative morbidity<sup>[9]</sup> and the placement of an epidural catheter, and its management, could present potential risks, most of which related to coagulation disorders<sup>[10]</sup>.

Another aspect to be taken into consideration is hemodynamics, in fact the cirrhotic hyperdynamic circulation could be particularly influenced by the sympathetic blockade produced by an epidural block, potentially leading to splanchnic malperfusion, which could be reflected in postoperative organ dysfunction.

In a previous study<sup>[11]</sup> we evaluated the incidence of post liver resection coagulopathy in cirrhotic patients, and discussed its hypothetic impact on the management of an epidural catheter (Figure 1). Following the results of this study, we have implemented a wider use of Epidural analgesia and anaesthesia also in a selected population of cirrhotic patients undergoing Liver resections. To date there are no studies considering the application of ERAS protocols to cirrhotic patients and the importance of epidural anesthesia within these protocols. Moreover most of the studies considering ERAS protocols applied to liver surgery populations have included patients undergoing liver resections for colorectal metastasis<sup>[3,5,6,12]</sup>, in whom underlying liver function is expected to be normal.

The primary objective of this retrospective observational study was to evaluate the use of epidural analgesia in an ERAS program dedicated to cirrhotic patients undergoing liver resection for hepatocellular carcinoma (HCC) in terms of length of hospital stay, and incidence of complications.

Secondary objectives of the study were to evaluate the differences in terms of intraoperative hemodynamic stability, fluid management and postoperative liver and kidney function tests.

## MATERIALS AND METHODS

Following the approval of our Hospital Ethics Committee (approval number: 100/2014/O/OssN), we conducted a retrospective observational review including all cirrhotic patients who underwent open liver resection between January 2013 and December 2015. Inclusion criteria

**Figure 1 Course of post-operative coagulopathy.** The figure displays the percentage of the patients in the two study groups presenting significant alterations of coagulation exams. Platelets count  $< 100000/\mu\text{L}$  or INR  $> 1.5$  post operatively at day 1, 3, 7. INR: International normalized ratio; POD: Postoperative days.

were: Age  $> 18$  years, histologically proven liver cirrhosis, open liver resection surgery for HCC. Exclusion criteria were: Abnormal preoperative coagulation profile contraindicating an epidural catheter placement [international normalized ratio (INR) values  $\geq 1.5$  and/or platelet count  $< 100.000/\mu\text{L}$ <sup>[13]</sup>], laparoscopic liver resection.

Major hepatic resection was defined as a resection of three or more hepatic segments, whilst a minor hepatic resection was defined as a resection of two or fewer hepatic segments in accordance to the IHPBA classification<sup>[14]</sup>. All the liver resections were performed to achieve a tumor-free margin of at least 1 cm based on intraoperative examination and ultrasonography.

Patients were divided into two groups on the basis of the placement of an epidural catheter. The control group was composed by the patients who refused the placement of an epidural catheter, at the pre operative interview with the anesthetist. The same team of surgeons performed all of the surgical procedures. The ERAS protocol was applied to each patient included in this study. The main features of the ERAS protocol for cirrhotic patients used at our unit are described in Table 1. The anesthetic management for liver resection at our unit includes: General endotracheal anaesthesia, arterial line and central venous catheter placement for fluid infusions, hemodynamic monitoring (EKG, arterial blood pressure, CVP), and acid-base parameter measurement (blood gas analysis data).

General anesthesia is induced with propofol (2-2.5 mg/kg), fentanyl (1-2 mcg/kg) and rocuronium (0.6 mg/kg), while Sevoflurane 0.7-1.0 MAC and boluses of rocuronium and fentanyl are used for maintenance.

For combined anesthesia a T8-T9 epidural catheter

**Table 1 Fast track protocol for cirrhotic patients undergoing liver resection**

**Fast track protocol for cirrhotic patients undergoing liver resection**

Preoperative counseling
Regular diet on the day before surgery
No bowel preparation
Intraoperative CVP target $< 6$ mmHg, restricted fluids administration
ICU admission for at least the first post-operative night (or on POD 0)
Maintenance fluids discontinued on POD 3
Nasogastric probe removal on POD 1
Liquid diet on POD 1
Regular diet on POD 3
Urinary catheter discontinued on POD 3
Drains removal on POD 3
Ambulation on POD 3
Discharge criteria: Liver and kidney function tests compatible with preoperative data or decreasing, able to tolerate food intake, able to ambulate, good pain control (NRS $< 3$ )

ICU: Intensive care unit; CVP: Central venous pressure; POD: Postoperative days; NRS: Numerical rating scale.

is positioned before anesthesia induction. Anesthesia is induced with propofol, fentanyl and rocuronium, at the same dosages mentioned above, the epidural anesthesia is induced with an initial bolus of L-bupivacaine 7.5-10 mg and 10 mcg sufentanil, followed by a continuous infusion at 5 to 7 mL/h of L-bupivacaine 2.5 mg/mL. Narcosis is maintained with Sevoflurane at a concentration of 0.5-0.7 MAC, adequate muscle paralysis is maintained with boluses of rocuronium.

Postoperative pain control in patients without epidural is maintained with a PCA system with intravenous morphine (1-2 mg/h continuous infusion, bolus 1 mg, lock-out 15 min, maximum dose in 4 h 18 mg) and boluses of paracetamol (1 g intravenous, max 3 g per day), when oral intake is possible, morphine is substituted with oxycodone.

Postoperative pain control in patients without epidural is maintained with a PCA system with intravenous morphine (1-2 mg/h, bolus 1 mg, lockout 15 s, maximum dose in 4 h 18 mg) and boluses of paracetamol (1 g intravenous, max 3 g/d), when oral intake is possible, morphine is substituted with oxycodone.

In patients with the epidural catheter, postoperative analgesia is maintained with a continuous epidural infusion of L-bupivacaine 1.25 mg/mL and sufentanil 0.5 mcg/mL at a rate of 5-7 mL/h. After the first 36 hour post operatively only the local anesthetic infusion was maintained and the opioid stopped. Intravenous paracetamol (1 g iv, max 3 g/d) is added if more analgesia is needed.

Fluid infusions during hepatic dissection follow the units protocol and target a low central venous pressure ( $\leq 6$  mmHg). Red blood cells in cirrhotic patients are transfused when hematocrit is lower than 24% and/or hemoglobin is lower than 8 g/dL. The occurrence of hypothermia was prevented by infusion of warm fluids, forced-air warming and the use of warm water on the surgical field.

HBV: Hepatitis B virus; BMI: Body mass index; HCV: Hepatitis C virus; AST: Aspartate aminotransferase; ALT: Alanine transaminase; INR: International normalized ratio.

Perioperative coagulation alterations are corrected according to POC coagulation testing using a tromboelastograph (TEG®).

All patients at end of surgery were admitted to the intensive care unit (ICU). The routine ICU admission for at least the first post-operative night is a part of the ERAS protocol for cirrhotic patients used at our unit (Table 1).

Data collected preoperatively included patient characteristics, underlying surgical pathology, etiology of cirrhosis, MELD score, baseline coagulation profile and blood tests.

Intraoperative data analyzed included type of hepatic resection, fluid infusions and transfusion of blood products, while hemodynamics and blood gas analysis data were registered at the beginning of the intervention, after resection and at the end of surgery.

Postoperative blood tests collected were liver and kidney function tests on postoperative days (POD) 1, 3 and 7. Postoperative complications were also evaluated using Clavien-Dindo classification, acute kidney injury was classified following AKI network criteria.

### Statistical analysis

Statistical analysis was carried out with IBM SPSS 21. Categorical data were expressed as numbers (percentages), continuous variables as mean and standard deviation. Differences in perioperative data between groups were evaluated with *t*-test for continuous variables and  $\chi^2$  test or Fisher exact test for nominal variables. A general linear model for repeated measures was used to compare postoperative function tests and intraoperative measures of arterial pressure, central venous pressure and blood gas analysis data. For Clavien-Dindo classification and postoperative kidney

injury evaluated with AKIN score, Mann-Whitney test was used.

## RESULTS

From January 2013 to December 2015, 183 cirrhotic patients underwent elective open hepatic resection for hepatocellular carcinoma at the Department of Surgery and Transplantation of Bologna University. Fifty-six of these were excluded because their preoperative coagulation profile was incompatible with the placement of an epidural catheter. The remaining 126 patients were included in the study and divided into two groups on the basis of the presence of an epidural catheter during surgery; 86 patients received a general endotracheal anesthesia (group no epidural) while 40 patients received a combined anesthesia (group epidural). All of the patients who received epidural anaesthesia, could effectively control post-operative pain with the epidural protocol and did not require intravenous opioids, also no catheter displacement occurred. The two groups were homogeneous for the demographic aspects, and etiology of cirrhosis, Table 2 shows preoperative data. Intraoperative data showed a significantly lower mean arterial pressure during resection and higher hypotension time and colloids infusions in the epidural group (Table 3), whilst central venous pressure (CVP) and metabolic data in terms of pH, lactate and base excess were not significantly different. Postoperative liver and kidney function tests, as well as platelet count did not significantly differ between the two groups (Table 4).

The course of postoperative coagulopathy is shown in Graph 1, we have to highlight that on POD 7, 6 patients out of 126 still had a measurable coagulopathy (INR > 1.5 and/or Plt < 100000/ $\mu$ L). Amongst these patients 3 had undergone a minor resection and one a major resection under general anaesthesia. The remaining 2 patients with coagulopathy had undergone a major liver resection with a combined anesthesia and had to have their coagulations profiles corrected before a safe removal of the epidural catheter could be performed. The correction was performed with the infusion of FFP and there were no complications after the removal of the catheter.

The length of ICU stay did not significantly differ between the two groups. The duration of mechanical ventilation and length of hospital stay were significantly lower in the epidural group (Table 5).

The rate of complications and their severity classified following Clavien-Dindo score and postoperative acute kidney injury did not differ, however 9 cases of post-operative delirium were recorded, all of which occurred in the general anesthesia group.

In the epidural group no complications related to epidural catheter placement or removal were recorded. Epidural catheters were usually removed between POD 3 and 5 and there was no need for major analgesics adjuncts in these patients.

For repeated measures, the *P* value expressed under the variable is referred to the between subjects effect test. AST: Aspartate aminotransferase; ALT: Alanine transaminase; INR: International normalized ratio; POD: Postoperative days.

## DISCUSSION

The results of this study suggest that the use of epidural anaesthesia and analgesia in the context of ERAS<sup>®</sup> protocols for cirrhotic patients undergoing liver surgery is feasible. In fact none of the patients in the epidural

group had complications related to the positioning or the removal of the epidural catheter. However, the incidence of an epidural complication requiring an elective surgical treatment varies between 1 event in 22189 and 1 event in 4330 epidural placements in the general population<sup>[15]</sup>. Hence to consistently rule out the potential

**Table 5** Hospital length of stay and complications

safety issues relating to epidural catheters in the specific subpopulation of cirrhotic patients, a larger sample should be considered.

Postoperative coagulopathy is considered another great risk in cirrhotic patients, often limiting the use of regional anesthesia techniques in this subpopulation. However the incidence of the postoperative coagulopathy, especially in minor resections, appears to be compatible with the safe management of an epidural catheter.

It also must be underlined that hemostasis alterations in cirrhotic patients are more complex than a simple increase in hemorrhagic risk due to coagulation factors deficiency<sup>[16]</sup>. Hence laboratory values such as the INR and platelet count do not describe entirely the wide array of alterations, which constitute the hemorrhagic risk of these patients. Probably in the near future thromboelastometry will have a major role in better defining the individual coagulation profile. Moreover, neuraxial blocks are safely undertaken even in patients assuming platelets inhibitors such as ASA and undergoing surgical interventions in which systemic anticoagulation is prescribed in the postoperative period, such as peripheral vascular surgery<sup>[17]</sup>.

Combined anesthesia had significant intraoperative hemodynamic effects in terms of lower mean arterial pressure and longer hypotension duration, which required more colloid infusions but had no metabolic effects on base excess and lactate concentration, even CVP was not significantly affected by the sympathetic blockade.

Postoperative data showed slightly higher AST and ALT values in the epidural group, however it must be noted that, in this group, major resections were more frequent than minor resections, hence these data are difficult to interpret. Finally these differences in postoperative transaminase levels did not have any clinical impact, as no cases of postoperative liver failure were observed, and the postoperative courses of INR bilirubin and kidney

functions were substantially comparable between the two groups.

A recent large retrospective study by Kambakamba *et al.*<sup>[18]</sup> postulated that epidural anesthesia could have a role in jeopardizing postoperative kidney function in major, but not in minor liver resections. The difference in our results could be explained primarily by the fact that cirrhotic patients were excluded from the analysis in the Kambakamba study; also our sample is much smaller in size and we did not register a use of vasoactive drugs to correct intraoperative hypotension as extensive as the one in their study group. Postoperative complications were not significantly different between the two groups, however it is interesting to note that in the group without epidural anesthesia we observed 9 cases of postoperative delirium, while none was observed in the group receiving epidural anesthesia.

Also respiratory complications were observed only in patients treated with general anesthesia and postoperative systemic opiates. Patients receiving epidural analgesia in 50% of the cases were extubated at the end of surgery in the operating theatre, and in general required fewer hours of mechanical ventilation. These results indicate a beneficial role of epidural anesthesia with regard to the respiratory system function and its possible postoperative complications.

The shorter postoperative hospital length of stay observed in the epidural group could be related to a better analgesia, faster ambulation and a better postoperative intestinal function. We registered a longer mean hospital length of stay than the one enounced in other studies; the composition of our study population considering only cirrhotic patients has contributed in altering our results in this sense.

Another important aspect to underline is the large number of patients which were considered not eligible for neuraxial analgesia (57 out of 183 patients), in which other analgesic techniques to reduce postoperative opiates use, such as continuous wound infusion of local anesthetics<sup>[19]</sup>, intercostal nerve blocks<sup>[20]</sup>, intrathecal morphine administration<sup>[21]</sup> and TAP block<sup>[22]</sup> could find an indication. In a recent review by Hughes *et al.*<sup>[23]</sup> these techniques appear to be in some cases even superior to epidurals in terms of reduction of postoperative complications, despite providing less relief from pain. Another recent RCT from Hughes *et al.*<sup>[24]</sup> has compared epidural anaesthesia and analgesia with a combination of TAP and rectus sheath block with continuous wound infiltration, confirming the superiority of this alternative technique to TEA in terms of post operative complications and recovery and also achieving comparable pain scores. These results are particularly promising especially because to our knowledge this is the first trial achieving comparable pain scores with a technique alternative to TEA, and need to be confirmed by larger multicenter trials. Finally it is our belief that, based on the most solid evidence available at the moment, the use of TEA still represents the technique providing the most comfort to the patient whilst accelerating post operative

recovery compared to standard general anesthesia and opiate analgesia; alternative analgesic techniques find their correct indication in those patients not eligible for an epidural catheter positioning making a complete avoidance of systemic opiates in this population achievable.

The main limitations of the present study lay in its retrospective design, and the limited numerosity of the sample, which originated from a single center.

In conclusion, the main results of this study show that the known benefits of thoracic epidural anaesthesia and analgesia within an ERAS protocol for perioperative management, seem to be reproducible in a subpopulation including only cirrhotic patients undergoing open liver surgery. Epidural anaesthesia plays a major role in accomplishing many of these benefits, and its systematic use has important effects on patient outcomes and comfort. Our results also show that, in a selected population of cirrhotic patients, the technique can be performed safely without complications even if this aspect needs to be confirmed in larger populations.

## COMMENTS

### Background

Enhanced recovery after surgery is a solid reality in most surgical specialties and has been successfully applied to liver surgery. The subpopulation of cirrhotic patients undergoing liver resections has been poorly studied and represents a challenge for the application of such protocols. Moreover the use of epidural anaesthesia and analgesia in this subpopulation is still a matter of debate.

### Research frontiers

Defining the possible benefits of using epidural anaesthesia within an Enhanced Recovery after Surgery (ERAS) protocol for cirrhotic patients undergoing liver resection surgery is of great relevance in order to further implement the use of such protocols.

### Innovations and breakthroughs

This is the first retrospective study showing improved post operative outcomes using an ERAS protocol and epidural anaesthesia in a population including only cirrhotic patients undergoing liver resection surgery.

### Applications

These data suggest that the implementation of an ERAS protocol for cirrhotic patients using epidural anaesthesia is feasible, safe and provides positive clinical outcomes. This could be of great value in spreading the implementation of ERAS protocols to this particular subpopulation of patients.

### Peer-review

The manuscript describes the findings of a retrospective review to determine if there are benefits with the use of ERAS and epidural during liver resection surgery. The study is reasonably large and could provide useful information to the readers.

### Abstract

#### AIM

To evaluate hepatitis B virus (HBV) vaccine response and correlation with human leukocyte antigens (HLA) and/or gluten intake in celiac patients at diagnosis.

#### METHODS

Fifty-one patients affected by celiac disease, diagnosed at the Department of Pediatrics of the University of Catania (Italy), were recruited. All patients were tested at admission for immunization against HBV, according to findings from analysis of quantitative HBV surface antibody (anti-HBs). The anti-HBs titer was measured by enzyme-linked immunosorbent assay. Following the international standards, subjects with antibody titer < 10 IU/L were defined as non-responders. The prevalence of responders and non-responders among celiac subjects and the distribution of immunization for age were examined. In addition, the prevalence of responders and non-responders was assessed for correlation to HLA and clinical features at diagnosis of celiac disease.

#### RESULTS

The entire study population was divided into three groups according to age: 24 patients aged between 0

to 5.5 years (48.9%, group A); 16 aged between 5.5 and 9.5 years (30.61%, group B); 9 aged between 9.5 and 17 years (18.75%, group C). Comparison of the percentage of responders and non-responders between the youngest and the oldest age group showed no significant difference between the two groups ( $P > 0.05$ ). With regard to the HLA haplotype, comparison of the distribution of vaccination response showed no statistically significant difference between the different genotypes (homozygosity for the HLADQ2 haplotype compared with HLADQ2/DQ8 heterozygosity or other haplotypes;  $P > 0.05$ ). Moreover, distribution of the responders according to clinical features of celiac disease showed no statistically significant differences ( $P > 0.05$ ).

## CONCLUSION

This prospective study confirmed the lower percentage of response to HBV vaccine in celiac subjects. However, the underlying mechanism remains unclear and further studies are needed.

**Key words:** Celiac disease; Hepatitis B virus vaccination; Human leukocyte antigens; Gluten; Poor response

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Correlation between celiac disease and lower response to hepatitis B virus (HBV) vaccine has been demonstrated, but the causes remain unclear. The lack of prospective data represents an extensive gap between the time of vaccination and development of the immune response, contributing to select “false non-responders” (*i.e.*, those who are destined to lose the antibody titer over time). The originality of our prospective study is that of analyzing the response to HBV vaccine in a group of celiac patients at the time of diagnosis in an attempt to nullify the percentage of error related to confounding factors.

## INTRODUCTION

Celiac disease (CD) is a permanent immune-mediated enteropathy, triggered by gluten in genetically predisposed individuals. The genetic predisposition consists of the presence of alleles encoding for the molecules DQ2 or DQ8 of the human leukocyte antigen (HLA)<sup>[1]</sup>. A significant correlation between CD and a lower response to the hepatitis B virus (HBV) vaccine was demonstrated several years ago, but the causes of this phenomenon remain unclear. Many authors have postulated the role of

HLA molecules (DQ2 and DQ8) in affecting an impaired immune response to HBV vaccine in CD<sup>[2]</sup>. On the other hand, it has been theorized that gluten intake could represent the main factor involved, because according to some studies the percentage of responders among celiac patients who are compliant with a gluten-free diet (GFD) is similar to that among healthy subjects<sup>[3,4]</sup>.

Despite the many hypotheses, the debate on poor response to hepatitis B vaccination in CD remains largely open. It could be hypothesized that many confounding factors in some of the previous studies have contributed to maintaining this uncertainty. First of all, the lack of prospective data determines a more extensive gap between time of vaccination and development of the immune response, contributing to select “false non-responders” (*i.e.*, those who are destined to lose the antibody titer over time)<sup>[5]</sup>. Moreover, it could be easier to evaluate the effective role of HLA in influencing HBV vaccine response when CD has just been diagnosed and no other factors have yet intervened.

For all these reasons, the aim of our prospective study was to eliminate or reduce such confounding factors and to evaluate hepatitis B vaccination response in celiac patients at diagnosis of the disease and its possible correlation with HLA and/or gluten intake.

## MATERIALS AND METHODS

In this prospective study we recruited 51 patients affected by CD, diagnosed at the Department of Pediatrics of the University of Catania (Italy). The diagnosis of CD was made according to the European Society for Paediatric Gastroenterology, Hepatology and Nutrition criteria updated in 2012<sup>[6]</sup>. The total serum IgA levels were measured in all patients in order to exclude the presence of a selective deficit of IgA. Inclusion criteria required that subjects must have completed obligatory vaccinations, including the HBV vaccine. All patients were tested at admission for immunization against HBV, according to finding from quantitative analysis of the HBV surface antibody (anti-HBs). The anti-HBs titer was measured by enzyme-linked immunosorbent assay. Following the international standards, subjects with antibody titer < 10 IU/L were defined as non-responders<sup>[7]</sup>.

Two of the 51 celiac patients were excluded because of insufficiency of their serum samples for analysis of the anti-HBs titer.

We examined the prevalence of responders and non-responders among celiac subjects and the distribution of immunization for age. For this, all patients were divided into three groups on the basis of their age at diagnosis: Group A children were aged between 1.5 and 5.5 years; group B children were aged between 5.5 and 9.5 years; group C children were aged between 9.5 and 17 years.

Moreover, we divided all 49 patients on the basis of clinical features at diagnosis of CD and distinguished them in the following three groups: Group 1 patients had typical form (onset with diarrhea, abdominal pain, cramping or distension, dyspepsia, vomiting or failure to

**Table 1** Serologic and histologic findings of the duodenal biopsies for celiac disease diagnosis

	TTG IgA ( $\mu$ A/mL)			Marsh score

Patients, <i>n</i>	20	10	19	26	23

thrive); group 2 patients had atypical form (onset with other symptoms such as deficiency iron-anemia, chronic fatigue, behavior change, dermatitis and joint pain); group 3 patients had silent form (asymptomatic onset). The prevalence of responders and non-responders was assessed for correlation to HLA and the clinical features at diagnosis of CD (typical or atypical onset).

At the end, we compared the results obtained by the present observational study with the results of a retrospective study previously conducted in our Department of Pediatrics.

### Statistical analysis

The statistical analysis of data was performed with the use of SPSS version 21.0 software (SPSS Inc. Chicago, IL, United States). The results for quantitative variables were expressed as mean  $\pm$  SD, and those of qualitative variables were expressed as frequencies and percentages. Differences between groups were compared using the Mann-Whitney *U* test for two independent samples. The Fisher's exact test was used to compare frequencies. For all analyses, statistical significance was defined as  $P < 0.05$ .

## RESULTS

Data for the serologic and histologic findings of duodenal biopsies (according to Marsh classification) used for the diagnosis of CD are summarized in Table 1, while characteristics of the 49 patients included in the study (sex, age, percentage of responders, HLA haplotype) are summarized in Table 2.

When we divided the entire study population into the three age groups, we found 24 patients were aged between 0 to 5.5 years (48.9%, group A), 16 were aged between 5.5 and 9.5 years (30.61%, group B) and 9 were aged between 9.5 and 17 years (18.75%, group C). The responders were distributed into the three age groups as follows: 19 (38.77%) in group A; 11 (22.44%) in group B; 4 (8.16%) in group C. Comparing the percentage of responders and non-responders between the youngest and the oldest group, no significant difference was found ( $P > 0.05$ ).

With regard to the HLA haplotype, comparison of the distribution of vaccination response showed no statistically significant difference between the different genotypes (Table 2). Moreover, the distribution of responders according to clinical features of CD was as follows: 20 out of 26 patients in group 1; 11 out of 17 in group 2; 3 out of 6 in group 3. The typical form showed significant association with the presence of

HLADQ2 ( $P < 0.05$ ). Comparison of the immunological vaccine response between the three groups showed no statistically significant differences related to the clinical features (Table 2).

Finally, we found a statistically significant difference in the vaccination response for patients in the present observational study as compared to patients analyzed in the previous retrospective study. In the present study, 34 out of 49 patients were responders compared to 30 out of 60 patients in the retrospective study ( $P < 0.01$ ).

## DISCUSSION

CD is defined as an immune-mediated systemic disorder elicited by gluten and related prolamines in genetically-susceptible individuals and is characterized by the presence of a variable combination of gluten-dependent clinical manifestations, CD-specific antibodies, HLA-DQ2 or DQ8 haplotypes and enteropathy<sup>[6]</sup>.

The reasons why CD could be related to an inadequate response to hepatitis B vaccination have long been discussed. Some previous studies have suggested a genetically-related failure of response, attributed to particular HLA antigens, mainly the DQ2 haplotype, which is also involved in autoimmunity<sup>[8,9]</sup>. In fact, while DQ2 is present in only approximately 40% of the general population, it is expressed in up to 81% of CD patients. The HLA-DQ2 status would induce an inadequate Th2 response, leading to inefficient B cell differentiation and formation of memory T cells<sup>[8,10,11]</sup>. In 2007, a study by Park *et al.*<sup>[2]</sup> demonstrated that more than 50% of the enrolled children with CD did not show a response to standard vaccination regimens for HBV, in contrast to a physiological response that was observed with other vaccinations (tetanus, rubella, and *Haemophilus influenzae* type b). This finding supported the hypothesis that HLA haplotype played a specific role in response

to HBV vaccine. One year later, a subsequent study conducted by Ahishali *et al.*<sup>[12]</sup> confirmed this theory by finding responsiveness to hepatitis B vaccination in 68% of celiac patients, in contrast to the 100% response observed for the controls, emphasizing the genotypic coincidence.

In 2009, Leonardi *et al.*<sup>[13]</sup> published a case control retrospective study about the prevalence of HBV vaccine non-responders among celiac and healthy subjects. The anti-HBs titer was measured after a successful period of time on a GFD, as demonstrated by the normalization of serum markers of CD. The study confirmed that celiac patients have a lower percentage of response to hepatitis B vaccination than healthy controls. However, the authors also found a significantly higher number of responders among the celiac patients that were younger than 18-month-old at diagnosis and a significantly lower number of responders in adolescent patients older than 14-year-old at diagnosis. The drawback of the study was that the HLA typing was performed in few patients, so that the study could not demonstrate the correlation of the phenomenon observed with HLA-DQ2 or HLA-DQ8, and that there was a long interval between the time of hepatitis B vaccination and the time of collecting samples for analysis of the anti-HBs titer. In this regard, a recent case control retrospective study by Zanoni *et al.*<sup>[11]</sup> investigated the serological response to HBV and measles-containing vaccines in three groups of individuals: Diabetes mellitus type 1 (T1DM) patients, celiac patients and controls. No significant differences were found in the percentage of responders to HBV and measles vaccines among the T1DM and CD patients and the control group, and there was also a lack of correlation between HBV vaccine response and DQ2. According to the authors, these conflicting results between their findings and the data reported in the literature may be due to differences in ages of the examined subjects at time of vaccination and in time intervals between vaccination and blood sample collection for testing. They concluded that prospective studies of pathological and healthy groups, with same age at hepatitis B vaccination and same time interval for blood sample collection to determine antibody levels, are necessary to provide more conclusive data.

For these reasons, the originality of our prospective study is that of analyzing the response to hepatitis B vaccination in a group of 49 celiac patients at the time of diagnosis, helping us to nullify the percentage of error related to a long interval from time of hepatitis B vaccination to time of serum anti-HBs analysis. In fact, when we compared the results of our prospective study (based upon patients at time diagnosis of CD) with those retrospectively obtained by Leonardi *et al.*<sup>[13]</sup> in 2009 (based upon celiac patients on a GFD), we found a higher percentage of responders among the celiac subjects, probably due to our study design having eliminated more of the potential confounding factors related to loss of immunity over the time, which have been documented extensively in the literature<sup>[14-16]</sup>.

Meanwhile, we also observed that whereas more than half of our celiac population represented responders (69.39%), the percentage still remained lower than in the general population (90%), suggesting a role of genetic predisposition. However, comparison of the distribution of vaccination response showed no statistically significant difference between the different genotypes, providing an argument against the theory that homozygosity for the HLA-DQ2 haplotype could act in isolation to negatively influence the response to vaccination, in comparison with the HLA-DQ2/DQ8 heterozygosity or other haplotypes.

In this regard, several studies hypothesized that gluten intake at the time of vaccination could influence immune response, *via* competition of both gliadin peptides and hepatitis B surface antigen protein fragments for binding to HLA-DQ2 molecules, which could result in defective antibody production<sup>[3,17,18]</sup>. In support of this hypothesis, Nemes *et al.*<sup>[19]</sup> showed that seroconversion after hepatitis B vaccination was 95.5% in CD patients vaccinated during dietary treatment; in contrast, in a second group of CD patients that were either untreated or with a diet status ranging from strict to non-strict, the response was 50.9%. The HLA-DQ alleles did not seem to play a primary role because all of the patients carried the HLA-DQ2. In our study, patients were enrolled at diagnosis of CD, when their diet contained gluten; although, we do not know the exact period of exposure. It could be of interest to administer a booster dose of HBV vaccine in these subjects after a period of GFD and to subsequently evaluate the effects on the immune response. However, since our study did not reveal a significant correlation between HBV vaccine response and HLA alone, we now question whether it is possible that impaired immune response in CD is the result of a combination of several factors. Indeed, it could be possible that genetic predisposition, gluten intake and phenotype of the disease interact to influence a lower HBV vaccine response in CD.

In conclusion, our study is the first prospective study on HBV vaccine response in CD. The findings confirm the lower percentage of response to hepatitis B vaccination in the celiac population, as compared with healthy subjects. The mechanism that causes this phenomenon, however, remains unclear. According to our results, the mechanism does not appear to be related to HLA haplotype alone but could result from several variables working in combination. Further studies are needed to support this hypothesis and to establish the best surveillance program of response to HBV vaccine in CD.

## COMMENTS

### Background

The correlation between celiac disease and a lower response to the hepatitis B virus (HBV) vaccine has been demonstrated, but the causes remain unclear. Many confounding factors identified by previous studies have contributed to this uncertainty; moreover, the lack of prospective data represents a more extensive gap between the time of vaccination and the development of an immune response, contributing to select false non-responders (*i.e.*, those who are destined to lose the antibody titer over time). The originality of the authors' prospective

study lies in the authors' analysis of the response to hepatitis B vaccination in a group of celiac patients at the time of diagnosis, which allowed the authors' study to nullify the percentage of error related to these confounding factors.

### Research frontiers

In this study, there is suggestion that genetic predisposition, gluten intake and phenotype of celiac disease could work in conjunction to influence a lower HBV vaccine response.

### Innovations and breakthroughs

This study is the first prospective study in literature on the topic of lower HBV vaccine response in patients with celiac disease. This study confirms the lower percentage of response to hepatitis B vaccination in the celiac population, as compared with healthy subjects. According to the authors' results, the mechanism that causes this phenomenon is unlikely to be related to human leukocyte antigens haplotype alone but could be a result of several variables together.

### Applications

This study provides additional evidence that, along with the collective data in the literature, will help to establish an optimal surveillance program of response to HBV vaccine in celiac disease.

### Terminology

Non-responders are all subjects with a titer of hepatitis B surface antibody < 10 IU/mL after the primary vaccination cycle.

### Peer-review

The authors have studied antibody response to HBV vaccine in celiac patients. This is an interesting study, well designed and performed.

### Abstract

Hepatocellular adenoma (HCA) was recently classified into four pathological subtypes. There have been few studies describing the findings of contrast-enhanced ultrasonography (CEUS) of each type. Our case concerns a 78-year-old man who had undergone routine medical check-ups for hepatitis C for 11 years. Abdominal ultrasonography showed a 28 mm, hypo-echoic mass in the segment 4 of the liver. His integrating amount of drinking was 670 kg convert into ethanol. CEUS with Sonazoid demonstrated mild uniform hypo-enhancement with inflow of microbubbles from the periphery of the tumor in the arterial phase, and heterogeneously hypo-enhancement in the post vascular phase. Because the mass increased in size within 3 mo, a well differentiated hepatocellular carcinoma was suspected, and hepatic resection was performed. Microscopic findings showed homogeneous cell proliferation with low grade atypia, infiltration of inflammatory cells, ductular reactions, fatty deposit in part, and sinusoidal dilation. Immunohistochemistry revealed geographic positive for serum amyloid A (SAA), focal positive for glutamine

synthetase, diffuse and strong positive for C-reactive protein, and positive for liver-type fatty acid binding protein. These pathological features corresponded to that of an inflammatory HCA. However, we could not make a clear diagnosis, because HCAs were defined as not to arise in cirrhotic liver. Finally, this tumor was diagnosed as a SAA positive hepatocellular neoplasm.

**Core tip:** Hepatocellular adenoma (HCA) was classified into four pathological subtypes. And HCA usually arises in the absence of significant fibrosis. Recently, some reports about serum amyloid A (SAA) positive hepatocellular neoplasm were published. All tumors shared features with inflammatory HCA arising in alcoholic cirrhosis. We describe the contrast-enhanced ultrasonographic findings of SAA positive HCA.

Contrast-enhanced ultrasonographic findings of serum amyloid A-positive hepatocellular neoplasm: Does hepatocellular adenoma arise in cirrhotic liver? *World J Hepatol* 2016; 8(26): 1110-1115 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i26/1110.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i26.1110>

## INTRODUCTION

Hepatocellular adenoma (HCA) was recently classified into four pathological subtypes; hepatocyte nuclear factor 1 alpha inactivated HCA, beta catenin activated HCA, inflammatory HCA, and unclassified HCA<sup>[1-4]</sup>. Although contrast-enhanced ultrasonographic features of HCA have been reported in several literatures till now<sup>[5-7]</sup>, there have been little studies that described those of each type of HCA<sup>[8]</sup>. HCAs usually arise in the liver without steatosis, because a nodule arising in fibrotic/cirrhotic liver was not to be a HCA according to World Health Organization classification 2010<sup>[1]</sup>. Recently, some reports about serum amyloid A (SAA) positive hepatocellular neoplasm were published. All nodules shared features with inflammatory HCA arising in alcoholic cirrhosis<sup>[9-11]</sup>. In this report, we describe contrast-enhanced ultrasonographic findings of SAA positive hepatocellular neoplasm which had features similar to inflammatory HCAs.

## CASE REPORT

A 78-year-old man had undergone routine medical check-ups for hepatitis C over 21 years. He received interferon therapy 21 years ago, but could not achieve

complete remission. In these years, he had compensatory hepatic cirrhosis and was given medication of glycyrrhizin formulation. Abdominal ultrasonography showed 20 mm, hypo-echoic in the segment 4 of the liver 3 mo ago. Because the tumor increased in diameter to 28 mm, he was admitted to our hospital for further examinations. He had no history of other disease. He drank two glasses of whisky and one glass of beer from 20 till 66-year-old. His integrating amount of drinking was 670 kg convert into ethanol. He had no symptoms. Physical examination showed untoward features. Blood examination demonstrated thrombocytopenia, mild hyper-bilirubinemia, elevated liver enzymes (aspartate aminotransferase, 36 IU/L; alanine aminotransferase, 35 IU/L), positive for HCV-antibody, and 6.4 log IU/mL for HCV-RNA (Table 1).

Sonographic examination showed a homogenous, hypo-echoic, round mass in the segment 4b of the liver (Figure 1A). Color Doppler sonography revealed no signals in the lesion (Figure 1B). Contrast-enhanced ultrasonography (CEUS) with 0.5 mL of Sonazoid (Daiichi Sankyo, Tokyo, Japan) demonstrated mild global hyper-enhancement with inflow of microbubbles from the periphery of the tumor in the arterial phase (Figure 1C and D), persist enhancement in the portal venous phase (Figure 1E), and heterogeneous hypo-enhancement in the post vascular phase (Figure 1F). Plain computed tomography (CT) showed a hypodense tumor (Figure 2A). Contrast-enhanced CT showed iso-enhancement in the arterial phase (Figure 2B) and slight hypo-enhancement in the portal phase (Figure 2C). Magnetic resonance imaging (MRI) demonstrated slightly high intensity in the T1 weighted image (Figure 3A), and slightly low intensity in the T2 weighted image (Figure 3B). Contrast-enhanced MRI using Gadolinium ethoxybenzyl diethylene triamine pentaacetic acid revealed slightly high intensity in the hepatobiliary phase (Figure 3C).

Because the mass increased in size, it was suspected as being a well differentiated hepatocellular carcinoma. Considering the risk of hemorrhage and dissemination, partial segment 4 resection was performed without biopsy. Because the mass was adjacent to horizontal portion of the left portal vein and pathological diagnosis was needed, percutaneous ablation was not chosen. Microscopic findings showed homogeneous cell proliferation with low grade atypia, infiltration of inflammatory cells, ductular reactions, fatty deposit in part, and sinusoidal dilation (Figure 4). Immunohistochemistry revealed geographic positive for SAA, focal positive for glutamine synthetase, diffuse and strong positive for C-reactive protein, and positive for liver-type fatty acid binding protein (Figure 5). These pathological features corresponded to that of an inflammatory HCA.

## DISCUSSION

Classification of HCA is based on molecular, pathologic, and immunohistochemical features<sup>[1]</sup>. Inflammatory HCA accounts for 45%-60% of all HCAs<sup>[1-4]</sup>, and has

**Table 1** Patient's laboratory results (the normal ranges)

WBC (3.3-8.6)	6200/ $\mu$ L	Total protein (6.6-8.1)	8.0 g/dL
Hgb (13.7-16.8)	15.0 g/dL	Albumin (4.1-5.1)	4.7 g/dL
Platelet (148-348)	$108 \times 10^3$ / $\mu$ L	HBs antibody	(-)
PT% (> 80)	99%	HBc antigen	(-)
INR	0.92	HCV antibody	(+)
Total bilirubin (0.4-1.5)	1.41 mg/dL	HCV-RNA	6.4 logIU/mL
Direct bilirubin (0.05-0.4)	0.37 mg/dL	Alpha-fetoprotein (< 20)	6.4 ng/mL
Aspartate transaminase (13-30)	36 IU/L	PIVKA-II (< 40)	91 mAU/mL
Alanine transaminase (10-42)	35 IU/L	ICG (15 s) (< 15.0)	14.0%

WBC: White blood cell; INR: International normalized ratio; HCV: Hepatitis C virus; PIVKA-II: Prothrombin induced by vitamin K absence-II; ICG: Indocyanine green.

**Figure 1** Sonography. Sonographic examination showed a homogenous, hypo-echoic, round mass in segment 4 of the liver (A). Color Doppler sonography revealed no signals in the lesion (B). CEUS demonstrated mild global hypo-enhancement (D, arrow) with inflow of microbubbles from peripheral of the tumor (C, arrow) in the arterial phase, persist enhancement in the portal venous phase (E, arrow), and heterogeneous hypo-enhancement in the post vascular phase (F, arrow). CEUS: Contrast-enhanced ultrasonography.

mutations of the *IL6ST* gene<sup>[12-14]</sup>. Alcohol intake and obesity are association with inflammatory HCA<sup>[9,15-17]</sup>.

The rate of malignant transformation is unknown. CEUS findings of HCA were described in previous

**Figure 2 Computed tomography.** Plain computed tomography (CT) showed a hypodense tumor (A, arrow); Contrast-enhanced CT showed iso-enhancement in the arterial phase (B, arrow); and slightly hypo-enhancement in the portal phase (C, arrow).

studies<sup>[5-8,18]</sup>. In one study which investigated 18 lesions, which were iso-hypoechoic in 9, hyper-enhancing in all in the arterial phase, and iso or hypo-enhancement in all in the late phase<sup>[18]</sup>. Ricci *et al.*<sup>[19]</sup> emphasized homogeneous and centripetal enhancement during artery phase was showed in almost all. In accordance with previous studies<sup>[19-21]</sup>, HCA lesions had some typical features, including early, homogeneous, centripetal, and strong enhancement in the arterial phase and the lack of a portal vein supply. According to a study<sup>[22]</sup>, a number of HCAs demonstrated persistent enhancement. Dong *et al.*<sup>[22]</sup> said “slow wash-out” (persistent enhancement during portal venous and late phase) may be a discriminant sign for HCAs in CEUS. In our case, the arterial phase findings were not so strong but homogenous and centripetal hyper-enhancement and some peripheral vessels were showed. The contrast medium that used in that study

**Figure 3 Magnetic resonance imaging.** Magnetic resonance imaging (MRI) demonstrated slightly high intensity in T1 weighted image (A, arrow), and slightly low intensity in T2 weighted image (B, arrow). Contrast-enhanced MRI using Gd-EOB-DTPA revealed slightly high intensity in the hepatobiliary phase (C, arrow). Gd-EOB-DTPA: Gadolinium ethoxybenzyl diethylene triamine pentaacetic acid.

**Figure 4 Microscopy** showed homogeneous cell proliferation with low grade atypia, infiltration of inflammatory cells, ductular reactions, fatty deposit in part, and sinusoidal dilation.

**Figure 5** Immunohistochemistry revealed geometric positive staining for serum amyloid A (A), focal positive for glutamine synthetase (B), diffuse and strong positive for C-reactive protein (C), positive for liver-type fatty acid binding protein (D). Upper side is tumor area.

was Sonovue (Bracco, Milan, Italy) whereas Sonazoid was administered to our patient. Sonovue and Sonazoid are phagocytosed by Kupffer cells, and visualize clearly malignant tumor as defect. CEUS using Sonazoid revealed hypo-enhancement in the post vascular phase in our patient which was interpreted as lack of Kupffer cells in the tumor.

Recently SAA-positive hepatocellular neoplasms were proposed<sup>[10,11]</sup>. Generally, HCA arises from normal liver<sup>[1,23]</sup>. Although SAA-positive hepatocellular neoplasms have similar features to inflammatory HCA, they arise from alcoholic cirrhosis. Sasaki *et al.*<sup>[10,11]</sup> suggested, considering that the patient exposed to alcohol in inflammatory HCA, it may be not be surprising that inflammatory HCA arise in alcoholic hepatic disease or cirrhosis. Our case had liver cirrhosis with HCV infection, moreover had a history of excessive amounts-alcohol consumption. We considered that our case is SAA-positive hepatocellular neoplasm.

In conclusion, CEUS revealed homogeneous mild hyper-enhancement in the arterial phase and heterogeneous hypo-enhancement in the post vascular phase in our case. Some of CEUS findings corresponded to features of HCA. Our patient had both HCV infection and alcohol abuse, and it was not typical for inflammatory HCA. It may be a case of so-called SAA-positive hepatocellular neoplasm.

## COMMENTS

### Case characteristics

A 78-year-old man with hepatitis C and hepatic cirrhosis received abdominal

ultrasonography, in which 20 mm, homogenous, hypo-echoic, round mass was shown in the segment 4b of the liver.

### Clinical diagnosis

Because the mass increased in size and he had hepatic cirrhosis, a well differentiated hepatocellular carcinoma was suspected.

### Differential diagnosis

Dysplastic nodule, large regenerative nodule, hepatocellular adenoma (HCA), and focal nodular hyperplasia.

### Laboratory diagnosis

Hepatic pre-cirrhosis with early hepatocellular carcinoma.

### Imaging diagnosis

A well differentiated hepatocellular carcinoma was suspected.

### Pathological diagnosis

Inflammatory HCA.

### Treatment

Segment 4 partial resection.

### Related reports

HCA was classified into four pathological subtypes and usually arises in the absence of significant fibrosis. Serum amyloid A (SAA)-positive hepatocellular neoplasm shares features with inflammatory HCA arising in alcoholic cirrhosis.

### Term explanation

SAA-positive hepatocellular neoplasms have similar features to inflammatory HCA, they arise from alcoholic cirrhosis.

### Experience and lessons

Considering that the patient exposed to alcohol in inflammatory HCA, it may

be not be surprising that it arise in alcoholic hepatic disease or cirrhosis. Recognizing SAA-positive hepatocellular neoplasm as differential diagnosis is important in the case that had both HCV infection and alcohol abuse.

### Peer-review

This is a very interesting case, well investigated and presented with also pathological comparison images.

### Abstract

In Pakistan which ranked second in terms of hepatitis C virus (HCV) infection, it is highly needed to have an established diagnostic test for antiviral therapy response

prediction. Interleukin 28B (*IL-28B*) genetic testing is widely used throughout the world for interferon based therapy prediction for HCV patients and is quite helpful not only for health care workers but also for the patients. There is a strong relationship between single nucleotide polymorphisms at or near the *IL-28B* gene and the sustained virological response with pegylated interferon plus ribavirin treatment for chronic hepatitis C. Pakistan is a resource limited country, with very low per capita income and there is no proper social security (health insurance) system. The allocated health budget by the government is very low and is used on other health emergencies like polio virus and dengue virus infection. Therefore it is proposed that there should be a well established diagnostic test on the basis of *IL-28B* which can predict the antiviral therapy response to strengthen health care set-up of Pakistan. This test once established will help in better management of HCV infected patients.

**Key words:** Diagnostics; Hepatitis C virus; Interferon therapy; Polymorphisms; *IL-28B*; Genetic testing; Pakistan

**Core tip:** Pakistan has a very heavy burden of hepatitis C virus (HCV) infection with around 11 million positive cases; however, in spite of well established prognostic value, the data regarding the role of interleukin 28B (*IL-28B*) single nucleotide polymorphisms (SNPs) in HCV antiviral therapy response are very limited. There are only six reports on the topic and it can be concluded from this limited information that *IL-28B* could be a good prognosis marker for HCV patient management in Pakistan. The major prevalent HCV genotype in Pakistan is 3a and *IL-28B* SNP rs12979860 showed a good prediction for interferon based antiviral therapy response against this viral genotype. It can be predicted that inclusion of *IL-28B* genetic testing in

routine diagnostic set-up of Pakistan will help in better management of the disease. A well directed antiviral therapy based on personalized *IL-28B* genotyping along with virus genotyping will help in lessening of therapy cost and better management of the disease.

## TO THE EDITOR

Recent advancements in molecular biology techniques help in identification of various host and pathogenic factors influencing the disease prognosis and therapeutic outcomes. One example is identification of various genetic factors through genome wide analysis studies (GWAS). In the field of gastroenterology and hepatology, an example is the discovery of an association between single nucleotide polymorphisms (SNPs) at or near the interleukin 28B (*IL-28B*) gene and the sustained virological response (SVR) rate with pegylated interferon (IFN) plus ribavirin treatment for chronic hepatitis C (CH-C)<sup>[1-3]</sup>. *IL-28B* (IFN- $\lambda$ 3) is produced by many immune cells like neuronal cells, alveolar epithelial cells, and hepatocytes in response to viral infection. IFN- $\lambda$  showed antiviral activity against many viruses. It not only inhibits viral replication but also has immune-modulatory functions<sup>[4]</sup>. It has been shown by four autonomous GWAS that SNPs of the *IL-28B* gene, which is located on chromosome 19q13, are strongly associated with treatment response to interferon based therapy and spontaneous viral clearance in chronic hepatitis C virus (HCV)-infected patients<sup>[4]</sup>. After these studies, the predictive potential of *IL-28B* genetic variations has been investigated and verified throughout the world in patients infected with HCV of all viral genotypes and currently *IL-28B* SNPs are in commercial use for antiviral therapy response prediction around the world.

In Pakistan, data regarding the role of *IL-28B* SNPs in HCV antiviral therapy response are very limited. To our knowledge, there are only six studies that investigated the role of *IL-28B* in HCV patients regarding interferon therapy response and disease prognosis (Table 1)<sup>[5-10]</sup>. These studies investigated the predictive potential of either *IL-28B* protein level or *IL-28B* SNPs (rs12979860, rs8099917, rs12980275). It can be concluded from existing limited data that *IL-28B* could be a good prognosis marker for HCV patient management. Recent studies by Shaikh *et al*<sup>[9]</sup> (2014) and Imran *et al*<sup>[8]</sup>

(2015) reported significant existence (47.5% and 6.4%, respectively) of circulation of diagnostically untypable HCV variants in local populations of Sindh Province of Pakistan. We have lately highlighted the issue of diagnostically untypable HCV circulation in Pakistan and recommended immediate need to resolve this problem for the better management of HCV patients as course and fate of antiviral therapy are viral genotype dependent<sup>[11]</sup>. The resolution of this problem will also help in understanding the potential role of *IL-28B* SNPs in antiviral therapy response prediction against each viral genotype.

HCV is highly endemic in Pakistan with around 11 million infections<sup>[12-14]</sup>. The major prevalent viral genotype is 3a along with 2a, 3b, 1b, 2b, 2a and a large number of untypable ones<sup>[11,15,16]</sup>. It is observed that irrespective of the HCV genotype, SVR rate of interferon plus ribavirin is quite good (80%-97%) in Pakistan<sup>[7,8,17,18]</sup>. Pakistan is a resource limited country with much low per capita income in the general population. According to the World Health Organization, the total expenditure on health is only 2.8% of GDP, which means total expenditure on health per capita is only 126 \$<sup>[19]</sup>. Other medical emergencies like polio virus and dengue virus endemics shift the government priorities and funds are becoming less available for HCV management. There is no health insurance for the general population in Pakistan, which also affect the patient's ability to bear therapy cost. *IL-28B* genetic test is an established diagnostic test for interferon based antiviral therapy response prediction across the world. In the current scenario of Pakistan, it is highly needed to have an established diagnostic test on the basis of *IL-28B* which can predict the antiviral therapy response.

The currently available literature on the role of *IL-28B* in HCV interferon therapy response in Pakistan shows that rs12979860 is a good predictor of therapy response against HCV 3a genotype. In the era of direct acting antivirals (DAAs), interferon based therapy against HCV will remain the major choice in Pakistan due to higher SVR and low cost compared with DAAs<sup>[20]</sup>. On the basis of the above discussion, we propose future studies across the country on different ethnic groups infected with all viral genotypes so that the results could be generalized for diagnostic purpose. It is also suggested that the forthcoming studies should include a comparatively larger number of patients so that the results could be applicable for commercial purpose. It is highly anticipated that inclusion of *IL-28B* genetic testing in routine diagnostic tests will help health care professionals in better management of the patients. Well directed antiviral therapy on the basis of personalized *IL-28B* genotyping along with viral genotyping will help in reduction of therapy cost and better management of the disease.

**Table 1 Summary of interleukin 28B and interferon based therapy response in hepatitis C virus patients in Pakistan**

Year	Viral genotype	Patients (n)	Objective/SNP investigated	Findings/conclusion	Ref.
2015	3a	66	IL-28B protein levels	IL-28B protein levels were significantly associated with therapy response	[5]
2015	3	105	rs8099917	TT genotype favors RVR	[6]
			rs12979860	CC genotype favors SVR	
2015	1a,1b, 3a	111	rs12979860	CC genotype favors SVR in HCV 3a genotype	[7]
2015	1a, 1b, 3a, 3b, 4, UT	140	rs8099917	No association was observed with therapy response	[8]
			rs12979860	CC genotype favors SVR	
2014	(2a, 3a, UT)	220	rs8099917	No association was observed with therapy response	[9]
			rs12979860	No association was observed with therapy response	
			rs12980275	AA genotype favors SVR	
2014	3a	200	rs12979860	TT genotype favors SVR	[10]

Genotyping performed only for non-responders patients. SVR: Sustained virological response; RVR: Rapid virological response; UT: Untypable; IL-28B: Interleukin 28B; HCV: Hepatitis C virus; SNP: Single nucleotide polymorphism.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Danny Ka-Ho Wong, BSc, MSc, PhD, Research Assistant Professor, Department of Medicine, the University of Hong Kong, Hong Kong, China

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Molecular pathological epidemiology (MPE) is a multi-disciplinary and transdisciplinary study field, which has emerged as an integrated approach of molecular patho-

logy and epidemiology, and investigates the relationship between exogenous and endogenous exposure factors, tumor molecular signatures, and tumor initiation, progression, and response to treatment. Molecular epidemiology broadly encompasses MPE and conventional-type molecular epidemiology. Hepatocellular carcinoma (HCC) is the third most common cause of cancer-associated death worldwide and remains as a major public health challenge. Over the past few decades, a number of epidemiological studies have demonstrated that diabetes mellitus (DM) is an established independent risk factor for HCC. However, how DM affects the occurrence and development of HCC remains as yet unclearly understood. MPE may be a promising approach to investigate the molecular mechanisms of carcinogenesis of DM in HCC, and provide some useful insights for this pathological process, although a few challenges must be overcome. This review highlights the recent advances in this field, including: (1) introduction of MPE; (2) HCC, risk factors, and DM as an established independent risk factor for HCC; (3) molecular pathology, molecular epidemiology, and MPE in DM and HCC; and (4) MPE studies in DM and risk of HCC. More MPE studies are expected to be performed in future and I believe that this field can provide some very important insights on the molecular mechanisms, diagnosis, personalized prevention and treatment for DM and risk of HCC.

**Key words:** Diabetes mellitus; Molecular pathological epidemiology; Hepatocellular carcinoma; Risk factor; Molecular mechanism

## INTRODUCTION

Molecular pathology examines the expression of molecular markers within bodily fluids, tissues or organs, and focuses on the diagnosis and studies of diseases, such as tumors<sup>[1,2]</sup>. Epidemiology is focused upon the studies of distributions and determinants of diseases and health conditions in specific populations<sup>[3,4]</sup>. Molecular pathological epidemiology (MPE) is a multidisciplinary and transdisciplinary study field, which has emerged as an integrated approach of molecular pathology and epidemiology, and investigates the relationship between tumour molecular markers, exposure of endogenous and exogenous factors, and development, progression and prognosis of tumors<sup>[5-8]</sup>. Molecular epidemiology broadly encompasses MPE and conventional-type molecular epidemiology.

In MPE, researchers investigate the relationships between: (1) changes of extracellular or cellular molecules (disease molecular signatures); (2) genetic, dietary, environmental and lifestyle factors; and (3) development and progression of diseases, such as tumors<sup>[6]</sup>. In 2010, Professor Shuji Ogino and Professor Meir Stampfer<sup>[5]</sup> were the first to introduce the concept of MPE. They consolidated this concept mainly based on the researches of colorectal cancer (CRC), particularly the prototypical study in the evolving field of MPE, which was conducted by Professor Peter T Campbell and others<sup>[9]</sup>.

This case-control study of Campbell *et al*<sup>[9]</sup> was conducted to determine the relationships between CRC microsatellite instability (MSI) status, risk of CRC, and human body mass index (BMI). The results showed that an increased CRC risk was found in those patients with a high BMI; however, this risk of CRC was associated with the MSI status. For patients with MS-stable, the adjusted odds ratio (OR) was 1.38 and 95%CI was 1.24-1.54, for an increment of 5 kg/m<sup>2</sup> of BMI; for patients with MSI-low, the OR was 1.33 and 95%CI was 1.04-1.72; however, for patients with MSI-high tumours, the value of OR and 95%CI were 1.05 and 0.84-1.31, respectively<sup>[9]</sup>. The authors concluded that the relationship between the high BMI and increased CRC risk was related to the tumor MSI status<sup>[9]</sup>. According to the concept and principle of MPE, this prototypical study addressed the relationship between exposure factor (high BMI), molecular change (CRC MSI status) and tumor initiation (risk of CRC)<sup>[5,10]</sup>.

MPE addresses two questions: (1) the association of particular exposure factors with specific molecular changes; and (2) the interaction of particular exposure factors with specific molecular changes to affect development, progression and prognosis of tumors. The typical research of cancer MPE is used to examine the relationship between exposure factors and risk of tumors according to the status of tumor signatures<sup>[9,10]</sup>. Cancer MPE techniques and studies can help us understand the carcinogenesis of certain exposure factors, through the examination of molecular pathological signatures associated with initiation and progression of tumors, and the exposures<sup>[5,6]</sup>.

## HEPATOCELLULAR CARCINOMA AND RISK FACTORS

Hepatocellular carcinoma (HCC) has been confirmed as the third leading cause globally, among all the cancer-related deaths<sup>[10-12]</sup>. For primary liver cancers, more than 80% are HCC and the incidence rate annually of HCC is 4.9 per 100000 persons. Although some advances have been gained in the diagnosis and treatment of HCC, the prognosis remains very poor. Similarly, the annual mortality rate remains very high and HCC has also been ranked as one of the most lethal cancers<sup>[13]</sup>.

With the using and popularization of hepatitis B virus (HBV) vaccination, the improvement of people's living standard and life style, and advancement of early diagnosis and treatment of premalignant lesions, the incidence of HCC had been anticipated to be decreased. However, the incidence rate of HCC has already been found to be increased significantly in the past thirty years in some countries, including the United States, China and Japan<sup>[14,15]</sup>. For example, during the period of 1981-1983 in the United States, the age adjusted incidence rate was 1.3 per 100000; however, this rate increased to 3.0 per 100000 during the period of 1996-1998<sup>[14,15]</sup>. Although more than fifty percent of this increase has been attributed to hepatitis virus C (HCV), other hepatitis viruses and alcoholic liver disease<sup>[16]</sup>, the reason remains as unclear.

The identified risk factors of HCC include liver cirrhosis, HBV, HCV, heavy alcoholic consumption, aflatoxin exposure, non-alcoholic steatohepatitis, positive family history, male sex, and increasing age<sup>[17-19]</sup>. Over the past few decades, a number of epidemiological studies have demonstrated that diabetes mellitus (DM) is an established independent risk factor for HCC<sup>[12,20-23]</sup>.

## DM AS AN ESTABLISHED INDEPENDENT RISK FACTOR FOR HCC

In the year of 1986, for the first time, Lawson *et al*<sup>[24]</sup> proposed accidentally the positive association of DM with HCC. The authors observed that, in Western Europe, the incidence rate of primary liver cancers was increased, and deduced that this increase might in part be associated

with the induction of hepatic microsomal enzyme caused by long-term usage of some drugs. On the basis of this assumption, the authors designed and performed an observational case-control study, which included 105 patients with HCC and long-term drug use, and 105 age and sex-matched patients with colorectal tumors and with fractures of femur<sup>[24]</sup>. Surprisingly, the results demonstrated that compared to the control group, the HCC group patients had four-fold excess of diabetic cases, and this association was independent of those pre-existing diseases, for example viral hepatitis, alcoholic cirrhosis and haemochromatosis<sup>[24]</sup>. The relationship between DM and HCC was proposed clearly although some limitations could not be avoided.

Following the publication of this study, only a few researches attempted to elucidate the association of diabetes with HCC in the next more than ten years; however, over the past more than one decade, more and more researches have been designed and performed to address this relationship<sup>[21,25-27]</sup>. Earlier epidemiologic studies showed inconsistent findings relating to the association of DM with HCC<sup>[21,28-30]</sup> whereas more and more recent studies have identified DM as an established independent risk factor for HCC, especially two prospectively large-scale population-based cohort studies<sup>[31,32]</sup>. In 2008, a review published in the journal of LANCET ranked diabetes as the fourth risk factor for HCC, following cirrhosis, viral hepatitis B and C, and non-alcoholic steatohepatitis<sup>[17]</sup>.

Of the two prospectively large-scale population-based cohort studies<sup>[31,32]</sup>, one was performed in the Sweden, which used the Swedish In-patient Register and included 153852 patients diagnosed with diabetes during the period between 1965 and 1983<sup>[31]</sup>. The patients were followed up through December 31, 1989. The authors identified those incident cases of cancer using the database and excluded those patients who were diagnosed with liver cancers during the first year of follow-up. The results showed that an increased risk of developing primary liver cancers was found in the diabetic patients (standardized incidence ratio, SIR = 4.1; 95%CI: 3.8-4.5). After exclusion of those concomitant diseases which have been associated with HCC, for example hepatitis, cirrhosis, and alcoholism, the persistence of an approximately threefold excess risk was observed<sup>[31]</sup>.

The conclusion from the Swedish study was supported by another followed cohort study conducted in the United States<sup>[32]</sup>, which was performed by doctors in the Department of Veterans Affairs. In this study, the authors also used the computerized records to identify all the patients with a hospital discharge diagnosis of DM in the period from 1985 to 1990, and matched randomly three patients without DM for every diabetic patient. Follow-up of these patients was taken through December 31, 2000. The major strength of this study was the strict inclusion and exclusion criteria and they were pre-determined perfectly on the basis of our current knowledge. The authors decided and used three periods, including: (1) the period dating back to 1980; (2) the period of index hospitalization; and (3) the period

of the first year of follow-up. During these three above-mentioned periods, those patients with all kinds of liver diseases, abnormal liver function tests, alcoholism, or other identified risk factors for HCC, such as HBV and HCV, had been excluded from the study population<sup>[32]</sup>. The authors concluded that among men with diabetes, the risk of HCC was increased, which was not associated with demographic features, viral hepatitis, cirrhosis, and alcoholic liver disease.

The recently published systematic review in this field was designed to evaluate the impact of DM on the risk of HCC among patients with HCV infection<sup>[33]</sup>. This research included seven articles and all of them were conducted in Asian cohorts, including three studies from Taiwan, China, and four from Japan<sup>[34-40]</sup>. Among these studies, six were observational cohorts and six studies were of good quality. The results showed that a significantly increased risk of HCC was associated with DM in five of these seven studies and the effect sizes ranged from HR = 1.73 (95%CI: 1.30-2.30) to RR = 3.52 (95%CI: 1.29-9.24)<sup>[33]</sup>.

## MOLECULAR PATHOLOGY, MOLECULAR EPIDEMIOLOGY AND MPE IN DIABETES

### *Molecular pathology in diabetes*

Pathology is an important constituent part of diagnostics, modern medicine and causal studies of diseases, which focuses upon four research fields of diseases: Etiology (causes), pathogenesis (mechanisms of development and progression), morphologic alterations (structural changes of cells, tissues and organs), and clinical manifestations (consequences of alterations)<sup>[41,42]</sup>. Molecular pathology (MP), whose focus is the examination of molecular signatures, has some similar aspects of practice to other disciplines, such as anatomic pathology, genetics, biochemistry, proteomics, molecular biology, and clinical pathology. Application of modern MP often encompasses three components: (1) exploration and confirmation of predictive molecular biomarkers for development, progression and treatment of diseases; (2) development of genetic and molecular approaches for diagnosis and classification of human diseases; and (3) susceptibility of individuals of different genetic constitution to particular disorders.

Molecular pathological studies in diabetes provide better insight into the etiology. For example type 1 or insulin-dependent diabetes, at least 20 genes have been identified and the dominant susceptibility locus maps to the major histocompatibility complex<sup>[43,44]</sup>. Major areas of MP research include environmental trigger factors, modification of the beta cells, infiltration of the islets by immuno-inflammatory cells, and autoimmune-mediated destruction of the beta cells. For T2DM, since the early genome-wide association studies (GWAS) in 2007, hundreds of genetic loci have been identified. Elucidating the pathology of DM at the molecular level is very important for developing innovative, personalized, and evidence-based treatments<sup>[45,46]</sup>.

From the viewpoint of MP of DM in cancers, disruption of homeostatic glucose metabolism has been significantly associated with the malignant cellular transformation and tumor progression. In addition, the pathophysiology of disrupted glucose-insulin axis pathways of DM has been understood deeply at the subcellular level, thanks for the recent advances in biochemical and molecular technology. They may be useful for better understanding of the malignant cellular transformation, such as HCC.

### **Molecular epidemiology in diabetes**

In the late 20<sup>th</sup> century, with great advancement of biomedical sciences, a number of molecular signatures or biomarkers were identified as predictors of disease initiation, progression, and response to treatment, including diabetes and tumors. Since the identification of these molecular signatures, molecular epidemiology has evolved and been broadly named, which refers to the branch of epidemiology, where investigators examine these signatures in special study populations and its interaction with environmental, lifestyle or dietary factors, to perform the causal studies of diseases with aetiological factors<sup>[6,10]</sup>. Since the 2000s, GWAS has been commonly performed to identify genetic risk factors for diseases and health conditions<sup>[47,48]</sup>.

Molecular epidemiology in diabetes is focused upon the contribution of possible environmental and genetic risk factors, to the distributions and determinants of DM within families and across populations, at the molecular level. For example, a number of molecular epidemiological studies demonstrate that some growth factors, including insulin, growth hormone, insulin-like growth factors and their binding proteins, may be important in the pathophysiological processes of T2DM<sup>[49]</sup>. In addition, many physiological changes have been associated with T2DM, including insulin resistance and hyperinsulinemia, increased estrogen levels, increased inflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$ , and interleukin (IL)-6, as well as altered levels of circulating adipokines<sup>[50]</sup>. It is well known that some of these molecular signatures and physiological changes may contribute to the development of cancers. Therefore, the relationship between DM and cancers, such as HCC, may be built *via* these molecular signatures or biomarkers.

### **MPE in diabetes**

MPE emerges as an integrated approach of molecular pathology and epidemiology, and investigates the relationship between risk factors, molecular signatures, and development and progression of diseases<sup>[10]</sup>. According to the concept and principle of MPE, the MPE approaches can also be used in non-neoplastic diseases, such as DM<sup>[51]</sup>. Although great advancements have been made in molecular pathology and molecular epidemiology, and a lot of molecular signatures have been associated with DM, no MEP studies in DM have been performed and the reason may be deduced that no identified risk factors are found for DM, such as HBV or HCV for HCC.

However, a few MPE studies had been performed when DM was treated as the risk factor for other diseases, such as cancers and coronary artery lesions, before the proposal and/or use of the concept of MPE, and they were conducted usually under the umbrella of molecular epidemiology. For example, one MPE study was designed to determine the relationship between 8-oxoguanine glycosylase (hOGG1) Ser326Cys gene polymorphism and coronary artery lesions in patients with DM<sup>[52]</sup>. In this study, 323 diabetic patients were included and the results showed that hOGG1 Ser326Cys polymorphism was correlated with coronary artery lesions in patients with DM, and Cys/Cys genotype may be associated with the more severity of lesions<sup>[52]</sup>.

## **MOLECULAR PATHOLOGY, MOLECULAR EPIDEMIOLOGY AND MPE IN HCC**

### **Molecular pathology in HCC**

For human cancers, including CRC and HCC<sup>[53-55]</sup>, molecular pathology is commonly used in the diagnosis and classification. Traditional molecular pathology studies are focused upon the molecular characteristics in cancer cells to improve our understanding of tumor cell behavior and carcinogenic processes<sup>[1,6,10]</sup>. However, human cancers are complex multifactorial diseases. Recent studies suggest that cancers should be classified based on salient clinical and pathologic features as well as on molecular fingerprints, which has been named "molecular classification", because of the premise that tumors with similar characteristics share common pathogenic mechanisms and progression patterns, despite each tumor undergoing its own unique neoplastic transformation<sup>[5,6,56]</sup>. Molecular classification is helpful to better understand the pathogenesis of tumors, predict the development and progression of each tumor, and for personalized cancer medicine, optimize the preventive and treatment strategies<sup>[5,6,56]</sup>. For cancer molecular classification, informative biomarkers are needed to be identified to stratify tumors or patients<sup>[57-62]</sup>.

Examples of well-established informative biomarkers include ESR1 (ER- $\alpha$ ), PGR and ERBB2 (HER2) expression in breast cancer<sup>[63-65]</sup>, EGFR mutations in lung cancer<sup>[66,67]</sup>, MSI in colorectal cancer<sup>[68-70]</sup>, TMPRSS2-ERG translocation in prostate cancer<sup>[71]</sup>, and TP53, PIK3CA, BRAF and KRAS mutations, and CpG island methylation in multiple cancers<sup>[72-74]</sup>. Some molecular changes or biomarkers in HCC have also been previously identified. Ojanguren *et al*<sup>[75]</sup> showed that the positive expression of mutant p53 was related to alcohol abuse (42%) and HBV infection (21%). Park *et al*<sup>[76]</sup> found that TNF and IL-6 signaling was correlated with obesity-associated HCC development. In the obese patients, insulin and insulin-like growth factors, TNF- $\alpha$ , IL-1 and IL-6, leptin, adipokines, adiponectin, and plasminogen activator inhibitor-1 are significantly associated with the occurrence and development of some cancers, including HCC<sup>[77]</sup>.

### **Molecular epidemiology in HCC**

HCC is also very complex, for example it occurs in about

1%-7% of cirrhotic patients annually, whereas most of the cirrhotic patients do not progress to HCC during their lifetimes<sup>[78]</sup>. Molecular biomarkers are expected to satisfy this need and resolve the question at the molecular level. To date, molecular epidemiology studies show that a number of molecular risk factors of HCC have been identified, such as numerous genetic polymorphisms reported as host genetic factors<sup>[79]</sup>. Most of HCC-associated single-nucleotide polymorphisms are identified in genes involved in biological pathways, including oxidative stress (GSTT1, GSTM1), cell cycle (MDM2), immune response (IL10, TNF), DNA damage repair (XPC), growth signaling (EGF), and iron metabolism (HFE) in viral hepatitis- or alcohol-related HCC<sup>[80-84]</sup>. Recent GWAS identifies the DEPDC5 locus as the risk loci in viral hepatitis-related HCC<sup>[85]</sup>.

Molecular factors associated with etiological agents, for example HBV and HCV could also influence the risk of HCC. It is well known that a high level of serum HBV DNA is indicative of increased risk of HCC. Some studies have demonstrated that HBV genotype is related to the HCC risk<sup>[86]</sup>. Genomics technology has revealed that HCC should be regarded as a heterogeneous group of diseases, not one single disease entity, because each sub-group HCC has different sets of epigenetic and genetic alterations<sup>[87]</sup>. The heterogeneous molecular features of HCC tumors are associated with the biological behavior, clinical outcome and prognosis<sup>[87-91]</sup>. Molecular classification is recommended to HCC, and previous studies have identified subsets of HCC tumors characterized by TP53 and CTNNB1 activation mutations, progenitor cell-like features, Met activation, Myc activation, and transforming growth factor- $\beta$  activation<sup>[92-94]</sup>. These molecular risk factors of HCC would play important roles in the design and implementation of MPE studies.

### MPE in HCC

Epidemiological studies have showed that DM is an established independent risk factor for HCC<sup>[12,20-23]</sup>; however, how DM affects the development and progression of HCC has not been explained clearly. MPE approaches and studies may be helpful to improve our understanding of the molecular mechanisms of carcinogenesis of HCC. MPE can be used to investigate the relationship between DM and risk of HCC by molecular subtypes. A few MPE studies have been performed for this question, although they were usually under the umbrella of molecular epidemiology. They would be described in the next section in detail. MPE can provide some useful insights for the pathological processes of DM in HCC, although a few challenges must be overcome.

### MPE IN DM AND RISK OF HCC

Currently, based on our knowledge, very few MPE researches are available for DM and risk of HCC<sup>[95-97]</sup>. For these studies, the original design are not for MPE, and the term of "molecular pathological epidemiology" have

not appeared in their articles, but they can be treated as MPE researches, according to the objectives and methods.

One MPE research which was performed in the Japan was designed to determine the relationship between PNPLA3 and JAZF1, and risk of HCC, in patients with non-viral hepatitis and type 2 DM<sup>[95]</sup>. The objective of this research was to identify genetic determinants associated with T2DM patients who have a high risk of developing HCC by genotyping T2DM susceptibility loci and PNPLA3. This study included 389 T2DM patients, including 59 patients with HCC (DM-HCC) and 330 patients without HCC (DM-non-HCC). Those patients who followed these criteria were included: (1) history of T2DM > 10 years; (2) alcohol intake < 60 g/d; and (3) negative for anti-HCV Ab and HBs-Ag. The authors found that the SNP rs738409 located in PNPLA3 was the greatest risk factor associated with HCC in these diabetic patients. Compared to DM-non-HCC patients, DM-HCC patients had the significantly higher frequency of the PNPLA3 G allele (OR = 2.53,  $P = 1.05 \times 10^{-5}$ ). Moreover, among the 115 DM patients homozygous for the PNPLA3 G allele, HCC patients had the significantly higher frequency of the JAZF1 rs864745 G allele (OR = 3.44,  $P = 0.0002$ )<sup>[95]</sup>. They concluded that PNPLA3 and JAZF1 were associated with an increased risk of developing HCC among T2DM patients without viral hepatitis<sup>[95]</sup>.

Another study was designed to evaluate the cytokinome profile, including the serum levels of growth factors, chemokines, cytokines, as well as of other diabetes and cancer biomarkers, in a cohort of patients, including 17 patients with T2DM, 20 patients with chronic hepatitis C infection, 34 patients with HCC, 10 patients with T2DM-HCC, and 20 healthy controls<sup>[96]</sup>. The results demonstrated that: (1) T2DM-HCC patients had the higher levels of IL-2R, sIL-6Ra, IL-16, IL-18, HGF,  $\beta$ -NGF, CXCL1, CXCL12, ADIPOQ, and IFN- $\alpha$  than those with T2DM or HCC; (2) T2DM-HCC patients had the lower level of LEP than those with T2DM or HCC; (3) T2DM-HCC and only HCC patients had the similar levels of CXCL9, PECAM-1, Prolactin, glucagon, sVEGFR-1 and sVEGFR-2; (4) T2DM-HCC patients had the higher levels of CXCL9, PECAM-1, Prolactin, and glucagon than those with only T2DM; and (5) T2DM-HCC patients had the lower levels of sVEGFR-1 and sVEGFR-2 than those with only T2DM<sup>[96]</sup>. The major limitation of this study was the very limited number of included patients; however, these molecular changes could be used to design and perform the MPE researches in DM and risk of HCC in future.

Some molecular pathology researches can also be regarded as MPE studies, for example one study which was conducted in the Second Military Medical University, Shanghai, China<sup>[97]</sup>. The objectives of this study were to determine the effect of p-Ser9-GSK-3 $\beta$  (glycogen synthase kinase-3 $\beta$ ) on the prognosis in HCC patients and to explore the interaction between GSK-3 $\beta$ , T2DM and prognosis of HCC. This research included 178 HCC patients after curative partial hepatectomy and showed that expression of P-Ser9-GSK-3 $\beta$  was significantly

higher in tumor tissues than that in their normal counterparts<sup>[97]</sup>. Moreover, the authors also found that: (1) over-expression of p-Ser9-GSK-3 $\beta$  was associated with T2DM; (2) T2DM and over-expression of p-Ser9-GSK-3 $\beta$  were closely related with each other; and (3) these two variables were independently associated with poor prognosis of HCC<sup>[97]</sup>. Therefore, p-Ser9-GSK-3 $\beta$  may be regarded as the mediator between T2DM and HCC.

One case report which was published in 2015 was also considered to be related to this field<sup>[98]</sup>. This report describes a 23-year-old woman with HCC and type 2 DM; and results of histological and immunohistochemical examination showed that this HCC arose in the background of hepatocyte nuclear factor-1 $\alpha$  mutated hepatocellular adenomas (H-HCA). However, traditionally, we consider that H-HCA have no minimal malignant potential. For the molecular changes and tumor biomarkers of HCC, the authors found that by immunohistochemical tests, CD34 expression in sinusoidal endothelial cells and expression of glutamine synthetase in tumor cells were increased, whereas exon 3 of CTNNB1 and TERT promoter mutations, and nuclear expression of  $\beta$ -catenin were absent in this patients with HCC and DM. Although such cases are rare, they reinforce the potential of H-HCA for HCC, which may be related to DM<sup>[98]</sup>.

Considering that DM is an independent risk factor for HCC, some efforts have been focused on understanding of the molecular mechanisms of DM in the development and progression of HCC, which may be useful for the design and implementation of MPE studies. For example, one mini-review focused on the impact of TNF- $\alpha$  and IL-6 along with epigenetic regulations<sup>[99]</sup>. Two approaches are suggested as followed: (1) the first is about the role of TNF- $\alpha$  and IL-6 as inflammatory mediators, from the point of role of apoptosis and inflammation in HCC; and apoptotic regulators can be used for this purpose, such as Bax (bcl-2-like protein 4 encoded by the BAX gene) and Bcl-2 (B-cell lymphoma 2 protein encoded by *BCL2* gene); and (2) the second is about the possible epigenomic reprogramming, from the point of role of epigenetic modification of DNA in HCC. According to these two approaches, apoptotic and inflammatory markers (Bcl2 and Bax), and DNA methylation, hypomethylation or histone modifications can be used as the candidate molecular biomarkers for the understanding of role of DM in HCC<sup>[99]</sup>.

Another review focused on the influence of insulin resistance and hyperinsulinemia of DM in the pathogenesis of hepatocarcinogenesis, and the author summarized that some molecular pathways were involved, for example phosphatase and tensin homolog/P13K/Akt and MAPK kinase<sup>[100]</sup>. It is well known that different anti-diabetic medications have different influences on the risk of HCC in diabetic patients<sup>[23,100]</sup>. Metformin has been associated with the decreased risk of HCC in patients diagnosed with DM<sup>[23]</sup>. The molecular mechanism is deduced that metformin can activate 5-adenosine monophosphate-activated protein kinase (AMPK) and decrease the expression of protein Livin<sup>[100]</sup>. AMPK can inhibit its downstream target mammalian target of rapamycin, and

then inhibit the growth of human cancer cell lines. Livin has been involved in both cell proliferation and survival. Thiazolidinediones seem to inhibit peroxisome proliferator-activated receptor gamma-independent regulation of nucleophosmin and prevent tumor formation<sup>[100]</sup>.

Although these studies are not enough for understanding of molecular mechanisms of DM in the increased risk of HCC, they and the involved molecular biomarkers can be very useful for future MPE researches. I hope that more and more MPE researches are performed exploring the molecular mechanisms as well as novel biomarkers.

## CONCLUSION

DM is an established independent risk factor for HCC; however, how DM affects the occurrence and development of HCC remains as yet unclearly understood. "MPE" is the branch of epidemiology and pathology, and its basis is the molecular classification of tumors. MPE is a multidisciplinary, interdisciplinary and transdisciplinary study field, and molecular pathology plays a central role in this relatively new field. In MPE, investigators examine the relationship between tumor molecular signatures, endogenous and exogenous factors, and development, progression and prognosis of tumors. I believe that this research field can be very helpful to improve our understanding of the pathogenesis, molecular mechanisms, diagnosis, personalized prevention and treatment for DM and risk of HCC in future.

### Abstract

The intestinal microbiome (IM) is altered in patients with cirrhosis, and emerging literature suggests that this impacts on the development of complications. The PubMed database was searched from January 2000 to May 2015 for studies and review articles on the composition, pathophysiologic effects and therapeutic modulation of the IM in cirrhosis. The following combination of relevant text words and MeSH terms were used, namely intestinal microbiome, microbiota, or dysbiosis, and cirrhosis, encephalopathy, spontaneous bacterial peritonitis, hepatorenal syndrome, variceal bleeding, hepatopulmonary syndrome, portopulmonary hypertension and hepatocellular carcinoma. The search results were evaluated for pertinence to the subject of IM and cirrhosis, as well as for quality of study design. The IM in cirrhosis is characterized by a decreased proportion of *Bacteroides* and *Lactobacilli*, and an increased proportion of *Enterobacteriaceae* compared to healthy controls. Except for alcoholic cirrhosis, the composition of the IM in cirrhosis is not affected by the etiology of the liver disease. The percentage of *Enterobacteriaceae* increases with worsening liver disease severity and decompensation and is associated with bacteremia, spontaneous bacterial peritonitis and hepatic encephalopathy. Lactulose, rifaximin and Lactobacillus-containing probiotics have been shown to partially reverse the cirrhosis associated enteric dysbiosis, in conjunction with improvement in encephalopathy. The IM is altered in cirrhosis, and this may contribute to the development of complications associated with end-stage liver disease. Therapies such as lactulose, rifaximin and probiotics may, at least partially, reverse the cirrhosis-associated changes in the IM. This, in turn, may prevent or alleviate the severity of complications.

**Key words:** Encephalopathy; Intestinal microbiome; Cirrhosis

**Core tip:** There has recently been an increasing understanding of the importance of the intestinal microbiome (IM) in the physiology of cirrhosis and its complications. Novel sequencing techniques have enabled a better characterization of the bacteria in the IM of patients with cirrhosis, and how this differs from the microbiome in a healthy individual. Additionally, therapeutics for enteric dysbiosis in patients with cirrhosis have been studied, and have shown promise in reducing the morbidity of complications in cirrhosis. In this review, we will critically review the literature on characterization of the IM in cirrhosis, its role in complications, and the evidence for strategies to address enteric dysbiosis.

## INTRODUCTION

Emerging literature has demonstrated that the intestinal microbiome (IM) plays an important role in health and disease. The intestine of a healthy adult harbors 100 trillion intestinal bacteria, and at least 500 different species have been identified with novel molecular biology techniques that allow for sequencing of whole genomes of the IM<sup>[1,2]</sup>. The healthy adult IM consists principally of *Bacteroides* and *Firmicutes*, which together comprise over 90% of the bacteria present in the colon<sup>[3]</sup>. The *Bacteroides* are Gram-negative, anaerobic, non-spore-forming bacteria, and especially produce carbohydrate-degrading enzymes, whereas the *Firmicutes* are Gram-positive, anaerobic, spore-forming bacteria, that ferment simple sugars leading to the production of short-chain fatty acids such as butyrate, acetate and propionate<sup>[4]</sup>. The concentrations of bacteria progressively increase from the proximal to the distal digestive tract, from a maximum of 10<sup>3</sup> bacteria/mL in the stomach to 10<sup>12</sup> bacteria/mL in the colon<sup>[5]</sup>. The IM has various functions that affect biochemical, metabolic and physiologic processes both within the intestine and elsewhere in the body<sup>[6]</sup>. These physiologic functions include the digestion of nutrients, with bacterial disaccharidases transforming unabsorbed dietary sugars to short chain fatty acids (SCFA)<sup>[7]</sup>. These SCFA can be used as a source of energy by the human body, as they are absorbed through the colon. In addition, butyrate and acetate can be a source of fuel for the enterocytes<sup>[8]</sup>, affect lipid metabolism<sup>[9]</sup>, and have anti-inflammatory effects<sup>[10]</sup>. Intestinal bacteria

can also produce vitamins such as folate and vitamin K<sup>[11,12]</sup>, which are absorbed into the bloodstream<sup>[12]</sup>. Additionally, the presence of the physiologic IM within the intestinal milieu prevents colonization by pathogenic bacteria and decreases intestinal permeability<sup>[8]</sup>. Crosstalk between bacteria and enterocytes *via* binding sites and Toll-like receptors help distinguish commensal from pathogenic bacteria<sup>[13]</sup>. The microbiota then generate an immune response to pathogenic bacteria, and enable oral tolerance by preventing a reaction to dietary protein antigens. Many endogenous bacteria can produce bacteriocins that hinder replication of pathogenic bacterial species<sup>[14]</sup>. Additionally, commensal microbiota have been shown to promote regulatory T cell function<sup>[15]</sup> and maturation of natural killer T cells<sup>[16]</sup>. Finally, many medications including digoxin, opiates, hormones and various antibiotics are transformed into their active forms through intestinal bacterial metabolism. Bacterial deconjugation of glucuronide, sulfate and cysteine conjugates decreases the polarity of drugs, and enables enterohepatic circulation, reabsorption, and prolonged retention<sup>[17]</sup>. One prime example of a compound whose bacterial metabolism is essential to its activity is sulfasalazine, which is broken down into 5-aminosalicylic acid and sulfapyridine<sup>[18]</sup>. Additionally, the effects of anticancer immunotherapy can be modulated by the intestinal microbiota. The antitumor effects of CTLA4 blockade were shown to be dependent on specific *Bacteroides* species<sup>[19]</sup>.

Bacterial growth and functions may be affected by several physiologic and anatomic conditions in the GI tract such as peristalsis (may inhibit mucosal attachment of ingested bacteria), the presence of gastric acid and bile (toxic effects), the presence of proteolytic enzymes (degradation of bacteria), the intestinal mucus layer (trapping of bacteria), the ileocecal valve preventing retrograde bacterial translocation<sup>[20,21]</sup>, and secretory IgA inhibiting bacterial proliferation<sup>[22]</sup>. Changes in small intestinal and colonic motility, gastric acid secretion, bile flow/composition, and the intestinal innate immune response can impact bacterial composition and lead to overgrowth<sup>[23]</sup>. In addition, external factors such as diet<sup>[24]</sup>, antibiotic use<sup>[25]</sup> and other environmental factors<sup>[26]</sup> affect IM composition.

IM composition can also be affected by disease states and vice versa, as shown in various types of autoimmune, metabolic and malignant conditions including colon and gynecologic cancers<sup>[3,27-30]</sup>. Intestinal microbial dysbiosis, with both qualitative and quantitative changes in bacterial species, has also been associated with the development of obesity<sup>[31]</sup>, diabetes<sup>[32]</sup>, metabolic syndrome<sup>[33]</sup> and inflammatory bowel disease<sup>[34]</sup>. In relation to liver disease, recent studies have reported differences in the IM associated with non-alcoholic fatty liver disease (NAFLD)<sup>[35,36]</sup>, alcoholic liver disease<sup>[37]</sup> and liver cancer<sup>[38]</sup>. The IM composition in cirrhosis has been shown to be associated with the development of complications, particularly spontaneous bacterial peritonitis and encephalopathy. The goal of this review is to highlight the unique composition of the IM in cirrhosis,

**Table 1** Characterization of Intestinal microbiota across spectrum of liver disease severity

Patient population	Changes in IM
Healthy patients	Comprised principally of <i>Bacteroides</i> and <i>Firmicutes</i> (over 90% of IM) <sup>[3]</sup>
Compensated cirrhosis	Higher <i>Enterobacteriaceae</i> , <i>Staphylococcaeae</i> , and <i>Enterococcaceae</i> <sup>[53,55,56]</sup> Decreased <i>Lachnospiraceae</i> , <i>Ruminococcaceae</i> , <i>Clostridiales</i> XIV, <i>Bacteroides</i> , <i>Faecalibacterium prausnitzii</i> and <i>Coprococcus comes</i> <sup>[45,53,55,56]</sup>
Alcoholic cirrhosis	Higher <i>Enterobacteriaceae</i> and endotoxemia compared to other cirrhosis <sup>[46]</sup>
Decompensated cirrhosis	<i>Enterobacteriaceae</i> species correlated with increasing MELD score, <i>Ruminococcaceae</i> species associated with lower MELD scores <sup>[56]</sup>
Overt hepatic encephalopathy	Higher <i>Enterobacteriaceae</i> <sup>[57]</sup>
Hepatorenal syndrome	No established data
Hepatocellular carcinoma	No established data
Therapeutic strategies and effects on IM	
Lactulose	No RCT or prospective studies of microbiome Decreased urea-producing <i>Klebsiella</i> and <i>Proteus</i> species, increased non-urease-producing lactobacilli <sup>[70]</sup>
Rifaximin	Improved cognitive function due to change in microbiome-metabolome correlation networks, particularly <i>Enterobacteriaceae</i>
Probiotics	Decreased risk of endotoxemia, TNF- $\alpha$ <sup>[74]</sup>
Fecal microbiota transplantation	Enteric dysbiosis reduced, relatively decreased proportion of <i>Enterobacteriaceae</i> and <i>Porphyromonadaceae</i> <sup>[74,75]</sup> Case report data <sup>[76]</sup> Resolution of hepatic encephalopathy with healthy IM transfer, however IM not characterized

MELD: Model for end stage liver disease; IM: Intestinal microbiome; RCT: Randomized controlled trial; TNF: Tumor necrosis factor.

its underlying pathophysiology, and its association with clinical manifestations and complications of cirrhosis. Additionally, we will review therapeutic strategies in cirrhosis aimed at restoring a healthy microbiome and at reducing complications.

## RESEARCH AND LITERATURE

The PubMed database was searched from 2000 to May 2015 for studies on the causes, outcomes and modulation of the IM in cirrhosis. The following combination of relevant text words and MeSH terms were used: "IM", microbiome, microbiota, or dysbiosis, and cirrhosis, encephalopathy, spontaneous bacterial peritonitis, hepatorenal syndrome, variceal bleeding, hepatopulmonary syndrome, portopulmonary hypertension and Hepatocellular carcinoma (HCC). Our search included both original and review articles as well as letters to the editor. We (Mamatha Bhat and Venkat Bhat) obtained 369 abstracts, manually searching the abstracts for pertinence to the subject of IM and cirrhosis. This resulted in 46 entries that provided information on the etiology, pathophysiology, characterization of the IM, and management of enteric dysbiosis in cirrhosis. Table 1 summarizes the results of our systematic review.

## ENTERIC DYSBIOSIS IN LIVER DISEASE

Emerging literature suggests that the IM is not only altered in liver disease of various etiologies, but that this dysbiosis may play an etiopathogenetic role. For example, dysbiosis may contribute to NAFLD<sup>[35,39]</sup> by contributing to enhanced hepatic fat accumulation<sup>[39]</sup>. In a cross-sectional study, patients with non-alcoholic steatohepatitis (NASH) had a significantly lower percentage of *Bacteroides* in their stool<sup>[35]</sup> compared to patients with simple steatosis and healthy controls, although a cause-effect relationship

could not be established. Mechanisms engendered by microbial genes, such as an increase in appetite signaling, energy extraction from the diet, and expression of lipogenic genes likely contribute to enhanced hepatic fat accumulation<sup>[31,40]</sup>. In addition, hepatic inflammation and fibrosis in patients with NASH are thought to occur due to bacterial translocation of intestine-derived microbial products (including endotoxin) and activation of Toll-like receptor (TLR) signaling<sup>[41,42]</sup>. This results in stimulation of hepatic stellate cell activity, with subsequent liver fibrogenesis<sup>[43]</sup>. The role of bacterial lipopolysaccharide (endotoxin) in fibrogenesis has been confirmed in mouse models, where TLR4 knockout significantly decreased expression of markers for liver fibrosis such as collagen,  $\alpha$ -smooth muscle actin, procollagen-I, transforming growth factor- $\beta$ 1 and matrix metalloproteinase-2<sup>[44]</sup>. It is thought that enteric dysbiosis in the context of liver disease of any etiology contributes through the above mechanism to liver disease progression.

## CHARACTERIZATION OF IM IN CIRRHOSIS

### Evidence of bacterial overgrowth in cirrhosis

Patients with cirrhosis have both qualitative and quantitative changes in their gut microbiota<sup>[45-47]</sup>. Small intestinal bacterial overgrowth, defined as  $>10^5$  CFU/mL and/or the presence of colonic bacteria in upper jejunal aspirate, is present in 48% to 73% of cirrhotic patients<sup>[48,49]</sup>. Impaired small intestinal motility<sup>[50]</sup>, decreased bile flow<sup>[51]</sup>, and dysregulated secretion of immunoglobulin A<sup>[51]</sup> and antimicrobial molecules<sup>[52]</sup> all contribute to small intestinal bacterial overgrowth in patients with cirrhosis (Figure 1).

