**Core tip:** Compared to the standard-of care treatment with peginterferon and ribavirin (PR), addition of boceprevir to PR results in a significant increase in rates of sustained virologic response achieved with substantially shorter treatment durations across a broad cross-section of patients with chronic hepatitis C virus infection in Russia.

## Abstract

**AIM:** To evaluate addition of boceprevir to peginterferon/ribavirin (PR) in Russian patients with chronic hepatitis C virus (HCV).

**METHODS:** Treatment-naïve (TN) and treatment-experienced (TE) patients (who had failed prior treatment with PR for  $\geq 12$  wk) with chronic HCV genotype 1 infection were enrolled in this placebo-controlled, double-blind study. All patients initially received PR for 4 wk. Patients randomized to control treatment then received PR for an additional 44 wk. TN patients randomized to triple therapy received boceprevir (800 mg three times daily) plus PR for 24 wk and then further therapy according to treatment week 8 (TW8) HCV RNA levels. TE patients received boceprevir plus PR for 32 wk and then further therapy according to TW8 HCV RNA levels. Treatment was discontinued for TN patients with detectable HCV RNA at TW24 and TE patients with detectable HCV RNA at TW12 because of futility. The primary efficacy end point was sustained virologic response (SVR) defined as undetectable HCV RNA 24 wk after completing all study therapy.

**RESULTS:** SVR was 74.8% in the boceprevir plus PR arm compared with 46.2% in the control arm, with a stratification-adjusted treatment difference of 29.2% (95%CI: 16.4-41.5;  $P < 0.0001$ ). Rates of SVR were higher in the boceprevir arm in both TN and TE patient groups (TN 78.4% *vs* 56.3%; TE 69.4% *vs* 30.0%). Within TE patients, the rates of SVR were higher with boceprevir plus PR compared with PR, regardless of treatment failure type (null responder, partial responder, and relapser). Most patients receiving boceprevir plus PR in both TN (86%) and TE (71%) populations were eligible for reduced treatment duration. Anemia was increased in patients receiving boceprevir plus PR *vs* PR alone (47.2% *vs* 24.4%); there was a corresponding increase in ribavirin dose reduction and erythropoietin use. Among patients receiving boceprevir plus PR, SVR rates were similar in patients with anemia ( $< 10$  g/dL) and those without anemia (71.2% *vs* 77.4%).

**CONCLUSION:** Regulatory approval has been obtained for boceprevir plus PR in Russian patients with HCV genotype 1 infection based on the results of this study.

**Key words:** Hepatitis C virus; Boceprevir; Peginterferon; Ribavirin; Randomized; Clinical trial; Sustained virologic response

Isakov V, Nikitin I, Chulanov V, Ogurtsov P, Lukyanova E, Long J, Wahl J, Helmond FA; The P08160 Trial Investigators. Boceprevir plus peginterferon/ribavirin for treatment of chronic hepatitis C in Russia. *World J Hepatol* 2016; 8(6): 331-339 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i6/331.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i6.331>

## INTRODUCTION

Boceprevir is an orally administered, serine protease inhibitor of the hepatitis C virus (HCV) nonstructural protein 3 protease<sup>[1]</sup>. The addition of boceprevir to peginterferon and ribavirin (PR) improves rates of sustained virologic response (SVR) in adult patients with HCV genotype 1 (GT1) infection<sup>[2,3]</sup>. In the phase 3 SPRINT-2 study in previously untreated patients and the RESPOND-2 study in patients who had failed previous treatment, the addition of boceprevir to PR increased SVR rates compared with PR alone. In both studies, the implementation of response-guided therapy (RGT) permitted a shortened treatment duration for patients with an early response to therapy. In SPRINT-2, 44% of patients receiving boceprevir RGT required only 28 wk of treatment with triple therapy, and the SVR rate in this group was 96%<sup>[3]</sup>. Similarly, in RESPOND-2, 46% of patients had undetectable HCV RNA at treatment week 8 (TW8) and were eligible for a shortened 36-wk treatment regimen: SVR in this population was 86%<sup>[2]</sup>. In these studies, the safety profile of boceprevir plus PR largely resembled the safety profile of PR alone, with the notable exceptions of increased rates of dysgeusia and anemia in patients receiving boceprevir.