### IM composition in cirrhosis

In addition to this increased bacterial burden, taxonomic

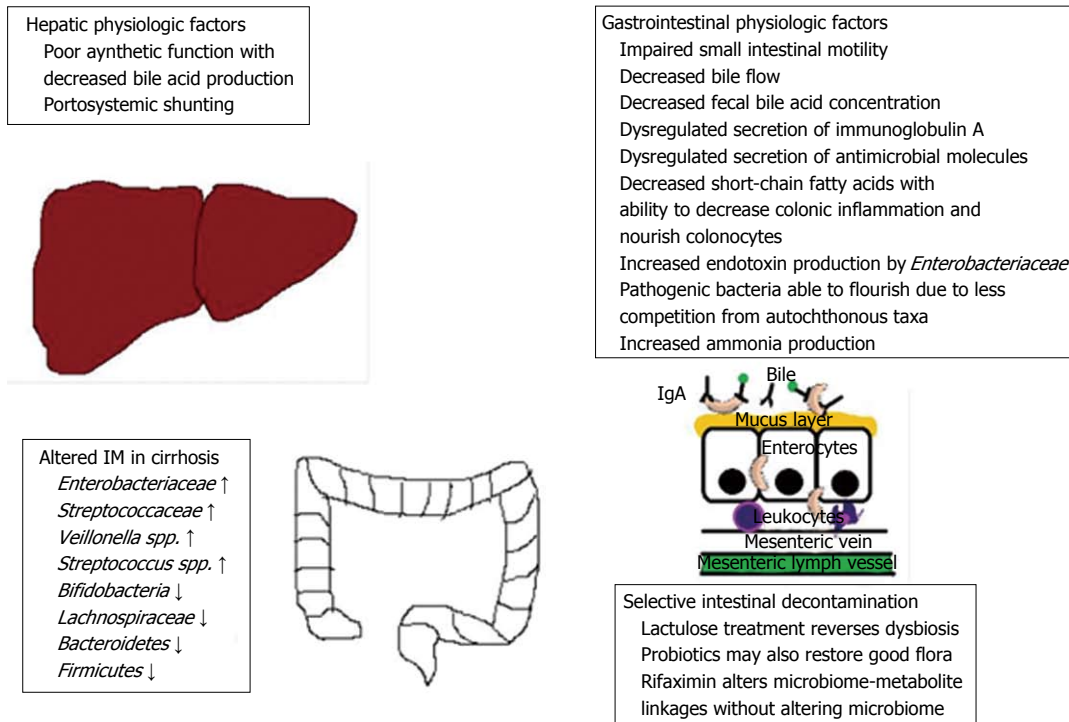

Figure 1 Factors influencing intestinal microbiome composition in cirrhosis. IM: Intestinal microbiome.

differences in the fecal microbial communities have been demonstrated<sup>[51,53-56]</sup>. Patients with cirrhosis commonly have decreased proportions of beneficial, autochthonous taxa, such as *Lachnospiraceae*, *Ruminococcaceae* and *Clostridiales* XIV. There is a relative overgrowth of potentially pathogenic bacteria such as *Enterobacteriaceae*, *Staphylococcaceae*, and *Enterococcaceae*, whose abundance correlates with disease progression and endotoxemia<sup>[53,55,56]</sup>. A recent study comparing the microbiome in cirrhosis vs healthy controls revealed that the beneficial *Bacteroides* genus was significantly decreased in patients with cirrhosis<sup>[24]</sup>. Additional bacterial species that enrich the health and diversity of the microbiome, such as *Faecalibacterium prausnitzii* (anti-inflammatory properties) and *Coprococcus comes* (butyrate production) were found to occupy a relatively lower proportion of the microbiome in cirrhosis<sup>[41]</sup>. Most studies have shown that the etiology of cirrhosis does not affect taxonomic composition, with similar fecal microbial communities across the spectrum of liver disease etiologies<sup>[51,57]</sup>. Recently however, the pattern of dysbiosis has been reported to be slightly different in alcoholic cirrhosis, with higher *Enterobacteriaceae* and a higher proportion of patients with endotoxemia compared to cirrhotic patients of non-alcoholic etiologies. This held true after adjusting for severity of disease (MELD score) and abstinence<sup>[42]</sup>.

#### Mechanisms associated with dysbiosis in cirrhosis

The beneficial, autochthonous taxa of the IM generate SCFA that sustain colonocytes and decrease inflammation, in addition to anti-bacterial peptides that help prevent colonization by pathogenic taxa and reinforce the intestinal barrier<sup>[58]</sup>. The decreased presence of

certain benign bacteria is thought to be due to decreased bile acid production in cirrhosis. This environment allows pathogenic bacteria to thrive and outgrow the "beneficial" species<sup>[6]</sup>. The combination of a decreased, "leaky" intestinal barrier with increased endotoxin production by pathogenic taxa such as the *Enterobacteriaceae* can lead to endotoxemia<sup>[41]</sup>.

#### IM and severity of cirrhosis

The IM composition appears to vary with the severity of cirrhosis and the presence of complications. The increased presence of the *Streptococcaceae* taxon has been correlated with worsening Child-Pugh score, whereas the *Lachnospiraceae* taxon was associated with less severe disease<sup>[53]</sup>. However, the Child-Pugh score includes hepatic encephalopathy as a component, and encephalopathy itself is associated with a distinct IM as described further below. Later studies of the IM in cirrhotics have therefore employed the MELD score, in order to allow for simple correlation of the IM with severity of liver dysfunction. *Enterobacteriaceae* species have been reported to be associated with higher MELD scores, whereas the *Ruminococcaceae* species have been associated with lower MELD scores<sup>[56]</sup>. A study of the IM in patients with advanced liver disease revealed that decreased abundance of *Bifidobacterium* and increased abundance of *Enterococcus* were associated with increasing liver dysfunction<sup>[59]</sup>. The term "cirrhosis dysbiosis ratio" was coined to describe the ratio of autochthonous taxa (taxa that are benign and usually present in the gut such as *Ruminococcaceae*, *Lachnospiraceae*, and *Clostridiales*) to non-autochthonous ones (*Enterobacteriaceae* and *Bacteroidaceae*). This ratio was highest

among healthy individuals as expected, and decreased with worsening MELD score and degree of hepatic decompensation<sup>[57]</sup>. Those with compensated cirrhosis had a cirrhosis-dysbiosis ratio of 0.89, whereas those with decompensated cirrhosis had a ratio of 0.66, and patients hospitalized for cirrhosis related complications had a ratio of 0.32 ( $P < 0.0001$ ). An increase in the relative abundance of pathogenic bacteria was associated with the development of complications such as hepatic encephalopathy. Liver disease stability over months was associated with a stable cirrhosis-dysbiosis ratio<sup>[57]</sup>.

Interestingly, salivary dysbiosis is concomitantly present with enteric dysbiosis, with a relative increased abundance of *Enterobacteriaceae* and decrease in autochthonous species<sup>[60]</sup>. Dysbiosis of the salivary microbiome was particularly pronounced in patients requiring 90-d liver-related hospitalizations. Thus, the salivary microbiome may serve as a substitute for the IM, and would be an easier sample to obtain.

Patients with cirrhosis show changes in both serum and fecal bile acids, which results from decreased liver synthetic function, altered enterohepatic circulation and altered IM composition. Overgrowth of *Enterobacteriaceae* leads to impaired conversion of primary to secondary bile acids<sup>[61]</sup>. This results in a decreased ratio of secondary to primary bile acids, along with a reduced overall fecal bile acid concentration, which correlate with increasing severity of liver disease. These findings are accompanied by a concomitant increase in serum bile acids<sup>[61]</sup>.

## IMPACT OF MICROBIOME ON COMPLICATIONS OF CIRRHOSIS

### IM and sepsis

Complications of end-stage liver disease, such as spontaneous bacterial peritonitis and hepatic encephalopathy, have been linked to pathological bacterial translocation. The translocation of bacteria or their products (such as muramyl-dipeptides, lipopolysaccharides (endotoxin), peptidoglycans and bacterial DNA) from the intestine to the mesenteric lymph nodes is a normal physiological process that bolsters host immunity<sup>[62]</sup>. Pathological bacterial translocation occurs due to an increase in the rate or degree of translocation. This is the case in cirrhosis, given the leaky intestinal barrier and relatively immunodeficient state<sup>[49]</sup>. The bacteria causing SBP are mostly gram-negative bacilli such as *Escherichia coli* and other members of the *Enterobacteriaceae* family (*Proteus*, *Klebsiella* and *Enterobacter*), which are present in higher abundance in the gut microbiota of cirrhotic patients<sup>[51,53,55,56]</sup>. Migration of these bacteria to the peritoneal cavity or systemic circulation results in peritonitis and bacteremia, respectively. Pathological bacterial translocation triggers inflammation and the hyperdynamic circulation of cirrhosis that contributes to portal hypertension. These in turn result in serious systemic infections with up to 38% mortality<sup>[6,63]</sup>. Therefore, translocation of bacteria from an altered IM represents an important determinant of

mortality in cirrhotic patients.

### IM and hepatic encephalopathy

The IM contributes to development of hepatic encephalopathy through ammoniogenesis and an endotoxin-driven inflammatory response. Additional compounds produced by the microbiota, such as mercaptans, phenols, short- and medium-chain fatty acids and benzodiazepine-like compounds, potentially contribute as well<sup>[2]</sup>. In a metagenomic study of the microbiome in cirrhosis, Qin *et al.*<sup>[64]</sup> performed in-depth assessment of functions of the microbiome enriched in liver cirrhosis. In cirrhosis, bacterial genes involved in the assimilation or dissimilation of nitrate to or from ammonia, denitrification, gamma-aminobutyric acid biosynthesis, and amino acid transport were highly represented<sup>[64]</sup>. Additionally, manganese-related transport system modules were enriched in the IM of patients with cirrhosis<sup>[64]</sup>. This may be associated with manganese accumulation within the basal ganglia of cirrhotic patients, which is thought to contribute to hepatic encephalopathy<sup>[65]</sup>. A patient discrimination index was developed based on a group of 15 bacterial species, and it was highly accurate as a biomarker for cirrhosis. In addition to the enteric dysbiosis described above, altered intestinal permeability results in translocation of bacteria and their products, which has an important effect on the progression of cirrhosis<sup>[66]</sup>.

### IM and hepatocellular carcinoma

HCC is another complication of cirrhosis whose development may be influenced by the altered IM in the cirrhotic patient<sup>[67]</sup>, although there is no concrete evidence as yet. It is well known that chronic inflammation can foster the initiation and progression of malignancies. Translocation of intestinal bacteria can lead to hepatic inflammation, with release of key inflammatory mediators such as NF- $\kappa$ B and TLR4. Downregulation of the NF- $\kappa$ B signaling pathway *in vivo* (by ablating the protein that activates this transcription factor) was shown to sequentially induce NAFLD, fibrosis and finally HCC<sup>[68]</sup>. TLR4 and the IM contributed to tumor progression in an HCC mouse model, and have therefore been proposed as chemopreventive targets<sup>[69]</sup>. This study suggests that the IM may have adverse effects on hepatic stellate cell function, activating the release of inflammatory mediators that promote HCC development.

## MODULATION OF IM IN CIRRHOSIS

### Lactulose

The longstanding practice of treating hepatic encephalopathy with lactulose not only decreases ammonia absorption, but also results in modulation of the IM with decreased ammonia production<sup>[70]</sup>. Lactulose acidifies the colonic pH, which renders the environment hostile to the urease-producing *Klebsiella* and *Proteus* species. Conversely, the intestinal lumen becomes friendlier to non-urease-producing lactobacilli and bifidobacteria.

The end-result of these changes in the microbiome is decreased ammonia production<sup>[71]</sup>.

### Antibiotics

Antibiotics such as neomycin, metronidazole and ciprofloxacin have been used in the past to treat hepatic encephalopathy, although the IM was never characterized in this context. More recently, rifaximin has been offered to patients with lactulose-resistant hepatic encephalopathy. In a prospective, open-label study, 20 cirrhotic patients with minimal hepatic encephalopathy were treated with rifaximin 550 mg twice daily for 8 wk<sup>[72]</sup>. The IM, serum metabolome, and cognitive function were assessed before and after rifaximin treatment in all 20 patients. Although a significant improvement in cognitive function and endotoxemia was seen, the composition of the IM was not distinctly different. Rather, there was a shift from pathogenic to beneficial metabolite linkages around pathogenic bacterial species (*Enterobacteriaceae* and *Porphyromonadaceae*). Therefore, although the IM composition itself was not altered, the metabolic profile produced by the pathogenic species was more beneficial. On the other hand, the correlation networks around the autochthonous bacteria (looking at the interactions between the microbiome and metabolome) remained the same. This study therefore illustrated how rifaximin could alter intestinal microbial linkages with metabolites, without any significant effect on microbial composition or abundance *per se*<sup>[72]</sup>.

### Probiotics

The effect of probiotic therapy on the IM in cirrhotic patients has also been studied<sup>[73]</sup>. One appealing benefit of probiotics is their excellent safety profile. A phase I, 8-wk, randomized controlled trial of the probiotic *Lactobacillus* GG in 30 patients with minimal hepatic encephalopathy revealed that it was safe and well-tolerated, while decreasing the risk of endotoxemia and lowering TNF- $\alpha$  in the serum, plasma and liver<sup>[74]</sup>. Enteric dysbiosis was reduced, with a relatively decreased proportion of *Enterobacteriaceae* and *Porphyromonadaceae* (both associated with worse disease in cirrhosis). Conversely, the abundance of autochthonous species like *Lachnospiraceae*, *Ruminococcaceae*, and *Clostridiales* XIV increased. There was no change in the *Lactobacillaceae* abundance, and it was hypothesized that this species either promoted colonization by beneficial microbiota or enhanced intestinal epithelial function and the immune system, thereby displacing pathogens<sup>[74]</sup>. Additionally, changes in metabolites related to amino acid, vitamin and secondary bile acid were found. Cognition however was not improved, although this trial was a phase I study without the statistical power to determine this outcome<sup>[72,74]</sup>.

A second randomized, double-blind, placebo-controlled trial of VSL#3 daily for 6 mo assessed the probiotic's efficacy in preventing recurrent encephalopathy, reducing severity of liver disease and reducing hospitalizations<sup>[75]</sup>. There was a tendency towards decreased episodes of

recurrent encephalopathy (primary outcome), with 34.8% in the probiotic group vs 51.6% in the placebo group ( $P = 0.12$ ). In addition, there was a significantly reduced risk of hospitalization, as well as improved Child-Pugh and MELD scores with daily use of VSL#3.

### Fecal microbiota transplantation

This is a potentially interesting approach to addressing enteric dysbiosis, although the only evidence to date is a single case report where healthy gut microbiota transfer was used to treat hepatic encephalopathy<sup>[76]</sup>. This was recently described in a case report of a patient with Grade 1-2 encephalopathy not responsive to lactulose, and unable to afford rifaximin. Fecal microbiota from a healthy stool donor was transplanted into the patient by colonoscopy and by retention enemas weekly over a 5-wk period. The patient's alertness, as well as his performance on measures of encephalopathy (inhibitory control test and Stroop test) significantly improved and normalized. This case demonstrates that fecal microbiota transplantation is a plausible strategy in treating mild encephalopathy by correcting enteric dysbiosis, although further larger-scale studies are required.

In summary, the IM is significantly altered in cirrhosis, with a decrease in beneficial, autochthonous bacterial species such as *Bacteroides*, and an increase in pathogenic bacteria such as the *Enterobacteriaceae*. Except for alcoholic liver disease, IM composition appears to be similar across etiologies of hepatic cirrhosis. The dysregulated IM likely is associated with and may contribute to the development of complications of end-stage liver disease, including hyperdynamic circulation, portal hypertension, bacteremia, spontaneous bacterial peritonitis, and encephalopathy. The role of the IM in the development of hepatorenal syndrome and HCC is suspected, but not yet elucidated. Treatment with lactulose, antibiotics, and probiotics may be effective in preventing or improving these complications by targeting the enteric dysbiosis.

## Abstract

### AIM

To investigate the independent effects of 6-mo of dietary energy restriction or exercise training on whole-body and hepatic fat oxidation of patients with non-alcoholic fatty liver disease (NAFLD).

### METHODS

Participants were randomised into either circuit exercise training (EX;  $n = 13$ ; 3 h/wk without changes in dietary habits), or dietary energy restriction (ER) without changes in structured physical activity (ER;  $n = 8$ ). Respiratory quotient (RQ) and whole-body fat oxidation rates (Fat<sub>ox</sub>) were determined by indirect calorimetry under basal, insulin-stimulated and exercise conditions. Severity of disease and steatosis was determined by liver histology; hepatic Fat<sub>ox</sub> was estimated from plasma  $\beta$ -hydroxybutyrate concentrations; cardiorespiratory fitness was expressed as  $\dot{V}O_{2peak}$ . Complete-case analysis was performed (EX:  $n = 10$ ; ER:  $n = 6$ ).

### RESULTS

Hepatic steatosis and NAFLD activity score decreased with ER but not with EX.  $\beta$ -hydroxybutyrate concentrations increased significantly in response to ER ( $0.08 \pm 0.02$  mmol/L *vs*  $0.12 \pm 0.04$  mmol/L,  $P = 0.03$ ) but remained unchanged in response to EX ( $0.10 \pm 0.03$  mmol/L *vs*  $0.11 \pm 0.07$  mmol/L,  $P = 0.39$ ). Basal RQ decreased ( $P = 0.05$ ) in response to EX, while this change was not significant after ER ( $P = 0.38$ ).  $\dot{V}O_{2peak}$  ( $P < 0.001$ ) and maximal Fat<sub>ox</sub> during aerobic exercise ( $P = 0.03$ ) improved with EX but not with ER ( $P > 0.05$ ). The increase in  $\beta$ -hydroxybutyrate concentrations was correlated with the reduction in hepatic steatosis ( $r = -0.56$ ,  $P = 0.04$ ).

### CONCLUSION

ER and EX lead to specific benefits on fat metabolism of patients with NAFLD. Increased hepatic Fat<sub>ox</sub> in response to ER could be one mechanism through which the ER group achieved reduction in steatosis.

**Core tip:** We investigated hepatic fat oxidation and whole-body substrate oxidation under basal, insulin-stimulated and exercise conditions before and after 6 mo of circuit exercise training (EX) or dietary energy restriction (ER) in patients with non-alcoholic fatty liver disease. ER increased  $\beta$ -hydroxybutyrate concentrations (a marker of hepatic fat oxidation) and reduced severity of steatosis, but did not change substrate oxidation rates during acute exercise. EX improved substrate oxidation under basal, insulin-stimulated and exercise conditions, but not  $\beta$ -hydroxybutyrate concentrations and severity of disease. Increase in  $\beta$ -hydroxybutyrate was associated with decrease in hepatic steatosis and this could be one

mechanism through which the ER group achieved reduction in steatosis.

## INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is the most prevalent liver disease in industrialised countries and its prevalence is increasing globally<sup>[1]</sup>. The term NAFLD describes a range of liver damage ranging from simple steatosis to non-alcoholic steatohepatitis (NASH) and cirrhosis that occur in the absence of hazardous alcohol consumption. NAFLD is linked with obesity, visceral adiposity, physical inactivity, insulin resistance<sup>[2]</sup>, and genetic predisposition<sup>[3]</sup>. Intrahepatic triglycerides (TGs) (steatosis) accumulate when the sum of *de novo* hepatic fatty acid synthesis rate and hepatic fatty acid uptake rate is greater than those of TG export and hepatic fat oxidation<sup>[4]</sup>. In a recent cross-sectional study we have shown that overweight patients with NAFLD do not adequately adapt fuel oxidation to fuel availability, with reduced fat oxidation rates (Fat<sub>ox</sub>) in resting and fasting conditions, a reduced suppression of Fat<sub>ox</sub> after insulin stimulation and a lower increase in Fat<sub>ox</sub> during exercise compared to lean controls<sup>[5]</sup>. Further, we observed that patients with NAFLD had reduced hepatic Fat<sub>ox</sub>, as measured by plasma  $\beta$ -hydroxybutyrate, when compared to lean controls.

Lifestyle interventions consisting of diet (improved diet quality with or without energy restriction) or diet in conjunction with exercise training are currently the most commonly advocated therapies for NAFLD management<sup>[6-8]</sup>. Limited research has assessed the effect of a lifestyle intervention in NAFLD on whole-body Fat<sub>ox</sub>. Hallsworth *et al*<sup>[9]</sup> showed that 8 wk of resistance training without weight loss did not change substrate oxidation rates in the basal state (resting and fasting) but increased Fat<sub>ox</sub> during aerobic exercise. However, substrate oxidation during exercise was assessed at a single intensity and at the same absolute intensity pre and post intervention (50% of the pre-intervention  $\dot{V}O_{2peak}$ ). Therefore, assessment of maximal rate of Fat<sub>ox</sub> (MFO) and the intensity at which it occurs (Fat<sub>max</sub>) was not possible, and participants likely were assessed at a lower relative intensity post-intervention (due to improved  $\dot{V}O_{2peak}$ ). Gaining a deeper understanding of substrate metabolism during exercise is of interest because the full body metabolic demands are higher and potential alterations not observable at rest may become apparent.

The effect of different treatment options for NAFLD on

hepatic Fat<sub>ox</sub> is also unclear. In response to dietary energy restriction (ER), little information is available. A study in which 18 patients with NAFLD underwent 2 wk of dietary ER reported increased plasma  $\beta$ -hydroxybutyrate concentrations (indicating increased hepatic Fat<sub>ox</sub>), and this was correlated with reduction in steatosis<sup>[10]</sup>. This is in agreement with findings in animal models showing that an increase in hepatic Fat<sub>ox</sub> leads to a reduction in hepatic steatosis<sup>[11,12]</sup>. However, whether a similar response is seen in response to a longer dietary intervention, with the assessment being performed in energy balance (as opposed to energy deficit), needs to be established. Furthermore, the effect of an exercise training program on plasma  $\beta$ -hydroxybutyrate concentrations is unknown<sup>[13]</sup>. Understanding the independent effect of energy restriction and exercise training on whole-body Fat<sub>ox</sub> and hepatic Fat<sub>ox</sub> in patients with NAFLD can contribute to elucidate how these interventions impact on the disease and could lead to more specific guidelines for NAFLD management.

Improvement in cardiorespiratory fitness (CRF) is a key endpoint in exercise training interventions. Cross-sectional evidence shows that lower levels of physical activity and CRF correlate with more severe hepatic injury on histology and greater steatosis<sup>[14-17]</sup>. However, the relationship between change in CRF measured with a graded exercise test and change in steatosis (measured quantitatively) has not been explored longitudinally in NAFLD<sup>[18,19]</sup>. Investigating the associations between changes in markers of CRF, substrate oxidation, and histological, metabolic and biochemical features of NAFLD in response to exercise can help understand the mechanisms through which exercise may benefit features of NAFLD.

This study aimed to investigate changes in hepatic Fat<sub>ox</sub> and in whole-body substrate oxidation rates under basal, insulin-stimulated and exercise conditions, in patients with NAFLD who completed either 6 mo of dietary energy restriction or circuit exercise training. The second aim was to assess whether changes in CRF, whole-body fat and hepatic Fat<sub>ox</sub> were associated with changes in hepatic steatosis.

## MATERIALS AND METHODS

### Participants

Overweight patients with NAFLD (diagnosed on liver biopsy) participated in the study ( $n = 21$ ). Exclusion criteria included: Type 2 diabetes, cirrhosis, decompensated liver disease, presence of other causes of liver disease, and daily ethanol consumption > 20 g in females or > 40 g in males. The study was approved by the local Human Research Ethics Committees (Princess Alexandra Hospital and University of Queensland, Australia). All participants provided informed written consent. The randomised controlled clinical trial was registered with the Australian and New Zealand Clinical Trials Registry (<http://www.anzctr.org.au>). The registration identification number is ACTRN12612001087842.

### General design

Participants were randomised into either a dietary energy restriction intervention (ER;  $n = 8$ ) or an exercise training intervention (EX;  $n = 13$ ). A consort diagram describing the flow of patients through the randomised controlled trial is presented in Figure 1. Outcome measures were assessed prior to randomisation (pre-intervention) and after 6 mo of intervention. At both time-points participants undertook three testing sessions within a 7-d period. Patients had stable body weight for at least 2 wk before the post intervention testing.

During the first testing session, body composition was assessed by dual-energy X-ray absorptiometry. The second session involved a hyperinsulinaemic-euglycaemic clamp with indirect calorimetry measurements to assess substrate oxidation rates under basal and insulin-stimulated conditions. This session also involved clinical assessments, including blood pressure and anthropometry. During the third testing session, indirect calorimetry measurement was performed during a graded exercise test on an ergocycle to determine substrate oxidation rate and CRF (as measured by  $\dot{V}O_{2peak}$ ). The second and third sessions were conducted in the morning after an overnight fast. Both ER and EX groups were instructed not to change exercise and physical activity patterns throughout the intervention and this was monitored with accelerometers at three time points during the intervention.

The primary outcomes of the trial were hepatic steatosis and IR and have been published elsewhere<sup>[20]</sup>. The present manuscript focuses on secondary outcome measures including plasma  $\beta$ -hydroxybutyrate concentrations, and whole-body Fat<sub>ox</sub> under basal, insulin-stimulated and exercise conditions. The flow of participants for the present analysis is presented in the Consort Diagram in Figure 1. Complete-case analysis, including 10 EX and 6 ER participants, was performed.

### Exercise training intervention

EX, as previously detailed<sup>[20]</sup>, involved 3 sessions per week of circuit exercise training during 6 mo without dietary restriction. The aim was to improve CRF, muscle strength and body composition without significant body weight loss. EX was selected based on preliminary research conducted in our laboratory<sup>[21]</sup>.

Training intensity was fixed at 50% of 1-RM for the entire duration of the training program; 1-RM was reassessed monthly to account for strength adaptations. The training volume was progressively increased from one circuit (12 min) in week 1 to five circuits (60 min) in week 11; and then remained constant at five circuits from week 11 until the end of the intervention. Each circuit comprised 12 light resistance exercises covering the major muscle groups. The training program consisted of alternating 30 s exercise intervals and 30 s rest periods. Pneumatic resistance training machines were employed (Ab Hur Oy, Kokkola, Finland). All training sessions were supervised by an exercise physiologist.

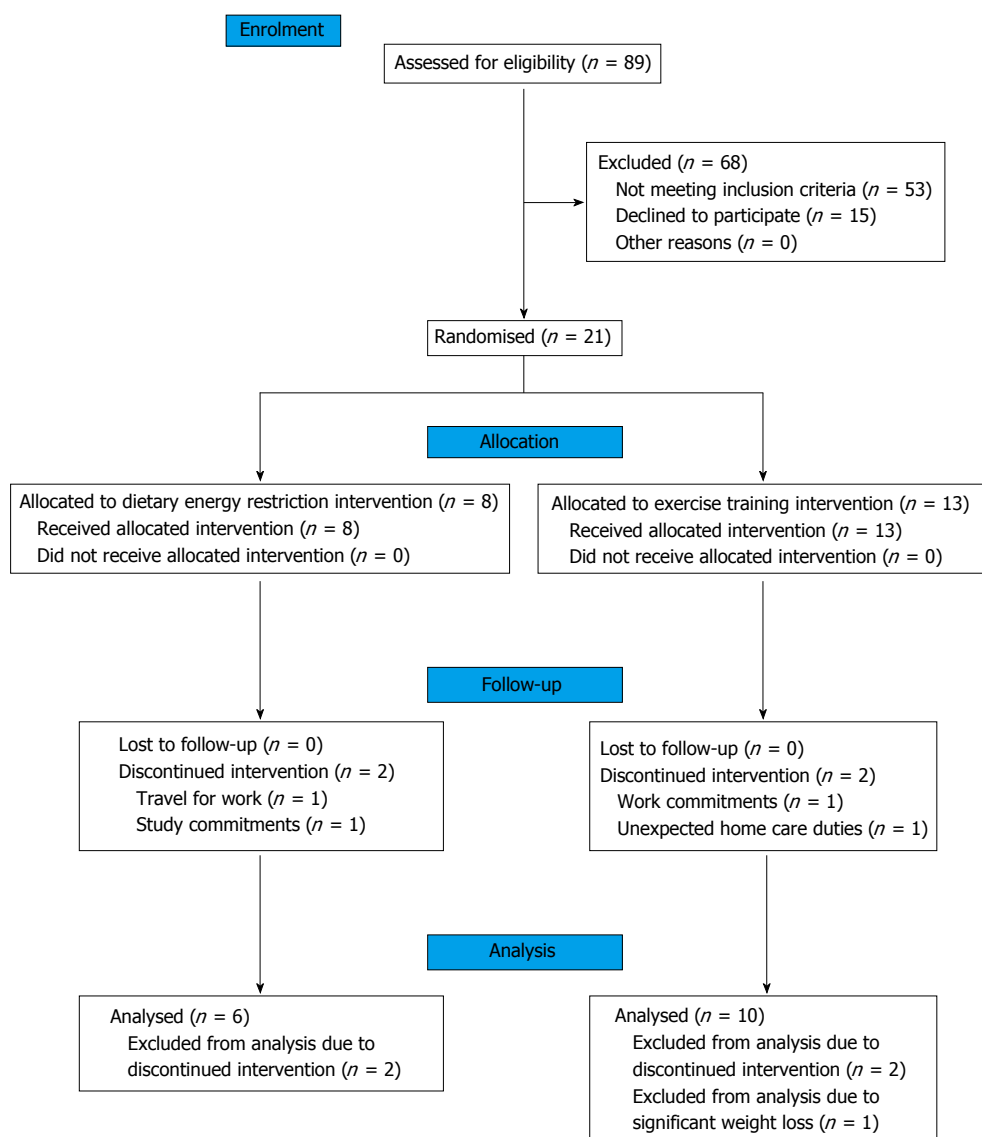

Figure 1 Consort diagram describing the flow of patients through the randomised controlled trial.

### Energy restriction

ER involved a weight loss program under the guidance of a dietitian. Patients attended weekly face-to-face appointments for 16 wk and were provided with an individualised dietary prescription with the aim of 5%-10% of body weight loss within 16 wk. This was followed by an 8-wk period aimed at body weight maintenance, with fortnightly reviews with the dietitian. The target macronutrient composition was 40% carbohydrate, 20% protein and 40% fat (< 10% saturated fat). Recommendations included choosing foods that are low in saturated fats; avoiding micronutrient-poor/energy-dense food options; avoiding added sugar; and aiming for regular meal patterns. Weekly weight and waist measures, and 24-h diet recalls encouraged adherence and self-monitoring.

### Histological analysis of liver biopsy

Liver biopsy specimens were analysed as previously detailed<sup>[5,20]</sup>. The severity of liver injury was determined

with the NAFLD activity score (NAS)<sup>[22]</sup> and the criteria described by Brunt<sup>[23]</sup>. Using conventional histologic criteria<sup>[24]</sup>, a diagnosis of NASH or steatosis alone was made.

### Body composition

Body composition assessments including determination of fat-free mass (FFM) and fat mass by dual-energy X-ray absorptiometry. Subcutaneous abdominal fat and visceral abdominal fat were assessed by computed tomography as previously described<sup>[25]</sup>.

### Insulin sensitivity

Insulin sensitivity was assessed with the hyperinsulinemic-euglycemic clamp technique<sup>[26]</sup>, as we previously detailed<sup>[20]</sup>. Briefly, primed insulin was infused at a rate of 1 mU/kg per minute throughout the procedure (2 h), and a 25% glucose solution was infused at a variable rate to maintain euglycemia<sup>[26]</sup>. The glucose infusion rate in the steady state of the hyperinsulinemic-euglycemic clamp

(M-value) corresponded to the whole-body glucose disposal rate.

### Biochemical analysis

Biochemical analyses were performed as previously described<sup>[5,20]</sup>. Plasma  $\beta$ -hydroxybutyrate concentrations, an index of hepatic ketogenesis<sup>[27-30]</sup>, were measured with an enzymatic assay (Stanbio, Boerne, TX, CV 2.2%).

### Exercise testing

Maximal aerobic power and substrate utilization were assessed with a graded exercise test on an ergocycle. Testing comprised a sub-maximal phase to determine  $\text{Fat}_{\text{ox}}$  and  $\text{CHO}_{\text{ox}}$  at multiple intensities (with workload increments occurring every 5 min), and a maximal phase to assess peak oxygen consumption ( $\dot{V}\text{O}_{2\text{peak}}$ ) (increments every min). The testing protocol adopted has been described in detail in a previous publication<sup>[5]</sup>.

### Indirect calorimetry measurements

Indirect calorimetry measurements (TrueOne 2400 Metabolic Measurement System, Parvo Medics, UT) were conducted in three physiological states (basal, insulin-stimulated and exercise). Whole-body  $\text{Fat}_{\text{ox}}$  and  $\text{CHO}_{\text{ox}}$  were calculated using stoichiometric equations, with the assumption that the urinary nitrogen excretion rate was negligible<sup>[31]</sup>. The methodological approach adopted has been previously described in detail<sup>[5]</sup>.

$\text{Fat}_{\text{ox}}$  rates during exercise were estimated from respiratory gases averaged over the last minute of each exercise stage. Then, the stage at which MFO was achieved was determined, and the corresponding intensity was identified ( $\text{Fat}_{\text{max}}$ )<sup>[32]</sup>.  $\Delta\text{RQ}$  represented the RQ change from basal to hyperinsulinemic state (RQ in the insulin-stimulated condition minus basal RQ).

Testing sessions involving indirect calorimetry measurements were conducted in the morning after a 10-12 h overnight fast and under standardised conditions<sup>[5]</sup>. Standardisation of pre-test conditions was in line with previous studies<sup>[32-40]</sup>.

### Daily physical activity

Daily physical activity was quantified with RT3 accelerometers Activity Monitor, 2003, Stayhealthy, Incorporated, Monrovia, CA, United States) worn for 7 consecutive days at 0, 3 and 6 mo, as previously described<sup>[20]</sup>.

### Statistical analysis

A secondary analysis of outcomes from a larger clinical trial was performed. Independent *t*-tests were used to compare the pre-intervention (baseline) characteristics between groups (ER vs EX). Paired Student *t*-tests were used to compare within group outcome measures pre and post intervention. Wilcoxon matched-pair signed rank test was used if samples were not normally distributed. Correlation analyses were performed using Pearson's correlation coefficient or Spearman's non-parametric rank correlation coefficient. As outlined in the consort dia-

gram (Figure 1), complete-case analysis was performed. Complete-case analysis was deemed more suitable than intention to treat analysis given that the aim of this study was to study mechanisms of benefit of the two interventions. Statistical analysis was performed with SPSS 17.0 (SPSS, Chicago, IL, United States) and Graph Pad Prism 5.0 (GraphPad Software, San Diego, CA, United States). Data are expressed as mean  $\pm$  SD or median and range. For all statistical analyses, the level of significance was set at  $P < 0.05$ . Statistical methods used in this study were reviewed a biostatistician.

## RESULTS

### Characteristics of study groups

Two patients from each arm ( $n = 4$ ) did not complete the study due to time constraints. One participant ( $n = 1$ ) from the EX group was excluded from analysis due to significant weight loss at 6 mo ( $-13.3\%$  body weight, which cannot be achieved with the type and volume of exercise prescribed as part of this exercise intervention). Data analysis (complete-case analysis) was thus performed on 10 participants from the EX and 6 participants from the ER groups (see the Consort Diagram presented in Figure 1). There were no significant differences between pre-intervention patients' characteristics of completers and non-completers. Compliance with both interventions was good. The ER group achieved an average weight loss of  $9.7\% \pm 4.6\%$ , and the EX group attendance to the exercise sessions was greater than 90% with no significant weight loss. As per protocol, usual daily time spent on low, moderate and high intensity physical activity did not change in either group ( $P > 0.05$ ). ER and EX interventions were well tolerated by participants with no adverse events reported.

Characteristics of the EX and ER groups are presented in Table 1. At baseline, the prevalence of NASH was not different between ER and EX groups ( $67\%$  vs  $80\%$ ,  $P = 0.64$ ). Primary results of the randomised controlled trial are reported elsewhere<sup>[20]</sup>. Briefly, in the ER group steatosis and the NAS decreased significantly, while in the EX group neither steatosis nor NAS decreased significantly. Skeletal muscle insulin resistance (M-value) improved significantly in response to EX, while it did not improve in patients from the ER group.

### Substrate oxidation under basal conditions

Total energy expenditure in resting and fasted conditions (basal) did not significantly change in response to both interventions ( $P > 0.05$ ). However, with the EX intervention the relative contribution of fat and CHO to energy expenditure changed: The RQ and the  $\text{CHO}_{\text{ox}}$  decreased (by  $30\%$ ,  $P = 0.02$ ), while  $\text{Fat}_{\text{ox}}$  tended to increase (Table 2). With the ER intervention, the same direction of change as for EX was seen, however statistical significance was not reached. In the whole-group, the pre-post intervention change in basal RQ was not associated with the pre-post intervention changes in steatosis ( $r = 0.05$ ,  $P = 0.88$ ) or

**Table 1** Characteristics of the study groups at baseline (pre-intervention) and after 6 mo of energy restriction or exercise training (post-intervention)

	Energy restriction ( <i>n</i> = 6)		Exercise training ( <i>n</i> = 10)

Complete-case analysis performed. <sup>a</sup>*P* < 0.05, within group difference in response to the intervention; <sup>b</sup>*P* value < 0.10, within group trend in response to the intervention. Pre-intervention there was no difference between energy restriction and exercise groups in any of the parameters presented (*P* > 0.05). M:F: Male: Female; BMI: Body mass index; HDL: High density lipoprotein; LDL: Low density lipoprotein; VLDL: Very low density lipoprotein; hsCRP: High sensitivity C reactive protein.

NAS (*P* = 0.35).

### β-hydroxybutyrate concentrations

As shown in Figure 2, basal plasma β-hydroxybutyrate concentrations, increased significantly in response to ER (0.08 ± 0.02 mmol/L vs 0.12 ± 0.04 mmol/L, *P* = 0.03) but remained unchanged in response to EX (0.10 ± 0.03 mmol/L vs 0.11 ± 0.07 mmol/L, *P* = 0.39). This result (unchanged β-hydroxybutyrate concentrations in response to EX) was confirmed also when the analysis was performed excluding the outlier (0.09 ± 0.03 mmol/L vs 0.09 ± 0.03 mmol/L, *P* = 0.87) (Figure 2). In the combined cohort including participants from both groups, there was a negative association between pre-post intervention changes in β-hydroxybutyrate and in hepatic steatosis (*r* = -0.56, *P* = 0.04) (Figure 3). This relationship persisted after controlling for changes in body weight (*r* = -0.67, *P* = 0.02) and percentage body weight (*r* = -0.56, *P* = 0.05).

### Substrate oxidation under insulin-stimulated conditions

Hyperinsulinaemic concentrations were reached by both groups at both times points (ER, 79.0 ± 31.5 mU/L vs 80.0 ± 21.5 mU/L; EX, 83.0 ± 0.5 mU/L vs 78.1 ± 18.0 mU/L; all *P* > 0.05). The effect of the two interventions on substrate oxidation in insulin-stimulated conditions is presented in Table 3. Post-intervention, the EX group tended to increase the insulin-stimulated suppression of Fat<sub>ox</sub> compared with pre-intervention (-0.24 ± 0.36 mg/kgFFM per minute vs -0.55 ± 0.35 mg/kgFFM per

minute, *P* = 0.06). The ER group displayed a similar response, however statistical significance was not reached. In the pooled group, the pre-post intervention increase in ΔRQ (change in RQ from the basal to the insulin-stimulated state) was not correlated with the change in the severity of steatosis (*r* = 0.28, *P* = 0.28) or NAS (*P* = 0.31).

### Substrate oxidation during exercise

VO<sub>2peak</sub> and MFO improved significantly (by 18% and 71%, respectively) in response to EX but did not change in the ER group (Table 4 and Figure 4). Fat<sub>max</sub> increased by 72% in response to EX when expressed in absolute terms (45 ± 20 vs 76 ± 46 Watts, *P* = 0.03), whereas it remained unchanged after both interventions when expressed in relative terms (%VO<sub>2peak</sub>). Within the EX group, the increase in VO<sub>2peak</sub> (mL/kgFFM per minute) was correlated with the increase in ΔRQ (*r* = 0.73, *P* = 0.02) and the reduction in systolic blood pressure (*r* = -0.81, *P* = 0.01). The improvement in VO<sub>2peak</sub> was not related with the change in steatosis (*r* = 0.14, *P* = 0.73), NAS (*P* = 0.40) or basal RQ (*r* = -0.18, *P* = 0.62). Similarly, the change in MFO was not related to changes in hepatic steatosis (*r* = 0.03, *P* = 0.91), or changes in NAS (*P* = 0.63).

## DISCUSSION

ER and EX are standard interventions for the management of obesity and related comorbidities, including NAFLD. ER

induced weight loss, reduced hepatic steatosis, increased β-hydroxybutyrate concentrations (a marker of hepatic Fat<sub>ox</sub>) but did not lead to changes in substrate oxidation rates tested during an acute exercise session. EX lead to improvements in CRF and in substrate oxidation rates under basal, insulin stimulated and exercise conditions. However, this dose of circuit exercise did not lead to improvements in hepatic Fat<sub>ox</sub> or hepatic steatosis. In the combined cohort, the reduction in hepatic steatosis was associated with increased β-hydroxybutyrate concentrations.

A novel finding from this study was that ER and EX interventions had different effects on β-hydroxybutyrate concentrations in patients with NAFLD. In response to ER, the increase in β-hydroxybutyrate (product of the oxidation pathway) was accompanied by the trend for a decrease in the very low-density lipoprotein (product of the esterification pathway), despite no change in free fatty acids concentrations. These are favourable changes given that pre-intervention patients with NAFLD showed lower β-hydroxybutyrate and higher very low-density lipoprotein compared to healthy controls<sup>[5]</sup>. These changes may suggest that the ER intervention lead to

a change in hepatic fatty acid partitioning, with free fatty acids being more directed towards oxidation than towards esterification<sup>[41]</sup>. Increase in hepatic Fat<sub>ox</sub> could be a mechanism through which the ER group achieved reduction in steatosis. Accordingly, it was shown in animal models that interventions that increase hepatic Fat<sub>ox</sub> lead to a reduction in hepatic steatosis<sup>[11,12]</sup>.

In contrast, β-hydroxybutyrate concentrations remained unaltered in response to EX. This observation is valuable because, as highlighted in a recent review, no information is available on the chronic effects of exercise training on β-hydroxybutyrate concentrations<sup>[13]</sup>. Results from the present study do not confirm findings from rodent models, which showed that chronic exercise training increased hepatic Fat<sub>ox</sub><sup>[42]</sup> and that the shift from an active to a sedentary lifestyle reduced hepatic Fat<sub>ox</sub><sup>[43]</sup>. Future studies assessing the effects of different training prescriptions (volume, intensity, frequency, duration) and the optimal type of exercise (aerobic vs circuit vs resistance) on hepatic lipid metabolism are warranted. Inclusion of genetic and molecular parameters in future investigations might provide insights on the mechanisms responsible for the inter-individual variability observed in

**Figure 2** Basal  $\beta$ -hydroxybutyrate concentrations before and after 6 mo of energy restriction ( $n = 6$ ) or exercise training ( $n = 10$ ). A: Average responses; B: Individual responses. <sup>a</sup> $P < 0.05$  between pre and post treatment.

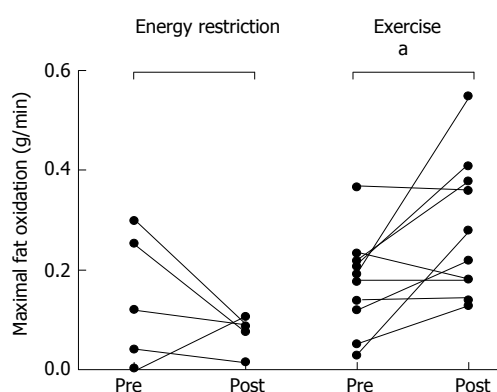

response to the treatments.

The effect of the two interventions on MFO was different: It markedly increased in response to EX, while it remained unchanged in response to ER. The improvement in MFO in the exercise group could be attributable to increased mitochondrial content, increased oxidative capacity and improved transport of free fatty acids across muscle and mitochondrial membranes<sup>[44-47]</sup>. Such changes likely were not achieved in response to ER<sup>[48]</sup>. To our knowledge, this was the first study comparing the effect of two types of lifestyle intervention (*i.e.*, ER and EX) on MFO in patients with NAFLD. It was also the first study to assess  $Fat_{max}$  and MFO in response to circuit exercise training. The improvement observed in MFO was consistent with previous studies conducted in other populations: Higher whole-body  $Fat_{ox}$  during exercise was observed in response to a moderate intensity aerobic training program conducted in obese males<sup>[49]</sup>, and in response to high-intensity aerobic training<sup>[50]</sup> or resistance exercise training<sup>[51]</sup> programs conducted in healthy individuals. Overall, the improvement in MFO in response to EX and lack of change in response to ER are in agreement with findings from a recent cross-sectional study showing that substrate oxidation rates during exercise are correlated with CRF but not with body weight or percentage body fat<sup>[52]</sup>.

Another observation from the present study was that EX improved whole-body substrate oxidation rates in resting and insulin-stimulated conditions (greater

**Figure 3** Relationship between change in  $\beta$ -hydroxybutyrate concentrations and relative change in hepatic steatosis in response to 6 mo of energy restriction or exercise training ( $n = 13$ ). This relationship remained significant after controlling for changes in body weight ( $r = -0.67$ ,  $P = 0.02$ ).

**Figure 4** Maximal fat oxidation before and after six months of energy restriction ( $n = 6$ ) or exercise training ( $n = 10$ ); individual data. <sup>a</sup> $P < 0.05$  between pre and post intervention.

$Fat_{ox}$  in basal conditions and greater increase in  $CHO_{ox}$  in response to insulin stimulation). The increased basal whole-body  $Fat_{ox}$  observed in response to EX treatment is in agreement with studies conducted in obese patients<sup>[53,54]</sup>. On the other hand, no change was observed by the only other study which investigated whole-body fat oxidation in response to exercise training in NAFLD. The different outcome compared to the present study could be explained by the shorter duration of the intervention (8 wk) and the different baseline characteristics of the study population (less severe NAFLD)<sup>[9]</sup>. In response to ER, there appeared to be a change towards a greater proportion of basal energy expenditure derived from  $Fat_{ox}$ , however statistical significance was not achieved due to the small sample size. These results are in line with other dietary interventions involving high-fat diets with carbohydrate restriction<sup>[55-58]</sup>. Increase in whole-body  $Fat_{ox}$  after treatment is of relevance in this patient population because in a recent cross-sectional study<sup>[5]</sup> we showed that whole-body  $Fat_{ox}$  is reduced in patients with NAFLD compared to healthy controls, and that this alteration was associated with the degree of steatosis.

This study comprehensively investigated the independent effects of ER and EX, the cornerstones of lifestyle treatment, on fat and carbohydrate oxidation assessed in

different physiological conditions including basal, insulin stimulation, and exercise. This forms an ideal framework to study changes in whole-body energy homeostasis and elucidate mechanisms of change in response to a therapy. Assessment of severity of liver disease, insulin resistance and body composition were conducted using gold standard techniques. A further strength was that the EX program was supervised by an exercise physiologist and was the longest exercise training intervention performed in NAFLD to date.

The randomised controlled trial was powered for detecting within group changes in primary outcome measures (hepatic steatosis and M-value), meaning that type 2 error for other outcome measures cannot be excluded. However, this did not interfere with the interpretation of key results of the present manuscript (*i.e.*,  $\beta$ -hydroxybutyrate concentrations and  $\text{Fat}_{\text{ox}}$  during exercise) given that statistically significant differences were still observed. The sample size was relatively small but it was comparable to those from similar studies conducted in NAFLD to date<sup>[9,59]</sup>. Further, a very specific population was studied: Patients were non-diabetic with histologically proven NAFLD and a large proportion (> 75%) of those patients had NASH, which represents an important distinction because patients with NASH are more likely to progress to end stage liver disease<sup>[60]</sup>. Finally, it must be acknowledged that  $\beta$ -hydroxybutyrate concentrations, while being a commonly used marker of hepatic  $\text{Fat}_{\text{ox}}$ <sup>[41]</sup>, do not represent a direct measure of hepatic  $\text{Fat}_{\text{ox}}$ . Future studies assessing the effect of lifestyle intervention in NAFLD on rates of hepatic fatty acid uptake, oxidation, and storage using a newly validated method combining <sup>11</sup>C-palmitate imaging by positron emission tomography with compartmental modelling<sup>[61]</sup>, would be of interest. Studies including assessment of redox metabolism and gene expression are also warranted.

Based on the length of intervention and type of exercise training provided, the findings of this study suggest that exercise training should not be proposed as a sole therapy for NAFLD. Guidelines should remain unchanged to recommend a combination of both ER and exercise training given that these interventions provide complementary benefits. EX is particularly beneficial for improving skeletal muscle fat metabolism and CRF, while ER provided greater benefits on hepatic fat metabolism<sup>[6]</sup>. Future research is required to investigate the impact of different doses and types of exercise programs on the severity of disease as well as on hepatic and whole-body substrate metabolism. Dose and type of exercise are likely to be crucial factors impacting on the clinical benefits of an exercise intervention<sup>[62,63]</sup>. To date, the beneficial effects of exercise training on NAFLD have been mostly seen in response to aerobic training<sup>[59,64-69]</sup> or with an aerobic component<sup>[9]</sup>. It is possible that aerobic exercise training has a greater impact on hepatic steatosis and hepatic  $\text{Fat}_{\text{ox}}$  than other training regimes because during aerobic exercise substrate availability is more closely matched with substrate oxidation and

energy deficit is greater than during other training regimes.

In conclusion, this study showed ER and EX, standard care interventions for NAFLD management, have specific and complementary benefits on fat metabolism. ER induced weight loss, increased  $\beta$ -hydroxybutyrate concentrations in basal condition, reduced severity of steatosis and severity of disease, but did not lead to changes in substrate oxidation rates during an acute exercise session. EX without weight loss, led to improvements in substrate oxidation under basal, insulin-stimulated and exercise conditions. However, this dose of circuit exercise training was not sufficient for improvements in  $\beta$ -hydroxybutyrate and severity of liver disease. Increased hepatic  $\text{Fat}_{\text{ox}}$  in response to ER could be one of the mechanisms through which the ER group achieved reduction in steatosis.

## COMMENTS

### Background

Lifestyle interventions consisting of diet or diet in conjunction with exercise training are currently the most commonly advocated therapies for non-alcoholic fatty liver disease (NAFLD) management. Limited research has assessed the effect of a lifestyle intervention in NAFLD on whole-body and hepatic fat oxidation in NAFLD.

### Research frontiers

Understanding the independent effect of diet and exercise on whole-body and hepatic fat oxidation in patients with NAFLD can contribute to elucidate how these interventions impact on the disease and could lead to more specific guidelines for NAFLD management. Exercise training as a treatment option to reduce the burden of NAFLD is an emerging field of research.

### Innovations and breakthroughs

This study showed diet and exercise, standard care interventions for NAFLD management, have specific and complementary benefits on fat metabolism. Dietary energy restriction provided greater hepatic benefits, while exercise training provided greater peripheral (whole-body) improvements.

### Applications

Based on the length of intervention and type of exercise program provided (6 mo of circuit exercise training), the findings of this study suggest that exercise training should not be proposed as a sole therapy for NAFLD. Guidelines should continue to recommend a combination of both diet and exercise given that these interventions provide complementary benefits.

### Terminology

$\beta$ -hydroxybutyrate is a ketone body produced uniquely by the liver, therefore plasma concentrations of  $\beta$ -hydroxybutyrate are used as an index of hepatic fat oxidation or hepatic ketogenesis.

### Peer-review

Authors comment adequately the only problem of this study, which is the short number of individuals who completed the study. Results are interesting and the

study is well conducted.

### Abstract

#### AIM

To evaluate risk of recidivism on a case-by-case basis.

#### METHODS

From our center's liver transplant program, we selected patients with alcoholic liver disease who were listed for transplant based on Ohio Solid Organ Transplantation Consortium (OSOTC) exception criteria. They were considered to have either a low or medium risk of recidivism, and had at least one or three or more months of abstinence, respectively. They were matched based on gender, age, and Model for End-Stage Liver Disease (MELD) score to controls with alcohol-induced cirrhosis from Organ Procurement and Transplant Network data.

#### RESULTS

Thirty six patients with alcoholic liver disease were approved for listing based on OSOTC exception criteria and were matched to 72 controls. Nineteen patients

(53%) with a median [Inter-quartile range (IQR)] MELD score of 24 (13) received transplant and were followed for a median of 3.4 years. They were matched to 38 controls with a median (IQR) MELD score of 25 (9). At one and five years, cumulative survival rates ( $\pm$  standard error) were  $90\% \pm 7\%$  and  $92\% \pm 5\%$  and  $73\% \pm 12\%$  and  $77\% \pm 8\%$  in patients and controls, respectively (Log-rank test,  $P = 0.837$ ). Four (21%) patients resumed drinking by last follow-up visit.

## CONCLUSION

Compared to traditional criteria for assessment of risk of recidivism, a careful selection process with more flexibility to evaluate eligibility on a case-by-case basis can lead to similar survival rates after transplantation.

**Key words:** Alcohol-induced disorders; Alcoholic liver cirrhosis; Mortality; Survival; Liver transplantation

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** For the first time, we report the rates of liver transplant and survival for patients with alcohol-induced cirrhosis who were deemed eligible for liver transplant and listed based on approval under the Ohio Solid Organ Transplantation Consortium medically urgent exception criteria. These criteria allow patients with low to medium risk of recidivism, to receive a liver transplant after only one to three months of abstinence. We showed that transplant rate and short and long term survival after transplant is comparable between these patients and United States general population of patients with alcohol-induced cirrhosis who received liver transplant.

## INTRODUCTION

Cirrhosis due to alcoholic liver disease is an important cause of morbidity and mortality both globally and in the United States. Globally, in 2010 cirrhosis due to alcoholic liver disease led to more than 493000 deaths<sup>[1]</sup>. In United States in 2011 liver cirrhosis was responsible for 34860 deaths, 48% of which were related to alcohol consumption<sup>[2]</sup>. Among patients with cirrhosis due to alcoholic liver disease mortality rates vary based on presence or absence of complications of cirrhosis but it is generally high with a one-year mortality ranging from 17% to 64% and five-year mortalities ranging from 58% to 85%<sup>[3]</sup>.

Liver transplantation imparts great survival benefit

to appropriately selected patients with advanced and de-compensated cirrhosis due to alcohol consumption, which is comparable to survival benefit of transplant in other types of chronic liver disease<sup>[4,5]</sup>. The definition of "appropriately selected patients" in this context remains controversial<sup>[5]</sup>, with the most important factor being minimum duration of abstinence. Conventionally, most liver transplant programs in United States require patients to be abstinent for at least 6 mo and participate in an alcohol rehabilitation program to be considered for transplant<sup>[6,7]</sup>; while it is known that delayed referral for transplant and longer waiting times, even for a few months, will significantly decrease the probability of patient's survival in the pre-transplant period<sup>[8]</sup>. There are data suggesting that careful evaluation of patients for transplant on an individual basis instead of using general and inflexible enrollment rules might lead to favorable outcomes in highly selected patients with alcoholic liver disease<sup>[9,10]</sup>. The state of Ohio Solid Organ Transplantation Consortium (OSOTC) provides such a mechanism for case-by-case evaluation based on clinical guidelines for medically urgent patients with cirrhosis due to alcoholic liver disease. Based on factors such as estimated risk of recidivism, severity of their alcohol use history and previous attempts to remain sober, social support, insight into alcohol use, and willingness of the patient to comply with OSOTC regulations, these patients can be approved as an exception and listed for transplant after only one to three months of abstinence.

The aim of this study was to determine the effect of using OSOTC transplant eligibility criteria on patients' survival compared with conventional criteria for assessment of risk of recidivism, in patient with cirrhosis due to alcoholic liver disease.

## MATERIALS AND METHODS

### Study population and data collection

The study protocol was approved by the Cleveland Clinic Institutional Review Board. Since 2009 we selected patients with alcoholic cirrhosis for consideration of liver transplantation based on OSOTC exception criteria. No donor organs were obtained from executed prisoners or other institutionalized persons. As defined below these are medically urgent patients with low to medium risk of recidivism, who were approved for a medically urgent exception to be transplanted either during the time they were completing alcohol treatment, or some completed treatment after their transplant.

Transplant rates were compared between these patients and matched patients with alcoholic cirrhosis from Organ Procurement and Transplant Network (OPTN) data records who had complete data to calculate their Model for End-Stage Liver Disease (MELD) score<sup>[11,12]</sup> at the time of listing. To compare survival after transplant we used the OPTN patients with alcoholic cirrhosis who had complete data to calculate their MELD score at the time of transplant as well as follow-up data on survival after transplant. Patients from OPTN dataset

**Table 1 Ohio Solid Organ Transplantation Consortium medically urgent except criteria**

Ohio Solid Organ Transplantation Consortium Criteria	
Low-risk	1 mo confirmed abstinence, a signed contract and commitment to begin a rehabilitation program and finish it either before or after transplant No previous failure with substance rehabilitation; never been told that substance was affecting health; and good social support
Medium-risk	Three month confirmed abstinence, a signed contract and commitment to begin a rehabilitation program and/or finish it either before or after transplant One or more failures with rehabilitation; and minimal support system
High-risk	Two or more failures to remain abstinent despite medical complication Refusal to sign contract Minimal to poor social support Must complete standard criteria treatment plan, not eligible for an exception
Other barriers	No insight into their alcohol use consequences No recognition that alcohol caused their liver failure Refusal to start treatment No sober support network

were matched to our patients randomly and according to the following predetermined variables: 10-year age category, gender, and MELD score category same as the case patient's category (< 10, 10-19, 20-29, 30-39,  $\geq 40$ )<sup>[13]</sup>. MELD score was calculated as  $(9.57 \times \log \text{creatinine mg/dL}) + (3.78 \times \log \text{bilirubin mg/dL}) + (11.20 \times \log \text{international normalized ratio}) + 6.43$ . All laboratory values which were less than 1 were set to 1 and serum creatinine for patients with values of more than 4 or on dialysis was set to 4 in order to calculate MELD score. The MELD score was truncated at 40 for patients with a MELD score of more than 40 (<http://optn.transplant.hrsa.gov/resources/MeldPeldCalculator.asp?index=98>).

### OSOTC chemical disorder criteria

OSOTC follows standard criteria for patients in need of liver transplant who are diagnosed with substance use disorder at the time of evaluation (Table 1). This includes patients with alcohol-induced cirrhosis who are diagnosed with alcohol use disorder. The standard criteria includes demonstrating abstinence for at least 12 mo before listing, or at least three months of abstinence plus three months of current participation in an active recovery program and negative random toxicology screens prior to listing confirmed by collateral information (<http://www.osotc.org/resources/chemical-dependency-criteria/>). In addition, patients must show insight into substance use and understanding of the effects of substance use on their health.

OSOTC also provides exception criteria for medically urgent patients who have not been abstinent for 12 mo and are too ill to complete the recovery program participation conditions in the standard criteria. These exception criteria apply to patients with MELD score

of more than 22 (calculated or eligible for exception). According to OSOTC exception criteria, and after signing a contract and showing commitment to rehabilitation, patients at low risk of recidivism - defined as no previous failure with substance rehabilitation, never having been told that substance was affecting health, and good social support - can be listed for transplant after one month of abstinence. Patients at medium risk of recidivism - defined as one or more failures with rehabilitation, and minimal support system - can be listed after a minimum of three months of abstinence, and after signing a contract and showing commitment to rehabilitation. All patients' records are reviewed by OSOTC chemical disorder committee representatives and discussed in a committee conference call, in addition to our liver transplant patient selection committee, in order to decide approval or not of these exception criteria. Patients at high risk for recidivism - defined as two or more failures to remain abstinent despite medical complications, refusal to sign a contract, and minimal or poor social support - do not qualify for OSOTC exception criteria.

### Statistical analysis

All analysis was done with Stata Data Analysis and Statistical Software (version 11.2 SE, StataCrop LP). Variables are reported as number (percentage) or median (IQR). Survival probabilities are reported as percentage  $\pm$  SE. Categorical variables are compared between patients and controls with  $\chi^2$  test. Waiting time was defined as the period from the day an individual is listed for liver transplant to the day the transplant is done. Waiting time was compared between cases and controls with a Cox proportional hazards model containing patient group as the only independent variable to predict waiting time (*i.e.*, time to liver transplant). Follow-up time after transplant was defined as the period from the day an individual receives a liver transplant until death or the last follow-up visit. Data for patients who remained alive by the end of the follow-up period was censored at the time of last follow-up visit. Survival probabilities were estimated with Kaplan-Meier method and were compared between groups with Log-Rank test. All *P*-values are two-sided.

## RESULTS

### Patients' selection

Between 2009 and 2013, 326 patients with alcoholic liver disease were evaluated for liver transplant at the Cleveland Clinic, of whom 279 (85%) patients were considered high-risk for recidivism or alcohol relapse based on the OSOTC criteria (Figure 1). These high-risk patients underwent the standard chemical dependency requirements defined above before being considered eligible for liver transplant. Forty-seven (15%) patients were considered by our social workers and liver transplant committee at the Cleveland Clinic to be at medium or low-risk for recidivism or alcohol relapse based on the OSOTC criteria, but only 36 (13%) patients were approved by the consortium.

**Figure 1** Selection of patients with alcoholic liver disease for liver transplantation based on Ohio Solid Organ Transplantation Consortium Criteria. OSOTC: Ohio Solid Organ Transplantation Consortium.

### Baseline characteristics

Thirty-six patients with alcoholic cirrhosis were approved for liver transplant at the Cleveland Clinic based on OSOTC exception criteria. They were matched based on age, gender, and MELD score category to a random sample of 72 controls from OPTN database with alcohol-induced cirrhosis that underwent liver transplant following conventionally used criteria of alcohol rehabilitation. Table 2 represents the baseline characteristics of patients and control groups. Sixty four percent of patients and controls were male. At the time of listing five patients had a MELD score of 10-19 (14%), 18 had a MELD score of 20-29 (50%), 12 had a MELD score of 30-39 (33%), and one patient (3%) had a MELD score of 40 or more. These were individually matched to controls with the same MELD score category, leading to a median (IQR) MELD score of 27 (11) among patients and 24 (11) among controls (Table 1). At the time of liver transplant one patient had a MELD score of less than 10 (5%), two had MELD scores of 10-19 (11%), 11 had MELD scores of 20-29 (58%), four had MELD scores of 30-39 (21%), and one patient had a MELD score of 40 or more (5%). Again, these patients were individually matched to controls with the same MELD score category leading to a median (IQR) MELD score of 24 (13) among patients and 25 (9) among controls.

### Liver transplantation

Nineteen out of 36 (53%) patients received a liver transplant and 17 dropped off the transplant list. The most common cause of drop-off transplant list was infection and the vast majority of dropped off patients died ( $n = 15$ , 88%). The transplant drop-off rate was not different for controls of whom 41 (57%) received a transplant ( $P$ -value = 0.681). Patients in the OSOTC group received their liver after a median waiting time of 19 d after listing, and

**Table 2** Characteristics of study patients and controls

	Patients	Controls
At listing		
<i>n</i>	36	72
Age, median (IQR)	58 (14)	60 (11)
Male, <i>n</i> (%)	23 (64)	46 (64)
INR, median (IQR)	1.8 (0.6)	1.9 (0.7)
Total Bilirubin, median (IQR)	8.9 (19.3)	5 (7.7)
Creatinine, median (IQR)	2.1 (2.4)	1.5 (2)
Albumin, median (IQR)	3.2 (0.9)	2.9 (1)
MELD, median (IQR)	27 (11)	24 (11)
At transplant		
<i>n</i>	19	38
Age, median (IQR)	56 (17)	55 (13)
Male, <i>n</i> (%)	13 (68)	26 (68)
INR, median (IQR)	1.6 (0.5)	1.9 (0.8)
Total Bilirubin, median (IQR)	8.3 (12.1)	6 (5.7)
Creatinine, median (IQR)	2.6 (2.9)	1.3 (1.3)
Albumin, median (IQR)	2.9 (0.8)	2.8 (1)
MELD, median (IQR)	24 (13)	25 (9)

IQR: Inter-quartile range; INR: International normalized ratio; MELD: Model for end stage liver disease.

controls received their transplant after a median 21 d of waiting time ( $P$ -value = 0.648). Although the majority of both patients and controls received their transplant in less than 2 mo (Table 3), 10% of controls had to wait more than five months while all patients received their transplants before the five months mark.

### Survival outcome and recidivism

Both patients and controls had a median follow-up of more than three years after transplant (Table 3). One year after transplant 90%  $\pm$  7% of patients were alive compared with 92%  $\pm$  5% of controls. At five years, 73%  $\pm$  12% of patients was still alive compared with 77%  $\pm$  8% of controls (Figure 2). Survival rates after transplant did not differ significantly between patients and controls (log rank test,  $P$ -value = 0.837).

Among 19 patients who received their transplant based on OSOTC medically urgent exception criteria, four patients had resumed drinking by last follow-up visit for a 21% relapse rate after a median follow up of 3.4 years.

## DISCUSSION

For the first time, we report the rates of liver transplant and survival for patients with alcohol-induced cirrhosis who were deemed eligible for liver transplant and listed based on approval under the OSOTC medically urgent except criteria. These criteria allow patients with low to medium risk of recidivism, to receive a liver transplant after only one to three months of abstinence. These patients all committed to begin an alcohol treatment program before or during listing and to finish the program, even if it was after their transplant. We showed that transplant rate and short and long term survival after transplant is comparable between these patients and United States general population of patients with alcohol-induced cirrhosis who received their transplant after being eva-

luated for risk of recidivism based on conventionally used criteria. The risk of recidivism in our patients was comparable to previously published rates ranging from 15% to more than 20%<sup>[14-17]</sup>.

Our findings challenge the notion of a defined abstinence period as the only criterion for liver transplant eligibility in patient with alcoholic liver cirrhosis<sup>[18]</sup>. However, the stringency of OSOTC process resulted in our selecting a very small number of patients with alcoholic cirrhosis for liver transplantation. Numerous studies have observed that the enforcement of sobriety period delays listing for transplantation in a significant number of patients with a low probability of alcohol relapse following liver transplant<sup>[17,19-23]</sup>. Indeed, the duration of alcohol abstinence before liver transplant is a poor indicator of relapse of alcoholism following transplantation<sup>[24]</sup>.

Although our results are encouraging, the study has several limitations. The number of patients included in the study was small. Matched controls may not have been comparable to OSOTC patients in terms of family support, intention to remain abstinent from alcohol, or availability of counseling services at transplant center in the event of alcohol relapse. Future studies will benefit from a control group of patients with alcoholic liver disease undergoing liver transplantation that are matched to OSOTC patients on the basis of social and familial support.

In summary, liver transplantation may be an appropriate rescue option for selected patients with alcoholic liver disease after only one to three months of abstinence. Our results show that OSOTC transplant eligibility criteria provide a valid method to identify these patients who may benefit from liver transplantation with low to medium risk of recidivism.

## COMMENTS

### Background

A minimum of 12 mo of abstinence, or three months of abstinence and participation in an alcohol rehabilitation program, are the standard requirements

No. at risk							
Patients	19	17	16	11	7	4	2
Controls	38	30	25	19	15	9	7

**Figure 2** Kaplan–meier estimates of survival after liver transplant in the 19 study patients and the 38 matched controls.

before patients with alcoholic liver disease are eligible for transplantation in Ohio. Some patients are too ill to participate in a rehab program. The Ohio Solid Organ Transplantation Consortium (OSOTC) has a mechanism to evaluate risk of recidivism on a case-by-case basis.

### Research frontiers

Liver transplantation imparts great survival benefit to appropriately selected patients with advanced and de-compensated cirrhosis due to alcohol consumption, which is comparable to survival benefit of transplant in other types of chronic liver disease.

### Innovations and breakthroughs

The aim of this study was to determine the effect of using OSOTC transplant eligibility criteria on patients' survival compared with conventional criteria for assessment of risk of recidivism, in patient with cirrhosis due to alcoholic liver disease.

### Applications

Patients can be approved as an exception and listed for transplant after only one to three months of abstinence.

### Terminology

They were matched based on gender, age, and MELD score to controls with alcohol-induced cirrhosis from Organ Procurement and Transplant Network data.

### Peer-review

The manuscript "Ohio solid organ transplantation consortium criteria for liver transplantation in patients with alcoholic liver disease" by Hajifathalian *et al* is an interesting paper and the important contribution from OSOTC group supporting an update of the Criteria for Liver Transplantation based on alcohol abstinence duration potentially help to obtain the transplant for larger group of patients with a low probability of alcohol relapse.

### Abstract

There is a need to reassess the application of MELD and the impact of renal insufficiency with consideration for developing an algorithm with exception points that would lead to timely allocation of livers to patients with hepatorenal syndrome prior to occurrence of permanent renal damage without jeopardizing post-transplant survival.

**Key words:** MELD; Hepatorenal syndrome; Cirrhosis; Graft survival; Liver allocation

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The decompensation of patients with cirrhosis is associated with the development of hepatorenal syndrome (HRS) and renal insufficiency. There are several consequences of a high serum creatinine level in cirrhotic patients, including increased post-liver transplant mortality and increased risk of non-reversal of renal insufficiency/renal failure. We propose a change to the MELD scoring that would lead to timely liver transplantation in patients with HRS.

Sibulesky L, Leca N, Blosser C, Rahnama-Azar AA, Bhattacharya R, Reyes J. Is MELD score failing patients with liver disease and hepatorenal syndrome? *World J Hepatol* 2016; 8(27): 1155-1156  
Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i27/1155.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i27.1155>

### TO THE EDITOR

The decompensation of patients with cirrhosis is associated with the development of complications. This physiology can lead to renal hypoperfusion which contributes to the development of hepatorenal syndrome (HRS) and renal insufficiency<sup>[1,2]</sup>. It is rare to develop HRS with well-compensated liver disease.

There are several consequences of a high serum creatinine level in cirrhotic patients.

Serum creatinine is one of the most important independent predictors of waitlist and post-liver transplant (LT) mortality. While having the same MELD score, patients with higher serum creatinine level have a significantly higher mortality rate<sup>[3]</sup>. Analysis of the Scientific Registry of Transplant Recipients database linked with Centers for Medicare and Medicaid Services' end-stage renal disease (ESRD) data by Sharma *et al*<sup>[4]</sup> demonstrated that post-LT ESRD is associated with higher post-LT mortality (HR = 3.32;  $P < 0.0001$ ).

Serum creatinine prior to liver transplantation is one of the most significant predictors of post-liver transplantation ESRD<sup>[5]</sup>. Wong *et al*<sup>[6]</sup> recently demonstrated that the only predictor of type 1 HRS non-reversal was the duration of pre-transplant dialysis with a 6% increased risk of non-reversal with each additional day of dialysis. Prolonged ischemic physiology may lead to structural renal damage and thus, prevent renal recovery. This has led many to consider combined liver-kidney transplantation (CLKT) for patients whose HRS has lasted longer than 6 wk because the outcomes for patients who receive CLKT seem to be better than those of patients who receive a liver transplant alone<sup>[7,8]</sup>. Since the introduction of MELD score, the number of patients treated with CLKT has increased markedly<sup>[9]</sup>. Almost 1000 kidneys a year are used in a combined transplantation, thus, diminishing the donor pool for patients on the kidney list.

It has also been shown that patients with renal insufficiency have longer hospital and intensive care unit stays and an increased need for dialysis, which likely increases the cost of transplantation. It likely adds to already increased healthcare costs through additional dialysis cases, and increased hospitalization rates secondary to morbidities associated with ESRD<sup>[10]</sup>.

While MELD score is the gold standard for predicting wait list mortality, a notable weakness for liver allocation lies in predicting post transplantation survival, particularly with renal insufficiency<sup>[11,12]</sup>. In addition to MELD, various scoring systems, including Child Pugh score, the risk, injury, failure, loss, end-stage kidney disease criteria, sequential organ failure assessment (SOFA) score, and the Chronic Liver Failure-SOFA score have been designed to predict outcomes in post liver transplant patients<sup>[13]</sup>. Without a timely liver transplant for patients with acute kidney injury, the patient mortality is shifting from the waitlist to the post-transplant period<sup>[14]</sup>. It is time for a conversation within the transplant community to reassess the application of MELD and the impact of renal insufficiency with consideration for developing an algorithm with exception points that would lead to timely allocation of livers to patients with HRS prior to occurrence of permanent renal damage without jeopardizing post-

transplant survival.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Qiang Li, MD, PhD, Chief Doctor, Director, Professor, Department of Liver Diseases, Jinan Infectious Disease Hospital, Shandong University, Jinan 250021, Shandong Province, China

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### Abstract

Primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC) and autoimmune hepatitis (AIH) constitute the classic autoimmune liver diseases (AILDs). While

AIH target the hepatocytes, in PBC and PSC the targets of the autoimmune attack are the biliary epithelial cells. Persistent liver injury, associated with chronic AILD, leads to un-resolving inflammation, cell proliferation and the deposition of extracellular matrix proteins by hepatic stellate cells and portal myofibroblasts. Liver cirrhosis, and the resultant loss of normal liver function, inevitably ensues. Patients with cirrhosis have higher risks of morbidity and mortality, and that in the decompensated phase, complications of portal hypertension and/or liver dysfunction lead to rapid deterioration. Accurate diagnosis and monitoring of cirrhosis is, therefore of upmost importance. Liver biopsy is currently the gold standard technique, but highly promising non-invasive methodology is under development. Liver transplantation (LT) is an effective therapeutic option for the management of end-stage liver disease secondary to AIH, PBC and PSC. LT is indicated for AILD patients who have progressed to end-stage chronic liver disease or developed intractable symptoms or hepatic malignancy; in addition, LT may also be indicated for patients presenting with acute liver disease due to AIH who do not respond to steroids.

**Key words:** Hepatic fibrosis; Cirrhosis; Myofibroblasts; Primary biliary cirrhosis; Primary sclerosing cholangitis; Autoimmune hepatitis; Liver transplantation

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** In chronic liver disease, including autoimmune liver diseases, perpetual liver injury leads to persistent inflammation, cell proliferation and the deposition of extracellular matrix proteins. If left untreated, this process eventually leads to the development of liver cirrhosis, characterised by the presence of fibrosis and nodular regeneration. Liver biopsy is currently the gold standard technique, but highly promising non-invasive methodology is under development.

## INTRODUCTION

Liver disorders with probable autoimmune aetiology include autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). Each disease complies with, to varying extents, a proposed “multiple hit hypothesis” accounting for autoimmunity development, in which interacting environmental, infectious, genetic, epigenetic and immunological factors account for the loss of tolerance to self-constituents<sup>[1]</sup>. While AIH target the hepatocytes, in PBC and PSC the targets of the autoimmune attack are the biliary epithelial cells. Each of the autoimmune liver diseases (AILDs) is associated with distinct epidemiological and clinical characteristics. However, overlap syndromes, characterised by the coexistence of features of more than one AILD, are increasingly being recognised<sup>[2]</sup>.

## AILDS

### PBC

PBC is a cholestatic autoimmune liver disease characterised by progressive destruction of the small and intermediate-sized bile ducts<sup>[3]</sup>. The histologic picture of PBC involves non-suppurative cholangitis with destruction of the biliary epithelium and portal infiltration of inflammatory cells. PBC also presents with biochemical evidence of cholestasis. PBC has pronounced female preponderance and a strong tendency to present in middle age<sup>[3]</sup>. Epidemiological characteristics of PBC are outlined in Table 1.

High titre positivity for serum anti-mitochondrial autoantibodies (AMAs) is pathognomonic for PBC, being detected in up to 95% of patients<sup>[3-5]</sup>. Moreover, asymptomatic people with AMA-positivity eventually progress to disease development<sup>[6]</sup>. AMAs target lipoylated domains of the 2-oxoacid dehydrogenase complexes, with the immunodominant epitope belonging to the E2 components of the pyruvate dehydrogenase complex<sup>[3,4,7]</sup>. PBC-specific anti-nuclear autoantibodies (ANAs), with a characteristic “multiple nuclear dot” or “nuclear membrane” pattern, are found in 25%-40% of patients<sup>[8]</sup>.

There is mounting evidence that the development of PBC can be accounted for by a proposed “multiple hit” hypothesis for the development of autoimmunity (Figure 1). The molecular mimicry hypothesis postulates that microorganisms with epitopes that are structurally similar to self-components trigger an immune response with interspecies promiscuity. Several potential infectious triggers have been proposed<sup>[9]</sup> including *Escherichia coli*<sup>[10-14]</sup> and *Nosfingobium aromaticivorans*<sup>[15-17]</sup>.

Numerous lines of evidence demonstrate that genetic factors alter susceptibility to PBC development. Female

relatives of patients are at increased risk of developing PBC, and there is a high concordance rate between monozygotic twins<sup>[18]</sup>. Strong genetic associations lying within the MHC, for example HLA-DR8 in Europe and North America, have consistently been reported<sup>[19,20]</sup>. Genome wide association studies (GWAS) have revealed non-MHC gene associations that could be related to abnormal immune activation, including *IL12A*, *IL12RB2*, *STAT-4* and *CTLA-4*<sup>[21-23]</sup>.

Ursodeoxycholic acid (UDCA) is the standard treatment for PBC, improving both biochemical and histological indicators of disease activity and elongating transplant-free survival time in a significant proportion of patients<sup>[24,25]</sup>.

### PSC

PSC is a chronic inflammatory disease of the biliary epithelium, characterised by progressive bile duct destruction. The small, medium and large bile ducts are affected by obliterative concentric fibrosis which leads to the development of biliary strictures<sup>[26]</sup>. In contrast to the other AILDs, PSC affects males more commonly than females<sup>[27]</sup>. The median age of onset is approximately 41 years of age<sup>[27]</sup> (Table 1).

The most common biochemical abnormality in PSC patients is elevated serum alkaline phosphatase (AP)<sup>[28]</sup>. The most reliable diagnostic tool is cholangiography, which enables visualisation of characteristic multifocal strictures within the intra- and extra-hepatic bile ducts<sup>[29]</sup>. Concomitant inflammatory bowel disease (IBD), most frequently ulcerative colitis, is found in up to 80% of patients<sup>[28,30]</sup>.

As with the other AILDs, the aetiology of PSC remains unknown but it is likely to follow the proposed multiple hit hypothesis (Figure 1), resulting from interplay between numerous genetic and environmental factors. The strong link with IBD has led to the emergence of the gut/lymphocyte homing hypothesis, which postulates that memory lymphocytes primed in the gut-associated lymphoid tissue, and therefore expressing the gut-homing integrin  $\alpha 4\beta 7$  and the chemokine receptor CCR9, migrate from the gastrointestinal tract to the liver<sup>[31,32]</sup>. Importantly, the ligand for  $\alpha 4\beta 7$ , MAdCAM-1, and the cognate chemokine for CCR9, CCL25, both usually restricted to the gut<sup>[32,33]</sup>, are aberrantly expressed in the portal vein endothelium and sinusoidal endothelium respectively in PSC patients. Moreover, approximately 20% of liver-infiltrating T cells express  $\alpha 4\beta 7$  and CCR9, and have an effector memory phenotype<sup>[34,35]</sup>. The “leaky gut hypothesis”, on the other hand, involves direct translocation of intestinal flora *via* the portal vein<sup>[28]</sup>. Although direct evidence of this phenomenon is lacking<sup>[36]</sup>, future studies investigating the influence of the gut microbiota on PSC development/progression are warranted.

Similarly to the other AILDs, the strongest PSC genetic associations lie within *HLA* gene. In GWAS, the strongest association signals have been found near *HLA-B*<sup>[37-39]</sup>. There are, however, also believed to be *HLA* class II

**Table 1** Epidemiological characteristics associated with the three autoimmune liver diseases

	PBC	PSC	AIH
Female/male ratio	10/1	1/2	4/1
Average age at presentation	50	41	Childhood/adolescence and approximately 40
Incidence	0.33-5.8/100000	0-1.3/100000	0.08-3/100000
Prevalence	1.91-40.2/100000	0-16.2/100000	11.6-35.9/100000
Risk within family	1 <sup>st</sup> degree relative incidence 4%-6%	Unknown	Unknown
Concordance in monozygotic twins	60%	Only case reports	Only case reports
Note	AMA positivity	Frequent association with IBD Increased risk of hepatobiliary/colorectal malignancies	Positivity for ANA and/or SMA (AIH type-1) or anti-LKM-1 (AIH type-2)

AIH: Autoimmune hepatitis; AMA: Anti-mitochondrial autoantibodies; ANA: Anti-nuclear autoantibody; IBD: Inflammatory bowel disease; LKM: Liver kidney microsomal; PBC: Primary biliary cirrhosis; PSC: Primary sclerosing cholangitis; SMA: Smooth muscle autoantibody.

**Figure 1** “Multiple hit hypothesis” accounting for the development of autoimmune disease. Interplay between immunological, genetic, epigenetic and environmental factors is thought to account for the loss of tolerance to self constituents in AILD. AILD: Autoimmune liver disease.

susceptibility genes contributing to the association signal found within in this region<sup>[38,39]</sup>. Non HLA associations identified by GWAS include *BCL2L1*, which encodes the pro-apoptotic protein *BIM*, *TNFRSF14* and *IL2RA*<sup>[37-39]</sup>.

### AIH

AIH is a progressive inflammatory disease which, in contrast to the two cholestatic AILDs, targets the hepatocytes themselves. AIH has marked female predilection. AIH can present at all ages, but the two peak ages of incidence are in childhood or adolescence and at around 40 years of age<sup>[40]</sup> (Table 1). Trademark biochemical/serological characteristics of AIH are elevated aminotransferase levels, positivity for autoantibodies and increased IgG. A histological picture of interface hepatitis is typical of AIH. Autoantibody positivity is an important clinical feature of AIH, facilitating diagnosis and enabling distinction between two types of the disease. Patients seropositive for ANA and/or anti-smooth muscle autoantibodies (SMA) have AIH type-1 whereas those presenting with positivity for anti-liver kidney type-1 autoantibody (anti-LKM-1) or anti-liver cytosol type-1 (anti-LC-1) have AIH type-2<sup>[41,42]</sup>.

Although AIH aetiology remains to be elucidated, available evidence is strongly suggestive of interplay between genetic and environmental factors (Figure 1).

The observation that the hepatitis C virus shares high sequence homology with the auto-antigenic target of anti-LKM-1 autoantibodies, cytochrome P450-2D6, has led to the suggestion that molecular mimicry could trigger AIH development in a genetically predisposed host<sup>[43,44]</sup>. Other potential triggers for AIH include the hepatitis B virus, cytomegalovirus and the herpes simplex virus<sup>[43]</sup>.

Genetic associations affecting susceptibility to disease development, response to therapy and prognosis have been reported<sup>[45]</sup>. The most significant genetic associations lie within the MHC, at the HLA-DRB1 locus. Susceptibility to AIH type-1 is linked to alleles encoding the HLA-DR3 and DR4 molecules<sup>[46]</sup>, while AIH-2 susceptibility and severity have been linked to alleles encoding the HLA-DR3 and DR7 molecules<sup>[47]</sup>. Susceptibility to AIH has also been linked to polymorphisms in genes located outside the MHC, including *CTLA-4*<sup>[48]</sup>, *TNF-α*<sup>[49]</sup> and *Fas*<sup>[50]</sup>.

With the standard treatment regimen for AIH - prednisolone, with or without the addition of azathioprine - up to 80% of AIH patients are able to reach remission<sup>[51]</sup>.

### Overlap syndromes

It is not uncommon for patients to present with features characteristic of AIH and either PSC or PBC. Because standardised and validated diagnostic criteria are lacking, these “overlap syndromes” remain ill defined. PBC/AIH overlap is present in some 10% of AIH or PBC patients<sup>[52,53]</sup>, and the most commonly used method for diagnosis is the presence of two of the following features of AIH in conjunction with two of the following features of PBC. The AIH features are: (1) ALT at least 5 times the upper limit of normal (ULN); (2) SMA positivity or IgG level of at least 2 times ULN; and (3) liver histology showing moderate or severe periportal or periseptal inflammation. The PBC criteria are: (1) AP at least twice ULN or gamma glutamyl transferase above 5 times ULN; (2) AMA positivity; and (3) bile duct lesions on liver biopsy<sup>[52,54,55]</sup>. AIH/PSC overlap is now believed to represent a significant proportion of patients with AILD<sup>[56,57]</sup>. The characteristics of AIH/PSC overlap are the classical features of AIH-1 - positivity for ANA and/or SMA, high IgG levels and interface hepatitis on biopsy - in addition to biochemical evidence of cholestasis, frequent

**Figure 2 Development of fibrosis and cirrhosis in autoimmune liver disease.** Persistent autoimmune-mediated inflammation and liver cell injury leads to the activation and differentiation of quiescent hepatic stellate cells (HSC) and portal fibroblasts (PF) into activated myofibroblasts. These proliferative, pro-inflammatory and pro-fibrogenic myofibroblasts increase collagen synthesis and deposit extracellular matrix proteins (ECM), leading to the development of fibrous scar tissue. Cirrhosis, characterised by significant fibrosis and nodular regeneration, eventually ensues, with the resultant loss of liver function and eventually liver failure.

occurrence of IBD, histological features consistent with PSC<sup>[58]</sup>. Cholangiographic evidence of intrahepatic or extrahepatic PSC also supports this diagnosis<sup>[59]</sup>.

## FIBROSIS: KEY PLAYERS

In chronic liver disease, including AILD, perpetual liver injury leads to persistent inflammation, cell proliferation and the deposition of extracellular matrix proteins. If left untreated, this process eventually leads to the development of liver cirrhosis, characterised by nodular regeneration diffuse nodular regeneration surrounded by fibrotic septa with consequent extinction of the parenchyma, together leading to distortion of hepatic vascular architecture<sup>[60]</sup>. Loss of normal liver function inevitably ensues (Figure 2)<sup>[61]</sup>.

Hepatic stellate cells, found in the space of Dissé, have long been believed to be the main contributors to liver fibrosis. Liver damage induces hepatic stellate cells to differentiate into proliferative and contractile myofibroblasts, with a pro-inflammatory and fibrogenic phenotype<sup>[61-63]</sup>. Portal fibroblasts, located in the connective tissue of the portal triad are another source of myofibroblasts<sup>[64]</sup>. These are of particular importance in the context of the cholestatic AILDs. Liver damage leads to the myofibroblastic differentiation of quiescent

portal fibroblasts<sup>[64]</sup>, a process which can be enhanced in these conditions by the cholangiocytes themselves. When cholangiocytes become “reactive”, they proliferate and express co-stimulatory molecules, chemokines and pro-fibrogenic molecules, therefore further promoting fibrogenesis<sup>[65-70]</sup>. Bile acids, elevated as a consequence of cholestasis, could also perpetuate fibrogenesis indirectly by damaging hepatocytes<sup>[71]</sup>, or by directly targeting myofibroblasts<sup>[72]</sup>.

It has also been suggested that hepatic myofibroblasts could arise from hepatocytes or cholangiocytes *via* epithelial-mesenchymal transition, whereby polarised epithelial cells undergo phenotypic transformation in response to microenvironmental cues<sup>[73]</sup>. There are reports that hepatic epithelial cells can acquire some of the phenotypic characteristics of myofibroblastic cells *in vitro*. Co-expression of epithelial and fibroblastic cell markers has also been described in human tissue sections<sup>[74,75]</sup>. However, partly because these cell “markers” inadequately define both the epithelial and fibroblastic populations, conclusive evidence of epithelial-mesenchymal transition has been hard to come by. Furthermore, lineage tracing studies, using Cre/lox recombination, have failed to find evidence of liver epithelial cell-mesenchymal transition in murine models of bile-duct ligation or hepatitis induced by carbon tetrachloride (CCl<sub>4</sub>) or 3,5-diethoxycarbonyl-1,4-dihydrocollidine<sup>[76,77]</sup>.

## NATURAL HISTORY OF CIRRHOSIS

It is well known that, compared with pre-cirrhotic patients, patients with cirrhosis have higher risks of morbidity and mortality<sup>[78]</sup>. Cirrhosis can be divided into a compensated phase, free of symptoms, and a decompensated phase, in which complications of portal hypertension and/or liver dysfunction lead to rapid deterioration. The two stages can be considered separate clinical entities according to the AASLD and EASL guidelines<sup>[79]</sup>. Median survival time in the compensated phase is over 12 years, whereas survival in the decompensated phase drops to approximately 2 years. The decompensated phase is defined by the development of jaundice, ascites, variceal haemorrhage or encephalopathy<sup>[80,81]</sup>. The compensated stage has been further divided into stage 1, consisting of patients lacking varices, and stage 2, characterised by the presence of varices in the absence or variceal bleeding. The decompensated stage has been split into stage 3, associated with ascites and a lack of variceal haemorrhage, and stage 4, comprising patients with variceal haemorrhage (with or without ascites). One year mortality rates of 1%, 3%, 20% and 57% respectively have been reported<sup>[82,83]</sup>. In a recent study, however, Zipprich *et al.*<sup>[84]</sup> (2012) failed to replicate entirely these reported values, finding that stage 3 and stage 4 patients had one year survival rates of approximately 20% and 18% respectively. The authors of this study cite recent advances in variceal haemorrhage therapy<sup>[85]</sup> as a potential reason for this discrepancy and proposed modifications to the system of stratification. The newly defined

stage 3 consists of patients with variceal haemorrhage but without ascites, while stage 4 is characterised by the presence of ascites (with or without variceal bleeding)<sup>[84]</sup>.

The risk of progression from compensated to decompensated cirrhosis is approximately 31% in the first year of diagnosis and 5%-7% thereafter<sup>[86]</sup>. Because of the striking reduction in survival time in the decompensated state, it is important to identify patients at greatest risk of cirrhosis progression. Newly developed non-invasive techniques for fibrosis/cirrhosis assessment are currently being tested.

The Child-Pugh, and more recently developed Model of End-Stage Liver Disease (MELD) Scores are the most widely used methods by which prognosis is assessed in the context of end-stage liver disease. The Child-Pugh Score incorporates values between 1 and 3 for each of the following criteria: Degree of encephalopathy, presence of ascites, serum bilirubin and albumin levels and international normalised ratio (INR). The MELD score encompasses bilirubin, INR and creatinine levels<sup>[87]</sup>. MELD was initially developed for predicting survival following transhepatic portosystemic shunt, but is now used to accurately predict survival in the context of cirrhosis<sup>[88]</sup>, list patients for transplant and allocate organs.

## DIAGNOSING CIRRHOSIS

Liver biopsy is still the most accurate and widely used method by which cirrhosis can be diagnosed and staged. There are, however, notable disadvantages to this method of examination, including cost, risk of bleeding, and sampling error<sup>[89]</sup>. Non-invasive tests for both diagnosis and assessment of fibrosis/cirrhosis progression are becoming increasingly sought. Proposed tests include those using the results of routine liver-function examinations, such as the AST-to-platelet ratio index, as well as examinations to measure liver stiffness; FibroTest and transient elastography (TE; FibroScan)<sup>[90,91]</sup>. There are promising indications that non-invasive methods could be used in the context of AILD. In PBC, liver stiffness tests show high performance in diagnosing significant fibrosis, severe fibrosis and cirrhosis. Progression of liver stiffness has also been used as an accurate measure of overall prognosis in PBC<sup>[92-94]</sup>. The addition of serological markers to the liver stiffness score does not appear to improve test outcome<sup>[93]</sup>. In a study also involving both PBC and PSC patients, liver stiffness was also shown to correlate with progression of fibrosis and histological scores<sup>[95]</sup>. Using a cohort of 404 patients with varied liver diseases, including PBC, PSC and AIH, Malik *et al*<sup>[96]</sup> (2010) found that liver stiffness scores accurately identified patients with compensated cirrhosis. Although highly promising, these results, particularly in the context of AIH, need to be confirmed in larger cohorts of patients.