According to the World Health Organization (WHO), there were an estimated 5.8 million patients with HCV infection in Russia in 2010, accounting for 4.1% of the total Russian population<sup>[4]</sup>. In Western countries, treatment of HCV infection has advanced dramatically over the last 5 years with the introduction of new targeted therapies that substantially shorten treatment duration and improve SVR rates<sup>[5,6]</sup>. However, in resource-constrained countries, standard treatment protocols are lacking, and PR dual therapy frequently remains the cornerstone of treatment<sup>[7,8]</sup>. Recent guidelines from the WHO note the low rates of treatment uptake for patients in low- and middle-income countries. The aim of this study was to evaluate the safety and

**Figure 1 Study design.** BOC: Boceprevir; D/c: Discontinued; HCV: Hepatitis C virus; PR: Peginterferon/ribavirin; TW: Treatment week.

efficacy of boceprevir plus PR therapy in treatment-naïve (TN) and treatment-experienced (TE) Russian patients with chronic HCV GT1 infection.

## MATERIALS AND METHODS

This was a randomized, placebo-controlled, double-blind clinical trial (ClinicalTrials.gov identifier, NCT01425203; protocol P08160), carried out in accordance with the Declaration of Helsinki, current guidelines on Good Clinical Practice, and local ethical and legal requirements. All patients provided voluntary written informed consent before trial entry.

### Study design

Patients were randomized in a 2:1 ratio to receive experimental or control therapy, stratified by previous treatment (naïve vs experienced) and interleukin-28B (*IL28B*) status (CC allele vs non-CC allele) (Figure 1). All patients initially received PR [peginterferon alfa-2b (1.5 µg/kg per week) plus ribavirin (800-1400 mg/d)] for 4 wk. Patients in the control arm then received PR for an additional 44 wk. In the experimental arm, TN patients received boceprevir [800 mg three times daily (TID)] plus PR for 24 wk and then further therapy according to TW8 HCV RNA levels. Patients with undetectable HCV RNA at TW8 concluded treatment at week 28 while those with detectable HCV RNA at TW8 continued therapy with PR from weeks 28-48. TE patients received boceprevir (800 mg TID) plus PR for 32 wk and then further therapy according to TW8 HCV RNA levels. Patients with undetectable HCV RNA at TW8 concluded treatment at week 36, while those with detectable HCV RNA at TW8 continued PR therapy from weeks 36-48. Treatment was discontinued for TN patients with detectable HCV RNA at TW24 and TE patients with detectable HCV RNA at TW12

because of futility. Patients in the control arm (PR only) who failed treatment because of the futility rule could cross over to receive triple therapy. TN patients with  $< 2 \log_{10}$  decline in HCV RNA at TW12, or with detectable HCV RNA at TW24 could cross over to receive boceprevir plus PR for 32 wk. TE patients with detectable HCV RNA at TW12 could also cross over to receive boceprevir plus PR for 32 wk. Duration of further therapy depended on HCV RNA detectability at crossover week 4 (COW4). Crossover treatment duration was 32 (COW4 HCV RNA undetectable) or 44 wk (COW4 HCV RNA detectable).

### Patients

The study population included TN and TE adult patients with chronic HCV infection (enrollment ratio 60:40). TN patients had received no previous therapy for HCV infection, whereas TE patients were required to have received prior treatment with PR for  $\geq 12$  wk without interruption or dose reduction. Inclusion criteria for the study included a baseline viral load of  $\geq 10000$  IU/mL, and a liver biopsy consistent with chronic HCV infection. Cirrhotic patients were required to have an ultrasound within 6 mo of screening with no evidence of hepatocellular carcinoma. Exclusion criteria included a platelet count of  $< 100000/\text{mm}^3$ ; hemoglobin levels  $< 12$  g/dL for females or  $< 13$  g/dL for males; human immuno-deficiency virus or hepatitis B virus infection; previous discontinuation of PR due to a treatment-related adverse event (AE); or decompensated liver disease, including a history or presence of ascites, bleeding varices, or hepatic encephalopathy.

### Assessments

The primary efficacy end point was SVR, defined as undetectable HCV RNA 24 wk after completing treatment in randomized patients who received at least 1 dose

of any trial medication. HCV RNA was detected using COBAS® AmpliPrep/COBAS® TaqMan® HCV Test, version 1.0 (Roche Diagnostics, Basel Switzerland); lower limit of quantification = 43 IU/mL; limit of detectability = 18.0 IU/mL. The key secondary end point was the achievement of SVR in randomized patients who received at least 1 dose of boceprevir or boceprevir placebo therapy. Other end points included the relationship between early virologic response and SVR (summarized using the proportion of patients who achieved SVR among those with undetectable HCV RNA at TW4, TW8 or TW12), the proportion of patients with virologic breakthrough (undetectable HCV RNA and subsequent HCV RNA above the limit of quantification while on study therapy), the proportion with incomplete virologic response (> 1 log<sub>10</sub> increase in HCV RNA from nadir value while on study therapy), and safety.