## CIRRHOSIS IN AILDS

### *Cirrhosis in PBC*

PBC progresses through a number of stages: Preclinical,

asymptomatic, symptomatic, and liver failure. The pre-clinical phase is symptom-free and is associated with AMA positivity in the absence of biochemical indications of liver disease<sup>[6,97]</sup>. Biochemical abnormalities eventually appear after a median time of 5.6 years (range, 1-20 years)<sup>[6]</sup>, but this phase is not yet associated with the presence of symptoms. When symptoms eventually develop, they are most commonly fatigue and pruritus, and later varices, oedema or ascites.

Liver failure is characterised by the accelerated development of jaundice, and is associated with poor prognosis<sup>[98]</sup>. Mean survival for patients with a bilirubin of 2.0 mg/dL is 4 years, while for those with bilirubin of 6.0 mg/dL is only 2 years<sup>[98]</sup>. PBC prognosis has dramatically improved in the last 20 years thanks to earlier diagnosis and the introduction of UDCA as the mainstay of treatment<sup>[99,100]</sup>.

UDCA slows fibrosis progression and delays cirrhosis development<sup>[101]</sup>. In clinical trials, UDCA treatment of PBC patients decreased the development of oesophageal varices and prolonged survival<sup>[102-106]</sup>. Cirrhosis does, however, still develop in UDCA-treated PBC patients<sup>[107]</sup>. Indeed, the development of cirrhosis under UDCA treatment is an independent predictor of negative outcome<sup>[101,107]</sup>.

Histologically, PBC can be divided according to the presence of fibrosis/cirrhosis into four stages<sup>[108,109]</sup>. Stage one is characterised by portal inflammatory cell infiltrate, which, in stage two, invades the liver parenchyma. In stage three, bridging fibrosis, in which fibrotic septa extend from and link the portal tracts, can be seen. Stage four is characterised by progression to cirrhosis<sup>[109]</sup>. The development of cirrhosis does not occur uniformly throughout the liver, thus features of all four stages can occur simultaneously in a single biopsy specimen. Histological staging should depend upon the most advanced histological features<sup>[25]</sup>.

Histological stages can predict survival of PBC patients<sup>[110]</sup>. In untreated PBC patients, the median time to the development of extensive fibrosis is 2 years. The probability of remaining in early stages after 4 years is 29%, whereas development of cirrhosis occurs in 50% of patients originally demonstrating histological evidence of interface hepatitis without fibrosis<sup>[111]</sup>. In two studies the proportion of patients developing liver failure during a follow-up time of 5 years was found to be 15%<sup>[112]</sup> and 25%<sup>[113]</sup>. The development of oesophageal varices, and the associated impact on survival, has been examined in a prospective study over the course of 5.6 years, which included 256 patients<sup>[114]</sup>. Twenty-eight percent of patients were cirrhotic. Nearly one-third of patients developed oesophageal varices, after which the 3-year survival was 59%. Survival after the first bleeding episode was 46%<sup>[114]</sup>.

The introduction of UDCA as first line treatment for PBC patients has changed the natural history of the disease<sup>[25,100,115,116]</sup>. Indeed, the number of PBC patients requiring liver transplantation (LT) decreased by 20% in between 1996 and 2006<sup>[115]</sup>. Additionally, PBC has fallen in the ranking of the most common indications for LT

from the first to the sixth place LT over a period of 20 years<sup>[25]</sup>.

Several papers have also assessed the impact of UDCA therapy on the progression rate of cirrhosis in PBC patients. Corpechot *et al.*<sup>[107]</sup> examined progression to cirrhosis in 183 UDCA-treated PBC patients. In this study, 21% of patients developed cirrhosis during follow-up. The incidence of cirrhosis in patients followed up from stages 1, 2 and 3 was 4%, 12% and 59% respectively and the median length of times to cirrhosis development was 25, 20 and 4 years respectively. Albumin and bilirubin levels, and the histological severity of interface hepatitis were independently associated with progression to cirrhosis; cirrhosis was most likely to develop in patients with serum bilirubin over 17  $\mu\text{mol/L}$ , serum albumin below 38 g/L and in patients with moderate to severe interface hepatitis<sup>[107]</sup>. The impact of UDCA treatment oesophageal varices development has been examined in a 4-year prospective study including patients who received UDCA vs patients who received placebo. In the UDCA arm, the risk of varices development was 16%, while for those in the placebo group was 58%<sup>[103]</sup>.

### Cirrhosis in PSC

Typical symptoms of PSC, occurring in a variable number of patients include pruritus, abdominal pain, malaise, weight loss, and episodes of fever and chills<sup>[117]</sup>. About 50% of PSC patients will present symptomatically<sup>[118,119]</sup>. Similarly to PBC, PSC progresses through four histological stages<sup>[120]</sup>. In stage 1, which is known as the portal stage, changes are restricted to the portal tracts with features of mild hepatitis and cholangitis. Stage 2, known as the periportal stage, is characterised by extension of the lesion to include periportal fibrosis and occasionally interphase hepatitis. In this phase, the portal tracts are often notably enlarged. By stage 3, the septal stage, bridging fibrous septa have developed and the bile ducts have begun to degenerate and disappear. Stage 4 is characterised by cirrhosis<sup>[120]</sup>. The rate of progression through these stages has been investigated. Of PSC patients in the periportal stage, 42%, 66% and 93% progressed over 1, 2 and 5 years respectively. Of patients in the septal stage, 14%, 25% and 52% progressed over 1, 2 and 5 years respectively. In 15% of total observations, regression of histologic stage could be observed, highlighting the problem of sample variability when serial liver biopsies are used during the period of follow-up<sup>[121]</sup>.

PSC can present at later stages of disease development, with complications of cirrhosis and portal hypertension<sup>[122]</sup>. Similarly to other causes of cirrhosis, portal hypertension gradually develops in cirrhotic PSC patients<sup>[119]</sup>. In one study, 36% of 283 newly diagnosed PSC patients had varices<sup>[123]</sup>.

### Cirrhosis in AIH

In a cohort of over 450 AIH patients, 30% had evidence of cirrhosis at diagnosis, with a further 10% developing cirrhosis during a median follow-up time of 7.2 years.

The presence of cirrhosis at diagnosis correlated with negative outcome (LT or death)<sup>[124]</sup>. In another study, including 126 AIH patients, Feld *et al.*<sup>[125]</sup> (2005) reported that 33% of patients had histological evidence of cirrhosis at diagnosis. With the exception of platelet count, which was lower in patients with cirrhosis, laboratory parameters, patient demographics and AIH scores did not differ between cirrhotic and non-cirrhotic patients. A similar frequency of patients from each group were symptomatic at diagnosis and an equivalent proportion had good response to treatment<sup>[125]</sup>. Importantly, similar response to treatment has also been reported elsewhere<sup>[126]</sup>. Feld *et al.*<sup>[125]</sup> (2005) also found, however, that the presence of cirrhosis significantly increased risk of progression to LT or death. Consistent with the above studies, Verma *et al.*<sup>[127]</sup> (2004) reported that 28% of AIH patients were cirrhotic at diagnosis. In this study, a further 20% of patients developed cirrhosis during 52 mo of follow-up. Again, cirrhosis was an independent predictor of poor outcome in this cohort<sup>[127]</sup>. On the other hand, studies in the adult<sup>[126,128]</sup> and paediatric<sup>[129]</sup> settings, of comparable size and methodology to those described above, have not found associations between the presence of cirrhosis at diagnosis and the likelihood of poor outcome.

In one study, patients diagnosed between the ages of 21 and 60 years of age were more likely to present with cirrhosis than those outside of this range. Male patients were also more likely to have cirrhosis compared to their female counterparts. Low serum albumin concentrations, prolonged INR and low platelet count were all more frequently associated with the cirrhotic group of AIH patients<sup>[130]</sup>.

There are indications that cirrhosis is more common among AIH type-1 patients compared to patients with type-2 AIH. In a paediatric study, 69% of ANA/SMA positive patients had evidence of "definite cirrhosis" on initial biopsy, whereas only 38% of patients positive for anti-LKM-1 were cirrhotic. On follow-up these values increased to 74% and 44% respectively<sup>[131]</sup>.

## LT IN AILDS

LT is indicated for AILD patients who have progressed to end-stage chronic liver disease or developed intractable symptoms or hepatocellular carcinoma (HCC)<sup>[132,133]</sup>; in addition, LT may also be indicated for patients presenting with acute liver disease due to AIH who do not respond to steroids<sup>[134]</sup>. In total, AILDs accounts for almost one fourth of LTs performed in the United States and in Europe<sup>[135]</sup>.

### LT for PBC

The indications for LT in PBC are, for the most part, identical to those in patients with end-stage chronic liver disease of other aetiology<sup>[100,132]</sup>. The majority of transplants occur due to end-stage chronic liver disease when the MELD score is higher than 16<sup>[136]</sup>. Other indications for LT include HCC, portopulmonary hypertension or hepato-pulmonary syndrome<sup>[137]</sup>. Other than this, few

PBC patients with non-cirrhotic portal hypertension associated with obliterative portal venopathy or nodular regenerative hyperplasia will benefit from transplant<sup>[138]</sup>. Finally, even when liver function is sufficient<sup>[139]</sup>, LT may be indicated if intractable symptoms, most notable refractory pruritus, are present<sup>[137,140]</sup>.

The immunosuppressive regimen most commonly used following LT is a combination of corticosteroids, which are withdrawn over a period of three months, a calcineurin inhibitor (CNI) and mycophenolate mofetil or azathioprine. This regimen has a very successful outcome<sup>[136]</sup>; with 1, 3 and 5 year patient survivals of 94%, 91% and 82% respectively, and graft survivals of 85%, 83% and 75% respectively<sup>[141]</sup>. Analysis of the UNOS database showed that PBC living donor transplant recipients had estimated 1, 3 and 5 year patient survivals of 93%, 90% and 86% and deceased donor transplant recipients had estimated survivals of 90%, 87% and 85% respectively. Estimated graft survivals at 1, 3 and 5 years for living donor LT was 86%, 81% and 77% respectively, and for deceased donor LT was 85%, 83% and 81% respectively<sup>[142]</sup>.

### LT for PSC

Similarly to PBC, and other liver diseases associated with cirrhosis, LT is indicated in PSC patients with end-stage liver disease (*i.e.*, with a MELD score above 16)<sup>[143,144]</sup>. HCC can occur in PSC patients with cirrhosis, and in this context, LT prioritisation follows the same rule as that for other cirrhotic patients with HCC<sup>[137,145]</sup>. In PSC, LT may also be indicated in patients with intractable pruritus or those with recurrent bacterial cholangitis, and limited stage cholangiocarcinoma<sup>[118,122,143]</sup>.

LT for PSC usually has good outcome<sup>[139]</sup>. In one report, the 1, 2 and 5 year actuarial patient survivals for LT for PSC were 90%, 86% and 85%, and graft survivals were 82%, 77% and 72% respectively<sup>[146]</sup>. In a study from the Mayo Clinic comprising 150 transplanted PSC cases, similar patient survival at 1, 2, 5 and 10 years of 94%, 92%, 86% and 70%, and graft survival of 83%, 83%, 79% and 61% was reported<sup>[147]</sup>.

### LT for AIH

Overall, AIH accounts for some 3% of paediatric and up to 6% of adult LTs<sup>[40]</sup>. The natural course of AIH is understood mostly thanks to the last placebo-controlled trials published 4 decades ago<sup>[148-150]</sup>. These reports demonstrated that, without treatment, AIH patients have poor survival with 40% of deaths within 6 mo from diagnosis. With treatment, 10-year survival rate of AIH patients is over 80%<sup>[125,151]</sup>.

LT is indicated for AIH patients presenting with acute liver failure who do not respond to steroids, for those patients with advanced cirrhosis and for those with HCC<sup>[136,152]</sup>.

The immunosuppressive strategy most commonly adopted consists in the combination of prednisolone and a CNI<sup>[153]</sup>, leading to excellent outcome with 5 and 10 year patient survivals of 90% and 75%<sup>[51]</sup>, and 1 and 5 year graft survivals of 84% and 75%<sup>[51,154]</sup>.

### Abstract

*Echinococcus granulosus* (*E. granulosus*) and *Echino-*

*coccus multilocularis* (*E. multilocularis*) infections are the most common parasitic diseases that affect the liver. The disease course is typically slow and the patients tend to remain asymptomatic for many years. Often the diagnosis is incidental. Right upper quadrant abdominal pain, hepatitis, cholangitis, and anaphylaxis due to dissemination of the cyst are the main presenting symptoms. Ultrasonography is important in diagnosis. The World Health Organization classification, based on ultrasonographic findings, is used for staging of the disease and treatment selection. In addition to the imaging methods, immunological investigations are used to support the diagnosis. The available treatment options for *E. granulosus* infection include open surgery, percutaneous interventions, and pharmacotherapy. Aggressive surgery is the first-choice treatment for *E. multilocularis* infection, while pharmacotherapy is used as an adjunct to surgery. Due to a paucity of clinical studies, empirical evidence on the treatment of *E. granulosus* and *E. multilocularis* infections is largely lacking; there are no prominent and widely accepted clinical algorithms yet. In this article, we review the diagnosis and treatment of *E. granulosus* and *E. multilocularis* infections in the light of recent evidence.

**Key words:** *Echinococcus granulosus*; *Echinococcus multilocularis*; Liver; Ultrasonography; Albendazole

## INTRODUCTION

*Cystic echinococcus* (CE) is a parasitic illness, caused by infection with *Echinococcus granulosus* (*E. granulosus*) in its larval stage<sup>[1]</sup>. Although the disease occurs worldwide, it is endemic in Africa, South America, and Eurasia<sup>[2-4]</sup>. The liver is the most commonly affected organ; however, the lungs, spleen, kidney, brain, and breasts may be involved<sup>[5]</sup>. Mortality from CE is usually due to the development of complications and is reported to be 2%-4%<sup>[6,7]</sup>. The disease course is typically slow and most CE patients remain asymptomatic for several years. In addition, due to non-specific symptoms, the diagnosis is often incidental<sup>[8]</sup>. Hepatic alveolar echinococcus (AE) referring to the intrahepatic growth of the larvae of *Echinococcus multilocularis* (*E. multilocularis*) is a rare yet serious disease. When the epidemiology of AE is analyzed, it is striking that the disease is encountered in the northern hemisphere only<sup>[9]</sup>.

Complications of the echinococcal disease include allergic reactions to the dissemination of cyst contents due to spontaneous, traumatic or iatrogenic rupture, secondary infection, and cholangitis<sup>[3,10-12]</sup>. While most CE patients have a single cyst, 20%-40% tend to harbor multiple cysts<sup>[13]</sup>.

Although a wide range of treatment methods have been identified (medical, percutaneous, monitoring, and surgical), a standardized treatment protocol has yet to be defined.

In this article, we present an update on the diagnosis and treatment of the CE and AE diseases in the liver in the light of emanating evidence.

## E. GRANULOSUS INFECTION

### Life cycle

*E. granulosus* is a small sized tapeworm with 10 different genotypes. The definitive host of this parasite is the dog and other members of canids; the intermediate hosts include members of the ungulates such as sheep, goat, and pigs. The adult parasites localize in the liver of the definitive host; eggs are excreted *via* the stool of the host. Upon oral ingestion of the eggs by the intermediate host, the eggs hatch within the stomach and intestine. Oncosphere larvae emerge and cling onto the small intestine by its hooks. Subsequently, the oncosphere larvae migrate to organs such as the liver and lungs through the blood and lymph vessels. Humans are accidental hosts and not essential to the life-cycle of *Echinococcus*. Infection occurs after the oral ingestion of eggs. The eggs grow inside the host organs and form a cyst (hydatid cyst). Hydatid cysts are round in shape and

are usually filled with a clear fluid. The inner part of the cyst features a germinating membrane while the outer part features a laminated layer. In time, the parasite matures and evokes a granulomatous inflammatory reaction which leads to walling off of the cyst by fibrous tissue. In time, budding (germination) occurs from the germinative membrane and blisters are formed (Figure 1). The protoscolexes, which occur inside the organ that the definitive host consumed, open up and *Echinococcus* matures into adult from clinging onto the intestine of the definitive host, thus completing the cycle<sup>[14-17]</sup> (Figure 2).

### Clinical presentation

Most patients have an asymptomatic disease course. The most important reason for this is the slow growth rate of the cysts (1-5 mm per year). Therefore, symptoms usually develop in adulthood<sup>[13,14,18]</sup>. The most common presenting symptoms are discomfort in the right upper quadrant of abdomen and loss of appetite. Other symptoms may include pain caused by an increase in the size of the cyst, anaphylactic reaction<sup>[11]</sup> induced by the rupture of the cyst, hepatitis, and cholangitis due to biliary obstruction caused by the daughter vesicles<sup>[19]</sup>, secondary infection of the cyst, embolism<sup>[14]</sup>, and subphrenic or intracystic abscess<sup>[13]</sup>. In 90% of the patients, the cysts open into the biliary tract, which causes the complications listed above<sup>[20]</sup>. In approximately 10% of cases, intraperitoneal rupture of the cyst induces anaphylaxis. In addition, secondary CE may develop due to the rupture of the cyst, and this may lead to a much larger mass developing over a relatively short period<sup>[13]</sup>. Patients are usually diagnosed incidentally during radiological examination conducted for complaints unrelated to CE. During physical examination, hepatomegaly, palpable mass in one right upper quadrant, and abdominal distension may be encountered as well.

For patients who develop hepatitis, colic pain, portal hypertension, acidity, pressure in inferior vena cava, and Budd-Chiari syndrome, liver hemangioma, liver cysts, adenoma, liver abscess, hepatocellular cancer, liver metastasis, and in addition, liver *Echinococcus* should be taken into account during the differential diagnosis of the masses that are found in the liver<sup>[21,22]</sup>.

### Diagnosis

Most of CE patients at the asymptomatic early stage are diagnosed incidentally. Diagnosis relies on imaging and immunological tests. Ultrasonography is a convenient tool for diagnosis that indicates the location, number, and size of the cysts with relative ease<sup>[2,3,13,18,23,24]</sup>.

However, small-sized cysts may not be detected by ultrasonography. The criteria for classification of liver cysts on ultrasonography, which were first developed by Gharbi in 1981, were improved by the World Health Organization (WHO) in 2001 (WHO-IWGE)<sup>[25,26]</sup> (Tables 1 and 2). The WHO classification includes cysts of unknown origin and includes modified subtypes of the Types 2 and 3 cysts<sup>[14]</sup>. There are three categories of cysts: Active,

**Table 1 The Gharbi classification of hydatid cysts**

Type	Characteristics
I	Unilocular cyst, wall and internal echogenicities
II	Cyst with detached membrane (water-lily sign)
III	Multivesicular, multiseptated cyst, daughter cyst (honeycomb pattern)
IV	Hererogeneous cyst, no daughter vesicles
V	Cyst with partially or completely calcified wall

**Table 2 The World Health Organization classification of hydatid cysts**

WHO stage	Characteristics	Activity
CE1	Unilocular, anechoic cyst with double line sign	Active
CE2	Multiseptated "rosette-like" "honeycomb pattern" cyst	Active
CE3a	Cyst with detached membrane (water-lily sign)	Transitional
CE3b	Daughter cysts in solid matrix	Transitional
CE4	Hererogeneous cyst, no daughter vesicles	Inactive
CE5	Solid matrix with calcified wall	Inactive

WHO: World Health Organization.

transitional, and inactive<sup>[27]</sup>. Types 1 and 2 cysts are considered "active" while Type 3 cysts are considered "transitional". Types 4 and 5 cysts are categorized as "inactive"<sup>[27]</sup>. However, this classification has changed with the long term results of the medical and percutaneous treatment and the usage of the high-field magnetic resonance spectroscopy. Type 3 cysts, which are considered transitional, are further divided into two sub-groups: CE3a (separated endocysts) and CE3b (solid type containing daughter vesicle)<sup>[7,28]</sup>. Some studies have suggested that CE3a cysts are inactive while CE3b cysts are active<sup>[14,29]</sup>. Ultrasonography may also be used for monitoring of the lesion. For patients who have received treatment, post-treatment follow-up examinations every 3-6 mo until stabilization of the cyst, and annual examinations thereafter, are recommended. In general, a period of 5 years without recurrence is considered sufficient<sup>[30]</sup>. Magnetic resonance imaging (MRI) and computer tomography (CT) may be required in some cases, where ultrasonography fails to provide a definitive diagnosis. These include obese patients, patients with subdiaphragmatic cyst or secondary infection of cysts, complicated cases such as biliary fistula, cases with extra-abdominal spread, and patients who have a common disease. CT and MRI are particularly useful for pre-operative and follow-up examinations. Use of MRI for diagnosis and follow-up examination is known to be superior to CT<sup>[28,31,32]</sup>.

There are no workups amongst the routine blood workups that may be used specifically for CE. Hyperbilirubinemia and increased levels of alkaline phosphatase and gamma glutamyl transferase may indicate opening of the cyst into the biliary tract<sup>[15,30,33]</sup>. Although EC is

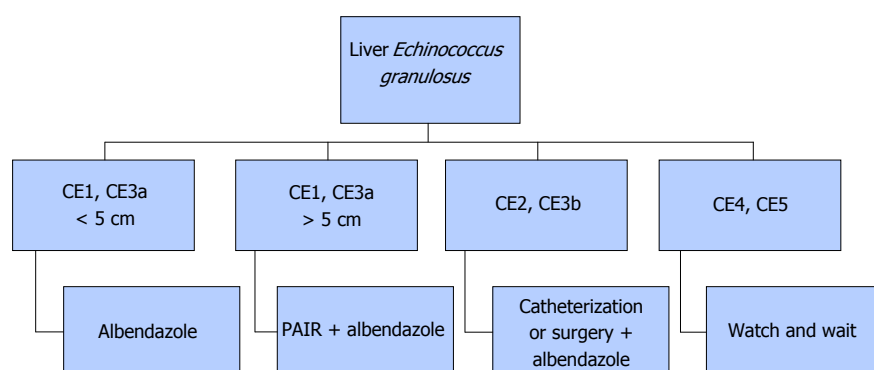

**Figure 1 Daughter vesicles of *Echinococcus granulosus*.**

a parasitic infection, eosinophilia may not be always present. Serologic diagnostic methods are used to support the radiological diagnosis and for follow-up assessment. The immunological response to the disease tends to vary from one individual to another. Rugged and intact cysts tend to show minimal immune response, while leaking or ruptured cysts tend to evoke a strong immune response<sup>[2,34,35]</sup>.

The indirect hemagglutination (IHA) is usually non-specific and is of value in tandem with other investigations such as enzyme-linked immunosorbent assay (ELISA) and immunoblotting<sup>[36]</sup>. Concomitant use of IHA and ELISA is associated with diagnostic sensitivity rates up to 85%-96%<sup>[37-41]</sup>. Immunoblotting is generally used to confirm the diagnosis in cases where IHA and ELISA findings are not definitive<sup>[14]</sup>. *E. granulosus* antigen B and antigen 5 (Ag5) are the most specific antigens used for immunological diagnosis<sup>[2,35]</sup>. However, these immunological methods often show cross reactivity with other parasitic antigens or with non-parasitic diseases such as malignancy or liver cirrhosis<sup>[15,42-45]</sup>. Sensitivity of the serological tests tends to vary with the location, stage, and size of the cyst<sup>[11]</sup>.

While seronegativity is observed in 20% of patients with CE, those with multiple cysts are usually seropositive. Rate of seronegativity is relatively higher in patients with CE1, CE4, and CE5 cyst types as compared to those with CE2 and CE3 types. Moreover, seropositive patients may continue to remain so for more than 10 years despite treatment<sup>[14,46-48]</sup>. This may lead to unnecessary treatment and an increase in costs.

Percutaneous fine needle aspiration (FNA) biopsy under ultrasound guidance is used in suspected cases with equivocal radiological and serological test results. Observing the protoscolexes and cyst membranes, or Echinococcal antigen or DNA in aspirated fluid confirms the diagnosis<sup>[49]</sup>. Percutaneous procedure requires meticulous care due to the associated risk of anaphylaxis; informed consent of the patient should be obtained prior to the procedure<sup>[50]</sup>. Anaphylaxis risk of FNA is 2.5%<sup>[51]</sup>. In order to prevent secondary CE, pretreatment with albendazole for 4 d prior to the biopsy and continuation of treatment for one month after the biopsy are recommended<sup>[20,52]</sup>.

Figure 2 Life cycle of *Echinococcus granulosus*.Figure 3 Treatment algorithm for *Echinococcus granulosus* infection. PAIR: Puncture, aspiration, injection of a scolecidal agent, and reaspiration.

### Treatment and management of *E. granulosus* infection

The treatment options for CE included surgery, percutaneous treatment, medical pharmacotherapy, and monitoring<sup>[10]</sup>. In the literature, there is no randomized clinical study that compares the treatment methods with each other. Therefore, there is no standardized and widely accepted treatment approach for CE either<sup>[14]</sup>. The treatment planning is done according to the WHO diagnostic classification. In case CE1 and CE3a cysts are < 5 cm in diameter, albendazole alone may suffice, while for cysts exceeding 5 cm in size, the puncture, aspiration, injection of a scolecidal agent, and reaspiration (PAIR) treatment in tandem with albendazole is preferred. Types CE2 and CE3b cysts are treated by catheterization or surgery. For types CE4 and CE5 inactive cysts, monitoring is often sufficient<sup>[10]</sup> (Figure 3).

**Medical treatment:** Exclusive medical pharmacotherapy is used in special cases where surgical or percutaneous treatment (such as elderly patients, cases with high comorbidity, patients who opt out of surgical and percutaneous treatment, and inoperable cases) is not suitable, or as an adjunct to surgical and percutaneous treatment.

Ever since benzimidazoles became available for use in 1970s, therapeutic efficacy of albendazole and mebendazole for larval stage of *E. granulosus* has been

proved<sup>[14]</sup>. At present, albendazole is the most commonly used drug in the treatment of *E. granulosus* infection<sup>[53]</sup>. The dose of albendazole is 10-15 mg/kg per day and the treatment usually lasts for 3-6 mo. Efficacy of mebendazole is comparable to that of albendazole, but requires higher doses for a longer period of time, due to its poor absorption<sup>[53-55]</sup>. The dose of mebendazole is 40-50 mg/kg per day for the patients who can not use albendazole.

With benzimidazoles, the duration of treatment is 3-6 mo without interruption for CE1, CE3a cysts that are < 5 cm<sup>[10,56]</sup>. Studies have demonstrated that 28.5%-58% of patients who undergo medical treatment are cured, and that cure rates do not increase with the increase in the duration of treatment<sup>[54,57-61]</sup>.

According to the recommendations of WHO, the medical treatment should be initiated 4-30 d prior to the surgical operation and continued for at least 1 mo thereafter for albendazole, and at least 3 mo for mebendazole. Medical pharmacotherapy is also indicated in patients with spontaneous or traumatic ruptured of cysts. In these cases, too, albendazole should be used for at least 1 mo or mebendazole for 3 mo<sup>[62-64]</sup>.

In a large study (929 cysts) of the effectiveness of medical therapy in late stages, albendazole therapy was associated with a significantly higher incidence of degenerative changes than that with mebendazole the-

rapy (82.2% vs 56.1%;  $P < 0.001$ ). However, the relapse rates were comparable between the two groups<sup>[65]</sup>.

Headache, nausea, neutropenia, hair loss, and hepatotoxicity are the most commonly reported side effects of albendazole and mebendazole. Monthly monitoring of leukocyte counts and liver function tests is recommended in patients who experience significant side effects. Contraindications to medical treatment include liver failure, pregnancy, and bone marrow suppression<sup>[13]</sup>.

Praziquantel has protoscolicidal activity and can be used for treatment of CE, either as a standalone therapy or in combination with albendazole. A study suggested higher efficacy of the combination of praziquantel plus albendazole<sup>[66]</sup>. More studies on the efficacy of praziquantel are required.

**Percutaneous treatment:** The percutaneous treatment methods defined in the 1980s for liver CE continue to be popular today<sup>[67-70]</sup>. These are classified under two main categories. The first and more popular one is the PAIR method<sup>[71]</sup>. This method is based on the destruction of the germinal membrane by use of a scolical agent. However, PAIR is not a suitable method for cysts that contain daughter vesicles and for multi-vesicular cysts that have a higher solid content<sup>[7,69,72]</sup>.

Secondary percutaneous treatment modalities include catheterization of the cyst with a broad tube to remove the solid contents of the cyst as well as the daughter vesicles. Several catheterization methods such as percutaneous evacuation, a modified catheterization technique, and dilatable multi-function trocar have been described<sup>[73-75]</sup>. This treatment method can be used for treatment of Types CE2 and CE3a cysts and for post-PAIR relapsing cysts<sup>[76]</sup>.

A review of percutaneous CE treatment ( $n = 5.943$ ) revealed a 0.03% incidence of lethal anaphylaxis and 1.7% incidence of allergic reactions<sup>[49]</sup>. Using albendazole starting from 4 h prior to the percutaneous treatment until 30 d after the percutaneous treatment is convenient<sup>[10]</sup>.

The PAIR treatment is a less invasive method than surgery. In selected patients (CE1 and CE3b) success rates of up to 97% have been reported; the reported mortality and morbidity rates have varied from 0%-1% to 8.5%-32%<sup>[77-80]</sup>. In a study of ethanol plus PAIR treatment ( $n = 231$ ), only one case of relapse was reported<sup>[80]</sup>. Eleven percent to thirteen percent of patients undergoing PAIR tend to develop fever and rash; however, the risk of anaphylaxis is quite low<sup>[77,81]</sup>.

PAIR treatment is not recommended for the cysts which are containing materials that can not be absorbed, cysts which carry the risk of spread into the abdominal cavity, cysts that have already opened into the peritoneal cavity or biliary tract, and inactive and calcified cysts<sup>[7]</sup>.

The relation of the cyst with the biliary tract should be examined prior to administration of scolical agent. Although no cases of scolical agent-related cholangitis after PAIR procedure have been reported, several such

cases have been reported after surgical procedure<sup>[82-84]</sup>. The commonly used scolical agents used during PAIR are hypertonic saline and ethanol<sup>[14]</sup>. Successful intra-cystic application of albendazole and mebendazole solutions as scolical agents during PAIR has been reported in sheep<sup>[85]</sup>.

The reported success rate of percutaneous treatment plus albendazole in non-complicated cysts is similar to that of surgery but has the advantage of a shorter duration of hospital stay<sup>[86]</sup>. In a retrospective comparison of conservative surgery and PAIR, the incidence of biliary fistula and residual cavity relapse was considerably lower with the latter<sup>[87]</sup>.

**Surgical treatment:** While surgical treatment was once the most commonly used treatment modality, it is currently, to a large extent, reserved for complicated cysts (such as cysts that develop biliary fistula or perforated cysts) or is applied to the cysts that contain daughter cysts (CE2, CE3b). In addition, it is a suitable treatment option for superficial cysts that are smaller than 10 cm or are at high risk of rupture and for cases not suitable for percutaneous treatment<sup>[7,10,53,88]</sup>. The surgical treatment options include open surgery and laparoscopic surgery<sup>[5,89,90]</sup>. Open surgical options include radical and conservative surgery. Radical surgery refers to the removal of the cyst along with the pericystic membrane (Figure 4) and may also include liver resection if indicated. Conservative surgery includes removal of the cyst contents only, while the pericystic membrane is retained (Figure 5). Omentoplasty, external drainage, or obliteration of the residual cavity by imbricating sutures from within (capitonnage) is used for drainage from the residual cavity. The complication rates of the surgical treatment options vary between 3%-25%, while the recurrence rates vary between 2% and 40%<sup>[89,91-93]</sup>. The complication and recurrence rates tend to differ based on the location and size of the cyst, as well as the experience of the surgeon and the selected treatment method.

It is not clear which one of the given treatment options is the safest and the most effective. However, recurrence and complication rates tend to be higher with conservative surgery as compared to those with radical surgery<sup>[94]</sup>. Many retrospective studies have revealed similar results<sup>[93,95]</sup>.

The recurrences usually occur due to failure of complete removal of the endocysts and/or their dissemination during the surgery. For this reason, special attention should be paid to prevent spread during the operation<sup>[96,97]</sup>. Of note, spread during the surgery may also lead to other complications such as anaphylaxis.

The most common complication of liver EC is the infection and the contact with the biliary tract. The contact of the cyst with the biliary tracts is encountered in 3%-7% of all cases<sup>[98]</sup>. A relationship between cyst size and its contact with the biliary tract has been reported. In cases where the radius of the cyst is  $> 7.5$  cm, the sensitivity

Figure 4 An example of pericyclectomy material.

of the contact of the cyst with the biliary tract is reported to be 73% while its specificity is indicated to be 79%<sup>[99]</sup>. Prior to intraoperative administration of drugs in the cyst, the relation of the cyst with the biliary tract should be ascertained as protoscolicidal agents are known to induce sclerosis, cholangitis, and pancreatitis.

In case of preoperative evidence of opening of the cyst into the biliary tract, sphincterotomy by endoscopic retrograde cholangiopancreatography (ERCP) prior to surgery decreases the risk of postoperative external fistula from 11.1% to 7.6%<sup>[100]</sup>. When the relation of the cyst with the biliary tract is noticed during the surgery, presence of a cystic component within the biliary branches or within the common biliary duct should be checked. For this, intraoperative cholangiography is often required. In addition, the width of the biliary tract would be in normal range if there is no cystic component within the biliary branches or within the common biliary duct. The biliary tracts, which can be clearly seen through the cyst, should be sutured. In case there is a cystic component inside the biliary tract, the biliary tract would be widened. In such cases, removal of the cystic components within the biliary branches and applying T-tube or choledochoduodenostomy is recommended<sup>[101,102]</sup>. In addition, postoperative bilioma or high flow biliary fistula requires ERCP and sphincterotomy along with nasobiliary drainage or biliary stenting<sup>[103,104]</sup>.

The most commonly used protoscolicidal agent during the surgery is 20% hypertonic saline. The hypertonic saline should be in contact with the germinal membrane for at least 15 min. Albendazole, ivermectin, and praziquantel can also be used as protoscolicidal agents<sup>[105,106]</sup>. In a recently conducted *ex vivo* research, use of selenium nano-particles (250-500 µg/mL) as a protoscolicidal agent for 10-20 min showed good results<sup>[107]</sup>.

Intraoperative dissemination of the mass in the peritoneum should be rinsed with hypertonic saline. Postoperative albendazole for 3-6 mo plus praziquantel for 7 d is recommended<sup>[108]</sup>.

In a retrospective review of conservative surgery methods ( $n = 304$ ), use of external drainage was associated with a statistically significant increase in com-

Figure 5 An example of conservative surgery.

plication rates as compared to patients who received omentoplasty or capitonnage<sup>[109]</sup>. In another randomized clinical trial and one retrospective study, patients who received omentoplasty in addition to the conservative surgery showed fewer complications as compared to patients with external drainage<sup>[5,110]</sup>.

The first laparoscopic surgery for CE was reported in 1992<sup>[111]</sup>. While the laparoscopic surgery offers some advantages such as shorter duration of hospital stay, lesser postoperative pain, and lower infection rates, it is applicable only to selected cases. Further laparoscopic procedures are associated with an increased risk of intraoperative dissemination of the cyst contents due to the increased pressure inside the mass<sup>[5,88]</sup>. No studies comparing open surgery with laparoscopic surgery were retrieved on the literature search. Appropriate patient selection is critical to the success of laparoscopic surgery. Deep-seated cysts in the hepatic parenchyma, posterior cysts close to the vena cava, multiple cysts ( $> 3$ ), and cysts with calcified walls are unsuitable for laparoscopic surgery<sup>[88,112-114]</sup>.

**Monitoring:** Some studies suggest that inactive cysts, such as CE4 and CE5, require no treatment<sup>[7,49,76]</sup>. However, more studies in this regard are required.

## E. MULTILOCULARIS INFECTION

### Life cycle

*E. multilocularis* is a small cestode. The definitive hosts of the sylvatic cycle are feral carnivores, and the definitive hosts of the synanthropic cycle are domestic cats and dogs. The fully grown parasites within the small intestine of the definitive host excrete their eggs with the feces of the definitive host. Upon ingestion of the eggs by intermediate hosts such as small rodents, echinococcal metacestodes form alveolar structures with multiple vesicles of different sizes within the liver. Humans get infected after oral ingestion of eggs<sup>[3,17]</sup>. Each vesicle has a structure, similar to the cysts of *E. granulosus*<sup>[115]</sup>. Potential complications include the formation of pseudocysts due to fluid accumulation or central necrosis. Small cysts usually do not contain liquid within them and

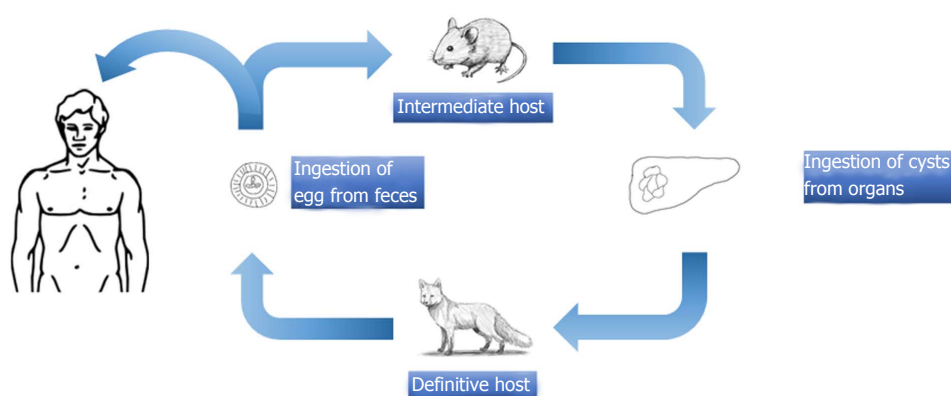

Figure 6 Life circle of *Echinococcus multilocularis*.

are semisolid in structure<sup>[16]</sup> (Figure 6).

### Clinical symptoms of *E. multilocularis* infections

The latent period for infection in which the patients are asymptomatic lasts around 5-15 years and is rather longer compared to the CE. In general, the AE is set into the right lobe of the liver and its size may vary from a few millimeters to 20 cm<sup>[11,13]</sup>. The AE may spread locally or metastasize to the brain, bones, and lungs *via* blood<sup>[115]</sup>. Extrahepatic manifestations are rare in primary disease<sup>[11]</sup>. The typical presenting symptoms include fatigue, weight loss, abdominal pain, and signs of hepatitis or hepatomegaly. Up to one-third of patients suffer from hepatitis and abdominal pain<sup>[115-117]</sup>. The prognosis for untreated cases or cases with incomplete treatment is grim; liver failure, splenomegaly, portal hypertension, and acidity may occur in advanced stages. The life expectancy may extend up to 20 years with treatment<sup>[118]</sup>.

### Diagnosis of *E. multilocularis* infection

The radiological imaging methods are the main methods of diagnosis of AE and the serologic examinations are used to support the diagnosis<sup>[3,4,10,119]</sup>. Ultrasonography is the diagnostic method of choice. On ultrasonography, a pseudotumoral mass with hypo and hyperechoic areas together that contain irregular, limited, and dispersed calcifications is diagnostic<sup>[120,121]</sup>. Doppler ultrasonography may be useful for imaging of biliary tracts and vascular infiltrations. Although CT renders the anatomical details in a better manner, MRI is considered the best method to determine invasion of the contiguous structures<sup>[120-122]</sup>. Percutaneous cholangiography is an important method for diagnosis in order to view the relation between the alveolar lesions and the biliary tracts. In addition cranial and thoracic imaging should be required to rule out extra-hepatic involvement in AE patients<sup>[120]</sup>. Despite the fact that the fluorodeoxyglucose positron emission tomography can be used for diagnosis, negative results do not necessarily mean that the parasite is active<sup>[123]</sup>. The WHO classification developed for *Echinococcus* is based on the imaging methods and aims to establish standardization in the diagnosis and treatment

of the disease<sup>[3,10,124]</sup>. WHO-IWGE PNM classification system resembles the TNM classification used for the tumors<sup>[3,124]</sup>. P indicates the size and location of the parasite within the liver, N indicates the adjunct organ involvement while M indicates distant metastasis (Table 3).

The immunological diagnostic methods are helpful for diagnosis as well as for monitoring the effectiveness of the treatment<sup>[125,126]</sup>. The serological investigations for AE (ELISA or IHA test) are more specific than the ones used for the diagnosis of CE (antigens Em2 and Em II/3-10 are highly specific to AE)<sup>[127]</sup>. However, EM2-ELISA may remain positive for many years even in the treated cases as the EM2 antigen is present in inactive lesions. The most active component of AE is the protoscolex that has EM16 and EM18 antigens. The activity of the lesion can be obtained by using those antigens in immunoblot tests<sup>[128]</sup>. In addition, EM18 is helpful for distinction between AE and CE<sup>[2]</sup>. In some studies, AE patients had high levels of IgG1 and IgG4 antibodies and their IgG4 antibody levels decreased after treatment. Therefore, an increase in IgG4 levels may be a surrogate marker of reactivation of the parasite<sup>[129-132]</sup>. Demonstration of alveolar vesicles in the samples extracted by percutaneous needle biopsy in suspected cases helps confirm the diagnosis. Although PCR imaging of the *E. multilocularis* DNA in the liver biopsy samples has high positive predictive value, negative results do not necessarily rule out the presence of an active parasite<sup>[10]</sup>. There are several studies evaluating the serologic agents best suited for post-treatment follow-up<sup>[133,134]</sup>.

### Treatment and management of *E. multilocularis* infection

AE is comparatively difficult to treat than CE. The main treatment modalities are medical pharmacotherapy and surgery (Figure 7).

Surgical treatment is the primary method for AE; radical resection is often required for hepatic lesions. Conservative and palliative surgery is not recommended since they offer no advantage over medical pharmacotherapy<sup>[135,136]</sup>. Treatment is based on pre-operative assessment and the disease stage as per the WHO-IWGE PNM classification<sup>[124]</sup>. Liver transplantation is an option for patients with advanced stage liver failure,

**Table 3** PNM classification of *Echinococcus multilocularis*<sup>[146]</sup>

P	Hepatic localization of the metacestode
Px	Primary lesion unable to be assessed
P0	No detectable hepatic lesion
P1	Peripheral lesion without biliary or proximal vascular involvement
P2	Central lesions with biliary or proximal vascular involvement of one lobe
P3	Central lesions with biliary or proximal vascular involvement of both lobes or two hepatic veins or both
P4	Any lesion with extension along the portal vein, inferior vena cava or hepatic arteries
N	Extra-hepatic involvement of neighbouring organs
Nx	Not evaluable
N0	No regional involvement
N1	Involvement of neighboring organs or tissues
M	Absence or presence of distant metastasis
Mx	Not completely assessed
M0	No metastasis on chest radiograph and computer tomography brain scan
M1	Metastasis present

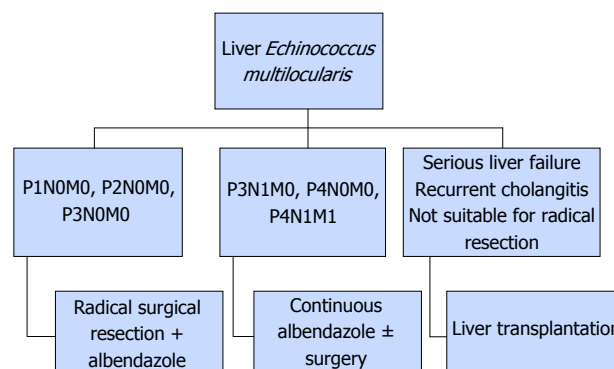

patients that have recurrent cholangitis, and patients unsuitable for radical surgery. Extrahepatic spread of AE during surgery is particularly hazardous in liver transplant recipients, due to drug-induced immunosuppression<sup>[10]</sup>. These patients are at risk of relapse<sup>[137]</sup>.

Although there is no information regarding the effectiveness of pre-operative pharmacotherapy, it is generally used for liver transplant recipients. Postoperative albendazole is recommended in all patients for at least 2 years<sup>[30,137]</sup>. Although there are alternative drugs such as mebendazole, praziquantel, and amphotericin, none is as effective as albendazole<sup>[138,139]</sup>. In a recently conducted study, it was revealed that nitazoxanide has no effect on the treatment of AE<sup>[140]</sup>.

Optimal duration of albendazole treatment in patients not treated by surgery is not clear. However, cases have been documented where albendazole was continuously used for up to 20 years without any complications<sup>[10]</sup>. The use of albendazole in patients who do not undergo surgical treatment increases the 15-year survival from 0% to 53%-80%<sup>[141-145]</sup>. Interventions such as endoscopic sclerosis of the varicose veins of the esophagus and stent implantation may be required during treatment<sup>[53]</sup>.

## CONCLUSION

*E. granulosus* and *E. multilocularis* infections are the most common parasitic diseases that involve the liver. Due to the typical slow growth, these often present in adulthood. Their symptoms include right upper quadrant abdominal pain, chlorosis, cholangitis, and anaphylaxis due to cyst rupture. AE is one of the most fatal helminthic infections. Ultrasonography plays a special role in diagnosis. WHO classification is used for staging and treatment selection. Immunological diagnostic methods are used to support the diagnosis. Cysts smaller than 5 cm (WHO stages CE1 and CE3a) are treated with albendazole only, while PAIR plus albendazole therapy is recommended for cysts > 5 cm.

**Figure 7** Treatment algorithm for *Echinococcus multilocularis* infection.

PAIR treatment for patients with CE2 and CE3b cysts is associated with frequent relapses. Therefore, broad tube percutaneous treatment should be considered in these cases. During open surgery and percutaneous treatment, all necessary efforts should be made to prevent dissemination of cyst contents; albendazole should be used at least for 4 d prior to such procedures and for 1 mo after the procedures. For AE, despite the fact that albendazole is not used preoperatively, postoperative treatment for 2 years is recommended. For CE, radical surgery is reported to be more effective than conservative surgery. For AE, the radical treatment option is also recommended as palliative surgery offers no advantages over medical treatment. Despite the fact that the general templates regarding the treatment seem clear, the lack of randomized clinical studies that compare the treatment options leads to failure in the selection of treatment.

### Abstract

Cirrhosis is a major cause of morbidity and mortality

worldwide with liver transplantations as it only possible cure. In the face of a significant organ shortage many patients die waiting. A major complication of cirrhosis is the development of portal hypertension and ascites. The management of ascites has barely evolved over the last hundred years and includes only a few milestones in our treatment approach, but has overall significantly improved patient morbidity and survival. Our mainstay to ascites management includes changes in diet, diuretics, shunt procedures, and large volume paracentesis. The understanding of the pathophysiology of cirrhosis and portal hypertension has significantly improved in the last couple of decades but the changes in ascites management have not seemed to mirror this newer knowledge. We herein review the history of ascites management and discuss some its current limitations.

**Key words:** Portal hypertension; Cirrhosis; Ascites; Transhepatic portosystemic shunts; Paracentesis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Few randomized control studies have been performed in the management of refractory ascites, of which all were performed either in the pre-model for end-stage liver disease (MELD) era or done in patients with low MELD scores. As such, most of the management guidelines have significant limitations in its utility for patients admitted to the hospital with significant hemodynamic dysfunction and other complications of cirrhosis. Our objective is to review the origins of our current management of refractory ascites and its limitations.

## INTRODUCTION

Ascites is the most common complication of liver cirrhosis, affecting over half of all cirrhotic patients within ten years of their cirrhosis diagnosis. The onset of ascites marks a critical point in the progression of liver disease, indicating a 50% mortality rate within 2-5 years<sup>[1]</sup>. Ascites is typically well managed with strict adherence to a low sodium diet and diuretic therapy<sup>[2]</sup>. However, in 10% of cirrhotic patients with ascites, maximal diuretic therapy is not effective<sup>[3]</sup>. In these patients with refractory tense ascites, repeated large-volume paracentesis (LVP) becomes the mainstay of chronic management.

LVP for treatment of refractory ascites is fast and effective. However, the removal of large fluid volumes may result in impaired circulatory function up to 6 d after paracentesis<sup>[4]</sup>. This complication, termed paracentesis induced circulatory dysfunction (PICD), is associated with a disruption in the renin-angiotensin axis and results in a hyperdynamic state<sup>[4]</sup>. Defined as an increase in the plasma renin activity by more than 50% of the pre-treatment value to a level of > 4 ng/mL per hour on the 6<sup>th</sup> day after paracentesis, PICD is clinically silent and not spontaneously reversible<sup>[5]</sup>. The occurrence of PICD is associated with a rapid recurrence of ascites, renal failure, and a significant decrease in the probability of survival.

Over the last three decades, only a few prospective studies with limited sample sizes and several large retrospective studies have examined PICD. Therefore, there continues to be a lack of understanding of PICD pathophysiology and management. The purpose of this review is to highlight the evidence supporting current guidelines for the management of patients with refractory tense ascites requiring repeated paracentesis.

## HISTORY OF MANAGEMENT OF TENSE REFRACTORY ASCITES IN CIRRHOTIC PATIENTS

### *The role of paracentesis in the management of ascites*

Paracentesis was first described for the management of tense ascites in the first half of the twentieth century. In the 1950's, however, paracentesis lost favor due to data associating ascitic fluid removal with complications such as hypotension, hyponatremia, acute kidney injury, and hepatic encephalopathy (HE)<sup>[6]</sup>. Two studies, one in 1967, by Knauer *et al*<sup>[7]</sup> and one by Guazzi *et al*<sup>[8]</sup> in 1975, reexamined the value of paracentesis, showing that removing between 1 and 5 L of fluid improved cardiac output (CO). They theorized that small volume removal improved CO by decreasing intra abdominal pressure, increasing venous drainage of the lower extremities, and increasing negative thoracic pressure. Several studies

have since been performed in order to understand the pathophysiology and management of refractory ascites (Table 1).

In 1985, Quintero *et al*<sup>[9]</sup> found that paracentesis with albumin replacement adversely affected hemodynamics, renal function, hospital readmission, and mortality when compared with diuretic therapy in patients treated for tense ascites. Later that same year, Kao *et al*<sup>[10]</sup> studied the effects of paracentesis on circulating blood volume and suggested that paracentesis was a safe therapy in the management of tense ascites secondary to chronic liver disease. This study provided a foundation for current paracentesis guidelines in the setting of cirrhosis in which the authors "arbitrarily selected a volume of 5 L," claiming 5 L of fluid removal to be "large enough to adequately decompress the distended abdomen while affording the patient a reasonable length of time before re-accumulation of ascites becomes a serious problem again". The 18 patient study with strict inclusion/exclusion criteria concluded that no untoward symptoms or findings were caused by 5 L paracentesis, specifically stating that no patients were found to have symptomatic orthostatic hypotension, hyponatremia, worsening renal function, acute renal failure, or HE relatable to paracentesis. The authors did note that all patients had pitting edema, which partially improved soon after paracentesis. They concluded that the absence of clinically significant effects from LVP in their patient cohort could partially be explained by the mobilization of peripheral edema replenishing the plasma volume as it rapidly equilibrated to the loss of ascetic fluid. Thus, the authors did not recommend that their findings be applied to patients without peripheral edema.

In 1987, Salerno *et al*<sup>[11]</sup> investigated the role of paracentesis as a therapy for ascites when compared with traditional diuretic therapy. The study included 41 patients randomized into 2 groups who either received LVP and intravenous (IV) albumin infusions of 20-60 g after each paracentesis or were treated with diuretics and did not receive paracentesis. Salerno concluded that LVP can be performed safely and successfully with equivalent outcomes to diuretics alone. Additionally, Salerno *et al*<sup>[11]</sup> included patients without pitting edema in their study, administering albumin to replace 60%-80% of the protein lost in paracentesis. The authors also found that LVP decreased hospital length of stay without additional risk.

In 1988, Ginès *et al*<sup>[12]</sup> demonstrated that paracentesis followed by IV administration of albumin decreased the risks of renal impairment, hyponatremia, and mortality by preventing systemic hemodynamic alterations. Their study included 105 patients randomized into 2 groups; Group A ( $n = 52$ ) underwent LVP followed by IV albumin infusion of 40 g and Group B ( $n = 53$ ) underwent LVP (4-6 L/d) only. Serious complications were observed in 9 (17%) patients in Group A and 16 (30%) patients in Group B. Hyponatremia and renal impairment were significantly more frequent in Group B, affecting 11 (21%) patients in Group B compared with 1 (2%) patient in Group A. These findings indicated that,

**Table 1 Studies evaluating large-volume paracentesis with albumin infusion and diuretic therapy in hospitalized patients with cirrhosis and refractory ascites**

Ref.	Study design	Results	Conclusions/comments
Quintero <i>et al</i> <sup>[9]</sup> , 1985	Total <i>n</i> : 72 Group 1: LVP and albumin - <i>n</i> of 38 Group 2: Diuretic therapy - <i>n</i> of 34	LVP with albumin had worse outcomes than diuretic therapy with adverse effects on hemodynamics, renal function, readmission, mortality	Diuretic therapy is better than LVP
Kao <i>et al</i> <sup>[10]</sup> , 1985	Total <i>n</i> : 18 underwent LVP of exactly 5 L Exclusion criteria: Cardiac disease chronic renal disease active intestinal bleed encephalopathy 500 mg/d Na and 1 L/d fluid restriction Diuretic discontinued 3 d prior	No untoward effects LVP of 5 L No symptomatic hypotension or hyponatremia No worsening or acute renal failure No encephalopathy Improved pitting edema	LVP is safe in patients with peripheral edema due to mobilization of fluid to intravascular space
Salerno <i>et al</i> <sup>[11]</sup> , 1987	Total <i>n</i> : 41 patients randomized into 2 groups Group A: Paracentesis + IV albumin: 20 patients Group B: Paracentesis + diuretics: 21 patients Exclusion criteria: Urinary sodium excretion rate > 20 mEq/d on a sodium-restricted diet and without diuretics Presence of cancer, encephalopathy, active gastrointestinal bleeding, renal failure, diabetes, infection, or primary cardiac disorders Hemoglobin < 9 g/dL Total bilirubin > 6 mg/dL Aminotransferases > 200 U/L Serum urea > 60 mg/dL Serum creatinine > 1.5 mg/dL	Deaths: Group A: 2/20 Group B: 3/21 Complications (encephalopathy, renal failure, and gastrointestinal bleeding): Group A: 3/20 patients Group B: 4/21 patients Group A: Satisfactory mobilization for ascites for 19/20 patients 4/20 patients did not reaccumulate ascites while 15/20 patients did reaccumulate ascites Group B: Resolution of ascites in 19/21 patients Diuretic treatment was unsuccessful for 2/21 Group B patients who were receiving the highest doses of diuretic therapy Group A: Mean body weight significantly reduced at all times after paracentesis, slight decrease in heart rate and urine osmolality (day 10). Increase noted in PAC (days 5 and 10) and urine flow rates (days 5, 10, and 15). Increased urine flow rates in 14 patients who also had significantly lower baseline urine excretions than the other 5 responsive Group A patients In the 19/21 responsive Group B patients, significant body weight reductions observed on days 10 and 15. Mean blood pressure and heart rate did not change. Significant increases noted in urine flow rate, sodium and potassium excretion, plasma albumin and potassium concentrations. Significant decrease in urine osmolality	LVP is faster and equally effective alternative to diuretic therapy and suggested that LVP might be used to decrease hospital length of stay without additional risk
Ginès <i>et al</i> <sup>[12]</sup> , 1988	105 patients randomized into 2 groups Group A: Paracentesis + IV albumin: 52 patients Group B: paracentesis without fluid replacement: 53 patients Exclusion criteria: Similar to study by Salerno <sup>[10]</sup>	Died in hospital: Group A: 2/52 Group B: 2/53 Deaths at 1 yr: Group A: 20/52 Group B: 16/53 Complications of hyponatremia, renal impairment, encephalopathy, gastrointestinal hemorrhage, and severe infection: Group A 9/52 Group B 16/53 Group A: Significant increase in serum albumin, GFR, free water clearance Group B: No change in serum albumin, significant increase in BUN, PRA, PAC, significant decrease in serum sodium PRA significant increase at 48 h and 5 d post LVP Group B 23/24 and 9/24 respectively Group A had none Readmission: Group A 29/52 Group B 36/53 Renal impairment: Group A: None Group B: 11/53	These findings indicated that, aside from systemic hemodynamics, there are likely multiple factors, such as renal production of vasodilators or ADH antagonists, which contribute to the development of renal failure

Ginès <i>et al</i> <sup>[5]</sup> , 1996	289 patients randomized into 3 groups	Deaths:	PICD found to not be spontaneously reversible and persists during follow-up
	Group A: Paracentesis + IV albumin: 97 patients	Group A 2/97	PICD associated with faster reaccumulation of ascites and impaired prognosis
	Group B: Paracentesis + Dextran 70: 93 patients	Group B 4/93	
	Group C: Paracentesis + Polygeline: 99 patients	Group C 6/99	
	Exclusion criteria: Similar to study by Salerno <sup>[10]</sup>	PICD (based on 280 patients who developed dysfunction and had PRA measured at baseline and 6 d after the procedure):	The authors suggest that albumin is more effective than dextran 70 or polygeline at preventing postparacentesis circulatory dysfunction and is the volume expander of choice for cirrhotics who undergo paracentesis with > 5 L of ascites removed
		Total 85/289	The authors discussed the pathophysiology of PICD, theorizing that PICD was most likely secondary to variable changes in neurohormonal responses, which accelerate the disease and lead to decreased long-term survival. They felt that PICD was unlikely due to a more advanced disease state, as patients with and without PICD did not differ in their degree of liver, renal, or hemodynamic function after paracentesis
		PRA > 50% increase (at 2 d after LVP) if PICD occurred: 47/85	
		PICD associated with shorter survival	
		Complications of hyponatremia, renal impairment, hepatic encephalopathy, gastrointestinal bleeding, bacterial infection	
		Group A: 28/97 patients, 30 complications	
		Group B: 28/93 patients, 43 complications	
		Group C: 30/99 patients, 39 complications	
		Incidence of death with PICD: 5/85	
		Incidence of death without PICD: 6/195	

LVP: Large-volume paracentesis; IV: Intravenous; PICD: Paracentesis induced circulatory dysfunction; ADH: Antidiuretic hormone.

aside from systemic hemodynamics, there are likely multiple factors, such as renal production of vasodilators or antidiuretic hormone (ADH) antagonists, which contribute to the development of renal failure.

In 1988, Pinto *et al*<sup>[13]</sup> and Gentile *et al*<sup>[14]</sup> both independently studied the hemodynamic and hormonal impacts of LVP of exactly 5 L in 12 non-edematous cirrhotic patients. Both studies concluded that LVP of 5 L could be safely performed without significant changes in plasma volumes, PRA, or vasopressin. They did, however, note a significant decrease in diastolic pressure and a significant increase in aldosterone, which corresponded with reduced urinary sodium excretion.

In 1990, Panos *et al*<sup>[15]</sup> confirmed an earlier finding of Simon *et al*<sup>[16]</sup> in 1987 that, up to 3 h after LVP, CO increased, right atrial pressure decreased, and pulmonary capillary wedge pressure (PCWP) remained the same. After 3 h post-LVP, right atrial pressure, PCWP, and CO all decreased significantly. These findings indicated that, although paracentesis initially results in hemodynamic improvement, a relative hypovolemia occurs hours after paracentesis.

Two studies in 1990 and two in 1991 evaluated the effect of various IV infusions to prevent hypovolemia after LVP<sup>[17]</sup>. The studies included comparisons between albumin, dextran-70, dextran-40, hemaccel, and saline<sup>[18]</sup>. They concluded that dextran-70, albumin, and hemaccel were all equally effective in preventing renal and electrolyte complications, while dextran-40 was ineffective. A third study by Cabrera *et al*<sup>[19]</sup> in 1990 found that IV saline prevented hypovolemia with no changes in PRA or aldosterone.

Albumin was effective in preventing hypovolemic complications, however, it was a costly product. To investigate possible alternatives, Planas *et al*<sup>[18]</sup> conducted a

randomized trial comparing the efficacy of three different plasma expanders for preventing, PICD. PICD was defined as an increase in PRA of more than 50% of the pretreatment value to a level of > 4 ng/mL per hour on the 6<sup>th</sup> day after paracentesis. This pretreatment value was determined by the upper value of PRA found in 36 healthy subjects studied on a 50-mmol/d sodium diet and was arbitrarily chosen to represent physiologically relevant activation of the renin-angiotensin system. In the study of Planas *et al*<sup>[18]</sup>, patients were randomized to receive one of the three infusion types: Albumin, dextran-70, or polygeline. Eighty-five patients developed PICD, with a significantly greater frequency when treated with dextran-70 (34.4%) and polygeline (37.8%) than when treated with albumin (18.5%). Additionally, they found a significantly higher 6-mo mortality rate in patients who develop PICD. They further concluded that PICD was predictive in fluid removal > 5 L with the use of dextran-70 or polygeline. This trend did not appear in patients receiving > 5 L of fluid removal followed by albumin infusion. The authors discussed the pathophysiology of PICD, theorizing that PICD was most likely secondary to variable changes in neurohormonal responses, which accelerate the disease and lead to decreased long-term survival. They felt that PICD was unlikely due to a more advanced disease state, as patients with and without PICD did not differ in their degree of liver, renal, or hemodynamic function after paracentesis.

The following year, in 1997, Ruiz-del-Arbol *et al*<sup>[20]</sup> demonstrated an inverse correlation between PRA and systemic vascular resistance (SVR) associated with PICD. Out of the 37 patients who underwent LVP (mean > 7 L) followed by a dextran-70 infusion, 10 (27%) developed PICD. More specifically, they found that despite the normalization of PRA, aldosterone, and norepinephrine

by the 6<sup>th</sup> day after paracentesis, cardiopulmonary pressures and SVR remained lower than baseline. The authors believed that LVP is an inciting event that leads to an accentuation of the vasodilatory response already present in cirrhotic patients. This exaggerated vasodilatory response then causes an increase in PRA to compensate for increases in SVR. In addition, utilizing a transjugular intrahepatic venous catheter they found that the hepatic venous pressure gradient did not change in patients without PICD but increased significantly, secondary to PRA, if PICD occurred. They theorized that this was also likely due to endogenous vasoactivation.

In 1998, Vila *et al*<sup>[21]</sup> confirmed these conclusions and also found that if effective hypovolemia did not develop, there were no significant changes in CO, CVP, or SVR and there was a significant reduction in PRA at the 1 and 3 h period after paracentesis. In contrast, if effective hypovolemia did develop, there were significant reductions in CO, CVP and SVR, no change in PRA or aldosterone level, and an increase in CO. This paradoxical finding was believed to be due to physiological responses secondary to abrupt falls in intraabdominal pressure after paracentesis procedures.

In a pilot study in 2002, Moreau *et al*<sup>[22]</sup> compared the effect of terlipressin and albumin on arterial blood volume in 20 cirrhotic patients who underwent paracentesis. Assuming that PICD is predominantly caused by exacerbation of an already dilated arterial system, the authors theorized that terlipressin, a vasoconstrictor, may prevent PICD more effectively than albumin. After paracentesis, 10 patients received albumin and the other 10 received terlipressin. They found that both treatments had the same beneficial effect of preventing arterial vasodilation. The authors favored the use of terlipressin, arguing for cheaper cost.

In 2003, Sola-Vera *et al*<sup>[23]</sup> compared PICD in 37 patients receiving albumin and 35 patients receiving saline infusion after LVP. They found that patients who received saline had a significant increase in PRA and PAC on the 6<sup>th</sup> day after paracentesis, which contradicted data published by Cabrera *et al*<sup>[19]</sup> in 1990. Only 11% of patients developed PICD after albumin infusion compared to 33% after saline infusion. If < 6 L was removed, the PICD was similarly low in both groups (6.7% in albumin group vs 5.6% in saline group). Additionally, they found that nitric oxide (NO) was elevated in the saline group and likely contributed to the pathogenesis of PICD.

The prevention of PICD using albumin infusion was compared to the use of midodrine post-paracentesis in a study by Appenrodt *et al*<sup>[24]</sup> in 2008. They performed a blinded study in 24 patients with tense ascites and included patients with similar comorbidities as prior studies. Additionally, since this study was conducted after the inception of MELD scoring in 2002, they reported a mean MELD of 11 in both the midodrine and albumin groups. Midodrine was given immediately after paracentesis at a dose of 12.5 mg orally every 8 h for 2 d. In the midodrine group, they found a large, but

insignificant, increase in the PRA level on day 6 after paracentesis. They concluded that the use of midodrine was less effective than albumin in preventing PICD.

In 2010, Nasr *et al*<sup>[25]</sup> evaluated the risk factors for PICD. The study included 45 patients with cirrhosis and used similar inclusion criteria as the prior studies mentioned. The patients received either albumin or dextran-70 post-paracentesis and the volume removed ranged from 8 to 18 L. They evaluated several demographic, clinical and laboratory factors, and found, based upon logistic regression analysis, that only the use of dextran-70 and younger age were independent predictors of PICD.

A multicenter trial including 26 patients was published in 2011 by Fimiani *et al*<sup>[26]</sup>. This trial evaluated the impact of a combination of diuretics, albumin, and terlipressin in treating tense ascites. The study examined several clinical factors after paracentesis, including ascites recurrence, body weight, abdominal circumference, and urinary sodium excretion. The combination of changes in these factors was given a grade of severity and a degree of response. Based upon these definitions, they concluded that combination treatment decreased the need for repeated LVP, improved urinary sodium, reduced abdominal circumference, and decreased the severity of ascites.

In the same year, Alessandria *et al*<sup>[27]</sup> compared the efficacy of different volumes of post-paracentesis albumin infusion, comparing the incidence of PICD between patients who received 4 g of albumin per liter of fluid removed and patients who received 8 g of albumin per liter of fluid removed. They found the same incidence of PICD, hyponatremia, and renal failure in both groups and concluded that half the standard dose of albumin is as effective and safe as the full standard dose in patients undergoing paracentesis.

In 2013, Carl *et al*<sup>[28]</sup> performed a small trial including 10 patients with the purpose of studying the relationship between inflammation and PICD after LVP. They looked at several factors over a 24-h period, including blood pressure, BUN, creatinine (Cr), PRA, aldosterone, angiotensin II, asymmetrical dimethylarginine (ADMA), norepinephrine, CD14, interleukin-6, tumor necrosis factor- $\alpha$ , and monocyte chemoattractant protein-1 (MCP-1). Both MCP-1 and CD14 increased concurrently while blood pressure decreased in the 24 h after LVP. These results suggested that the inflammatory cascade may be involved in the genesis and severity of PICD.

### **The role of transhepatic portosystemic shunts in the management of ascites**

Until 1996, large volume paracentesis was the standard therapy for refractory tense ascites. Although this was proven to be an effective treatment approach, it did not address the underlying issue of portal hypertension. After LVP, ascites would quickly re-accumulate and require repeated paracentesis. On the other hand, a transhepatic portosystemic shunts (TIPS) has the potential to mitigate portal hypertension by diverting portal blood flow from the liver directly into the systemic

venous circulation *via* an intrahepatic shunt. Several studies have been conducted comparing TIPS to LVP<sup>[29]</sup> (Table 2).

In 1996, Lebrech *et al.*<sup>[30]</sup> compared the effect of TIPS and LVP in 25 cirrhotic patients with refractory ascites who were randomized to TIPS or repeat LVP. The authors concluded that intrahepatic shunts were selectively effective in patients with Childs-Pugh class B, although they did not improve survival, and actually decreased survival in class C patients compared to LVP. They believed that the prominent factor is ascites management were dependent on both neurohormonal factors which control natriuresis and the hepatic sinusoidal pressures.

In 2000, Rössle *et al.*<sup>[31]</sup> conducted a similar randomized study in 60 patients comparing TIPS to LVP. Fifteen of the 29 TIPS patients died while 23 of the 31 LVP patients died at 1 year. Although 10 patients required rescue shunt treatment, no deaths or long-term illnesses occurred secondary to the shunting procedure. In comparison with LVP, the creation of a transjugular intrahepatic portosystemic shunt can improve the chance of survival without liver transplantation in patients with refractory or recurrent ascites.

In 2002, Ginès *et al.*<sup>[32]</sup> published a study comparing survival rates and associated healthcare costs between patients receiving TIPS and patients receiving paracentesis with albumin replacement. Seventy cirrhotic patients with refractory ascites were selected for the study and randomly assigned to either undergo TIPS ( $n = 35$ ) or repeat LVP ( $n = 35$ ) with albumin infusions. MELD scores were not used, as this study was conducted prior to the start of MELD scoring. They concluded that TIPS lowers the rate of ascites recurrence and the risk of developing hepatorenal syndrome, but does not improve survival and has increased occurrence of encephalopathy and higher cost than LVP.

In 2003, Sanyal *et al.*<sup>[33]</sup> also compared TIPS to LVP in 109 patients with refractory ascites. The LVP group consisted of 57 patients who received low sodium diets, diuretics, and LVP. The TIPS group consisted of 52 patients who received TIPS in addition to the same low sodium diets and diuretics as the LVP group. In the first year following randomization, they found that 22 (42%) TIPS patients and 48 (84%) LVP patients required repeat LVP's for recurrent tense ascites. The average rate of paracentesis per patient in the first year was 1.69 for TIPS patients and 6.11 per year for LVP patients. Mortality was 21 (40%) in the TIPS group and 21 (37%) in the LVP group. Sixteen (31%) TIPS patients and 17 (30%) LVP patients received liver transplants.

In 2004, Salerno *et al.*<sup>[34]</sup> randomized 65 cirrhotic patients with refractory ascites into 2 groups. Thirty-two patients received TIPS and 33 patients received LVP. Mean baseline MELD was  $11.1 \pm 0.8$  in the TIPS group and  $11.1 \pm 0.9$  in the LVP group. The Cox proportional hazard model indicated that the treatment assigned and MELD scores were independent predictors of mortality. In 2007, Salerno *et al.*<sup>[35]</sup> published a meta-analysis based

upon individual patient data on outcomes of TIPS for refractory ascites. The study included all published data from randomized control trials with available patient data. This excluded the study by Lebrech *et al.*<sup>[30]</sup>, which was the only study to show a negative effect of TIPS on survival. Salerno *et al.*<sup>[35]</sup> concluded: (1) TIPS improves transplant-free survival compared to LVP; (2) patient survival is independently associated with age, bilirubin levels, and serum sodium concentrations; (3) the risk of ascites recurrence is decreased with TIPS; (4) the probability of HE after TIPS is increased; and (5) patients with low arterial pressure, high MELD score, and low portosystemic pressure gradient after TIPS have the greatest probability of experiencing post-TIPS HE.

## **PATHOPHYSIOLOGY OF PICD**

Over the last three decades, as LVP has become more widely accepted as the standard first line approach in treating refractory tense ascites, we have gained further insight into the pathophysiology of PICD. Portal hypertension is a major sequel of cirrhosis and occurs secondary to increases in intrahepatic resistance to portal blood flow<sup>[36]</sup>. The deposition of collagen in the hepatic acinus of the cirrhotic patient leads to narrowing of the sinusoidal lumen, compression of the venules due to regenerative nodules, the development of fibrosis, and portal inflammation<sup>[1]</sup>. Each of these sequelae contribute to liver stiffness, which resists the inflow of portal blood<sup>[37]</sup>. In addition to these structural changes, there are several neuro-hormonal factors that alter the contractile tone of intrahepatic endothelial cells<sup>[38]</sup>. Shear stress and bacterial translocation occurs, leading to endothelial dysfunction in the pre-sinusoidal areas. This causes the release of NO and the increased production of COX-derived prostanoids<sup>[2]</sup>. The combination of portal blood flow resistance due to cirrhosis and increased arterial inflow from splanchnic vasodilation leads to portal hypertension. Portal hypertension is maintained by the opening of portal-systemic collaterals as well as the generation of new vessels *via* angiogenesis. Splanchnic vasodilation is mediated by several substances, including glucagon, prostacyclin, intestinal vasoactive peptide, histamine, substance P, estrogens, cholecystokinin, ammonia, endotoxins, adenosine, biliary acids, NO, alpha-calcitonin gene-related peptide, vascular endothelial growth factor, adenomedullin, carbon monoxide, and endogenous cannabinoids<sup>[39]</sup>.

There is a complex and relatively poorly understood interaction between these mediators in controlling blood flow. Recently, it has been suggested that NO plays a prominent role. However, several *in vitro* studies have demonstrated variable changes in compensatory factors when NO is inhibited or promoted, suggesting that its control is not the only important factor. In response to the release of vasodilators in the splanchnic system, there is a release of vasoconstrictors. Due to the high levels of NO and CO, these vasoconstrictors have a blunted effect on splanchnic circulation and mostly affect the kidneys

**Table 2 Randomized control studies evaluating transhepatic portosystemic shunts vs paracentesis in patients with cirrhosis and refractory ascites**

Ref.	Study design	Results	Conclusions/comments
Lebrec <i>et al</i> <sup>[30]</sup> , 1996	Total of 25 13 TIPS 12 LVP Excluded: Age > 70 Severe diseases other than liver Pulmonary hypertension Hepatocellular carcinoma Hepatic encephalopathy Sepsis/spontaneous bacterial peritonitis Severe alcoholic hepatitis Portal/hepatic vein obstruction/ thrombosis Obstruction of biliary tract or hepatic artery Plasma creatinine > 150 mmol/L	Deaths: TIPS - 9/13 LVP - 4/12 3/13 TIPS unsuccessful, of the remaining 10/13 TIPS patients: 8 required a second shunt and 2 required 3 shunts 1/12 LVP patients received liver transplant Survival at 2 yr with "intention to treat" analysis 29% $\pm$ 13% for TIPS and 60% $\pm$ 16% for LVP Survival at 2 yr with "per protocol" analysis was 38% $\pm$ 16% for TIPS and 70% $\pm$ 15% for LVP	The authors concluded that intrahepatic shunts were selectively effective in patients with Childs-Pugh class B, although they did not improve survival, and actually decreased survival in class C patients compared to LVP. They believed that the prominent factor is ascites management were dependent on both neurohormonal factors which control natriuresis and the hepatic sinusoidal pressures
Rössle <i>et al</i> <sup>[31]</sup> , 2000	Total of 60 patients Randomized to 2 groups: TIPS 29/60 LVP 31/60 Excluded: Hepatic encephalopathy > Grade 2 Serum bilirubin > 5 mg/dL Serum creatinine > 3 mg/dL Portal-vein thrombosis Hepatic hydrothorax Advanced cancer Continual ascites after paracentesis or multiple paracentesis within 1 wk	Deaths: TIPS - 15/29 LVP - 23/31 13/29 patients had shunt insufficiency, 11/29 underwent reestablishment of the shunt after 10 $\pm$ 16 mo and 5 of these patients required a second reestablishment 1/29 TIPS patients received liver transplant 2/31 LVP patients received liver transplant These patients were alive 60 mo following transplant Of the patients assigned to paracentesis in whom this procedure was unsuccessful, 10 received a transjugular shunt a mean of 5.5 $\pm$ 4 mo after randomization; 4 had a response to this rescue treatment Estimated probability of survival without transplant: TIPS: 69% and 58% at 1 and 2 yr; LVP: 52% and 32% at 1 and 2 yr In a multivariate analysis, treatment with transjugular shunting was independently associated with survival without the need for transplantation ( $P = 0.02$ ) At three mo, 61% of the patients in the shunt group and 18% of those in the paracentesis group had no ascites ( $P = 0.006$ ) Age > 60 yr, female sex, bilirubin > 3 mg/dL, and serum sodium < 125 mmol/L significantly decreased survival in the TIPS group	In comparison with large-volume paracentesis, the creation of a transjugular intrahepatic portosystemic shunt can improve the chance of survival without liver transplantation in patients with refractory or recurrent ascites
Ginès <i>et al</i> <sup>[32]</sup> , 2002	Total of 70 patients randomized into 2 groups TIPS: 35 LVP + Albumin (8 g/L ascites removed): 35 Primary endpoint: Survival without liver transplantation Secondary endpoints: Complications of cirrhosis and cost Excluded: < 18/> 75 years old Serum bilirubin > 10 mg/dL Prothrombin time < 40% Platelet count < 40000/mm <sup>3</sup> Serum creatinine > 3 mg/dL Hepatocellular carcinoma Complete portal vein thrombosis Cardiac/respiratory failure Organic renal failure Bacterial infection Hormonal measurements (plasma renin	Deaths: TIPS 20/35 LVP 18/35 Transplanted: TIPS 7/35 LVP 7/35 1 TIPS patient required repeat LVP's 3 LVP patients required TIPS placement Ascites recurrence: TIPS - 17 patients developed 60 episodes of ascites (30 episodes attributed to 1 patient who experienced a total occlusion of their shunt), LVP - 29 patients developed 341 episodes of ascites Median time of the first recurrence of ascites: TIPS - 171 d LVP - 20 d 13 TIPS patients experienced shunt dysfunction	They concluded that TIPS lowers the rate of ascites recurrence and the risk of developing hepatorenal syndrome, but does not improve survival and has increased occurrence of encephalopathy and higher cost than LVP

	activity, aldosterone, norepinephrine, and atrial natriuretic peptide) were measured at 1 wk, 1 mo and 6 mo in 18 TIPS patients and 23 LVP patients	Total costs for TIPS patients (calculated separately in United States dollars on intention-to-treat basis from Spanish and then United States hospitals that participated in the study) demonstrated that total costs and costs per patient were greater in the TIPS group TIPS \$693460, or \$19813 per patient. LVP patients were \$341760, or \$9765 per patient	
Sanyal <i>et al</i> <sup>[33]</sup> , 2003	109 patients with refractory ascites were randomized into 2 groups 52 patients received TIPS with medical therapy (low sodium diets, diuretics, and LVP) 57 patients received medical therapy without TIPS Excluded: Similar criteria to prior studies All patients placed on low Na diets and diuretics All patients placed on low Na diets and diuretics Diuretics stopped 5 d prior to LVP Albumin infusion followed LVP at 6-8 g/L removed TIPS patients received shunts Some patients from both groups received repeat LVP's plus Albumin for tense, symptomatic ascites with weight gain > 10 pounds	Deaths: TIPS - 21/52 LVP 21/57 Failed Treatments: TIPS 3/52 unsuccessful LVP 2/57 patients required TIPS Failed treatments in the first year after randomization requiring repeat LVP for tense ascites: TIPS - 22/52 LVP 48/57 Average rate of LVP per patient in the first year after randomization: for TIPS - 1.69 LVP - 6.11 Transplants: TIPS 16/52 LVP 17/57	Although TIPS plus medical therapy is superior to medical therapy alone for the control of ascites, it does not improve survival, affect hospitalization rates, or improve quality of life
Salerno <i>et al</i> <sup>[34]</sup> , 2004	66 patients randomized into 2 groups TIPS group: 33 LVP + Albumin group: 33 Excluded: Similar criteria to prior studies Diuretic doses continued throughout the study and doses adjusted for each patient's clinical needs All patients on low Na diets (80 mg/d) TIPS placed LVP patients received Albumin replacements at 8 g/L ascites removed Patients discharged and followed at 1, 3 and 6 mo, then every 3-6 mo or as clinically necessary Mean follow up time was 18.2 ± 2.3 mo	Deaths: TIPS - 13/33 LVP - 20/33 Failed treatments: TIPS - 3/33 Initial LVP - 0/33 reported Estimated probability of survival at 1 yr: TIPS - 77% LVP - 52% Estimated probability of survival at 2 yr: TIPS 59% LVP 29% Transplanted: TIPS 4/33 LVP 4/33 Cox proportional hazard model indicated that treatment assigned and MELD scores were independent predictors of mortality Failure of treatment noted in 7/33 TIPS patients: 2 patients received LeVeen Shunts and 5 LVP's Failure of treatment noted in 19/33 LVP patients: 1 received a LeVeen Shunt, 11 received TIPS, and 7 elected to continue with LVP treatment	Treatment failure was more frequent in patients assigned to paracentesis, whereas severe episodes of hepatic encephalopathy occurred more frequently in patients assigned to TIPS The number and duration of re-hospitalizations were similar in the two groups Compared to large-volume paracentesis plus albumin, TIPS improves survival without liver transplantation in patients with refractory ascites

LVP: Large-volume paracentesis; TIPS: Transhepatic portosystemic shunts; MELD: Model for end-stage liver disease.

and the brain<sup>[39]</sup>.

Splanchnic vasodilation leads to an abnormally increased distribution of blood into the mesenteric circulation. Over time, there is an exaggerated disequilibrium of blood supply between the central and non-central volumes, characterized by a decrease in the central (heart, lungs, and brain) blood volume and an increase in the non-central (splanchnic) blood volume. These shifts in blood volume are not clinically significant in the early stages of cirrhosis but become more relevant

as the disease worsens. With the development of non-central vasodilation and pooling of blood in the mesenteric circulation, there is an initial compensatory increase in CO and a decrease in MAP and SVR. With the activation of baroreceptors, this is accentuated over time, causing further increases in CO and heart rate. As the sympathetic nervous system, renin-angiotensin-aldosterone system, arginine-vasopressin, and endothelin responses heighten, renal vascular resistance increases. This increase causes vasoconstriction and decreased

renal blood flow leading to sodium and water retention. Over time, as more blood volume sequestration occurs in the splanchnic system, the compensatory mechanisms are unable to sustain blood flow, leading to tissue hypoxemia and end-organ damage. This cascade of pathophysiological responses to portal hypertension is termed hyperdynamic circulatory syndrome and is generally characterized by an increase in CO and heart rate and a decrease in SVR and MAP<sup>[36]</sup>.

Most patients who require LVP to manage refractory ascites exhibit hyperdynamic physiology, with increased CO and heart rate and decreased MAP. Generally after paracentesis, there is an immediate and significant decrease in intraabdominal pressure. This leads to initial hemodynamic improvement, increasing CO as venous return and negative thoracic pressures improve. In general if less than 5 L of fluid is removed, there appears to be no ill effects of paracentesis. If > 5 L, or an "LVP", is performed, relative hypovolemia develops hours after the procedure<sup>[40]</sup>. This causes a series of complex neuro-hormonal responses that are not well understood. It appears that within 1 h after LVP, there is an increase in cardiac index and an associated decrease in SVR. There are discrepant findings in the literature regarding the pathophysiological cause of the decrease in SVR. However, it may be related to improved CO alone or changes in both the renin-angiotensin system and the sympathetic nervous system. The exact neurohormonal changes, sequence of events, progression over time, and impact on the cardiovascular and renal systems are also not clear. Overall, the initial improvement in hemodynamics after paracentesis is followed by a relative hypovolemia. This leads to circulatory dysfunction demonstrated by increased PRA, ADH, and aldosterone levels and decreased MAP and SVR. This constellation of events, termed PICD, is most commonly associated with hyponatremia and renal insufficiency<sup>[5]</sup>.

## SUMMARY AND CURRENT CLINICAL PRACTICE GUIDELINES ON MANAGEMENT OF REFRACTORY ASCITES

Refractory ascites is defined as fluid overload that is unresponsive to high-dose diuretics (spironolactone 400 mg/d and furosemide 160 mg/d) and sodium-restrictive diets, recurring rapidly after therapeutic paracentesis<sup>[36]</sup>. Diuretic therapy is considered to have failed when there is minimal or no weight loss coupled with poor urinary sodium restriction (< 78 mmol/d) or when there are clinical complications of encephalopathy, serum Cr > 2.0 mg/dL, serum sodium < 120 mmol/L, or serum potassium > 6.0 mmol/L. Initial failure of diuretic therapy should be treated medically (fluid restriction, sodium restriction, and diuretic therapy), followed by serial LVP while awaiting liver transplant. If LVP is not feasible, TIPS or surgical peritoneovenous shunting is recommended<sup>[1,41]</sup>.

The American Association for the Study of Liver Disease (AASLD), the European Association for the Study of Liver Disease, and International Ascites Club have written review articles and recommended summary guidelines for the management of ascites secondary to portal hypertension in cirrhotic patients. The most recent AASLD practice guideline update, published in 2012 by Runyon, made several recommendations for treating cirrhotic patients diagnosed with refractory ascites. The guidelines stated that: (1) beta blockers should be discontinued or not initiated due to risks of complications of systemic hypotension and evidence of decreased survival (Class III, Level B); (2) angiotensin converting enzyme inhibitors should be avoided due to complications of hypotension (Class III, Level B); (3) in patients with hypotension, randomized trials have shown that oral midodrine (7.5 mg TID) improves urinary volume, urine sodium, MAP, and survival theoretically due to its ability to improve blood pressure and convert patients from diuretic-resistant to diuretic-sensitive (Class II a, Level B); (4) after discontinuation of beta blockers and administration of midodrine, refractory ascites should be treated with serial LVP (Class I, Level C); (5) following a single paracentesis of < 4-5 L, albumin infusion may not be required to prevent PICD (Class I, Level C); (6) LVP (> 5 L), requires albumin infusion of 6-8 g/L of fluid removed to improve survival (Class II a, Level A); (7) TIPS should be considered in patients who meet criteria as described in above mentioned randomized trials but is considered a second line therapy after LVP (Class I, Level A); and (8) peritoneovenous shunting should be performed if patients are not candidates for paracentesis, TIPS, or transplant (Class II b, Level A). These are the current management guidelines to which most transplant centers in North America adhere.

## ISSUES AND CONTROVERSIES

In our review of the literature regarding the management of refractory ascites, there are several major issues. The first liver transplant was performed in 1963 but it did not become a practical therapy for patients with end-stage liver disease until the 1980's when the use of cyclosporine for preventing organ rejection allowed long-term patient survival. Research efforts in cirrhosis have since intensified, but the pathophysiology of the complications of cirrhosis remain incompletely understood. As such, research has tended to compartmentalized each of the various complications. While many complex diseases are evaluated using this method of scientific research, cirrhosis may require a more holistic approach since cirrhosis occurs affects essentially every organ system in the body during its progression.

Our current understanding of ascites and its management seems to be based, in large measure, on evidence and observations derived from research performed decades ago. Furthermore, the evidence is based on a focused perspective rather than a global one and does not take into account the dynamic and evolving

systemic nature of cirrhosis.

Large volume paracentesis is defined as a volume of > 5 L. This amount of fluid removal is somewhat arbitrary, originally coined in 1987 by Kao *et al.*<sup>[10]</sup> based upon a description of the volume required to “flatten the abdomen”. Since then, LVP of > 5 L has been used universally as the gold standard when considering fluid replacement. We could not find a single study that examined the impact of variations in paracentesis volume on neuro-hormonal changes in equivalent patients. Hence, we would challenge the validity of defining a 5 L paracentesis as what constitutes a “large volume”.

In addition, a paracentesis volume of > 5 L is considered the amount above which PICD occurs. Before 1986, there were few studies that analyzed patients with paracentesis of < 5 L. In the studies published since 1986, which evaluate the impact of fluid replacement, neuro-hormonal responses, and effects of medications on PICD, the mean volumes of paracentesis were always > 5 L. Thus, it is unclear how the conclusion that a paracentesis of > 5 L causes PICD can be made when no significantly sized group of similar patients with < 5 L fluid removal have been compared. It is likely that the occurrence of physiologically significant changes after paracentesis are dependent upon a multitude of factors and not only on this “minimum” amount of 5 L of removal.

Patient volume status, fluid responses, medication doses, and many other physiological effects are based upon patient sex, height, weight, muscle mass, renal function, or body mass index (BMI). Along the same lines, one would assume that the effect, responses, and management of fluid shifts in cirrhotic patients undergoing paracentesis should be affected similarly. The accepted management guidelines for refractory ascites requiring paracentesis does not incorporate any of these principles and is instead based only on a removal volume of > 5 L. Although never studied, it is more likely that physiological responses after paracentesis in cirrhotic patients have a graded effect based upon variables such as milliliter of fluid removed per kilogram body weight, BMI, muscle mass, and sex.

Additionally, the definition of PICD as “an increase in the plasma renin activity by more than 50% of the pretreatment value to a level of > 4 ng/mL per hour on the 6<sup>th</sup> day after paracentesis” appears to have been arbitrarily created based upon the mean PRA levels of 36 healthy subjects. Studies conducted based upon this definition showed that PICD is associated with decreased 6-mo survival. It can be safely concluded that there is survival disadvantage when untoward effects of paracentesis occur, but it is not exactly clear what the “cut-off” values of PRA should be. Another approach may be to linearly determine the effect of changes in PRA on mortality and hence determine what correctly defines LVP. Because PICD has been associated with hyponatremia and renal insufficiency, there may be some utility in proving end organ damage. However, it is not clear how this can be

achieved in cirrhotic patients who already have significant multi-organ compromise. One crude method would be to assess mixed venous oxygenation or lactate levels at different time points after paracentesis.

Our current management guidelines for refractory ascites and PICD are based upon physiological effects of LVP determined in studies conducted before the inception of MELD scoring in 2002. Although individual patient data is not available, based upon the patient characteristics published in each manuscript, the mean MELD scores of the groups of patients included in these studies appears to be < 15. In our current era, the mean MELD at the time of transplant ranges from 23-35 depending on the UNOS Region. Given this difference in disease severity, the effects of paracentesis established in previous studies may not be applicable in patients with more advanced cirrhosis. There is no published data comparing the effects of similar volumes of paracentesis with more progressive cirrhosis or higher MELD scores.

Furthermore, all of these studies had very strict inclusion criteria, excluding patients with common cirrhosis complications, such as HE, active gastrointestinal bleeding, renal failure, diabetes, infection, cardiac disorders, hemoglobin < 9 g/dL; total bilirubin lower than 6-10 mg/dL; and serum creatinine < 1.5-3 mg/dL, or platelet count > 40000. As cirrhosis progresses, most patients develop these complications and begin to exhibit hyperdynamic physiology. These patients often have refractory ascites and require more frequent paracentesis. However, the exact same paracentesis guidelines are applied in these patients with decompensated cirrhosis as in patients with a MELD < 15. It is likely that patients with advanced cirrhosis lack the pathophysiological reserve to compensate for paracentesis-induced fluid shifts. It is therefore imperative that we continue to examine the evolving hemodynamic and neurohormonal responses in this sicker group of patients and adjust the way we manage paracentesis and PICD.

## CONCLUSION

Paracentesis is a mainstay for the treatment of refractory ascites in patients with cirrhosis. There is clear evidence that there is a decrease in survival in patients who undergo paracentesis and develop circulatory dysfunction. Our current guidelines for the management of patients requiring paracentesis are founded on a few studies from several decades ago, which include only patients with well-compensated cirrhosis. Moreover, current guidelines are based on definitions of LVP and PICD created arbitrarily and without a significant amount of comparative evidence. Yet, we continue to apply these guidelines to all cirrhotic patients with ascites, regardless of patient demographics, co-morbidities, or degree of disease decompensation. A more acute and discriminating understanding of the acute neuro-hormonal, hemodynamic, and end organ effects of fluid shifts and how these factors impact patients with more

decompensated cirrhosis is needed.