### Statistical analysis

The statistical methods of this study were reviewed by Jianmin Long from Merck and Co., Inc. Analyses were based on the full analysis set population, which included all randomized and treated patients. Target enrollment was 70 patients in the PR control group and 140 in the boceprevir plus PR arm, providing 98% power to demonstrate the superiority of boceprevir plus PR vs PR at an overall 1-sided, 2.5% alpha level, if the underlying difference in SVR was 30%. The power and sample size calculations were based on the assumption of an

underlying response rate of 30% for the PR control arm. The minimum criterion for success was that the *P* value for the comparison of SVR between the boceprevir plus PR arm and the control PR arm was < 0.05. An interim analysis was performed when all patients had completed at least 8 wk of treatment or had discontinued therapy. The results of this interim analysis were used as the basis for regulatory submission in Russia.

Achievement of SVR was summarized using descriptive statistics. The primary statistical comparison was conducted on the full analysis set using the stratified Miettinen and Nurminen method at alpha level of 0.05 adjusted for stratification factors (*IL28B* genotype CC vs non-CC and TN vs TE) as specified at the time of randomization. Multiplicity adjustment for controlling the type 1 error for the primary and key secondary comparisons was based on the step-down approach. The key secondary comparison was tested only if the statistical significance of the primary comparison reached an alpha level of 0.05. Any patient with missing data at, or after follow-up week 24, and undetectable HCV RNA at follow-up week 12, was considered a sustained virologic responder. For efficacy analyses, patients in the PR control arm who rolled over to the crossover arm were considered as failures at and after the time of the crossover.

## RESULTS

### Patients

A total of 238 patients were randomly assigned: 159 were assigned to receive boceprevir plus PR and 79 were assigned to PR (Figure 2). One patient assigned to PR did not receive any study medication and was therefore excluded from the full analysis set population. Four patients discontinued during lead-in (boceprevir plus PR, *n* = 3; PR, *n* = 1), yielding 233 patients in the modified intent-to-treat data set. Fifty-nine patients (boceprevir plus PR, *n* = 24; PR, *n* = 35) discontinued after adding boceprevir/placebo, with the most common reason for discontinuation being treatment failure (5% of patients receiving boceprevir plus PR and 34% of those receiving PR alone were discontinued based on futility criteria, Figure 2). Twenty-seven patients in the PR control arm entered crossover because of treatment failure at the futility time points. In total, 229 patients entered the follow-up phase (Figure 2). The majority of patients were white, with GT1b infection, and the *IL28B* non-CC genotype (Table 1). Few patients were cirrhotic. Compliance rates with boceprevir therapy were high (97.5% of patients had ≥ 80% compliance).

### SVR

SVR at follow-up week 24 was higher in the boceprevir plus PR arm compared with the control arm [74.8% (119/159) vs 46.2% (36/78)], with a stratification-adjusted treatment difference of 29.2% (95%CI: 16.4–41.5; *P* < 0.0001) (Figure 3). The end of treatment response rate was 87.4% (139/159) for the boceprevir

Figure 2 Patient disposition. BOC: Boceprevir; PR: Peginterferon/ribavirin.

Figure 3 Analysis of sustained virologic response, end of treatment response, and relapse rate. If a patient had missing data at and after the FW24 window and had undetectable HCV RNA at FW12, the patient was considered a sustained virologic responder. The  $P$  value was adjusted for stratification factors of *IL28B* genotype (CC vs non-CC) and previous treatment (TN vs TE), based on the Miettinen and Nurminen method. EOT was defined as the last dose date in treatment phase  $\pm 14$  d inclusive. The closest value to the last dose date was considered to be the EOT value. If there was no value within this window, the closest available value after this window was used. Relapse was defined as any patient who had detectable HCV RNA following end of all study therapy, after becoming undetectable and remaining so until end of treatment. EOT: End of treatment; HCV: Hepatitis C virus; PR: Peginterferon/ribavirin; SVR: Sustained virologic response; TE: Treatment experienced; TN: Treatment naive; *IL28B*: Interleukin-28B.

plus PR arm, and 59.0% (46/78) for the PR control arm. The relapse rate was 14.6% (20/137) for the boceprevir plus PR arm, and 20.0% (9/45) for the PR control arm.

#### Virologic failure

Rates of virologic breakthrough were 3.8% (6/159) in the boceprevir plus PR arm, and 5.1% (4/78) in the PR control arm. No patients in the PR control arm exhibited virologic rebound. Incomplete virologic response/rebound rate in the boceprevir plus PR arm was 3.1% (5/159). Five patients with incomplete virologic response had samples sequenced, of which 3 samples had variants detected (V36M,  $n = 1$ ; T54A,  $n = 2$ ; T54S,  $n = 1$ ; T54T,  $n = 2$ ). Similarly, 5 patients with virologic breakthrough had samples sequenced, of which 3 had detectable HCV variants (T54A,  $n = 1$ ; T54S,  $n = 1$ ; T54T,  $n = 2$ ; V55A,  $n = 1$ ).

#### SVR according to on-treatment virologic response

All patients with undetectable HCV RNA at TW4 in both treatment arms attained SVR (Table 2). In both treatment arms, all patients received PR alone for the first 4 wk of therapy. The proportions of patients with  $< 1$  log drop [boceprevir 43/159 (27%) and PR 22/78

**Table 2** Sustained virologic response by previous treatment, interleukin-28B genotype, and on-treatment virologic response *n* (%)

No	72/93 (77.4)	30/67 (44.8)
SVR according to EPO use		
Yes	10/15 (66.7)	3/3 (100)
No	109/144 (75.7)	33/75 (44)
SVR according to ribavirin dose reduction		
Yes	46/67 (68.7)	12/17 (70.6)
No	73/92 (79.4)	24/61 (39.3)

SVR is defined as the virologic response at follow-up week 24. If a patient had missing data at and after the follow-up week 24 window and had undetectable HCV RNA at follow-up week 12, the patient was considered a sustained virologic responder. EPO: Erythropoietin; HCV: Hepatitis C virus; SVR: Sustained virologic response; TW: Treatment week; PR: Peginterferon/ribavirin; *IL28B*: Interleukin-28B.

(28%)] and ≥ 1 log drop [boceprevir 90/159 (57%) and PR 45/78 (58%)] in HCV RNA at TW4 were similar in both treatment arms. However, SVR was higher in patients receiving boceprevir + PR compared with PR within the subgroups of patients with < 1 log drop in HCV RNA at TW4 (46.5% vs 0%) and those with ≥ 1 log drop in HCV RNA at TW4 (83.3% vs 57.8%).

A TW8 interim analysis was submitted for regulatory approval in Russia. In this analysis, rates of undetectable HCV RNA at TW8 in the boceprevir RGT and PR arms were 91% (88/97) vs 48% (23/48) in TN patients and 82% (51/62) vs 33% (22/67) in TE patients. Overall, the rates of undetectable HCV RNA at TW8 in all patients

were higher in patients receiving boceprevir plus PR compared with control therapy (87.4% vs 42.3%, *P* < 0.0001). SVR rates in patients with undetectable HCV RNA at TW8 were similar between treatment arms [boceprevir + PR 82.7% (115/139) vs PR 87.9% (29/33)].

### SVR according to baseline variables

SVR rates are presented by previous treatment and response, and *IL28B* genotype (Table 2). SVR rates were higher in patients receiving boceprevir plus PR compared with PR in both TN (78.4% vs 56.3%) and TE (69.4% vs 30.0%) subgroups. Within TE patients, the rates of SVR were higher with boceprevir plus PR compared with PR, regardless of treatment failure type (null responder, partial responder, and relapser). SVR rates were high among all patients with *IL28B* CC genotype, regardless of treatment arm or previous treatment history. Conversely, the rates of SVR in patients with *IL28B* CT or TT genotypes were higher with boceprevir plus PR compared with PR alone (Table 2). SVR rates were also higher with boceprevir compared with PR, regardless of baseline viral load. SVR was 87% in TN patients with baseline viral load ≤ 800000 IU/mL. Among patients receiving boceprevir, rates of SVR were generally higher in TN patients with low viral load compared with those with high baseline viral load (86.5% vs 68.9%); however, SVR was similar in TE patients with high vs low baseline viral load receiving boceprevir (70.3% vs 68.0%) (Table 2).

### SVR in patients requiring anemia management

Among patients receiving boceprevir plus PR, SVR rates were similar in patients with anemia (< 10 g/dL) and those without anemia (71.2% vs 77.4%). SVR rates were also relatively similar in boceprevir recipients requiring erythropoietin (EPO) for anemia management and those not using EPO (66.7% vs 75.7%, Table 2), and in those who received ribavirin dose reduction and those who did not (68.7% vs 79.4%).

### Crossover therapy

The SVR rates for the crossover group are presented in Table 3. Overall, 70.4% of patients who crossed over from PR alone to boceprevir plus PR had SVR at follow-up week 24.