## Abstract

### AIM

To clarify whether *Agtr1a* methylation is involved in the development of nonalcoholic steatohepatitis (NASH)-related liver fibrosis in adult rats.

### METHODS

A choline-deficient amino acid (CDAA) diet model was employed for methylation analysis of NASH-related liver fibrosis. *Agtr1a* methylation levels were measured in the livers of CDAA- and control choline-sufficient amino acid (CSAA)-fed rats for 8 and 12 wk using quantitative methylation-specific PCR. Hepatic stellate cells (HSCs) were isolated by collagenase digestion of the liver, followed by centrifugation of the crude cell suspension through a density gradient. *Agtr1a* methylation and its gene expression were also analyzed during the activation of HSCs.

## RESULTS

The mean levels of *Agtr1a* methylation in the livers of CDAA-fed rats (11.5% and 18.6% at 8 and 12 wk, respectively) tended to be higher ( $P = 0.06$  and  $0.09$ , respectively) than those in the livers of CSAA-fed rats (2.1% and 5.3% at 8 and 12 wk, respectively). *Agtr1a* was not methylated at all in quiescent HSCs, but was clearly methylated in activated HSCs (13.8%,  $P < 0.01$ ). Interestingly, although *Agtr1a* was hypermethylated, the *Agtr1a* mRNA level increased up to 2.2-fold ( $P < 0.05$ ) in activated HSCs compared with that in quiescent HSCs, suggesting that *Agtr1a* methylation did not silence its expression but instead had the potential to upregulate its expression. These findings indicate that *Agtr1a* methylation and its upregulation of gene expression are associated with the development of NASH-related liver fibrosis.

## CONCLUSION

This is the first study to show that DNA methylation is potentially involved in the regulation of a renin-angiotensin system-related gene expression during liver fibrosis.

**Key words:** Epigenetics; DNA methylation; Angiotensin II receptor; Liver fibrosis; Nonalcoholic steatohepatitis

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** We report the first study to show that *Agtr1a* methylation occurred during the development of nonalcoholic steatohepatitis-related liver fibrosis. Interestingly, *Agtr1a* gene expression was upregulated during liver fibrosis, although *Agtr1a* was methylated. This study demonstrates for the first time that renin-angiotensin system-related gene expression is regulated by DNA methylation during liver fibrosis. This finding raises expectations about the therapeutic application of demethylating agents for the treatment of liver fibrosis.

DNA methylation of angiotensin II receptor gene in nonalcoholic steatohepatitis-related liver fibrosis. *World J Hepatol* 2016; 8(28): 1194-1199 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i28/1194.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i28.1194>

## INTRODUCTION

Liver fibrosis is a characteristic feature of chronic liver disease regardless of the etiology. Cirrhosis is the terminal condition of chronic liver diseases, and hepatic failure due to liver cirrhosis is caused by progressive fibrosis that ultimately results in nodular regeneration with loss of function<sup>[1-3]</sup>. Considering that hepatocellular carcinoma (HCC) also develops from liver fibrosis, it is necessary to investigate the molecular mechanisms

underlying liver fibrosis development to reduce the morbidity and mortality of chronic liver disease.

The renin-angiotensin system (RAS) is continually activated in patients with chronic liver diseases, such as cirrhosis<sup>[4]</sup>. Angiotensin II (AT-II), an octapeptide produced mainly via the enzymatic cleavage of angiotensin I by angiotensin I-converting enzyme, reportedly plays an important role in chronic liver disease progression. AT-II activates a series of signal transduction pathways in activated hepatic stellate cells (HSCs) by binding to the AT-II type 1 receptor (AT1-R)<sup>[5]</sup>. We previously reported that AT1-R blockers significantly attenuate experimental liver fibrosis development with the suppression of activated HSC proliferation<sup>[6-8]</sup>. However, the molecular mechanisms regulating RAS-related gene expression remain unelucidated.

Epigenetic alterations, including DNA methylation, are involved in the progression of liver fibrosis and HCC in human and animal studies<sup>[9-11]</sup>. Recently, Chen *et al.*<sup>[12]</sup> reported that RAS-related genes, especially *Agtr1a* encoding rat AT1-R, are methylated in rats born to mothers fed a methyl donor-deficient diet during gestation and lactation. They showed that *Agtr1a* methylation can be a surrogate marker to predict susceptibility in developing nonalcoholic fatty liver disease (NAFLD) later in life. However, it is unclear whether *Agtr1a* methylation is associated with the development of nonalcoholic steatohepatitis (NASH)-related liver fibrosis.

Here we employed choline-deficient amino acid (CDAA)-fed rats to evaluate the importance of *Agtr1a* methylation in the development of NASH-related liver fibrosis. Our results demonstrate that *Agtr1a* methylation is potentially associated with liver fibrosis development and HSC activation.

## MATERIALS AND METHODS

### Animal model of liver disease

Six-week-old male Fisher 344 rats (CLEA Japan, Inc., Osaka, Japan) were housed in a room under a controlled temperature and a 12/12-h light-dark cycle. The animals were divided into the following four experimental groups: (1) choline-sufficient amino acid diet (CSAA) for 8 wk ( $n = 4$ ); (2) CSAA for 12 wk ( $n = 11$ ); (3) CDAA for 8 wk ( $n = 10$ ); and (4) CDAA for 12 wk ( $n = 12$ ). Initially, sample sizes for group (1)-(5) were 5, 12, 10, and 12, respectively, but two animals (one for CSAA-diet for 8 wk and the other for CSAA-diet for 12 wk) were dropped out because of entry in another experiment. All animal procedures were performed in accordance with standard protocols and following the standard recommendations for the appropriate care and use of laboratory animals. This study was approved by the animal experiment ethical committee at the Nara Medical University (protocol number: 9354).

### Isolation and activation of HSCs

HSCs were isolated by the collagenase digestion of the liver of a 6-week-old male Fisher 344 rat using a

**Figure 1** *Agtr1a* genomic structure. Each vertical tick on the top line shows an individual CpG site. GenBank accession number is listed at the left end on the bottom line. Open box shows exon 1, and dashed lines show the ambiguous boundary region of exon 1. Quantitative real-time methylation-specific PCR was performed in the region marked with closed arrowheads.

perfusion system, followed by the centrifugation of the crude cell suspension through a density gradient, as described previously<sup>[13]</sup>. Genomic DNA and total RNA were isolated from freshly isolated HSCs in a quiescent state. Thereafter, HSCs were activated in a culture on a plastic dish for 5 d.

#### Genomic DNA isolation, sodium bisulfite modification, and quantitative real-time methylation-specific PCR

Genomic DNA was isolated using a DNeasy® Blood and Tissue Kit (Qiagen, Hilden, Germany). Fully methylated control DNA was prepared by methylating genomic DNA with SssI methylase (New England Biolabs, Beverly, MA), and completely unmethylated control DNA was purchased from EpigenDx (Hopkinton, MA). Bisulfite modification was performed using an EZ DNA Methylation-Gold Kit (Zymo Research, Irvine, CA). *Agtr1a* genomic structure is illustrated in Figure 1. An aliquot of 1  $\mu$ L was used for quantitative real-time methylation-specific PCR (qMSP) with primers specific to a methylated sequence of *Agtr1a* (forward 5'-GGT TGG AAT TTG TAG AGT AGC GAC-3', reverse 5'-CAA CGC TAA TAC CGA CCT CG-3') and to a B2 repeat sequence, regardless of the methylation status, as demonstrated in a previous report<sup>[14]</sup>.

qMSP was performed by real-time PCR using a Power SYBR® Green PCR Master Mix (Thermo Fisher Scientific, Waltham, MA) and a StepOnePlus™ Real-Time PCR® (Thermo Fisher Scientific, Waltham, MA). The methylation level was calculated as the methylation percentage obtained as follows: {[number of DNA molecules methylated at a target CpG island (CGI) in a sample]/(number of B2 repeats in the sample)}/[(number of DNA molecules methylated at the target CGI in completely methylated control DNA)/(number of B2 repeats in the completely methylated control DNA)]  $\times$  100, as described previously<sup>[15]</sup>.

#### Quantitative real-time reverse transcription PCR

Total RNA was extracted using an RNeasy® Mini Kit (Qiagen, Hilden, Germany). cDNA was synthesized from 1  $\mu$ g of total RNA using a High Capacity RNA to cDNA Master Mix (Thermo Fisher Scientific, Waltham, MA). *Agtr1a* mRNA level was measured by quantitative PCR using the StepOnePlus™ Real-Time PCR® (Thermo Fisher Scientific, Waltham, MA). Primer sequences for *Agtr1a* and for *Ppia* were reported previously<sup>[14,16]</sup>. The number of *Agtr1a* cDNA molecules was normalized to that of *Ppia* cDNA molecules.

**Figure 2** Levels of *Agtr1a* methylation in the livers of control choline-sufficient amino acid - and choline-deficient amino acid - fed rats. The livers of choline-deficient amino acid (CDAA) - fed rats show higher *Agtr1a* methylation than that shown by the livers of choline-sufficient amino acid (CSAA) - fed rats at 8 (mean, 11.5% and 2.1%,  $P = 0.06$ ) and 12 wk (mean, 18.6% and 5.3%,  $P = 0.09$ ), respectively.

#### Statistical analysis

The difference in mean methylation levels was analyzed using Welch's *t*-test. The results were considered significant with a  $P$  value of  $< 0.05$ .

## RESULTS

#### *Agtr1a* methylation in the livers of CDAA-fed rats and activated HSCs

To evaluate the status of *Agtr1a* methylation in the whole liver, we performed qMSP using the liver samples of CSAA- and CDAA-fed rats after the two feeding periods, 8 and 12 wk. The mean levels of *Agtr1a* methylation in the livers of CDAA-fed rats were 11.5% and 18.6% at 8 and 12 wk, respectively, whereas those in the livers of CSAA-fed rats were 2.1% and 5.3% at 8 and 12 wk, respectively. These findings suggested that the levels of *Agtr1a* methylation in the livers of CDAA-fed rats tended to be higher than those in the livers of CSAA-fed rats at 8 and 12 wk ( $P = 0.06$  and  $0.09$ , respectively; Figure 2).

Next, we evaluated the level of *Agtr1a* methylation during HSC activation *in vitro*. We found that *Agtr1a* methylation was not detected at all in quiescent HSCs, but was clearly observed in activated HSCs (13.8%,  $P < 0.01$ ; Figure 3). Taken together with the *in vivo* results, our findings indicate that *Agtr1a* is hypermethylated in accordance with the development of NASH-related liver fibrosis.

#### *Agtr1a* expression in activated HSCs, and its association with methylation

To address the contribution of *Agtr1a* methylation to its

**Figure 3 Levels of *Agtr1a* methylation in the quiescent and activated hepatic stellate cells.** *Agtr1a* is not methylated at all in quiescent hepatic stellate cells (HSCs) but hypermethylated (13.8%,  $P < 0.01$ ) in activated HSCs. Data are presented as the mean  $\pm$  SE.

**Figure 4 Relative *Agtr1a* expression normalized to *Ppia* in quiescent and activated hepatic stellate cells.** Activated hepatic stellate cells (HSCs) show 2.2-fold higher ( $P < 0.05$ ) *Agtr1a* expression than that shown by quiescent HSCs. Data are presented as the mean  $\pm$  SE.

gene expression, we performed quantitative real-time reverse transcription PCR using quiescent and activated HSCs. *Agtr1a* expression was observed in quiescent HSCs in which *Agtr1a* was unmethylated. Unexpectedly, *Agtr1a* expression increased up to 2.2-fold ( $P < 0.05$ ) in the activated HSCs compared with that in quiescent HSCs, although *Agtr1a* was methylated (Figure 4). Interestingly, in contrast to the general relationship between promoter CGIs and gene expression, *Agtr1a* methylation did not silence its expression but instead had the potential to upregulate its expression.

## DISCUSSION

In this study, we found that *Agtr1a* methylation occurred during the development of NASH-related liver fibrosis. *Agtr1a*, which encodes rat AT1-R, the receptor for AT-II, is an important factor in liver fibrosis development<sup>[17,18]</sup>. Our previous reports demonstrated that both *AT-II* and *AT1-R* gene expressions were upregulated during fibrosis development in rat liver, and the blockage of AT-II/AT1-R signaling could attenuate liver fibrosis<sup>[6-8]</sup>. Considering that *Agtr1a* methylation upregulates its gene expression, *Agtr1a* demethylation can suppress liver fibrosis.

*Agtr1a* methylation was first demonstrated in the liver of rats born to mothers fed a methyl donor-deficient diet during gestation and lactation, and it was reported that rat pups with *Agtr1a* methylation have a high risk of developing NAFLD<sup>[12]</sup>. Epigenetics derived from mother-pup interaction is a prominent research field, and epigenetic susceptibility to phenotypes and diseases, such as yellow coat color, stress response, and breast cancer in offspring, has been identified<sup>[19-21]</sup>. However, few studies have focused on whether these epigenetic changes responsible for susceptibility to particular diseases occur when the diseases actually develop in adults. Here we

found that *Agtr1a* methylation, associated with susceptibility to NAFLD in pups, occurs in liver fibrosis development in adult NASH model rats.

As an experimental NASH model, we employed the CDAA model in this study. In the CDAA model, liver fibrosis develops at 8 wk and severely progresses at 12 wk<sup>[22,23]</sup>. This model has an advantage of histological progression of liver fibrosis, which is very similar to human NASH. However, there are critical disadvantages of this model. For examples, obesity, glucose intolerance, and insulin resistance, which are common features in human NASH, are not observed in this model. It remains to be elucidated whether *Agtr1a* methylation is induced in other experimental NASH models.

In CDAA model, *Agtr1a* methylation in the livers of CDAA-fed rats tended to be higher than that in the livers of CSAA-fed rats, but it was not statistically significant. We consider that methylation levels are highly variable in each diet group and the difference between CDAA- and CSAA-fed rats appears to be small. This variability depends on individual differences in rats and tissue heterogeneity in each sample, but both of them are hardly avoided. On the other hand, in HSC analysis, *Agtr1a* methylation and upregulation was clearly observed. Even in the CDAA model, it would be better to isolate HSC from the livers of CDAA-fed rats to obtain clear methylation changes.

*Agtr1a* hypermethylation was associated with *Agtr1a* upregulation. As for the promoter CGI, hypermethylation is generally considered to be strongly associated with gene silencing<sup>[24]</sup>. On the other hand, in the case of a CGI at the gene body, hypermethylation occasionally contributes to overexpression<sup>[25]</sup>. In the *Agtr1a* gene, 5'-CGI was not located at the promoter region but was just downstream of the transcription initiation site (Figure 1),

which might contribute to gene overexpression. It is hoped that the mechanism by which gene body methylation induces overexpression can be demonstrated.

In conclusion, this study demonstrates for the first time that RAS-related gene expression is regulated by DNA methylation during liver fibrosis. This finding raises expectations about the therapeutic application of demethylating agents for the treatment of liver fibrosis.

## COMMENTS

### Background

The renin-angiotensin system (RAS) plays a crucial role in the development of liver fibrosis. Among the RAS-related genes, the methylation of *Agtr1a*, the rat Angiotensin II type 1 receptor gene, is a potential risk marker for the development of nonalcoholic fatty liver disease in rat pups. However, it remains to be elucidated whether *Agtr1a* methylation occurs in liver fibrosis development in adult rats with nonalcoholic steatohepatitis (NASH).

### Research frontiers

Epigenetics derived from mother-pup interaction is a prominent research field. However, few studies have focused on whether these epigenetic changes responsible for susceptibility to particular diseases occur when the diseases actually develop in adults.

### Innovations and breakthroughs

This study demonstrates for the first time that the expression of *Agtr1a*, a RAS-related gene, is regulated by DNA methylation during liver fibrosis.

### Applications

The authors finding raises expectations about the therapeutic application of demethylating agents for the treatment of liver fibrosis.

### Terminology

Epigenetics refers to heritable marks regulating tissue-specific gene expression without changes in the DNA sequence. Prominent epigenetic marks consist of DNA methylation and histone modifications. Aberrant epigenetic changes are involved in various diseases, including cancer.

### Peer-review

This manuscript addresses the role of DNA methylation of angiotensin II receptor in fibrosis development in a rat model of NASH. The study is original and well designed.

## Abstract

### AIM

To clarify the clinical factors associated with liver regeneration after major hepatectomy and the hypertrophic rate after portal vein embolization (PVE).

### METHODS

A total of 63 patients who underwent major hepatectomy and 13 patients who underwent PVE in a tertiary care hospital between January 2012 and August 2015 were included in the analysis. We calculated the remnant liver volume following hepatectomy using contrast-enhanced computed tomography (CT) performed before and approximately 3-6 mo after hepatectomy. Furthermore, we calculated the liver volume using CT performed 2-4 wk after PVE. Preoperative patient characteristics and laboratory data were analyzed to identify factors affecting postoperative liver regeneration or hypertrophy rate following PVE.

### RESULTS

The remnant liver volume/total liver volume ratio negatively correlated with the liver regeneration rate after hepatectomy ( $\rho = -0.850, P < 0.001$ ). The regeneration rate was significantly lower in patients with an indocyanine green retention rate at 15 min (ICG-R15) of  $\geq 20\%$  in the right hepatectomy group but not in the left hepatectomy group. The hypertrophic rate after PVE positively correlated with the regeneration rate after hepatectomy ( $\rho = 0.648, P = 0.017$ ). In addition, the hypertrophic rate after PVE was significantly lower in

patients with an ICG-R15  $\geq 20\%$  and a serum total bilirubin  $\geq 1.5$  mg/dL.

### CONCLUSION

The regeneration rate after major hepatectomy correlated with hypertrophic rate after PVE. Both of them were attenuated in the presence of impaired liver function.

**Key words:** Regeneration after hepatectomy; Major hepatectomy; Portal vein embolization; Clinical factors; Hypertrophy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Little is known about the clinical factors associated with liver regeneration after major hepatectomy. In the present study, the liver regeneration rate after major hepatectomy correlated with the remnant liver volume and hypertrophic rate after portal vein embolization. The regeneration rate after major hepatectomy and hypertrophic rate after portal vein embolization were attenuated in the presence of impaired liver function.

Impaired liver function attenuates liver regeneration and hypertrophy after portal vein embolization. *World J Hepatol* 2016; 8(28): 1200-1204 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i28/1200.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i28.1200>

## INTRODUCTION

Curative resection is the most effective treatment for liver cancer<sup>[1]</sup>. Although resection-related mortality and morbidity have substantially decreased in recent years, the postoperative mortality rate remain to be as high as 1%-5%<sup>[2-7]</sup>. The capacity of hepatic regeneration after hepatectomy and the hypertrophic rate after portal vein embolization (PVE) are important for allowing surgeons to determine the appropriate extent of resection<sup>[8-11]</sup>. Better regeneration after hepatectomy and liver hypertrophy after PVE may prevent posthepatectomy complications, including hepatic failure<sup>[12,13]</sup>. Little is known about preoperative clinical factors influencing postoperative liver regeneration.

The aim of this study was to clarify the relationship between preoperative clinical factors and the regenerative capacity of the remnant liver after hepatectomy. Furthermore, we examined the relationship between the regeneration rate after hepatectomy and hypertrophic rate after PVE and clinical factors that affect the hypertrophic rate after PVE.

## MATERIALS AND METHODS

### Liver volume analysis

A total of 63 patients who underwent major hepatectomy

in the Division of Gastroenterological Surgery, Saitama Cancer Center, between January 2012 and August 2015 were included in the analysis. The liver volume was measured using enhanced computed tomography (CT) images taken before and approximately 3-6 mo after hepatectomy<sup>[14]</sup>. For volumetric analysis, a three-dimensional image analysis software was used (SYNAPSE VINCENT; Fuji Medical Systems, Tokyo, Japan). The regeneration rate was calculated as follows: [(liver volume after hepatectomy/estimated remnant liver volume before hepatectomy)  $\times 100$ ] - 100 (%). The indications for PVE were determined by the balance between the indocyanine green fractional disappearance rate (ICG-K) and the volumetric ratio of the future remnant liver volume. PVE was performed in patients whose values were estimated as follows: (ICG-K)  $\times$  (remnant liver volume/total liver volume)  $< 0.05$ <sup>[15]</sup>. The liver volume after PVE was calculated using enhanced CT images taken 2-4 wk after PVE. The hypertrophic rate after PVE was estimated as follows: [(remnant liver volume after PVE/remnant liver volume before PVE)  $\times 100$ ] - 100 (%). Preoperative patient characteristics and laboratory data, including platelet count, total bilirubin, and indocyanine green retention rate at 15 min (ICG-R15), were analyzed to identify factors affecting postoperative liver regeneration. For the measurement of ICG-R15, Indocyanine green (Diagnogreen, Daiichi-Sankyo, Tokyo, Japan) was administered at dose of 0.5 mg/kg by the antecubital vein of the opposite arm. Then, venous peripheral blood samples were collected every 5 min for 15 min to measure the ICG absorbance. ICG-K and ICG-R15 were calculated by fitting the serum disappearance curve by a single-exponential decay equation.

### Statistical analysis

Statistical analysis was performed using the JMP 11 software (SAS Institute, Inc., Cary, NC). Categorical variables were analyzed using the Wilcoxon rank sum test. Correlations between two parameters were examined by calculating the Spearman's rank correlation coefficient. A 2-tailed *P* value of  $< 0.05$  was considered statistically significant.

## RESULTS

### Liver regeneration after hepatectomy

Among the 63 patients, 42 were men and 21 were women, with a mean age of 68.1 years (range: 45-89 years). The diseases indicating the need for hepatectomy were metastatic liver carcinoma ( $n = 31$ ), intrahepatic cholangiocarcinoma ( $n = 14$ ), hilar cholangiocarcinoma ( $n = 10$ ), hepatocellular carcinoma ( $n = 4$ ), gallbladder carcinoma ( $n = 2$ ), hemangioma ( $n = 1$ ), and neuroendocrine tumor ( $n = 1$ ). A total of 22 patients had background liver diseases, including chronic viral hepatitis ( $n = 6$ ), alcoholic hepatitis ( $n = 1$ ), and obstructive jaundice ( $n = 15$ ). Preoperative chemotherapy within 6 mo was performed in 18 patients and 13 patients underwent preoperative PVE. The operative procedures

**Figure 1** Relationship between the remnant liver volume/total liver volume ratio and the liver regeneration rate after hepatectomy ( $n = 63$ ).

**Figure 2** Relationship between indocyanine green retention rate at 15 min and liver regeneration rate in patients who underwent right hepatectomy or extended right hepatectomy ( $n = 13$ ).

performed in the 63 patients included right hepatectomy or extended right hepatectomy ( $n = 26$ ), left hepatectomy or extended left hepatectomy ( $n = 32$ ), right trisegmentectomy ( $n = 3$ ), and left trisegmentectomy ( $n = 2$ ). The median remnant liver volume/total liver volume ratios after right hepatectomy and extended right hepatectomy, left hepatectomy and extended left hepatectomy, right trisegmentectomy, and left trisegmentectomy were 42.5%, 68.4%, 26.2% and 40.3%, respectively. Their median regeneration rates were 65.6%, 25.7%, 138.1% and 101.2%, respectively. The remnant liver volume/total liver volume ratio negatively correlated with the regeneration rate after hepatectomy ( $\rho = -0.850$ ,  $P < 0.001$ ; Figure 1).

#### Factors associated with liver regeneration

Because the liver regeneration rates were significantly different between the patients who underwent right hepatectomy or extended right hepatectomy (right hepatectomy group) and left hepatectomy or extended left hepatectomy (left hepatectomy group), we analyzed these

**Figure 3** Relationship between liver regeneration rate after major hepatectomy and hypertrophic rate after portal vein embolization ( $n = 13$ ).

two groups separately. In the right hepatectomy group, regeneration rate was significantly lower in patients with an ICG-R15 of  $\geq 20\%$ . It was not associated with platelet count, total bilirubin, diabetes mellitus, viral hepatitis, obstructive jaundice, or preoperative chemotherapy. The ICG-R15 value negatively correlated with liver regeneration rate in the right hepatectomy group ( $\rho = -0.477$ ,  $P = 0.014$ ; Figure 2). In the left hepatectomy group, no factor was associated with the regeneration rate (Table 1). In the 13 patients who underwent preoperative PVE, the median hypertrophic rate was 32.2% (range: 2.7%-58.3%). The hypertrophic rate positively correlated with the regeneration rate after hepatectomy ( $\rho = 0.648$ ,  $P = 0.017$ ; Figure 3). The hypertrophic rate was significantly lower in patients with an ICG-R15 of  $\geq 20\%$  and total bilirubin of  $\geq 1.5$  mg/dL (Table 2).

## DISCUSSION

Our study demonstrated that the liver regeneration rate was significantly lower in patients with an ICG-R15 of  $\geq 20\%$  in the right hepatectomy group, but not in the left hepatectomy group. The hypertrophic rate after PVE positively correlated with the regeneration rate after hepatectomy. In addition, the hypertrophic rate after PVE was significantly lower in patients with an ICG-R15 of  $\geq 20\%$  and a serum total bilirubin of  $\geq 1.5$  mg/dL.

Although several studies reported factors affecting liver regeneration after hepatectomy, the factors vary among studies. Yamanaka *et al.*<sup>[16]</sup> reported that the extent of resection and impaired liver function were associated with the liver regeneration, whereas Ogata *et al.*<sup>[17]</sup> reported that serum hyaluronan was a predictor of liver regeneration in patients with hepatocellular carcinoma. In living-donor liver transplantation, remnant liver volume<sup>[18]</sup>, sex<sup>[19]</sup>, and age<sup>[20]</sup> have been reported to be associated with liver regeneration. Aoki *et al.*<sup>[14]</sup> reported that sex and alanine aminotransferase values were associated with liver regeneration in the early phase, and the final regeneration rate was associated with the ratio of re-

<sup>1</sup>Median. ICG-R15: Indocyanine green retention rate at 15 min.

sected liver volume. In our study, the remnant liver volume in the right hepatectomy group was significantly larger than that in the left hepatectomy group, and together with previous reports, the regeneration rate was highly affected by remnant liver volume/total liver volume ratio. Therefore, left and right hepatectomy should be separately considered when analyzing liver regeneration.

The regeneration rate was significantly lower in patients with a higher ICG-R15 in the right hepatectomy group, whereas no variables related to liver regeneration were identified in the left hepatectomy group. These results also confirmed that liver regeneration after right and left hepatectomy should be separately considered.

Our study demonstrated the correlation between the hypertrophic rate after PVE and liver regeneration rate after hepatectomy. The hypertrophic rate positively correlated with the regeneration rate, and regeneration rate after major hepatectomy and hypertrophic rate after PVE were attenuated in the presence of impaired liver function.

In conclusion, the regeneration rate after major hepatectomy correlated with the remnant liver volume and hypertrophic rate after PVE. The regeneration rate after right hepatectomy and hypertrophic rate after PVE were

attenuated in the presence of impaired liver function.

## COMMENTS

### Background

Although resection-related mortality and morbidity have substantially decreased in recent years, the postoperative mortality rate has remained as high as 1%-5%. Portal vein embolization (PVE) is proposed to induce hypertrophy of the anticipated liver remnant to reduce such complications. The capacity of hepatic regeneration after hepatectomy and the hypertrophic rate after PVE are important for allowing surgeons to determine the appropriate extent of resection. Better regeneration after hepatectomy and liver hypertrophy after PVE may prevent posthepatectomy complications, including hepatic failure.

### Research frontiers

Little is known about preoperative clinical factors influencing postoperative liver regeneration and liver hypertrophy after PVE.

### Innovations and breakthroughs

In this study, the relationship between preoperative clinical factors and the regenerative capacity of the remnant liver after hepatectomy were clarified. Furthermore, the authors examined the relationship between the regeneration rate after hepatectomy and hypertrophic rate after PVE and clinical factors that affect the hypertrophic rate after PVE.

### Applications

This study suggests that the regeneration rate after major hepatectomy correlated with the remnant liver volume and hypertrophic rate after PVE, and the

regeneration rate after right hepatectomy and hypertrophic rate after PVE were attenuated in the presence of impaired liver function.

### Terminology

PVE: A procedure in the preoperative treatment of patients selected for major hepatic resection. PVE is performed via either the percutaneous transhepatic or the transileocolic route and is usually reserved for patients whose future liver remnants are too small to allow resection.

### Peer-review

The manuscript is an interesting one. The authors, using 63 patients who underwent major hepatectomy and 13 patients who underwent portal vein embolization, calculated regeneration rate correlated with the remnant liver volume. In conclusion, they found that the regeneration rate after right hepatectomy and the hypertrophic rate after PVE were attenuated in the presence of impaired liver function. It is a well-written and presented manuscript.

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Protein-calorie malnutrition (PCM) is a common condition in cirrhotic patients, leading to a worse prognosis, complications, poor quality of life and lower survival rates. Among ways of assessing nutritional status, there are anthropometric methods such as the evaluation of the triceps skinfold, the arm circumference, the arm muscle circumference and the body mass index, and non-anthropometric methods such as the subjective global assessment, the handgrip strength of non-dominant hand, and the bioelectrical impedance analysis (BIA). PCM is frequently under-diagnosed in clinical settings in patients with cirrhosis due to the limitations of nutritional evaluation methods in this population. BIA is a useful method, but cannot be indicated in patients with abnormal body composition. In these situations, the phase angle (PA) has been used, and can become an important tool in assessing nutritional status in any situation. The PA is superior to anthropometric methods and might be considered as a nutritional indicator in cirrhosis. The early characterization of the nutritional status in patients with cirrhosis means an early nutritional intervention, with a positive impact on patients' overall prognosis. Among the usually accepted methods for nutritional diagnosis, the PA provides information in a quick and objective manner.

**Key words:** Malnutrition; Bioelectrical impedance; Phase angle; Sarcopenia; Nutrition

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Malnutrition in cirrhotic patients is a common clinical condition, but there is currently no nutritional diagnosis method defined as the gold standard. Presently, the only nutritional indicator compatible with the clinical condition through the Child-Pugh score in cirrhosis is the phase angle (PA). The PA has been

a reliable method and is free of influences regarding changes in body composition of cirrhotic patients at an advanced stage. The PA measured by bioelectrical impedance analysis promises to be a significant parameter for early nutritional intervention in patients with chronic liver disease.

## INTRODUCTION

Many factors favor the development of protein-calorie malnutrition (PCM) in cirrhosis, a common condition that leads to serious repercussions regarding the general state and clinical course of patients<sup>[1]</sup> and that presents a worse prognosis, complications, poor quality of life and lower survival rates<sup>[2,3]</sup>. However, malnutrition is often underdiagnosed in this situation<sup>[4]</sup>. It is difficult to evaluate the nutritional status of patients with cirrhosis, as there are particularities due to the clinical condition that make it hard to precisely inform the real nutritional status and its consequent prognosis<sup>[5]</sup>.

Malnutrition can be directly related to a poor survival rate in patients with cirrhosis, and its improvement is a strong indicator of quality of life, especially for those who are on the waiting list for liver transplantation<sup>[6]</sup>. Early detection of malnutrition in cirrhotic patients is of great clinical relevance and interferes positively in patient recovery<sup>[7,8]</sup>.

The new European Society of Clinical Nutrition and Metabolism (ESPEN) consensus<sup>[9]</sup>, recommends that subjects at risk of malnutrition be identified by validated screening tools, and they advocate two options for the diagnosis of malnutrition: The body mass index (BMI, kg/m<sup>2</sup>) lower than 18.5 to characterize malnutrition, and the combined finding of unintentional weight loss and either reduced BMI or a low fat-free mass index (FFMI), or both. Weight loss could be either greater than 10% of habitual weight regardless of time, or greater than 5% over 3 mo. Low FFMI is characterized as lower than 15 or lower than 17 kg/m<sup>2</sup> in females or males, respectively. However, many other tools, such as anthropometric and non-anthropometric methods as well as laboratory tests may be used, classifying the degrees of malnutrition as mild, moderate and severe in different ways - although none of these other tools are widely recognized as a gold standard, and thus must be considered together. Various nutritional parameters has been used to assess the nutritional status such as anthropometry parameters [mid arm circumference, triceps skinfold thickness (TSF)], hand grip, serum albumin level, creatinine height index, and total lymphocyte count<sup>[8-10]</sup>. Recently electrical bioimpedance has been proposed for body composition

analysis of patients with chronic liver disease<sup>[8,11-13]</sup>. In view of paucity of data on prevalence of malnutrition and its relationship with morbidity and mortality in patients with liver cirrhosis as well as the absence of a gold standard method for nutritional evaluation in these patients, we conducted this study to determine the prevalence of malnutrition by various methods and its clinical importance in cirrhotic patients according the severity of disease.

Considering the scarcity of data in the evaluation of malnutrition in patients with liver cirrhosis as well as the absence of a gold standard for nutritional evaluation in these patients, the present review was performed, critically addressing the following points: Malnutrition in cirrhosis; sarcopenia; nutritional assessment in cirrhosis; bioelectrical impedance analysis and the phase angle<sup>[10]</sup>.

## MALNUTRITION IN CIRRHOSIS

Malnutrition is one of the most frequent complications in cirrhotic patients<sup>[11]</sup>. However, its frequency in cirrhosis is highly variable, and may affect between 20% of the patients with compensated cirrhosis and more than 60% of these patients with severe hepatic dysfunction<sup>[12,13]</sup>.

Alberino *et al*<sup>[6]</sup> studied 212 hospitalized patients with liver cirrhosis that were followed for 2 years or until death. The severely and moderately malnourished patients had lower survival rates than normal and over nourished patients, and severe depletion of muscle mass and body fat was found to be an independent predictor of survival. This data suggests that malnutrition is an independent predictor of survival in patients with liver cirrhosis. Additionally, a nationwide analysis of the prevalence of PCM in patients with cirrhosis and portal hypertension (PHTN) and its mortality was conducted in the United States<sup>[13]</sup>. There were 114703 admissions with cirrhosis and PHTN between 1998 and 2005, and the prevalence of PCM was higher among patients with cirrhosis and PHTN compared with general medical inpatients; this prevalence was also associated with higher in-hospital mortality and resource utilization. The authors concluded that PCM may be an indicator of disease severity and should be routinely assessed on admission.

Besides the metabolic changes observed in cirrhosis, there are factors that can contribute to increased malnutrition in this population. Factors such as anorexia and early satiety, triggered by changes in endogenous leptin, mineral deficiencies and reduction in gastric expandability favor a negative energetic balance, with an imbalance between ingestion and energy intake and expenditure, and PCM may develop as a result<sup>[14]</sup>. The zinc and magnesium deficiencies that may be often seen in the population of patients with cirrhosis contribute to the development of dysgeusia, which aggravates the intake capacity<sup>[15,16]</sup>.

The clinical complications that can occur in decompensated cirrhosis - such as gastrointestinal bleeding,

hepatic encephalopathy (HE) and ascites - can further accentuate the PCM situation<sup>[14]</sup>, alongside the diet offered to these patients, which is restrictive in most cases. Thus, although for a short period of time, a hypoproteic diet may be eventually implemented, especially in cases of HE grades III and IV<sup>[4]</sup>. It is worth highlighting that the protein restriction has been banned in HE in order to prevent the worsening of PCM, and a diet with 1 to 1.5 g of protein per kilogram of weight is suggested<sup>[4]</sup>.

The recommended low-sodium diet in the treatment of patients with ascites and peripheral edema makes the food intake even more difficult and significantly decreases the daily calorie intake, thus stimulating PCM. A low-sodium diet with a daily intake of 2 g of salt is recommended<sup>[17]</sup>.

It is known that skeletal muscles contribute in the proper metabolic functioning of macro and micro-nutrients, favoring body homeostasis. In individuals with cirrhosis, there is a significant loss and dysfunction of such musculature, often characterizing sarcopenia<sup>[18,19]</sup>. This state generates systemic and inflammatory changes associated with the PCM, negatively impacting the patient's clinical status<sup>[20]</sup>.

The classical study by Merli *et al.*<sup>[21]</sup> prospectively evaluated a total of 1053 cirrhotic patients to determine whether malnutrition is a risk factor for mortality in cirrhosis. They found that the cumulative survival was lower in patients with a reduction in muscle mass in Child-Pugh classes A and B.

Montano-Loza *et al.*<sup>[22]</sup> studied 112 cirrhotic patients consecutively evaluated for liver transplantation, and observed that sarcopenia occurred in up to 40% of the patients and was related to the worsening of clinical conditions represented by biochemical and clinical parameters; moreover, by multivariate Cox analysis, the Child-Pugh (HR = 1.85;  $P = 0.04$ ), the model for end-stage liver disease (MELD) scores (HR = 1.08;  $P = 0.001$ ) and sarcopenia (HR = 2.21;  $P = 0.008$ ) were independently associated with mortality. The median survival time for patients with sarcopenia was  $19 \pm 6$  mo, compared with  $34 \pm 11$  mo among non-sarcopenic patients ( $P = 0.005$ ). Sarcopenia can be considered an indicator of risk of infection in cirrhotic individuals, directly reflecting a decline in immune function, worsening the quality of life and decreasing survival.

## SARCOPENIA

Malnutrition in cirrhosis is closely related to the development of sarcopenia, which will be one of the most common complications related to survival in this population of patients. Nevertheless, there is a lack of an optimal index for sarcopenia and of a consensus definition for sarcopenia in patients with cirrhosis in whom ascites and edema may interfere with body composition analysis<sup>[23]</sup>.

Sarcopenia is a syndrome characterized by progressive and generalized loss of skeletal muscle mass

and strength with a risk of adverse outcomes such as physical disability, poor quality of life and death<sup>[24,25]</sup>. The European Working Group on Sarcopenia in Older People recommends using the presence of both low muscle mass and low muscle function (strength or performance) for the diagnosis of sarcopenia<sup>[26]</sup>.

Montano-Loza *et al.*<sup>[19]</sup> evaluated a population of 248 cirrhotic patients enlisted for liver transplantation and identified sarcopenia in 45% of patients; sarcopenia was associated with a longer period of hospitalization and higher risk of bacterial infection after transplantation.

Similarly, Tandon *et al.*<sup>[5]</sup> evaluated 142 patients with cirrhosis listed for liver transplantation, and found that 41% were sarcopenic. Male gender, the BMI, and Child-Pugh class C cirrhosis (but not the MELD score) were independent predictors of sarcopenia, which was an independent predictor of mortality after adjustments for age and MELD scores. The authors concluded that sarcopenia is associated with increased waiting-list mortality and is poorly predicted by subjective nutritional assessment tools such as BMI and subjective global assessment (SGA). The objective assessment of sarcopenia holds promise for prognostication in this patient population.

## NUTRITIONAL ASSESSMENT IN CIRRHOSIS

Among the different ways of assessing nutritional status, there are anthropometric methods such as determining the TSF, the arm circumference (AC), the arm muscle circumference (AMC) and the BMI, as well as non-anthropometric methods such as SGA, handgrip strength (HS) of non-dominant hand, the adductor pollicis muscle thickness (APMT) and the phase angle (PA) by bioelectrical impedance analysis (BIA).

Classical anthropometry assesses the measurement of body size and its proportions. The results obtained are compared with the points of reference previously described<sup>[27]</sup>.

Cirrhotic individuals present significant changes regarding body weight by hydric retention, making BMI an inadequate method for nutritional diagnosis<sup>[28]</sup>. Such distortion was observed in the study performed by Gottschall *et al.*<sup>[29]</sup>, in which 61.8% of patients were classified as overweight, while other techniques, such as SGA or HS, found malnutrition in 38% and 85.7% in the same population of patients, respectively.

The TSF measurement indirectly estimates fat mass by measuring the thickness of two layers of skin and the adjacent subcutaneous fat. This is a good assessment method, although some studies have found a low prevalence of malnutrition in cirrhosis when comparing this method to others<sup>[30-32]</sup>.

Abbott *et al.*<sup>[33]</sup> and Alberino *et al.*<sup>[6]</sup> described, in their studies, that 54% of the evaluated cirrhotic patients were malnourished when utilizing AC and AMC, supporting the findings of Merli *et al.*<sup>[21]</sup>, which suggest

AMC as an accurate indicator of malnutrition in patients in the early stages of cirrhosis. On the other hand, a study performed in our center by Fernandes *et al.*<sup>[34]</sup> showed that AC and AMC are not sensible parameters for the nutritional diagnosis.

As a general rule, the anthropometric parameters may be affected when there is hydric retention; the results are observer-dependent and can be conflicting, becoming inadequate in the nutritional assessment of patients with cirrhosis.

When considering the non-anthropometric methods, SGA is a method of interest that uses easily reproducible parameters such as the clinical history and physical conditions of the individual, focusing on the nutritional aspects and offering a score that provides the nutritional diagnosis<sup>[35]</sup>. However, this method shows limitations, especially when the patient has some difficulty to understanding or even HE, as patients will not report their nutritional history adequately<sup>[36]</sup>.

Figueiredo *et al.*<sup>[37]</sup> observed that SGA has a sensitivity of only 22% in cirrhotic individuals and underestimates their nutritional status in 57%, while overestimating it in 6%<sup>[38]</sup>. On the other side, Ritter and Gazzola<sup>[38]</sup> established SGA as a good option for the nutritional assessment of patients with liver disease.

Although some authors<sup>[36,39,40]</sup> have suggested that SGA might be useful to assess the nutritional status evolution of cirrhotic patients who are liver transplant candidates, these studies have detected malnutrition in only 25% of cases with this method.

The HS assessment through dynamometry refers to the measurement of muscle strength and of pressure distribution<sup>[41]</sup>, classifying the nutritional status of individuals by gender and age. In dynamometry, there is the assumption that in PCM there is a decrease in muscle mass, hindering one's functional capacity<sup>[42]</sup>. Studies with cirrhotic patients have shown the superiority of HS assessment when compared to SGA in diagnosing malnutrition; HS is considered a low-cost and simple method that is not influenced by the presence of hydric retention<sup>[42]</sup>. Curiously, in different studies, HS - while proving to be a good method in assessing nutritional risk - does not present a correlation between malnutrition and the staging of liver disease through the Child-Pugh score, although it is considered that liver disease patients, when classified as Child-Pugh C, are malnourished *per se*<sup>[41]</sup>.

The APMT has been suggested as a promising marker of muscle mass<sup>[43,44]</sup>. The adductor pollicis muscle is the only muscle that allows direct thickness assessment, as it is anatomically well defined and flat in shape<sup>[45]</sup>. However, few have looked into it as a marker of nutritional status<sup>[46]</sup>.

## BIOELECTRICAL IMPEDANCE ANALYSIS

The BIA is a method for assessing body composition that has shown good results regarding the nutritional state, as it shows fat mass, lean mass and basal metabolic rate, in addition to total body water in

healthy subjects<sup>[47]</sup>. The distribution of body fat has an important influence in the severity of certain diseases, such as in cardiovascular disease and depending on the type of fat mass distribution, may pose a higher risk of developing tumors<sup>[48]</sup>. Thus, in addition to providing a nutritional status assessment, BIA can also be a good prognosis method that is characterized as a practical, quick, non-invasive and low-cost method<sup>[48,49]</sup>.

In the clinical nutritional assessment of a cirrhotic patient, it is possible to perform compartmentalized body assessment through BIA not only in the classical model that is normally used (fat mass and fat-free mass), but also in a quantitative manner, obtaining cellular distribution and providing information on body composition<sup>[50]</sup>.

In the past, there were restrictions on the use of BIA for individuals with abnormal body composition; that is, amputations, electrolyte disorders (edema and ascites), obesity, dystrophies and pregnancy, because the BIA assumes that the human body resembles a cylinder of constant hydration and invariably lean mass<sup>[47,51]</sup>.

Some tissues with high water and electrolyte composition - such as cerebrospinal fluid, blood or muscles - are high electrical conductors. On the other hand, fatty tissues or bones are highly resistant to electric current<sup>[47]</sup>. The conductivity of biological tissues is virtually ionic, meaning that electric charges are transferred by the ionization of the salts, bases or acids in body fluid. Thus, organic conductivity is directly proportional to the quantity of body fluid volume. Therefore, if the patient is in a state of overhydration, the amount of lean body mass is overestimated, modifying the result of the body assessment, which is one of the limitations of this method<sup>[47]</sup>.

For the assessment of nutritional state by BIA, there are monofrequencial or multifrequencial portable equipment, differing on the options of the amperage of the electric current to allow greater sensitivity of the examination. The patient remains in dorsal decubitus position, with hands and legs parallel to the body. One electrode is placed on the dorsal hand, at the middle finger level, and one in the wrist joint, both on the right side. Another pair of electrodes is placed on the dorsal foot, at the middle toe level, and in the ankle joint, also on the right side. The electrical current enables measuring resistance and reactance and obtaining the PA value.

## THE PHASE ANGLE

In view of the limitations of BIA, the clinically established bioelectrical impedance parameter is the PA. The PA was originally described by Baumgartner *et al.*<sup>[51]</sup> for the diagnosis of metabolic disorders. The data is obtained through BIA and is directly calculated through the arc tangent formula ( $X_c/R$ ). The tissues' capacitance ( $X_c$ ) is related to cellularity, cell-size and integrity of cellular membrane. The resistance ( $R$ ) is dependent on the hydration state of the tissues. The ratio of components results in a geometric graphic, where the ratio of  $R$  and

Xc results in an angle called the PA.

BIA is represented by the vector Z, which is a combination of the perpendicular vectors R and Xc. The vector Z has a module M, and the horizontal axis defines the PA<sup>[52]</sup>.

The PA reflects the cellular vitality and integrity, where normal values (according to gender and age) indicate preserved cellular activity<sup>[34,53,54]</sup>, being highly predictive of clinical progression in a number of diseases<sup>[55]</sup>.

It has been suggested that the PA can become an important tool in assessing nutritional status in any situation, being superior to anthropometric and biochemical methods<sup>[44]</sup>.

There are reference values according to age and gender<sup>[8]</sup>, and some authors prefer to establish cutoff points according to the disease being studied<sup>[47]</sup>.

The PA has also been studied as a prognostic marker in different clinical situations, such as tumors, acquired immunodeficiency syndrome, and heart and liver diseases<sup>[54]</sup>.

In a review, Llamas *et al.*<sup>[55]</sup> concluded that the PA may be sufficient to monitor the nutritional status of an individual. In a population-based study, they observed a higher PA in men than in women, except in individuals over 70 years of age. When stratified by age and gender, the values tend to increase as BMI increases in values of up to 35 kg/m<sup>2</sup>; however, there is a decrease in PA in groups with BMI above 35 kg/m<sup>2</sup><sup>[55]</sup>.

There are few studies evaluating the PA in cirrhotic patients.

Selberg *et al.*<sup>[56]</sup>, in a prospective study of 305 patients with cirrhosis, correlated the PA with muscle mass, muscle strength, and survival rates. They observed that patients with a PA equal to or lower than 5.4 degrees showed lower survival rates than those with PA values above 6.6 degrees. In those with PA under 4.4 degrees, survival was even (and significantly) lower. Variables such as total body potassium, anthropometric measurements and BIA were evaluated separately; however, only the PA proved to be an isolated predictor of survival. The authors concluded that the PA appears to be superior to conventional methods in the clinical assessment of patients with cirrhosis.

In a retrospective study, Pirlich *et al.*<sup>[53]</sup> evaluated the cellular mass composition of 41 cirrhotic patients (20 with ascites and 21 without) through BIA, which was considered the reference method. The study shows that the PA is a tool that is able to detect body cellular mass and to identify its decrease in cirrhotic patients. The PA offers reliable PCM estimates even in patients with large amount of ascites, proving to be superior to commonly used techniques.

In a cohort that assessed 66 cirrhotic patients stratified by their clinical condition through the Child-Pugh score and followed-up during a 17-mo period, the established PA for this population was 5.18 degrees. Patients with values below this angle were considered

to have poor prognosis and shorter survival rates. It is worth highlighting that as the patients' clinical situation worsened, the PA decreased, showing a prognostic value<sup>[57]</sup>.

Corroborating these findings, we assessed the nutritional status of 129 cirrhotic patients through different methods and demonstrated that the only method that is able to correlate malnutrition with the staging of liver disease, evaluated through the Child-Pugh classification, was the PA. We set the PA cutoff point as 5.4 degrees, and patients with values below this discriminatory level showed a worse prognosis. We should point out the discrepancies between the results of different evaluation methods (anthropometry, HGS and BIA) used to diagnose PCM, once the diagnosis for malnutrition may vary from 5.4% to 69.3% in the same population, depending on the assessment method employed<sup>[34]</sup>. The PA evaluated through the BIA presented a sensitivity and specificity of 68.9%-70.0% and 49.2%-56%, respectively, when compared to the HGS<sup>[34]</sup>.

Later, another study performed in our center evaluated 195 cirrhotic patients, reinforcing the idea that the PA is a good prognostic marker when compared to other methods, as it is the only one that correlates with the real clinical condition of the patient<sup>[58]</sup>.

Recently, Ruiz-Margáin *et al.*<sup>[59]</sup> assessed 249 compensated cirrhotic patients in a prospective cohort study with a 48-mo follow-up period. The PA cutoff point for malnutrition was lower than or equal to 4.9 degrees. This study also concluded that the PA is a good prognostic marker, associating the PCM with mortality rate.

A cohort study conducted in our center evaluated 32 cirrhotic patients enlisted for liver transplantation<sup>[36]</sup>. The patients were interviewed and evaluated on the day of or on the day before the transplant, and 1, 6, and 12 mo after surgery. The assessment of nutritional status was performed applying diagnostic procedures in sequence: Anthropometry, HS, APMT and PA. Methods that better demonstrated the real prevalence of malnourished patients before transplantation were PA (25%), AMC (21.9%) and AC (18.8%). The percentage of malnourished patients was significantly higher after 1 mo of transplantation when compared to the percentage in 6 mo and 1 year after transplantation. It was suggested that the PA could be widely used with this population, since the results are consistent, reliable and reproducible.

Wagner *et al.*<sup>[60]</sup> evaluated nutritional methods that informed the nutritional status of 71 post-transplantation patients. Patients were divided into 3 groups according to time since transplantation: 5 years, between 5 and 10 years, and over 10 years. They used the PA cutoff point as below 5 degrees in order to diagnose malnutrition. The PCM diagnosis was made in 81.2%, 31.6% and 31.7% in each group, respectively ( $P = 0.008$ ). In this study, the PA showed a higher prevalence of malnutrition among the population of patients in the first years after liver transplantation.

## CONCLUSION

The cirrhotic patient is malnourished *per se*, regardless of etiology and the severity of the disease. The early characterization of the nutritional status in patients with cirrhosis means an early nutritional intervention, with a positive impact on patients' overall prognosis. Compared to the usually accepted methods for nutritional diagnosis, the PA obtained through BIA is the only appropriate method to evaluate the nutritional status of cirrhotic, providing safe information in a quick and objective manner as a prognostic index.

### Abstract

#### AIM

To explore the role of killer immunoglobulin receptor (*KIR*) genes in responsiveness or non-responsiveness to vaccination against hepatitis B virus.

#### METHODS

We recruited 101 voluntary participants between March 2010 and December 2011. Sera samples from vaccinated and non-vaccinated participants were tested for the presence of anti-HBs antibodies as a measure of protection against hepatitis B, hepatitis B surface antigen and hepatitis B core antibody as indicators of

infection by enzyme-linked immunosorbent assay. *KIR* gene frequencies were determined by polymerase chain reaction.

## RESULTS

Sera samples from 99 participants were tested for the levels of anti-HBs as an indicator of protection ( $\geq 10$  mIU/mL) following vaccination as defined by the World Health Organization international reference standard. Among the vaccinated participants, 47% (35/74) had anti-HBs titers above 100 mIU/mL, 22% (16/74) had anti-HBs ranging between 10-100 mIU/mL, and 20% (15/74) had values of less than 10 mIU/mL. We report the lack of significant association between the number of vaccine dosages and the titer of antibodies among our vaccinated participants. The inhibitory KIR2DL1, KIR2DL4, KIR3DL1, KIR3DL2, and KIR3DL3 were detected in more than 95%, whereas KIR2DL2, KIR2DL3, KIR2DL5 (KIR2DL5A and KIR2DL5B) were expressed in 56%, 84% and 42% (25% and 29%) of participants, respectively. The observed frequency of the activating *KIR* genes ranged between 35% and 55% except for KIR2DS4, detected in 95% of the study participants (40.6% 2DS4\*001/002; 82.2% 2DS4\*003/007). KIR2DP1 pseudogene was detected in 99% of our participants, whereas KIR3DP1\*001/02/04 and KIR3DP1\*003 had frequencies of 17% and 100%, respectively. No association between the frequency of *KIR* genes and anti-HBs antibodies was detected. When we compared the frequency of *KIR* genes between vaccinated individuals with protective antibodies titers and those who lost their protective antibody levels, we did not detect a significant difference. KIR2DL5B was significantly different among different groups of vaccinated participants (group I > 100 mIU/mL, group II 10-100 mIU/mL, group III < 10 mIU/mL and group IV with undetectable levels of protective antibodies).

## CONCLUSION

To our knowledge, this is the first study screening for the possible role of *KIR* genes among individuals vaccinated against hepatitis B virus (HBV). Our results can be used to design larger studies to better understand the role of *KIR* genes in protection against or susceptibility to HBV post vaccination.

**Key words:** Hepatitis B virus; Killer immunoglobulin receptors; Hepatitis B vaccine; Lebanon; Natural killer cells

**Core tip:** Currently, there are no data supporting the use of booster doses of hepatitis B vaccine among immuno-competent individuals responding to a complete primary vaccination regimen. Importantly, 5%-10% of healthy adults do not generate protective levels of antibodies and are hence considered non-responders. This study aims to explore the role of killer immunoglobulin receptor genes in responsiveness or non-responsiveness

to vaccination against hepatitis B virus.

Potential role of killer immunoglobulin receptor genes among individuals vaccinated against hepatitis B virus in Lebanon. *World J Hepatol* 2016; 8(29): 1212-1221 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i29/1212.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i29.1212>

## INTRODUCTION

Infection with hepatitis B virus (HBV) results in a spectrum of clinical outcomes ranging from acute hepatitis to end-stage liver disease and hepatocellular carcinoma<sup>[1]</sup> with an estimated lifetime risk of 25%-40%<sup>[2]</sup>. Booster studies suggest that memory begins to decline 15 years following vaccination among adolescents vaccinated in infancy<sup>[3-6]</sup>. Other studies suggest the persistence of immune memory for 20 years or longer<sup>[7-9]</sup>. Currently, there are no data supporting the use of booster doses of hepatitis B vaccine among immuno-competent individuals responding to a complete primary vaccination regimen (3 doses). Importantly, 5%-10% of healthy adults do not generate protective levels of antibodies and are hence considered non-responders<sup>[10]</sup>. Consequently, long-term protection is still debatable<sup>[11]</sup> and not linked to genetic factors.

Natural killer (NK) cells are known to induce antiviral and antitumor immunity via production of pro-inflammatory cytokines and lysis of infected or transformed cells<sup>[12]</sup>. Killer immunoglobulin receptor (*KIR*) genes encode receptors expressed on NK cells. Based on the gene content, two groups of *KIR* haplotypes are known in humans: A and B. Haplotype A encodes inhibitory receptors and consists of nine genes (3DL3, 2DL3, 2DP1, 2DL1, 3DP1, 2DL4, 3DL1, one activating (2DS4), 3DL2, and 2DL5) whereas haplotype B carries a variety of gene combinations and encodes more activating receptors as compared to haplotype A (3DL3, 2DS2, 2DL2, 2DL5B (inhibitory) 2DS3, 2DP1, 2DL1, 3DP1, 2DL4, 3DS1, 2DL5A (inhibitory), 2DS5, 2DS1, and 3DL2)<sup>[13]</sup>.

KIR3DS1- and KIR3DL1-expressing NK cells were reported to expand in acute and chronic human immunodeficiency virus (HIV)-1 infection, respectively<sup>[14]</sup>. Similarly, reports suggest that KIR2DL2 and/or KIR2DL3 along with their ligand human leukocyte antigen (HLA)-C1 are associated with severe influenza infection; in addition, the frequency of KIR3DS1, KIR2DS5 and KIR2DL5 was also related to the severity of the disease<sup>[15]</sup>. KIR2DS2 and KIR2DS3 were found to be associated with susceptibility to chronic hepatitis B infection, whereas KIR2DS1, KIR3DS1 and KIR2DL5 may act as protective genes leading to viral clearance among the Chinese Han population<sup>[16]</sup>. A difference between the frequency of

different *KIR* haplotypes among chronically infected individuals and those spontaneously recovering from HBV infection was also demonstrated in this population<sup>[17]</sup>. Recently, the rates of KIR2DL3 and 3DS1 were reported to be higher in healthy Turkish individuals as compared to patients with chronic HBV and those with spontaneous remission<sup>[18]</sup>; authors suggested the possible role of these genes in protection against HBV infection. In addition, genetic factors have been reported to play a role in the regulation of post-vaccine immune responses<sup>[19]</sup>. This was observed with antibody responses to a number of vaccine antigens including hepatitis B.

It is clear that the interaction between KIRs and their corresponding HLA ligands is implicated in differential responses to HIV, hepatitis C virus (HCV) and HBV as well as other disease conditions<sup>[20-23]</sup>. Immune responses, like many biological responses, are characterized by a wide range of variation between individuals. This has been described following natural infection or in response to vaccination<sup>[24]</sup>. HLA, cytokines, toll-like receptors and related gene variants have been associated with a variety of immune responses following vaccinations. Recently, single-nucleotide polymorphism associations were described to be involved in innate and adaptive immune response regulation following measles and rubella vaccinations<sup>[25,26]</sup>. Similarly, a difference in gene expression was also reported between high and low responders to smallpox vaccine<sup>[27]</sup>. The fact that antibody response to hepatitis B vaccine is non-protective in up to 10% of individuals<sup>[10]</sup>, and that a genetic basis to non-responsiveness is reported<sup>[19,24]</sup>, prompted us to explore the role of *KIR* genes in response to hepatitis B vaccine in a cohort of healthy vaccinated Lebanese adults.

## MATERIALS AND METHODS

### Study participants and samples

Human subject approval was obtained for this study from the institutional review board of the American University of Beirut and all the methods were carried out in accordance with the approved ethical guidelines. A written informed consent was signed by the study subjects before participation in the study. A data collection form was administered to the study participants ( $\geq 18$  years old) to collect demographic information, data related to exposure and risk behavior information. One hundred and one subjects were recruited during the time period March 2010–December 2011. Subjects were excluded if they had a prior or current history of HCV, HIV-1, renal disease or cancer. Children or adolescents of HBV carrier mothers and vaccinated in infancy were not included in the study. Blood was drawn from the study participants and peripheral blood mononuclear cells<sup>[28]</sup> and sera were collected and stored in liquid nitrogen and at  $-80^{\circ}\text{C}$ , respectively. DNA was extracted from whole blood of the study participants using the QIAamp DNA Blood Midikit (Qiagen, Germany), as per manufacturer's

instructions. The integrity of the purified DNA was checked by gel electrophoresis and storage was at  $-20^{\circ}\text{C}$ .

### Enzyme-linked immunosorbent assay

While we recruited 101 voluntary participants, sera samples of 99 HBV vaccinated and non-vaccinated study participants were tested in duplicate for the presence of anti-HBs antibodies as a measure of protection against hepatitis B, hepatitis B surface antigen (HBsAg) and hepatitis B core antibody (anti-HBc) as indicators of infection. We did not have enough sera to use in the analysis for two of our study participants. The Monolisa HBsAg ULTRA, anti-HBs PLUS and anti-HBc PLUS assays (BIO-RAD, France) were used as per manufacturer's instructions, respectively. Anti-HBs antibodies were measured in mIU/mL and levels  $\geq 10$  mIU/mL were indicative of post-vaccination protection<sup>[29,30]</sup>.

### KIR genotyping

The polymerase chain reaction (PCR)-based *KIR* genotyping SSP Kit (Invitrogen, Brown Deer, WI, United States) was used to detect the presence and absence of *KIR* genes, as per manufacturer's instructions. Briefly, 25  $\mu\text{L}$  of DNA was used along with the primer sets to amplify the alleles described by the World Health Organization (WHO) international nomenclature committee (<http://www.ebi.ac.uk/ipd/kir/>). All amplifications were performed using PX2 thermocycler (ThermoHybrid, United Kingdom) programmed with a 1-min denaturation step at  $95^{\circ}\text{C}$ , followed by 30 cycles of  $94^{\circ}\text{C}$  for 20 s,  $63^{\circ}\text{C}$  for 20 s, and  $72^{\circ}\text{C}$  for 90 s and finally  $4^{\circ}\text{C}$  in the thermal cycler. PCR products were gel-purified and visualized under UV transillumination (Sigma, California, United States)<sup>[31]</sup>. The presence and absence of the following gene loci and variants were tested: 2DL1, 2DL2, 2DL3, 2DL4, 2DL5A, 2DL5B, 2DS1, 2DS2, 2DS3, 2DS5, 3DL1, 3DL2, 3DL3, 3DS1, 2DP1, and 3DP1. The variants of the KIR3DP1 pseudogene, KIR3DP\*001/002/004 and KIR3DP1\*003 were also detected in addition to KIR2DS4 variants: 2DS4\*001/002 and 2DS4\*003/007. The frequency of *KIR* was calculated by direct count of the observed phenotype and referred to as observed frequency (OF). In addition, the estimated *KIR* gene frequency (KF) for the putative loci was calculated using the following formula:  $\text{KF} = 1 - \sqrt{1 - \text{OF}}$  based on the assumption of Hardy-Weinberg equilibrium<sup>[32]</sup>. The frequencies of haplotype A and B were calculated using the following formula: haplotype A =  $(2n_{AA} + n_{AB})/2n$  and haplotype B =  $(2n_{BB} + n_{AB})/2n$ , where  $n_{AA}$ ,  $n_{AB}$  and  $n_{BB}$  are the numbers of individuals with haplotype group AA, AB and BB, respectively and  $n$  is the total number of individuals<sup>[33]</sup>.

### Statistical analysis

SPSS 19 was used for statistical analyses. We compared vaccinated and non-vaccinated subjects for each of the *KIR* polymorphisms using  $\chi^2$  and Fisher-exact test (FET) and reported the odds ratio and 95%CI. Similar analyses

were conducted for the comparison of protected and non-protected subjects within the vaccinated group. We also examined the relationship between genotypes and the presence or absence of *KIR* genes and the levels of anti-HBs and *KIR* genes among the vaccinated subjects using  $\chi^2$  and FET; for these comparisons, post-hoc tests were conducted only if the omnibus test was significant. We corrected for multiple comparisons for post-hoc tests using Bonferroni correction.

## RESULTS

### Characteristics of study participants

One hundred and one subjects were recruited between March 2010 and December 2011; 39% of the study participants were males and 61% were females. The majority of our study participants were 19-29 years old (40%). Table 1 summarizes the characteristics of the study participants. The majority (75%) held a university undergraduate degree or higher and was employed. During recruitment and when participants were asked about their vaccine status, 50% of our voluntary participants self-reported that they were vaccinated against HBV whereas 25% thought they were not vaccinated and 26% did not know their vaccine status.

In an attempt to confirm the vaccination status of our study participants, sera samples from 99 participants were tested for the levels of anti-HBs as an indicator of protection ( $\geq 10$  mIU/mL) as defined by the WHO international reference standard<sup>[30,34]</sup>. This is especially due to the lack of documented dosages of hepatitis B vaccine for many of the study participants as well as lack of knowledge of the vaccination status of many of the

study participants. In the subsequent analyses, data on these 99 voluntary subjects are reported; participants with anti-HBs antibodies  $\geq 10$  mIU/mL will be considered vaccinated against hepatitis B. We also tested the sera samples for anti-HBc as a marker of previous infection and for HBsAg, a marker associated with recent exposure to HBV. All our participants were negative for HBsAg. Among the voluntary participants, 74/99 (75%) were vaccinated against hepatitis B as judged by the detection of anti-HBs titers; whereas 25% (25/99) were classified as non-vaccinated against hepatitis B. Among the vaccinated participants, 47% (35/74) had anti-HBs titers above 100 mIU/mL, 22% (16/74) had anti-HBs ranging between 10-100 mIU/mL, and 20% (15/74) had values of less than 10 mIU/mL. The time of vaccination (when available) ranged between the years 1999 and 2011, with some participants receiving 2 doses and others receiving 3 or more doses. When we tested for an association between the age groups of our study participants (19-29, 30-39, 40-49, 50-59, 60-69, 70-79 and 80-89) and the concentration of anti-HBs antibodies among vaccinated subjects, a *P* value of 0.047 was detected (FET). Nine percent (7/74) of the vaccinated participants had undetectable levels of protective antibodies. Five out of 7 (71%) of the former group were health-care workers; the latter are expected to be continuously monitored for protection against HBV due to the nature of their work. Importantly, anti-HBc was positive in 3% (3/99) of our study participants presenting with anti-HBs levels ranging between 110-1000 mIU/mL. This is associated with protection as a result of natural infection. One of these participants is a vaccinated female nurse, whereas the other 2 are non-vaccinated and are not in the health care profession. None of the anti-HBc positive participants were HBsAg positive.

### KIR genotypes and genes frequencies

We next determined the *KIR* genotypes among the study participants: 44%, 40% and 16% were carriers of AA, AB and BB genotypes, respectively, with a 1.77 A to B ratio. The genotype was classified as B if any of the following genes was detected: 2DL2, 2DL5, 3DS1, 2DS1, 2DS2, 2DS3 and 2DS5. If none of these was detected, the genotype was considered as AA. Similarly, if none of the A haplotypes was detected, the genotype was classified as BB; 77%, 75% and 69% of the AA, AB and BB carriers were vaccinated, respectively. There was no significant difference between the expression of AA, AB and BB among vaccinated and non-vaccinated participants (FET, *P* = 0.784). Similarly, we did not detect any significant difference when we compared the frequencies of *KIR* genotypes among the vaccinated with anti-HBs levels less than 10, 10-100 and above 100 mIU/mL. We did not detect any difference between the frequencies of *KIR* genotypes among vaccinated participants with protective and non-protective levels of anti-HBs (FET, *P* = 0.865).

<sup>1</sup>The statistical test performed to compare the frequencies of *KIR* gene expression among vaccinated and non-vaccinated study participants where by FET refers to Fisher's exact test and the rest of the values represent the Pearson  $\chi^2$  value. We compared the frequencies of *KIR* genes with enough variability between study participants that were vaccinated against hepatitis B virus. The vaccinated participants were divided for this analysis into 2 groups depending on the level of anti-HBsAg. Anti-HBsAg < 10 mIU/mL, not protected against hepatitis B virus infection; anti-HBsAg ≥ 10 mIU/mL, protected against hepatitis B virus infection as a result of vaccination. KIR: Killer immunoglobulin receptor; FET: Fisher-exact test; HBsAg: Hepatitis B surface antigen. OR: Odds ratio.

We divided the *KIR* genes expressed in our study participants into inhibitory, non-inhibitory (or activating) and those encoding inhibitory and activating signals, as previously described<sup>[13]</sup>. The inhibitory KIR2DL1, KIR2DL4, KIR3DL1, KIR3DL2, and KIR3DL were detected in more than 95%, whereas KIR2DL2, KIR2DL3, KIR2DL5 (KIR2DL5A and KIR2DL5B) were expressed in 56%, 84% and 42% (25% and 29%) of participants, respectively (Table 2). The OF of the activating *KIR* genes ranged between 35% and 55% except for KIR2DS4, detected in 95% of the study participants (40.6% 2DS4\*001/002; 82.2% 2DS4\*003/007). KIR2DP1 pseudogene was detected in 99% of our participants, whereas KIR3DP\*001/02/04 and KIR3DP1\*003 had frequencies of 17% and 100%, respectively. The corresponding estimated frequencies of each *KIR* gene followed the same trend or order as the OF data.

For this analysis and thereafter, we studied the genes with enough variability, particularly 2DL2, 2DL3, 2DL5 (2DL5A, 2DL5B), 2DS1, 2DS2, 2DS3, 2DS4 (and its variants), 2DS5, 3DS1 and the pseudogene 3DP1\*001/002/004 (Table 2). We report the lack of significant difference in the frequency of *KIR* genes among vaccinated and non-vaccinated participants (Table 3). Moreover, there was no significant difference in the frequency of these genes among participants protected against HBV and those that are not protected

against HBV, as judged by their level of anti-HBs antibodies (Table 4).

We performed similar analyses to determine the relationship between AA, AB, BB genotypes and the expression of *KIR* genes showing enough variability (Table 5). 2DL2 ( $\chi^2$ , *P* = 0.00), 2DL3 ( $\chi^2$ , *P* = 0.00), 2DS2 ( $\chi^2$ , *P* = 0.00), 2DS3 ( $\chi^2$ , *P* = 0.00), 2DL5B FET (*P* = 0.00), and 3DP1001/002/004 (FET, *P* = 0.006) were found to be significantly different between genotypes but not 2DS1 ( $\chi^2$ , *P* = 0.749), 2DL5A (FET, *P* = 0.782), 2DS4\*001/002 ( $\chi^2$ , *P* = 0.621), 2DS4\*003/007 (FET, *P* = 0.392) and 3DS1 ( $\chi^2$ , *P* = 0.948). For those genes showing significant differences among the AA, AB and BB genotypes, we computed post-hoc comparisons. These differences still hold significance between subgroups except for 2DL5B, 2DS2, 2DS3 and 3DP1\*001/002/004 between genotypes AB and BB.

#### ***KIR* gene frequencies among vaccinated and non-vaccinated participants**

To evaluate the role of *KIR* genes in protection against or susceptibility to HBV, we next compared the frequency of *KIR* genes among HBV-vaccinated and non-vaccinated participants (as judged by the level of anti-HBs antibodies). Depending on their anti-HBs levels that we tested for in this study, participants vaccinated against hepatitis B were divided into 4 groups: Group I >

**Table 4** Killer immunoglobulin receptor gene frequencies among study participants vaccinated against hepatitis B virus as compared to non-vaccinated subjects *n* (%)

KIR genes	Vaccinated ( <i>n</i> = 74)	Non-vaccinated ( <i>n</i> = 25)	Test <sup>1</sup>	OR (95%CI)	<i>P</i> value

<sup>1</sup>The statistical test performed to determine the relationship between AA, AB and BB genotypes and the expression of *KIR* genes among vaccinated and non-vaccinated study participants. FET refers to the Fisher's exact test and the rest of the values represent the Pearson  $\chi^2$  value. <sup>a</sup>*P* < 0.05, significant. KIR: Killer immunoglobulin receptor; FET: Fisher-exact test.

100 mIU/mL, group II 10-100 mIU/mL, group III < 10 mIU/mL and group IV with undetectable levels of protective antibodies. The frequency of only KIR2DL5B was significantly different among these categories (FET, *P* = 0.0263) (Table 6). When we performed post-hoc comparisons between these groups, we detected no significant difference in the expression of KIR2DL5B. These groups of vaccinated participants were also similar in relation to the expression of AA, AB and BB genotypes (FET, *P* = 0.669).

We identified 3 participants testing positive for anti-HBc with anti-HBs levels higher than 100 mIU/mL. Two out of three of these participants were non-vaccinated and thus we believe they are protected as a result of natural infection. The third participant was vaccinated against HBV. Two out of three (66.7%) of these participants carry the AB genotype and one participant is AA positive. The three participants expressed 2DL1,

2DL3, 3DL1, 3DL2, 3DL3 (inhibitory), activating genes (2DS3, 2DS4\*001/002 variant) and both inhibitory and activating genes (2DL4, 2DP1 and 3DP1\*003). These subjects did not express 2DL5A or 3DP1\*001/002/004. We did not test for the presence of HBV DNA among these participants. We did not find any significant relationship between the genotype of these participants and the expression of *KIR* genes, or between the *KIR* genes and the susceptibility to natural or breakthrough infection.

## DISCUSSION

The administration of hepatitis B vaccine in infancy is 95% effective and correlates with long-term protection<sup>[8,35,36]</sup>. However, vaccine failure has been reported in 5% of hepatitis B-vaccinated persons; moreover, breakthrough infection has also been reported following vaccination with hepatitis B vaccine<sup>[37]</sup>. The increase

**Table 6** Killer immunoglobulin receptor gene expression and levels of anti-HBs among the vaccinated study participants *n* (%)

<i>KIR</i> genes	Group I <sup>1</sup> ( <i>n</i> = 36)	Group II <sup>2</sup> ( <i>n</i> = 16)	Group III <sup>3</sup> ( <i>n</i> = 15)	Group IV <sup>4</sup> ( <i>n</i> = 7)	Test <sup>5</sup>	<i>P</i> value

in circulating NK cells, major players in the innate immune system and regulators of the virus-specific T cell responses through their cross-talk with dendritic cells and T cells<sup>[38-40]</sup>, was suggested to contribute to HBV viral control<sup>[41]</sup>. The impact of genetic regulation on immune responses following vaccinations has been previously reported<sup>[19,24]</sup>. This evidence prompted us to explore the potential role of KIR following hepatitis B vaccination. In Lebanon, hepatitis B vaccine is offered as part of the immunization program early in childhood as per the WHO guidelines. In this study, 69% of the vaccinated participants retained more than 10 mIU/mL of anti-HBs antibodies and hence are immune to HBV infection; whereas 30% are susceptible to the latter due to either undetectable levels of antibodies or levels below 10 mIU/mL. We do not have data on the time of vaccination of these participants to reflect on the duration of the retention or the loss of the immune response post-vaccination. We report the lack of significant association between the number of vaccine dosages (when vaccine dosage is available) and the titer of antibodies among vaccinated participants. Recent reports show that multiple immunizations against hepatitis B are inefficient at mounting antibody responses<sup>[42]</sup>, while others suggest that immunization against hepatitis in infancy is associated with a seroprotective response to a challenge dose of vaccine with extended duration of protection through adolescent years<sup>[43]</sup>. We cannot suggest similar trends from our results due to the lack of data on the time of vaccination, the age at vaccination, as well as the number of dosages administered for many participants.

Anti-HBc antibodies, indicators of HBV infection, were detected in 3 participants (3%) in the absence of HBsAg, with one being a nurse suspected of being exposed to HBV at the work place. This might suggest a "breakthrough" infection occurring following vaccination against hepatitis B; this is suggested since health care

workers are regularly monitored for protective levels of anti-HBs antibodies. However, due to the lack of data on the timing of vaccination and/or infection of this participant, we cannot confirm whether exposure to HBV has occurred before or after vaccination. The other 2 participants are non-vaccinated and are protected with high levels of anti-HBs antibodies as a result of natural infection. We do not have data pertaining to the time of infection following vaccination; moreover, we did not perform HBV DNA testing. Health care workers with undetectable anti-HBsAg levels detected in our study are clearly susceptible to HBV infection and consequently in need of booster vaccination to induce an anamnestic response in order to prevent acute disease and carrier state.

While hepatitis B vaccine booster doses are not currently recommended following vaccination, a better understanding of the correlates of long-term immunity is needed. This is critical especially since several studies show that vaccines with anti-HBs levels of 10-99 mIU/mL achieved following primary vaccination are less likely to produce an anamnestic response following a booster HBV vaccine as compared to those with anti-HBs  $\geq 100$  mIU/mL<sup>[35,44]</sup>. NK cells play a major role in the innate immune system as first line of defense and in the regulation of the virus-specific T cell responses through their cross-talk with dendritic cells and T cells<sup>[38-40]</sup>. Moreover, NK cells are suggested to contribute to HBV control<sup>[41]</sup>. Our data show that genotypes with 11 *KIR* genes were most prevalent, with AA genotype being more frequent among the study participants. The inhibitory *KIR* genes were more frequent among our study participants than the activating genes, which is in agreement with a finding associated with A haplotype being present in higher numbers in inhibitory *KIR* genes<sup>[39]</sup>.

KIR2DL4, KIR3DL2, KIR3DL3 and KIR3DP1\*003 were present in every participant. This is expected since these

are framework genes. The frequency of KIR2DL5B is the only significantly different gene among the vaccinated participants with different anti-HBs antibodies titer. The role of KIR2DL5, expressed at frequencies ranging between 26% and 86% in all human populations, is not completely understood<sup>[45]</sup>. The ligand of KIR2DL5 is also still unknown.

A number of limitations exist, and these include the lack of data on the time of vaccination and corresponding age at time of vaccination of the study participants, and more importantly, the small sample size. Our sample size is powered to detect medium to large effect sizes when some of the effect sizes for group differences are small. However, medium to large effect sizes are those where group differences have more clinical significance, which we are powered to detect. Consequently, the clear impact that *KIR* genes have on susceptibility to acquiring hepatitis B or protection against the infection cannot be addressed in these small groups.

To our knowledge, this is the first study screening for the possible role of *KIR* genes among individuals vaccinated against HBV. While studies have shown the association between gene variants and immune responses to a variety of vaccines, little is known about the strength and the sustainability of antibody responses following vaccination against HBV in relation to expression of *KIR* genes. Our results are useful to design larger studies to better elucidate the role of KIR in susceptibility or long-term protection against HBV as well as other diseases.

## ACKNOWLEDGMENTS

We thank all our voluntary participants and Mr. Doudar for his help in recruitment of volunteers, as well as Ms. Sarah Shamra for technical assistance in the lab.

## COMMENTS

### Background

Killer immunoglobulin receptor (*KIR*) genes encode receptors expressed on the surface of natural killer cells. The literature has described the relationship between KIRs and differential responses in many disease conditions, specifically human immunodeficiency virus and hepatitis C virus. The authors thought to explore the role of *KIR* genes in response to hepatitis B vaccine in a cohort of Lebanese adults.

### Research frontiers

This study aims at elucidating the possible role of genetic factors such as KIRs in the regulation of post-vaccine immune responses specifically following hepatitis B vaccine.

### Applications

While the sample size is powered to detect medium to large effect sizes, the impact that KIR and HLA have on the susceptibility to acquiring hepatitis B virus (HBV) or protection against the infection cannot be addressed in our sample. Nevertheless, our results are useful to design larger studies to better elucidate the role of KIR in susceptibility or long-term protection against HBV and other diseases.

### Terminology

Two groups of *KIR* haplotypes are known in humans: A and B. Haplotype A

encodes inhibitory receptors and consists of nine genes [3DL3, 2DL3, 2DP1, 2DL1, 3DP1, 2DL4, 3DL1, one activating (2DS4), 3DL2 and 2DL5]. Haplotype B carries a variety of gene combinations and encodes more activating receptors as compared to haplotype A [3DL3, 2DS2, 2DL2, 2DL5B (inhibitory), 2DS3, 2DP1, 2DL1, 3DP1, 2DL4, 3DS1, 2DL5A (inhibitory), 2DS5, 2DS1, and 3DL2].

## Peer-review

This is an interesting study aiming to screen for a possible role of *KIR* gene expression and antibody response following hepatitis B vaccination. The major point of this manuscript is that there is no significant association between the frequency of *KIR* genes and anti-HBs antibodies detected. Although it is a negative result, it could be an indicant for understanding the role of *KIR* loci in response to HB vaccine.

## Abstract

### AIM

To investigate the effect of lycopene extracted from tomatoes (LycT) on ultrastructure, glycolytic enzymes, cell proliferation markers and hypoxia during N-Nitrosodiethylamine (NDEA)-induced hepatocarcinogenesis.

### METHODS

Female BALB/c mice were randomly divided into four groups: The Control, NDEA (200 mg NDEA/kg b.w. given i.p.), LycT (5 mg/kg b.w. given orally on alternate days) and LycT + NDEA group. The mRNA and protein expression of various cell proliferation markers (PCNA, Cyclin D1, and p21) were assessed by reverse transcription-polymerase chain reaction and enzyme linked immunosorbent assay, respectively. The ultrastructure of hepatic tissue was analyzed using scanning and transmission electron microscopy. The enzymatic activity of glycolytic enzymes was estimated using standardized protocols, while glucose-6-phosphate dehydrogenase activity level was estimated using a kit obtained from Reckon Diagnostic P. Ltd. (India).

### RESULTS

Uncontrolled proliferation in the liver of NDEA ( $P \leq 0.001$ ) mice was evident from the high expression of cell-proliferation associated genes (PCNA, Cyclin D1, and p21) when compared to control and LycT mice. In addition, enhanced activities of hexokinase, phosphoglucose isomerase, aldolase, glucose-6-phosphate

dehydrogenase and hypoxia-inducible factor-1 $\alpha$  were observed in NDEA mice as compared to control ( $P \leq 0.001$ ) and LycT ( $P \leq 0.001$ ) mice. The alterations in hepatic ultrastructure observed in the NDEA group correlated with the changes in the above parameters. LycT pre-treatment in NDEA-challenged mice ameliorated the investigated pathways disrupted by NDEA treatment. Moreover, hepatic electron micrographs from the LycT + NDEA group showed increased macrophages, apoptotic bodies and well-differentiated hepatocellular carcinoma (HCC) in comparison to undifferentiated HCC as observed in the NDEA treated group.

## CONCLUSION

This study demonstrates that dietary supplementation with LycT has a multidimensional role in preventing HCC development.

**Key words:** Hepatocellular carcinoma; Ultrastructure; Hypoxia; Cell proliferation; Lycopene; Glycolysis

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The present study was designed to evaluate the chemopreventive role of lycopene extracted from tomatoes (LycT) against N-Nitrosodiethylamine-induced hepatocellular carcinoma (HCC). The findings suggested the mechanism underlying LycT-mediated chemoprevention of HCC.

## INTRODUCTION

The continuous rising trend in cancer worldwide necessitates potential action against this deadly disease. Cancer is a complex disease and requires attention in multiple directions to prevent its development. Nearly two-thirds of all cancer cases are linked to inadequate components in the diet, environmental exposure to pollutants and occupational exposure to toxic materials<sup>[1,2]</sup>. Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide and is the second most common cause of cancer-related death<sup>[3]</sup>. N-Nitrosodiethylamine (NDEA) is a known potent environmental hepatic carcinogen and has been used as an initiator in several hepatic cancer models<sup>[4,5]</sup>. Besides direct exogenous exposure, humans are also exposed to endogenously produced nitrosamines<sup>[6]</sup>. NDEA is metabolized in the liver to its active ethyl radical metabolite and various other reactive metabolites, which are highly reactive towards DNA, proteins and lipids, thus exhibiting sequential cellular and molecular alterations leading to its hepatocarcinogenic effect<sup>[4,7-9]</sup>.

Natural and experimental chemical hepatocarcino-

genesis is accompanied by altered cellular redox status, altered cytochemical pathways, altered molecular phenomena, chromosomal instability and altered physiological environment in cells. Of the various carcinogenic insults, uncontrolled proliferation, dysregulated carbohydrate metabolism and hypoxia play very crucial roles in HCC development. Aerobic glycolysis and diversion to a biosynthetic pathway, *i.e.*, the pentose phosphate pathway are the metabolic hallmarks of carcinogenesis<sup>[10]</sup>. In recent years, interest in these pathways has been renewed in the tumor microenvironment which has a profound effect on core tumor metabolism. Hypoxia inducible factor-1 $\alpha$  (HIF-1 $\alpha$ ) is involved in many compensatory pathways such as angiogenesis, glucose metabolism, survival and tumor development<sup>[11]</sup>. Although there have been advances in therapeutic approaches a complete cure is still unavailable. Dietary multi-targeted agents have attracted the attention of cancer biologists as these agents may provide a solution to this complex problem by targeting multiple targets simultaneously<sup>[12]</sup>. A large body of evidence has revealed an association between phytochemicals and a reduced risk of developing chronic diseases<sup>[13,14]</sup>.

Lycopene, a polyunsaturated hydrocarbon imparting red colour to various fruits is a nutritionally important carotenoid exhibiting beneficial health effects by virtue of its antioxidant activity with minimal side effects<sup>[15]</sup>. A large number of studies have shown an association between lycopene and a reduced risk of developing chronic diseases such as cancer, diabetes, cardiovascular disorders and degenerative diseases<sup>[15-18]</sup>. In addition to its antioxidant property, lycopene is known to modulate other non-oxidative pathways such as regulation of gap junction communication, the hormonal system, the immune system and the metabolic pathways of xenobiotics<sup>[16,19]</sup>. Phytochemicals also tend to be more effective for long-standing health problems that do not respond well to synthetic medicines<sup>[20]</sup>.

In our previous studies we developed a standardized detailed protocol for lycopene extracted from tomatoes (LycT), its characterization and its beneficial effect in inhibiting NDEA-induced HCC development in terms of histopathological observations, tumor statistics, apoptosis, antioxidative capacity and toxicity<sup>[21-23]</sup>. However, further studies are warranted to determine the modulating effect of lycopene on dysregulated glucose metabolism and hypoxia, as these processes play critical roles in cancer. Thus, the present study was designed to explore the influence of LycT on various glycolytic and non-glycolytic enzymes, the expression of HIF-1 $\alpha$  and potent cell proliferation-associated genes, while preventing NDEA-induced HCC. Moreover, an attempt was made to demonstrate the impact of an imbalance between energy production and metabolic demands on the gross morphology and ultrastructure of hepatocytes in HCC.

## MATERIALS AND METHODS

### Chemicals

Azino-bis(ethylbenzthiazoline sulfonic acid) (ABTS),

diaminobenzidine, ethidium bromide, TRI-reagent and NDEA were obtained from Sigma Chemicals (St. Louis, MO, United States). Primary and secondary antibodies were obtained from Santa Cruz Biotechnology, CA, United States. Invitrogen superscript (III) one step reverse transcription-polymerase chain reaction (RT-PCR) was purchased and used for RT-PCR analysis. Other chemicals were purchased from local reputable companies including Sisco Research Laboratory (P) Ltd. Detailed information regarding extraction and characterization of LycT has been reported previously (Gupta *et al.*<sup>[21]</sup>).

### **Animal model and experimental conditions**

The animal protocol was designed to minimize pain or discomfort to the animals. All animals were acclimatized to laboratory conditions, *i.e.*, temperature of 21 °C ± 1 °C and humidity of 50%-60% for one week prior to the various treatments. All the mice were provided with drinking water and a standard animal pellet diet *ad libitum*. Female BALB/c mice (25-30 g) were randomly divided into four groups (*n* = 7 per group). Animals in Group I (Control) received 0.1 mL olive oil (vehicle) orally throughout the experiment. Group II (NDEA) animals received a cumulative dose of 200 mg NDEA/kg body weight (b.w.) given intraperitoneally in 8 wk as described previously<sup>[5]</sup>. Group III (LycT) mice received LycT orally at a dose of 5 mg/kg b.w. thrice a week for 24 wk. Group IV (LycT + NDEA) animals received NDEA in the same manner as Group III and were also given LycT at a dose of 5 mg/kg b.w. thrice a week for 24 wk. LycT administration was commenced two weeks prior to NDEA treatment. Animals were sacrificed after the 24<sup>th</sup> week to evaluate the modulatory effect of LycT in NDEA-induced hepatocarcinogenesis. The experimental study was reviewed and approved by the Institutional Animal Ethics Committee (IAEC) of Panjab University, Chandigarh (India) and conducted according to the Indian National Science Academy guidelines for the use and care of experimental animals (IAEC/284-295 at Sr. No. 48).

### **Scanning and transmission electron microscopy**

After 24 wk, liver tissues from animals in the different groups were immediately fixed in 2% para-formaldehyde and 2.5% glutaraldehyde prepared in 100 mmol/L phosphate buffer (pH 7.4) for 6 h at 4 °C. Critical point drying, trimming of the tissue and gold coating were carried out and the tissues were viewed under a LEO 435 VP scanning electron microscope. Secondary fixation, treatment with a mixture of propylene oxide and epoxy resin (1:1), embedding in freshly prepared epoxy resin and ultrathin sections mounted on colloid on-carbon coated grids were carried out and examined with a Philips CM-10 transmission electron microscope.

### **Estimation of the activities of glycolytic enzymes, glucose-6-phosphate dehydrogenase and glycogen content**

The specific activity of hexokinase, phosphoglucoisomerase (PGI) and aldolase was estimated according

to the reported standard protocols<sup>[24-26]</sup>. Glucose-6-phosphate dehydrogenase (G6PD) activity level was estimated in a tissue homogenate using an ENZOPAK G6PD kit obtained from Reckon Diagnostic P. Ltd. (India). The activity of G6PD in the samples was further calculated using 6.22 mmol/L per centimeter as the extinction coefficient of NADPH at 340 nm. The glycogen content in liver was estimated using the protocol described by Seifter *et al.*<sup>[27]</sup>. The amount of glycogen in the aliquot was determined using a glucose standard.

### **mRNA expression analysis**

Total RNA isolation from liver tissue was carried out using TRI-reagent. For RT-PCR analysis, primers for *HIF-1 $\alpha$* , *PCNA*, *p21* and *Cyclin D1* were searched from the database "Gene Runner" and were synthesized by Sigma-Aldrich (United States). The lengths of the primers chosen were approximately 20bp (Table 1). RT-PCR was performed according to the described protocol of the Superscript (III) one step RT-PCR kit. The DNA bands were visualized in agarose gel using an ultraviolet transilluminator and photographed on Gel Doc. Densitometric analysis of the bands was performed using Image J software (National Institute of Health, United States).

### **Quantitation of protein expression**

**Sample preparation:** The animals were fasted overnight before liver dissection. Mice were euthanized by cervical dislocation under light ether anesthesia. Liver perfusion was carried out with 0.9% NaCl and the liver was carefully removed and placed in a Petri plate containing ice-cold saline. The tissue was homogenized in ice-cold 100 mmol/L potassium phosphate buffer (pH 7.4) containing 150 mmol/L KCl in an ice-chamber to obtain 25% homogenate (w/v) using a mechanically driven Teflon fitted Potter Elvehjem homogenizer. The homogenate (25%) was then subjected to centrifugation at 10000 rpm for 30 min at 4 °C for preparation of the post-mitochondrial fraction.

**ELISA:** Post mitochondrial fractions obtained from the hepatic tissue of different groups were quantitated for protein concentration by the method of Lowry *et al.*<sup>[28]</sup>. Two point five microgram protein was loaded onto an ELISA strip containing carbonate buffer. Further, protein expression of *HIF-1 $\alpha$* , *PCNA*, *p21* and *Cyclin D1* were analyzed according to the standard protocol of ELISA using specific primary antibodies and enzyme conjugated secondary antibodies. ABTS in citrate buffer was added along with hydrogen peroxide for color generation. The color thus obtained was quantified at 405 nm.

### **Statistical analysis**

The statistical methods used in this study were reviewed by Dr. Neha Arora Chugh, Department of Biophysics, Panjab University, Chandigarh. Data were expressed as mean ± SD. The results were subjected to analysis of variance (one-way ANOVA) followed by the post

hoc test for statistical significance using SPSS (version 14.0) software.  $P \leq 0.05$  was considered statistically significant.