### Safety

The reported AEs were consistent with the known safety profile of boceprevir (Table 4), with treatment-emergent AEs noted frequently in both treatment arms (97.5% in the boceprevir plus PR arm and 91.0% in the PR control arm). The number of patients discontinuing treatment because of AEs was 4.4% in the boceprevir plus PR arm (*n* = 7, of which 5 were considered treatment related) and 2.6% in the PR control arm (*n* = 2, of which 1 was considered treatment related). Serious AEs were reported in 10.7% (*n* = 17, of which

**Table 3 Sustained virologic response at follow-up week 24 in the crossover group *n* (%)**

	SVR
Total	19/27 (70.4)
TN TW12 failure (< 2 log decline HCV RNA)	8/11 (72.7)
TE TW12 failure (detectable HCV RNA)	11/16 (68.8)
TN TW24 failure (detectable HCV RNA)	0/0

HCV: Hepatitis C virus; SVR: Sustained virologic response; TE: Treatment-experienced; TN: Treatment-naïve; TW: Treatment week.

12 were considered drug related) and 11.5% (*n* = 9, of which 5 were considered drug related) of patients in the boceprevir plus PR and PR arms, respectively. Dose modifications due to an AE were reported in 56% (89/159) in the boceprevir plus PR arm, and 33.3% (26/78) for PR alone. There were no deaths reported during the study.

Anemia was reported at a higher rate in patients receiving boceprevir plus PR compared with those receiving PR alone (47.2% vs 24.4%). However, few patients in either treatment group had on-treatment hemoglobin levels < 8.5 g/dL (boceprevir + PR 6.3% vs PR 2.6%). EPO use was reported for 9.4% of patients receiving boceprevir plus PR and 3.8% of those receiving PR alone. Ribavirin dose reduction was required for 65 patients (40.9%) receiving boceprevir plus PR and 14 patients (17.9%) receiving PR alone.

## DISCUSSION

Data from the present study indicate that, similar to activity seen in Western populations, boceprevir added to PR results in a marked improvement in SVR rates compared with PR alone in TN and TE Russian patients with HCV GT1 infection. The high rate of undetectable HCV RNA at TW8 in TN and TE patients receiving boceprevir plus PR resulted in a high proportion of patients being deemed eligible for RGT with consequent reductions in their treatment durations. The treatment effect (*i.e.*, difference in response between boceprevir plus PR and PR alone) was comparable between this study in Russian patients, and the phase 3 trials (Table 5). However, whereas 42%-46% of patients receiving boceprevir RGT in the phase 3 studies had undetectable HCV RNA at TW8, in the present study 87.4% of boceprevir recipients had undetectable HCV RNA at TW8. This suggests that the proportion of Russian patients eligible for shortened treatment duration may be higher than reported in the phase 3 studies, and is suggestive of a favorable cost/efficacy ratio in Russian patients. Response rates were particularly high among patients with favorable disease characteristics such as the *IL28B* CC genotype. In patients with this genotype, SVR rates were high regardless of treatment regimen; however, patients with the *IL28B* non-CC genotype derived a substantial benefit from boceprevir therapy.

The tolerability profile seen with boceprevir in

**Table 4 Adverse events ( $\geq 20\%$  in any treatment arm) *n* (%)**

	Boceprevir plus PR ( <i>n</i> = 159)	PR ( <i>n</i> = 78)
Any AE	155 (97.5)	71 (91.0)
Neutropenia	84 (52.8)	31 (41.0)
Pyrexia	77 (48.4)	36 (46.2)
Anemia	75 (47.2)	19 (24.4)
Leukopenia	62 (39.0)	25 (32.1)
Dysgeusia	59 (37.1)	3 (3.8)
Asthenia	44 (27.7)	23 (29.5)
Headache	43 (27.0)	25 (32.1)
Influenza-like illness	39 (24.5)	14 (17.9)
Nausea	39 (24.5)	9 (11.5)
Anemia		
8.5-10 g/dL	56 (35.2)	9 (11.5)
< 8.5 g/dL	10 (6.3)	2 (2.6)

Discontinued because of an AE	7 (4.4)	2 (2.6)
Dose modification due to an AE	89 (56.0)	26 (33.3)

AE: Adverse event; EPO: Erythropoietin; PR: Peginterferon/ribavirin.