## RESULTS

Scanning electron microscopy (SEM) of the control and LycT groups revealed normal hepatic surface morphology with polyhedral hepatocytes radially arranged around central veins in cords separated by sinusoids (Figure 1A-C). Bile canaliculi were observed on the apical surface of hepatocytes. A few red blood cells were also visible in the sinusoids. However, serious and irreversible alterations in liver architecture were observed in the NDEA and LycT + NDEA groups. Smoothing or rounding of the hepatocytes with hyperplastic tumor along with clumps of hepatocytes with intercellular surfaces covered with numerous microvillus projections were visible (Figure 1D-E). The discernible nodules were of irregular shape and size. Necrotic tumor nodules and uncontrolled cell density revealed the presence of undifferentiated HCC in the NDEA group. In contrast, the surface morphology of liver tissue from the LycT + NDEA group revealed well differentiated HCC characterized by stromal invasion and a trabecular pattern of two to three cells thick plates of hepatocytes (Figure 1H). High cell density with pleomorphism of tumor cells was also evident (Figure 1F). Apoptotic bodies were observed indicating a high rate of apoptosis (Figure 1G). Thus, LycT pre-treatment of NDEA-challenged mice significantly reduced the severity caused by NDEA. Table 2 shows the results of a quantitative comparison of hepatic tissues from the NDEA and LycT + NDEA groups using SEM.

Transmission electron microscopy (TEM) of the control and LycT groups revealed normal hepatic ultrastructural architecture (Figure 2A-C). At low magnification, hexagonal hepatocytes radially arranged around blood vessels with an intact cell membrane, clear and granulated cytoplasm comprising oval-shaped mitochondria, rough endoplasmic reticulum (RER) and smooth endoplasmic reticulum were observed. A smooth, rounded and prominent nucleus with intact double layered nuclear membrane, a darkly stained single and prominent nucleolus along with uniformly distributed chromatin in the nucleoplasm

**Table 2** Comparative analysis of the N-Nitrosodiethylamine and lycopene extracted from tomatoes + N-Nitrosodiethylamine group by scanning electron microscopy

Groups/parameters	NDEA	LycT + NDEA
Cell density	+++	+
Rounding of hepatocytes	+++	+
Trabecular structures	-	+++
Necrotic tumor nodules	+++	+
Apoptotic bodies	-	+++
Type of HCC	Undifferentiated	Well-differentiated

Where “+++” indicates that more than 70%-90% of mice in a group showed this feature; “+” indicates that < 70% of mice showed this feature; “-” indicates that the < 20% of mice showed this feature. LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine; HCC: Hepatocellular carcinoma.

were also visible. Irregular non-membrane bound, faintly stained granules of hepatocellular glycogen were also observed. The presence of lipid granules as darkly stained spots and a few bi-nucleated hepatocytes were found in the LycT group in addition to the above features. Several irreversible alterations in the nucleus of liver cells from the NDEA group were observed (Figure 2D-E). A prominent large and irregular nucleus with interrupted nuclear membrane, multiple prominent nuclei and pseudo-inclusions were observed in liver sections from the NDEA group with an increased nuclear/cytoplasmic ratio. Karyotin (reticular material) deposition along the nuclear membrane was the striking difference when compared with normal nuclei. Loss of organization of cytoplasmic components such as pleomorphic mitochondria varying in shape and size, dilated cisternae of RER associated with mitochondria and decreased lysosomes were observed in tumor cells from the NDEA group. Variable light and dark granules of fat and glycogen deposits were also observed. The liver cells from the LycT + NDEA group showed mild damage to the nuclear membrane with fewer karyotin deposits (Figure 2F). Hepatocytes were evident with prominent nucleoli, pleomorphic mitochondria and a higher number of lysosomes. Moreover, liver sections showed many macrophages in sinusoids and apoptotic cells (Figure 2G-H). Table 3 shows the results of a quantitative comparison of hepatic tissues from the NDEA and LycT + NDEA groups using TEM.

A significant increase in the activities of liver hexokinase, PGI and aldolase in the NDEA and LycT + NDEA groups was evident when compared to the control and LycT groups. However, LycT pre-treatment significantly lowered the activity of hexokinase and PGI in the LycT + NDEA group when compared to the NDEA group. No significant change in aldolase level was observed in the LycT + NDEA group when compared to the NDEA group (Figure 3A-C). Moreover, NDEA treatment caused a significant increase in liver G6PD activity in the NDEA group when compared to the control and LycT groups. Moreover, a significant increase was also observed in the levels of liver G6PD in the LycT + NDEA group when compared to the control group. However, G6PD level

**Table 3** Comparative analysis of the N-Nitrosodiethylamine and lycopene extracted from tomatoes + N-Nitrosodiethylamine group by transmission electron microscopy

Groups/parameters	NDEA	LycT + NDEA
Hepatocytes	Rounded, smaller in size	Polygonal but rounded edges
Nucleus	Large and irregular shape	Oval shaped
Nuclear membrane	Not uniform and pseudoinclusions	Not uniform
Nucleoli	Large, irregular, multiple	One-two
Nuclear/cytoplasmic ratio	High	Low
Karyotin (reticular material)	Deposition along nuclear membrane	Fewer karyotin deposits
Cytoplasm	Loss of organization, dense	Organized
Mitochondria	Pleomorphic with increased density	Pleomorphic but number less than that in the NDEA group
Lysosomes	Few in number	High in number
Fat and glycogen globules	Variable	High
Macrophages	Very few	Many
Apoptotic bodies	No	Clearly visible in the section

LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine.

**Figure 1** Scanning electron micrographs of liver tissue at  $\times 500$  and  $\times 1500$ . A and B: Control group, illustrating the central vein (CV), hexagonal hepatocytes (encircled) and biconcave RBCs in sinusoids (arrowed); C: LycT group illustrating hexagonal hepatocytes with bile canaliculi (BC) on their surface (arrowed); D and E: NDEA group illustrating tumor nodules (encircled) with abnormal cell proliferation and disturbed ultrastructure; F-H: LycT + NDEA group respectively illustrating high cell density, CV, apoptotic bodies (arrowed) along with various alterations and two-three cell plate thickening indicating well-differentiated hepatocellular carcinoma, respectively. LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine; RBCs: Red blood cells.

**Figure 2 Transmission electron micrographs (× 2550) of liver tissue.** A and B: Control group illustrating round nucleus (N), nuclear membrane (Nm), nucleolus (Nu), and chromatin (C) and nucleoplasm (Np). Clear cytoplasm with mitochondria (M), dark bodies as lysosomes (Ly), smooth endoplasmic reticulum (SER), rough endoplasmic reticulum (RER), and Golgi bodies (GB) surrounded by plasma membrane (PM) were observed; C: LycT group illustrating similar characteristics to those in the control liver micrograph; D and E: NDEA group illustrating deformed N with disrupted and convoluted Nm, darkly masses in the nucleolus (white arrows), deposition of karyotin (k) and pseudo-inclusions (Pi). Cytoplasm was also found to be compactly packed with multiple pleomorphic M and RER. Percentage of other organelles was found to be lower, and variable light and dark granules of fat (encircled) and glycogen (Gy) deposits were also observed; F-H: LycT + NDEA group illustrating perforated nuclear membrane. Cytoplasm contained was occupied with pleomorphic mitochondria, with a however higher percentage of organelles such as GB, Ly, RER and higher glycogen deposits. Macrophages in the sinusoid (S) were characterized by a large nucleus to cytoplasmic ratio, abundant mitochondria and microvilli (Mi). Apoptotic body characterized by cell shrinkage and condensation of nuclear chromatin into delineated masses (Cm), forming extensions (Ex), and crowded with closely packed cellular organelles (white arrow) and fragments of nucleus (Fr). LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine.

**Table 4** Effect of N-Nitrosodiethylamine and/or lycopene extracted from tomatoes on protein expression in mice hepatic tissue using ELISA

Protein (absorbance at 405 nm)	Control	NDEA	LycT	LycT + NDEA
PCNA	0.31 ± 0.01	0.47 ± 0.01 <sup>a</sup>	0.31 ± 0.01 <sup>b</sup>	0.39 ± 0.01 <sup>a,b,c</sup>
Cyclin D1	0.25 ± 0.02	0.38 ± 0.02 <sup>a</sup>	0.24 ± 0.02 <sup>b</sup>	0.36 ± 0.01 <sup>a,c</sup>

HIF-1α	0.22 ± 0.03	0.41 ± 0.01 <sup>a</sup>	0.23 ± 0.03 <sup>b</sup>	0.36 ± 0.04 <sup>a,c</sup>

<sup>a</sup>*P* ≤ 0.05, compared to the NDEA group; <sup>b,c,e</sup>*P* ≤ 0.001, compared to the control group, NDEA group and LycT group, respectively; <sup>f,g</sup>*P* ≤ 0.01, compared to the control group and NDEA group, respectively. LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine; PCNA: Proliferating cell nuclear antigen; p21: Cyclin-dependent kinase inhibitor 1A; HIF-1α: Hypoxia inducible factor-1α.

following LycT pre-treatment in NDEA-challenged mice was observed to be significantly lower than that in the NDEA group. No significant change was observed in the level of G6PD in the LycT group when compared to the control group (Figure 3D). A significant decrease in liver glycogen level was observed in the NDEA group when compared to the control and LycT groups. LycT pre-treatment in NDEA-challenged mice caused a significant increase in the levels of tissue glycogen when compared to the NDEA group. However, a significant decrease in tissue glycogen level was observed when compared to the control and LycT groups (Figure 3E). No significant change was observed in the activities of these enzymes and the level of glycogen in the LycT group when compared to the control group.

Figure 4 shows the mRNA expression of various genes involved in proliferation during HCC in the different treatment groups. Densitometric analysis of *HIF-1α* expression revealed a significant increase in the NDEA and LycT + NDEA groups when compared to the control and LycT groups (Figure 4). A significant increase in the expression of *PCNA* and *Cyclin D1* was observed in the NDEA group when compared to the control and LycT groups. The LycT + NDEA group showed a significant decrease in mRNA expression of *PCNA* and *Cyclin D1* when compared to the NDEA group. A significant increase in the expression of *Cyclin D1* was observed in the LycT + NDEA group when compared to the control and LycT groups. Densitometric analysis of *p21* expression revealed a significant decrease in the NDEA group when compared to the control and LycT groups. A significant increase in the expression of *p21* was observed in the LycT + NDEA group when compared to the control, NDEA and LycT groups. No change in the expression of these genes was observed when the LycT group was compared to the control group.

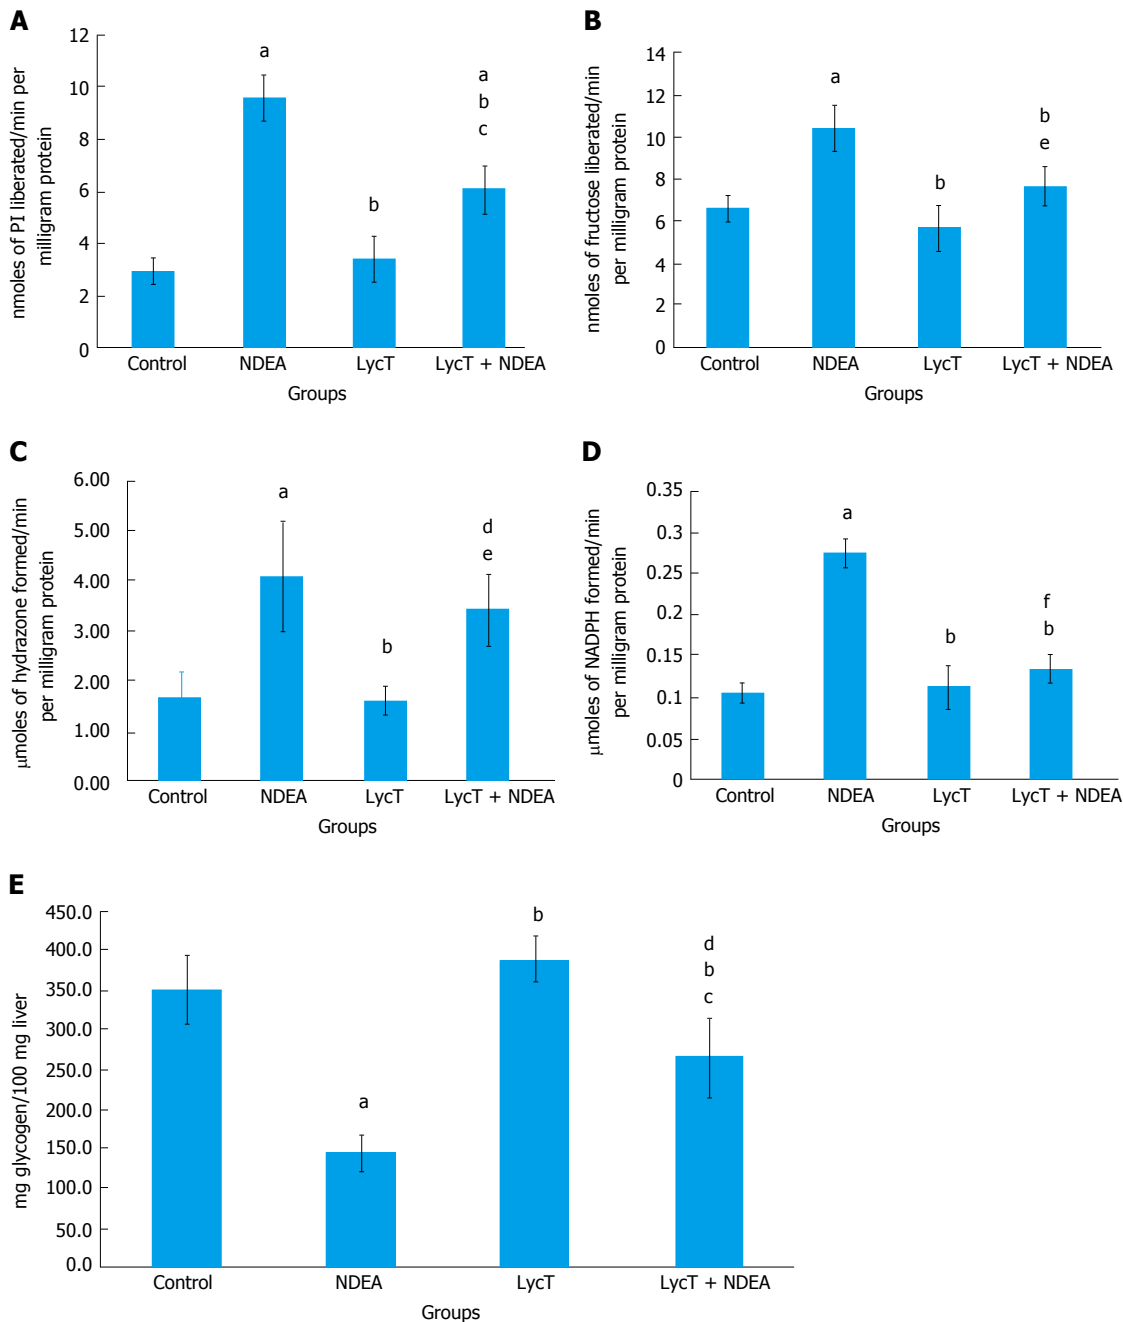

Table 4 shows the protein expression of various genes related to proliferation during HCC in the different treatment groups. The expression of *HIF-1α* was significantly increased in the NDEA and LycT + NDEA groups when compared to the control and LycT groups. Significantly enhanced expression of *PCNA* and *Cyclin D1* was attributed to significantly higher absorbance at 405 nm in the NDEA group when compared to the control and LycT groups (Table 4). A significantly lower absorbance at 405 nm was observed for *PCNA* expression following

LycT administration in NDEA-challenged mice when compared to the NDEA group. However, significantly enhanced expression of *PCNA* and *Cyclin D1* was observed in the LycT + NDEA group when compared to the control and LycT groups. Protein expression of *p21* was analyzed using ELISA in all treatment groups (Table 4). A significantly lower absorbance at 405 nm was found in the NDEA group when compared to the control and LycT groups. Significantly increased expression of *p21* was observed following LycT pre-treatment in NDEA-challenged mice when compared to the NDEA group. No significant change in the expression of *HIF-1α*, *PCNA*, *Cyclin D1*, and *p21* was observed between the LycT and control groups.

## DISCUSSION

Previously, we observed that LycT yielded lycopene phyto-complex (LycT) which delayed and reduced the severity of NDEA-induced HCC as indicated by histopathology, tumor statistics and antioxidant defence system analysis<sup>[21]</sup>. The presence of a myriad number of compounds in the extract has been reported to enhance the medicinal properties of active components through synergistic effects<sup>[29,30]</sup>. The therapeutic activity of a medicinal plant is not due to a single component or a few components. However, one substance is so dependent on the presence of another substance that the plant or part of the plant when used in its entirety often yields better results than any single component if used in isolation. Lycopene extraction following basic solvent separation has been proved to be a better agent as there is substantial evidence to show that synergism further enhances its activity and efficacy<sup>[31]</sup>. Lycopene phyto-complex has also shown high efficacy in triggering apoptosis in addition to its anti-oxidative property<sup>[31]</sup>. However, the study would be incomplete if the effects of LycT on other hallmark pathways of HCC development were not demonstrated. One of the essential and necessary alterations for the development of almost all cancers is the induction of aerobic glycolysis (Warburg effect). Recently, scientists have linked sustained aerobic glycolysis to oncogenic mutations leading to abnormal cell proliferation and apoptosis<sup>[32]</sup>. Limited literature is available regarding the irreversible alterations in hepatic architecture during HCC development and their

**Figure 3** Effect of lycopene extracted from tomatoes and/or N-Nitrosodiethylamine. A: Hexokinase activity (nmols of pseudo-inclusions liberated/min per milligram protein); B: Phosphoglucosomerase (nmols of fructose liberated/min per milligram protein); C: Aldolase (μmols of hydrazone formed/min per milligram protein); D: G6PD (μmols of NADPH formed/min per milligram protein); E: Glycogen (mg glucose/100 mg liver). <sup>a</sup>*P* ≤ 0.05, compared to the control group; <sup>b,c,d</sup>*P* ≤ 0.001, compared to the control group, NDEA group and LycT group, respectively; <sup>e,f</sup>*P* ≤ 0.01, compared to the control group and LycT group, respectively. LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine.

association with other dysregulated carcinogenic insults. With this in mind, the present study was designed to provide an insight into the alterations in ultrastructure, cell proliferation and aerobic glycolysis in NDEA-induced HCC and the effects of LycT on NDEA-induced HCC.

Several irreversible distortions using SEM and TEM were clearly observed and indicated the transformation of well-differentiated HCC to undifferentiated HCC in the NDEA group. Rapidly dividing tumor cells attaining a round contour during crowding of the cells has been reported in the literature<sup>[33]</sup>. Gross changes in nuclear mor-

phology, epigenetic regulation, chromatin packing and overall nuclear architecture can be related to alterations in the molecular machinery<sup>[34]</sup>. However, LycT pre-treatment in NDEA-challenged mice resulted in reduced severity as depicted in micrographs. Increased lysosomal bodies and the presence of apoptotic bodies in hepatic tissue from the LycT + NDEA treated group revealed a high apoptotic rate and thus confirms the observations and strengthened our reported data. Aerobic glycolysis arises as a compensatory mechanism due to altered respiration in tumor cells to fulfil the ATP requirements during

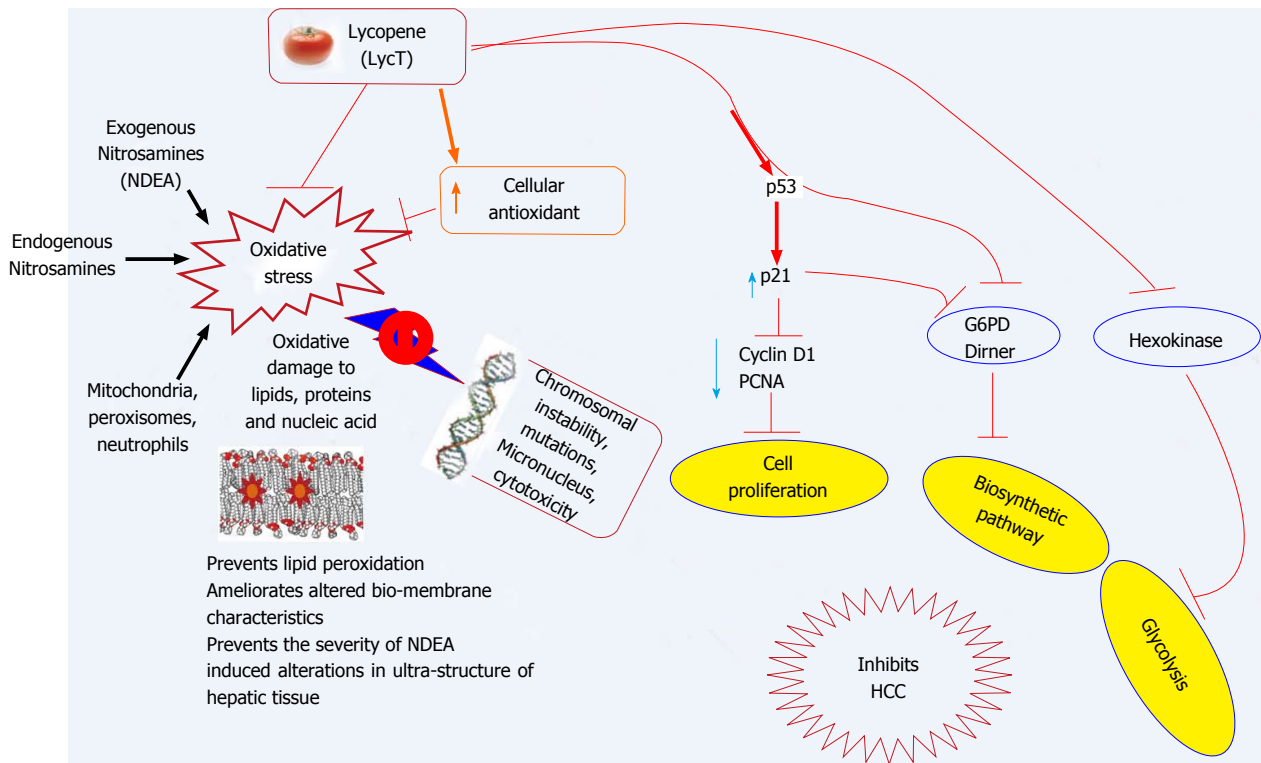

**Figure 4** Effect of lycopene extracted from tomatoes on mRNA expression of *PCNA*, *Cyclin D1*, *p21* and *HIF-1α* during N-Nitrosodiethylamine-induced hepatocarcinogenesis in mice. <sup>a,b,c</sup>*P* ≤ 0.001, compared to the N-Nitrosodiethylamine group, LycT group and control group, respectively. LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine.

abnormal cell proliferation<sup>[35]</sup>. Similarly, enhanced hepatic hexokinase, PGI and aldolase activities in the NDEA group can be attributed to the high cell density observed. Such observations are in accordance with the available literature where enhanced glycolytic enzymes have been linked with chemically induced HCC<sup>[36]</sup>. Elevated levels of PGI have recently emerged as an excellent response to cancer and PGI level is used as a marker of metastatic growth in patients<sup>[37]</sup>. Moreover, significant reductions in the activities of glycolytic enzymes following LycT pre-treatment in NDEA-challenged mice were inversely related to HCC development. Histopathological and ultrastructural observations revealed well-differentiated HCC in the LycT + NDEA group, whereas poorly to undifferentiated HCC was observed in the NDEA group<sup>[21]</sup>. These structural observations could be correlated with the observed modulation of the glycolytic pathway. Various studies based on <sup>18</sup>F-FDG uptake on PET scans in different HCCs revealed that well differentiated HCC showed lower <sup>18</sup>F-FDG uptake in comparison with poorly differentiated HCC<sup>[38]</sup>.

Ectopic expression of G6PD promotes the survival of tumor cells by maintaining both extracellular pH and redox potential<sup>[39]</sup>. Moreover, loss of p53 or mutated p53 has been linked with enhanced glucose consumption *via* increased activity of G6PD<sup>[40]</sup>. In the current study, LycT pre-treatment in NDEA-challenged mice resulted in significantly low expression of G6PD indicating the inhibitory role of lycopene in HCC by affecting metabolic pathways. Although there is limited research on the role of lycopene in regulating G6PD, some researchers have demonstrated the inhibitory effect of phytochemicals by regulating the activity of G6PD<sup>[41]</sup>. Decreased expression of Bcl-2 and enhanced p53 expression in

the LycT + NDEA group may be responsible for reduced G6PD activity. In the current study, liver glycogen content in HCC was found to be decreased in the NDEA group. However, the reasons for the lack of glycogen accumulation were not fully explored. The transformation of liver cells to tumor cells causes a loss of glucose production *via* gluconeogenesis. According to the literature, overproduction of the molecule, microRNA-23a, is responsible for inhibiting gluconeogenesis<sup>[42]</sup>. Glycogen metabolism then acts as an alternate energy source, enabling growth of the cell under metabolic stress. A significant increase in the level of glycogen content was observed in the LycT + NDEA group when compared to the NDEA group. The current observations indicate that lycopene may interfere with glycogen conversion to glucose or might be due to less severe early HCC followed by lower ATP requirement. Such observations are in accordance with the previously reported effect of lycopene in CCL<sub>4</sub>-challenged mice<sup>[43]</sup>.

These observations in the NDEA group clearly point to a high rate of cell proliferation, which was further evident from increased *PCNA* and *Cyclin D1* expression. Enhanced proliferation attributed to increased expression of *PCNA* and *Cyclin D1* has been reported in the literature<sup>[44]</sup>. Decreased expression of *p21* in the NDEA group could be correlated with enhanced expression of *Cyclin D1* as *p21* is known to inhibit the activity of cyclin-CDKs complexes<sup>[45]</sup>. *p21* is an important downstream mediator of p53 and its anti-proliferative property plays an important role in preventing tumor development. In our previous study it was observed that reduced p53 expression in the NDEA group was correlated with evasion of apoptosis<sup>[22]</sup>. Moreover, the LycT + NDEA group showed significantly enhanced expression of *p21* and reduced expression of *PCNA* when compared to the NDEA group indicating the anti-proliferative activity of LycT. Although it is difficult to comment on how lycopene or its metabolites inhibit HCC, the literature shows that treatment with lycopene or its metabolite increased *p21* expression and hence aided in preventing NDEA-induced cancer<sup>[46]</sup>. This observation is also supported by the current observation of increased cell density as shown by SEM and the hepatic glycolysis rate. Moreover, enhanced mRNA and protein expression of *HIF-1α* clearly indicated the existence of hypoxic conditions in NDEA-treated liver tissue. Various research groups have observed that the expression of *HIF-1* modulates apoptosis in HCC<sup>[11]</sup>. Reports have demonstrated that hypoxia enhances VEGF expression and decreases the ratio of Bax/Bcl-2, thus blocking apoptosis<sup>[47]</sup>. Pre-treatment with LycT in NDEA-challenged mice resulted in a significant reduction in the expression of *HIF-1α* at week 24 when compared to the NDEA group. Many reports have demonstrated similar observations where lycopene had an inhibitory response on HIF-1 in both *in vivo* and *in vitro* studies. Upadhyay *et al.*<sup>[48]</sup> performed a comparative study of different antioxidants in order to assess their cancer preventive activity through the inhibition of HIF-1 activity. According to the results, HIF-1α operated in the presence of free radicals and antioxidants with maximum scavenging

**Figure 5 Overall mechanism of lycopene extracted from tomatoes mediated chemoprevention.** LycT: Lycopene extracted from tomatoes; NDEA: N-Nitrosodiethylamine; HCC: Hepatocellular carcinoma; G6PD: Glucose-6-phosphate dehydrogenase.

efficiency for ROS cause inhibition of HIF-1 $\alpha$ <sup>[49]</sup>. The literature also supports the consumption of tomatoes and lycopene mostly inhibited the expression of HIF-1 $\alpha$  during prostate carcinogenesis<sup>[50]</sup>. Such reports strengthen our current observations, that the delay in HCC development may be attributed to the anti-proliferative effect of lycopene. In summary, our report demonstrates the potential of lycopene as a multi-targeted approach against chemically induced HCC.

Data from the present study and previously published studies show that LycT has beneficial effects against NDEA-induced HCC. Electron micrographs (SEM and TEM) of liver biopsies from the different treatment groups provided a picture of 3-D *in vivo* tissue modulations and thus served as an efficient and accurate tool for demonstrating carcinogenesis and the efficacy of chemopreventive agents along with histopathological observations. Moreover, aerobic glycolysis is also a potential target for determining the chemopreventive efficacy of lycopene and other phytochemicals in preventing carcinogenesis. As shown in the present study, LycT pre-treatment ameliorated disturbed metabolism, however, further studies are warranted to understand the in-depth pharmacokinetics and pharmacodynamics related to lycopene in experimental models of cancer. Finally, an attempt was made to represent diagrammatically the anti-carcinogenic effect of lycopene based on the current study and previous publications (Figure 5).

## COMMENTS

### Background

Cancer is a complex disease and requires attention in multiple directions to prevent its development. Among the various carcinogenic insults, uncontrolled proliferation, dysregulated carbohydrate metabolism and hypoxia play very crucial roles in the development of hepatocellular carcinoma (HCC). Although there have been advances in therapeutic approaches a complete cure is still unavailable. Dietary multi-targeted agents have attracted the attention of cancer biologists as these agents may provide a solution to this complex problem by targeting multiple targets simultaneously. Lycopene, a polyunsaturated hydrocarbon imparting red colour to various fruits, is a nutritionally important carotenoid exhibiting beneficial health effects due to its antioxidant activity with minimal side effects. In addition to its antioxidant property, lycopene is known to modulate other non-oxidative pathways such as regulation of gap junction communication, the hormonal system, immune system and metabolic pathways of xenobiotics. Previously, we demonstrated that lycopene from tomatoes is a potent agent for inhibiting HCC development in terms of histopathological observations, tumor statistics, apoptosis, antioxidative capacity and toxicity. However, studies are warranted to determine the modulating effect of lycopene on dysregulated glucose metabolism and hypoxia, as these processes play critical roles in cancer. Thus, in the current study, the influence of lycopene extracted from tomatoes on various glycolytic and non-glycolytic enzymes, the expression of hypoxia inducible factor-1 $\alpha$  (HIF-1 $\alpha$ ) and potent cell proliferation-associated genes while preventing N-Nitrosodiethylamine (NDEA)-induced HCC was investigated. Moreover, an attempt was made to demonstrate the impact of an imbalance between energy production and metabolic demands on the gross morphology and ultrastructure of hepatocytes in HCC.

### Research frontiers

Important areas related to the current study include: (1) carcinogenesis: Incidence rate, statistics, prognosis, consequences, mortality, molecular and biochemical markers, altered cellular pathways and therapeutic limitations;

and (2) chemoprevention: Natural agents, multifaceted approach, lycopene a colored pigment and its antioxidative and anti-carcinogenic potential.

### Innovations and breakthroughs

Despite significant research efforts, cancer is considered an incurable disease due to its high incidence rate, poor prognosis, high mortality rate, multifactorial causative agents, and side effects associated with chemotherapeutics. As natural agents are safer and have a multifaceted approach they are considered an alternative therapy. Lycopene is known to be a potent antioxidant and phytoagent with a protective effect against chronic diseases such as cancer. However, the detailed mechanism underlying its anti-carcinogenic effects is unclear. The basic requirement in the present investigation was to design a study that could demonstrate the action of lycopene at various stages to cover the maximum number of carcinogenic bioprocesses. The present study is part of this research design, in which hepatic tissue from different groups, *i.e.*, control, LycT, NDEA and LycT + NDEA groups was studied at different levels including structural markers, electro-physical markers, morphological markers, biochemical markers, and molecular markers that are known to be involved in the development of cancer. This type of study provides innovation and achievement for futuristic analyses of natural agents in disease models.

### Applications

The outcomes of the current study provide deeper insight into the mechanistic targets of lycopene which shows ameliorating effects. Lycopene administration directly or indirectly stimulated various molecular targets such as p53, which have been correlated with decreased G6PD activity or biosynthetic pathways that play important roles during tumor proliferation. The protective effect of lycopene can be studied at the ultrastructural level by scanning and transmission electron microscopy (SEM and TEM). A detailed explanation regarding hepatic SEM and TEM during carcinogenesis is also information which is ambiguous in the literature.

### Peer-review

This manuscript entitled "Lycopene modulates cellular proliferation, glycolysis and hepatic ultrastructure during hepatocellular carcinoma" investigated the effect of lycopene on ultra-structure, glycolytic enzymes, cell proliferation markers and hypoxia during NDEA induced hepatocarcinogenesis.

### Abstract

#### AIM

To evaluate the association of the risk factors and polymorphisms in *MTHFR C677T*, *MTHFR A1298C*, *MTR A2756G* and *MTRR A66G* genes.

#### METHODS

Patients with cirrhosis ( $n = 116$ ), hepatocellular carcinoma (HCC) ( $n = 71$ ) and controls ( $n = 356$ ) were included. Polymerase chain reaction followed by enzymatic digestion and allelic discrimination technique real-time PCR techniques were used for analysis. MINITAB-14.0

and SNPstats were utilized for statistical analysis.

## RESULTS

Showed that age  $\geq 46$  years (OR = 10.31; 95%CI: 5.66-18.76;  $P < 0.001$ ) and smoking (OR = 0.47; 95%CI: 0.28-0.78;  $P = 0.003$ ) were associated with cirrhosis. Age  $\geq 46$  years (OR = 16.36; 95%CI: 6.68-40.05;  $P < 0.001$ ) and alcohol habit (OR = 2.01; 95%CI: 1.03-3.89;  $P = 0.039$ ) were associated with HCC. *MTHFR A1298C* in codominant model (OR = 3.37; 95%CI: 1.52-7.50;  $P = 0.014$ ), recessive model (OR = 3.04; 95%CI: 1.43-6.47;  $P = 0.0051$ ) and additive model (OR = 1.71; 95%CI: 1.16-2.52;  $P = 0.0072$ ) was associated with HCC, as well as *MTR A2756G* in the additive model (OR = 1.68; 95%CI: 1.01-2.77;  $P = 0.047$ ), and *MTRR A66G* in the codominant model (OR = 3.26; 95%CI: 1.54-6.87;  $P < 0.001$ ), dominant model (OR = 2.55; 95%CI: 1.24-5.25;  $P = 0.007$ ) and overdominant model (OR = 3.05; 95%CI: 1.66-5.62;  $P < 0.001$ ). *MTR A2756G* in the additive model (OR = 1.54; 95%CI: 1.02-2.33;  $P = 0.042$ ) and smokers who presented at least one polymorphic allele for *MTRR A66G* (OR = 1.71; 95%CI: 0.77-3.82;  $P = 0.0051$ ) showed increased risk for cirrhosis. There was no association between clinical parameters and polymorphisms.

## CONCLUSION

Age  $\geq 46$  years, alcohol habit and *MTR A2756G*, *MTHFR A1298C* and *MTRR A66G* polymorphisms are associated with an increased risk of HCC development; age  $\geq 46$  years, tobacco habit and the *MTR A2756G* polymorphism are associated with cirrhosis.

**Key words:** Polymorphism; Folate metabolism; Liver cirrhosis; Hepatocellular carcinoma

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Our study is relevant because we can get better understanding on the mechanisms involved in the development of hepatocellular and Cirrhosis Carcinoma and folate metabolism. It is already known that polymorphisms cause DNA hypomethylation, which cause abnormal changes in gene expression inactivating suppressor genes tumor. In this study we have found some positive associations which was possible to understand the carcinogenesis of this tumor and offer new possibilities for diagnosis. Throughout these results it is possible to achieve better quality of life in early treatments.

## INTRODUCTION

Liver cancer is the second most common cause of death from cancer worldwide. Hepatocellular carcinoma (HCC) is considered the major form of primary liver cancer and is responsible for 70%-85% of all liver cancers<sup>[1]</sup>. Each year, more than half a million people are diagnosed with HCC. According to the most recent data, 782000 new cases per hundred thousand inhabitants have been diagnosed, with 745000 deaths resulting from this disease. HCC is the fifth most common cancer in men (554000 cases, 7.5% of all cases) and the ninth most common cancer in women (228000, 3.4% of all cases)<sup>[2]</sup>.

The major risk factor for HCC development, present in 90% of HCC patients, is liver cirrhosis, which is characterized by diffuse fibrosis, progressive and irreversible, with the presence of nodules delimited by fibrous septa<sup>[1,3]</sup>. There are other risk factors such as hepatitis B and C virus infection, liver disease derived from alcohol consumption, exposure to toxins such as aflatoxins and smoking, non-alcoholic fatty liver, obesity and diabetes<sup>[4,5]</sup>.

Cancer is a multifactorial disease that results from complex interactions between genetic and environmental factors<sup>[6]</sup>. Some studies have been conducted using genetic polymorphisms involved in folate metabolism in various types of cancers<sup>[7-11]</sup> because folate metabolism is essential for DNA synthesis and alterations in folate levels are associated with changes in DNA synthesis, methylation and repair, promoting genomic instability that contributes to the process of carcinogenesis<sup>[12]</sup>.

Several enzymes, including methylenetetrahydrofolate reductase enzyme (MTHFR), methionine synthase (MTR) and methionine synthase reductase (MTRR), are involved in folate metabolism<sup>[13]</sup>. Methylenetetrahydrofolate reductase (MTHFR) is a key regulatory enzyme in folate metabolism, and MTHFR can catalyze 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which is the predominant circulating form of folate. There are two common functional polymorphisms identified in the *MTHFR* gene, the *MTHFR C677T* polymorphism and *MTHFR A1298C* polymorphism<sup>[14]</sup>.

Moreover, 5-methyl-tetrahydrofolate donates one methyl group for homocysteine remethylation to methionine. The remethylation of this reaction is catalysed by the enzyme methionine synthase (MTR), which requires vitamin B12 as a cofactor. The enzyme methionine synthase reductase (MTRR) is responsible for maintaining the active state of the MTR enzyme. Polymorphisms *MTR A2756G* and *MTRR A66G* may cause decreased activity of the enzyme, leading to increased plasma homocysteine and DNA hypomethylation, which causes changes in gene expression, inactivating tumour suppressor genes and activate oncogenesis<sup>[15-19]</sup>.

Studies have confirmed that the genetic polymorphisms involved in folate metabolism may contribute to the development of HCC<sup>[16,19]</sup>. Therefore, the present

study was aimed to evaluate the association of risk factors and polymorphisms in the genes *MTHFR* C677T, *MTHFR* A1298C, *MTR* A2756G and *MTRR* A66G involved in folate metabolism with cirrhosis and HCC development in a case control study and to investigate the association of the polymorphisms with the clinical parameters of the disease in patients with cirrhosis and HCC.

## MATERIALS AND METHODS

### Ethical statement

Patients at the Liver, Intestine and Pancreas Transplant Unit of a university hospital in the northwest of the state of São Paulo, Brazil were included in the study after the diagnosis of liver cirrhosis and HCC, while the control group consisted of healthy individuals without cancer diagnosis. Individuals with a cancer family history were excluded from the control group. Informed consent was obtained from all subjects in this study, and the research protocol was approved by the Research Ethics Committee of FAMERP (CAAE: 20465713.1.0000.5415).

### Patients

In this case-control study, 543 subjects (116 patients with liver cirrhosis, 71 patients with HCC and 356 healthy individuals) were included regardless of sex and age, from 2013 to 2015. Patients with cirrhosis were included because it is known as a well-established risk factor in 90% of patients with HCC<sup>[1,3]</sup>.

The sample calculation was performed according to the reports of Kwak *et al.*<sup>[17]</sup> and Chang *et al.*<sup>[19]</sup> which presented a similar sample calculation. Furthermore, no study has evaluated polymorphisms in folate metabolism in HCC and cirrhosis development in the Brazilian population.

The diagnosis of HCC was based on the criteria of the American Association for the Study of Liver Diseases published in 2012<sup>[20]</sup>. Liver biopsy was performed when the diagnosis was not possible by imaging methods, and the diagnosis of cirrhosis was made by clinical, laboratory, ultrasound and histopathological examinations when possible.

The variables analysed in this study were age, gender, exposure to risk factors (smoking and alcohol habit) and the presence of the *MTHFR* A1298C, *MTHFR* C677T, *MTR* A2756G and *MTRR* A66G polymorphisms. We considered smokers to be those who consumed at least 100 cigarettes during their lifetime and alcohol consumers to be those who drink more than 4 drinks weekly, corresponding 30 mL of liquor, 102 mL of wine, and 340 mL of beer<sup>[21]</sup>.

Patients diagnosed with HCC were also classified according to the Barcelona Clinic Liver Cancer (BCLC) classification, which is a staging system that serves mainly for therapeutic guidance, in which the patient is ranked into five stages and includes other classifications. This classification uses variables related to tumour

stage, the functional state of the liver, physical condition, and symptoms related to cancer. Patients with stage 0, very early HCC and with only a minor 2-cm tumour were nominated for liver resection. Patients with early HCC phase A with up to 3-cm nodules were eligible for curative therapies (resection, liver transplantation or percutaneous treatments). Patients in phase B with intermediate HCC and this multinodular underwent chemoembolization. Patients in advanced stage C presenting portal invasion and metastases received new agents such as sorafenib, which is a palliative treatment, and patients in stage D with end-stage disease received symptomatic treatment<sup>[22]</sup>.

### Methods

Genomic DNA was extracted from peripheral blood leukocytes of the cases and controls according to Miller *et al.*<sup>[23]</sup> and was amplified by multiplex PCR-RFLP to identify the *MTHFR* C677T (rs1801133) and *MTHFR* A1298C (rs1801131), *MTR* A2756G (rs1805087) polymorphisms. The amplification product was subjected to digestion by the restriction enzymes Hinf I, Mbo II, and Hae III, respectively. Electrophoresis was performed in 2.5% agarose gels at 110 volts for 100 min. Allelic discrimination via the Real-Time PCR - SNP Genotyping Assay (Applied Biosystems) was used to identify the *MTRR* A66G (rs1801394) polymorphism, using primers and probes specific for each allele available by the manufacturer (*MTRR* A66G: C\_3068176\_10)<sup>[7]</sup>.

Genotyping confirmation was accomplished in 10% random samples of each group, and 100% concordance was observed.

### Statistical analysis

Hardy-Weinberg equilibrium (HWE) was performed using  $\chi^2$  test. The multiple regression logistic test by the Minitab program - Version 14.0 was used to determine the effects of variables. The model evaluated the following variables: Age (reference: < 46 years; median), smoking habits (reference: No smokers), alcohol habit (reference: Non-consumers) and gender (reference: Female). The polymorphisms were used to adjust the analysis.

The multiple logistic regression model adjusted for age, gender, smoking and alcohol habits was also used to assess the association between polymorphisms and the development of cirrhosis and HCC using the SNPStats program. The effect of the polymorphisms was evaluated in the following models: (1) codominant (heterozygous vs homozygous wild type and polymorphic homozygous vs homozygous wild type); (2) dominant (heterozygous more polymorphic homozygous vs homozygous wild type); (3) recessive (polymorphic homozygous vs homozygous wild type more heterozygous); (4) overdominant (wild homozygous vs heterozygous more polymorphic homozygote); and (5) additive (weight polymorphic homozygote vs heterozygote 2 more homozygous wild-type).

The SNPStats program was also used to assess the

**Table 1 Relationship between risk factors and hepatocellular carcinoma and liver cirrhosis development**

Variables	Controls <i>n</i> (%)	Cirrhosis <i>n</i> (%)	<sup>1</sup> OR (95%CI)	<i>P</i> -value	HCC <i>n</i> (%)	OR (95%CI)	<sup>2</sup> <i>P</i>
Age							
< 46 anos	238 (67)	22 (19)	10.31 (5.66-18.76)	<i>P</i> < 0.001	8 (11)	16.36 (6.68-40.05)	<i>P</i> < 0.001
≥ 46 anos	118 (33)	94 (81)			63 (89)		
Genre							
Female	95 (26.7)	30 (25.9)	0.96 (0.54-1.72)	<i>P</i> = 0.893	19 (26.8)	0.59 (0.29-1.22)	<i>P</i> = 0.154
Male	261 (73.3)	86 (74.1)			52 (73.2)

Nonsmokers	199 (56)	72 (62)	0.47 (0.28-0.78)	<i>P</i> = 0.003	31 (43.7)	0.9 (0.48-1.67)	<i>P</i> = 0.734
Smokers	157 (44)	44 (38)			40 (56.3)		

<sup>1</sup>Odds ratio (OR) adjusted for age, genre, alcohol consumption, smoking habits and polymorphisms; <sup>2</sup>*P* values significant at *P* ≤ 0.05. HCC: Hepatocellular carcinoma.

potential interaction between the polymorphisms with variables associated with cirrhosis and HCC development (tobacco and alcohol habits) through multiple logistic regression.

The *MTHFR* haplotypes were inferred using the Haploview 4.2 statistical program, which creates population frequency estimates of the haplotypes.

The association between the clinical parameters and polymorphisms with HCC development were also analysed by multiple logistic regression. The patients were subjected to classification and BCLC staging divided into five stages (0, A, B, C and D). The variables alpha fetoprotein dose values, hepatitis B and C, diabetes mellitus and death were utilized in the adjustment of the analysis. The models included BCLC classification (reference: 0, A), alpha fetoprotein (reference: < 500 ng/mL), hepatitis B (reference: No), hepatitis C virus (reference: No), diabetes (reference: Absence), death (reference: No) and the studied polymorphisms (reference: Wild-type genotype).

The Kaplan-Meier method was applied to evaluate the survival rate by considering the period between the disease diagnosis and death to be the end point.

The results were presented as ORs and 95%CIs. The level of significance was set at 5% (*P* = 0.05).

## RESULTS

The results for HWE were similar to those expected in both the case and control groups, respectively, for the *MTHFR* C677T ( $\chi^2$  = 0.8940, *P* = 0.3444 and  $\chi^2$  = 3.1218, *P* = 0.0772), *MTR* A2756G ( $\chi^2$  = 1.1554, *P* = 0.2824 and  $\chi^2$  = 1.1929, *P* = 0.2748) and *MTRR* A66G polymorphisms ( $\chi^2$  = 3, 2227, *P* = 0.0726 and  $\chi^2$  = 0.0530, *P* = 0.8018). However, the *MTHFR* A1298C polymorphism showed no equilibrium ( $\chi^2$  = 8.0244, *P* = 0.0046 and  $\chi^2$  = 8.6427, *P* = 0.0033) for patients with HCC and/or cirrhosis and controls.

Table 1 shows the results for multiple logistic regression analysis between patients with liver cirrhosis and control subjects to determine the effects of variables. Age

≥ 46 years (OR = 10.31; 95%CI: 5.66-18.76; *P* < 0.001) and smoking habit were associated with the disease (OR = 0.47; 95%CI: 0.28-0.78; *P* = 0.003), and the analysis of patients with HCC and control subjects showed that age ≥ 46 years (OR = 16.36; 95%CI: 6.68-40.05; *P* < 0.001) and alcohol habit (OR = 2.01; 95%CI: 1.03-3.89; *P* = 0.039) were associated with the disease.

Table 2 shows the association of the *MTHFR* C677T, *MTHFR* A1298C, *MTR* A2756G and *MTRR* A66G polymorphisms with HCC, adjusted for gender, age, smoking and alcohol habit according to the heritage models. The *MTHFR* A1298C polymorphism in the codominant model (OR = 3.37; 95%CI: 1.52-7.50; *P* = 0.014), recessive model (OR = 3.04; 95%CI: 1.43-6.47; *P* = 0.0051) and additive model (OR = 1.71; 95%CI: 1.16-2.52; *P* = 0.0072), the *MTR* A2756G polymorphism in the additive model (OR = 1.68; 95%CI: 1.01-2.77; *P* = 0.047), the *MTRR* A66G polymorphism in the codominant model (OR = 3.26; 95%CI: 1.54-6.87; *P* < 0.001), dominant model (OR = 2.55; 95%CI: 1.24-5.25; *P* = 0.007) and overdominant model (OR = 3.05; 95%CI: 1.66-5.62; *P* < 0.001) were associated with an increased risk of HCC development.

Table 3 shows the association of the *MTHFR* C677T, *MTHFR* A1298C, *MTR* A2756G and *MTRR* A66G polymorphisms with liver cirrhosis, adjusted for gender, age, smoking and alcohol habit according to the heritage models. The *MTR* A2756G polymorphism was associated with an increased risk of liver cirrhosis in the additive model (OR = 1.54; 95%CI: 1.02-2.33; *P* = 0.042).

Regarding the potential interaction among the polymorphisms with variables associated with the diseases, there was no interaction among the *MTHFR* C677T, *MTHFR* A1298C, *MTR* A2756G and *MTRR* A66G polymorphisms and smoking habit or alcohol habit regarding the risk of HCC (Table 4). However, smokers who presented with the heterozygous genotype (AG) or polymorphic homozygote genotype (GG) for the *MTRR* gene (OR = 1.71; 95%CI: 0.77-3.82; *P* = 0.0051) was associated with liver cirrhosis (Table 5).

The haplotype analysis showed a higher frequency

**Table 2** Association of *MTHFR C677T*, *MTHFR A1298C*, *MTR A2756G* and *MTRR A66G* polymorphisms with hepatocellular carcinoma, adjusted for gender, age, smoking and alcohol consumption

results.

There was no association in the multiple logistic regression analysis of the analysed clinical parameters and polymorphisms in patients with HCC stratified into tumours in stages 0 and A, and tumours in stages B, C and D, according to the BCLC criteria (Table 6).

The Kaplan-Meier survival curves for genotype showed no association of polymorphisms and overall survival with HCC development. No polymorphism was associated (*MTHFR C677T*,  $P = 0.5483$ ; *MTHFR A1298C*,  $P = 0.3861$ ; *MTR A2756G*,  $P = 0.6765$ ; *MTRR A66G*,  $P = 0.3840$ )

with overall survival.

## DISCUSSION

The results showed that age  $\geq 46$  years and alcohol habit were associated with an increased risk of HCC development, similar to the results of Fassio *et al.*<sup>[24]</sup>, Varela *et al.*<sup>[25]</sup>, Munaka *et al.*<sup>[26]</sup>, Carrilho *et al.*<sup>[3]</sup>, Donato *et al.*<sup>[27]</sup>, Hamed *et al.*<sup>[28]</sup> and Mittal *et al.*<sup>[1]</sup>.

Brazilian publications have reported that the mean age of the HCC patients is 54.6 years<sup>[3]</sup>; in Latin

<sup>1</sup>OR: Odds ratio, CI: Confidence interval; <sup>2</sup>Statistically significant at  $P \leq 0.05$ ; <sup>3</sup>Could not calculate due to numerical proximity.

America, the average age in one published study was 64 years<sup>[24]</sup>; in another multicentre study in Spain, the reported average age was 65.6 years<sup>[25]</sup>, and Mittal *et al.*<sup>[1]</sup> concluded that a more recent increase in the incidence of HCC in the United States population was seen in Hispanics and blacks between the ages of 45 and 65 years, results that are similar to ours.

Regarding the result that alcohol consumption was also significant and more frequent in patients with HCC, a prospective case-control study from Japan has observed that heavy alcohol drinkers had a five-fold increase in the risk of HCC compared with non-drinkers<sup>[26]</sup>. Donato *et al.*<sup>[27]</sup> 2002 in Italy, with a sample size of 464 cases and 824 controls individuals, found a positive relationship between alcohol consumption and HCC. The latter findings were confirmed in review of Hamed *et al.*<sup>[28]</sup>.

Evidence of a positive association between heavy alcohol drinking and liver cancer is derived mainly from case-control studies. The increased risk of those drinking 6 or more drinks per day compared with non-drinkers was 22%. Alcohol was the only cause present in 14% of cases in the 2010 Brazilian study by Carrilho *et al.*<sup>[3]</sup>. Thus, the significance indexes are increased because

drinking alcohol causes poor absorption of vitamin B complex, changing the folate metabolism and causing oxidative damage and breaks in the DNA strands<sup>[29]</sup>. In our study we found the association between alcohol and HCC development, this may be due the fact described above.

Regarding cirrhosis, we found that age  $\geq 46$  years and smoking habit was associated with risk of cirrhosis. As previously mentioned, 85%-90% of primary liver cirrhosis causes cancer, and multiple nonviral factors that are concerned with the development of liver cancer include iron overload syndromes, alcohol use, tobacco, oral contraceptives, aflatoxin, and pesticide exposure, which is prevalent in the developing world<sup>[28]</sup>. Regarding the tobacco habit, the data showed that 38% of individuals with cirrhosis had a tobacco habit. In addition to the liver, which is the target of chemical compounds in tobacco that can progress to cirrhosis, it was also observed in the literature that the development of diseases related to the progression to cirrhosis occurs more frequently in older individuals<sup>[30]</sup>.

In addition to the association that we found between tobacco habit and cirrhosis development, there can be a relationship of tobacco with the dysfunction of genes as

well as enzymes involved in the detoxification of nicotine, consequences that generate various types of liver-related diseases such as fibrosis, alcoholic hepatitis, cirrhosis and HCC<sup>[31]</sup>. Although alcohol habit is a well-established risk factor for cirrhosis development<sup>[32]</sup>, our study did not find this association. However, 53.4% of cirrhosis patients in the present study were alcohol consumers.

In relation to the genetic characteristics, the present study was the first to be performed in a Brazilian population with HCC and cirrhosis and revealed that the *MTR* A2756G, *MTHFR* A1298C and *MTRR* A66G polymorphisms were associated with an increased risk of HCC development, results similar to the studies of Kwak *et al.*<sup>[17]</sup> and Yu *et al.*<sup>[33]</sup>.

Chang *et al.*<sup>[19]</sup>, with a sample of 204 patients with liver cancer and 415 controls found an association between *MTR* A2756G and increased risk for the disease, as well the meta-analysis performed by Yu *et al.*<sup>[33]</sup> that reported a significantly higher association between the genotype and 2756GG cancer risk in Asian populations.

There are studies involving other cancers that have found a positive association with at least one polymorphic allele 2756G and an increased risk of the development of disease. For example, the Hosseini *et al.*<sup>[8]</sup> that evaluated 592 individuals in Iran found an association between in *MTR* GG genotype and breast cancer; Galbiatti *et al.*<sup>[7]</sup> also concluded that *MTR* A2756G polymorphism is involved in the risk of head and neck cancer; de Lima *et al.*<sup>[9]</sup> suggested an association between the *MTR* A2756G polymorphism and retinoblastoma susceptibility in a northeast population of Brazil, Ouerhani *et al.*<sup>[10]</sup> found that *MTR* A2756G affecting bladder cancer risk.

Regarding the *MTRR* A66G polymorphism, Kwak *et al.*<sup>[17]</sup> studied 96 patients and 201 controls and observed an association between the polymorphism and an increased risk of HCC, a finding that has also been found in other types of cancer; the Wu *et al.*<sup>[11]</sup> study demonstrated a positive relationship with the *MTRR* A66G polymorphism and breast cancer, and a meta-analysis performed by Zhou *et al.*<sup>[34]</sup> also found an association between this polymorphism and colorectal cancer, which is in agreement with our study. However, the study of Zhang *et al.*<sup>[35]</sup> did not find an association of this polymorphism with HCC development.

We also found an association between the *MTHFR* A1298C polymorphism and an increased risk of HCC development. Two meta-analyses reported an association of this polymorphism with a decreased risk of HCC, demonstrating a protective effect<sup>[36,37]</sup>. However, Liang *et al.*<sup>[38]</sup> meta-analysis of a total of seven studies showed that the homozygote genotype CC of the *MTHFR* rs1801131 polymorphism was significantly associated with a decreased risk of liver cancer (for CC vs AA: OR = 0.65, 95%CI: 0.47-0.89, *P* = 0.007; for CC vs AA + AC: OR = 0.65, 95%CI: 0.48-0.89, *P* = 0.006), similar our study.

Our results for cirrhosis and polymorphisms showed an association between *MTR* A2756G and an increased

risk of the disease. There are no studies in the literature that have evaluated the association between the *MTR* A2756G polymorphism and cirrhosis development. The present study is the first to investigate the *MTR* A2756G polymorphism and cirrhosis development, and the association that was found can be related to alteration of the *MTR* enzyme that occurs due to the presence of the *MTR* A2756G polymorphism. The alteration of the *MTR* enzyme causes elevation in the homocysteine levels and DNA hypomethylation, leading to chromosomal instability, mutations and the overexpression of proto-oncogenes that can be associated with the development of several types of diseases, including cirrhosis. However, more studies in different populations of individuals with cirrhosis are needed<sup>[39]</sup>.

Regarding the potential interaction among the polymorphisms with variables associated with the diseases, we found that smoking in those with the heterozygous genotype (AG) or polymorphic homozygote genotype (GG) for *MTRR* gene was associated with liver cirrhosis. There are no studies that have investigated this interaction, however, tobacco habit can be related to cirrhosis because the chemical compounds can modify the liver and lead to cirrhosis<sup>[39]</sup> independently of the *MTRR* A66G polymorphism.

Regarding BCLC classification, we did not find an association with the polymorphisms evaluated. Our data showed that 7% of patients in stage 0, 29.6% in stage A, 22.5% in stage B, 31% in stage C and 9.8% in stage D. The study of Varela *et al.*<sup>[25]</sup> reported that 49.8% of 705 cases were in the initial stage (A), 19.8% in the intermediate stage (B), 18.8% in the advanced stage (C) and 11.6% in the terminal phase (D). Additionally, the study of Raphe *et al.*<sup>[40]</sup> reported that 32.7% were in stage A, 22% in stage B, 30.4% in stage C, 14% in stage D. Current published data show that patients who are in stage A are asymptomatic and have preserved liver function have a 5-year survival of 50%-75%. Patients who are in stage B have a median survival of 20 mo; those who are already in the C and D stages have severe liver dysfunction and extrahepatic metastases reach an 11-mo survival, and only 10% of patients in the D stage survive more than a year with an average survival of 3-4 mo<sup>[26]</sup>.

In conclusion, age  $\geq$  46 years, alcohol habit and the *MTR* A2756G, *MTHFR* A1298C and *MTRR* A66G polymorphisms are associated with an increased risk of HCC development; age  $\geq$  46 years, tobacco habit and the *MTR* A2756G polymorphism are associated with cirrhosis development. There is an interaction between the *MTRR* A66G polymorphism and tobacco consumers with liver cirrhosis. The present study can collaborate to establish the etiologic factors related to HCC and cirrhosis development and to contribute to strategies related to health care.

## ACKNOWLEDGMENTS

We greatly appreciate the Faculdade de Medicina de

São José do Rio Preto, FAMERP and Medical School Foundation, FUNFARME for their institutional support and UPGEM-Genetics and Molecular Biology Research Unit.

## COMMENTS

### Background

Age  $\geq 46$  years, alcohol habit and the *MTR* A2756G, *MTHFR* A1298C and *MTRR* A66G polymorphisms are associated with an increased risk of hepatocellular carcinoma (HCC) development; age  $\geq 46$  years, tobacco habit and the *MTR* A2756G polymorphism are associated with cirrhosis development.

### Research frontiers

It is already known that polymorphisms cause DNA hypomethylation, which cause abnormal changes in gene expression inactivating suppressor genes tumor.

### Innovations and breakthroughs

The authors confirm the literature data that report a positive association between the presence of polymorphisms and consumption of alcohol and tobacco to the development in an cirrhosis and later HCC.

### Applications

These results may offer new possibilities of diagnosis with early initiation of treatment reflecting the improved quality of life.

### Peer-review

This is a good descriptive study in which the authors analysed patients with cirrhosis, HCC and healthy individuals in the 2013-2015 period, the authors evaluated the association of the risk factors and polymorphisms in *MTHFR* C677T, *MTHFR* A1298C, *MTR* A2756G and *MTRR* A66G genes involved in folate metabolism.

### Abstract

B cells lymphoma is one of the most challenging extra-hepatic manifestations of hepatitis C virus (HCV). Recently, a new kind of B-cell lymphoma, named double-hit B (DHL), was characterized with an aggressive clinical course whereas a potential association with HCV was not investigated. The new antiviral direct agents (DAAs) against HCV are effective and curative in the majority of HCV infections. We report the first case, to our knowledge, of DHL and HCV-infection successfully treated by new DAAs. According to our experience, a DHL must be suspected in case of HCV-related lymphoma, and an early diagnosis could direct towards a different hematological management because a worse prognosis might be expected. A possible effect of DAAs on DHL regression should be investigated, but eradicating HCV would avoid life-threatening reactivation of viral hepatitis during pharmacological immunosuppression in onco-hematological diseases.

**Core tip:** B cells lymphoma is one of the most chall-

enging extra-hepatic manifestations of hepatitis C virus. Recently, a new kind of B-cell lymphoma, named Double-hit B, was characterized with an aggressive clinical course. This is the first case described in literature of double hit lymphoma with co-existing chronic hepatitis C, successfully treated by new direct antiviral therapies. This case suggests a potential favorable effect of the new antiviral therapies on double hit lymphoma regression.

Hepatitis C and double-hit B cell lymphoma successfully treated by antiviral therapy. *World J Hepatol* 2016; 8(29): 1244-1250 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i29/1244.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v8.i29.1244>

## INTRODUCTION

Hepatitis C virus (HCV) is a major global public health problem, although the newest and most effective antiviral therapies (AVTs), free from severe side effects related to interferon (IFN), are spreading in developed countries. This could lead in the next future to a lower prevalence of chronic hepatitis C (CHC) and of its extra-hepatic manifestations. Among these, the hematologic manifestations are the most challenging. Indeed, HCV could induce B cell proliferation and cause mixed cryoglobulinaemia and non-Hodgkin lymphoma (NHL)<sup>[1]</sup>. The typical HCV-related lymphomas are marginal zone lymphoma (MZL) and diffuse large B cell lymphoma (DLBCL)<sup>[2]</sup>. The first could benefit from AVTs, whereas the second group needs more aggressive chemotherapies and the only AVTs seem to be ineffective. More recently, a new kind of lymphoma named double-hit B cell (DHL) was described, characterized by chromosomal rearrangements, specifically of *Myc* oncogene and either B cell lymphoma 2 and B cell lymphoma 6 oncogenes (*Bcl2-Bcl6*) or gene for Cyclin D1 (*Ccnd1*)<sup>[3,4]</sup>. DHL represents about 5% of all cases of DLBCL and affected patients generally have an aggressive clinical course with poor prognosis, despite combination chemotherapy, with a median overall survival of less than 1-2 years. To date, due to the limited literature concerning this type of lymphoma, the specific treatment is still not clear. A potential correlation between HCV and DHL has never been investigated.

We describe the first case, to our knowledge, of a patient affected by DHL and CHC who underwent a successful antiviral treatment with IFN-free therapy (ombitasvir/paritaprevir/ritonavir and dasabuvir).

## CASE REPORT

The patient was a 39-year-old Caucasian woman, who tested HCV positive in 2013 during a routine medical evaluation. She had not history of blood transfusions or

other risk factors for hepatitis virus transmission. The CHC was sustained by genotype 1b virus, with low necro-inflammatory activity and mild liver fibrosis according to non-invasive evaluation performed by Fibroscan® (4.5 kPa), whereas HCV showed a high replication rate (4500000 UI/mL, Cobas AmpliPrep/Cobas TaqMan®-Roche, Rotkreuz, Switzerland). Ultrasound scans of the liver did not demonstrate signs of fibrosis or spleen enlargement secondary to portal hypertension. Of interest, the patient reported a previous episode of major depression occurred in 2006 and, since then, she had been taking venlafazine 75 mg/d.

In July 2013, due to the enlargement of neck lymph nodes, the patient underwent a hematological evaluation and a lymph node biopsy, and she was finally diagnosed with DLBCL (CD20+, CD30-, *Bcl2*+, Ki67 50%, *Bcl6* + 25%, negativity for CD10 and *Mum1*), with involvement of nodes on both sides of the diaphragm, bone marrow and spleen (Figure 1). Treatment with cyclophosphamide, doxorubicin, vincristine, prednisolone plus Rituximab (R) (*R-CHOP* regimen) plus prophylactic intrathecal injection of methotrexate and prednisone, was started. In December 2013, *i.e.*, after six courses of *R-CHOP*, the patient showed a complete remission of lymphoma according both to Contrast Tomography plus Positron Emission Tomography scans and to bone marrow biopsy. Two additional doses of R were prescribed and, at that time, blood tests showed normal levels of transaminases, while HCV replication did not show any substantial changes (Figure 2). In the following months, the patient was referred to our Liver Unit and she was evaluated for AVT. However, since "all-oral" AVTs for CHC was at that time unavailable in Italy, the patient was evaluated for IFN-based AVT, but she presented relative and absolute contraindications to IFN use, such as a previous episode of major depression, mild anemia, leucopenia (*i.e.*, Haemoglobin 10.7 g/dL, White cells counts 1.980 cells/mm<sup>3</sup>), as well as to ribavirin (RBV) use (anemia). We therefore asked our case to be evaluated for the expanded access program (EAP) which was ongoing with Paritaprevir (PTV), a NS3/4A protease inhibitor co-formulated with NS5A inhibitor Ombitasvir (OBV) and the pharmacokinetic enhancer ritonavir (r), plus non-nucleoside polymerase inhibitor Dasabuvir (DSV). Since lymphoma is a possible extra-hepatic manifestation of HCV, the pharmaceutical industry committee accepted our patient for participation to the EAP. Unfortunately, in October 2014, the patient experienced the first relapse of lymphoma at the right maxillary sinus (Figure 3), whereas bilateral bone biopsies were negative. Since chemotherapy was urgent, cisplatin, cytarabin, dexamethasone plus R (*R-DHAP* regimen) were started. After the second cycle of *R-DHAP*, liver tests worsened, with a rapid evolution to liver failure, *i.e.*, jaundice and ascites (Figure 2). She was admitted to our Unit and the liver decompensation was successfully treated with diuretics and anti-oxidant infusion (glutathione 2 g/d until recovery).

From February 2015 to March 2015 she underwent local radiotherapy on the right maxillary sinus (30 Gray).

**Figure 1** Histological and immunohistochemical features of the diffuse large B cell lymphoma at the primary diagnosis. A: In the lymph node a polymorphic lymphoid population is seen; B: Large lymphoid cells prevailed; C: These large cells were B CD20+; D: The proliferation rate marked by Ki67 was around 20% with respect to the overall population, but about 40% if compared with the blastic B cell population; E: The large B cells expressed mainly the germinal center marker *Bcl6*; F: *Mum1* was not found expressed at the primary diagnosis. DLBCL: Diffuse large B cell lymphoma; H and E: Hematoxylin and eosin; CD: Clusters of differentiation; Ki67: Cellular marker for proliferation; *Bcl6*: B cell lymphoma 6; *Mum1*: Multiple myeloma oncogene 1.

**Figure 2** This figure shows the trends of gamma-glutamyl transpeptidase, alanine amino-transferase and hepatitis C viremia - RNA during chemotherapies and antiviral therapy. R: Rituximab; R-CHOP: Cyclophosphamide, doxorubicin, vincristine, prednisolone plus Rituximab; R-DHAP: Cisplatin, cytarabine, dexamethasone plus Rituximab; R-IEV: Ifosfamide, etoposide, epirubicin plus Rituximab; GGT: Gamma-glutamyl transpeptidase; ALT: Alanine amino-transferase; HCV: Hepatitis C viremia.

After the liver tests returned to normal levels, she started the triple DAAs regimen in the EAP, for a duration of

12 wk (Figure 2). The HCV-RNA showed a fast drop since after two weeks of AVT (42 UI/mL), while viremia

**Figure 3** Histological and immunohistochemical features of the diffuse large B cell lymphoma at the first relapse (mucosal). A: In the mucosal relapse a polymorphic lymphoid population was found; B: The rate of large lymphoid cells increased up to 80%; C: These large cells were B CD20+; D: The proliferation rate marked by Ki67 was around 50%-60% with respect to the blastic B cell population; E: The large B cells expressed the germinal center marker *Bcl6* (about 50%-60%); F: *Mum1* was found to be expressed now by about 70% of the cells. DLBCL: Diffuse large B cell lymphoma; H and E: Hematoxylin and eosin; CD: Clusters of differentiation; Ki67: Cellular marker for proliferation; *Bcl6*: B Cell lymphoma 6; *Mum1*: Multiple myeloma oncogene 1.

became undetectable (limit of quantification according to our virological test was 15 UI/mL) after 8 wk of therapy, and persisted undetectable both at the end of AVT and 24 wk after. However, in May 2015, *i.e.*, after 4 wk from the end of AVT, the patient experienced a new relapse of lymphoma (Figure 4). Due to the appearance of multiple cutaneous nodules on the middle third of the left arm, on the posterior region of the chest wall and on the right and left flanks, a biopsy of one of them was indicated, showing a dense lymphoid infiltrate with atypical growth pattern and cells of large size (CD20+, CD79a+, CD5+, Bcl2+, CD3-, CD30-, *Bcl6*-, *Mum1*-, Ki67 80%). A new PET scan showed multiple pathological uptake of fluorodeoxyglucose in inguinal regions and at the level of the subcutaneous nodules, while the bone marrow biopsy did not show any infiltration. Consistent with the history of two previous relapses and to the high expression of *Bcl2*, a histological reassessment was required on both the lymphoid tissue available at diagnosis and that from the biopsy of the subcutaneous nodule. An analysis with fluorescence *in situ* hybridization for the detection of lymphoma-associated chromosomal abnormalities was performed (Vysis LSI *Bcl2* break apart probe, Vysis LSI *Myc* break apart probe), showing additive copies of *Bcl2* (18q21) in 82% and rearrangement of *Myc* in 89% of the nuclei analyzed (8q24), respectively. Therefore, the final diagnosis was that of DHL, a more aggressive subtype of DBCL. In July 2015, the patient was firstly prescribed a cycle of ifosfamide, etoposide, epirubicin plus R (*R-IEV* regimen), followed by stem cell collection for a possible autologous stem cell transplantation;

subsequently, she underwent a second cycle of *R/IEV/R* (regimen with an additive administration of R), which was burdened by infective complications requiring hospitalization and prolonged antibiotic therapies. At the last hepatological follow-up visit in November 2015, *i.e.*, 24 wk after the end of AVT, HCV-RNA was permanently undetectable despite the immunosuppressive therapy. Afterwards, the patient was evaluated for an allogeneic stem cells transplantation, which was made in another Hospital in January 2016, and she is free from lymphoma recurrence according to recent clinical and radiological evaluations.

## DISCUSSION

The role of HCV in pathogenesis of NHL is well established. The regression of HCV-associated indolent lymphomas after a successful AVT adds the demonstration that there is a relationship between HCV and lymphomagenesis, but there are no data about the response of DHL to AVTs. Because HCV is not integrated into the host genome, there should be indirect mechanisms to induce malignancy ("hit and run theory"). The main hypothesis links the antigenic stimulation caused by CHC to the chronic proliferation of B cells, to produce firstly a polyclonal and after a monoclonal expansion of these cells resulting, in conjunction with further occurrence of additional genetic mutations, in an overt NHL<sup>[5]</sup>. Notably, several years have to pass in order to accumulate mutational changes, whereas a genetic predisposition or additional mutagenic effects in genes *Bcl2*, *Bcl6* or *Cnd1*

**Figure 4** Histological and immunohistochemical features of the diffuse large B cell lymphoma in the second relapse (cutaneous). A: In the cutaneous relapse a rather monomorphic lymphoid population was found; B: The rate of large lymphoid cells increased up to 100%; C: These large cells were B CD20+; D: The proliferation rate marked by Ki67 was around 95% in the blastic B cell population; E: The large B cells expressed poorly the germinal center marker *Bcl6*; F: *Mum1* was found to be poorly expressed by the large B cells. DLBCL: Diffuse large B cell lymphoma; H and E: Hematoxylin and eosin; CD: Clusters of differentiation; Ki67: Cellular marker for proliferation; *Bcl6*: B Cell lymphoma 6; *Mum1*: Multiple myeloma oncogene 1.

could explain the DHL mutation occurrence. Indeed, HCV could induce a mutator phenotype, which involves enhanced mutations of many somatic genes. In the management of HCV-related DLBCL, anthracycline-based chemotherapy, usually *CHOP*, associated with R (chimeric anti-CD20 monoclonal antibody) is the standard of care<sup>[6]</sup>. Unlike indolent B-cell lymphomas<sup>[7]</sup>, AVT does not play a significant role in HCV-positive DLBCL. Sequential immune-chemotherapy followed by ATV has been used in two studies with promising results leading to improved clinical outcome and prolonged disease free survival<sup>[8,9]</sup>. On the other hand, a French study reported a higher overall survival and progression free survival in patients treated firstly by AVT, followed in some cases by chemotherapy<sup>[10]</sup>. All these studies are developed in the "IFN era", both alone or in combination with RBV and, more recently, with protease inhibitors like telaprevir and boceprevir. An IFN-based immunomodulatory and anti-angiogenetic mechanism could be supposed, although IFN-based AVTs cannot be started in most cases, because of contraindications and heavy side effects.

A few reports demonstrated lymphoma regression after HCV clearance with new DAAs. Rossotti *et al.*<sup>[11]</sup> reported a rapid virological and hematological response with the combination of a NS3/NS4A inhibitor (faldaprevir) and a non-nucleoside NS5B inhibitor (deleobuvir) in a patient with HCV associated splenic marginal zone lymphoma. In another report, Sultanik *et al.*<sup>[12]</sup> showed complete regression of MZL after 12 wk of therapy with sofosbuvir (an NS5B RNA-dependent RNA polymerase inhibitor) and RBV. In a case series from France of five

patients with HCV-related lymphoma, two DLBCL were successfully treated with sofosbuvir and daclatasvir (an NS5A protease inhibitor), with complete hematological response after 6 mo<sup>[13]</sup>. There are no reported cases of DHL and CHC treated by new DAAs.

According to clinical data, we could exclude an advanced liver fibrosis in our patient and we estimated a minimal risk of liver decompensation. Therefore, the patient was firstly successfully treated with *R-CHOP*, but after the first hematological relapse, a new immunosuppressive therapy with *R-DHAP* schedule caused an overt liver failure. R has been described to enhance viral replication due to the immune system imbalance, but the rate of severe hepatic complications remains low, with some exceptions, such as in presence of hepatitis B virus or HIV infection, cirrhosis or hepatocellular carcinoma<sup>[7,14]</sup>. There are controversial studies about the impairment of liver function, which could be caused both by a toxicity of immune-chemotherapy treatment and by HCV reactivation. Indeed, it is not clear if the anecdotal episodes of liver failure in this setting are due to higher HCV replication and enhanced necro-inflammatory activity, or to a direct chemo-toxicity. Chemotherapy-induced HCV reactivation in DLBCL is rarely reported, whereas there are no data about HCV and DHL<sup>[15-17]</sup>. In our case the liver failure may have been caused by an add-on effect of HCV reactivation and liver chemo-toxicity, as well suggested by a higher increase of Gamma-Glutamyl Transpeptidase, marker of liver toxicity, instead of a pure elevation of Alanine Aminotransferase, a possible expression of an inflammatory response

HCV-mediated. Interestingly, during the liver failure HCV-RNA slightly dropped, so we can suppose that the event was caused by immune re-activation rather than by HCV direct effect on the necro-inflammatory activity. Following the second immune-chemotherapy and after recovering from the acute liver failure, the patient started antiviral therapy with second generation DAAs: OBV/PTV/r and DSV. This multi-targeted 3-DAAs regimen in combination with or without RBV is approved in many countries to treat HCV genotype 1-4 infection. Approval for the treatment of HCV genotype 1 patients with compensated cirrhosis was based on the evidence of a phase 3 trial of 380 patients in which OBV/PTV/r and DSV plus RBV achieved SVR rates at post-treatment week 12 (SVR12) of 91.8% and 95.9% after 12 or 24 wk of therapy, respectively<sup>[18]</sup>. In the past, the AVTs for HCV were conceived with IFN-based regimens, so an immunomodulatory effect due to interactions with both the adaptive and innate immune response of the host, further than an anti-inflammatory and antiviral effect by inhibiting the synthesis of various cytokines, were possibly responsible for the remission of HCV-related lymphomas. In this context, at the moment, there are no definitive data about IFN free therapies, and it remains to be solved whether IFN is crucial for its direct antitumor and anti-proliferative effect against NHL further than for its antiviral effect.

In conclusion, this is the first case, to our knowledge, of DHL and CHC successfully treated by new DAAs. According to our experience, DHL must be suspected in case of HCV-related lymphoma, and an early diagnosis could direct towards a different hematological management, because a poor prognosis should be expected. Moreover, DAAs triple regimen with OBV/PTV/r and DSV achieves a rapid virological response, and the result is sustained during immunosuppressive therapy, without evidence of HCV reactivation. Finally, we can suggest that in cases of aggressive HCV-related lymphoma, it is mandatory to treat the HCV infection with the new IFN-free regimens at least after the first chemotherapy cycle. This choice could avoid a liver failure in case of re-treatment with hepatotoxic drugs, and it allows a better and safer management of hematological disease. A potential favorable effect of the AVTs on DHL regression should be investigated.

We thank Cristina Madaudo and Lucia Lo Scalzo for preparing figures and graphics.

## COMMENTS

### Case characteristics

A 39-year-old Caucasian woman presented with neck lymph nodes enlargement and hepatitis C virus (HCV)-infection.

### Clinical diagnosis

Painless swelling in the right side of the neck with increased thickness.

### Differential diagnosis

Inflammatory process of the throat, metastatic cancer of head-neck sites, lymphoproliferative disease.

### Laboratory diagnosis

All blood tests were within normal limits except for high HCV-viremia.

### Imaging diagnosis

Computed tomography showed multiple lymph nodes on both sides of the diaphragm.

### Pathological diagnosis

Double-hit B cell lymphoma.

### Treatments

Chemotherapy, radiotherapy and antiviral therapy for HCV.

### Related reports

Double-hit B cell lymphoma is a rare entity with no standardized chemotherapeutic strategies and its association with HCV-infection is not ever been investigated. There are no reports about the efficacy of antiviral therapy for HCV plus chemotherapies, in order to cure this pathology in presence of HCV.

### Terms explanation

HCV could induce B cell proliferation and cause non-Hodgkin lymphoma. The typical HCV-related lymphomas are marginal zone lymphoma and diffuse large B cell lymphoma. Double-hit B cell (DHL) is a new kind of lymphoma with more aggressive outcome, and it is characterized by chromosomal rearrangements, specifically of *Myc* oncogene and either B cell lymphoma 2 and B cell lymphoma 6 oncogenes or gene for Cyclin D1.

### Experiences and lessons

DHL must be suspected in case of HCV-related lymphoma, and an early diagnosis could direct towards a different hematological management, because a poor prognosis should be expected. A potential favorable effect of new antiviral therapies on DHL regression should be investigated.

### Peer-review

This manuscript has reported the first case of DHL and CHC successfully treated by new DAA.

ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Nikolaos G Symeonidis, MD, MSc, PhD, Surgeon, Second Propedeutical Department of Surgery, Aristotle University of Thessaloniki, Medical School, Hippokratio General Hospital, 54642 Thessaloniki, Greece

AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

on top of hepatitis C virus (HCV). Here we will try to discuss the role genetic and epigenetic factors in pathogenesis of hepatocellular carcinoma. Understanding the role of these factors will help in discovering the mystery of liver carcinogenesis on top of chronic HCV infection. Moreover, use of the studied molecular factors will provide the hepatologists with tailored diagnostic promising biomarkers and flatten the way for establishment of emerging molecular treatment based on exploring the molecular subscription of this aggressive liver cancer.

**Key words:** Hepatitis C virus; Hepatocellular carcinoma; Genetic; Epigenetic; Diagnosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** It was evident that pathogenesis of hepatocellular carcinoma (HCC) among cases with hepatitis C virus (HCV) infection results from interaction between viral factors and host factors. The host factors include genetic and immunologic factors. Identifying the emerging genetic factors which are contributing in pathogenesis of liver cancer is considered as revolution in research fields of genetics and oncology. Detection of early promising diagnostic biomarkers and development of specific therapy for HCV related HCC is the hope of most researchers in the related fields.

Ezzat WM, Amr KS. Insights for hepatitis C virus related hepatocellular carcinoma genetic biomarkers: Early diagnosis and therapeutic intervention. *World J Hepatol* 2016; 8(30): 1251-1261 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i30/1251.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i30.1251>

### Abstract

The current review explores the role of emerging molecular contributing factors in liver carcinogenesis

### INTRODUCTION

Primary liver cancer is an increasing malignant disease,

being one of the most important causes of cancer deaths all over the world<sup>[1]</sup>. The journey from hepatitis C virus (HCV) infection to hepatocellular carcinoma (HCC) development takes 20-40 years while in some people it may take few years. This variable progression may refer to host factors that interfere; accelerate; delay or even stop HCC development.

Liver fibrosis is the corner stone in the process of hepatic carcinogenesis through course of chronic HCV infection. In cases with liver cirrhosis, the newly discovered cases with HCC are 1%-7% per year, although HCC does not usually develop in livers with early stages of fibrosis<sup>[2,3]</sup>. Recently, emerging efficient antivirals for chronic HCV infection as sofosbuvir is used to decrease the opportunity of liver carcinogenesis<sup>[4]</sup>. Surprisingly, completely cured cases could not guarantee the avoidance of liver cancer development, particularly cases with late stages of liver fibrosis<sup>[5,6]</sup>.

Underlying genetic mechanisms of HCC caused by HCV have not been fully understood. Clinical evaluations indicate that the main task of HCV in liver cancer is to make a cirrhotic tissue background for liver carcinogenesis<sup>[7]</sup>.

Hepatitis B virus can integrate into genetic material of hepatocytes leading to mutation and liver carcinogenesis. The situation in cases of chronic HCV infection is different; hepatocarcinogenesis develop due to direct effects of viral particles or through indirect way which is initiation of chronic hepatitis, liver fibrosis and cirrhosis<sup>[8]</sup>.

Scientists usually face a big challenge to explore the exact underlying mechanism for HCV related liver fibrosis and hepatocarcinogenesis due to the shortage of the ideal animal model for chronic HCV infection. HCV infection is restricted to human and chimpanzees. In a trial to do the researches on tissues which closely resemble that of human, some scientists used treated and modified animal models as HCV transgenic mice and immunocompetent humanized mice and they succeeded to detect known sides of chronic HCV infection natural history. We are still in need of an ideal animal model that can illustrate the chronic HCV infection and its complications as liver tumorigenesis<sup>[5,8]</sup>.

In the current review we explore some of the underlying molecular contributors for liver cancer development in cases with chronic HCV infection. These molecular players may act as promising early detectors or even an emerging therapeutic target for HCC tailored therapy.

## ONCOGENIC EFFECTS OF HCV PROTEINS

Development of HCC on top of HCV occurs due to contribution of viral and host factors. HCV can induce HCC through direct effects of its protein or through indirect way. The indirect way occurs as inflammation of liver tissue and/or its complication as cirrhosis which form the background for HCC in most of HCV - HCC patients. Hoshida *et al*<sup>[9]</sup> described HCV as a single-strand RNA

virus in the Flaviviridae family that encodes structural (core, E1, E2) and non-structural proteins (p7, NS2, NS3, NS4A, NS4B, NS5A and NS5B). The virus is established by a nucleocapsid containing viral genome; core protein and envelope glycoproteins E1 and E2. HCV infection induces the expression of the nucleocapsid core protein by infected cell. This core protein centralizes in the cytoplasm, lipid droplets, endoplasmic reticulum/Golgi apparatus, nuclei and mitochondria this expression is assumed to alter several cellular functions.

## ONCOGENIC EFFECTS OF CORE PROTEIN

Previous studies concluded that HCV core protein can cause apoptosis, signal transduction, share in oxidative stress by producing reactive oxygen species (ROS), affect metabolism of lipid, activate transcription, and modulate immunity and transformation<sup>[10,11]</sup>. Many scientists have reported frequent mutations in the core gene of HCV among subjects with liver cancer<sup>[12,13]</sup>.

Some scientists suggested that p53 and p73 are tumor suppressor proteins can be affected by HCV core protein<sup>[14,15]</sup>. HCV core protein binds with p73 to inhibit p73  $\alpha$ -dependent cell growth arrest in a p53 - dose dependent manner. This was supported by findings of Alisi *et al*<sup>[16]</sup>. Furthermore, study of Yamanaka *et al*<sup>[17]</sup> suggested that core can also modify the major target of p53 which is known as the cyclin dependent inhibitor p21WAF1 and could control functions of cyclin/cyclin-dependent kinase complexes included in cycle of cell and control and carcinogenesis. This was agreed by study of Kwun *et al*<sup>[18]</sup>. Moreover, other researchers found that signaling pathways such as Raf/MAPK<sup>[19]</sup>, Wnt/ $\beta$ -catenin, 41 and TGF- $\beta$  can be stimulated by HCV core protein<sup>[20,21]</sup>. The inclusion of different pathways is known to be activated in HCC and may help in progression of cirrhosis process; induce mutation for one or more oncogenes or tumor suppressor genes<sup>[22]</sup>.

## ONCOGENIC EFFECTS OF NS3 PROTEIN

HCV NS3 protein acts as an early oncogenic player on hepatocytes<sup>[23,24]</sup>. It inhibits the activity of both p53 and p21WAF1 promoter<sup>[25,26]</sup>. Meanwhile, NS3 protein promotes cell growth, DNA-binding functions of the reproduction agents, AP-1 and ATF-2 and JNK activation<sup>[27]</sup>. It was found that HCV NS3 can activate AP-1 and NF- $\kappa$ B to increase production of TNF- $\alpha$  which has a role in liver carcinogenesis<sup>[28]</sup>.

## ONCOGENIC EFFECTS OF NS5A PROTEIN

Hassan *et al*<sup>[27,28]</sup> proved that NS5A is necessary for replication of the virus and is present in the cytoplasm of infected hepatocytes in conjunction with endoplasmic reticulum. NS5A shares in many function of the cell as transcription, transformation, signal transduction, ROS production and apoptosis. Interestingly, wild-type NS5A gene was up regulated among HCC patients with liver

cirrhosis as background Compared with those who did not develop HCC, taken together, irregular data with regard to the function of core and NS5A proteins on hepatocytes signaling pathways, transcriptional activation, apoptosis and lipid metabolism oxidative stress propose a varied role for HCV proteins in the pathogenesis of chronic hepatitis due to HCV infection, liver fibrosis that results in liver tumorigenesis<sup>[28]</sup>.

## INFLAMMATION-RELATED LIVER CARCINOGENESIS

The indirect way for hepatocarcinogenesis during HCV infection is inflammation of hepatocytes, persistence of chronic hepatitis, liver fibrosis and cirrhosis ending to malignancy transformation. In liver cancer, close to 80% of patients develop malignancy on top of chronic hepatitis. However, the underlying genetic changes for HCC development are not yet fully understood. Continuous formation of regenerative nodules in liver cirrhosis shares in malignant transformation. Previous study reported activation of toll like receptor 4 which promotes the effect of translocation of intestinal microbiota to the liver in late stages of liver carcinogenesis<sup>[29]</sup>. In this study, Dapito *et al.*<sup>[29]</sup> used animal model (*i.e.*, TLR4 genetic inactivation, gut sterilization and long-term treatment with low doses of lipopolysaccharide (LPS)), in which chronic liver injury was modeled using diethyl nitrosamine and carbon tetrachloride.

The researchers proved that the NF- $\kappa$ B pathway is stimulated through identification of TLRs for microbial ligands, like LPS and pathogen-related molecular manner. As a result, the secretion of inflammatory molecules, such as TNF- $\alpha$  and cytokines is stimulated. These molecules regulate the function of liver cells particularly stellate cells which act as the maestro for liver fibrosis process, a step that forego liver cancer growth<sup>[30,31]</sup>. The findings of this study support that of other studies who concluded that the main predisposing factors for HCC development among cases with chronic HCV infection is late liver fibrosis and cirrhosis<sup>[2,3,7]</sup>.

## GENETIC CHANGES DURING HCV RELATED LIVER CARCINOGENESIS

Moeini *et al.*<sup>[31]</sup> suggested that human cancer diseases have been hallmarked by the acquisition of cancer cells to six capabilities: (1) growth signals self-adequacy; (2) loss of sensitivity to anti-growth signals; (3) escaping from apoptosis; (4) unlimited possibility for replication; (5) continuous formation of new blood vessels for the tumor; and (6) metastasis<sup>[32]</sup>. A growing line of evidence has shown that aberrant expression of miRNAs is included in different cancer diseases through deregulating target genes, collectively leading the cell to acquire the six capabilities. miRNAs can act as oncogenes, tumor suppressors, or both and this depends on the targeted genes<sup>[33]</sup>.

Changes in Genetic and epigenetic represent host factors for HCC pathogenesis in late stages of HCV infection. Several signaling Mediators are contributing in liver carcinogenesis, involving some control cell differentiation (Hedgehog, WNT, and Notch), signaling for growth factor (*e.g.*, HGF, IGF, PDGF, EGF, FGF,) and angiogenesis (VEGF). Intracellular modules as AKT/MTOR and RAS could share in pathogenesis of HCV related HCC. Other genetic causes are contributing to stimulate erratic pathway activation. These include mutations, chromosomal abnormalities, and epigenetic mechanisms<sup>[34]</sup>.

Heterogeneity and complexity of carcinogenesis has altered the way we believe concerned with induction, pathogenesis, diagnosis, progression and management of cancer. Although the great advance in exploring of cancer biology, the most of emerging therapies for malignancy do not achieve efficient success, which points to failure of conventional therapeutic interventions. The corner stone in applying of an emerging effective treatment against malignancy is the establishment of efficient clinical trials. Invasive surgical procedures and liver transplantation, the important procedures for HCC therapy, are considered to be the most curative options for treatment of cases of liver cancer. But the frequent recurrent HCC and metastasis after surgical approach is the main hurdle in HCC treatment. Applying effective curative therapeutic procedures to late stages of HCV-HCC disease usually faces big challenge. So that, detection of HCC as early as possible is the corner stone in raising the survival rate and improving the prognosis for cases with this aggressive disease. A main attempt to promote novel treatments should involve the implementation of genetic identification to describe tumors and supply exact foretelling as possible therapeutic targets during the process of liver carcinogenesis and an overall improvement in targeted therapies.

Insights of genetic profiling implying the development of HCC on top of HCV are obscure. The molecular mechanisms include up regulation of oncogenes, inhibition of malignancy oppressor genes, up regulation of growth agents<sup>[35]</sup>, stimulation of telomerase and DNA mismatch repair error may share in the development of liver carcinogenesis<sup>[20,36,37]</sup>. In this context, over expression or down expression of the studied genes which are related to cell cycle progression, growth, disease creation, and reaction to surrounding stimulants cooperate leading to this sophisticated process.

The genomic alterations in malignancy performs a constitutional signature which could involve the control through transcriptional pattern which in turn reflect on a quantitatively gene expression levels<sup>[38,39]</sup>.

Moinzadeh *et al.*<sup>[40]</sup> reported that the implementation of high technologies analysis are so paramount important to improve exploring of genomic alterations in the situation of its relation to pathogenesis of HCC; with the preface of copy number variation (CNV) notion in addition to single nucleotide polymorphisms (SNP), and with the amended mapping of such CNVs throughout the

whole genome of cases vs healthy subjects. In the same concept, Zhao *et al.*<sup>[41]</sup> proved that CNVs as chromosomal SNPs that are several megabases in size, is ending with the size range of CNVs proportionate with the great progress in bioinformatics. The identification of these polymorphisms, either at small (SNPs or mutations) or large CNVs scale as well as regions contains loss of heterozygosity (LOH) blocks may have a role in cancer formation.

## EPIGENETIC ALTERATIONS IN HCV RELATED HCC

Epigenetics refers to all stable alterations in gene expression with no underlying modifications in the genetic sequence itself<sup>[42]</sup>. Epigenetic and genetic mechanisms have a role in silencing of key cellular genes leading to destabilization of the genome and in turn resulting in carcinogenic transformation in human cancers, including HCC<sup>[43]</sup>. Contribution of different epigenetic factors, including genomic DNA methylation, histone modifications, and miRNA regulation, contribute to HCC dissemination, invasion, and metastasis. The reversal of deregulated epigenetic changes has emerged as a potential strategy for the treatment of HCC and is of paramount important in preclinical and clinical development<sup>[44]</sup>. However, obtaining a highly-specific potent epigenetic markers may provide an opportunity for targeting inflammation-epigenome cross-talk in HCC and needs employment of fast screening methods, such as high-throughput screening to navigate efficiently and discovering epigenetic targets<sup>[45]</sup>.

Administration of classical antiviral agents, INF administration with epigenetic drugs (such as DNMT inhibitors or HDAC inhibitors) could confirm an efficient counteracting between cytokines and epigenome changes<sup>[46]</sup>. It was reported that HCV core protein could increase the expression of mRNA and protein values of DNMT1 and DNMT3b, which in turn leads to epigenetic alteration of liver cells of patients with in HCV cells infection<sup>[47]</sup>.

Furthermore, the induction of HCV proteins or the infection of HCC cells with HCV cell culture (HCVcc) resulted in suppression of histone H4 methylation/acetylation and histone H2AX phosphorylation, with significantly altered expression of genes essential for HCC development, indicating that HCV-induced overexpression of PP2Ac involved in pathogenesis of HCC through deregulation of epigenetic histone modifications<sup>[48]</sup>. HCV infection may up regulate histone deacetylation activity through affecting hepcidin expression, a key suppressor of iron availability<sup>[49]</sup>. The induced HCV oxidative stress leads to suppression of hepcidin expression by increased histone deacetylase function.

Other epigenetic changes during HCV induced liver carcinogenesis is deregulation of a class of short, non-coding RNAs [microRNA (miRNA)] that play important roles in gene expression regulation. One miRNA can target several genes through mRNA, this function put

miRNAs in the top not only of diagnostic markers but some of them became a target for personalized therapy. They act as genetic signature for many diseases including HCC with different stages, supporting the potential use of miRNAs in HCC patient stratification of diagnosis and prognosis. Several studies suggested that miRNAs play an important role in carcinogenesis, either as oncogenes or tumor suppressors<sup>[50]</sup>.

Interestingly, miRNAs have been found to be differentially expressed in liver cancer, they are activated to share in pathogenesis of HCV related HCC. Moreover, some miRNAs could be related to different stages of liver carcinogenesis, supporting the possible use of miRNAs in HCC patient correspondence to diagnosis and prognosis. Some of these HCC-associated miRNAs have been validated in independent cohort studies. This confirms the ability of paving the way to develop HCC diagnosis, evaluation of risk exposure, and patient danger accordance with the eventual aim of tailored treatment.

Several previous studies have identified miRNAs expression in pathogenesis of liver cancer on top of chronic HCV infection. miR-21, miR-17, miR-222, miR-224, miR-221, are usually increased in liver cancer<sup>[51,52]</sup> while miR-200, let-7, miR-29, miR-123, miR-122, miR-199a, miR-199b, are decreased<sup>[53,54]</sup>, miR-199 is consistently down-regulated in HCC<sup>[55]</sup>. Since miR-199a/b-3p suppresses HCC in part by preventing the p21-stimulated kinase 4/Raf/MEK/ERL pathway, down-regulation of miR-199a/b is related to bad prognosis and low survival rate<sup>[56]</sup>. On the other hand, miR-224 has been found to be increased in liver cancer<sup>[57]</sup> and was reported to be related to malignancy aggression, deteriorated liver function, and poor prognosis<sup>[58]</sup>.

## BIOMARKERS FOR HCC EARLY DETECTION

Cancer diagnostics based on measuring biomarkers in tissue samples has already in the past decade provided revolutionary advances in diagnosis, prognosis, and therapy selection. A major drawback of the tissue-based approach centers on the need for invasive surgical procedures in sample collection, which in a great many instances preclude following the progression or regression of disease during therapy.

In recent years, an impressive number of cancer biomarker researchers have turned their attention to the demonstration of markers present in biological fluid or blood based biomarkers have also significantly impacted approach of "molecular pharmacogenomics and therapeutics"<sup>[59,60]</sup>. Deep understanding of pathogenic evolution of cancer has improved considerably through Launching of molecular diagnostics in the marketplace and involves expertise in managing resources and navigating a competitive environment. Rising healthcare costs have led to innovative solutions which include molecular testing matched with targeted therapies, point-of-care testing to provide rapid results for improved

patient outcomes, and non-invasive testing options<sup>[60]</sup>.

Screening for HCC among Patients with chronic HCV infection should be done by conventional abdominal ultrasonography; serum  $\alpha$ -fetoprotein (AFP); protein induced vitamin K absence-II and abdominal computed tomography scan. Other serum markers could be used as AFP-L3 (a glycosylated form of AFP); Des gamma carboxyprothrombin and Golgi membrane protein 73, Dickkopf-1<sup>[61]</sup>, and squamous cell carcinoma antigen<sup>[62]</sup> have increased the chance for early HCC detection. We face challenge in diagnosis of small tumors or in well-to-moderately differentiated HCC as serum markers are rarely elevated. Thus, development of sensitive and specific diagnostic biomarkers became an urgent need. It was found that use of autoantibody to tumor-associated antigens (TAA) as a diagnostic biomarker for early detection as indicators of disease prognosis has been explored. Hong *et al.*<sup>[63]</sup> investigated the serum autoantibodies to TAA, and detect that centromere protein F, and hot shock protein were new promising early detectors for HCC. Anti-TAA antibodies might reflect molecular events associated with tumorigenesis.

### AFP

The first serologic assay for diagnosis and clinical follow-up of patients with liver cancer was AFP which has been the conventional tumor biomarker for HCC for many years. Serum AFP levels are often increased in HCC, but this is not always the case. AFP levels may be elevated initially in the early stages of HCC and then drop or even normalize before increasing again as disease progression occurs<sup>[64]</sup>. Total AFP can be divided into three different glycoforms, AFP-L1, AFP-L2, and AFP-L3-based on their binding capability to lectin Lens culinaris agglutinin. High percentage of AFP-L3 has been shown to be associated with poor differentiation and biologically malignant characteristics, worse liver function, and larger tumor mass<sup>[65]</sup>.

### mRNAs circulating biomarker

The advantage of circulating nucleic acids in plasma offers another avenue for noninvasive monitoring of a variety of physiological and pathologic conditions<sup>[66,67]</sup>. Numerous applications based on the detection of circulating cell-free nucleic acids in human plasma have been reported for the management of malignancies. Cell-free plasma RNA detection methods offer an opportunity for the development of pathology-related markers<sup>[68,69]</sup>. From cell free mRNAs HCC biomarkers are the AFP mRNA, gamma-glutamyl transferase mRNA, insulin-like growth factor II, and Albumin mRNA.

Now, accumulating studies have addressed that biomarkers are validated components of tumor pathogenesis. Different biomarkers that better predict patients who are at higher risk of recurrence and shown poorer prognosis would help guide the alternative treatment<sup>[70-83]</sup>. Despite the investigation of curative or palliative treatments, prognosis is still poor due to underlying liver diseases and the unique biology of HCC.

**RNAi biomarker:** Derives its attractiveness as a therapeutic tool from several factors. Its principle based on its extreme specificity, the ease of siRNA synthesis, low cost of production and chemical stability makes RNAi an attractive candidate for therapeutic use<sup>[77]</sup>. RNAi, with its simplicity of design and specificity, is being investigated for its potential for cancer therapy. RNAi is advantageous in this case, in the sense that it can be used to target a large number of genes involved in different pathways. Genes involved in cancer can be classified into oncogenes, tumor suppressor genes, and tumor promoting genes (growth and angiogenesis) among others. RNAi can be used to silence oncogenes, tumor promoting genes and/or genes that negatively regulate tumor suppressor genes. Cancer-specific genes that are mutated are ideal targets for siRNA therapy as they can be efficiently targeted without affecting the wild type form of the gene<sup>[77]</sup>. *In vitro* studies using siRNAs directed toward mutated cancer-specific genes have shown extreme specificity towards the mutated form of the gene, whereas silencing of the wild type did not occur<sup>[78]</sup>. Several studies demonstrated the potential success of RNAi in cancer therapy. *In vitro* study targeting mutated oncogene K-Ras, its expression level was strongly inhibited, vs no inhibition of the wild-type. Upon injection of siRNA treated cells into nude mice, tumor formation was dramatically inhibited<sup>[77]</sup>. Another study targeted the epidermal growth factor receptor; epidermal growth factor receptor (EGFR), which confers an oncogenic activity when mutated leading to promotion of proliferation and survival of the cancerous cell. *In vitro* targeting of EGFR displayed as with K-Ras inhibited expression of mutated EGFR while the wild rapid and massive apoptosis<sup>[79]</sup>. Another potential target for cancer therapy by RNAi is P-glycoprotein; the product of the multidrug resistance gene.

**miRNAs biomarker:** miRNAs are regulatory factors that function to repress the transcription of mRNA. Because each miR contains a seed sequence that is complementary to the UTR region of up to around 50 mRNA, the biological impact from the modulation of just a single miR can be significant. Expression profiles are deregulated in cells undergoing pathophysiologic stress suggesting potential as markers of disease states. Based on numerous favorable characteristics of miRNAs as biomarkers as miRNAs are short, protein bound, highly stable in the circulation, and often travel encapsulated in micro vesicles have revealed their potential as diagnostic, prognostic, and treatment response biomarkers.

Several miRNA databases as miRBASE<sup>[80]</sup>, biological databases as those of National Center for Biotechnology Information, and others, ontologies as Gene Ontology, and pathway networks allow investigators to augment and validate relations between miRNA and other information on cellular locations and molecular processes, as well as pathways they contribute to<sup>[81,82]</sup>.

In particular, genetic and epigenetic changes in cells and high frequency of methylated genes in tumors

lead to adenocarcinoma and may serve as a promising marker in the detection of cancer DNA<sup>[83,84]</sup>. Identification of a panel of biomarker alterations can give us a recognizable pattern of molecular alterations in the HCC which can serve as a "signature" specific for each tumor.

### **Advanced methods used in identifying biomarkers related to HCC**

Numerous recent technologies such as next-generation sequencing (NGS)<sup>[85]</sup> and microarray technologies<sup>[86,87]</sup> have adopted in searching for different biomarkers emerged in era of "omics"<sup>[88,89]</sup>. The progress in high-throughput technologies used in ease way to examine a whole tumor genome (genomics, transcriptomics, proteomics) feature important advances in understanding of the underlying sophisticated pathomechanism for carcinogenesis and metastasis of HCC leading to discover of promising biomarkers with clinical potential. Involving loss of heterogeneity, copy number variations, single nucleotide polymorphism aneuploidy<sup>[90,91]</sup>, transcriptome<sup>[92,93]</sup>, proteome<sup>[94,95]</sup>, epigenome<sup>[83,84]</sup>, metabolome<sup>[96,97]</sup>, and miRNA profile<sup>[98]</sup>.

The use of genomics and bioinformatics techniques are inevitable for the generation and analysis of comprehensive datasets from patient samples, targeting the detection of hundreds thousands of genetic entities. They have facilitated the investigation of biological entities associated with the progression of tumors - array comparative genomic hybridization (aCGH) array platform have been applied to HCC samples to better deep understand the role of DNA genomic aberrations. Different microarrays companies began by Affymetrix Inc. then applied by Illumina Inc have developed similar approaches containing SNP probes. Numerous studies have used either CGH or aCGH techniques to investigate chromosomal alterations associated with HCC<sup>[40]</sup>. These array assays based on identification of critical regions commonly exhibit either increased or deletion dosage of gene, leading to alterations in DNA CNVs, aberrations or abnormal LOH blocks in different malignancies, involving liver cancer<sup>[99,100]</sup>.

## **HUMAN LIVER CANCER PCR ARRAY**

Liver cancer PCR Array profiles the expression of many important genes included in the development of HCC. Since numerous microarray studies have identified many deregulated genes, which are important for cellular signaling and other normal biological processes. RT Profiler PCR Array System directed at these genes may yield insights into the molecular mechanisms underlying liver carcinogenesis. This array includes genes commonly up- and down-regulated in HCC, genes involved of signal transduction pathways, and also genes involved in other deregulated biological pathways such as cell cycle, epithelial to mesenchymal transition, inflammation and apoptosis.

### **Next-generation sequencing**

Next-generation sequencing as Roche 454 and Illumina

has been recently introduced to enable massive parallel measurement of mRNA and miRNA expression<sup>[101]</sup>. NGS technology, once reserved for the largest and busiest of research centers, is now attainable to enterprises of all sizes discovering new knowledge on cancer, microbiology, agriculture, genetic disease, reproductive health, and forensics, and other emerging areas. Cancer Sequencing output data are of great important helping in shed light promising newer cancer diagnostics and making data potential of clinical use<sup>[102]</sup>.

### **Emerging therapeutic strategies for HCC**

HCV related HCC is a big health problem in our country Egypt due to the high prevalence of HCV infection among Egyptians. The national committee for viral hepatitis control has started emerging antiviral therapies known as direct acting antivirals. These drugs showed promising increase in the sustained virological response. But what about the role of these drugs on guarding against HCC development?

It is thought that it is early to have a conclusive answer about this question because these drugs act only on the HCV not on liver cells. Moreover, most of the candidate patients for use of these drugs have different grades of liver fibrosis. Can antivirals induce regression of liver fibrosis or even cause stasis of this liver inflammation? The answer for this question needs to follow-up these patients for 20 years at least to detect natural course of liver fibrosis among these patients after control the HCV. Gene therapy for liver cancer means transfer of genetic material to malignant cells, initiating therapeutic effect. This type of emerging therapy may complement or substitute the conventional treatment for HCC. It is important to minimize the transfer of genetic materials to nonmalignant tissues of the liver especially that HCC usually develops on top of cirrhotic liver, thus transfer of genetic material to adjacent non-malignant tissues will accelerate the deterioration of liver functions<sup>[103,104]</sup>.

Inside the target cells, gene expression could be regulated by tumor specific promoters (transcriptional) as surviving or AFP promoters or by targeting messenger RNA of the therapeutic gene (post-transcriptional) for destruction by micro-RNAs. Therapeutic genes used cause cell death through cytotoxicity; inhibition of oncogenic pathway function or stimulation of antitumor immune response<sup>[104]</sup>.

Viral gene therapy procedures aiming to deliver RNAi have shown promising response in animal models of liver cancer through aiming oncogenic pathways involving p28GANK<sup>[105]</sup>, survivin<sup>[106,107]</sup>, VEGF<sup>[108]</sup> and URG11<sup>[109,110]</sup>.

Other emerging tool of gene therapy for HCC are Replicating virus vectors. Using of specific retroviral replicating vector (RRV) could inhibit the growth of HCC tumor and generate suicide gene therapy effectively with no detectable RRV signal in extratumoral tissues. The resulted tumor-specific suicide-gene-encoding RRV may achieve the engagement application of retroviral gene therapy for HCC cancer<sup>[111]</sup>.

As discussed above, the possible use of miRNA expression in liver cancer as early detectors, miRNAs may themselves be used as therapeutic agents. Different studies clarify the role of miRNAs in HCC tumorigenesis. It was found that miR-26a which is involved in inducing arrest of cell cycle and known to be down-regulated in both human and mouse malignancies, including HCC. In a mouse model of liver cancer, miRNA expression from an AAV vector led to suppression of malignant cell growth and stimulates tumor-specific apoptosis<sup>[112]</sup>.

Recuperation of expression of miRNA 223<sup>[113]</sup>, miRNA 122, lead to decreased metastasis and angiogenesis<sup>[114]</sup>. Restoration of miRNA101 expression sensitized cells to killing by conventional chemotherapy<sup>[115,116]</sup>. Silencing of up regulated miRNAs in HCC may lead to disruption of pathways important to tumor survival and development. In this core, it was found that silencing of HCC through specific miR-21 and miR-221 each resulted in reduction of viable and tumor of HCC cells<sup>[117,118]</sup>.

## CONCLUSION

There is increasing evidence for HCC tumorigenesis in patients with HCV involves accumulation of genetic alterations. Underlying pathogenic mechanisms of HCC is complex and heterogeneous disease with multiple and variable of risk factors. Thus, signatures of a combination of non-invasive and cost-effective biomarkers may be more valuable for the diagnosis, staging, and prognosis of HCC. Multiple factors contribute in liver carcinogenesis during HCV infection, these factors may act in parallel to each other or they may act in intersecting lines, each in his role. Altogether, these players represent a big challenge in front of conventional therapeutic modalities for HCC. So we think that it's time to try to discover the underlying mechanism for hepatocarcinogenesis to pave the way for development of tailored therapy for those patients changing the basic researches into applied researches. More efforts must be paid by hepatologists especially in countries with high prevalence of HCV infection to identify the underlying genetic mechanisms for liver carcinogenesis among these patients. Cooperation between scientists all over the world with use of recent technology and bioinformatics will build up a strong network for diagnostic markers for HCC and help in early detection of this malignant disease. This network will act as a platform for development of tailored therapy for HCV related HCC.

## Abstract

### AIM

To apply the Frontal Assessment Battery to cirrhotic patients with or without overt hepatic encephalopathy (OHE) and controls.

### METHODS

The frontal assessment battery (FAB) was applied to 87 patients with liver cirrhosis (16 with and 71 without OHE) and 40 control subjects without cirrhosis treated at the alcohol and liver outpatient clinics and the gastroenterology ward of the Cassiano Antônio de Moraes University Hospital (Hospital Universitário Cassiano Antônio de Moraes - HUCAM), Espírito Santo, Brazil.

### RESULTS

The average FAB score was lower for the cirrhotic than for the non-cirrhotic patients ( $10.6 \pm 3.67$  vs  $12.25 \pm 2.72$ ,  $P = 0.015$ ). The FAB score was lower for the cirrhotic patients with OHE than for the patients without OHE ( $8.25 \pm 4.55$  vs  $11.14 \pm 3.25$ ,  $P = 0.027$ ). The total FAB score was lower for the cirrhotic patients without OHE than for the non-cirrhotic patients, although this difference was not significant ( $11.14 \pm 3.25$  vs  $12.25 \pm 2.72$ ,  $P = 0.067$ ). Nevertheless, the difference in the scores on the subtest that assessed the ability to inhibit a response previously conditioned to a stimulus was significant ( $1.72 \pm 0.93$  vs  $2.2 \pm 0.85$ ,  $P = 0.011$ ).

### CONCLUSION

The present study indicates that the FAB is a promising

tool for outpatient minimal HE screening and the assessment of HE severity.

**Key words:** Executive functions; Frontal lobe; Hepatic encephalopathy; Minimal hepatic encephalopathy; Liver cirrhosis; Frontal assessment battery

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The diagnosis of hepatic encephalopathy is based on the West Haven classification. Minimal hepatic encephalopathy is defined by cognitive changes in patients with liver cirrhosis or portosystemic shunting without changes in their physical examination. The diagnosis is performed by neurophysiological and/or neuropsychological tests that are difficult to apply and are expensive. The frontal assessment battery (FAB), which is quick and easy to apply, can be used by the clinician. In the present study, the FAB score was lower in cirrhotic patients, especially those with hepatic encephalopathy. The FAB is a promising test for minimal hepatic encephalopathy screening at the bedside and in outpatient clinics.

de Souza KZ, Zago-Gomes MP. Frontal assessment battery: A tool for screening minimal hepatic encephalopathy? *World J Hepatol* 2016; 8(30): 1262-1268 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i30/1262.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i30.1262>

## INTRODUCTION

Hepatic encephalopathy (HE) comprises a heterogeneous group of neuropsychiatric disorders that occur in patients with liver cirrhosis (LC) or portosystemic shunting in the absence of other known brain diseases<sup>[1]</sup>. The traditional HE classification comprises four grades based on the West Haven criteria for the semi-quantitative grading of mental status<sup>[2,3]</sup>. Overt HE (OHE) is characterized by the presence of clinical manifestations that are easily recognizable in clinical interviews and physical examinations and corresponds to grades 2 to 4. Sub-clinical HE includes forms of the disease that are not easily recognizable in the clinical interview and physical examination, such as West Haven grade 1 and minimal HE (MHE), in which the cognitive deficits can only be detected using specialized tests<sup>[4,5]</sup>. The cognitive deficits caused by MHE have negative impacts on the social and occupational lives of the patients and thus impair their quality of life<sup>[2]</sup> and are associated with a higher risk of accidents<sup>[6]</sup>. Because MHE cannot be recognized during a physical examination, its diagnosis is established through the application of tests to apparently normal individuals who exhibit risk factors for the development of this condition<sup>[7]</sup>.

Traditionally, the MHE diagnosis is established based on neurophysiological and/or neuropsychological tests<sup>[4]</sup>.

The majority of these tests are extensive and require a significant amount of time to perform; additionally, they are difficult to interpret and require the expertise of neuropsychiatry professionals<sup>[8]</sup>. The frontal assessment battery (FAB) developed by Dubois *et al*<sup>[9]</sup> is a quick tool; its application requires approximately 10 min. It is well accepted by patients and is useful for identifying the presence and assessing the severity of dysexecutive syndromes that affect cognition and motor behavior<sup>[10]</sup>. The FAB comprises six subtests (conceptualization, lexical fluency, motor series, conflicting instructions, inhibitory control, and automatic behavior)<sup>[9,11]</sup>. Originally, the FAB was used to assess patients with Parkinson's disease who exhibited abnormalities on the Wisconsin Card Sorting Test, Trail Making Test and verbal fluency tests<sup>[9,12]</sup> and patients with abnormal perfusion of the frontal lobe on imaging tests<sup>[13-17]</sup>. These studies suggest that the FAB evaluates executive functions of the frontal lobe. Additionally, it has proven useful for distinguishing between Alzheimer's disease (AD) and frontotemporal dementia (FTD)<sup>[18]</sup>, detecting subclinical dysexecutive alterations in alcoholic subjects, formulating differentiated therapeutic strategies for the management of alcoholic patients on an individual basis<sup>[19]</sup>, and correlating the use of crack cocaine with a decline in the frontal executive functions as a function of the duration of drug use<sup>[20]</sup>. The present study represents the first application of the FAB in patients with chronic liver disease. The results are compared between individuals with OHE and subclinical HE and the controls.

The aim of the present study was to determine whether the FAB could detect differences between patients with LC and the controls and between cirrhotic patients with and without OHE and to investigate whether this tool might be indicated for outpatient screening for MHE.

## MATERIALS AND METHODS

### Patients

The present study assessed 127 individuals treated at the gastroenterology ward and liver and alcohol outpatient clinics of Cassiano Antônio de Moraes University Hospital, Federal University of Espírito Santo (Hospital Universitário Cassiano Antônio de Moraes, da Universidade Federal do Espírito Santo), Espírito Santo, Brazil. A total of 87 patients had LC, including 16 with OHE and 71 without HE. The remaining 40 patients were defined as controls and were matched according to gender and the cirrhosis etiology (alcoholism, hepatitis B, or hepatitis C). All LC patients were assessed and classified based on the Child-Pugh classification for the severity of liver disease. Individuals with clinical manifestations of psychiatric diseases, those who had consumed alcohol in the past 15 d, and those under 18 years of age were excluded from the study.

### LC diagnosis

The LC diagnosis was established based on the com-

bination of clinical criteria and the results of imaging and/or histopathological tests.

### HE diagnosis

Patients with LC and neuropsychiatric disorders detected during the clinical interviews and physical examinations in the absence of other known brain diseases were diagnosed with OHE<sup>[1]</sup>. The following clinical manifestations were considered: Behavioral alterations, sleep disorders, irritability, and depression. The psychomotor abnormalities included asterixis, bradykinesia, tremors, and rigidity. Additionally, mental confusion and acute temporal-spatial disorientation were considered<sup>[21]</sup>.

### FAB

The FAB was applied to patients individually by the same examiner using only a paper and pencil; the tests

were applied to inpatients at the bedside and at the outpatient clinics. The FAB is described in Table 1.

To compare the FAB scores to dichotomous categorical variables, the scores were categorized as high ( $> 11$ ) or low ( $\leq 11$ ) based on the median scores of the LC patients.

### Ethics

The present study was approved by the ethics committee of the Center of Health Sciences, Federal University of Espírito Santo (Universidade Federal do Espírito Santo), which is associated with the National Commission of Research Ethics (Comissão Nacional de Ética em Pesquisa - CONEP). After receiving a detailed explanation of the study, the participants signed an informed consent form approved by the institutional medical ethics committee.

### Statistical analysis

The statistical analysis was performed with the Epi Info 6.04 e BioEstat 5.3 software. The data were subjected to a descriptive analysis, including the frequency distribution (in the case of qualitative variables), are expressed as absolute numbers ( $n$ ) and percentages (%), and the means and standard deviations (SD) were calculated. The means of data with a normal distribution were compared using Student's  $t$ -test. Categorical variables were subjected to a cross-tabulation analysis with a  $\chi^2$  test. Fisher's exact test was used to compare two variables when the expected frequency according to the null hypothesis was less than five, and the maximum likelihood ratio was used when the exposure variable comprised more than two categories.

The non-parametric Mann-Whitney test was used for continuous variables with a non-normal distribution. Associations with a value of  $P < 0.05$  were considered statistically significant.

## RESULTS

### Patient characteristics

The demographic characteristics of the sample are described in Table 2. The predominant cause of cirrhosis was alcoholism (65.5%). The cirrhosis etiology and the underlying diseases of the control subjects are described in Table 3. No significant differences were detected in the FAB scores related to the liver cirrhosis etiology.

Among the 87 cirrhotic patients, 33 were classified as Child-Pugh class A, 36 were classified as class B, and 17 were classified as class C. Most of the cirrhotic patients with OHE were classified as Child-Pugh class C (56% vs 11% of the cirrhotic patients without OHE,  $P < 0.001$ ).

Figure 1 shows that no difference was observed in the FAB scores as a function of the cause of disease when the cirrhotic patients and controls were compared.

The FAB score was lower (mean 10.6, SD  $\pm 3$ , maximum score 18) for the cirrhotic patients than for the controls (mean 12.5, SD  $\pm 2.72$ ,  $P = 0.015$ ). For the cirrhotic patients with OHE, the average score was

**Table 2** Characterization of the cirrhotic and non-cirrhotic patients *n* (%)

Variables	Cirrhotic ( <i>n</i> = 87)	Non-cirrhotic ( <i>n</i> = 40)	<i>P</i> -value
Gender			0.814
Male	68 (78)	32 (80)	
Female	19 (22)	8 (20)	
Age range			0.001
50 yr or older	69 (79)	20 (50)	
Under 50 yr	18 (21)	20 (50)	
Formal schooling			0.577
None	5 (6)	3 (7.5)

4 to 7 yr	33 (38)	18 (45)	
8 to 11 yr	28 (32)	12 (30)	
12 or more years	6 (7)	4 (10)	

**Figure 1** Percent distribution of the frontal assessment battery score, categorized as high or low, of the investigated patients (cases and controls) compared according to the cause of liver cirrhosis (Fisher's exact test). FAB: Frontal assessment battery; HbSAg: Hepatitis B virus surface antigen; HCV: Hepatitis C virus; NASH: Non-alcoholic steatohepatitis.

8.25 (SD  $\pm$  4.55) and the median score was 7.5. In comparison, the scores of the cirrhotic patients without HE were higher (mean 11.4, SD  $\pm$  3.25, median 11,  $P$  = 0.027). The FAB score was lower for the cirrhotic patients without OHE than for the controls, although the difference was not significant ( $P$  = 0.067) (Figure 2).

The poorest scores in the cirrhotic group corresponded to the inhibitory control subtest (GO/NO-GO) (mean 1.61, SD  $\pm$  0.98) compared with the controls (mean 2.2, SD  $\pm$  0.85,  $P$  = 0.02). The GO/NO-GO scores were lower for the cirrhotic group without OHE (mean 1.72; SD  $\pm$  0.93) than for the controls (mean 2.2, SD  $\pm$  0.85,  $P$  = 0.011). The GO/NO-GO scores were also lower for the cirrhotic group with OHE (mean 1.13, SD  $\pm$  1.09) than for the cirrhotic group without OHE (mean 1.72, SD  $\pm$  0.93,  $P$  = 0.02), as shown in Figure 3. In this subtest, the individuals were required to inhibit a learned behavior (clap once when the examiner claps twice) and then perform a different task (do not clap when the examiner claps twice). No significant differences were detected in any of the other subtests in the comparison between the cirrhotic patients without OHE and the control group (Figure 4).

Of the 16 cirrhotic patients with OHE, 12 exhibited

**Figure 2** Median (interquartile range) total scores on the frontal assessment battery for cirrhotic patients with overt hepatic encephalopathy (*n* = 16) vs cirrhotic patients without overt hepatic encephalopathy (*n* = 71) (Student's *t*-test) and the control group (non-cirrhotic patients, *n* = 40) vs the case group (cirrhotic patients with and without overt hepatic encephalopathy, *n* = 87) (Mann-Whitney test). FAB: Frontal assessment battery.

low FAB scores (12/16, 75%). Low FAB scores were exhibited by 37/71 (52%) cirrhotic patients without HE and 17/40 (43%) controls. The linear association test detected a significant difference among the groups ( $P$  = 0.038).

## DISCUSSION

Several studies have shown that MHE causes abnormalities in the attention, social interactions, behavior, and quality of sleep of patients, with consequent impairment of the performance of the activities of daily living. Additionally, interference with more complex activities, such as driving ability or planning a trip, impairs the quality of life of patients and may increase the risk of accidents involving themselves and others<sup>[2]</sup>.

The investigation of patients with cirrhosis by the West Haven test is not sufficient to identify subclinical forms of encephalopathy<sup>[22]</sup>. Traditionally, the MHE

**Figure 3** Median (interquartile range) total scores on the inhibitory control subtest (GO/NO-GO) for cirrhotic patients with overt hepatic encephalopathy ( $n = 16$ ) vs cirrhotic patients without overt hepatic encephalopathy ( $n = 71$ ) (Student's  $t$ -test) and the control group (non-cirrhotic patients,  $n = 40$ ) vs the case group (cirrhotic patients with and without overt hepatic encephalopathy,  $n = 87$ ) (Mann-Whitney test).

diagnosis is established based on the detection of neurological dysfunctions in neurophysiological and/or neuropsychological tests<sup>[4]</sup>. However, these tests are rather long, time consuming, and difficult to interpret<sup>[8]</sup>. Dhiman *et al.*<sup>[3]</sup> suggested that the Psychometric Hepatic Encephalopathy Score, which is a battery of neuropsychological tests that can detect abnormalities such as alterations of motor function, visuospatial orientation, visual perception, visual construction, attention, concentration, and (with somewhat lower efficacy) memory disorders, should be considered the gold standard for the assessment of MHE, whereas computer-based tests such as Critical Flicker Frequency and Inhibitory Control Test should be used for screening. However, neurophysiological tests are difficult to apply in an outpatient setting because they require modern facilities and equipment<sup>[2]</sup>.

A study was conducted in which the Mini-Mental State Examination was applied to patients with LC and OHE, MHE, or without HE to establish whether this test might be used as a screening method for MHE and HE West Haven grades 1 and 2. However, a significant difference was not found between the scores of patients with MHE and those without HE. Moreover, alteration of the mental status was only detected in patients with OHE West Haven grade 3, which could be clinically detected without additional assessment methods<sup>[21]</sup>.

Citro *et al.*<sup>[22]</sup> conducted a study that applied the Trail Making Test (a simple inexpensive test) in a recent series evidenced a poor psychometric performance in more than half of the patients who were free of manifest encephalopathy. The authors also observed that subclinical hepatic encephalopathy was mostly present in patients with HCV-related cirrhosis. In the present study, there was no difference in FAB scores related to the cirrhosis etiology.

The present study used the FAB described by

**Figure 4** Median (interquartile range) total scores on the frontal assessment battery for cirrhotic patients without overt hepatic encephalopathy vs the control group (non-cirrhotic patients) (Mann-Whitney test). FAB: Frontal assessment battery.

Dubois *et al.*<sup>[9]</sup> as a useful and practical tool to establish the presence and severity of dysexecutive syndromes affecting cognition and motor behavior<sup>[9]</sup> and to assess patients with and without LC.

Some studies have indicated that the FAB evaluates the executive functions of the frontal lobe. In clinical practice, the FAB has also been used to distinguish between AD and FTD at the bedside, even in the earliest stages of disease<sup>[23]</sup>. One case-control study compared a group of 170 alcoholic subjects to a group of 40 non-alcoholic controls to assess frontal functions in different categories of alcoholism according to the Lesch typology. The use of the FAB as an assessment instrument allowed the detection of subclinical dysexecutive abnormalities among the alcoholic subjects. These data might serve to formulate differentiated therapeutic strategies for the management of alcoholic patients on an individual basis<sup>[20]</sup>.

The FAB was also used as a tool in a descriptive cross-sectional case series study of 72 crack cocaine users in which their patterns of drug use, global cognition, and frontal executive functions were assessed. The results indicated a decline in executive functions associated with the duration of drug use, especially for the functions investigated by the Automatic behavior subtest<sup>[20]</sup>.

No reports exist in the literature of studies investigating the frontal executive functions in cirrhotic patients. Therefore, no reference values for normality existed to compare with the results of the cirrhotic and non-cirrhotic patients. In the present case-control study, the FAB was applied to cirrhotic and non-cirrhotic patients. The performance of the former group was poorer, suggesting a considerable difference in the performance on the FAB between these two patient groups. The lower scores exhibited by the cirrhotic patients might be attributed to the presence of MHE, which is a subclinical condition that affects less than 15% of cirrhotic Child-Pugh class A patients and approximately

50% of patients classified as Child-Pugh class B or C<sup>[10]</sup>. Among patients with advanced liver disease according to the Child-Pugh classification, the scores of patients classified as Child-Pugh class C were not significantly different from the overall group of cirrhotic patients who exhibited the lowest FAB scores. However, the cirrhotic patients classified as Child-Pugh class C exhibited poorer performance in the GO/NO-GO and Automatic behavior subtests.

Abnormalities in the FAB GO/NO-GO subtest indicate difficulty in inhibiting inappropriate responses due to injury to the ventral part of the frontal lobe<sup>[9]</sup>. In the present study, the scores exhibited by cirrhotic patients were significantly lower than the scores of the non-cirrhotic patients. This finding might be explained by the executive dysfunction caused by MHE<sup>[8]</sup>.

No other FAB subtest scores (conceptualization, verbal fluency, motor series, conflicting instructions, and automatic behavior) were significantly different between the cirrhotic and non-cirrhotic patients.

Detecting minimal hepatic encephalopathy in patients with cirrhosis may help improve their quality of life<sup>[22]</sup>. The FAB score was lower for patients with OHE than for cirrhotic patients without OHE. This finding indicates that the FAB can detect the psychomotor abnormalities characteristic of OHE<sup>[1]</sup>.

Regarding the FAB subtests, patients with OHE exhibited lower scores on the Motor series subtest, which indicated injury to the frontal lobe that impaired temporal organization and the maintenance and execution of successive actions. Additionally, this group of patients exhibited lower scores on the GO/NO-GO subtest, in which abnormalities indicated difficulty inhibiting inappropriate responses. These findings show that the FAB detects HE-related cognitive dysfunctions in the early subclinical stage of disease<sup>[2]</sup> via the GO/NO-GO subtest as well as the psychomotor abnormalities characteristic of OHE, which are recognizable in the physical examination<sup>[3]</sup> via the Motor series subtest.

Although the FAB score exhibited by the cirrhotic patients without MHE was lower than the average score of the controls, the difference was not significant. Further studies with larger sample sizes are needed to thoroughly investigate this difference. The score on the GO/NO-GO subtest was significantly lower for the cirrhotic patients without OHE than for the non-cirrhotic patients. We may infer that this difference is due to the presence of MHE-related executive dysfunctions in some cirrhotic patients who do not have clinical OHE manifestations.

Currently, no studies have applied the FAB to cirrhotic patients with or without complications such as HE to establish the cutoff point for defining normality. However, the differences in the FAB scores between the cirrhotic and non-cirrhotic patients and between patients with and without HE in the present study demonstrate its value. Further studies are needed to determine whether the FAB could be used as a screening tool for all grades of OHE severity and particularly as a helpful tool for the assessment of West Haven grade 1 and MHE in clinical

practice<sup>[1]</sup>.

In conclusion, the FAB is a promising tool with an easy and quick application that may be used by trained general practitioners in both the outpatient setting and at the bedside as a screening method for West Haven grade 1 HE and MHE. Further studies are needed to validate this tool and compare it to other neuropsychometric batteries currently used to detect MHE.

## ACKNOWLEDGMENTS

I thank my professor, Dr. Maria da Penha Zago-Gomes; my patients; and the institution Universidade Federal do Espírito Santo, where I graduated and developed my study.

## COMMENTS

### Background

The usual diagnostic minimal hepatic encephalopathy (MHE) tests are time consuming and require the participation of specialized professionals. The delay in diagnosis has a negative impact on the quality of life of patients and leads to a higher risk of progression to overt HE. The availability of an easily applicable screening test for MHE, such as the frontal assessment battery (FAB), allows early detection of MHE and its treatment.

### Research frontiers

The FAB is a battery of tests with easy and quick application that was originally used for the evaluation of patients with dysexecutive syndromes of the frontal lobe, such as Parkinson's disease, chronic alcohol abusers and crack users. The FAB can also be useful in differentiating the frontotemporal dementia of Alzheimer's disease. Therefore, the FAB would be a useful tool for evaluating the presence and severity of dysexecutive syndromes that affect cognition and motor behavior in liver cirrhosis patients.

### Innovations and breakthroughs

Previous articles in the literature unsuccessfully proposed simple and inexpensive screening tests for MHE, such as the Mini Mental and Trail Making Test. However, the application of the FAB for the evaluation of MHE and HE in patients with liver cirrhosis is unique. Their study suggests that the FAB should be considered a promising tool for screening MHE and HE by the clinician.

### Applications

The FAB is a promising tool for screening HE and MHE in patients both at the bedside and in outpatient clinics.

### Peer-review

It is a good paper.

### Abstract

#### AIM

To evaluate the bidirectional association between metabolic syndrome (MS) components and antiviral treatment response for chronic hepatitis C virus (HCV) infection.

#### METHODS

This retrospective cohort study included 119 HCV + patients treated with pegylated-interferon- $\alpha$  and ribavirin. Metabolic characteristics and laboratory data were collected from medical records. Differences in baseline clinical and demographic risk factors between responders and non-responders were assessed using independent samples *t*-tests or  $\chi^2$  tests. The effects of sustained viral response (SVR) to antiviral treatment on *de novo* impairments in MS components, including impaired fasting glucose (IFG) and type 2 diabetes mellitus (T2DM), were assessed using univariable and multivariable logistic regression analysis, while the effect of MS components on SVR was assessed using univariable logistic regression analysis.

#### RESULTS

Of the 119 patients, 80 (67%) developed SVR over the

average  $54 \pm 13$  mo follow-up. The cumulative risks for *de novo* T2DM and IFG were 5.07- (95%CI: 1.261-20.4,  $P = 0.022$ ) and 3.87-fold higher (95%CI: 1.484-10.15,  $P = 0.006$ ), respectively for non-responders than responders, when adjusted for the baseline risk factors age, sex, HCV genotype, high viral load, and steatosis. Post-treatment triglyceride levels were significantly lower in non-responders than in responders (OR = 0.27; 95%CI: 0.069-0.962,  $P = 0.044$ ). Age and HCV genotype 3 were significantly different between responders and non-responders, and MS components were not significantly associated with SVR. Steatosis tended to attenuate SVR (OR = 0.596; 95%CI: 0.331-1.073,  $P = 0.08$ ).

## CONCLUSION

SVR was associated with lower *de novo* T2DM and IFG incidence and higher triglyceride levels. Patients infected with HCV should undergo T2DM screening and antidiabetic treatment.

**Key words:** Hepatitis C virus; Type 2 diabetes mellitus; Antiviral therapy; Sustained viral response; Metabolic syndrome; Hepatic steatosis; Peg interferon alpha; Ribavirin; Direct acting antiviral agents

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hepatitis C virus (HCV) is associated with a unique metabolic syndrome (MS) type: Insulin resistance with type 2 diabetes mellitus (T2DM), hypocholesterolemia, and liver steatosis. We retrospectively investigated the association between MS components and HCV infection, including antiviral therapy response, for 119 patients infected with HCV treated with interferon alpha and ribavirin. After long-term follow-up, *de novo* T2DM incidence significantly decreased, and triglyceride levels significantly increased in treatment responders. Only steatosis tended to affect treatment response. The association between HCV and lipid metabolic pathways may be important even with new direct antiviral agents. Patients infected with HCV should be screened for T2DM.

## INTRODUCTION

A mutual association between hepatitis C virus (HCV) infection and host metabolism has been demonstrated in several studies. HCV depends on host lipids for entry into the hepatocytes and for its replication; in return,

HCV also affects the metabolism of host lipids<sup>[1-3]</sup>.

HCV causes insulin resistance, hepatic steatosis, type 2 diabetes mellitus (T2DM), and low serum cholesterol and triglyceride (TG) levels. Insulin resistance contributes to HCV-related disruption of glucose and lipid metabolism<sup>[4]</sup>, and it is a key factor in metabolic syndrome (MS). In addition, HCV infection might lead to hepatic steatosis *via* several pathways.

Hepatic steatosis might aggravate MS directly by causing further insulin resistance<sup>[5]</sup> or indirectly because of resultant hepatic fibrosis<sup>[6]</sup> or cirrhosis<sup>[4,7,8]</sup>. After HCV infection, cholesterol and TG levels decrease, creating a different lipid profile from that for MS<sup>[9]</sup>. However, T2DM might be twice as prevalent in patients infected with HCV compared to the general population<sup>[5]</sup>. HCV has been associated with a unique type of MS called hepatitis C-associated dysmetabolic syndrome (HCADS), which includes liver steatosis, insulin resistance, and hypocholesterolemia<sup>[5,10]</sup>. Reversal of hypocholesterolemia and steatosis after achieving sustained viral response (SVR) with antiviral therapy has been observed in several studies<sup>[11-13]</sup>.

Therefore, although MS is not clearly associated with HCV, there is an association between HCV and some MS components. HCV-induced fatty liver and insulin resistance leads to T2DM; with the additional presence of MS, HCV replication is accelerated by activation of hepatocyte transcription factors, leading to increased lipogenesis and the provision of lipids for HCV replication<sup>[5,9,10]</sup>. Furthermore, in patients with MS, immune responses to HCV can be attenuated by leptin resistance or other changes in adipokine secretion<sup>[5]</sup>. Thus, MS might interfere with SVR after treatment<sup>[11,14-17]</sup>.

Previous studies showed that HCV eradication decreases the risk of *de novo* glucose abnormalities and insulin resistance. On the other hand, some studies reported neither an association between metabolic syndrome and HCV infection<sup>[18]</sup> nor reduced incidence of *de novo* glucose abnormalities in responders to treatment with interferon alpha and ribavirin<sup>[19]</sup>.

Our study aimed to assess the association between MS components and HCV infection based on the response to the therapy as well as to evaluate the influence of MS components on the response to antiviral therapy in a younger cohort of HCV-infected patients with a long term follow-up.

## MATERIALS AND METHODS

During 2004-2008, 119 patients diagnosed with chronic HCV infection, based on positive HCV RNA findings on polymerase chain reaction (PCR), were treated with combination pegylated-interferon  $\alpha$  (Peg-IFN $\alpha$ ) and ribavirin in the department of gastroenterology at Emek Medical Center in Afula, Israel. All patients were eligible for the Peg-IFN $\alpha$  and ribavirin treatment, which consisted of 180  $\mu$ g Peg-IFN $\alpha$  administered subcutaneously once a week and 800-1200 mg ribavirin administered orally

daily. Treatment lasted 24 wk for patients with genotypes 2/3 and 48 wk for those with genotypes 1/4.

Patients with hepatocellular carcinoma (HCC), human immunodeficiency virus infection, other serious conditions, or evidence of drug abuse or excessive alcohol consumption during the year preceding the enrollment were excluded.

### Metabolic and demographic characteristics

Patients were evaluated before treatment, 6 mo after treatment, and every year after the end of treatment until 2011. Age, body mass index (BMI), serum fasting blood glucose, TG, total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, aspartate transaminase, alanine transaminase, viral load, blood pressure, liver biopsy results, and liver ultrasonography were obtained from medical records and were not available in some cases. To reduce data bias, all data were extracted from several independent sources, including patient hospital files, electronic files from the family physician, and laboratory results every year after the end of treatment. The study was performed after obtaining local ethics committee approval.

Impaired fasting glucose (IFG) was defined as a serum fasting glucose level  $> 100$  mg/dL, and T2DM was identified based on diagnoses documented in medical records, serum fasting glucose level  $> 126$  mg/dL, or use of antidiabetic drugs. MS was defined using the World Health Organization clinical criteria for MS<sup>[20]</sup>.

Serum anti-HCV antibodies were measured using a 2<sup>nd</sup> generation immunoassay, and HCV RNA was measured using real time-PCR (RT-PCR; Amplicor HCV test, Roche Diagnostic; detection rate = 50 IU/mL). HCV genotyping was determined using RT-PCR (HCV genotyping, DNA immunoassay).

Most, but not all, patients agreed to and underwent a baseline liver biopsy to determine hepatic inflammation and steatosis. In addition, ultrasonography was performed before treatment and during the follow-up period to determine hepatic steatosis.

### Statistical analysis

The statistical methods of this study were reviewed by Shira Zelber-Sagi from the School of Public Health at the University of Haifa and Ofir Ben-Assuli from Ono Academic College.

Continuous variables (MS components) are presented as means  $\pm$  SD. Statistical analyses were performed using SPSS version 21 (IBM Corp., Armonk, NY, United States), and  $P < 0.05$  was considered statistically significant for all analyses.

The response to treatment was the independent variable, and metabolic components were initially evaluated separately as dependent variables using independent samples *t*-tests or Mann-Whitney U tests, when appropriate, for continuous variables (e.g., age and BMI) and Pearson's  $\chi^2$  tests and odds ratios (ORs)

for categorical variables (e.g., sex and genotype).

To test differences from baseline to the average follow-up duration in continuous variables between the treatment responders and non-responders, independent samples *t*-tests were performed.

The difference in *de novo* occurrence of MS components (0 = normal values; 1 = abnormal values indicating presence of the component) between responders and non-responders was calculated after excluding patients with MS components prior to antiviral treatment. Then, logistic regression analysis of *de novo* occurrence of T2DM and other MS components was conducted at different time intervals using an unadjusted (univariable) logistic regression (model 1) and an adjusted (multivariable) logistic regression (model 2, adjusted for age, sex, BMI, and genotype). Additionally, the cumulative rates of the patients without *de novo* occurrence of IFG, T2DM, and MS were estimated using the Kaplan-Meier method and compared between responders and non-responders using the log-rank test.

The effects of metabolic, demographic, and clinical variables on treatment response were determined using univariable logistic regression analysis.

## RESULTS

The mean age of the 119 HCV-positive patients treated with Peg-IFN $\alpha$  and ribavirin (57% men, 43% women) was  $41 \pm 11.3$  years (Table 1). The sample population primarily included immigrants from the Union of Soviet Socialist Republics (77%). The proportions of patients with HCV genotypes 1, 2, 3 and 4 were 66%, 9.2%, 22% and 1.7%, respectively (Table 1). The mean follow-up duration for MS components after treatment was  $47.5 \pm 13.3$  mo.

Regarding MS components, hypertension, T2DM, and IFG were present in 17%, 9.2%, and 27.7% of patients, respectively (Table 1). Serum HDL values were within the lower limit of the normal range, and serum TG levels were within the normal range. Mean BMI was in the overweight range ( $27 \pm 5.4$  kg/m<sup>2</sup>). Steatosis was present in 36% or 16.5% of patients, as determined with liver biopsy or abdominal ultrasound, respectively (Table 1).

SVR was obtained in 67% ( $n = 80$ ) of patients. Only baseline age and HCV genotype 3 were significantly different between responders and non-responders (Table 2). Non-responders were significantly older ( $P = 0.017$ ), and significantly fewer non-responders had HCV genotype 3 ( $P = 0.005$ ).

In the unadjusted regression analysis of the effect of the baseline metabolic factors on treatment response, metabolic syndrome and metabolic components (except T2DM) negatively affected treatment response (OR = 0.448; OR = 0.597; respectively), though none of them were significantly associated with treatment response ( $P = 0.847$  and  $P = 0.483$ ; respectively) (Table 3).

<sup>1</sup>Adjusted for sex, age, and BMI; <sup>2</sup>Adjusted for sex, age, and genotype. The responders group is the reference group for all the dependent variables. Multivariable analysis could not be conducted owing to the small number of responders with *de novo* DM (n = 3) or small number of non-responders with hypertriglyceridemia (n = 3). OR: Odds ratio; BMI: Body mass index; IFG: Impaired fasting glucose; T2DM: Type 2 diabetes mellitus; HDL: High-density lipoprotein cholesterol; WHO: World Health Organization; DM: Diabetes mellitus.

crude ORs of 3.87 for IFG and 5.07 for T2DM ( $P = 0.006$  and  $0.022$ , respectively) in the unadjusted model, and a significant OR of 4.7 for IFG in the adjusted model ( $P = 0.02$ ; model 2). Because of the low incidence of T2DM in responders ( $n = 3$ ), T2DM could not be evaluated in the adjusted model (model 2; multivariable analysis) (Table 5). The crude OR for hypertriglyceridemia was 0.27 ( $P = 0.044$ ). Because of the low occurrence of hypertriglyceridemia in the non-responders ( $n = 3$ ), hypertriglyceridemia could not be evaluated in the adjusted model.

According to Kaplan-Meier analyses, there were lower rates of IFG and T2DM in responders than in the non-responders ( $P = 0.006$  and  $0.023$ , respectively) (Figure 1). Overall, the occurrence of MS in responders was not different from that in non-responders (Figure 2).

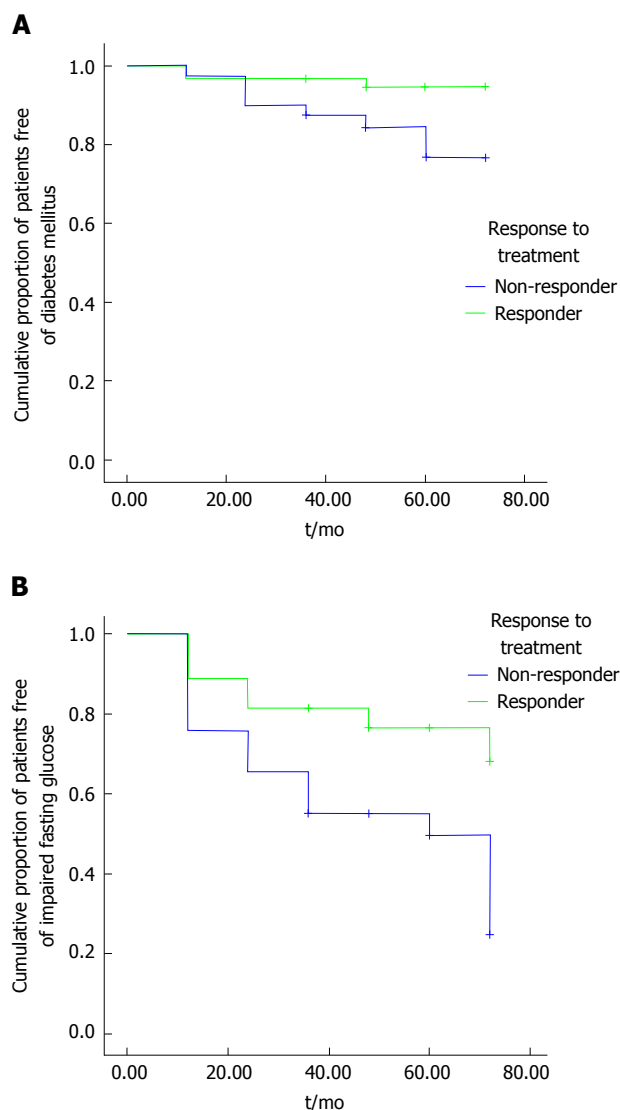

## DISCUSSION

Our study, which aimed to examine the association between MS components and HCV infection based on treatment response and the influence of MS components on the success of antiviral therapy, did not detect any differences in most pre- or post-treatment MS com-

ponent values between responders and non-responders to antiviral therapy. However, *de novo* IFG and T2DM occurred significantly more often in non-responders than in responders.

Our results regarding T2DM are consistent with those of other studies conducted with larger community cohorts. In a study conducted in Taiwan with a 7-year follow-up period, the cumulative incidence of T2DM was 14.3% in anti-HCV-positive patients and 8.6% in seronegative individuals ( $P < 0.0001$ )<sup>[21]</sup>. In another study conducted in Japan, 143 of 2842 HCV-positive patients treated with IFN $\alpha$  monotherapy or IFN $\alpha$  and ribavirin combination therapy developed T2DM during a mean observation period of 6.4 years, and only 26 of these patients with T2DM had SVR<sup>[22]</sup>.

HCV infection causes insulin resistance in the very early stage hepatic lesions (fibrosis stage 0 or 1). The progression of fibrosis, primarily owing to insulin resistance, worsens insulin resistance<sup>[23]</sup>, which may lead to T2DM in predisposed individuals. In addition to SVR, fibrosis stage is independently associated with T2DM in HCV-infected patients<sup>[24]</sup>. Furthermore, a recent meta-analysis<sup>[25]</sup> and systematic review included 11 studies, of which only five examined the influence of

**Figure 1** Kaplan-Meier analysis of the cumulative ratio of hepatitis C virus-positive patients. A: Without type 2 diabetes mellitus, based on the response to antiviral treatment; B: Without impaired fasting glucose, based on the response to antiviral treatment.

HCV eradication on the risk of *de novo* glucose abnormalities<sup>[19,24,26,27]</sup> and insulin resistance<sup>[27]</sup>. Of the 2 studies with long follow-up periods<sup>[19,26]</sup>, one (8-year follow-up) failed to demonstrate reduced *de novo* T2DM in patients with SVR<sup>[19]</sup>. The other (follow-up of  $5.7 \pm 2$  years) showed that SVR reduced *de novo* glucose abnormalities in patients with chronic HCV. However, patient ages were not reported<sup>[26]</sup>. In another study with a relatively short follow-up (24 mo), SVR in patients with chronic HCV who did not have T2DM ( $51.8 \pm 12.2$  years old) prevented the development of *de novo* insulin resistance<sup>[28]</sup>. A significant two-third reduction in T2DM development was reported in a large cohort of patients with HCV and SVR ( $51.8 \pm 9$  years old) after IFN $\alpha$  monotherapy or combination therapy with IFN $\alpha$  and ribavirin<sup>[22]</sup>. Thus, curing HCV infections decreases the incidence of T2DM or improves homeostatic model assessment insulin resistance (HOMA-IR) in most studies<sup>[22-33]</sup>. These effects

**Figure 2** Kaplan-Meier analysis of the cumulative ratio of hepatitis C virus-positive patients without metabolic syndrome, based on the response to antiviral treatment.

might be specific to patients with particular genotypes, with a reduction in HOMA-IR in patients with HCV genotype 1 but not those with genotypes 2/3<sup>[23]</sup>. Antiviral therapy might improve insulin resistance independent of virological outcomes<sup>[32]</sup> although a greater reduction in HOMA was observed in the patients who achieved persistent HCV clearance<sup>[33]</sup>. Antiviral therapy might also improve hepatic steatosis and fibrosis<sup>[29,34,35]</sup>. Thus, there might be an association between HCV and MS, and patients with HCV infection and MS have higher HOMA-IR values.

Several other components of MS, including waist circumference, BMI, and arterial hypertension, have been reported more frequently in non-responders to antiviral therapy<sup>[15]</sup>. The present study failed to demonstrate a significant relationship between baseline metabolic factors and treatment responses, potentially owing to the relatively young sample population. However, some metabolic factors (apart from T2DM) showed trends for differences based on the treatment response (e.g., *de novo* hypertriglyceridemia was 3.7 times more frequent in the responders than in the non-responders).

A bidirectional relationship between serum lipid levels and success of antiviral therapy for HCV has been reported<sup>[36]</sup>. Successful antiviral therapy might reverse the low LDL cholesterol, HDL cholesterol, and TG levels associated with HCV infection<sup>[7,12,13]</sup>. Low serum LDL levels in HCV infection result from the utilization of geranyl-geranyl phosphate, a product of the mevalonate pathway that is an early branch point of the cholesterol synthetic pathway, for HCV replication<sup>[1,7]</sup>. Higher baseline serum LDL cholesterol and lower serum TG levels were associated with higher rates of SVR<sup>[34]</sup>, and lower serum LDL cholesterol levels correlated with low rates of SVR<sup>[33,35]</sup> in non-diabetic, non-cirrhotic patients infected with genotype 1 HCV. High serum LDL cholesterol levels

might improve the rates of SVR by competing with binding to hepatocyte LDL receptors and subsequently reducing the infection of hepatocytes with HCV<sup>[4,11,34]</sup>. In contrast, HDL cholesterol enhances HCV infection by facilitating its entry into hepatocytes<sup>[2]</sup>. However, high baseline serum HDL cholesterol levels reportedly interfere with the early viral response, but not with SVR<sup>[3,4]</sup>, while serum HDL cholesterol inversely correlates with the rate of SVR in men but not in women, resulting in a lack of an association between overall baseline HDL levels and SVR<sup>[11]</sup>.

Hepatic steatosis might also attenuate the antiviral treatment response, a trend that was demonstrated in the present study based on steatosis identified *via* liver biopsy. The insulin resistance and hepatic steatosis present during HCV infection are genotype-specific. Lower HOMA values are reported in patients infected with genotype 3 than in those infected with genotype 1. Insulin resistance-associated steatosis, which is present in patients with HCV genotype 3, is caused mainly by viral inhibition of the enzyme microsomal triglyceride transfer protein (viral steatosis), which might resolve with successful antiviral therapy. With the other HCV genotypes, steatosis is due to insulin resistance, stimulation of fatty acid synthesis, and inhibition of mitochondrial  $\beta$ -oxidation (metabolic steatosis)<sup>[37-39]</sup>. Metabolic steatosis might be associated with a high BMI and central obesity, which are not usually improved by viral eradication. HCV 1 and 4 core proteins might cause insulin resistance by functionally inhibiting insulin signaling pathways *via* increased levels of pro-inflammatory cytokines including tumor necrosis factor (TNF)- $\alpha$  and suppressors of cytokine signaling (SOCS) proteins, which impair insulin signaling and activate sterol regulatory element binding proteins, resulting in increased hepatic lipid synthesis<sup>[37-39]</sup>. The increased levels of hepatic proinflammatory cytokines have additional effect of negative regulate IFN $\alpha$  transduction.

This might explain the molecular link between insulin resistance and the nonresponse to antiviral therapy<sup>[4]</sup>. Furthermore, steatosis has been demonstrated to decrease SVR in HCV genotype 1 but not in HCV genotype 3, although steatosis is a predictor of HCV infection relapse with genotype 3 HCV<sup>[16]</sup>. This effect of steatosis on SVR might be the result of its association with insulin resistance<sup>[40]</sup>, which is caused by excretion of TNF $\alpha$  and SOCS protein from the increased trunk fat in HCV infection. The lower level of PPAR- $\alpha$  mRNA also mediates genotype 3 hepatic steatogenesis<sup>[7,8,39]</sup>. However, Peg-IFN $\alpha$  and ribavirin treatment response with HCV genotype 3 infection is better than with HCV genotype 1, despite more severe steatosis and lower cholesterol levels<sup>[10,37,40]</sup>. This might be related to the association between steatosis and higher BMI with genotypes 1 and 4<sup>[14,15]</sup>.

It is noteworthy that, even in the era of direct acting antiviral (DAA; *e.g.*, telaprevir and boceprevir)-based

triple therapy, some baseline metabolic variables might affect SVR, albeit to a lesser degree than with IFN and ribavirin combination therapy<sup>[41]</sup>. However, insulin resistance does not predict SVR to telaprevir-based triple therapy or to the protease inhibitor danoprevir monotherapy<sup>[16,42]</sup>, while low serum LDL levels might affect SVR in telaprevir-treated patients, and obesity impairs SVR in patients treated with boceprevir-based regimen<sup>[16,41]</sup>. An additional link between DAA and MS has been demonstrated with danoprevir monotherapy, an inhibitor of NS3/3A HCV serine protease, which might increase insulin sensitivity considerably, independent of its antiviral effect<sup>[15,38,42]</sup>. Furthermore, DAAs are less effective against genotype 3 HCV infection, partly due to steatosis<sup>[43]</sup> and relapse after IFN-free therapy with the polymerase inhibitor sofosbuvir and ribavirin is associated with a low baseline LDL level.

This study has certain limitations. First, the study was retrospective, and some data were missing for some cases. Serum glucose levels were examined for diagnosis and monitoring glycemic control of T2DM and IFG. However, due to the retrospective nature of this manuscript, HbA1c and glycated albumin (GA) values were not available in most of the patients' charts. Nevertheless, liver cirrhosis and INF  $\alpha$  treatment may falsely decrease HbA1c owing to hemolysis. On the other hand, GA as a glycemic control marker in patients with chronic liver disease may be overestimated, due to prolonged albumin half-life.

Additionally, the small sample size resulted in a small number of responders with *de novo* T2DM and non-responders with *de novo* hypertriglyceridemia, which limited the ability to assess these data in the multivariable logistic regression analysis.

However, the strengths of the study include the relatively young age of the patients and the relatively long follow-up period for all MS components after antiviral treatment, which enabled us to observe the effect of SVR on the cumulative incidences of IFG and T2DM. MS, including insulin resistance, hyperglycemia, high BMI, and liver steatosis, might complicate the disease course of patients infected with HCV, by enhancing cirrhosis, HCC, and cardiovascular disease<sup>[29,43-47]</sup>. Thus, it is worthwhile to screen these patients for T2DM<sup>[46,47]</sup>. Furthermore, with T2DM in the presence of HCV, there are specific considerations for antidiabetic treatment. Insulin and sulfonylurea administration might increase the risk of HCC<sup>[45,48]</sup>, while the insulin sensitizers metformin and pioglitazone might decrease the risk of HCC and steatosis. However, these agents are harmful and might cause lactic acidosis and hepatic toxicity, respectively, in patients with liver cirrhosis<sup>[45]</sup>. The new dipeptidyl peptidase-4 inhibitors appear promising<sup>[45,47,49]</sup>.

In conclusion, the results presented here suggest that MS components did not have any significant effect on the response to antiviral therapy, although hepatic steatosis tended to impair the response to antiviral treatment.

There were no differences in the post-treatment changes in most MS components between responders and non-responders to antiviral therapy. However, the incidences of *de novo* T2DM and IFG were significantly higher in non-responders. Given the younger age of the patient population in the present study compared to previous similar studies, the findings might suggest a direct effect of HCV on the development of T2DM independent of fibrosis or cirrhosis. The higher serum TG levels after SVR exemplify the interaction between HCV infection and lipid metabolic pathways. Due to the increased risk of HCV infection with T2DM, it might be appropriate to screen HCV patients for T2DM and insulin resistance and to consider treatment of T2DM in the presence of HCV with new antidiabetic agents.

## COMMENTS

### Background

A bidirectional association exists between chronic hepatitis C virus (HCV) infection and some components of metabolic syndrome (MS).

### Research frontiers

Most, but not all, previous studies showed an association between chronic HCV infection and MS components, including type 2 diabetes mellitus (T2DM), insulin resistance, elevated body mass index, and hepatic steatosis. Several host MS components might affect the disease course and sustained virological response (SVR) of HCV-infected patients treated with pegylated-interferon  $\alpha$  (Peg-IFN $\alpha$ ) and ribavirin. On the other hand, SVR can affect some MS components, mainly decreased insulin resistance (IR) and decreased *de novo* occurrence of T2DM.

### Innovations and breakthroughs

This study, which included a younger patient cohort, was designed to assess associations between MS components and HCV infection, but it did not show increased prevalence of T2DM with HCV infection. However, after long term follow-up T2DM was more frequent in non-responders to treatment with Peg-IFN $\alpha$  and ribavirin.

### Applications

Patients with HCV infection should be frequently monitored for T2DM and treated appropriately, considering the increased risk of cirrhosis and HCC in young patients with HCV-associated diabetes mellitus. The authors think that further studies are needed to evaluate the mutual association of MS components with direct acting antiviral (DAA) drug therapy in chronic HCV infection.

### Terminology

MS components refer to the metabolic syndrome factors; IR refers to insulin resistance; SVR refers to sustained virological response, which means viral eradication and cure; DAA refers to direct acting antiviral agents.

### Peer-review

This is a very interesting study which shows the association between metabolic syndrome mechanism and response to antiviral treatment for chronic HCV infection. Patients were followed up for about 4 years; univariable and multivariable logistic regression analysis were applied. Data are well presented and discussed.

## Abstract

### AIM

To evaluate the reversibility of minimal hepatic encephalopathy (MHE) following liver transplantation (LT) in Egyptian cirrhotic patients.

### METHODS

This prospective study included twenty patients with biopsy-proven liver cirrhosis listed for LT and twenty age- and sex-matched healthy control subjects. All underwent neuro-psychiatric examination, laboratory investigations, radiological studies and psychometric tests including trail making test A (TMT A), TMT B, digit symbol test and serial dotting test. The psychometric hepatic encephalopathy score (PHES) was calculated for patients to diagnose MHE. Psychometric tests were repeated six months following LT in the cirrhotic patient group.

### RESULTS

Before LT, psychometric tests showed highly significant deficits in cirrhotic patients in comparison to controls ( $P < 0.001$ ). There was a statistically significant improvement in test values in the patient group after LT; however, their values were still significantly worse than those of the controls ( $P < 0.001$ ). The PHES detected MHE in 16 patients (80%) before LT with a median value of  $-7 \pm 3.5$ . The median PHES value was significantly improved following LT, reaching  $-4.5 \pm 5$  ( $P < 0.001$ ), and the number of patients with MHE decreased to 11 (55%). The pre-transplant model for end-stage liver disease (MELD) score  $\geq 15$  was significantly related to the presence of post-transplant MHE ( $P = 0.005$ ). More patients in whom reversal of MHE was observed had a pre-transplant MELD score  $< 15$ .

### CONCLUSION

Reversal of MHE in cirrhotic patients could be achieved by LT, especially in those with a MELD score  $< 15$ .

**Key words:** Liver transplantation; Model for end-stage liver disease score; Psychometric tests; Minimal hepatic encephalopathy; Cirrhosis

Reversibility of minimal hepatic encephalopathy following liver transplantation in Egyptian cirrhotic patients. *World J Hepatol* 2016; 8(30): 1279-1286 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i30/1279.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i30.1279>

## INTRODUCTION

The prevalence of overt hepatic encephalopathy (HE) in patients with decompensated liver cirrhosis ranges from 16% to 21%, while that of minimal HE (MHE) or covert HE is 20%-80%<sup>[1]</sup>.

MHE impairs daily functioning, driving performance, work capability and learning ability in cirrhotic patients. It also predisposes to overt HE and increased mortality<sup>[2]</sup>. There are several methods of diagnosing MHE, such as comprehensive neuropsychological examinations, standard psychometric batteries, and computerized testing<sup>[3]</sup>.

The psychometric hepatic encephalopathy score (PHES) battery can detect neuropsychiatric abnormalities and MHE. It assesses visual perception, construction, visual/spatial orientation, motor speed and accuracy, concentration, and attention in cirrhotic patients with end-stage liver disease. When PHES was compared to the standard methods of determining HE, its sensitivity and specificity were 96% and 100%, respectively<sup>[4]</sup>.

The PHES was initially composed of seven tests. The portosystemic encephalopathy battery was introduced later to exclude tests with poor sensitivity. It includes the line tracing test (LTT) and/or the digit symbol test, in addition to the number connection tests A and B (NCT A and B)<sup>[5]</sup>. The sum of the scores of these tests ranges between +5 and -15. A score of below or equal to -4 is diagnostic for MHE<sup>[4]</sup>.

The LTT requires the longest time to calculate its score, and there is an existing controversy in interpretation of its two outcomes: Time and errors. Thus, only three of the four tests, NCT-A, NCT-B and DST, have been commonly used for MHE detection<sup>[6]</sup>. The result of any test was regarded to be abnormal if it was beyond the 2 standard deviation range of the control subjects. In some previous studies, MHE was diagnosed when two of these tests were abnormal<sup>[7]</sup>. In others, it was diagnosed when only one test was abnormal<sup>[8]</sup>.

Liver transplantation (LT) is now considered an established effective and innovative treatment option for patients with end-stage liver diseases for a wide range of indications over the last fifty years<sup>[9]</sup>. The surgical outcomes and survival rates following LT have been previously estimated; however, the effect of LT on MHE has not been properly studied. A few studies have compared the cognitive performance of cirrhotic patients before and after LT. Some demonstrated cognitive improvement, and others have suggested reversibility of MHE after LT<sup>[10,11]</sup>.

This study aimed to evaluate the reversibility of MHE following liver transplantation in Egyptian cirrhotic patients.

## MATERIALS AND METHODS

This prospective study was conducted at Ain Shams Center for Organ Transplant, Ain Shams Specialized Hospital, Cairo, Egypt from June 2014 to April 2015. It included twenty right-handed patients with biopsy-proven liver cirrhosis listed for LT.

In addition, twenty age- and sex-matched healthy persons were enrolled, constituting the control group. The groups were similar regarding number of education years and handedness. The healthy controls were collected from the outpatient clinics among those coming for pre-employment screenings. Liver and systemic diseases were excluded by history, physical examination, laboratory and radiologic assessment.

Written informed consent was obtained from patients and controls prior to inclusion in the study. The study protocol was approved by the Research Ethical Committee of Faculty of Medicine, Ain Shams University according to the ethical guidelines of the 1975 Declaration of Helsinki.

### Patients' selection

**Exclusion criteria:** (1) patients with clinical or laboratory evidence of any concomitant infection, severe gastrointestinal bleeding, anemia, electrolyte abnormalities, or renal insufficiency; (2) overt hepatic encephalopathy (persistent or episodic) as revealed by a standard clinical neurological examination; (3) significant cortical atrophy or other structural brain changes as revealed by conventional neurological imaging studies; (4) regular use of psychotropic drugs, such as benzodiazepines; (5) known major psychiatric disorder; (6) patients unable to perform the tests (illiterate or with upper limb motor handicaps); (7) less than 6 mo of complete alcohol abstinence; and (8) post-transplant toxic levels of immunosuppressive drugs.

All of the following were performed to recruited patients and controls: (1) full history taking together with a full clinical, neurological and psychiatric examination done by both an experienced hepatologist and neuropsychiatrist; (2) laboratory investigations including complete blood count; liver function tests: Alanine transaminase, aspartate transaminase, total and direct bilirubin, international normalized ratio (INR), prothrombin time, serum albumin; kidney function tests and full electrolytes including blood urea nitrogen, creatinine, sodium, potassium, magnesium, calcium, phosphorus; C-reactive protein to exclude patients with any infections; and post-transplant immunosuppressive drug levels for patients only to exclude those with toxic levels. The modified Child-Pugh score was calculated for patients, and each patient was categorized as A, B or C. Additionally, the model for end-stage liver disease (MELD) score was calculated for patients using laboratory results collected immediately before LT with no adjustments

for malignancy. We calculated the MELD score using the following formula:  $MELD = [0.957 \times \ln(\text{creatinine mg/dL}) + 0.378 \times \ln(\text{bilirubin mg/dL}) + 1.12 \times \ln(\text{INR}) + 0.643 \times 10^8]$ ; (3) radiological studies included pelvi-abdominal ultrasound with examination of liver size, echogenicity, splenomegaly, amount of ascites, portal vein diameter and patency, presence of any hepatic focal lesions or any abdominal malignancy and a detailed kidney examination pre- and post-transplantation (Hitachi, EUB-5500). A computerized tomography (CT) for the brain was performed to all patients to exclude any brain pathology (Toshiba, High Speed 16 Slice); and (4) psychometric tests included the following neuropsychological tests.

**Trail making test A:** Patient should draw a line from number (1) to number (2) and from (2) to number (3) till reaching number (24), without elevating the pencil from the paper. The time was recorded in seconds. If the patient made an error, the examiner told him to correct it, but the timing was not stopped. The average score was 29 s, while the deficient score was > 78 s and the rule of thumb was that most completed it in 90 s. The rule of thumb is a broadly accurate guide or principle, based on practice rather than theory<sup>[12,13]</sup>.

**Trail making test B:** Patient should draw a line from number (1) to letter (A), then from letter (A) to number (2), then from number (2) to letter (B), and so on, alternating the number and letter respecting the alphabetical order till letter (L). After explaining the test to the patient, timing should be started and recorded in seconds, including time needed to correct any error done. The average score was 75 s, while > 273 s was considered deficient and the rule of thumb was that most completed it in 3 min.

**Digit symbol (substitution) test:** A coding key was presented consisting of nine abstract symbols, each paired with a number. The patient was required to scan the key and write down the symbol corresponding to each number as rapidly as possible. Ninety seconds were given to the patient and when the time was finished, the number of symbols performed by the patient was counted. The score was recorded in points. If the patient made any errors, timing continued towards their 90 s, and the patient might lose time. A healthy individual should be able to complete the test in 90 s or less. A fall of 1 to 1.5 SD below the mean is considered suggestive of cerebral dysfunction.

**Serial dotting test:** Also called the circle dotting test, the serial dotting test (SDT) was used to test pure motor speed. The patient was asked to put a dot in each of the 100 circles given on the sheet after being prepared first by dotting the 20 circles at the top of the sheet.

The results of the trail making test A (TMT A), TMT B, and SDT were measured in seconds, including the time needed to correct any errors, and the results of digit symbol (substitution) test (DST) were measured as

points.

Accordingly, a better performance was reflected by a higher result of DST and lower results of other tests.

**Interpretation of the score:** To obtain the measure of overall visual-motor and visual-constructive performance, we calculated the average percentile score of the 4 selected tests: TMT A, TMT B, DST and SDT. The average score of these tests was arbitrarily named the visual-motor and visual-constructive performance (VMCP) score or PHES. The patient was diagnosed to have MHE when his total score was equal or below -4.

### Post-transplantation follow-up

The immunosuppressive regimen included cyclosporine or tacrolimus, mycophenolate mofetil (MMF), and corticosteroids in all patients except those transplanted for hepatocellular carcinoma (HCC). In patients transplanted for HCC, the regimen included calcineurin inhibitors and steroids only. Trough levels of cyclosporine were maintained between 200 and 300 ng/mL while those of tacrolimus were maintained between 8 and 12 ng/mL. Rapid withdrawal of corticosteroids within three months was routine in all patients.

In cases of acute rejection, the first-line therapy consisted of optimization of the maintenance level of immunosuppression. If there was no response, then MMF or rapamycin were added to the patient's regimen, if not already being taken. In some cases, a shift from cyclosporine to tacrolimus was beneficial. A small dose of steroids was used if all other measures failed.

The complete psychometric battery was repeated six months following LT in the cirrhotic patient group. The post-transplant testing was done while the patient was in a stable condition with no clinical or laboratory evidence of any concomitant infection, anemia, electrolyte abnormalities, acute transplant rejection episode or other severe clinical problems.

### Statistical analysis

Data were analyzed using the SPSS software computer program version 18 (SPSS, Chicago, IL, United States). They were described as the mean  $\pm$  standard deviation (SD) for quantitative (parametric) variables and as median  $\pm$  inter-quartile range (IQR) for quantitative (non-parametric) variables. Qualitative (categorical) variables were presented as frequency and percentage. The independent samples *t*-test was used for the comparison of quantitative parametric variables among two independent groups and the Mann Whitney *U* test was used for non-parametric data. The Wilcoxon Signed Ranks test was used for the comparison of quantitative non-parametric variables among two dependent groups (before and after transplantation). The  $\chi^2$  test (or Fisher's exact test when appropriate) was used for comparison of distribution of qualitative variables among different groups.

Significance level (*P*) value: (1)  $P \leq 0.05$  was significant; (2)  $P < 0.01$  was highly significant; and (3)  $P >$

0.05 was non-significant.

The statistical methods of this study were reviewed by Azza M Hassan, Department of Community, Environmental and Occupational Medicine, Faculty of Medicine, Ain Shams University, Cairo, Egypt.

## RESULTS

This prospective study included twenty patients with biopsy-proven hepatitis C virus (HCV)-related liver cirrhosis listed for LT. Their mean age was  $53.2 \pm 5.39$  years and they consisted of 17 males (85%) and 3 females (15%). Five patients were diagnosed with hepatocellular carcinoma on top of liver cirrhosis.

In addition, twenty age- and sex-matched healthy subjects were enrolled, constituting the control group. Their mean age was  $53.4 \pm 6.49$  years and they consisted of 15 males (75%) and 5 females (25%).

Before LT, the median  $\pm$  IQR of Child-Pugh score of the enrolled patients was  $9 \pm 4.5$ ; five patients (25%) were Child A, six (30%) were B and nine (45%) patients were Child C. Their median  $\pm$  IQR of MELD score was  $14.5 \pm 6.5$ , where 50% (10 patients) had a MELD score below 15 and 50% (10 patients) had a MELD score above 15.

Six months following LT, the median  $\pm$  IQR of Child-Pugh and MELD scores were  $6 \pm 1.8$  and  $11.5 \pm 4.5$ , respectively, with a statistically significant improvement ( $P < 0.001$  and  $0.002$ , respectively) (Table 1).

Table 2 shows the analysis of the median score values of different psychometric tests (TMT A, TMT B, DST and SDT) and the VMCP score in patients before and after LT, as well as in healthy control subjects. Before LT, the psychometric tests and the VMCP score showed highly significant deficits in cirrhotic patients in comparison to controls ( $P < 0.001$ ).

After LT, there were statistically significant improvements in test values in the patient group when compared to their values before LT. However, the values of patients after LT were still significantly worse than those of the control subjects ( $P < 0.001$ ).

Among the studied 20 cirrhotic patients, the PHES, represented by the VMCP score, detected MHE in 16 patients (80%) before LT, with a median value of  $-7 \pm 3.5$ . The median PHES value was significantly improved following LT, reaching  $-4.5 \pm 5$  ( $P < 0.001$ ), and the number of patients with MHE decreased to 11 (55%) post-LT.

Table 3 shows that the pre-transplant MELD score  $\geq 15$  was significantly related to the presence of post-transplant MHE ( $P = 0.005$ ). In cirrhotic patients with a pre-transplant MELD score  $\geq 15$ , 100% had pre-transplant MHE and 90% had post-transplant MHE. On the other hand, among those with a MELD score  $< 15$ , 60% had pre-transplant MHE and 20% had post-transplant MHE. A higher number of patients in whom reversal of MHE was observed had a pre-transplant MELD score  $< 15$ .

**Table 1** Laboratory data, Child-Pugh and model for end-stage liver disease scores before and after liver transplantation in the patients' group

Variable	Before LT (median $\pm$ IQR)	After LT (median $\pm$ IQR)	Z	P value

**Table 3** Relation between pre-transplant model for end-stage liver disease score and the presence of pre- and post-transplant minimal hepatic encephalopathy n (%)

		Pre-transplant MELD score		$\chi^2$	P value
		< 15 (n = 10)	$\geq$ 15 (n = 10)		
Pre-transplant	-ve	4 (40)	0 (0)	5.000 <sup>1</sup>	0.087
MHE	+ve	6 (60)	10 (100)		
Post-transplant	-ve	8 (80)	1 (10)	9.899 <sup>1</sup>	0.005 <sup>2</sup>
MHE	+ve	2 (20)	9 (90)		

<sup>1</sup>Fisher's exact test; <sup>2</sup>Highly significant. MELD: Model for end-stage liver disease; MHE: Minimal hepatic encephalopathy; -ve: Negative; +ve: Positive.

Table 4 shows comparison between patients who recovered from MHE ( $n = 5$ ) and those who didn't recover ( $n = 11$ ) regarding age, sex, pre-transplant lab investigations and pre-transplant Child and MELD scores. We found that non-recovered patients had significantly higher INR, total bilirubin, Child and MELD scores than recovered ones ( $P = 0.027$ ,  $0.013$ ,  $0.038$  and  $0.009$ , respectively).

## DISCUSSION

In the current study, twenty cirrhotic patients listed for

LT and twenty healthy controls were included. Patients with pre or post-transplant clinical or laboratory evidence of infection, electrolyte imbalance, renal impairment or immunosuppressive drugs toxicity were excluded from the study. The etiology of liver cirrhosis in the included patients was chronic hepatitis C. Egypt has the highest prevalence of HCV worldwide, with an exceptionally high burden of liver disease<sup>[14]</sup>.

A neuropsychological test battery, consisting of TMT A, TMT B, SDT and DST was applied to both the cirrhotic patient and control groups before and six months after LT. These are the same tests used by Wang *et al.*<sup>[3]</sup> and Tsai *et al.*<sup>[15]</sup> to diagnose MHE. They have high sensitivity and specificity and are easily applied with no difficulty in their score calculation<sup>[15,16]</sup>. These tests monitor changes in attention, motor speed and executive functions, which are the first to improve in the post transplantation period<sup>[3,16]</sup>. The TMT is a measure of attention, speed, and mental flexibility. It also tests spatial organization, visual pursuits, recall, and recognition<sup>[12]</sup>. Part A tests visual scanning, numeric sequencing, and visuo-motor speed, while part B tests cognitive demands including visual motor, visual spatial abilities and mental flexibility<sup>[16,17]</sup>. The DST measures the perceptual ability<sup>[18]</sup>, while the SDT tests the pure motor speed<sup>[19]</sup>.

The total score of the four tests (TMT A, TMT B, SDT

and DST), which represents the VMCP score or PHES, has a cutoff level of -4. Any patient with a score below or equal to -4 is defined as having MHE<sup>[3,15,16]</sup>.

With regard to the scores of TMT A, TMT B, DST and SDT, and the total PHES score in the current study; significant differences were found between patients and control subjects, together with the significant improvement in the patient scores after LT. This is in agreement with Mattarozzi *et al*<sup>[20]</sup>.

The significant improvement of the patients' MELD score after LT agrees with Lin *et al*<sup>[10]</sup> and Mattarozzi *et al*<sup>[20]</sup>.

The present study supports the relation between MHE and higher values of a MELD score. This is also in agreement with Mattarozzi *et al*<sup>[20]</sup> and Montagnese *et al*<sup>[21]</sup>. More patients with a pre-transplant MELD score > 15 experienced pre- and post-transplant MHE. More patients in whom reversal of MHE was observed had a pre-transplant MELD score < 15, indicating that early LT for patients with a MELD score < 15 may be associated with a higher incidence of reversal of MHE and could save the brain from the irreversible damages associated with end-stage liver disease. These findings may change the LT priority for patients with MHE with a MELD score < 15 receiving priority over those with a MELD > 15.

In a trial to find the factors affecting the reversibility of MHE, comparison between patients who recovered and those who didn't was done in the present study. Pre-transplant Child and MELD scores were significantly lower in patients who recovered from MHE. Age and sex differences were insignificant between those who recovered and those who didn't.

This is different from the study of Mechtcheriakov *et al*<sup>[22]</sup>, in which the duration of liver cirrhosis and its severity (as determined by the Child classification) did not influence the improvement after LT. However, O'Carroll *et al*<sup>[23]</sup> reported that severe liver disease at pre-transplant assessment was associated with more slowing of reaction times and increased bioelectric dysfunction of the brain. In the study of Mechtcheriakov *et al*<sup>[22]</sup>, patients' age was not related to recovery from MHE after LT which is similar to our study.

Although there was improvement in the cognitive function after LT in the current study, it did not reach the normal optimal levels of the healthy controls. This observation agrees with O'Carroll *et al*<sup>[23]</sup>, Tarter *et al*<sup>[24]</sup> and Garcia-Martinez *et al*<sup>[25]</sup> indicating that MHE and the deterioration in cognitive function in liver disease patients are not completely reversible after LT.

It was hypothesized by Rose *et al*<sup>[26]</sup> that hepatic encephalopathy may be manifested by either "delirium-like" or "dementia-like" clinical features. The former is likely to be metabolic in origin, whereas the latter is likely to be due to a structural brain lesion, which may be specific to liver disease.

Ammonia has been suggested to have a role in the metabolic pathogenesis of MHE. Hyperammonemia in patients with liver cirrhosis may result in an increase in the brain glutamine with subsequent reduction in the brain magnetization-transfer ratio<sup>[25]</sup>.

Teperman<sup>[11]</sup> demonstrated that patients who survived 10 years post-LT had significant cognitive dysfunction and poor health-related quality of life. This supports the evidence for a "dementia-like" parameter

of MHE that is irreversible after LT. Lin *et al.*<sup>[10]</sup> showed improvement of both the extracellular cerebral edema and the demyelination of white matter in patients with MHE following LT, but they still did not reach the control level.

In the current study, gross structural brain lesions were excluded by CT brain before and after LT. Future studies should expand and should include larger sample size in order to investigate different metabolic, neurological and physical tests that could identify the exact causes of incomplete recovery of the brain cognitive functions.

In conclusion, the reversal of minimal hepatic encephalopathy in cirrhotic patients can be achieved by liver transplantation, especially in those with a pre-transplant MELD score < 15.

## COMMENTS

### Background

Minimal hepatic encephalopathy (MHE) impairs daily functioning, driving performance, work capability and learning ability in cirrhotic patients. It also predisposes to overt hepatic encephalopathy and increases mortality. The psychometric hepatic encephalopathy score (PHES) battery can detect neuropsychiatric abnormalities. It assesses visual perception, construction, visual/spatial orientation, motor speed and accuracy, concentration, and attention in cirrhotic patients with end-stage liver disease. Liver transplantation (LT) is now considered an established effective and innovative treatment option for patients with end-stage liver diseases. The effects of LT on MHE are poorly studied.

### Research frontiers

The authors evaluated the reversibility of MHE following LT in Egyptian cirrhotic patients. Twenty right-handed patients with biopsy-proven liver cirrhosis listed for LT and twenty age- and sex-matched healthy control subjects were included. All underwent psychometric tests including trail making test A (TMT A), TMT B, the digit symbol test and the serial dotting test. The PHES was calculated to diagnose MHE. Psychometric tests were repeated six months following LT in cirrhotic patient group. They found that reversal of MHE in cirrhotic patients could be achieved by LT, especially in those with a MELD score < 15.

### Innovations and breakthroughs

This is the first Egyptian study that addresses the reversibility of minimal hepatic encephalopathy following LT.

### Applications

The findings of this study may represent a future strategy, indicating that early LT for patients with a MELD score < 15 may be associated with a higher incidence of reversal of MHE and could save the brain from the irreversible damage associated with end-stage liver disease.

### Terminology

MHE is a neuropsychiatric syndrome that may occur in cirrhotic patients with no recognizable clinical symptoms of hepatic encephalopathy but with mild cognitive and psychomotor deficits, impairing daily functioning.

### Peer-review

This study provides very interesting results which indicate that liver transplantation cannot fully recover all Egyptian patients from MHE caused by hepatitis C virus-induced cirrhosis, and has the most beneficial effect in patients with pre-transplant MELD score less than 15. This is the first study that investigated the reversibility of MHE in Egyptian population after liver transplantation, and provides important information regarding the effect of transplantation on the course of MHE.

### Abstract

#### AIM

To investigate how Tregs are regulated in chronic hepatitis C virus (HCV) patients *via* assessment of Tregs markers (granzyme 2, CD69 and FoxP3), Teffs markers [TNFRSF4 (OX40), INFG] and *CD4*, *CD25* genes.

#### METHODS

A prospective study was conducted on 120 subjects divided into 4 groups: Group I ( $n = 30$ ) treatment naïve chronic HCV patients; Group II ( $n = 30$ ) chronic HCV treated with Peg/Riba; Group III ( $n = 30$ ) chronic HCV associated with non-organ specific autoantibody and Group IV ( $n = 30$ ) healthy persons as a control group. Tregs and Teffs markers were assessed in peripheral blood mononuclear cells by quantitative real time reverse transcriptase-polymerase chain reaction.

#### RESULTS

Chronic HCV patients exhibited significant higher levels of both Teffs and Tregs in comparison to healthy control group. Tregs markers were significantly decreased in Peg/Riba treated HCV patients in comparison to treatment naïve HCV group. In HCV patients with antinuclear

antibody (ANA) +ve, Tregs markers were significantly decreased in comparison to all other studied groups. Teffs markers were significantly elevated in all HCV groups in comparison to control and in HCV group with ANA +ve in comparison to treatment naïve HCV group.

## CONCLUSION

Elevated Tregs cells in chronic HCV patients dampen both CD4<sup>+</sup> and CD8<sup>+</sup> autologous T cell immune response. Interferon- $\alpha$  and ribavirin therapy suppress proliferation of Tregs. More significant suppression of Tregs was observed in HCV patients with autoantibodies favoring pathological autoimmune response.

## INTRODUCTION

Over 200 million people worldwide are suffering from chronic hepatitis C virus (HCV) infection and liver cirrhosis will be developed in about a quarter of these patients<sup>[1]</sup>. The prevalence rate of HCV genotype 4 in high risk populations in Egypt ranges from 73% to 90% and it was also found to be highly prevalent in sub-Saharan Africa and in the Middle East<sup>[2,3]</sup>.

T lymphocytes play a major role in cell mediated immunity<sup>[4,5]</sup>. The several subsets of T cells have distinct functions and the majority is part of the adaptive immune system. Other subtypes can effectively present antigens to other T cells and are considered to be part of the innate immune system<sup>[6]</sup>.

HCV is accompanied with different autoimmune manife-

stations<sup>[7]</sup>, and could be a stimulator for the autoimmune reactions causing production of autoantibodies<sup>[8]</sup>. More recently, Acay *et al*<sup>[9]</sup> stated that the auto-antibodies in chronic HCV infection are highly incident. The authors stated that high percentages of patients with chronic hepatitis C had anti-mitochondrial antibodies, anti-smooth muscle antibodies, antinuclear antibody (ANA), thyroid antibody and anti-liver kidney microsomal antibodies.

The old HCV therapeutic protocol recommended by National Institutes of Health<sup>[10]</sup> was pegylated interferon (PEG-IFN) and ribavirin. Either endogenous or exogenous IFN- $\alpha$  leads to down regulation of CD4<sup>+</sup> FoxP3<sup>hi</sup> IFN- $\gamma$ <sup>neg</sup> activated T regulatory cells (aTregs) while at the same time induces induction of CD4<sup>+</sup> FoxP3<sup>low/neg</sup> IFN- $\gamma$ <sup>pos</sup> T-activated cells (aTeffs). IFN- $\alpha$  play an essential role in suppression of Tregs *via* inhibition of interleukin-2 secretion<sup>[11]</sup>.