Russian patients was consistent with the established tolerability profile documented in Western patients. The majority of AEs were associated with PR therapy. As seen in Western patients, anemia was increased with boceprevir, and there was also a corresponding increase in the use of anemia management strategies (ribavirin dose reduction and EPO use) among patients receiving boceprevir. In SPRINT-2 and RESPOND-2, approximately 3%-8% of patients receiving boceprevir plus PR had hemoglobin levels < 8.0 g/dL; EPO use was required in 41%-46% of patients, and 21% required dose reduction due to anemia<sup>[2,3]</sup>. In the present study, 6.3% of patients receiving boceprevir plus PR had nadir hemoglobin < 8.5 g/dL. There were also differences in the rates of anemia management strategies with lower rates of EPO use (9.4%) but higher rates of dose reduction (41%) in the present study compared with the phase 3 studies in Western patients<sup>[2,3]</sup>. These differences between studies are a reflection of the different anemia management strategies. In the phase 3 protocols, investigators were free to choose between ribavirin dose reduction and EPO use as a first-line strategy while in the present study ribavirin dose reduction was the first-line strategy and EPO use was the second-line strategy.

Response rates in this study are higher for both boceprevir plus PR and PR alone, compared with rates seen in previous phase 3 studies (Table 5). This increase in response may be explained by differences in the patient populations enrolled in the current study and the phase 3 studies<sup>[2,3]</sup>. Compared with patients enrolled in the boceprevir phase 3 studies, more Russian patients were aged  $\leq 40$  years (62% vs 13%), had baseline viral load  $\leq 800000$  IU/mL (60% vs 14%), and had HCV GT1b infection (98% vs 35%).

Data from the present study support the use of boceprevir in Russian patients with HCV GT1 infection. However, boceprevir-based triple therapy may not be

**Table 5 Comparison of virologic response rates between Russian patients and western patients receiving boceprevir-based triple therapy in the serine protease inhibitor therapy 2 and retreatment with hepatitis C virus serine protease inhibitor boceprevir and pegIntron/rebetol 2 studies *n* (%)**

Relapse	7/48 (14.6)	3/12 (25.0)	-	-	14/121 (12)	8/25 (32)

BOC: Boceprevir; EOT: End of treatment response; PR: Peginterferon/ribavirin; RESPOND-2: Retreatment with hepatitis C virus serine protease inhibitor boceprevir and pegIntron/rebetol 2 study; RGT: Response-guided therapy; SPRINT-2: Serine protease inhibitor therapy 2 study; SVR: Sustained virologic response; TE: Treatment experienced; TN: Treatment naive.

appropriate for all patients with GT1 infection. Patients with low viral load at baseline who achieve undetectable HCV RNA at TW4 may achieve high SVR rates with 24-wk of therapy with PR alone and would not require the addition of boceprevir<sup>[9]</sup>. Despite the world-wide acceptance of interferon-free regimens as a standard of care due to the near 100% efficacy and low adverse events rate, some patients will continue to receive interferon-based treatment. This is due largely to the fact that the approval of interferon-free regimens is not immediately followed by total reimbursement in many countries, or that access to these regimens is dependent on the stage of the liver disease, prioritizing treatment of cirrhotic patients<sup>[10-12]</sup>. Easy-to-treat patients can be successfully treated with interferon-based regimens which may be easier to access through reimbursement.

In conclusion, data from the present study support the use of boceprevir plus PR for the treatment of Russian patients with HCV GT1 infection. The safety and efficacy profile of boceprevir in Russian patients was generally similar to that previously reported in phase 3 studies in Western patients; however, this treatment may be more cost-effective in Russia as approximately 88% of patients had undetectable HCV RNA at TW8, suggesting that a higher proportion of Russian patients receiving boceprevir plus PR would be eligible for reduced treatment duration with RGT compared with Western patients. Regulatory approval has been obtained for boceprevir in Russia based on the results of this study.

## COMMENTS

### Background

In the treatment of hepatitis C virus (HCV), genotype 1 infection, peginterferon

plus ribavirin is associated with low efficacy and poor tolerability. Phase 3 studies have shown that addition of a direct-acting antiviral agent such as boceprevir can improve efficacy and shorten treatment durations.

### Research frontiers

The safety and efficacy of boceprevir plus peginterferon and ribavirin in Russian patients with HCV infection is currently unknown.

### Innovations and breakthroughs

In the present study, patients receiving boceprevir plus peginterferon and ribavirin achieved significantly higher rates of sustained virologic response compared with patients treated with peginterferon and ribavirin alone. Patients receiving boceprevir-based therapy frequently required substantially shorter treatment durations compared to patients receiving PR alone. Rates of anemia were higher among patients receiving boceprevir.

### Applications

Regulatory approval has been obtained for boceprevir in Russia based on the results of this study.