Together, these observations support the fact that in early antiviral response there is a production of IFN- $\alpha$  which enhances CD4 effector functions by inhibiting Tregs activation, whereas sustained elevation of IFN- $\alpha$  reverses Tregs/Teffs balance towards Teffs activation, generation of auto antibody and development of autoimmunity.

The objective of the present study is to evaluate the extent of Teffs/Tregs imbalance in chronic HCV and its association with old standard of care as well as the presence of ANA.

## MATERIALS AND METHODS

### Study outcomes

Our research hypothesis was that HCV with or without IFN- $\alpha$  and ribavirin is usually associated with Tregs/Teffs imbalance with subsequent generation of autoantibodies.

The primary outcome for this study was to evaluate Teffs/Tregs balance and regulation in chronic HCV through assessment of Tregs markers (granzyme 2, CD69 and FoxP3), Teffs markers (TNFRSF4, INF $\gamma$ ) and CD4, CD25 genes. Assessment of the effect of IFN- $\alpha$  and ribavirin on Teffs/Tregs balance as well as the association of Teffs/Tregs balance with the presence of antinuclear antibody were also conducted.

### Study population

This was a prospective study conducted in Biochemistry and Molecular Biology Unit, Cairo University, Faculty of Medicine. The study included one hundred and twenty subjects categorized into 4 groups: Group I (30 patients) treatment naïve chronic HCV patients; Group II (30 patients) chronic HCV patients treated with the old standard of care therapy; Peg-IFN- $\alpha$  and ribavirin (Peg/Riba), group III (30 patients) chronic HCV patients associated with non-organ specific autoantibody and group IV, 30 healthy persons served as a control group. The patients attended the Internal Medicine Department at Beni-Sueif General Hospital. Healthy controls matched the age and sex of other patients. Cairo University Institutional

review board in Faculty of Medicine approved the study. Informed written consent was signed by all subjects of the study.

The eligibility of selected patients included: (1) age between 18 and 65 years old; (2) anti-HCV positive serum; (3) positive HCV RNA detected by reverse-transcription/polymerase chain reaction (RT/PCR); (4) non-organ specific autoantibody by positive ANA test (titer > 1/32) in group III only and < 1/16 in all other groups; and (5) white blood cell > 3.500/mm<sup>3</sup>.

A signed informed consent was got in accordance with Declaration of Helsinki ethics guidelines.

Exclusion criteria include patients with: Hepatocellular carcinoma, HBV co-infection, severe psychiatric disease, HIV-positive patients, co-morbid serious conditions, schistosomiasis mansoni, past history of alcohol abuse or long use of hepatotoxic drugs.

All HCV-infected patients in the treated group had a 48 wk course of old standard of care (Peg/Riba therapy) and achieved sustained virologic response. The T cells markers were analyzed after more than 6 mo of the end of the Peg/Riba course.

### Study analytic procedure

Whole blood was obtained from all subjects of the study. The mononuclear cell layer was isolated using Ficoll (Sigma, St. Louis, MO, United States) and centrifugation was conducted for 30 min at 400 g in cooling centrifuge.

**RNA extraction:** Total RNA was isolated from mononuclear cell layer using Qiagen purification reagent (Qiagen, CA, United States). The extracted RNA was quantified and checked for purity using a spectrophotometer (260/280 w.l.).

**Primer sequence:** PCR primers were got from GenBank RNA sequences cited at the following website: <http://www.ncbi.nlm.nih.gov/tools/primer-blast> (Table 1).

**Real-time quantitative PCR using SYBR Green I:** Step One plus real-time PCR system was used in the analysis using software version 3.1 (Applied Biosystems,

United States). Optimization of the annealing temperature was conducted for the PCR protocol and for the primer sets.

All cDNA were prepared for all gene markers, glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and for non-template negative control.

Five microliter of total RNA was used to generate cDNA using 20 pmol antisense primer and 0.8  $\mu$ L AMV reverse transcriptase at 37 °C for 60 min. The relative abundance of mRNA species was evaluated using the SYBR® Green method (Applied Biosystems, CA, United States).

Annealing temperature of 60 °C was optimized for all primer sets. Real time polymerase reaction was performed in 25  $\mu$ L reaction volume consisting of Mater Mix of SYBR Green, 3  $\mu$ L of cDNA, 900 nmol/L of every primer. Amplification conditions were conducted according to the manufacturer specifications: 2 min at 50 °C, 10 min at 95 °C, 40 repeated cycles with 15 s denaturation and 10 min of annealing/extension at 60 °C.

### Calculation of relative quantification (relative expression)

The resulting data were expressed in Cycle threshold (Ct). The PCR data results show Ct values of all studied genes (*CD69*, *CD4*, *granzyme 2*, *TNFRSF4*, *FoxP3*, *CD25* and *IFN $\gamma$* ) and the house keeping gene (GAPDH). A negative control sample was no template cDNA was used. Target gene expression was related to GAPDH.

Data were calculated using the Applied Biosystems Step One plus software. Relative gene expressions of all assessed genes were calculated using the comparative Ct method. All values were normalized to GAPDH house-keeping gene and expressed as fold changes relative to the background levels found in the control samples.

### Statistical analysis

Statistical Package of Social Studies (SPSS) version 16.0.1 (SPSS Inc., Chicago, IL, United States) was utilized. Numerical data were presented as mean  $\pm$  standard deviation. The null hypothesis was calculated for multiple groups by a single-factor ANOVA and for two groups by

unpaired *t*-test. Statistically significant was considered if *P* value was < 0.05.

## RESULTS

This study included 120 subjects divided into four groups. There weren't any difference between the four groups with statistical significance regarding age, sex distribution, albumin and T.bilirubin values (*P*-value > 0.05).

Findings of the present study exhibited that chronic HCV patients exhibited significant higher levels of both Teffs and Tregs markers as compared to healthy control group. Tregs markers (granzyme 2, CD69, FoxP3) were significantly decreased in Peg/Riba treated HCV patients in comparison to treatment naïve HCV group (Tables 2 and 3).

In HCV patients with autoantibodies, Tregs markers were significantly decreased in comparison to all the other studied groups (Tables 2 and 3, Figure 1).

Teffs specific genes (*TNFRSF4* and *IFN- $\gamma$* ) and *CD4*, *CD25* showed significant elevation in treatment naïve HCV group in comparison to control group (Tables 2 and 4, Figure 2).

More significant elevation in *Teffs* genes was observed in both Peg/Riba treated HCV and HCV with autoantibodies groups as compared to treatment naïve HCV and control groups (Tables 2 and 4, Figure 2).

## DISCUSSION

HCV is reported to suppress immune system to sustain chronic infection. Accumulation of Tregs and activation of inhibitory signaling pathways play essential roles in suppressing antiviral effector T cells (Teffs). The mechanisms by which HCV impairs Teffs include: Induction of Tregs, Th1 deficiency or Th2 dominance, blunted T cell activation, T cell apoptosis and T cell anergy<sup>[12]</sup>.

The objectives of the present study were to assess the extent of upregulation of Tregs in HCV patients whether or not associated with auto-antibodies. In the present study, we have evaluated certain markers of Tregs and Teffs in peripheral blood mononuclear cells.

FOXP3 (forkhead box P3) is a member of forkhead/winged-helix family of transcriptional regulators which are master regulators in the development and function of Tregs<sup>[13,14]</sup>.

Our results exhibited significant upregulation of FOXP3 in all HCV patients groups as compared to healthy controls. Other studies also confirmed accumulation of FOXP3<sup>+</sup> Tregs in most chronic viral infections with subsequent suppression of antiviral CD4<sup>+</sup> and CD8<sup>+</sup> T cell responses<sup>[15-18]</sup>.

Moreover, findings of our study demonstrated more significant decrease in Tregs specific genes (*CD69*, *FoxP3*, and *granzyme 2*) in HCV patients group after Peg/

**Figure 1 Relative gene expression of Tregs specific genes in the studied groups.** <sup>a</sup>Significant difference vs control group; <sup>b</sup>Significant difference vs treatment naïve HCV group; <sup>c</sup>Significant difference vs HCV group after treatment. HCV: Hepatitis C virus; IFN: Interferon.

Riba therapy. Similar findings were reported by Langhans *et al.*<sup>[19]</sup> who stated that ribavirin can inhibit functions of HCV-specific Tregs beside its immuno-stimulatory effects on TH1 cells. Ribavirin can subsequently inhibit Treg-mediated suppression of Teffs in chronic HCV infections pushing the disease towards autoimmune responses.

Golding *et al.*<sup>[11]</sup> stated that IFN- $\alpha$ , promotes proliferation of FoxP3<sup>Low/Neg</sup>IFN- $\gamma$ <sup>Pos</sup> activated Teffs while simultaneously suppresses the development of FoxP3<sup>HI</sup>IFN- $\gamma$ <sup>Neg</sup> activated Tregs. These data coincided with our findings in group II in relation to the other groups.

CD4 gene product is a membrane glycoprotein of T lymphocytes that mediates initiation and augments early phase of T-cell activation<sup>[20-22]</sup>. Findings of the present study demonstrated significant elevation of CD4 gene in

**Figure 2 Relative gene expression of Teffs specific genes and CD4, CD25 in the studied groups.** <sup>a</sup>Significant difference vs control group; <sup>b</sup>Significant difference vs treatment naïve HCV group. HCV: Hepatitis C virus.

all HCV groups in comparison to control group suggesting increase in activated T cells function. More significant elevation of CD4 was observed in HCV after treatment and in HCV with auto-antibodies groups.

CD25 is a type I transmembrane protein present on activated T cells, activated B cells and in memory CD8 T cells<sup>[23-27]</sup>. Our results demonstrated significant elevation of CD25 in all HCV studied groups with more significant elevation after Peg/Riba therapy. Similar findings were reported by Caetano *et al.*<sup>[28]</sup> in chronic HCV patients during Peg/Riba treatment who presented an amplified CD8 T-cell responses specific to HCV and more increase Teffs.

Moorman *et al.*<sup>[12]</sup> showed that many inhibitory signaling pathways were up-regulated during chronic HCV infection, resulting in expansion of Tregs and contraction of Teffs. Thus, this inhibitory pathway may not only regulate proliferation and differentiation of naïve T cells, but also control responses of Teffs, memory cells, and expansion of Tregs<sup>[29]</sup>.

These facts coincided with our results that showed significant elevation of Tregs specific genes (*CD69*, *FoxP3*, and *granzyme 2*) and significant elevation of Teffs specific genes (*TNFRSF4*, *INF- $\gamma$* ) and *CD4*, *CD25* genes in both groups of HCV whether naïve or after treatment in comparison to healthy controls.

Granzyme B encodes a protein that is essential in induction of cell-mediated immune response for the faster initiation of target cell apoptosis by cytolytic T lymphocytes<sup>[30]</sup>. Tregs possess granzyme B, enabling them to induce apoptosis in effector T-cells<sup>[31,32]</sup>. Our results demonstrated that granzyme B was found to be significantly elevated in naïve HCV patients with significant decrease after Peg/Riba therapy. More significant decrease in its levels was observed in HCV patients with autoantibodies favoring autoimmune response in those patients.

CD69 expression was studied by Colbeck *et al.*<sup>[33]</sup> and they stated that Tregs expressing CD69(+) are more proliferative and more suppressive than their CD69(-) counterparts. This finding explains our results that showed significant lower CD69 expression in HCV patients with autoantibodies suggesting inhibition of Tregs activity favoring autoimmune environment.

IFN- $\gamma$  is a member of the type II class of interferons<sup>[34]</sup>. Longhi *et al.*<sup>[31]</sup> stated that CD8<sup>+</sup> T cells when cultured on their own secrete much higher levels of IFN- $\gamma$  in patients with autoimmune hepatitis when compared to normal subjects and have a high proliferation rate. This finding coincided with our results that demonstrated significant higher levels of IFN- $\gamma$  in patients with autoantibodies than healthy controls.

The protein encoded by the *TNFRSF4* gene belongs to tumor necrosis factor - receptor superfamily that has essential roles in CD4<sup>+</sup> T cell response<sup>[35,36]</sup>.

Our findings showed that, in HCV patients with ANA +ve, *TNFRSF4* and *INF- $\gamma$*  (T effector gene) were significantly higher as compared to HCV naïve and healthy control groups. This means that T effector cells dominate over T regulatory cells favoring autoimmunity and initiating pathological immune response with production of autoantibodies. Similar findings were reported by González-Amaro *et al.*<sup>[37]</sup>.

Also, our results agreed with similar findings reported by Longhi *et al.*<sup>[31]</sup> who stated that regulatory T cells are decreased numerically and impaired functionally in autoimmune hepatitis. Similar to our results, several studies reported that HCV infection induces a dramatic increase in Tregs, which contributes to the immune response failure during HCV infection<sup>[38]</sup>.

In conclusion, chronic HCV patients exhibited signi-

ficant higher levels of both Teffs and Tregs in comparison to healthy controls. Moreover, elevated levels of Treg cells in patients with chronic HCV dampen both the CD4<sup>+</sup> and CD8<sup>+</sup> autologous T cell immune response. IFN- $\alpha$  and ribavirin therapy suppress proliferation of Tregs and do not restore the Teffs/Tregs imbalance. More significant suppression of Tregs was observed in HCV patients with autoantibodies favoring pathological autoimmune response.

## COMMENTS

### Background

Hepatitis C virus (HCV) is accompanied with different autoimmune manifestations, and could be a stimulator for the autoimmune reactions causing production of autoantibodies. More recently, Acay *et al* stated that the auto-antibodies in chronic HCV infection are highly incident. The authors stated that high percentages of patients with chronic hepatitis C had anti-mitochondrial antibodies (AMA), anti-smooth muscle antibodies (ASMA), anti-nuclear antibodies (ANA), thyroid antibody and anti-liver kidney microsomal antibodies (anti-LKM-1). The old HCV therapeutic protocol was pegylated interferon (IFN) and ribavirin. IFN- $\alpha$  leads to down regulation of CD4<sup>+</sup> FoxP3<sup>hi</sup> IFN- $\gamma$ <sup>neg</sup> activated T regulatory cells (aTregs) while at the same time induces induction of CD4<sup>+</sup> FoxP3<sup>low/neg</sup> IFN- $\gamma$ <sup>pos</sup> T-activated cells (aTeffs). Together, these observations support the fact that sustained elevation of IFN- $\alpha$  reverses Tregs/Teffs balance towards Teffs activation, generation of auto antibody and development of autoimmunity. The objective of the present study is to evaluate the extent of Teffs/Tregs imbalance in chronic HCV and its association with old standard of care as well as the presence of ANA.

### Research frontiers

IFN- $\alpha$ /ribavirin old therapeutic protocol enhances CD4 effector (Teffs) functions by inhibiting Tregs activation. The old protocol reverses Tregs/Teffs balance towards Teffs activation, generation of auto antibody and development of autoimmunity.

### Innovations and breakthroughs

New direct acting antiviral drugs do not induce Tregs/Teffs imbalance, whereas the old standard of care IFN- $\alpha$  and ribavirin induce Tregs/Teffs imbalance. Replacing the old therapeutic protocol by the new direct acting antiviral drugs is mandatory because beside its efficacy, the new direct acting antiviral drugs do not induce autoimmunity.

### Applications

Chronic HCV patients exhibited significant higher levels of both Teffs and Tregs in comparison to healthy controls. Moreover, elevated levels of Treg cells in patients with chronic HCV dampen both the CD4<sup>+</sup> and CD8<sup>+</sup> autologous T cell immune response. IFN- $\alpha$  and ribavirin therapy suppress proliferation of Tregs and do not restore the Teffs/Tregs imbalance. More significant suppression of Tregs was observed in HCV patients with autoantibodies favoring pathological autoimmune response. Replacing the old therapeutic protocol; IFN- $\alpha$  and ribavirin by the new direct acting antiviral drugs is mandatory and is also essential avoid Teffs/Tregs imbalance.

### Terminology

Tregs also known as suppressor T cells, are a subpopulation of T cells that down-regulates or suppress induction, proliferation and activation of effector T cells. Tregs also maintain tolerance to self-antigens and prevent autoimmunity. Teffs includes various T cell types that actively respond to antigenic stimuli, such as co-stimulation. This includes helper T cells, cytotoxic or killer T cells, and potentially other T cell types as memory cells. HCV-induced autoantibodies involves: AMA, ASMA, ANA, thyroid antibody and anti-LKM-1. Forkhead box P3 is a member of forkhead/winged-helix transcriptional regulators which master the development and function of Tregs. *CD4* gene product is a membrane glycoprotein of T lymphocytes that mediates initiation and augments early phase of T-cell activation. Granzyme B is a protein that enables Tregs to induce apoptosis in effector T-cells. *TNFRSF4* gene belongs to tumor necrosis factor

-receptor superfamily that plays essential roles in CD4<sup>+</sup> T cell response.

## Peer-review

The manuscript presents the gene expression of immune molecules in peripheral blood mononuclear cell by reverse transcription polymerase chain reaction. And to investigate the immune changes induced by HCV, as well as after PR therapy. This paper may be interest to the readers of the journal and provide some knowledge for clinicians and researchers.

## Contents

*World Journal of Hepatology*  
Volume 8 Number 31 November 8, 2016

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Dr. Yu-Bao Zheng, MD, PhD, Associate Professor, Chief Doctor, Teacher, Department of Infectious Diseases, the Third Affiliated Hospital, Sun Yat-sen University, Guangzhou 510630, Guangdong Province, China

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Alcohol use disorder (AUD) and hepatitis C virus (HCV) infection frequently co-occur. AUD is associated with greater exposure to HCV infection, increased HCV infection persistence, and more extensive liver damage due to interactions between AUD and HCV on immune responses, cytotoxicity, and oxidative stress. Although AUD and HCV infection are associated with increased morbidity and mortality, HCV antiviral therapy is less commonly prescribed in individuals with both conditions. AUD is also common in human immunodeficiency virus (HIV) infection, which negatively impacts proper HIV care and adherence to antiretroviral therapy, and liver disease. In addition, AUD and HCV infection are also frequent within a proportion of patients with HIV infection, which negatively impacts liver disease. This review summarizes the current knowledge regarding pathological interactions of AUD with hepatitis C infection, HIV infection, and HCV/HIV co-infection, as well as relating to AUD treatment interventions in these individuals.

**Key words:** Hepatitis C virus; Human immunodeficiency virus; Hepatitis C virus/human immunodeficiency virus co-infection; Liver; Alcohol

Alcohol use disorder and its impact on chronic hepatitis C virus and human immunodeficiency virus infections. *World J Hepatol* 2016; 8(31): 1295-1308 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i31/1295.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i31.1295>

## INTRODUCTION

Alcohol abuse is a major cause of preventable liver disease worldwide, and alcohol use disorder (AUD) is associated with substantial disease burden in western countries<sup>[1]</sup>. According to 5<sup>th</sup> edition of the Diagnostic and Statistical Manual of Mental Disorders<sup>[2]</sup>, AUD encompasses both alcohol abuse and alcohol dependence. Table 1 presents the diagnostic criteria for AUD and other definitions of unhealthy alcohol use, such as the recommendations of the United States National Institute on Alcohol Abuse and Alcoholism.

In the United States, almost 9% of the adult population meets the AUD criteria and alcohol contributes to 79000 deaths annually<sup>[3]</sup>. Within the European Union, alcohol misuse causes 14% of deaths in men and nearly 8% of deaths in women, with alcohol-related mortality disproportionately impacting young people<sup>[4]</sup>. In Spain, unhealthy alcohol use is exhibited by 5% of the population between 15 and 64 years old, and 15% report at least one binge drinking episode within the prior year<sup>[5]</sup>. Moreover, the pattern of binge drinking is becoming increasingly prevalent, mainly among young individuals.

Per capita alcohol consumption is strongly correlated with liver cirrhosis mortality rates globally<sup>[6]</sup>. However, the short- and long-term impacts of binge drinking with regards to the development and severity of alcoholic liver disease (ALD) are not yet known. Per capita alcohol consumption is strongly correlated with liver cirrhosis mortality rates across countries<sup>[5]</sup>. Notably, the medical literature reveals wide heterogeneity in the methods used to assess alcohol exposure, and it can be challenging to analyze time-varying exposures like alcohol consumption over time<sup>[7]</sup>.

### Epidemiology of AUD in hepatitis C virus and human immunodeficiency virus infection

Addressing alcohol use is critical in the management of hepatitis C virus (HCV)-infected patients, as AUD is associated with poor clinical outcomes and liver-related deaths in this patient group<sup>[8]</sup>. Compared to the general population, HCV-infected adults tend to consume greater amounts of ethanol<sup>[9]</sup>, being over twice as likely to consume more than one alcoholic drink per day (34% vs 14%) and almost 8 times more likely to consume over three drinks per day (19% vs 2%)<sup>[10]</sup>.

Moreover, alcohol abuse is associated with concomitant use of illegal substances, and 30% to 50% of patients with a history of substance abuse consume alcohol<sup>[11]</sup>. This is highly important since 2/3 of new HCV infections in the western world are associated with drug injection<sup>[12]</sup>. Accordingly, the prevalence of HCV infection is higher among patients with AUD who are current or past injecting drug users<sup>[13]</sup>. Within a cohort of patients with AUD admitted for hospital detoxification in the Barcelona area, HCV prevalence was as high as 20%<sup>[14]</sup>. However, other researchers in Spain reported a much lower prevalence of 3.5%<sup>[13]</sup>, possibly due to differences in patient selection.

The prevalence of HCV infection is confounded by the degree of liver disease. Cross-sectional studies performed in hepatology clinics showed that HCV prevalence was higher among patients with advanced liver fibrosis, and almost universal among HCV-infected patients with hepatocellular carcinoma<sup>[15,16]</sup>. On the other hand, HCV prevalence ranged from 1% to 10% in community-oriented studies of individuals with AUD but without clinically apparent liver disease<sup>[17,18]</sup>. A recent meta-analysis including 24 studies reported that the average weighted prevalence of HCV infection among patients with AUD was 16.3%<sup>[13]</sup>.

AUD may also be common among human immunodeficiency virus (HIV)/AIDS patients, with a prevalence ranging from 30% to 50%<sup>[19]</sup>. High prevalences of alcohol consumption have been reported in HIV/AIDS cohort studies from the United States<sup>[20,21]</sup>, Europe<sup>[22-24]</sup>, South Africa<sup>[25]</sup>, and other parts of the world<sup>[26]</sup>. In the Women's Interagency HIV Study, 14%-24% of female HIV/AIDS participants reported hazardous alcohol use within the past year<sup>[27]</sup>. On the other hand, patients with AUD show a lower prevalence of HIV infection than HCV infection<sup>[14]</sup>, which is confounded by prevalence of injection drug use.

## AUD AND CHRONIC HCV INFECTION

### Effect of alcohol on HCV replication

Alcohol metabolites apparently enhance viral protein expression as well as the heterogeneity of HCV quasi-species<sup>[28]</sup>. Some authors describe RNA-HCV increases among patients who use alcohol<sup>[29]</sup>. However, a meta-analysis performed by Anand *et al*<sup>[30]</sup> in 2005 showed no association between RNA-HCV and alcohol consumption.

### Impact of alcohol on HCV infection persistence

Spontaneous resolution of HCV infection requires an early and wide immune response against HCV viral proteins<sup>[31]</sup>. Once acute HCV infection is controlled, the presence of memory T-cell populations is associated with reduced persistence of infection in re-exposed individuals<sup>[32]</sup>. HCV infection persistence is also associated with loss of specific T-cell proliferation, and reduced migration of effector T cells to the liver<sup>[33]</sup>. HCV-infected patients with AUD show functional impairment of dendritic cells<sup>[34]</sup>, which partly explains the association between alcohol use

**Table 1** Diagnostic criteria for alcohol use disorder and other definitions of unhealthy alcohol use

## AUD (DSM-5)

In the past year<sup>[2]</sup>, have you<sup>1</sup>

Had times when you ended up drinking more, or longer than you intended?

More than once wanted to cut down or stop drinking, or tried to, but couldn't?

Spent a lot of time drinking? Or being sick or getting over the aftereffects?

Experienced craving - a strong need, or urge, to drink?

Found that drinking or being sick from drinking often interfered with taking care of your home or family? Or caused job troubles? Or school problems?

Continued to drink even though it was causing trouble with your family or friends?

Given up or cut back on activities that were important or interesting to you, or gave you pleasure, in order to drink?

More than once gotten into situations while or after drinking that increased your chances of getting hurt (such as driving, swimming, using machinery, walking in a dangerous area, or having unsafe sex)?

Continued to drink even though it was making you feel depressed or anxious or adding to another health problem? Or after having had a memory blackout?

Had to drink much more than you once did to get the effect you want? Or found that your usual number of drinks had much less effect than before?

Found that when the effects of alcohol were wearing off, you had withdrawal symptoms, such as trouble sleeping, shakiness, irritability, anxiety, depression, restlessness, nausea, or sweating? Or sensed things that were not there?

Risky alcohol use<sup>[178]</sup>

Drinking more than the recommended amount by the National Institute on Alcohol Abuse and Alcoholism

&gt; 14 drinks per week or &gt; 4 drinks on any day for men

&gt; 7 drinks per week or &gt; 3 drinks on any day for women or men &gt; 65 yr

## Problem drinking

Use of alcohol accompanied by alcohol-related consequences but not meeting criteria for AUD

<sup>1</sup>Meeting any two of the 11 criteria during the same 12-mo period is consistent with AUD. The severity of an AUD-mild, moderate, or severe-is based on the number of criteria met. AUD: Alcohol use disorder; DSM-5: Diagnostic and statistical manual of mental disorders.

and lower odds of spontaneous HCV resolution<sup>[35,36]</sup>.

**Effect of alcohol on HCV-related immunity**

Mice that are chronically exposed to ethanol exhibit diminished immune responses to HCV-core protein, mainly due to impaired maturation of dendritic cells<sup>[34]</sup>. In HCV-infected patients, dendritic cells present impaired allostimulation capacity, which is more apparent in the presence of alcohol<sup>[34]</sup>. Alcohol and HCV infection exert synergistic effects, suppressing major histocompatibility complex class II<sup>[37]</sup> *via* functional impairment of the proteasome (intracellular protein complexes that degrade unnecessary or damaged proteins) and alterations in interferon signaling<sup>[38]</sup>. This could partly explain the lower efficacy of interferon-based HCV treatment regimens among patients with AUD<sup>[39]</sup>.

**Effect of alcohol on cytotoxicity**

Enhanced hepatocyte apoptosis is observed in HCV infection, which is apparently associated with impaired immune responses rather than directly attributable to the viral infection<sup>[40]</sup>. Hepatocyte apoptosis is mediated by cytotoxic T cells and natural killer cells *via* caspase activity<sup>[40]</sup>. BCL-2 protein is associated with mitochondrial permeability, and its expression is reduced in HCV-infected hepatocytes<sup>[41]</sup>. Alcohol seems to enhance hepatocyte apoptosis through down-regulation of BCL-2 expression<sup>[40]</sup>.

**Alcohol and oxidative stress**

The HCV core viral protein is associated with higher oxidative stress. It binds the mitochondrial wall, facilitating calcium entrance, electron transport, and increased

reactive oxygen species, which results in increased oxidative stress that damages the cell<sup>[42]</sup>. This protein also targets microsomal triglyceride transfer protein activity, thus modifying hepatic very-low-density lipoprotein particle assembly and secretion, which leads to liver steatosis<sup>[43]</sup>. Moreover, the HCV core viral protein alters the oxidant/antioxidant state of the liver in the absence of inflammation, consequently producing mitochondrial DNA damage<sup>[44]</sup>.

In HCV-core transgenic mice, chronic ethanol administration is associated with higher lipid peroxidation and synergic induction of TGF- $\beta$ 1 and hepatic stellate cells<sup>[45]</sup>. The HCV-core protein cooperates with ethanol to activate some p38 mitogen-activated protein kinase pathways, resulting in polygene modulation, and contributing to liver disease pathogenesis<sup>[46]</sup>. In alcohol-fed NS5A transgenic mice, the synergistic effect between HCV infection and alcohol is dependent on mechanisms involving Toll-like receptor 4, which belongs to the innate immune system<sup>[47]</sup>. Alcohol consumption and HCV infection impact FOXO3 expression, thus impairing antioxidant capacity in the liver<sup>[48]</sup>.

In humans, indirect evidence suggests that oxidative stress is associated with more extensive liver injury in patients with AUD and HCV infection, as they tend to show higher serum levels of malondialdehyde (a lipid peroxidation product), poor glutathione peroxidase activity, and stimulation of Th1 response cytokines<sup>[49]</sup>. Moreover, patients with AUD present major lipid peroxidation, and the loss of antioxidant capacity is associated with liver fibrosis<sup>[50]</sup>. Among HCV-infected patients who drink alcohol, liver fibrosis is independently associated with liver steatosis, oxidative stress, age, and iron

deposits in the liver<sup>[51]</sup>.

### **Alcohol and progression of HCV-related liver disease**

Alcohol consumption is associated with more extensive progression of HCV-related liver damage<sup>[52,53]</sup>. No safe level of alcohol consumption has been described, as even HCV-infected patients who drink moderate amounts of alcohol (30 g/d) experience progressive liver fibrosis<sup>[54-56]</sup>. A meta-analysis assessed 20 studies that were published between 1995 and 2004, and found that the relative risk of progression to liver cirrhosis or decompensated liver disease among HCV-infected patients was 2.3 times higher, with a 95%CI of 1.7-3.3, among those who drank alcohol compared to abstainers<sup>[52]</sup>. However, the majority of included studies were performed in liver units, and thus might be biased towards patients with more severe forms of liver disease<sup>[52]</sup>. Alcohol consumption is also associated with higher risks of cirrhosis decompensation and liver-related death<sup>[57]</sup>. Moreover, alcohol consumption has a synergistic effect with chronic hepatitis C, increasing the risk of liver cancer<sup>[58]</sup>.

### **Assessment of liver disease in patients with AUD and HCV infection**

In both HCV infection and ALD, liver fibrosis is the main prognostic factor of liver disease progression<sup>[59,60]</sup>. Although liver biopsy is the gold standard for liver fibrosis assessment<sup>[61]</sup>, it is associated with several rare complications and is not usually performed in patients with substance use disorders<sup>[62]</sup>. Recent reports describe the estimation of liver fibrosis using several non-invasive biological markers derived from laboratory parameters routinely used in clinical practice, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), and platelet count.

Of these potential markers, FIB-4<sup>[63]</sup> and the aspartate aminotransferase/platelet ratio index (APRI)<sup>[64]</sup> have been validated against the gold standard of liver biopsy in HCV-monoinfected patients as well as HCV/HIV-coinfected patients<sup>[65-68]</sup>. These markers perform better for detecting either the absence of liver fibrosis or the presence of advanced liver fibrosis<sup>[63,64]</sup>. However, clinical experience using these markers in patients with AUD is limited<sup>[69]</sup>, and concerns have been raised about the possibility of overestimating liver fibrosis in patients with alcoholic steatohepatitis. Moreover, ALD is a formal contraindication for the use of Pohl's score<sup>[70]</sup>-an index that uses aminotransferase levels and platelet count. Transient elastography has also been used to assess liver fibrosis in ALD<sup>[71]</sup>, but the presence of severe liver steatosis may distort results, leading to overestimation of advanced liver fibrosis<sup>[72]</sup>.

In prior studies, we have defined alcohol-related liver disease (ARLD) as the presence of any two of the following criteria: Elevated AST to between 74 and 300 U/L, AST/ALT  $\geq 2$ , and total bilirubin  $> 1.2$  mg/dL<sup>[73,74]</sup>. Within a cohort of AUD patients admitted for hospital detoxification in metropolitan Barcelona, Spain, 14.6%

met those criteria, and ARLD was associated with mid-term mortality<sup>[75]</sup>.

### **Impact of HCV infection on hospitalizations and mortality of patients with AUD**

As previously mentioned, alcohol use is associated with worse prognosis in HCV-related liver disease. It is estimated that 36% of liver cirrhosis among HCV-infected individuals is attributable to alcohol use<sup>[76]</sup>. HCV infection also has a deleterious impact on clinical outcomes among patients with AUD<sup>[77-80]</sup>. Tsui *et al.*<sup>[77]</sup> identified 6354 AUD-related hospital admissions, and reported that the HCV-positive patients were twice as likely to die (4.4% vs 2.4%,  $P < 0.01$ ), and showed significantly longer hospital stays (19% longer, 95%CI: 12%-27%). Another study included patients from the United States Nationwide Inpatient Sample Dataset who had a primary or a secondary discharge diagnosis of alcoholic hepatitis, and reported that HCV-positive patients had higher mortality with an odds ratio (OR) of 1.29 (95%CI: 1.12-1.49,  $P < 0.01$ )<sup>[78]</sup>.

Patients with AUD who are exposed to HCV infection probably differ from those who are not exposed with regards to co-morbidities or behaviors associated with poorer survival, such as the use of illicit drugs<sup>[81]</sup>. However, even in studies that have accounted for various lifestyle factors, HCV infection remains associated with both overall mortality, showing a hazard ratio (HR) of 2.55 (95%CI: 1.50-4.33,  $P < 0.01$ ), and liver-related mortality (HR = 3.24, 95%CI: 1.18-8.94,  $P = 0.02$ )<sup>[79]</sup>.

In our study of 675 AUD patients admitted for hospital detoxification, we examined the impact of HCV infection on mortality. Our results showed that HCV infection was associated with higher mortality, and that this effect was more apparent in patients with younger ages at admission (HR = 3.1, 95%CI: 1.3-7.3,  $P < 0.01$ ) and those who were co-infected with HCV/HIV (HR = 3.9, 95%CI: 2.1-7.1,  $P < 0.01$ )<sup>[80]</sup>. In the same Barcelona cohort, we recently reported that AUD patients with HCV mono-infection showed an increased risk of liver-related death in comparison to AUD patients without HCV-infection (HR = 3.92, 95%CI: 2.03-7.59)<sup>[82]</sup>.

### **Interferon-based treatment of HCV infection in patients with AUD**

In the era of HCV antiviral therapy including interferon, infection treatment was challenging in individuals who consumed alcohol<sup>[8]</sup>. In fact, alcohol use was a major reason for a lack of HCV treatment<sup>[83,84]</sup>. Several researchers analyzed strategies to extend HCV treatment to patients with unhealthy alcohol use. Le Lan *et al.*<sup>[85]</sup> performed an observational study of HCV treatment in alcohol-drinking patients, in which drinking in moderation was encouraged but not required. Of the study population, 30% continuously abstained, 34% consumed low-risk amounts of alcohol, and 36% continued to drink risky amounts. The overall sustained viral response (SVR) rate was 48% with no difference observed between

**Table 2 Treatment interventions for unhealthy alcohol use and alcohol use disorder**

Condition	Intervention
Unhealthy alcohol use	Brief intervention
AUD	Motivational interviewing
	Hospital detoxification
	Individual and group therapy
	Approved pharmacological treatments:
	Disulfiram
	Acamprosate
	Naltrexone
	Nalmefene
	Investigational treatments:
	Baclofene
	Topiramate
	Gabapentin

AUD: Alcohol use disorder.

abstainers and low-risk drinkers<sup>[85]</sup>, confirming prior results in a Swiss HCV cohort<sup>[86]</sup>.

Evon *et al*<sup>[87]</sup> performed a randomized clinical trial in the United States, which included 9-mo intervention comprising counseling, case management, and motivational interviewing for patients ineligible for HCV treatment (31% due to alcohol abuse). The intervention was associated with a 2.38 relative risk of being deemed eligible (95%CI: 1.21-4.68). The groups did not differ with regards to the proportion of patients that eventually received HCV antiviral therapy<sup>[87]</sup>.

### **Interferon-free treatment of HCV infection in patients with AUD**

The advent of direct-acting antivirals and interferon-free regimens has dramatically changed the landscape of HCV treatment, with most registration trials and pilot real-life experiences reporting SVR rates of over 90%<sup>[88]</sup>. Although treatment is now more feasible for patients with substance use disorders<sup>[89,90]</sup>, to date, very few patients with AUD have been included in clinical trials<sup>[91-93]</sup>.

The current American Association for the Study of Liver Diseases - Infectious Diseases of America guidelines for HCV treatment advocate abstinence from alcohol<sup>[94]</sup>. When appropriate, these guidelines suggest interventions to facilitate the cessation of alcohol consumption, ranging from brief interventions for patients with low alcohol intake<sup>[94]</sup>, to referral to mutual help groups and specialty treatment for patients with established AUD<sup>[94]</sup>. While alcohol consumption is not a formal contraindication for HCV treatment, a year of abstinence from alcohol is thought to be necessary to achieve adequate treatment adherence<sup>[95]</sup>.

There remains a need for a change in the provision of HCV treatment such that patients with AUD and HCV infection can benefit from viral eradication. Expansion of the capacity of primary care clinics or addiction clinics to provide HCV treatment has been successfully tested in several areas of the United States<sup>[96]</sup> and Australia<sup>[90]</sup>. These experiences should be replicated worldwide to

more effectively treat difficult-to-reach populations<sup>[97]</sup>.

### **AUD treatment in patients with HCV infection**

Brief interventions involving feedback and discussion of the negative consequences of alcohol abuse are efficacious at motivating reduced alcohol consumption among among patients with unhealthy alcohol use<sup>[98]</sup>, but not patients with alcohol dependence. Such brief interventions can be targeted towards patients with HCV infection, with delivery at the primary care level or in hepatology clinics<sup>[94,99]</sup>. More intensive treatments, such as motivational enhancement therapy, can also reduce the number of drinking days among patients with chronic HCV infection<sup>[100]</sup>. Other type of interventions, such as group therapy, can reportedly motivate abstinence from alcohol in 44% of patients in an HCV clinic<sup>[101]</sup>.

Table 2 summarizes the various treatment strategies for patients with AUD. Specialty treatment should be favored in such cases, and patients should be offered detoxification; specific pharmacotherapy including disulfiram, acamprosate, naltrexone, or nalmefene; and psychosocial support<sup>[3]</sup>. Some researchers have reported satisfactory results with baclofene in patients with overt end-stage liver disease<sup>[102]</sup>.

## **AUD AND HIV INFECTION**

### **Effect of alcohol on the immune system**

The combined effects of alcohol and HIV on the immune system have been investigated in simian models<sup>[103]</sup>. Alcohol and HIV infection show a synergistic impact on gastrointestinal tract integrity, causing initial depletion of intestinal CD4 cells<sup>[104,105]</sup>. Loss of intestinal wall integrity is associated with increased permeability, microbial translocation, and immune activation<sup>[106]</sup>. Immune activation is crucial for HIV disease progression<sup>[107]</sup>, and is reportedly a better predictor of disease progression than HIV viral load<sup>[106,108]</sup>. While alcohol seems to impact the adaptive immune responses to HIV infection in animal models, the results in humans are mixed<sup>[103]</sup>. In a study of HIV-infected patients, blood alcohol levels relative to alcohol intake were higher before antiretroviral treatment compared to after treatment<sup>[109]</sup>.

### **Alcohol and HIV disease progression**

Prior to widespread use of antiretroviral therapy (ART), epidemiological data suggested that alcohol use was not associated with HIV disease progression<sup>[110,111]</sup>. However, following the advent of ART, several authors have reported reduced ART effectiveness among patients with AUD<sup>[19,112]</sup>. In 2003, Samet *et al*<sup>[113]</sup> investigated a cohort of HIV-infected patients, and reported cross-sectional data suggesting that alcohol consumption negatively impacted HIV disease progression. Alcohol consumption was associated with lower CD4 cell counts and higher HIV viral loads in patients receiving ART. A later longitudinal study of the same cohort demonstrated that heavy alcohol use in patients not receiving ART was

associated with lower CD4 cell counts but not with HIV viral load<sup>[114]</sup>.

Chander *et al.*<sup>[115]</sup> at John Hopkins University reported that heavy alcohol consumption was associated with reduced viral suppression of HIV infection and lower treatment adherence. Wu *et al.*<sup>[116]</sup> investigated 325 subjects receiving ART and found that, after adjusting for adherence, daily drinkers showed a nearly four-fold increase in the odds of detectable HIV viral load. This association was non-significant for regular drinkers. Their results further showed that alcohol use was not associated with CD4 cell count, and that alcohol consumption was not associated with HIV viral load among patients not receiving ART<sup>[116]</sup>. On the other hand, Baum *et al.*<sup>[117]</sup> investigated HIV-infected patients receiving ART, and reported that alcohol use was associated with lower CD4 cell counts, greater risk of showing a CD4 cell count of < 200, and an increased HIV viral load over time.

More recent studies indicate that the benefits of ART seem to outweigh the detrimental effects of alcohol use, reinforcing the importance of initiating ART and ensuring adequate treatment adherence<sup>[118]</sup>. A study in a Swiss HIV cohort revealed no effect of alcohol consumption on either virological failure or CD4 cell count, both among ART-receiving and ART-naïve patients<sup>[119]</sup>. That study also demonstrated that heavy drinkers were more likely to interrupt ART; however, only 2.8% of participants were heavy drinkers<sup>[119]</sup>. A recent French study of HIV/AIDS patients reported that low levels of alcohol consumption (< 10 g/d) were associated with higher CD4 counts compared to in abstainers<sup>[120]</sup>. However, the beneficial effects of such low levels of alcohol consumption may be confounded by other healthier behaviors exhibited by moderate drinkers<sup>[121]</sup>.

Overall, evidence acquired during the first decade of ART use suggested that AUD may impact HIV disease progression; however, more recent studies do not support those findings. These contradictory results may be partly explained by poor adherence to treatment and barriers to proper medical care associated with AUD.

### **Alcohol and comorbidities**

Alcohol use is associated with unprotected sex and syringe sharing, thus elevating the risks of HIV acquisition and transmission<sup>[122-124]</sup>. Moreover, alcohol use is associated with higher prevalence of depressive symptoms<sup>[125]</sup>, which can influence ART initiation<sup>[126]</sup>, treatment adherence<sup>[127]</sup>, treatment discontinuation<sup>[128]</sup>, and disease progression<sup>[129,130]</sup>. Other substance use disorders frequently co-exist in patients who exhibit alcohol abuse<sup>[11]</sup>, which is also associated with poorer treatment adherence, reduced HIV viral suppression, and lower retention in care<sup>[112,131]</sup>.

Heavy alcohol use is related to liver disease among patients with HIV infection<sup>[132,133]</sup>, and is also associated with cardiovascular disease<sup>[134]</sup> and exacerbations of chronic obstructive pulmonary disease<sup>[135]</sup>. A systematic review of 13 studies reported that heavy alcohol use was associated with elevated risk of cardiovascular

disease, with a risk ratio of 1.78 (95%CI: 1.09-2.93)<sup>[134]</sup>.

### **Alcohol and mortality in HIV infection**

Alcohol is commonly regarded as an underappreciated modifiable risk factor in individuals with HIV infection, with or without HCV co-infection<sup>[116]</sup>. A retrospective study from northern California evaluated data from between 1996 and 2005, and found that higher mortality rates were associated with diagnosis of a substance use disorder (alcohol only, drug only, or alcohol and drug)<sup>[136]</sup>. In the HIV-LIVE cohort of HIV-positive patients with alcohol problems, short-term mortality was associated with homelessness and drug use<sup>[137]</sup>, and long-term mortality was associated with HCV infection and high levels of inflammation markers<sup>[79,138]</sup>. A study from the VACS cohort revealed that even non-hazardous levels of alcohol consumption were associated with decreased survival<sup>[139]</sup>. Recent data from the same VACS cohort shows that among HIV-positive participants, alcohol use was associated with greater physiological injury. Moreover, within this cohort, a greater risk of mortality was associated with an Alcohol Use Disorders Identification Test value of  $\geq 4$  drinks/mo (HR = 1.25, 95%CI: 1.09-1.44), and of  $\geq 30$  drinks/mo (HR = 1.30, 95%CI: 1.14-1.50)<sup>[140]</sup>.

### **HIV treatment in patients with AUD**

Alcohol use co-existing with other substance use is associated with lower quality of HIV care<sup>[141]</sup> and poor retention in care<sup>[131]</sup>. A systematic review of 53 studies published between 2010 and 2015 showed that 77% of studies revealed that alcohol use was negatively associated with the HIV treatment cascade, *i.e.*, access to care, ART prescription, and treatment adherence<sup>[142]</sup>. This suggests that unhealthy alcohol use should be targeted to increase the proportion of HIV/AIDS patients who achieve viral suppression.

Even modest alcohol consumption has been associated with poor ART adherence<sup>[139]</sup>. Hendershot *et al.*<sup>[143]</sup> performed a meta-analysis of 40 studies, and showed that patients who drank relatively more were 50%-60% less likely to adhere to ART compared with those who abstained or drank relatively less. Alcohol consumption appears to be dose-dependently related to ART adherence<sup>[115]</sup>, and shows a temporal relationship to missed ART treatments<sup>[144]</sup>.

### **AUD treatment in HIV-infected patients**

Among HIV/AIDS patients who drink alcohol, brief interventions are reportedly efficacious for reducing the frequency of alcohol use and the frequency of unprotected sex<sup>[145,146]</sup>. However, patients abusing alcohol might need more intensive treatment. Some authors report that the addition of motivational interviewing<sup>[147]</sup> and problem solving therapy may be necessary to improve ART adherence<sup>[148]</sup>. An intervention called retention through enhanced personal contact has also been tested to improve retention among HIV-positive patients with alcohol use or mental illness<sup>[149]</sup>.

**Table 3** Non-invasive methods for analyzing liver fibrosis in patients with alcohol use disorder, hepatitis C virus infection and hepatitis C virus - human immunodeficiency virus co-infection

Ref.	Setting	Non-invasive method	Method for detecting alcohol consumption	Finding
Lieber <i>et al</i> <sup>[69]</sup>	VA studies (2) of alcoholic liver disease	APRI <sup>1</sup>	Average alcohol intake	Low sensitivity and specificity of APRI in comparison to liver biopsy, especially in subjects with HCV
Chaudhry <i>et al</i> <sup>[169]</sup>	HIV Hopkins clinical cohort	APRI	Past 6-mo hazardous drinking	No effect of alcohol on APRI values in HCV/HIV co-infection
Blackard <i>et al</i> <sup>[170]</sup>	WIHS cohort	FIB-4 <sup>2</sup>	Recent drinking	No association between alcohol intake and FIB-4 values in HCV/HIV co-infection
Muga <i>et al</i> <sup>[171]</sup>	AUD patients admitted for detoxification	FIB-4	Past 6-mo unhealthy drinking	No association between FIB-4 and alcohol use in HCV/HIV co-infection
Fuster <i>et al</i> <sup>[173]</sup>	HIV-live cohort	FIB-4 and APRI	LDH	No association between LDH and liver fibrosis measured with FIB-4 or APRI
Lim <i>et al</i> <sup>[174]</sup>	VACS cohort	FIB-4	AUDIT-C <sup>3</sup>	Advanced liver fibrosis correlated with alcohol use

<sup>1</sup>APRI: AST to platelet ratio index= {[AST/AST upper limit of normal (IU/L)]/platelet count (10<sup>9</sup>/L)} × 100<sup>[64]</sup>; <sup>2</sup>FIB-4 = age × AST (IU/L)/platelet count (10<sup>9</sup>/L) × ALT (IU/L)<sup>1/2</sup><sup>[63]</sup>; <sup>3</sup>AUDIT-C: Alcohol Use Disorders Identification Test<sup>[79]</sup>. HIV: Human immunodeficiency virus; AUD: Alcohol use disorder; APRI: Aminotransferase/platelet ratio index; HCV: Hepatitis C virus; LDH: Lifetime drinking history; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; VA: United States Department of Veteran Affairs; WIHS: Women's Interagency HIV study; VACS: Veterans Aging Cohort study.

Chander *et al*<sup>[150]</sup> recently performed a cross-sectional survey among HIV care providers, and found that although the majority reported that they usually screen for alcohol use, only 10% used a formal screening tool. Moreover, knowledge of pharmacotherapy for AUD was low, and most care providers referred patients to outside resources for treatment<sup>[150]</sup>.

## AUD AND HCV/HIV CO-INFECTION

A proportion of patients with both AUD and HCV infection also have HIV infection. In fact, HCV/HIV co-infection is clinically relevant among individuals with history of injection drug use<sup>[151]</sup>. HIV infection is associated with faster progression of HCV-related liver fibrosis<sup>[152,153]</sup> as well as earlier occurrence of decompensated liver disease<sup>[154,155]</sup>, liver cancer<sup>[156]</sup>, and liver-related death<sup>[157]</sup>. During the interferon era, co-infection with HIV compromised HCV treatment response<sup>[158,159]</sup>. However, interferon-free regimens have greatly increased the efficacy of HCV antiviral treatment among co-infected patients, both in clinical trials<sup>[160]</sup> and in real-life scenarios<sup>[161,162]</sup>. On the other hand, HCV infection is associated with increased risk of ART-related liver toxicity<sup>[163]</sup>, which is even higher with concurrent alcohol use<sup>[164]</sup>. In cases of HCV/HIV co-infection, alcohol use is also associated with poorer treatment adherence<sup>[165]</sup>, and seems to increase HCV RNA levels<sup>[166,167]</sup>.

Until recently, the impact of alcohol use on HCV-related liver disease in HIV-infected patients had not received much attention in the literature. Older studies suggest that alcohol use is associated with biopsy-proven liver fibrosis in cases of co-infection<sup>[152,168]</sup>. However, studies using non-invasive methods have produced mixed results, highlighting the shortcomings of non-invasive methods-including methods relying on ALT, AST, and platelets-in patients with ALD<sup>[70,69]</sup>. Table 3

summarizes the different studies that have used non-invasive methods to evaluate liver fibrosis in patients with AUD and HCV infection or HCV/HIV co-infection.

A cross-sectional study in an urban HIV/AIDS cohort revealed that heavy alcohol use was associated with advanced liver fibrosis measured using the APRI score<sup>[169]</sup>. However, when the patients were stratified by HCV infection, high APRI score was associated with hazardous alcohol use only among patients without HCV infection<sup>[169]</sup>. Blackard *et al*<sup>[170]</sup> investigated a cohort of women, and demonstrated that alcohol use was not associated with FIB-4 values among HCV/HIV co-infected patients. Within our cohort of AUD patients, FIB-4 was significantly higher among HCV/HIV co-infected patients compared to in HCV monoinfected patients<sup>[171]</sup>. In the HIV-LIVE cohort, lifetime alcohol consumption<sup>[172]</sup> was not associated with the absence of liver fibrosis (FIB-4 < 1.45), and similar results were found for the presence of advanced liver fibrosis (FIB-4 ≥ 3.25) and among patients with HCV infection<sup>[173]</sup>. A study in the VACS cohort-which included a larger number of patients and a different measure of alcohol consumption-reported greater risks of advanced liver fibrosis (measured based on FIB-4) among co-infected patients who exhibited nonhazardous drinking (OR = 14.2, 95%CI: 5.91-34.0) or hazardous/binge drinking (OR = 18.9, 95%CI: 7.98-44.8), or who had alcohol-related diagnoses (OR = 25.2, 95%CI: 10.6-59.7) relative to uninfected individuals who were nonhazardous drinkers<sup>[174]</sup>. The somewhat discordant results among studies may be partly due to differences in the methods used to describe alcohol use and other characteristics of the study population<sup>[169-174]</sup>.

French researchers investigating HCV/HIV co-infected patients recently found that advanced liver fibrosis (measured with transient elastography) was more common among those with an alcohol-related diagnosis (OR = 3.06, 95%CI: 1.42-6.60) compared

to non-hazardous drinkers<sup>[175]</sup>. Elastography may be more reliable than laboratory markers for assessing liver fibrosis in HCV/HIV co-infected patients with AUD. Additionally, the combination of HCV infection and alcohol use is associated with greater mortality within HIV/AIDS cohorts<sup>[79,176]</sup>, highlighting the need to further address alcohol use in co-infection. Although it can be challenging, it is feasible to reduce alcohol use in the setting of HCV/HIV co-infection<sup>[177]</sup>.

## CONCLUSION

To reduce the impact of HCV, HIV and ethanol on liver disease, patients with AUD should be screened for HCV and HIV infection, and interventions should focus on both reducing alcohol consumption and treating viral infections. Moreover, patients with HCV infection or HCV/HIV co-infection should be screened for unhealthy alcohol use to prevent end-stage liver disease. Several treatment interventions are efficacious for reducing alcohol consumption among individuals with HCV infection or HCV/HIV co-infection.

In settings where AUD often coexists with other substance use and viral co-infections, higher levels of co-morbidities are expected. Health care facilities for treatment interventions and multidisciplinary approaches must be widely accessible for managing AUD and associated diseases.

### Abstract

Hepatocellular carcinoma (HCC) is the second most common cause of cancer-related death in the world. Radical treatment of HCC in early stages results in a long disease-free period and improved overall survival. The choice of optimal management strategy for HCC mainly depends on the severity of the underlying liver disease. For patients with decompensated liver cirrhosis and HCC within Milan criteria (MC), liver transplant (LT) is the choice of treatment. However, for patients with good residual liver reserve and HCC within MC, selection of other curative treatments such as liver resection (LR) or radiofrequency ablation may be a reasonable alternative. For patients without cirrhosis, LR can result in an overall survival similar to that provided by LT. Therefore, it is an accepted alternative to LT especially in areas with organ shortage. However, the cumulative 5-year recurrence rate of HCC post LR might be as high as 70%. For initial transplant-eligible (within MC) patients with recurrent HCC post LR, salvage liver transplant (SLT) was first proposed in 2000. However, most patients with recurrent HCC considered for SLT are untransplantable cases due to HCC recurrence beyond MC or comorbidity. Thus, the strategy of opting for SLT results in the loss of the opportunity of LT for these patients. Some authors proposed the concept of "de principe liver transplant" (*i.e.*, prophylactic LT before HCC recurrence) to prevent losing the chance of LT for these potential candidates. Factors associated with the failure of SLT will be dissected and discussed in three parts: Patient, tumor, and underlying liver disease. Regarding patient-related factors, the rate of transplantability depends on patient compliance. Patients without regular follow-up tend to develop HCC recurrence beyond MC at the time of tumor detection. Advancing age is another factor related to severe comorbidities when LT is considered for HCC recurrence, and these elderly candidates become ineligible as time goes by. Regarding tumor-related factors, histopathological features of the resected specimen are used mostly for determining the prognosis of early HCC recurrences. Such

prognostic factors include the presence of microvascular invasion, poor tumor differentiation, the presence of microsatellites, the presence of multiple tumors, and the presence of the gene-expressing signature associated with aggressive HCC. These prognostic factors might be used as a selection tool for SLT or prophylactic LT, while remaining mindful of the fact that most of them are also prognostic factors for post-transplant HCC recurrence. Regarding underlying liver disease-related factors, progression of chronic viral hepatitis and high viral load may contribute to the development of late (*de novo*) HCC recurrence as a consequence of sustained inflammatory reaction. However, correlation between the severity of liver fibrosis and tumor recurrence is still controversial. Some prognostic scoring systems that integrate these three factors have been proposed to predict recurrence patterns after LR for HCC. Theoretically, after excluding patients with high risk of post-transplant HCC recurrence, either by observation of a cancer-free period or by measurement of biological factors (such as alpha fetoprotein), prophylactic LT following curative resection of HCC could be considered for selected patients with high risk of recurrence to provide longer survival.

**Key words:** Liver transplant; Hepatocellular carcinoma; Salvage; Risk factor; Resection; Microvascular invasion; Recurrence; Prophylactic

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary liver cancer. It has a high prevalence in Asia and sub-Saharan Africa due to the high incidence of chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections in these regions. It is much more common in men than in women. In men, HCC is the second leading cause of cancer-related death in developing countries and worldwide<sup>[1]</sup>.

It is well established that liver transplant (LT) is the treatment of choice for patients with early HCC and decompensated liver disease<sup>[2]</sup>. The most notable criteria for transplant in HCC cases is the Milan criteria (MC)

described by Mazzaferro *et al.*<sup>[3]</sup> in 1996. In selected patients with a single tumor less than 5 cm in diameter, or no more than 3 tumors each 3 cm or less in diameter, LT can offer a > 70% 5-year survival and a < 10% 5-year recurrence rate<sup>[4]</sup>. However, for patients with early HCC and cirrhotic liver with preserved function, the choice between liver resection (LR) and LT has been an issue of debate<sup>[5]</sup>. Donor organ shortage is the major problem with using LT for this group of patients<sup>[6]</sup>. Primary LR can achieve comparable 5-year overall survival rates (> 70%) with proper patient selection and application of advanced surgical techniques over the last decades<sup>[7-10]</sup>. However, the intrahepatic recurrence rate within 5 years of LR in cirrhotic patients is > 70%<sup>[11]</sup>. In the era of organ shortage, Majno *et al.*<sup>[12]</sup> first proposed a treatment strategy that involves performing LR as the first-line treatment for patients with single small HCC and preserved liver function and reserving LT for patients with recurrent HCC within MC. This is the so-called "salvage liver transplant (SLT)" strategy. Most patients with HCC recurrence cannot benefit by this strategy in the real-world clinical setting due to recurrent HCC beyond MC at detection or poor general condition unsuitable for LT. We speculate whether early LT before the development of untransplantable recurrence can save their lives and eradicate the cancer. This concept of prophylactic LT for high-risk recurrent HCC before the development of recurrence is also called "de principe LT"<sup>[13]</sup>. Recently, some authors suggested the use of the histopathological features of the specimen of the resected tumor as the selection tool for LT to improve the outcome of cases with high recurrence rate after LR<sup>[13-16]</sup>. However, most of these histopathological features are also prognostic factors of post-transplant HCC recurrence. This review will discuss the treatment strategy of LT before HCC recurrence (*de principe*) and at recurrence (*salvage*) for initial transplant-eligible patients developing recurrent tumors after LR. Poor prognostic clinicopathological factors associated with early and late HCC recurrence are also reviewed in three parts, "patient", "tumor", and "underlying liver disease". At last, we introduce some scoring systems for predicting HCC recurrence after LR.

## LT AT HCC RECURRENCE: SALVAGE LT

LR as the first-line treatment for primary small HCC in compensated cirrhotic liver is widely adopted with an acceptable survival rate but a high recurrence rate. No treatment guidelines exist for recurrent HCC after LR. Salvage curative treatment for recurrent HCC following primary LR includes SLT, repeat LR, and radiofrequency ablation (RFA). In our group, Lee *et al.*<sup>[17]</sup> first reported in 1995 that the cumulative 5-year survival rates in patients undergoing repeated hepatic resection after the first operation was 65.1%, and according to Ho *et al.*<sup>[18]</sup>, the latest 5-year survival rates after recurrence in patients receiving repeat hepatectomy was 72%,

which is similar to that of patients who have undergone primary resection and have no recurrence. Chan *et al.*<sup>[19]</sup> report comparable survival rates and tumor-free survival rates in SLT and repeat LR, but RFA yields poorer outcome than SLT and repeat LR (5-year survival rates in SLT, repeat LR, and RFA: 50.0%, 48.0%, 11.4%, respectively; 5-year tumor-free survival rates in SLT, repeat LR, and RFA: 57.9%, 49.3%, 10.6%, respectively). RFA is associated with poor survival rates but can be considered for patients not suitable for LR. In another series by Yamashita *et al.*<sup>[20]</sup> which compared the outcomes between repeat LR and SLT, the perioperative outcomes including the operation time, intraoperative blood loss, the length of hospital stay, and post-operative morbidity, were all significant worse in the SLT group. No significant difference was observed in the overall survival between these two groups, but patients who underwent SLT had better disease-free survival<sup>[20,21]</sup>. The difference between the results of these two salvage treatments is similar to the difference between primary LT and initial LR for early HCC in compensated liver. However, in areas without sufficient donors, repeat LR is the only treatment for patients with recurrent HCC and enough remnant liver that can provide an overall survival comparable to SLT. Mise *et al.*<sup>[22]</sup> report the result of third or more repeat hepatectomies for recurrent HCC. The 5- and 10-year overall survival rates from the initial hepatectomy are 91.4% and 75.5% respectively, and the 5-year disease-free survival rate after the second hepatectomy is 17.9%.

Comparison of primary LT and SLT for HCC within MC in recent studies revealed similar perioperative course, morbidity, overall survival, and disease-free survival<sup>[16,23-28]</sup>, while a previous study showed the association of LT after resection and higher operative mortality, an increase of recurrence, and poorer outcomes<sup>[29]</sup>. In the systemic review by Chan *et al.*<sup>[30]</sup> the median 5-year overall and disease-free survival rates in SLT are 62% and 67%, respectively. In the era of organ shortage, LR should be considered as the primary curative treatment for resectable tumors in compensated livers, and SLT is a safe and effective strategy for initial transplant-eligible patients when recurrent HCC or hepatic function deterioration occur<sup>[12]</sup>.

The SLT strategy is widely acceptable for patients with previous transplant-eligible HCC. However, some authors also advocate the strategy of performing LR as one of the locoregional therapies for tumor downstaging in patients with initial HCC beyond LT criteria and performing LT after HCC recurrence<sup>[31]</sup>. The results of this downstaging strategy showed better survival outcomes as compared with patients with HCC recurrence who undergo LR without SLT. However, for post-LR recurrent HCC beyond MC, the results of SLT are not beneficial and not recommended in a recent report<sup>[22]</sup>. Prospective studies are needed to examine the long-term outcomes of extending the criteria of LT for intermediate-advanced HCC either before or after tumor recurrence.

## LT BEFORE RECURRENCE: CONCEPT OF PROPHYLACTIC LT

As previous study stated, SLT has been proven effective for patients with recurrent HCC within the criteria of the following: Tumor recurrence within MC, patient adherence to a regular follow-up with imaging to detect early recurrence, and good general patient condition for LT. However, the intention-to-treat analysis by Fuks *et al.*<sup>[32]</sup> showed that nearly half of the patients with recurrent HCC following LR did not undergo LT, including one-third due to recurrence beyond MC. Other studies also report that 20% to 80% of the patients considered for SLT are not transplantable due to recurrence beyond transplant criteria or advanced age with significant comorbidity<sup>[8,15,29,33,34]</sup>. This means that with the strategy of SLT, we lose the chance of LT in originally transplantable patient. Sala *et al.*<sup>[13]</sup> first reported four cases of prophylactic LT, performed based on the expectation of early recurrence according to the gross and microscopic features of the resected specimen, including microvascular invasion and additional nodules. Patients with high risk of recurrence as identified by histopathological findings were enlisted for LT. Scatton *et al.*<sup>[14]</sup> predicted the risk of HCC recurrence after LR on the basis of the histological features of the resected specimen (including Edmondson score, vascular invasion, nuclear grade, and architectural growth pattern), which are used as the selection tool for LT. In this series, six patients were enlisted and underwent prophylactic LT without evidence of residual disease. However, the population of this study was heterogeneous, with three of the six patients in this study having HCC beyond MC at resection, and the other three patients having resected HCC within MC. These six patients are all alive without recurrence with mean follow-up of 55 mo.

Tribillon *et al.*<sup>[34]</sup> report the largest series of prophylactic LT in intention-to-treat analysis of 63 patients with intermediate or bad pathological factors (microvascular invasion and/or moderate/poor differentiation) in the resected specimen being enlisted for LT prior to recurrence (de principe group). The overall survival of this group was compared to 48 patients with favorable pathological features being enlisted for LT at the time of HCC recurrence (salvage group). The 5-year survival rate since primary LR was significantly better in the de principe group as compared with the salvage group (84.6% vs 74.8%), and the 5-year disease survival rate was also better in the de principe group (79.3% vs 72.3%).

This active attitude of enlisting patients for LT prior to recurrence can treat both potential recurrent HCC and underlying liver disease. However, literature about this strategy is scarce. The most important viewpoint discussed in the literature about this prophylactic strategy is preventing original transplant-eligible patients from developing beyond MC at recurrence and provide longer survival. However, if more stringent follow-ups and increased accuracy of imaging studies lead to

**Table 1 Comparison between prophylactic liver transplant and wait-and-see before hepatocellular carcinoma recurrence**

The strategy	Prophylactic LT	Wait-and-see
Immunosuppressant exposure	Life-long	Nil
Surgical morbidity and mortality	Present	Nil
Long-term HCC recurrence	Lower <sup>[32]</sup>	Higher <sup>[11]</sup>
Survival benefit (5-year survival rate)	84.6% <sup>[32]</sup>	Around 70% <sup>[7-10]</sup>
Further management after recurrence	Hepatectomy, RFA, TACE, Sorafenib, Yttrium-90	SLT, repeat hepatectomy, RFA, TACE, Sorafenib, Yttrium-90

LT: Liver transplant; RFA: Radiofrequency ablation; TACE: Transcatheter arterial chemoembolization; HCC: Hepatocellular carcinoma.

**Table 2 Prognostic factors of early hepatocellular carcinoma recurrence after liver resection and after liver transplantation**

Risk factor of HCC recurrence	After liver resection	After liver transplantation
Serological		
AFP	> 400 ng/mL <sup>[49]</sup>	> 1000 ng/mL <sup>[34,35]</sup>
Tumor gross		
Tumor size	> 3 cm <sup>[30]</sup> or > 5 cm <sup>[37,41,65]</sup>	> 6 cm <sup>[35]</sup>
Tumor number	> 3 <sup>[65]</sup>	≥ 4 <sup>[35]</sup>
Satellite nodules	Yes <sup>[30,63,66]</sup>	Yes <sup>[33]</sup>
Tumor microscopic		
Tumor differentiation	Intermediate, or poor differentiation, or undifferentiation <sup>[30,49,65]</sup>	Poor differentiation, or undifferentiation <sup>[33]</sup>
Microvascular invasion	Yes <sup>[30,37,41,49,64-66]</sup>	Yes <sup>[33,34]</sup>
Liver parenchyma		
Severity of cirrhosis	Controversial <sup>[67-69]</sup>	No
Milan criteria	Yes <sup>[68]</sup> (predict recurrence within/beyond MC)	Yes <sup>[3]</sup>

HCC: Hepatocellular carcinoma; AFP: Alpha-fetoprotein; MC: Milan criteria.

early detection of recurrent tumor for these patients, does the result still justify this novel strategy? Salvage treatment after detection of recurrent HCC includes LT, repeat hepatectomy, RFA, transcatheter arterial chemoembolization, sorafenib, and trans-arterial radio-rembolization (Yttrium-90). The choice of these salvage treatment depends on the extent of underlying liver disease, the aggressiveness of tumor at recurrence, and the general condition of the patient. LT has been proven to be correlated with better overall survival and disease-free survival rates with careful patient selection as a curative method, as compared with other salvage treatments previously stated<sup>[17-19]</sup>. However, for cases without evidence of recurrence, it is unclear if we should choose prophylactic LT for patients with a high risk of recurrence or just close follow-ups and salvage treatment at recurrence. The accompanying morbidity and mortality with prophylactic LT and the limited number of organs also hinder this aggressive strategy. The comparison of the benefits and risks between prophylactic LT and the wait-and-see strategy followed by salvage treatment is listed in Table 1.

On the other hand, is a higher probability of recurrence after initial hepatectomy equivalent to a shorter disease-free survival after salvage or prophylactic LT? If HCC recurs easily after salvage or prophylactic LT, this strategy became meaningless. Most prognostic factors associated with recurrence after LR are also relevant to post-transplant recurrence, including microvascular invasion of HCC, larger tumor size, higher tumor number, poorer differentiation of the tumor, and higher level of alpha-fetoprotein (AFP)<sup>[35-37]</sup> (Table 2). It is difficult to

distinguish patients with higher recurrence after hepatectomy from those with possible post-transplant HCC recurrence. A period of observation should be considered after primary LR to identify the aggressiveness of occult HCC in the absence of specific predicting factors. Further investigation is needed to stratify patients for better application of treatment after hepatectomy.

## CLINICOPATHOLOGICAL FACTORS ASSOCIATED WITH HIGH-RISK RECURRENCE

The most important issue in adopting prophylactic LT is the identification of prognostic factors associated with high-risk recurrence. Tumor dissemination from primary tumor before resection and new lesion development in underlying oncogenic cirrhotic parenchyma are two major pathways leading to recurrence<sup>[38-42]</sup>. The former is associated with early recurrence within 2 years after primary resection, while the latter is more likely associated with late recurrence<sup>[42-45]</sup>. We summarize the recent data in the literature on the clinicopathological factors linked with HCC recurrence.

## PATIENT-RELATED FACTORS: DEMOGRAPHIC AND BIOCHEMICAL FACTORS

The age factor associated with recurrence after resection remains controversial. Older age at resection may be

suggestive of long-standing chronic liver disease and higher susceptibility to HCC recurrence over time. Older age (65 years or more) is an independent risk factor for tumor recurrence, as shown in the recent major series by Fan *et al.*<sup>[46]</sup> and Pompili *et al.*<sup>[47]</sup>. However, in the series of HBV-related HCC by Mathews *et al.*<sup>[48]</sup> younger age (40 years or less) was closely associated with more aggressive disease and shorter disease-free survival after resection. The other major series by Hung *et al.*<sup>[49]</sup> does not show old age (60 years or more) to be a poor independent factor for tumor recurrence.

Serum AFP level has been conventionally used as a simple and effective tool for routine surveillance of HCC and for monitoring recurrence following treatment<sup>[50]</sup>. Elevated serum AFP level at the time of resection has been frequently reported to predict the risk of post-resection recurrence of HCC<sup>[51-56]</sup>. Many studies have proposed the relationship between the pretreatment AFP level and tumor-free survival using different cut-off values of AFP level (for example, 20, 100, 400 or 1000 ng/mL)<sup>[44,49,57,58]</sup>. Higher pretreatment serum AFP level is associated with shorter disease-free period. Ho *et al.*<sup>[51]</sup> proposed the value of 400 ng/mL as the cut-off AFP level to predict untransplantable recurrence after primary curative resection of HCC. However, in another study by Shim *et al.*<sup>[59]</sup> the result of a test based on propensity score, included 525 patients who underwent HCC resection and showed no correlation between preoperative serum AFP level and the risk of recurrence. Serum AFP level can also be abnormally high in chronic hepatitis C and advanced cirrhotic liver without HCC<sup>[60]</sup>. It is controversial to use serum AFP level as the predictor of HCC recurrence. Instead of predicting the risk of recurrence, the higher level of serum AFP should be considered as the consequence of aggressive tumor features such as microvascular invasion and poorer tumor differentiation, which indicate worse prognosis<sup>[61]</sup>. Serum AFP level > 1000 ng/mL is also reported to be associated with higher post-transplant recurrence due to the correlation with more aggressive tumor biology<sup>[35-37]</sup>.

## TUMOR-RELATED FACTORS: HISTOPATHOLOGICAL FACTORS

It is well known that early recurrence after HCC resection is related to tumor dissemination prior to operation<sup>[42]</sup>. The histopathological profile obtained from the resected specimen has been used to predict the risk of tumor dissemination and as an objective selection tool for LT in the last decade<sup>[13,14,32,34]</sup>. Among these factors, microvascular invasion of the tumor is the most critical factor in disease dissemination. As seen in most cancers, angiogenesis, or new vessel formation, is essential for HCC growth<sup>[62]</sup>. In advanced stages of tumor progression, HCC cells develop the ability to invade adjacent blood vessels and potentially begin to metastasize. The presence of microvascular invasion is the hallmark of aggressive tumor behavior

and associated with high recurrence rate after curative resection<sup>[63]</sup>. Sumie *et al.*<sup>[64]</sup> report 3-year recurrence-free survival rates in HCC with and without microvascular invasion to be 27.7% and 67.5%, respectively. Other poor histopathological features, like the presence of satellite nodules and poor tumor differentiation, are also recognized, along with microvascular invasion, to predict early recurrence<sup>[32,39,43,65-68]</sup>. Most of these poor histopathological factors associated with early recurrence after LR are also predictors of recurrence after LT, including larger tumor size, larger tumor number, satellite nodules, poorer tumor differentiation, and microvascular invasion (Table 2). These features are linked to the aggressiveness of the tumor biology and predict the recurrence both after LR and LT. Patients with a tendency of post-LR recurrence may also develop a risk of post-LT recurrence. While considering prophylactic LT for patients with these poor histopathological features, cut-off criteria should be made to exclude those with more aggressive HCC and also potentially easy recurrence after LT.

## UNDERLYING LIVER DISEASE-RELATED FACTORS: VIROLOGICAL FACTORS

The preneoplastic status of underlying liver disease is considered to relate with elevated carcinogenesis and de novo tumor development in late phase recurrence (2 years after resection)<sup>[42]</sup>. The correlation between stage of liver fibrosis and disease-free survival is controversial. Grazi *et al.*<sup>[69]</sup> and Taura *et al.*<sup>[70]</sup> showed that HCC without cirrhosis has better disease-free survival compared with HCC with cirrhosis after curative resection in Asia, while Beard *et al.*<sup>[71]</sup> showed the reverse results for western countries. Instead of the severity of liver cirrhosis, the sustained necroinflammatory reaction resulting from higher hepatitis activity may play a more important role in the development of secondary primary HCC two years after resection. Initial high HBV viral loads > 2000 IU/mL<sup>[72]</sup> or 10<sup>6</sup> copies/mL<sup>[45]</sup> at the time of HBV-related HCC resection or one month post resection HBV DNA > 20000 IU/mL<sup>[49]</sup> are all proven to be independent risk factors for tumor recurrence. Ongoing HBV replication can induce active hepatitis and subsequent inflammation in oncogenic liver parenchyma leading to *de novo* recurrent HCC. Regarding Hepatitis C, patients with HCV infection tend to have higher hepatitis activity, which is related to elevated carcinogenesis, than patients with HBV infection<sup>[42]</sup>. However, the difference in recurrence-free survival is not significant between patients with HBV infection or those with HCV infection<sup>[73,74]</sup>. A recent national study of 11950 patients in Japan by Utsunomiya *et al.*<sup>[75]</sup> showed that patients without viral hepatitis have a significant lower risk of HCC recurrence than those with HBV or HCV infection.

## SCORING SYSTEM

Some authors propose the scoring system that integrated

**Table 3** Scoring systems for predicting hepatocellular carcinoma recurrence

Ref.	Basis of scoring system	Prognostic factors	Discriminated scores
Pan <i>et al</i> <sup>[76]</sup>	Glasgow prognostic score	Preoperative CRP > 10 mg/L (1 point) Albumin < 3.5 g/L (1 point)	0, 1, 2
Fuks <i>et al</i> <sup>[32]</sup>	Histological features	Microscopic vascular invasion Presence of satellite nodules Tumor size > 3 cm Poor differentiated tumor Cirrhosis	< 3 factors ≥ 3 factors
Roayaie <i>et al</i> <sup>[66]</sup>	Degree of vascular invasion	Invasion of a vessel with a muscular wall (1 point) Invasion of a vessel ≥ 1 cm from the tumor capsule (1 point)	0, 1, 2
Lee <i>et al</i> <sup>[68]</sup>	Clinical risk score	Initial disease beyond Milan criteria Microsatellites or multiple tumors Lymphovascular invasion (1 point for each factor)	0, 1, 2, 3

Higher scores indicate higher recurrence rate. CRP: C-reactive protein.

clinical, biochemical, and histopathological factors to classify the risk of HCC recurrence after resection<sup>[32,66,68,76]</sup> (Table 3). Most scoring systems consist of the extent of tumor invasiveness, while the Glasgow prognostic score originally used in the prediction of outcomes among non-small-cell lung cancer patients<sup>[77]</sup> is composed of the serum levels of C-reactive protein (CRP) and albumin. The higher serum level of CRP and lower serum level of albumin present in the systemic inflammatory response is associated with a more active viral hepatitis in the remnant liver parenchyma<sup>[76]</sup>. The higher scores in each system indicate shorter disease-free period and poorer outcome. The clinical risk score system by Lee *et al*<sup>[68]</sup> uses pathological factors to predict the likelihood of recurrence after LR, and it can be used to identify patients who may lose the chance of SLT at recurrence. Whether this strategy system applies to prophylactic liver transplantation needs further validation.

## CONCLUSION

Prophylactic LT is a novel concept for patients with high-risk recurrent HCC after primary resection before recurrence. Microvascular invasion, larger tumor size, larger tumor number, and poor tumor differentiation are all predictors for recurrence after LR and LT, while serum AFP level > 1000 ng/mL is the unique feature for predicting recurrence after LT. The length of observation after prophylactic LT should be established to examine the occult aggressiveness of the HCC resulting in recurrence after LT. It is safe and effective when patients who fulfilled MC at the time of resection are carefully selected. Large prospective studies are required to clarify the long-term results of this strategy.

## Abstract

### AIM

To study impact of baseline mental health disease on hepatitis C virus (HCV) treatment; and Beck's Depression Inventory (BDI) changes with sofosbuvir- and

interferon-based therapy.

## METHODS

This is a retrospective cohort study of participants from 5 studies enrolled from single center trials conducted at the Clinical Research Center of the National Institutes of Health, Bethesda, MD, United States. All participants were adults with chronic HCV genotype 1 infection and naïve to HCV therapy. Two of the studies included HCV mono-infected participants only (SPARE, SYNERGY-A), and 3 included human immunodeficiency virus (HIV)/HCV co-infected participants only (ERADICATE, PFINPK, and ALBIN). Patients were treated for HCV with 3 different regimens: Sofosbuvir and ribavirin in the SPARE trial, ledipasvir and sofosbuvir in SYNERGY-A and ERADICATE trials, and pegylated interferon (IFN) and ribavirin for 48 wk in the PIFNPK and ALBIN trials. Participants with baseline mental health disease (MHD) were identified (defined as either a DSM IV diagnosis of major depression, bipolar disorder, schizophrenia, generalized anxiety, and post-traumatic stress disorder or requiring anti-depressants, antipsychotics, mood stabilizers or psychotropics prescribed by a psychiatrist). For our first aim, we compared sustained virologic response (SVR) and adherence (pill counts, study visits, and in 25 patients, blood levels of the sofosbuvir metabolite, GS-331007) within each study. For our second aim, only patients with HIV coinfection were evaluated. BDI scores were obtained pre-treatment, during treatment, and post-treatment among participants treated with sofosbuvir-based therapy, and compared to scores from participants treated with interferon-based therapy. Statistical differences for both aims were analyzed by Fisher's Exact, and *t*-test with significance defined as a *P* value less than 0.05.

## RESULTS

Baseline characteristics did not differ significantly between all participants with and without MHD groups treated with sofosbuvir-based therapy. Among patients treated with sofosbuvir-based therapy, the percentage of patients with MHD who achieved SVR was the same as those without (SPARE: 60.9% of those MHD compared to 67.6% in those without, *P* = 0.78; SYNERGY-A: 100% of both groups; ERADICATE: 100% compared to 97.1%). There was no statistically significant difference in pill counts, adherence to study visits between groups, nor mean serum concentrations of GS-331007 for each group at week 2 of treatment (*P* = 0.72). Among patients with HIV co-infection, pre-treatment BDI scores were similar among patients treated with sofosbuvir, and those treated with interferon (sofosbuvir-based 5.24, IFN-based 6.96; *P* = 0.14); however, a dichotomous effect on was observed during treatment. Among participants treated with directly acting antiviral (DAA)-based therapy, mean BDI scores decreased from 5.24 (pre-treatment) to 3.28 during treatment (1.96 decrease, *P* = 0.0034) and 2.82 post-treatment. The decrease in mean score from pre- to post-treatment was statistically significant (-2.42, *P* = 0.0012). Among participants treated with IFN-based therapy, mean BDI

score increased from 6.96 at pre-treatment to 9.19 during treatment (an increase of 2.46 points, *P* = 0.1), and then decreased back to baseline post-treatment (mean BDI score 6.3, *P* = 0.54). Overall change in mean BDI scores from pre-treatment to during treatment among participants treated with DAA-based and IFN-therapy was statistically significant (-1.96 and +2.23, respectively; *P* = 0.0032). This change remained statistically significant when analysis was restricted to participants who achieved SVR (-2.0 and +4.36, respectively; *P* = 0.0004).

## CONCLUSION

Sofosbuvir-based therapy is safe and well tolerated in patients with MHD. A decline in BDI associated with sofosbuvir-based HCV treatment suggests additional MHD benefits, although the duration of these effects is unknown.

**Key words:** Sofosbuvir; Direct acting antivirals; Directly acting antiviral; Hepatitis C; Mental health disease; Depression; Interferon; Beck's Depression Inventory

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The prevalence of mental health disease (MHD) among patients with chronic hepatitis C virus (HCV) can be high. However, patients with MHD may be marginalized with respect to HCV therapy and MHD is one of the most frequently cited reason for exclusion from HCV therapy. HCV therapy has evolved from interferon-based to directly acting antiviral (DAA)-based therapy with excellent tolerability and efficacy. Our study found that baseline MHD did not impact efficacy nor treatment adherence to sofosbuvir-based therapy. Furthermore, we found that Beck's Depression Inventory scores improved with sofosbuvir-based therapy, suggesting that HCV treatment with the newer DAA therapies may have additional mental health benefits.

Safe and effective sofosbuvir-based therapy in patients with mental health disease on hepatitis C virus treatment. *World J Hepatol* 2016; 8(31): 1318-1326 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i31/1318.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i31.1318>

## INTRODUCTION

An estimated 185 million people worldwide are currently infected with chronic hepatitis C virus (HCV), and approximately 3 to 4 million new infections occur each year<sup>[1]</sup>. Chronic infection with HCV is a leading cause of progressive liver disease, end-stage liver disease, hepatocellular cancer, and remains the leading indication for liver transplantation in the United States<sup>[2-4]</sup>.

A complex interplay exists between mental health

disorders (MHD) and HCV infection<sup>[5-9]</sup>. In some cohorts, 30%-44% of all patients with HCV have an active psychiatric-most frequently depression-disorder<sup>[7,10-14]</sup>. MHD is one of the most frequently cited reason for exclusion from HCV therapy, contributing to 44% of exclusions in one study<sup>[13]</sup>. Exacerbation of psychiatric complications, adherence, concurrent substance abuse, and concern for reinfection are just some of the barriers to treatment<sup>[5]</sup>. These concerns are primarily related to interferon-based therapies, which require long treatment durations of 24 to 48 wk, high pill burdens, and multiple associated dose-limiting neuropsychiatric side effects<sup>[8,14-16]</sup>. Recent reports, however, suggest that patients with MHD can successfully achieve sustained virologic response (SVR, considered cure) rates with interferon-based regimens comparable to those without MHD<sup>[8,14,17]</sup>.

Treatment has shifted to combination all-oral, interferon-free directly acting antiviral (DAA) therapy characterized by short treatment durations of 8-24 wk<sup>[18-22]</sup>, low pill burdens, improved tolerability, and achieving SVR rates of over 90% for both treatment naïve and interferon treatment experienced<sup>[20-24]</sup>. In this study, we present data from five National Institute of Allergy and Infectious Diseases (NIAID) trials - SPARE<sup>[19]</sup> (using sofosbuvir and ribavirin), SYNERGY-A<sup>[18]</sup>, and ERADICATE<sup>[25]</sup> (both using ledipasvir and sofosbuvir), and PIFNPK<sup>[26]</sup> and ALBIN<sup>[27]</sup> [studies of interferon (IFN)-ribavirin-based therapy among patients with human immunodeficiency virus (HIV)/HCV co-infection]. This study has two aims. Firstly, we address the impact of baseline MHD on SVR and adherence to sofosbuvir-based, interferon-free therapy. Secondly, we characterize the change in Beck's Depression Inventory (BDI) scores among patients with HIV/HCV co-infection treated with sofosbuvir-based therapy and with interferon-based therapy. For our first aim we present data from three NIAID trials - SPARE<sup>[19]</sup> (using sofosbuvir and ribavirin), SYNERGY-A<sup>[18]</sup>, and ERADICATE<sup>[25]</sup> (both using ledipasvir and sofosbuvir). For our second aim, BDI scores were obtained from patients enrolled in ERADICATE, PIFNPK and ALBIN.

## MATERIALS AND METHODS

### Patients

Patients for all studies were enrolled from single center trials conducted at the Clinical Research Center of the National Institutes of Health, Bethesda, MD, United States. Adult patients with chronic HCV genotype 1 (GT-1) infection naïve to HCV therapy were included. Written or oral informed consent approved by the NIAID Institutional Review Board was obtained from all patients. Full eligibility criteria for all 5 studies are as previously published<sup>[18,19,25-28]</sup>.

### Baseline MHD and impact on SVR and adherence

SPARE was a 2-part, randomized controlled trial from October 2011 through April 2012<sup>[19]</sup>. Patients with early

to moderate liver fibrosis were treated for 24 wk with 400 mg/d of sofosbuvir and weight-based ribavirin, 400 mg in the morning, 600 mg in the evening if < 75 kg or 600 mg twice a day if > 75 kg). A second cohort of patients with all stages of fibrosis (including compensated cirrhosis) was randomized to receive 400 mg/d of sofosbuvir in combination with either weight-based ribavirin or low-dose (600 mg/d) ribavirin for 24 wk<sup>[19]</sup>.

SYNERGY-A was a phase 2a cohort study<sup>[18]</sup>. From January 2013 to December 2013, twenty GT-1 HCV-infected patients were treated for 12 wk with ledipasvir 90 mg and sofosbuvir 400 mg administered as a single combination pill (ledipasvir-sofosbuvir) taken once daily. Neither patient nor investigators were blinded<sup>[18]</sup>.

ERADICATE was an open-label phase 2b trial of ledipasvir-sofosbuvir once daily to non-cirrhotic GT-1 HCV-infected patients with stable HIV-disease<sup>[25]</sup>. From June 2013 to February 2014, fifty HCV GT-1 patients were treated for 12 wk with ledipasvir and sofosbuvir.

### Identification of baseline mental health disorders

In all three clinical trials of sofosbuvir-based therapy, patients with MHD were included. We retrospectively identified patients with baseline MHD defined as either: (1) a DSM IV diagnosis of major depression, bipolar disorder, schizophrenia, generalized anxiety, and post-traumatic stress disorder; or (2) requiring anti-depressants, anti-psychotics, mood stabilizers or psychotropics prescribed by a psychiatrist.

### Efficacy assessment

SVR, defined as undetectable HCV RNA 12 wk post completion of treatment, was the primary outcome. Plasma HCV RNA levels were measured using the real time HCV assay (Abbott), with a lower limit of quantification (LLOQ) of 12 IU/mL, and COBAS TaqMan HCV RNA assay version 2.0 (Roche), with an LLOQ of 43 IU/mL.

### Adherence assessment

For all 3 studies, we performed pill counts at set time points: Sofosbuvir and ribavirin counts in SPARE; ledipasvir-sofosbuvir counts in SYNERGY-A and ERADICATE. Sofosbuvir adherence was documented during 11 time points based on participant recall and pill counts. Missed doses were recorded only through the time of treatment discontinuation in patients who stopped treatment early. We compared the percentage of patients who completed treatment with 3 or less missed pills to those who missed more than 3. For SYNERGY-A and ERADICATE, the average number of sofosbuvir-ledipasvir pills taken by patients in each group was also calculated.

In SPARE, attendance at study visits for all participants was monitored. In addition, pharmacokinetics and pharmacodynamics of sofosbuvir and its metabolite GS-331007 were obtained and calculated on 25 participants. Levels in serum were measured at 0, 1, 2, 4, 8, 12, 24, 36 h and at 14 d after administration of sofosbuvir and ribavirin using a high-performance liquid

**Table 1** Baseline demographics of participants with mental health disease treated with ledipasvir-sofosbuvir *n* (%)

### Change in BDI among patients with HIV/HCV coinfection

PIFNPK and ALBIN were open label, non-randomized studies designed to look at the safety, toxicity, pharmacokinetics, and efficacy of interferon in combination with ribavirin. In the PIFNPK study, peginterferon alfa-2a 180 µg twice weekly (Pegasys; Roche Laboratories, Palo Alto, CA), was evaluated. In the ALBIN study, Alb-interferon (albumin/interferon alfa 2b fusion protein 900 µg subcutaneous injection every two weeks, Peg-Intron; Schering-Plough) was evaluated. Eligibility criteria as previously published<sup>[26-28]</sup>.

BDI scores were collected prior to treatment (baseline), during treatment, and one to eight weeks post-end of treatment on participants with HIV/HCV co-infection from ERADICATE, PIFNPK, and ALBIN. BDI scores for all participants, and those who achieved SVR were evaluated.

### Statistical analysis

Statistical differences in mean and observed frequencies for both aims were analyzed by Fisher's Exact, and *t*-test with significance defined as a *P* value less than 0.05. Changes in observed frequencies in SVR and adherence between participants with MHD and those without for aim 1 were analyzed by Fisher's Exact test within each study. Analyses were performed using PRISM 6.0 (GraphPad).

## RESULTS

### SVR and adherence among patients with MHD treated with sofosbuvir-based therapy

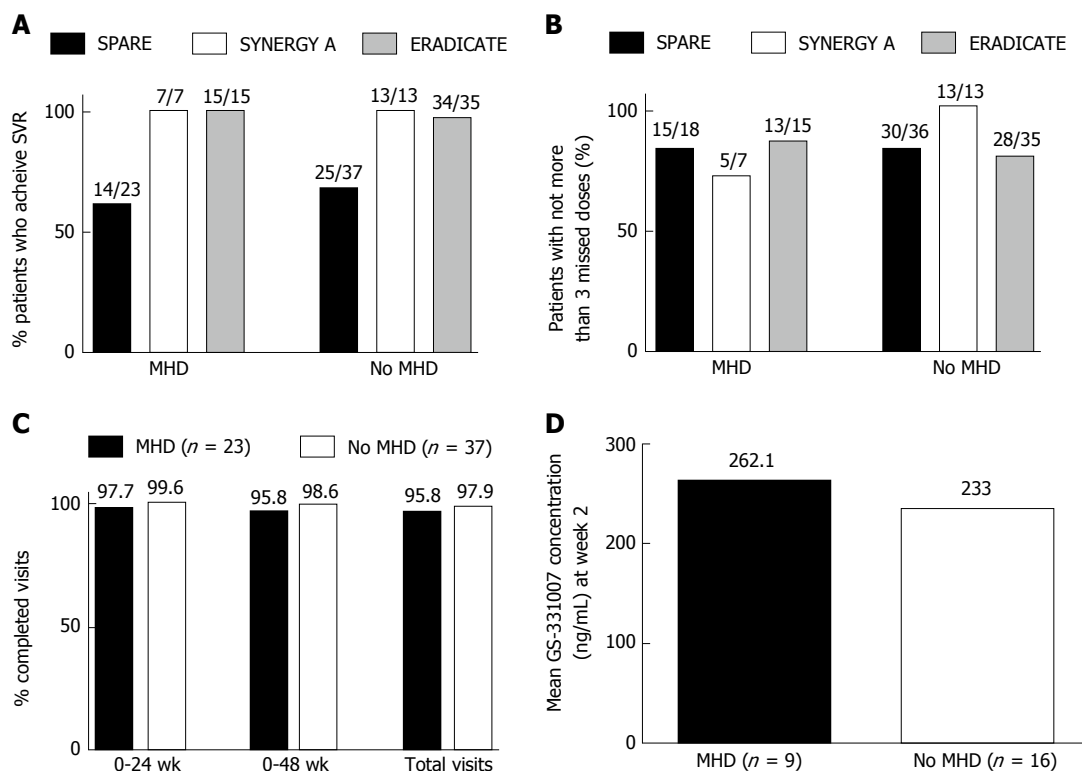

**Baseline demographics:** In all 3 studies, differences in baseline characteristics were not statistically significant between treatment groups (Table 1). The average age

was 50-60 years, and participants were predominantly African American males with GT-1a genotype.