### Peer-review

This manuscript evaluates the efficacy and safety of boceprevir plus peginterferon and ribavirin in treatment-naïve and treatment-experienced Russian patients with HCV genotype 1 infection.

### Abstract

We describe a case of 42-year-old female presenting with abdominal pain associated with loss of weight and fever for 8 mo. On evaluation she had gross hepatomegaly with raised alkaline phosphatase and raised GGT levels with normal transaminases and bilirubin. On imaging she had diffuse enlargement of liver with heterogeneous contrast uptake in liver. Her viral marker and autoimmune markers were negative. Liver biopsy depicted massive deposition of amyloid in peri-sinusoidal spaces which revealed apple green birefringence on polarizing microscopy after Congo red staining. Cardiac and renal evaluation was unremarkable. Abdominal fat pad and rectum biopsy was negative for amyloid deposit. There was no evidence of primary amyloidosis as bone marrow examination was normal. Serum and urine immunofixation electrophoresis were normal. Immunoperoxidase staining for serum amyloid associated protein for secondary amyloidosis was negative from liver biopsy. We present this rare case of primary hepatic amyloidosis and review the literature regarding varied presentations of hepatic involvement in amyloidosis.

**Key words:** Amyloidosis; Congo red staining; Isolated hepatic amyloidosis; Amyloid associated protein; Immunofixation electrophoresis

**Core tip:** Amyloidosis is a pathological process that encompasses a spectrum of disease resulting from the extracellular deposition of fibrillar amyloid protein. It can involve any organ isolated or in conjunction with other organs and can do so in the form of a focal, tumour-like lesion, or an infiltrative process. Amyloidosis localized to the liver has been rarely described. This case represents a rare instance of primary hepatic amyloidosis without

evidence of primary or secondary cause of amyloid deposit posing considerable diagnostic and therapeutic challenge for the clinicians.

## INTRODUCTION

Amyloidosis is a pathological process that encompasses a spectrum of disease resulting from the extracellular deposition of fibrillar amyloid protein, which can involve any organ in isolation or in conjunction with other organs and can do so in the form of a focal, tumour-like lesion, or an infiltrative process. Amyloidosis localized to the liver has been rarely described, although it is possible that these patients have yet to exhibit evidence of systemic disease. Hepatic involvement in both primary (AL) and secondary (AA) forms of systemic amyloidosis is common; however, clinically dominant hepatic amyloidosis is unusual<sup>[1]</sup>. Accumulation of amyloids in the liver produces hepatomegaly in 33%-92% of patients, as well as moderate jaundice and moderate to severe cholestasis<sup>[2,3]</sup>. Our patient presented with constitutional symptoms of fever, weight loss, and hepatomegaly without jaundice with evidence of amyloid deposit in perisinusoidal spaces without any systemic evidence of primary or secondary amyloidosis. Isolated hepatic amyloidosis has rarely been described in literature which poses great diagnostic and therapeutic challenge.

## CASE REPORT

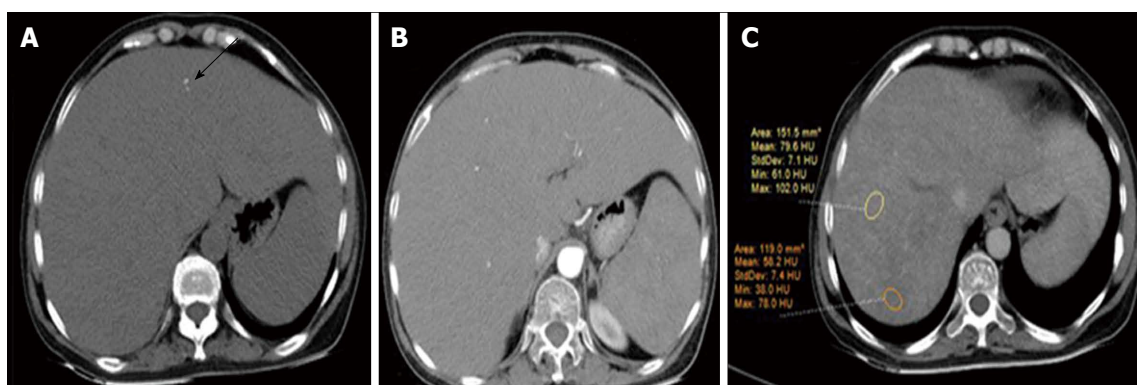

A 42-year-old female, presented with complaints of right hypochondriac and epigastric pain, which was dull aching, occurring intermittently, associated with weight loss of 15 kg over 8 mo. There was no history of jaundice, hematemesis, melena, and abdominal distension, alteration in bowel habit or bleeding from any site. There was no history of joint pain, rash, oral ulceration, cough, skin tightness, peripheral tingling, and weakness in limbs or breathlessness. She had an episode of acute febrile illness due to uncomplicated plasmodium vivax malaria in the recent past. There was history of acute viral hepatitis two times in remote past. She was hypothyroid on supplementation since 2 years. There was no history of tuberculosis in past.