**Mental health disease:** Thirty-eight percent of participants in SPARE, 35% in SYNERGY-A, and 30% in ERADICATE were classified as having baseline MHD. The prevalence of disorders for each study is shown in Table 1. Depression was the most common disorder and many participants had more than one diagnosis.

**Treatment outcome:** In all 3 studies the percentage of patients with MHD who achieved SVR was not statistically different from those without MHD (Figure 1A). In SPARE, 60.9% of those with MHD achieved SVR compared to 67.6% in those without (*P* = 0.78). In SYNERGY-A, 100% of both groups achieved SVR and in ERADICATE 100% of those with and 97.1% of those without MHD achieved SVR.

**Patient adherence:** (1) pill counts; in SYNERGY-A those with MHD and those without took, on average, 96.9% and 98.9% of their pills, respectively (*P* = 0.5). Both groups in ERADICATE took, on average, 97.8% of their pills. There was no statistically significant difference between groups with respect to the numbers that completed treatment with no more than 3 missed pills (Figure 1B): In SPARE, 83% in both groups completed treatment with no more than 3 missed pills. In SYNERGY-A, 5 of the 7 patients (71%) with MHD missed no more than 3 pills compared to 13 out of 13 (100%) among those without MHD (*P* = 0.11). In ERADICATE 13 out of 15 (87%) of those with MHD compared to 28 out of 35 (80%) of those without completed treatment with no more than 3 missed pills (*P* = 0.7); (2) adherence to study visit-SPARE; there was no difference in the proportion of patients with MHD and those without who completed the total required visits (95.8% vs 97.9%,

**Figure 1** Sustained virologic response and measures of adherence among participants with and without mental health disease. A: Sustained virologic response (SVR) achieved (ERADICATE, SYNERGY-A, SPARE). The comparisons of achieved SVR between groups within each study showed no significant differences for those with mental health disease (MHD) from those without MHD; B: Patients with not more than 3 missed doses (ERADICATE, SYNERGY-A, SPARE). The comparisons of adherence tracked by number of patients who had 3 or fewer total missed doses by pill count showed no significant differences for those with MHD from those without MHD in each study; C: Visit adherence (SPARE). Comparisons of total numbers of required visits completed showed no difference between those with MHD and those without during treatment (0-24 wk), through SVR24 (0-48 wk) and overall ( $P = 0.12$ ); D: GS-331007 concentration at week 2 (SPARE). Comparisons of mean GS-331007 concentration showed no difference between those with MHD and those without at week 2 of treatment ( $P = 0.72$ ).

$P = 0.12$ ) (Figure 1C); and (3) Serum levels of GS-331007-SPARE; We obtained pharmacodynamic and pharmacokinetic data for GS-331007 from 25 patients. Nine had MHD compared to 16 without. There was no statistically significant difference in the mean serum concentrations of GS-331007 for each group at week 2 of treatment ( $P = 0.72$ ) (Figure 1D).

#### BDI scores among patients with HIV/HCV co-infection treated with sofosbuvir- and IFN-based therapy

Table 2 shows the baseline characteristics of the patients treated with ledipasvir-sofosbuvir and IFN-based therapy. Age and sex were similar in both groups; however, the ledipasvir-sofosbuvir-treatment group included more African-American and fewer patients with late stage 2-4 disease. While more participants had baseline MHD in the IFN-based treatment group, baseline BDI scores were similar among the patients of both treatment groups (ledipasvir-sofosbuvir  $5.24 \pm \text{SD } 5.48$ , IFN-based  $6.96 \pm \text{SD } 8.67$ ;  $P = 0.14$ ).

#### BDI scores among all patients

**Patients treated with ledipasvir-sofosbuvir:** Mean BDI scores decreased from 5.24 at baseline to 3.28 during treatment (1.96 decrease,  $\pm \text{SD } 4.50$ ,  $P = 0.0034$ ) and 2.82 post-treatment. The decrease in

mean score from baseline to post-treatment was also statistically significant ( $-2.42 \pm \text{SD } 4.99$ ,  $P = 0.0012$ , Figure 2A).

**Patients treated with IFN:** Mean BDI score increased from 6.96 at day zero to 9.19 during treatment. This change was not statistically significant (an increase of  $2.46 \pm \text{SD } 8.96$ ;  $P = 0.1$ ), and then decreased back to baseline post-treatment (mean BDI score  $6.3 \pm \text{SD } 7.91$ ;  $P = 0.54$ , Figure 2A).

**Comparison of change in BDI scores from baseline to during and post-treatment:** The overall change in BDI scores from baseline to during treatment among patients treated with ledipasvir-sofosbuvir ( $-1.96 \pm \text{SD } 4.5$ ) compared to the change among those treated with IFN ( $+2.23 \pm \text{SD } 7.5$ ) was statistically significant ( $P = 0.0032$ , Figure 2A). However, change from baseline to post-treatment was not statistically significant ( $-2.42 \pm \text{SD } 4.99$  vs  $-0.65 \pm \text{SD } 6.24$ ;  $P = 0.18$ ).

#### BDI scores among patients who achieved SVR

**Patients treated with ledipasvir-sofosbuvir who achieved SVR:** Forty-nine out of the 50 (98%) patients treated achieved SVR. Baseline BDI was  $5.35 \pm \text{SD } 5.48$ . Mean BDI decreased to  $3.35 \pm \text{SD } 4.75$  during treatment

**Table 2** Baseline demographics of participants with hepatitis C/human immunodeficiency virus coinfection who had baseline, during, and post-treatment Beck's Depression Inventory scoring analyzed *n* (%)

Demographic	Sofosbuvir-based therapy ( <i>n</i> = 50)	Interferon-based therapy ( <i>n</i> = 26)	<i>P</i> value
Age, median	58	47	
Male	37 (74)	22 (84)	0.79
African American	42 (84)	11 (42)	0.0004
Fibrosis			0.00132
F0-1	35 (70)	10 (38)	
F2-4	15 (30)	16 (62)	
SVR	49 (98)	13 (50)	0.0001
Baseline mental health disease	15 (30)	15 (58)	0.0264

SVR: Sustained virologic response.

(an overall change of  $-2 \pm \text{SD } 4.45$ ,  $P = 0.0034$ ), and further decreased to  $2.88 \pm \text{SD } 5$  post-treatment. The change in mean BDI from baseline to post-treatment was statistically significant ( $-2.47 \pm \text{SD } 5.03$ ,  $P = 0.0012$ ).

**Patients treated with IFN and achieved SVR:** Eleven out of 26 (42%) patients achieved SVR. Among these participants, mean baseline BDI was  $4.55 \pm \text{SD } 4.48$ . This increased to  $8.91 \pm \text{SD } 7.67$  during treatment ( $P = 0.07$ ) and then returned to baseline of  $5.81 \pm \text{SD } 6.4$ .

#### Comparison of change in BDI scores from baseline to during and post-treatment among patients who achieved SVR

Mean BDI among participants treated with ledipasvir-sofosbuvir decreased  $2 \pm \text{SD } 4.54$  from baseline to during-treatment, whereas among participants treated with IFN-based therapy, mean BDI increased by  $4.36 \pm \text{SD } 7.2$ . This difference in changes in mean BDI scores was statistically significant ( $P = 0.0004$ ).

Similarly, the difference in change in mean BDI from baseline to post-treatment was also statistically significant ( $-2.47 \pm \text{SD } 5.03$ , compared to  $+1.27 \pm \text{SD } 6.36$ ,  $P = 0.038$ ).

## DISCUSSION

Sofosbuvir-based therapy was equally effective among participants with MHD, and among those without MHD. Patients with baseline MHD demonstrated similar levels of adherence with study visits, study drugs, and achieved similar rates of SVR to those who did not have a baseline MHD diagnosis. Furthermore, among participants with HIV/HCV coinfection treated with DAA therapy, we observed a statistically significant improvement in BDI scores during and after the end of treatment time point (post-treatment) compared to baseline (pre-treatment), while participants treated with IFN-based therapy saw no significant change in BDI scores.

In a study of 4084 United States veterans, psychiatric disease was identified as a predictor of non-treatment (odds ratio = 9.45)<sup>[29]</sup>. Furthermore, due to shared

**Figure 2** Beck's Depression Inventory scores among participants with hepatitis C/human immunodeficiency virus coinfection and treated with ledipasvir-sofosbuvir and interferon-based therapy. A: Mean BDI scores pre-, during, and post-treatment among all participants; Decrease in mean score from baseline to during treatment, <sup>a</sup> $P = 0.0034$ , DAA vs IFN; Decrease in mean score from baseline to post-treatment, <sup>b</sup> $P = 0.0012$ , DAA vs IFN; B: Change in mean BDI scores from baseline to post-treatment among participants who achieved SVR, <sup>d</sup> $P = 0.0004$ , DAA vs IFN. SVR: Sustained virologic response; BDI: Beck's Depression Inventory; DAA: Directly acting antiviral; IFN: Interferon.

transmission routes, HIV/HCV coinfection can be high among certain cohorts. A cross sectional study of a large cohort of patients with HIV found that 21% were coinfecting with HCV. Among these patients with HIV/HCV coinfection, depression severity scores were higher, and antidepressant medications were more often prescribed, compared to patients with HIV mono-infection<sup>[30]</sup>. Concern for emergent or worsening of neuropsychiatric side effects associated with interferon-based HCV therapy resulted in treatment deferment even for patients with stable MHD<sup>[14,31,32]</sup>. The treatment of chronic HCV, however, has evolved to interferon-free, all-oral, DAA regimens. Concerns regarding adherence to and subsequent success with DAA regimens among patients with MHD remains to be addressed.

This study has 2 aims: Firstly, to address the impact of baseline MHD on adherence to and subsequent success with DAA regimens among patients with MHD; and secondly, to describe the change in BDI scores among patients treated with a sofosbuvir-based regimen (ledipasvir-sofosbuvir) and compare this to the change among patients treated with IFN-based therapy.

In the current study, we combined results from three studies using interferon-free regimens. We compared the

effect of MHD on outcome (SVR) and three modalities of adherence (pill count, study visits and serum levels of GS-331007). The prevalence of MHD among the 3 studies (approximately 35%) was comparable to the baseline prevalence reported in other studies<sup>[7,10-14]</sup>. This study demonstrates that patients with MHD can achieve SVR at rates comparable to those without MHD. Six patients from SPARE did not complete treatment, 5 of which were identified as suffering from MHD but only one discontinuation from study could be attributed to MHD as determined by evaluation by the principal investigator. This suggests that these interferon-free regimens did not affect adherence and subsequent efficacy of therapy.

For our second aim, we analyzed baseline pre-treatment, during treatment, and post-treatment BDI scores among HIV/HCV coinfecting participants treated with a sofosbuvir-based regimen (ledipasvir-sofosbuvir) in the ERADICATE study and coinfecting participants treated with IFN-based therapy (PFINPK and ALBIN). Mean changes from baseline to during and to post-treatment were compared within, and between, each treatment group. We demonstrate that despite similar baseline BDI scores in both treatment groups, participants treated with ledipasvir-sofosbuvir saw a decrease in BDI scores during treatment and post-treatment compared to baseline. However, participants treated with IFN-based therapy did not see any change in BDI scores. In fact, when treatment groups were compared to each other and adjusted for participants who achieved SVR, the overall decrease in BDI score from baseline to post-treatment among participants treated with ledipasvir-sofosbuvir was significantly different compared to the overall increase in BDI score among participants treated with IFN-based therapy. It is conceivable that successful treatment of HCV alone should be associated with improvement in mental health. However, our findings suggest that sofosbuvir-based (and possibly any IFN-free) anti-HCV therapy may have additional mental health benefits beyond end of treatment.

This study is strengthened by multiple measures of adherence: Pill counts for all 3 studies; and in SPARE study visits with the additional objective measure of serum levels of the sofosbuvir metabolite GS-331007 at week 2 of therapy. Adherence to oral DAA therapy was high in all 3 studies, regardless of baseline MHD status, with no significant differences in pill counts, study visits, and serum GS-331007 levels between those with and without MHD. Whether the high adherence was a consequence of participant selection and the more intensive adherence interventions and counseling that are inherent to clinical trials, or related to the improved tolerability and ease of administration of the medications cannot be determined.

Limitations of this study include its small sample sizes for the three patient groups analyzed and therefore may not be sufficiently powered to detect differences. This did not allow for addressing the hypothesis that a regimen of fewer pills for shorter duration (1 pill once a day in ERADICATE and SYNERGY-A for 12 wk

compared to several pills a day for 24 wk in SPARE) was associated with significantly higher adherence. Furthermore, combining more than one study did result in a non-homogenous study population, most evident in the difference in baseline fibrosis stage among the participants undergoing BDI evaluation. Finally, this study did not include patients with severe, uncontrolled MHD therefore may have been biased towards those who already had a background of good adherence or lower BDI scores.

We hope that these preliminary findings will open the dialogue to further expand eligibility to those with MHD and lead to further, larger studies involving patients with more challenging characteristics: Not just those with baseline MHD, but also those with substance abuse - two diagnoses which are frequently paired<sup>[5-8]</sup>. Inclusion of these marginalized groups will be necessary if we are to gain an advantage in the battle to eradicate hepatitis C.

In conclusion, our study supports that patients with baseline MHD can be successfully engaged and treated with DAA therapies, and that sofosbuvir-based therapy is associated with improvement in BDI scores.

## COMMENTS

### Background

The treatment of chronic hepatitis C has evolved from interferon-based to direct acting antiviral-based therapy, with high tolerability and efficacy. Much focus has now shifted to increasing access to these new agents. However, the prevalence of mental health disease (MHD) is high among patients with hepatitis C and MHD is one of the most frequently cited reasons for withholding hepatitis C therapy.

### Research frontiers

The author's group focuses on hepatitis C eradication strategies among urban populations with unique patient populations that are predominantly African American, with advanced liver fibrosis, and high prevalence of human immunodeficiency virus co-infection and MHD. The authors believe that patients with MHD can be safely and effectively treated for hepatitis C with direct acting antiviral therapy. The findings of this study supports this hypothesis.

### Innovations and breakthroughs

Patients with mental health diseases may be excluded from hepatitis C therapy due to concerns for exacerbation of psychiatric complications, adherence, concurrent substance abuse, and reinfection due to continued high-risk behaviors. Hepatitis C therapy has evolved from interferon-based to direct acting antiviral agents, which are associated with minimal side effects. However, the high cost of these agents has led to restricted access to these medications. This study addresses the concerns regarding adherence to and subsequent success with directly acting antiviral regimens among patients with MHD. Furthermore, the findings of this study suggest that sofosbuvir-based therapy may be associated with improvements in Beck's Depression Inventory (BDI) scores.

### Applications

The findings of this study supports policy change to increase eligibility and access to hepatitis C therapy with new direct acting antiviral therapies among patients with mental health disease.

### Terminology

Sofosbuvir is a direct acting antiviral nucleotide inhibitor that acts upon the hepatitis C NS5B polymerase, preventing viral replication, and is the backbone to several hepatitis C treatment regimens. BDI is a multiple-choice tool for

measuring the severity of depression.

## Peer-review

Study of mental health in hepatitis C virus treated patients is considered to be a good practical point.

Yoichi Kawano, Department of Surgery, Nippon Medical School, Tokyo 113-0022, Japan

Zhao-You Tang, Liver Cancer Institute and Zhongshan Hospital, Fudan University, Shanghai 200043, China

Jun-Fang Ji, Life Sciences Institute, Zhejiang University, Hangzhou 310058, Zhejiang Province, China

**Author contributions:** All the authors contributed to the manuscript.

**Institutional review board statement:** This study was reviewed and approved by the University of Hawaii Institutional Review Board. Data from Shanghai is from a cohort in which the anonymous data is publically available. Data from the Nippon Medical Center did not require Institutional review as it is retrospective anonymous data.

**Informed consent statement:** This is not applicable since this is a retrospective study. Patients were not required to give informed consent to the study because the analysis used anonymous clinical data that were obtained after each patient agreed to treatment by written consent.

**Conflict-of-interest statement:** Dr Wong is a speaker for Bayer Healthcare. The other authors have no conflicts of interest to declare.

**Data sharing statement:** No additional data are available.

**Open-Access:** This article is an open-access article which was selected by an in-house editor and fully peer-reviewed by external reviewers. ## Abstract

### AIM

To compare patients who underwent resection of early stage hepatocellular cancer (HCC) in three different countries.

### METHODS

This retrospective study characterizes 573 stage I / II HCC patients treated with liver resection in 3 tertiary-referral centers: Tokyo ( $n = 250$ ), Honolulu ( $n = 146$ ) and Shanghai ( $n = 177$ ).

### RESULTS

Shanghai patients were younger, predominantly male, hepatitis-B seropositive (94%) and cirrhotic (93%). Tokyo patients were older and more likely to have hepatitis-C (67%), smaller tumors, low albumin, and normal alpha-fetoprotein. The Honolulu cohort had the largest tumors and 30% had no viral hepatitis. Age-adjusted mortality at 1 and 5-years were lower in the

Tokyo cohort compared to Honolulu and there was no difference in mortality between Shanghai and Honolulu cohorts. Elevated alpha-fetoprotein, low albumin and tumor > 5 cm were associated with increased 1-year mortality. These factors and cirrhosis were independently associated with increased 5-year mortality. Independent risk factors of survival varied when examined separately by center.

### CONCLUSION

The profile of early-stage HCC patients is strikingly different across countries and likely contributes to survival differences. Underlying differences in patient populations including risk factors/comorbidities influencing disease progression may also account for variation in outcomes.

**Key words:** Hepatocellular cancer; Liver resection; Viral hepatitis

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Treatment for hepatocellular cancer (HCC) depends on stage and liver function. Single-institution studies have characterized resection for HCC but this unique study combines the experience of three large hepatobiliary centers in different countries with 573 resections for stage I / II HCC in Tokyo ( $n = 250$ ), Honolulu ( $n = 146$ ) and Shanghai ( $n = 177$ ). Groups differed in viral hepatitis, tumor size, alpha fetal protein (AFP) and cirrhosis. One and 5-year mortality was lowest in the Tokyo cohort. Elevated AFP, low albumin, tumor > 5 cm and cirrhosis were independently-associated with increased 5-year mortality. The profile of early-stage HCC patients is strikingly different across countries and likely contributes to survival differences.

Liver resection for early hepatocellular cancer: Comparison of centers in 3 different countries. *World J Hepatol* 2016; 8(31): 1327-1335 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i31/1327.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i31.1327>

### INTRODUCTION

Hepatocellular cancer (HCC) is the fifth most common cancer in males and the ninth in females worldwide and is the second most deadly cancer. In 2012, there were 782000 HCC cases and 745000 deaths. HCC is more prominent in less-developed countries and more than 50% of cases were diagnosed in Asia<sup>[1]</sup>. In the United States, there were 35000 new cases of liver and intrahepatic bile duct cancer in 2015 and HCC is one of the few cancers that is increasing in both incidence and mortality<sup>[2]</sup>. The best treatments for early stage HCC include liver resection for those with adequate liver function and liver transplant for those with decompensated

cirrhosis or tumor that is not amenable to resection. Multiple single center studies have demonstrated success with liver resection and transplant, but patient populations largely differ in underlying risk factors (viral hepatitis, diabetes, obesity, alcohol and smoking) and may differ by technique of resection, indications for resection, patient management, use of adjuvant therapy, and follow-up<sup>[3-8]</sup>. The use of liver resection may also vary depending on the availability of liver transplantation. Countries with relatively limited donor liver availability or new transplant programs may depend more on resection for curative therapy. Because of limited donor livers, some countries, such as Japan, have made great efforts at developing successful surveillance and diagnosis programs that detect more than 60% of HCC at a very early stage<sup>[9]</sup>. Early detection allows more patients to undergo resection or liver-directed therapy such as local ablation with curative intent.

Because of potential differences in surveillance, tumor size, and available therapies, it is difficult to directly compare a particular therapy for HCC in different countries. The aim of the present study is to compare patient and clinical characteristics and survival of early (stage I , II ) HCC patients treated by resection in three different countries. These centers include large tertiary referral centers for HCC in Shanghai (China), Nippon (Japan) and Hawaii, the United States with the highest incidence of HCC.

### MATERIALS AND METHODS

This is a retrospective analysis of 573 liver resections performed in 3 tertiary referral centers for liver disease performed in 3 different countries.

#### Honolulu cohort (United States)

The Honolulu cohort consisted of 936 HCC cases referred between 1993 and 2014 to the only liver transplant program in Hawaii and the only referral center for liver disease/surgery for the American territories of the Pacific Basin (including Samoa, Guam, Saipan, and the Marshall Islands). Patients were primarily United States citizen of diverse racial/ethnic backgrounds including Whites, Asians, and Pacific Islanders but also included foreign nationals from Asian countries who sought medical care in the United States. Race/ethnicity and birthplace were assessed as risk factors for HCC were previously shown to vary by these demographic characteristics in this study population<sup>[10]</sup>. This clinic and the transplant center were initially affiliated with Hawaii Medical Center-East (formerly St. Francis Medical Center) and after 2012, the Queens Medical Center. This center sees about 60%-70% of the HCC cases in Hawaii. Liver resections were performed by a single group of hepatobiliary/transplant surgeons, with about 80% of these cases done by a single surgeon (LW).

HCC was confirmed histologically by percutaneous biopsy or at surgery. In the first decade, HCC consistent

with the previous United Network for Organ Sharing policy regarded transplant for HCC patients without biopsy. More recently, the diagnosis of HCC was made with only imaging if a dynamic contrast-enhanced study showed typical arterial enhancement with venous “washout” as described by the American Association for the Study of Liver Disease guidelines<sup>[11,12]</sup>.

Data collected included demographic data (age, sex, birthplace, self-reported ethnicity) and the presence of diabetes mellitus, hyperlipidemia, smoking, viral hepatitis, alcohol abuse, obesity and other chronic liver diseases. Laboratory data collected included bilirubin, albumin, prothrombin time, creatinine, alanine aminotransferase, aspartate aminotransferase, platelet count, Model for End-stage Liver Disease score and alpha fetal protein (AFP). The size, number, and location of the tumor(s) were used to determine the Tumor Node Metastases stage according to the American Joint Commission on Cancer (AJCC) staging manual<sup>[13]</sup>.

After excluding patients who presented with ruptured HCC and underwent embolization prior to resection, 146 HCC cases were included in the study. During this time period, 84 patients underwent liver transplant for HCC. This study was approved by the University of Hawaii Institutional Review Board.

#### **Shanghai cohort (China)**

The Shanghai cohort was comprised of 241 HCC cases diagnosed between 2002–2003 and followed for up to 70 mo. Patients were diagnosed and treated at Zhongshan Hospital (Fudan University) in Shanghai, China. Zhongshan Hospital is a major teaching hospital affiliated with the Ministry of Health of China. This is a 1700 bed medical facility that serves approximately 80000 inpatients and 3 million outpatients/emergency visits annually.

All patients were of Chinese ethnicity and were initially seen by medical organizations in the surrounding areas but the final diagnosis was made in this facility. Patients were diagnosed based on imaging criteria, as well as with a history of chronic viral hepatitis and elevated AFP. Three surgeons including Dr. Zhao-You Tang (author) performed all of the liver resections in this cohort. The diagnosis of HCC was confirmed by two independent pathologists.

The patient enrollment criteria included those with detailed information on clinical presentation and pathological characteristics; and detailed follow-up data for at least 3 years, which included recurrence-free survival, overall survival, as well as the cause of death. The detailed clinical presentation characteristics included but were not limited to sex, age, OKUDA staging, CLIP staging, BCLC staging, Child-Pugh score, TNM staging, multiple nodules, satellite nodule, tumor size, tumor capsule, cirrhosis, tumor thrombosis, lymph node, alanine transaminase, Albumin, international normalized ratio, hepatitis B surface (HBV) Ag, hepatitis C antibody, HBV viral status, pre-treatment AFP, preoperative therapy,

and postoperative other therapies. A majority of patients were long-term carriers of HBV (94%). The updated TNM classification was used in this cohort, and 177 early stage HCC patients (TNM stage I and II) with survival information were therefore chosen to perform comparison analysis in our study. Data for this cohort are publically available and have been used in many HCC translational research studies<sup>[14,15]</sup>.

#### **Tokyo cohort (Japan)**

The Tokyo cohort consisted of 504 HCC cases diagnosed between 1986 and 2014 in the Department of Surgery at Nippon Medical School, which has a primary medical center (1000 beds) and 3 smaller branch hospitals. Decisions on therapy were made by hepatologists and surgeons and all liver resections were performed at the primary medical center by members of a dedicated liver surgery team (10 hepatobiliary surgeons, surgical residents and medical students). Living-donor liver transplantation is done in this medical center, but only 15 cases have been done and no deceased-donor liver transplants were performed during this time period.

Although the treatment strategy has been changing in Japan, decisions on therapy were based on an algorithm for treatment of HCC reported by Makuuchi *et al.*<sup>[16,17]</sup>. This algorithm was based on three factors: Degree of liver damage (Childs A, B or C), number of tumors (single, 2–3 or 4 or more), and tumor diameter ( $\leq 3$  cm or  $> 3$  cm). Indications for surgery were according to modified-Makuuchi criteria incorporating the indocyanine green test<sup>[18]</sup>. The final diagnosis of HCC was histologically confirmed at surgery by a group of expert pathologists. Use of transplantation for HCC was extremely limited because of scarcity of organs from deceased donors. Hepatectomy is generally the first choice for Child-Pugh class A and selected class B cirrhotic patients.

In this cohort of 504 patients with HCC, the vast majority of patients were Japanese. The pre-operative diagnosis of HCC was made primarily with imaging and confirmed at resection. Liver biopsy prior to surgery was rarely performed. Data collected in this cohort included: Age, gender, HBV, hepatitis C virus (HCV), presence of coma, ascites, bilirubin, albumin, protime, AFP, Childs-Pugh class, presence of cirrhosis, stage, tumor size, recurrence and survival. Additional data that were collected but not used in this analysis included ICG (indocyanine green), AFP-LC, PIVKA, tumor differentiation, vascular invasion and details on the segments of liver that were removed. Of the 504 HCC patients in this cohort, 250 diagnosed at TNM stage I and II were included in the present analysis.

#### **Statistical analysis**

All analyses were conducted with SAS version 9.3 (SAS Institute, Inc., Cary NC). All *P*-values were two-sided, and *P* < 0.05 was defined as significant. Characteristics of Honolulu, Tokyo and Shanghai HCC patients were compared using generalized linear models (continuous variables) and  $\chi^2$  tests (categorical variables). Differences

**Table 1** Characteristics of resected stage 1 and 2 hepatocellular cancer patients: Honolulu, Tokyo and Shanghai

Characteristic	Honolulu ( <i>n</i> = 146)	Tokyo ( <i>n</i> = 250)	Shanghai ( <i>n</i> = 177)	<i>P</i> value
	<i>n</i> (%)	<i>n</i> (%)	<i>n</i> (%)	
Mean age in years	62.7 (SD 11.4)	67.0 (SD 8.7)	50.6 (SD 11.1)	< 0.0001
Age < 50 yr	18 (12.3)	8 (3.2)	83 (46.9)	< 0.0001

AFP < 20 ng/mL	72 (49.3)	144 (57.6)	70 (39.6)	0.0011
Albumin < 3.5 g/dL	23 (15.8)	85 (34)	21 (11.9)	< 0.0001

Hepatitis B surface (*n* = 6); hepatitis C virus (*n* = 32); Child-Pugh (*n* = 2); cirrhosis (*n* = 17); albumin *n* = 17). AFP: Alpha fetal protein.

in HCC mortality among patients treated in Honolulu, Tokyo and Shanghai were examined using Kaplan-Meier estimates and Cox proportional hazards regression. Survival period was computed from the date of HCC diagnosis to the date of death from any cause. Patients alive at the end of the follow-up period were considered censored. The proportional hazard assumption for Cox models was checked by plotting scaled Schoenfeld residuals against time to event<sup>[19]</sup>. There was evidence of non-proportionality of hazards with respect to time. For this reason and due to the uneven follow-up period between the three centers, survival was partitioned into two time periods: Survival at 1 year after diagnosis and at 5 years following diagnosis were modeled separately. Analyses were adjusted for patients' age at time of diagnosis. Predictors of overall survival were also evaluated in 1-year and 5-year models. Univariate analyses were used to model age (< 50 year; ≥ 50 year), sex (male; female); stage (I; II); Child-Pugh Score (A; B); tumor size (< 5 cm; ≥ 5 cm) presence/absence of cirrhosis; AFP (< 20 ng/mL; ≥ 20 ng/mL); albumin levels (< 3.5 g/dL; ≥ 3.5 g/dL), HBV (positive; negative); and HCV (positive; negative). The three center locations were modeled as indicator variables with Honolulu as the reference. Along with age, factors found to be significant at the  $P \leq 0.10$  level in univariate analyses were included in the full multivariate models. A statistical review of the study was performed by a biomedical statistician.

## RESULTS

A total of 573 HCC patients diagnosed at AJCC stage I or II who underwent resection were included in the present analyses. Patients included 146 from Honolulu, 250 from Tokyo, and 177 from Shanghai. Patient and clinical characteristics varied widely across countries (Table 1). Patients were youngest in Shanghai and oldest in Tokyo ( $P < 0.0001$ ). Males comprised 82% of Shanghai patients, 72% of Tokyo cases, and 69% of Honolulu cases ( $P =$

0.01). HBV seropositivity was highest among Shanghai HCC cases (94%), followed by Honolulu (43%) and Tokyo (14%) cases ( $P < 0.0001$ ). Conversely, HCV seropositivity was highest among Tokyo cases (67%), followed by Honolulu (27%) and Shanghai (3%) patients ( $P < 0.0001$ ). Stage I cases were predominant in Honolulu (89%), compared to Shanghai (51%) and Tokyo (27%) cases ( $P < 0.0001$ ). Cirrhosis was present in most Shanghai cases (93%), compared to 57% of Tokyo and 41% of Honolulu cases ( $P < 0.0001$ ). Mean tumor size was largest in Honolulu cases (6.4 cm), compared to Shanghai and Tokyo cases (3.9 cm and 3.0 cm, respectively) ( $P < 0.0001$ ). Elevated AFP levels were present in 60% of Shanghai patients, 51% of Honolulu cases, and 42% of Tokyo patients ( $P = 0.001$ ). Abnormal albumin levels (< 3.5 g/dL) were present in 34% of Tokyo patients compared to 16% and 12% in the Honolulu and Shanghai cohorts, respectively ( $P < 0.0001$ ).

Overall, 1-year and 5-year mortality varied across the three centers (Figure 1). Thirty-day mortality was 2.8%, 1.6% and 0% for Honolulu, Tokyo and Shanghai groups, respectively. Mortality was compared across the three centers with Honolulu as the reference (Table 2). (Estimates adjusted for age at diagnosis only and additionally adjusted for the year of surgery were comparable. Therefore, estimates adjusted for age at diagnosis only are reported). During the 1-year survival and 5-year periods, Tokyo patients had lower mortality than those in Honolulu (age-adjusted HR = 0.28; 95%CI: 0.15-0.51 and age-adjusted HR = 0.70; 95%CI: 0.50-0.98, respectively). One-year and 5-year survival did not differ between the Shanghai and Honolulu cohorts.

Predictors of overall 1-year and 5-year survival were examined (Table 3). For 1-year survival, the multivariate model included age, AFP, tumor size, albumin and center as covariates. In the final multivariate model, the following were positively associated with increased risk of mortality at 1-year: AFP levels ≥ 20 (adjusted HR = 2.27; 95%CI: 1.32-3.90), tumor size ≥ 5 cm

**Table 2 Overall age-adjusted survival in resected stage 1 and 2 hepatocellular cancer patients: Honolulu, United States, Tokyo, Japan and Shanghai, China**

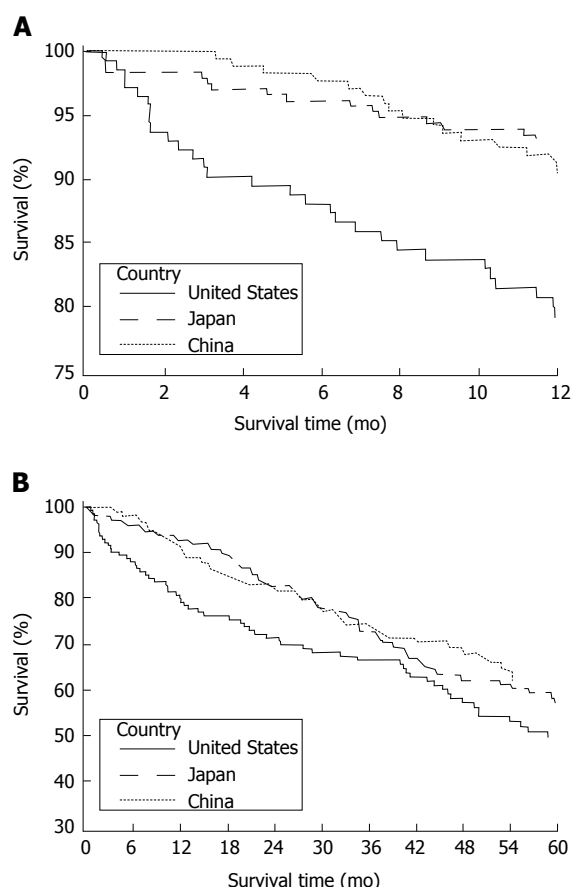

Center		Honolulu	Tokyo	Shanghai
No. patients		146	250	177
No. deaths		29	17	6
Mean follow-up (yr)		4.04	3.75	3.55
Median follow-up (yr)		3.33	2.83	4.36
1-yr survival	Hazard ratio <sup>1</sup>	1	0.28	0.63
	95%CI	Reference	0.15-0.51	0.32-1.21
	P value		< 0.0001	0.17
5-yr survival	Hazard ratio	1	0.7	0.74
	95%CI	Reference	0.50-0.98	0.51-1.09
	P value		0.04	0.13

<sup>1</sup>Age-adjusted.

(adjusted HR = 2.00; 95%CI: 1.17-3.43) and albumin < 3.5 g/dL (adjusted HR = 2.10; 95%CI: 1.20-3.68). The Tokyo cohort had lower 1-year mortality than Honolulu (adjusted HR = 0.33; 95%CI: 0.17-0.65). For 5-year survival, the multivariate model included age, stage, Child-Pugh Score, AFP, albumin, cirrhosis, tumor size, and center as covariates. In the final multivariate model, predictors of 5-year survival were AFP  $\geq$  20 (adjusted HR = 1.57; 95%CI: 1.17-2.10), cirrhosis (adjusted HR = 1.59; 95%CI: 1.12-2.26), tumor size  $\geq$  5 cm (adjusted HR = 1.84; 95%CI: 1.34-2.54), and albumin < 3.5 g/dL (adjusted HR = 1.72; 95%CI: 1.21-2.46). Both Tokyo and Shanghai centers had better 5-year survival than the Honolulu cohort (adjusted HR = 0.51; 95%CI: 0.33-0.78 and adjusted HR = 0.47; 95%CI: 0.31-0.72). Predictors of overall 1-year and 5-year survival were examined separately by center. In Honolulu, predictors of both 1-year and 5-year survival were AFP  $\geq$  20 (1-year: adjusted HR = 3.21; 95%CI: 1.36-7.56; 5-year: adjusted HR = 3.18; 95%CI: 1.35-7.51) and albumin < 3.5 g/dL (1-year: adjusted HR = 4.17; 95%CI: 1.92-9.04; 5-year: adjusted HR = 4.13; 95%CI: 1.90-8.98). In the Tokyo cohort, there were no significant predictors of 1-year survival. Five-year survival was associated with cirrhosis (adjusted HR = 1.90; 95%CI: 1.17-3.09) and tumor size  $\geq$  5 cm (adjusted HR = 2.29; 95%CI: 1.33-3.94). For the Shanghai cohort, 1-year mortality risk was associated with tumor size  $\geq$  5 cm (adjusted HR = 2.99; 95%CI: 1.14-7.80) and 5-year predictors included AJCC stage 2 (vs 1) (adjusted HR = 2.30; 95%CI: 1.35-3.92) and Child-Pugh Score (B vs A) (adjusted HR = 4.51; 95%CI: 1.59-12.81).

## DISCUSSION

Therapy for hepatocellular cancer has evolved and there are current practice guidelines based on Barcelona Clinic Liver Cancer (BCLC) staging<sup>[11,12]</sup>. These guidelines provide a general framework, but what occurs in the real world is likely center and country specific. In developed countries with resources to perform liver transplant, multiple studies have compared outcome between resection

**Figure 1 Overall survival analysis of hepatocellular cancer patients from Honolulu, Tokyo, and Shanghai.** A: Kaplan-Meier survival curves for one-year survival analysis; B: Kaplan-Meier survival curves for five-year survival analysis; A and B: Log-rank test were used for statistical analysis.

and transplant and those treated with transplant have better survival and less recurrence<sup>[7,20-30]</sup>. Nonetheless, widespread use of transplant is constrained by the availability of donor livers. Other reports compared liver resection and local ablation. Although ablation was effective especially for tumors less than 2.0 cm and can be performed with fewer complications, liver resections had better long-term, recurrence free-survival in some series<sup>[3,31-34]</sup>. Good short-term outcomes occur in small tumors, whether resected, ablated or transplanted, but recurrence rates, cost and donor livers are major factors in the decision-making. Worldwide, strategies to treat liver cancer have evolved based on the burden of liver cancer and the available resources in that particular area.

This is the first study that attempts to assess one surgical modality in 3 different countries, each of which has a high burden of disease, but different resources and treatment strategies. We chose liver resection because this was uniformly available and not dependent on technology or donor livers. Rather than comparing data in the form of a meta-analysis or systematic review, we developed a working relationship between the surgeons and scientists in these three centers. In this study, we selected only stage I / II HCC who underwent liver resection, in an attempt to make a comparison in as

**Table 3** Predictors of 1-year and 5-year overall mortality in resected stage 1 and 2 hepatocellular cancer patients in Honolulu, Tokyo and Shanghai

Covariates	Univariate			Multivariate		
	Hazard ratio	Confidence interval	P value	Hazard ratio <sup>1</sup>	Confidence interval	P value

<sup>1</sup>Multivariate model adjusted for covariates listed. AFP: Alpha fetal protein; AJCC: American Joint Commission on Cancer.

homogeneous a group as possible. We showed that although the survival outcomes are different in various centers, overall survival is mostly dependent on tumor factors and underlying liver function. Although the patients in each center differ in many respects (mean age, gender, viral risk factor, tumor size, mean tumor size and AFP), all centers had excellent 30-d mortality. Our study showed that tumor size, AFP, and albumin were factors associated with early mortality. By 5 years post-resection, these same factors in addition to the presence of cirrhosis were predictors of mortality. Both the Tokyo and Shanghai cohorts had better 1- and 5-year survival compared to the Honolulu cohort even after adjustment for clinical factors. Differences in patient populations across the centers may account for these differences. Compared to the generally homogeneous Tokyo and Shanghai patients, the Honolulu cohort was comprised of racially and ethnic diverse individuals born within and outside the United States. Many Honolulu patients had comorbidities including those that may contribute to disease progression (obesity, type-2 diabetes, excess alcohol consumption and past intravenous drug use)<sup>[10]</sup>. We were unable to account for these differences in comorbidities and risk factors as this information was not available for the Tokyo and Shanghai cohorts. Differences in the patient populations are further supported by our observation that independent risk factors of survival differed across centers. In Honolulu, elevated AFP and albumin were associated with both 1-year and 5-year

survival. In the Tokyo cohort, cirrhosis large and tumor size were associated with 1-year survival. For the Shanghai cohort, tumor size was a predictor of 1-year survival while AJCC stage and Child-Pugh Score were associated with 5-year mortality risk.

Single-center studies have similarly demonstrated that tumor characteristics (size, vascular invasion) and underlying liver function are predictors of survival<sup>[3,5,21,35,36]</sup>. Kao *et al.*<sup>[3]</sup> examining 1265 liver resections for early stage HCC, showed that low albumin, AFP  $> 20$  ng/mL, and tumor size  $> 3$  cm affected mortality. Kang *et al.*<sup>[34]</sup> studying 353 South Korean patients, found that vascular invasion and thrombocytopenia were risk factors for poor disease-free survival. Many of these studies were large series of liver resections in centers outside the United States. Large United States studies of liver resection for HCC have been primarily based on cancer databases with limited information on underlying liver function<sup>[30,33,37]</sup>, or were conducted in single centers that focused on the comparison between liver transplant and resection<sup>[29-38]</sup>.

A few studies have also compared the outcome of liver resections in patients with HBV vs HCV. Chen *et al.*<sup>[38]</sup> studying 2920 patients in Taiwan, showed that patients with HBV were younger, had higher AFP and larger tumor size and lower mean survival (11.1 mo vs 23.9 mo with HCV). Dohmen *et al.*<sup>[39]</sup> demonstrated that among 692 patients in Japan, HBV patients were younger, presented with more advanced stage and had poorer overall survival. Wu *et al.*<sup>[40]</sup> reported that

among 110 Taiwanese patients who underwent hepatic resection for HCC, neither underlying cirrhosis nor viral status affected operative morbidity or mortality, but the poorer liver reserve in HCV cirrhotic patients resulted in worse survival compared to the HBV patients. Franssen *et al.*<sup>[37]</sup> reported that among 567 United States patients who underwent liver resection, HBV rather than HCV-related HCC had better survival and less recurrence. Our study allowed comparison of a primarily HBV-related HCC group of patients (China), a primarily HCV-related HCC group (Japan) and a mixed group (Hawaii), and when considered together viral hepatitis status had little bearing on overall 1- and 5-year survival as the cirrhosis, tumor size, AFP and underlying liver function had the greatest effect on outcome.

This study is limited in that the time frame was different in the three groups. In the Tokyo and Honolulu cohorts, this study represented a 20+ year experience, whereas the Shanghai cohort underwent liver resection over a 2-year period. Because this study was done retrospectively, each group collected different parameters, so there was limited data collected by all groups that could be directly compared. There are also likely differences in the quality of long-term follow up between the centers. This study also has variable data on recurrence of HCC and treatment of these recurrences, which may affect long-term survival. Survival was also expressed as all-cause survival so it is difficult to determine the contribution of HCC to overall patient outcome. Finally, differences in survival after liver resection may be due to availability of liver transplant and other locoregional therapies in a particular country. The increased availability of liver transplant in the Honolulu group may have prompted fewer resections in those with smaller tumors, leaving liver resections for larger tumors with reasonable liver function. Unfortunately, we would not be able to determine this without information on all HCC referred to each of these centers.

In spite of these differences and limitations, this study represents a large experience of liver resections by expert hepatobiliary surgeons in their respective countries. In the final analysis, the very early outcome after liver resection for HCC is similar in specialized centers in different countries but later survival is better in the Tokyo and Shanghai groups. Tumor factors, underlying liver function, comorbidities and availability of other therapies may be playing a role patient selection for resection and the ultimate outcome. Nevertheless, this study demonstrates that collaborations at an international level will be important for understanding how to better manage and treat HCC.

## COMMENTS

### Background

Treatment for hepatocellular cancer depends on stage and liver function. How liver cancer is treated in different country may also depend on available therapy. Liver transplant has the best long-term disease free survival for early liver cancer, however the availability of liver transplant differs in various countries

and may limit this therapy.

### Research frontiers

Single-institution studies have characterized resection for hepatocellular but this unique study combines the experience of three large hepatobiliary centers in different countries with 573 resections for stage I/II hepatocellular cancer in Tokyo ( $n = 250$ ), Honolulu ( $n = 146$ ) and Shanghai ( $n = 177$ ).

### Innovations and breakthroughs

Groups differed in viral hepatitis, tumor size, alpha fetal protein (AFP) and cirrhosis. One and 5-year mortality was lowest in the Tokyo cohort. Elevated AFP, low albumin, tumor > 5 cm and cirrhosis were independently-associated with increased 5-year mortality. The profile of early-stage hepatocellular patients is strikingly different across countries and likely contributes to survival differences.

### Applications

This study is important as it demonstrates the importance of collaboration between centers in different countries so that we can better diagnose and manage hepatocellular cancer.

### Terminology

Liver resection is a surgical procedure involving removal of a portion of liver that has a malignant cancer. Liver transplantation is performed for those patients with hepatocellular cancer and poor underlying liver function.

### Peer-review

The authors of this paper observed excellent early outcomes after liver resection for early stage hepatocellular cancer. Differences in longer term survival were likely related to tumor size, albumin, AFP and the presence of cirrhosis.

## Abstract

### AIM

To investigate mortality and rebleeding rate and identify associated risk factors at 6 wk and 5 d following acute variceal haemorrhage in patients with liver cirrhosis and schistosomal periportal fibrosis.

### METHODS

This is a prospective study conducted during the period from March to December 2014. Patients with portal hypertension presenting with acute variceal haemorrhage secondary to either liver cirrhosis (group A) or schistosomal periportal fibroses (group B) presenting within 24 h of the onset of the bleeding were enrolled in the study and followed for a period of 6 wk. Analysis of data was done by Microsoft Excel and comparison between groups was done by Statistical Package of Social Sciences version 20 to calculate means and find the levels of statistical differences and define the mortality rates, the *P* value of < 0.05 was considered to be significant.

### RESULTS

A total of 94 patients were enrolled in the study. Thirty-two patients (34%) had liver cirrhosis (group A) and

62 (66%) patients had periportal fibrosis (group B). Mortality: The 6-wk and 5-d mortality were 53% and 16% respectively in group A compared to 10% and 0% in group B ( $P$  value  $< 0.000$  and  $< 0.004$ ). In group A; a Child-Turcotte-Pugh class C and rebleeding within 5 d were significantly associated with 5-d mortality ( $P$  value  $< 0.029$  and  $< 0.049$  respectively) and Child-Turcotte-Pugh class C was also a significant risk factor for 6-wk mortality ( $P$  value  $< 0.018$ ). In group B; mortality was significantly associated with rebleeding within the 6-wk follow-up period and requirement for blood transfusion on admission ( $P$  value  $< 0.005$  and  $< 0.049$ ). Rebleeding: The 6-wk and 5-d rebleeding rate in group A were 56% and 25% respectively compared to 32% and 3% in group B ( $P$  value  $< 0.015$  and  $< 0.002$ ). Clinical presentation with encephalopathy was a significant risk factor for 5 d rebleeding in group A ( $P$  value  $< 0.005$ ) while grade III periportal fibrosis and requirement for blood transfusion on admission were significant risk factors for 6-wk rebleeding in group B ( $P$  value  $< 0.004$  and  $< 0.02$ ).

### CONCLUSION

The 6-wk and 5-d mortality and rebleeding rate were significantly higher in patients with liver cirrhosis compared to patients with schistosomal periportal fibrosis.

**Core tip:** This study was conducted to investigate the rate and risk factors associated with rebleeding and mortality at 6 wk and 5 d following acute variceal haemorrhage in patients with liver cirrhosis and schistosomal periportal fibrosis (PPF). The 6-wk and 5-d mortality in cirrhosis were 56% and 16% compared to 10% and 0% in patients with schistosomal PPF ( $P$  value  $< 0.000$  and  $< 0.004$ ). The 6-wk and 5-d rebleeding rate in cirrhosis were also high at 53% and 25% compared to 32% and 3% respectively in patients with schistosomal PPF ( $P$  value  $< 0.015$  and  $< 0.002$ ). In conclusion the 6-wk and 5-d mortality and rebleeding were significantly higher in patients with liver cirrhosis compared to patients with schistosomal periportal fibrosis.

### INTRODUCTION

Variceal bleeding is a devastating complication of portal hypertension. The 6-wk mortality in patients with liver cirrhosis is between 17%-28%<sup>[1-3]</sup> and the risk of

rebleeding after acute variceal haemorrhage (AVH) is highest within the first 6 wk with a peak in the first 5 d<sup>[2]</sup>. In Sudan, a country endemic with schistosomiasis, AVH in the majority of cases is caused by portal hypertension due to schistosomal periportal fibrosis (PPF), while cirrhosis is less common<sup>[4]</sup>. Published data from Sudan showed that the crude mortality rate of schistosomiasis in a village in the Gezira state; an area endemic for schistosomiasis was 51/100000 per year with a case fatality per year of 1/1000 in those secreting eggs and 11/100 in those with bleeding varices<sup>[5]</sup>. Significant risk factors for variceal bleeding in patients with schistosomal portal hypertension, after at least one episode of bleeding compared to patients with schistosomal PPF without bleeding were splenic longitudinal dimension of more than 11 cm and PPF of  $\geq$  grade III<sup>[6]</sup>. The 6-wk and 5-d mortality and rebleeding rate following AVH in schistosomal portal hypertension have not been well studied.

The objectives of this study were to investigate mortality and rebleeding rate and identify associated risk factors for 6 wk and 5 d following acute variceal haemorrhage in patients with portal hypertension secondary to liver cirrhosis and schistosomal PPF.

### MATERIALS AND METHODS

This is a prospective study conducted at Mohamed Salih Idris bleeding centre in Khartoum state, Sudan from March to December 2014. Patients presenting with acute upper gastrointestinal (GI) bleeding, whether it was their first bleeding episode or otherwise, were included if they were  $> 16$  years old, had portal hypertensive variceal bleeding (diagnosed on upper gastrointestinal endoscopy) secondary to liver cirrhosis (group A) or PPF (group B) presenting within 24 h of the onset of the bleeding. Patients were excluded if they were  $\leq 16$  years, had hepatocellular carcinoma or had non variceal upper gastrointestinal bleeding. Data were collected in a specially designed sheet which included patients' demographics and clinical presentation, baseline laboratory tests done upon initial presentation (CBC, RFT, LFT's and INR), patients' hemodynamic status upon presentation, the number of blood units transfused, the amount of the vasopressor agent Terlipressin acetate (Glypressin<sup>®</sup>, Ferring, Germany) used, endoscopic findings and endoscopic management done. All patients received Terlipressin 2 mg intravenously bolus dose followed by 1 mg 6 hourly whenever the drug was available. All patients underwent upper gastrointestinal endoscopy within 12 h of admission to identify the source of bleeding. Oesophageal varices were graded according to Paquet<sup>[7]</sup> and gastric varices were graded according to Sarin *et al*<sup>[8]</sup>. Oesophageal varices and junctional varices (GOV1) were treated with injection sclerotherapy or band ligation, whichever was available, 5% ethanolamine oleate was the agent used for injection sclerotherapy and the volume used for each patient was documented, junctional varices (GOV2) and isolated gastric varices

were treated with the injection of cyanoacrylate (Histoacryl®, B Braun, Spain) and Sengstaken Blakemore tube was used to control bleeding if initial endoscopy was not successful. Cirrhotic patients were covered with prophylactic antibiotics. An appointment for secondary prophylactic endoscopic treatment was given within 2 wk and B-blockers were prescribed if not contraindicated. The diagnosis of cirrhosis was established by clinical, radiological and laboratory findings and the cause of cirrhosis was looked for and documented. Child-Turcotte-Pugh (CTP) classification and the model for end stage liver disease (MELD) score were calculated for each patient. In the case of schistosomal PPF, the severity of liver fibrosis was graded as described by Homeida *et al.*<sup>[9]</sup> from I - III as follows: Grade I : Mild echogenic thickening of one or two portal vein radicles with little change in the walls of the portal vein; Grade II : Moderate to severe periportal irregular thickening of most of the portal vein radicles, with marked narrowing of the central lucency, marked thickening at the bifurcation of the portal vein, and mild thickening of the main portal vein; and Grade III: Marked thickening of the walls of the portal vein radicles with obliteration of the central lucency in the peripheral branches forming thick irregular echogenic 10-20 mm bands reaching the periphery of the liver with thickening down to main portal vein walls.

Patients were followed every 24 h for the first 5 d and then at 6 wk for mortality and rebleeding. Rebleeding was defined according to the Baveno V consensus as a single episode of clinically significant rebleeding from portal hypertensive sources (recurrent melena, hematemesis resulting in hospital admission, blood transfusion, 3 g drop in haemoglobin or death). Rebleeding during the first 120 h (5 d) was regarded as treatment failure, whereas rebleeding up to 6 wk was regarded as failure of secondary prophylaxis<sup>[10]</sup>.

The primary endpoint of this study was the rate of variceal rebleeding and mortality at 5 d and at 6 wk following AVH in portal hypertension secondary to cirrhosis or PPF. The secondary endpoints were to determine risk factors associated with variceal rebleeding and

mortality at 5 d and 6 wk among the study population.

The study was reviewed and approved by the Research and Ethics Review Committee at Mohamed Salih Idris Centre. All study participants or their legal guardian provided their informed consent before being enrolled in the study.

### Statistical analysis

Analysis of data was done by Microsoft Excel and comparison between groups was done by Statistical Package of Social Sciences version 20 to calculate means and find the levels of statistical differences and define the mortality rates, the *P* value of < 0.05 was considered to be significant.

## RESULTS

A total of 94 patients were enrolled in the study with a mean age of 49 ± 1.0 years, and males constituted 88% with M:F ratio of 7:1.

### Group A (liver cirrhosis)

There were 32 patients (34%) in group A. Demographic criteria and clinical presentation are shown in Table 1, clinical findings and medical management in Table 2 and endoscopic findings/management are shown in Table 3. After discharge from the bleeding centre, patients were advised to attend for further endoscopic management in order to eradicate the varices with the earliest session to be done at 2 wk. A total of 19% underwent upper endoscopy at less than 2 wk because of rebleeding, 31% performed the session at the advised 2 wk, 13% at 3 wk, 3% at 4 wk and 3% beyond 4 wk, whereas 31% did not attend for the second endoscopy session.

### Group B (schistosomal PPF)

There were 62 patients (66%) in group B. The clinical and demographic data are shown in Table 1, ultrasound findings and medical management in Table 2 and endoscopic findings/management are presented in Table 3.

After discharge from the bleeding centre patients were advised to continue endoscopic management in order to eradicate the varices with the earliest session to be done at 2 wk. A total of 5% of the patients underwent upper endoscopy at less than 2 wk because of rebleeding, 48% performed the session at the advised 2 wk, 23% at 3 wk, 8% at 4 wk and 11% beyond 4 wk while 5% did not attend for the second endoscopy session.

### Overall mortality

The 6-wk and 5-d mortality were 53% and 16% respectively in group A compared to 10% and 0% in group B (*P* value < 0.000 and < 0.004 respectively) (Table 4).

### Factors related to mortality

In group A, the CTP class C and rebleeding within 5 d were significant risk factors for 5 d mortality (*P* value < 0.029 and < 0.049 respectively). CTP class C was also

a significant risk factor for 6-wk mortality (*P* value < 0.018) (Table 5).

In group B, rebleeding within the 6-wk follow-up period and blood transfusion on admission were significant risk factors for mortality (*P* value < 0.005 and < 0.049 respectively) (Table 6).

### Rebleeding rate

The 6-wk and 5-d rebleeding rate in group A were 56% and 25% respectively compared to 32% and 3% in group B (*P* value < 0.015 and < 0.002) (Table 4).

### Factors related to variceal rebleeding within 6 wk

In group A, no significant factors were related to rebleeding within 6 wk.

In group B, grade III PPF and blood transfusion on admission were significant risk factors associated with rebleeding in this group with a *P* value < 0.004 and < 0.02 respectively (Tables 5 and 6).

### Factors related to variceal rebleeding within 5 d

In group A, clinical presentation with encephalopathy was a significant risk factor for rebleeding within 5 d (*P* value < 0.005). In group B there were no significant factors

<sup>1</sup>Significant risk factor. PPF: Periportal fibrosis.

contributing to rebleeding within 5 d (Tables 5 and 6).

## DISCUSSION

In this study, we evaluated early mortality and rebleeding following AVH. In this part of Africa minimal data is available with regards to mortality following AVH due to scarcity of endoscopy services. This study is unique because we evaluated the patients in two groups according to the etiology of the underlying liver disease, either liver cirrhosis or schistosomal periportal fibrosis. Previous studies on early mortality following AVH were done exclusively on patients with liver cirrhosis<sup>[3,11-13]</sup>.

In this study, in the cirrhosis group, the 6-wk and 5-d mortality were both high at 53% and 16% respectively, whereas the 6-wk mortality following AVH in patients with schistosomal PPF was 10% with no deaths reported during the first 5 day (*P* value < 0.000 and < 0.004). This high rate of mortality in cirrhosis following variceal bleeding is well described by D'Amico; where four clinical stages of cirrhosis were agreed upon in the Baveno IV consensus conference. Each stage with different features and a different prognosis as follows: Stage 1 no varices or ascites, mortality rate is 1%, stage 2 varices without ascites and without bleeding, mortality rate is 3.4% per year, stage 3 is characterised by ascites with or without varices but never bled, mortality rate is 20% per year, stage 4 is characterised by GI bleeding with or without ascites, in this stage the one year mortality is 57% and

**Table 5** Factors associated with mortality and rebleeding in 32 patients with liver cirrhosis

Study outcome	Factors	P value
Mortality at 6 wk	CTP score C	0.018 <sup>1</sup>
Mortality at 5 d	CTP score C	0.029 <sup>1</sup>
	Rebleeding within 5 d	0.049 <sup>1</sup>
Rebleeding at 6 wk	Non	Non
Rebleeding at 5 d	Encephalopathy	0.005 <sup>1</sup>

<sup>1</sup>Significant risk factor. CTP: Child-Turcotte-Pugh.

nearly half of these deaths occur within 6 wk from the initial episode of bleeding<sup>[14]</sup>.

This difference in mortality rate between the two groups is most likely due to preserved liver cell function in most patients with PPF compared to patients with liver cirrhosis<sup>[15]</sup>. In this study we observed that only a minority of patients with schistosomal PPF presented with clinical evidence of liver cell failure; mainly ascites in 2% and encephalopathy in 3%, it has been reported that a few patients with schistosomiasis do evolve to an end stage of the disease with hepatocellular failure, this is known as decompensated schistosomiasis<sup>[15]</sup>.

Le Moine *et al*<sup>[3]</sup> reported predictive factors for mortality at 6 wk in cirrhotic patients being prolonged prothrombin time, encephalopathy and number of blood units transfused. Krige *et al*<sup>[12]</sup> found in a study done exclusively in alcoholic cirrhosis, that CTP class C, encephalopathy, ascites, bilirubin > 51 mmol/L, INR > 2.3, albumin < 25 g/L and patients who require balloon tamponade were factors related to 6-wk mortality. In this study we also found that the CTP class C was significantly related to 6-wk mortality (*P* value < 0.02) this was similar to findings in other studies<sup>[3,12,13]</sup>. Furthermore factors related to mortality within the first 5 d following AVH in cirrhosis were again the CTP class C and the rebleeding within these 5 d. Bambha *et al*<sup>[11]</sup> suggested that the MELD score rather than CTP class was more powerful in predicting 6-wk mortality. In this study, the MELD score was not a significant risk factor for mortality. We found that mortality following AVH in schistosomal PPF (10%) is much less when compared to cirrhotic patients (56%). There is scanty data on the early outcomes of patients with schistosomal PPF presenting with AVH, however, a study from Tanzania found that mortality following AVH in patients with schistosomal PPF after 8 wk of follow-up was quite similar to this study at 10%<sup>[16]</sup>. In this study, no deaths occurred within the first 5 d in the PPF group.

Factors significantly contributing to the 6-wk mortality in PPF included blood transfusion within the first 24 h and rebleeding within the 6-wk follow-up period (*P* values < 0.049, < 0.005 respectively). The 6-wk rebleeding rate in the PPF group was (32%), less than cirrhosis group at 56% (*P* value < 0.004). Significant factors contributing to the 6-wk rebleeding rate in PPF group were grade III PPF on abdominal ultrasound and blood transfusion on admission (*P* value < 0.004 and < 0.02 respectively). A previous study from Sudan demonstrated that rebleeding

**Table 6** Factors associated with mortality and rebleeding in 62 patients with periportal fibrosis

Study outcome	Factors	P value
Mortality at 6 wk	Blood transfusion	0.049 <sup>1</sup>
	Rebleeding within 6 wk	0.005 <sup>1</sup>
Mortality at 5 d	Non	Non
Rebleeding at 6 wk	Blood transfusion	0.021 <sup>1</sup>
	Grade III PPF	0.004 <sup>1</sup>
Rebleeding at 5 d	Non	Non

<sup>1</sup>Significant risk factor. PPF: Periportal fibrosis.

was more in grade III PPF<sup>[17]</sup>. A study from Brazil also found that the sonographic grade of periportal fibrosis was an important tool in predicting variceal complications in patients with schistosomal PPF<sup>[18]</sup>, whereas the longitudinal spleen dimension of more than 11 cm, was an important tool in predicting variceal bleeding in another study<sup>[6]</sup>. It is well known that a conservative blood transfusion strategy is associated with better survival outcomes in patients with upper gastrointestinal bleeding<sup>[19]</sup>. In this study blood transfusion was provided to 58% of patients with PPF with a mean of 2 ± 1 units of blood. Requirement of blood transfusion was a significant factor for both mortality and rebleeding in PPF group (*P* value < 0.049 and < 0.02 respectively).

Rebleeding within 5 d in PPF occurred in two patients (3%), which is much less than in cirrhosis group at 25% (*P* value < 0.002). Both patients had grade III PPF, were hemodynamically stable and did not require blood transfusion, however, none of the factors evaluated contributed to rebleeding within 5 d. Further studies are needed to reveal other causes contributing to rebleeding such as the portal vein pressure and intra variceal pressure.

In this study, the rebleeding rate among cirrhosis group was high at 56% and 25% of these patients developed rebleeding within the first 5 d. The 6-wk rebleeding rate reported in literature was 16.2%, 30% and 24.2%<sup>[2,12,13]</sup>.

It has been reported that the severity of liver disease in terms of presence of ascites and encephalopathy contributes to the rebleeding rate<sup>[3,12]</sup>. In this study, the presence of hepatic encephalopathy in patients with cirrhosis was a significant factor for rebleeding within 5 d of AVH (*P* value < 0.005). Non of the other factors evaluated were found significant for 6-wk rebleeding in cirrhosis, perhaps larger studies with bigger sample sizes are needed to reveal the factors contributing to rebleeding in patients with cirrhosis in our region.

It is known that the use of vasopressor agents improve outcomes following AVH<sup>[20]</sup>. In this study, Terlipressin was provided to patients whenever available, however there was no significant difference on survival or rebleeding rate between patients with liver cirrhosis and patients PPF with use of Terlipressin.

In patients with PPF and cirrhosis the mean portal vein diameter was 17.4 ± 3.3 mm and 16.4 ± 3.1 mm

respectively, reflecting high portal pressure and hence high variceal pressure. Therefore, effective lowering of portal pressure should be paramount in order to prevent the dreadful complication of variceal bleeding.

HBsAg seroprevalence among PPF patients was 6%, similar to seroprevalence of HBsAg among the general population in central Sudan<sup>[21]</sup>, hence HBV screening and vaccination in patients with PPF should be encouraged.

In conclusion, this study has demonstrated that the 6-wk and 5-d mortality and rebleeding are significantly higher in patients with liver cirrhosis compared to patients with schistosomal periportal fibrosis. Effective secondary prophylaxis after AVH needs to be adhered to and when resuscitating patients with AVH, blood transfusion should be given carefully and HBV vaccination should be actively encouraged.

## COMMENTS

### Background

Variceal bleeding is a devastating complication of portal hypertension. In patients with liver cirrhosis the risk of rebleeding after acute variceal haemorrhage is highest within the first 6 wk with a peak in the first 5 day.

### Research frontiers

In Sudan, a country endemic with schistosomiasis, acute variceal haemorrhage (AVH) in the majority of cases is caused by portal hypertension due to schistosomal periportal fibrosis, while cirrhosis is less common. The 6-wk and 5-d mortality and rebleeding following AVH in schistosomal portal hypertension have not been well studied.

### Innovations and breakthroughs

In this study, the authors evaluated early mortality and rebleeding following AVH. In this part of Africa minimal data is available with regards to mortality following AVH due to scarcity of endoscopy services. This study is unique because the authors evaluated the patients in two groups according to the etiology of the underlying liver disease, either liver cirrhosis or schistosomal periportal fibrosis. Previous studies on early mortality following AVH were done exclusively on patients with liver cirrhosis.

### Applications

This study has demonstrated that the 6-wk and 5-d mortality and rebleeding are significantly higher in patients with liver cirrhosis compared to patients with schistosomal periportal fibrosis.

### Terminology

Schistosomiasis is endemic in Sudan; the mortality of schistosoma mansoni infection is mostly due to development of periportal fibrosis with subsequent development of portal hypertension and oesophageal varices causing significant morbidity and mortality.

### Peer-review

This is a well conducted prospective study about variceal bleeding complications in African Setting.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Hong-Chuan Zhao, MD, PhD, Associate Professor, Attending Doctor, Director, Editor, Surgeon, Department of General Surgery, the First Affiliated Hospital of Anhui Medical University, Hefei 230022, Anhui Province, China

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Hepatitis C virus (HCV) mainly targets the liver but can

also induce extrahepatic manifestations. The kidney may be impacted *via* an immune mediated mechanism or a cytopathic effect. HCV patients are clearly at a greater risk of chronic kidney disease (CKD) than uninfected patients are, and the presence of CKD increases mortality. Interferon-based therapies and ribavirin are difficult to manage and are poorly effective in end-stage renal disease and hemodialysis. These patients should be given priority treatment with new direct anti-viral agents (DAAs) while avoiding peginterferon and ribavirin. The first results were convincing. To aid in the correct use of these drugs in patients with renal insufficiency, their pharmacokinetic properties and potential renal toxicity must be known. The renal toxicity of these new drugs was not a safety signal in clinical trials, and the drugs are generally efficient in these frail populations. These drugs are usually well tolerated, but recent cohort studies have demonstrated that these new regimens may be associated with renal side effects, especially when using sofosbuvir combinations. HCV, renal diseases and comorbidities are intimately linked. The close monitoring of renal function is required, particularly for at-risk patients (transplanted, HIV-coinfected, CKD, hypertensive or diabetic patients). New DAA regimens, which will soon be approved, will probably change the landscape.

**Key words:** Nephrotoxicity; Hepatitis C; Direct anti-viral agents; Kidney; End-stage renal disease

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hepatitis C patients are clearly at risk of chronic kidney disease (CKD). New direct anti-viral agents (DAAs) with different pharmacokinetic properties are generally efficient in such populations. However, renal toxicity has been described in frail patients such as patients with CKD, transplants and human immunodeficiency virus co-infections under real-life conditions, especially with sofosbuvir combinations. New DAAs, which will be soon approved, will probably change the

landscape favorably. Close monitoring of renal function is required for at-risk patients, but patients without comorbidities are probably at a very low risk of renal toxicity.

Anti-hepatitis C virus drugs and kidney. *World J Hepatol* 2016; 8(32): 1343-1353 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i32/1343.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i32.1343>

## INTRODUCTION

Hepatitis C virus (HCV) mainly targets the liver but also targets the kidney *via* either an immune mediated mechanism (cryoglobulinemic vasculitis) or a cytopathic effect<sup>[1-3]</sup>.

Epidemiological studies show that the risk of chronic kidney disease (CKD) is 20% higher in HCV patients than in uninfected individuals<sup>[4]</sup>. HCV increases the risk of both end-stage renal disease (ESRD)<sup>[5]</sup> and renal mortality<sup>[6]</sup>. Moreover, patients who are infected with HCV exhibit an increased risk of developing diabetes, high blood pressure and secondary vascular renal diseases<sup>[7]</sup>. Finally, chronic hepatitis C is the most commonly seen viral infection in patients with renal insufficiency<sup>[8]</sup>; its treatment is warranted and remains a great challenge.

Historically, interferon-based therapy was considered nephrotoxic in a dose-dependent or idiosyncratic manner<sup>[9]</sup>. First-generation protease inhibitors (*i.e.*, telaprevir and boceprevir in association with peginterferon and ribavirin) have also been implicated<sup>[10]</sup>, although their role remains controversial<sup>[11]</sup>. Although ribavirin is not nephrotoxic, it accumulates in patients with CKD, and its secondary effects (particularly anemia) are much more severe.

Although new direct anti-viral agents (DAAs) were very well tolerated in phase III trials, recent real-life studies have demonstrated some nephrotoxicity in frail populations that were treated with sofosbuvir-based regimens<sup>[12,13]</sup>.

After a brief review of the pharmacokinetics of anti-HCV drugs, we review their potential renal toxicity and clinical experiences related to the use of these drugs in populations at risk of renal disease.

## PHARMACOKINETICS OF HCV

### TREATMENTS

#### *Treatments that are available in 2016*

The combination of pegylated interferon and ribavirin with or without first-generation protease inhibitors (boceprevir and telaprevir) is no longer used in many developed countries<sup>[14-16]</sup>. However, it may still be relevant in developing countries.

Standard care in countries where DAAs are available is based on the combinations of two or three DAAs from

different families: Second-generation protease inhibitors, NS5B polymerase inhibitors, and NS5A inhibitors. Ribavirin may be added in cirrhotic patients to shorten treatment duration.

All but two DAA phase III studies did not include patients with severe renal insufficiency (4-5 CKD stages)<sup>[17,18]</sup>. Sparse data are thus available, and guidelines recommend that these patients be referred to expert centers<sup>[14]</sup>.

To justify the proper use of HCV treatments in renal insufficiency, the pharmacokinetic properties of these drugs should be remembered.

#### *Pharmacokinetics of interferon, pegylated interferons and ribavirin*

Interferons are natural cytokines. Alpha interferon and its pegylated form are active against viral replication. Pegylation prolongs the half-life of interferon, thus necessitating fewer injections<sup>[19-21]</sup>. The kidney plays a central role in interferon clearance. Interferon is filtered through glomeruli and undergoes lysosomal proteolytic degradation during proximal tubular reabsorption<sup>[22,23]</sup>.

Ribavirin is a guanosine analog that exhibits broad-spectrum activity against DNA and RNA viruses. Its mechanism of action is based on the erroneous incorporation of ribavirin triphosphate into replicating RNA strands, thereby inhibiting chain elongation<sup>[24]</sup>. When used with interferon, ribavirin acts synergistically, preventing relapses and breakthroughs, and remains relevant in the DAA era in special circumstances. The major side effects of ribavirin are hemolytic anemia and teratogenicity. The renal excretion of ribavirin and its metabolites accounts for 40% of its clearance; the remainder is eliminated through the spleen *via* its principal metabolite, ribavirin triphosphate, which is captured in erythrocytes. Based on the product characteristics, the ribavirin area under the concentration curve (AUC) is doubled when calculating estimated glomerular filtration rates (eGFRs) between 30 and 45 mL/min per 1.73 m<sup>2</sup> and is tripled when calculating eGFRs between 13 and 30 mL/min per 1.73 m<sup>2</sup><sup>[25]</sup>.

#### *Pharmacokinetics of DAAs*

**First-generation protease inhibitors:** Telaprevir and boceprevir are significantly high CYP3A4, P-glycoprotein (P-gp) inhibitors and are also OATP1B1/2 and OCT 1 and 2 inhibitors, respectively.

Thus, they interact significantly with calcineurin inhibitors in transplant patients and with some human immunodeficiency virus (HIV)-specific medications, thereby increasing the renal toxicity of these drugs by increasing their exposure<sup>[26,27]</sup>. These drugs are poorly eliminated by the kidney (1% for telaprevir<sup>[28]</sup>, 9% for boceprevir<sup>[29]</sup>). Telaprevir is excreted by the tubular cells through organic cation transporter 2 (OCT2) and presents a risk of interaction with medications such as dolutegravir<sup>[30]</sup>.

**New DAAs:** Most new DAAs are eliminated in the bile, with the exception of sofosbuvir, which is the keystone

of the main approved DAA regimens.

Sofosbuvir weakly inhibits CYP3A4, intestinal P-gp, and BCRP. Seventy-two percent of sofosbuvir is eliminated by the kidney, primarily as its main metabolite GS-331007<sup>[31]</sup>. The mechanism of clearance warrants study, even if it is reasonable to evoke tubular excretion by analogy with HIV or hepatitis B virus (HBV) analogs. GS-331007 AUC is greater than 55%, 88% and 451% in cases of mild, moderate and severe renal insufficiency, respectively. GS-331007 exposure is increased by at least 10 to 20 times in patients with ESRD<sup>[32]</sup>.

**Several DAAs can be used in combination with sofosbuvir:** (1) NS3/4 protease inhibitor: Simeprevir moderately inhibits CYP3A and intestinal P-gp and potentially inhibits OATP1B1 and MRP2. Its urinary excretion is less than 1%<sup>[33]</sup>. On average, the simeprevir AUC is increased by 62% in subjects with severe renal impairment. The drug is not eliminated by dialysis; and (2) NS5A inhibitors: Daclatasvir is a substrate of CYP3A4 and P-gp and moderately inhibits OATP1B1/3 and P-gp. Its excretion in urine is < 1%. In case of severe renal insufficiency, AUC is increased by 27%, but no dose adjustment is needed<sup>[34]</sup>. Ledipasvir is a weak inhibitor of P-gp and BCRP. Its renal excretion is < 1%<sup>[35]</sup>, and its pharmacokinetics are not altered by severe renal impairment<sup>[36]</sup>. Velpatasvir moderately interacts with CYP3A4, CYP2C8, OATP and P-gp<sup>[37]</sup> and is primarily eliminated in the feces (> 99%). The sofosbuvir/velpatasvir combination will be available soon. According to very preliminary data, this combination appears well tolerated in subjects with severe renal impairment. Velpatasvir AUC is approximately 50% higher in these subjects than in subjects with normal function<sup>[38]</sup>.

**Other combinations exist:** (1) paritaprevir/ritonavir (anti-protease inhibitor), ombitasvir (anti-NS5A inhibitor) and dasabuvir (anti-polymerase inhibitor). Paritaprevir/ritonavir is a powerful CYP3A4 inhibitor. Ritonavir is a well-known inhibitor of many renal transporters including OAT1, OAT2, MRP2, MRP4 and MATE1<sup>[39]</sup>. The four-drug combination is a substrate of P-gp and CYP3A4 and is mainly eliminated in the bile<sup>[40,41]</sup>. In case of CKD 1, paritaprevir and dasabuvir AUCs are increased by 20%, and ritonavir AUC is increased by 42%. In patients with CKD 2 and 3, paritaprevir and dasabuvir AUCs are increased by 37% and ritonavir AUC is increased by 80%. In patients with CKD 4, paritaprevir and dasabuvir AUCs are increased by 50%, and ritonavir AUC is increased by 114%. Ombitasvir AUC remains unchanged<sup>[42]</sup>, and (2) grazoprevir and elbasvir: This regimen will be available soon. Both molecules are substrates of CYP3A4, OATP and P-gp<sup>[43]</sup>. Less than 1% of grazoprevir and elbasvir are excreted by the kidney; the AUC<sub>0-24h</sub> values of grazoprevir and elbasvir are higher in subjects with severe renal insufficiency relative to controls [1.65- (1.09, 2.49) and 1.86-fold (1.38, 2.51) (90%CI), respectively]. Drug removal by hemodialysis is negligible<sup>[44]</sup>. Clinical

experience shows that dose adjustment is not needed in the setting of non-dialysis-dependent stage 4-5 CKD and dialysis-dependent stage 5 CKD<sup>[17]</sup>.

## SPECIFIC NEPHROTOXICITY OF HCV DRUGS

### *Interferon or pegylated interferon and ribavirin*

A dose-dependent or idiosyncratic renal toxicity of alpha interferon and pegylated interferon is well established although rare<sup>[45]</sup>. This nephrotoxicity is mostly reported in cases of malignancy<sup>[46,47]</sup>. However, no correlations were found among the occurrence of renal involvement, the type of interferon used, administration route, treatment dosage and duration, and the patient's profile. The histological features are nonspecific and various, mainly involving minimal forms of glomerular damage, including cellular hyperplasia and focal segmental glomerulosclerosis, which are often associated with nephrotic syndrome<sup>[45,48-51]</sup>. Interferon may worsen any pre-existing glomerular lesions<sup>[52]</sup>. Microangiopathic thrombosis has also been described<sup>[53,54]</sup>. More rarely, interstitial fibrosis (usually mild) as well as nonspecific interstitial inflammation and tubular atrophy, and interstitial nephritis associated with nephrotic syndrome<sup>[55]</sup> or acute tubulopathy<sup>[47,56,57]</sup> have been reported.

Proteinuria (usually a self-limited proteinuria that does not exceed 1 g/d) is observed in 15% to 20% of patients taking interferon<sup>[58,59]</sup>. Nevertheless, hepatitis C-associated glomerulonephritis may be cured with alpha interferon-based treatment, independent of SVR<sup>[60]</sup>.

Renal failure generally occurs during the first weeks of treatment and rarely occurs after several months<sup>[61]</sup>.

The involved physiopathological mechanisms are not clear. In a cellular model, Lechner *et al.*<sup>[62]</sup> demonstrated that interferon directly affects tubular barrier function in renal epithelial cells in a reversible time- and dose-dependent manner. More recently, the same team showed that alpha interferon can activate caspase-3, -8 and -9, which favors the apoptosis cascade in renal proximal tubular epithelia. Gresser *et al.*<sup>[63]</sup> showed that the daily administration of interferon to newborn mice can lead to severe glomerulopathy associated with glomerular sclerosis and IgG and C3 deposits<sup>[64]</sup>.

Ribavirin renal toxicity has not been documented and is not probable in monotherapy<sup>[65,66]</sup>. Nevertheless, by analogy with the ribavirin apoptotic activity observed in K562 leukemia cells, potential tubular toxicity has been hypothesized<sup>[65,67]</sup>.

### *New treatments and nephrotoxicity*

**Boceprevir and telaprevir:** The first-generation protease inhibitors boceprevir and telaprevir have been combined with pegylated interferon and ribavirin. No renal side effect was found in phase III studies<sup>[68-74]</sup>, which is consistent with the weak renal clearance of these drugs. Nevertheless, in a large cohort (1486 patients),

Mauss *et al.*<sup>[10]</sup> showed a reversible decrease of eGFR in patients taking telaprevir or boceprevir. Similar reports involving telaprevir therapy confirmed this observation and suggested a link with anemia occurrence<sup>[75-78]</sup>. Recently, Kunze *et al.*<sup>[30]</sup> described competition between telaprevir and OCT2, which interacts with creatinine tubular transport and is involved in proximal tubular secretion. Our team validated this hypothesis with a predictive model suggesting that the clinically observed creatinine increase is not due to renal toxicity of the drug<sup>[11]</sup>. Independent of this pharmacological effect, one of our patients experienced acute renal failure at week 20 of telaprevir treatment. In addition to extra-membranous glomerulonephritis, the renal biopsy showed particularly intense interstitial fibrosis that would exceptionally be described by pegylated interferon and probably implies telaprevir or a combination of telaprevir-pegylated interferon<sup>[3]</sup>.

**New DAAs:** The renal toxicity of new DAA was not a safety signal in phase III clinical trials<sup>[79-83]</sup>; however, most of the included patients presented with eGFR values of greater than 60 mL/min per 1.73 m<sup>2</sup> and few comorbidities. The prescription of sofosbuvir is not desirable for patients with an eGFR of less than 30 mL/min per 1.73 m<sup>2</sup>. In practice, however, half of the daily dose<sup>[84]</sup> or a full dose taken every other day<sup>[85]</sup> was found safe. Various recommendations<sup>[14-16]</sup> specify that renal function should be monitored during treatment with sofosbuvir (grade B). Indeed, on the one hand, the drug is cleared by the kidney; on the other hand, a structural analogy with HBV nucleotide analogs is observed. Therefore, competitive risks with other drugs (antiviral or anti-calcineurins) that are eliminated by the tubule are awaited. In a prospective unselected HCV population, we were unable to find evidence for the induction of subclinical tubulopathy by the antiviral treatment when using tools for the early detection of proximal tubular injury (unpublished data). However, potential proximal tubular toxicity can be hypothesized.

DAAs are usually combined with sofosbuvir, *i.e.*, simeprevir, daclatasvir and ledipasvir do not appear to increase renal risk, although it is difficult to distinguish between the contributions of sofosbuvir and other drugs with which it is combined to the occurrence of renal failure: (1) simeprevir: Renal failure resulting from simeprevir therapy was not found in phase III studies<sup>[86,87]</sup>, except in association with sofosbuvir<sup>[13,88]</sup>; (2) daclatasvir: No renal warning was observed in phase III studies<sup>[89]</sup>, except when daclatasvir was associated with sofosbuvir in liver transplant patients<sup>[90]</sup>; and (3) ledipasvir: One case report suggested possible acute renal toxicity, but this occurred in association with sofosbuvir<sup>[91]</sup>.

Concerning the combination ombitasvir, paritaprevir/ritonavir, dasabuvir, plasma creatinine increase was described in 2 of the 293 patients who had experienced previous interferon-based treatment<sup>[92]</sup>. Other phase III studies did not describe any renal adverse event<sup>[93-96]</sup>.

## EXPERIENCES ON ANTI-HCV THERAPIES IN POPULATIONS AT RENAL RISK

### ESRD and hemodialysis

HCV prevalence is high among patients on long-term dialysis (5% to 10% in Europe and in the United States and 10% to 70% in developing countries)<sup>[97]</sup>. HCV decreases global survival in this population<sup>[98]</sup>.

HCV screening is recommended once yearly in hemodialysis patients. Patients generally present with normal transaminase levels<sup>[99]</sup>, low viral load<sup>[100]</sup>, and moderate fibrosis stage<sup>[8,101,102]</sup>, although fibrosis appears to progress more rapidly in this population. For these reasons, anti-HCV treatment is warranted.

Three meta-analyses of historical treatment with pegylated alpha interferon and ribavirin showed a 40% SVR in ESRD<sup>[103-105]</sup>. The results obtained did not differ between alpha interferon and pegylated alpha interferon<sup>[106]</sup>. Ribavirin is generally contra-indicated in patients with eGFR values of less than 50 mL/min due to the high risk of ribavirin metabolite accumulation in erythrocytes, which increases the amplitude of hemolytic anemia<sup>[24,107]</sup>. However, at minimal doses, ribavirin was used after each dialysis session<sup>[108]</sup> or 5 d per week<sup>[109]</sup>. The erythropoietin doses were usually increased<sup>[109]</sup>.

First-generation protease inhibitors in combination with pegylated interferon and ribavirin gave potentially interesting results<sup>[110-113]</sup>, but the observed high antiviral efficacy was accompanied by numerous serious adverse effects<sup>[112]</sup>.

ESRD and dialysis patients should be given priority treatment with new DAAs while avoiding peginterferon and ribavirin.

The currently available data on the approved DAAs are sparse. The adequate dose of sofosbuvir is unknown, and ribavirin should be avoided (see above).

Small preliminary studies, mainly based on the sofosbuvir/simeprevir combination<sup>[84,114,115]</sup>, have shown a SVR rate of between 87% and 100% in ESRD genotype 1 patients. In a real-life TARGET cohort evaluating a sofosbuvir and simeprevir regimen, similar results were observed, with an increased benefit when adding ribavirin; however, anemia risk was increased<sup>[13]</sup>. In summary, the safety of sofosbuvir in ESRD is unclear, and larger trials are awaited.

Recently, preliminary results of the RUBY-1 trial including 20 patients with CKD 4 renal insufficiency receiving the approved regimen of ombitasvir, paritaprevir/ritonavir, and dasabuvir with (genotype 1a) or without (genotype 1b) ribavirin showed a SVR of 90%; however, ribavirin had to be stopped in 9 of the 13 G1a patients<sup>[18]</sup>.

More recently, elbasvir and grazoprevir were administered together once daily in the largest trial to date (the Phase III C-SURFER study); the trial included 224 ESRD patients, 179 of whom were hemodialysis dependent, and achieved a 99% SVR12 in genotype 1 patients<sup>[17]</sup>. Elbasvir and grazoprevir are expected to be approved shortly.

Thus, two regimens are or will be recommended in genotype 1 patients with severe renal insufficiency: Paritaprevir-ritonavir-ombitasvir-dasabuvir for patients with G1b and grazoprevir-elbasvir for patients with all G1 subtypes.

### **Patients with renal impairment**

In the TARGET cohort, the sofosbuvir/simeprevir combination (with or without ribavirin or pegylated interferon) was found to be efficacious and safe in HCV-infected patients of differing CKD stage. Compared with patients without renal insufficiency, these patients experienced a deterioration of their eGFR (25% with an initial eGFR < 30 mL/min per 1.73 m<sup>2</sup>, 13% with an eGFR of between 31 and 45 mL/min per 1.73 m<sup>2</sup>, and 1% to 2% with an eGFR > 45 mL/min per 1.73 m<sup>2</sup>). These results suggest that sofosbuvir-based treatments used in kidney patients warrant close monitoring<sup>[13]</sup>. In the TARGET cohort, patients with a basal eGFR of less than 30 mL/min per 1.73 m<sup>2</sup> showed a high risk of acute renal insufficiency (25%)<sup>[13]</sup>.

### **Kidney transplantation**

HCV prevalence among kidney transplant patients is approximately 10%, and most of the patients are viremic<sup>[116]</sup>. HCV decreases global survival in this population<sup>[117]</sup>.

HCV also increases sepsis, diabetes, glomerulonephritis and rejection<sup>[102,117-120]</sup>.

Anti-viral treatment is recommended for preventing fibrosis progression, risk of fibrosing cholestatic hepatitis and sepsis. Interferon is no longer recommended in this setting due to the strong risk of rejection<sup>[121]</sup>, although this risk has been shown to be lower than expected<sup>[122,123]</sup>. Moreover, meta-analyses have demonstrated a weak SVR rate (18% to 26.9%) and a high rate of withdrawal: 21.1% to 35% with alpha interferon<sup>[124,125]</sup> and 40.6% with pegylated interferon<sup>[125]</sup>. No data with pegylated interferon and boceprevir or telaprevir-based triple therapy are available. However, the data obtained from liver transplant experience show that it is very difficult to manage drug interactions with calcineurin inhibitors, thus leading to serious adverse events<sup>[26]</sup>.

A few published preliminary studies using sofosbuvir-based combinations showed a SVR > 95%; however, the immunosuppressing drug concentrations varied, a finding that should be studied and monitored<sup>[126-130]</sup>. Liver transplantation experience is more important, and treatment of such patients has shown good results in terms of efficacy, tolerance and medication interactions<sup>[90,131]</sup>.

Recently, the concept of pre-transplant treatment has become preeminent, especially for patients of genotypes 1 and 4, due to the availability of regimens avoiding sofosbuvir<sup>[17]</sup>. However, patients with genotypes 2 and 3 for whom sofosbuvir-based regimens are recommended should be treated after kidney transplantation while awaiting new pangenotypic combinations<sup>[132]</sup>.

### **Liver transplantation**

In the French CUPILT cohort of liver transplant patients who were treated with sofosbuvir and daclatasvir,

37.1% experienced a 25% decrease of GFR during or after treatment; however, in 10.9% of the cases, this GFR decrease was not reversible. The existence of prior kidney disease and fibrosing cholestatic hepatitis were both independent predictors of decreased GFR. The authors emphasized the importance of close renal function monitoring in this population<sup>[12]</sup>. These data were confirmed in an American multicenter study<sup>[133]</sup>. Moreover, patients with fibrosing cholestatic hepatitis who were treated with sofosbuvir, ribavirin and pegylated interferon ( $n = 8$ ) or daclatasvir, sofosbuvir and ribavirin ( $n = 14$ ) experienced high rates of renal failure (4/8 and 7/14, respectively), including 1 with creatinine clearance of less than 30 mL/min per 1.73 m<sup>2</sup><sup>[90]</sup>.

### **Coinfected patients**

In coinfecting patients of the ION-4 study, who were treated with sofosbuvir/ledipasvir, 4 of the 335 patients exhibited worsened renal function (a creatinine increase of 35  $\mu$ mol/L or more); tenofovir AUC<sub>tau</sub> increased by 20% and 30% in two patients, one patient discontinued tenofovir, and the drug dose was reduced for one patient<sup>[134]</sup>.

Renal function improved in all patients after treatment discontinuation.

### **Particular cases**

**Acute renal insufficiency:** Acute renal insufficiency has mainly been reported in cohorts with high renal risk. Recently, the first case of acute kidney injury, as documented by renal biopsy, was described in a patient receiving sofosbuvir and ledipasvir and suffering from hypertension and diabetes mellitus type 2: The biopsy showed an acute allergic interstitial nephritis with diabetic nephropathy. Corticosteroid therapy was introduced, and this stabilized the renal function<sup>[91]</sup>.

**Adolescents and children:** The pharmacokinetics of new antiviral drugs are not known in this population. To our knowledge, only one study using ledipasvir/sofosbuvir (90/400 mg) in 100 adolescent patients (12 to 17 years old) with HCV genotype 1 for 12 wk resulted in an SVR12 rate of 97%, a similar result to that obtained in adults. Ledipasvir/sofosbuvir was well tolerated with no grade 3-4 adverse events, serious adverse events, or treatment discontinuations due to adverse events<sup>[135]</sup> in particular renal events. In the context of the universal use of new DAAs, a study in children aged 3 to < 12 years is ongoing (ClinicalTrials.gov Identifier: NCT02249182).

In summary, sofosbuvir-based combinations have exhibited renal toxicity in frail patients such as CKD, transplant and HIV co-infected patients under real-life conditions. Real-life studies suggest a risk of eGFR deterioration in patients with previous renal impairment, suggesting that these combinations be used cautiously in this setting including, in particular, diabetes mellitus and hypertension.

Physiopathologically, tubular toxicity can be suggested by structural analogy between this drug and antiretroviral analogs; however, this was not demonstrated in patients

with normal renal function. Nevertheless, these new anti-HCV DAAs appear to act synergistically with drugs that are known to exert a toxic action on the tubule, such as anticalcineurins and tenofovir. Finally, a classic drug-induced renal tubulointerstitial disease of immunological origin has recently been described in at least one documented case with renal biopsy.

New combinations, such as paritaprevir-ritonavir-ombitasvir-dasbuvir for genotype 1b and grazoprevir-elbasvir for all genotype 1 subtypes, show promise in patients with severe renal impairment.

## CONCLUSION

HCV treatment should be offered to all patients with ESRD or kidney transplant candidates, regardless of liver fibrosis stage, due to the intimate link between HCV, renal diseases and comorbidities such as cardiovascular complications and diabetes and because of the impact of HCV on mortality.

There is no clear recommendation for the use of currently approved DAAs in cases of severe renal insufficiency; these drugs may be prescribed under certain conditions, preferably without ribavirin. However, expert opinions are needed.

New DAAs, which will soon be approved, will probably favorably change the landscape.