On General examination patient was afebrile with pulse rate 80/min, blood pressure 16.2/10 kPa and had pallor. Systemic examination revealed liver enlarged for 2.4 inch below right costal margin which was firm, with sharp margin, smooth surface, non-tender, without hepatic rub with liver span of 8.8 inch. Spleen was also enlarged.

On evaluation investigations revealed normocytic normochromic anemia, aspartate aminotransferase level of 0.52  $\mu$ kat/L (upper normal limit 0.6  $\mu$ kat/L) and alanine aminotransferase level of 0.47  $\mu$ kat/L (upper normal limit 0.51  $\mu$ kat/L), alkaline phosphatase value of 7.46  $\mu$ kat/L (upper normal limit 2  $\mu$ kat/L) raised to 3.5 times the upper limit of normal, gamma glutamyl transferase value of 9.29  $\mu$ kat/L (upper normal limit 0.51  $\mu$ kat/L). Prothrombin time was 14 s with INR of 1, serum urea was 3.57 mmol/L (normal up to 8.2 mmol/L) and creatinine was 70.72  $\mu$ mol/L (normal upto 106  $\mu$ mol/L). Her thyroid stimulating hormone was 3.1  $\mu$ IU/mL (normal upto 5  $\mu$ IU/mL), FT4 was 14.16 pmol/L (normal 12 to 30 pmol/L), and FT3 was 4.62 pmol/L (normal 2 to 7 pmol/L). Erythrocyte sedimentation rate was 55 mm at end of 1<sup>st</sup> h by Westergreen method, C-reactive proteins was 47.62 nmol/L (normal up to 28.5 nmol/L). Her serum calcium was 2.23 mmol/L, fasting blood sugar was 5 mmol/L, triglycerides were 1.02 mmol/L and cholesterol was 3.37 mmol/L. Vitamin D3 was 239.2 nmol/L (normal > 150 nmol/L); intact-parathyroid hormone was 13 pg/mL (normal 10-65 ng/mL). Human immunodeficiency virus antibodies, HBsAg, anti-hepatitis C virus antibody were negative. Autoimmune markers including anti-nuclear antibodies, anti-Liver Kidney Microsome type 1 antibody (anti-LKM 1), anti-smooth muscle antibodies, anti-mitochondrial antibodies were negative.

Ultrasonography abdomen revealed hepatomegaly (7 inch) with coarse echo texture with compressed intrahepatic inferior vena cava and splenomegaly. Oesophagus-DuodenoScopy revealed mild antral gastritis. Pre-contrast computed tomography (CT) abdomen revealed gross hepatomegaly with tiny foci of calcification (Figure 1A). There was heterogeneous post contrast enhancement with diffuse low density areas in liver on venous phase (Figure 1). On further evaluation for infiltrative liver disorders, liver biopsy was done which revealed diffuse eosinophilic homogenous material throughout sinusoids with compressed hepatocytes (Figure 2). These areas were Congo red stain positive with apple green birefringence on polarizing microscopy suggestive of Amyloid deposits (Figure 3). Ultrasonography and fine needle aspiration cytology from the thyroid gland was done which was suggestive of colloid goiter without any evidence of amyloid deposit.

The patient had normal serum and urine protein immunofixation electrophoresis, with normal serum free light chain assay. There was no albuminuria or no bence-jones proteinuria. Her electrocardiogram and echocardiogram was normal. Bone marrow biopsy did not reveal any plasma cell dyscrasia or amyloid deposit. Contrast enhanced CT of thorax and nuclear medicine whole body bone scan was normal with no evidence of extra osseous uptake. Skeletal survey showed no gross abnormalities. Abdominal fat pad biopsy and rectum biopsy was negative for amyloid deposit. Her serum Rheumatoid factor, pAnti-neutrophilic cytoplasmic antibodies (ANCA), cANCA, anti-rho, anti-

**Figure 1** Pre-contrast computed tomography image of abdomen. A: Gross hepatomegaly with tiny foci of calcification in segment IV of liver (black arrow); arterial phase; B: Diffuse low contrast attenuation; C: Venous show heterogeneous contrast enhancement with diffuse low density areas scattered throughout liver parenchyma (yellow and orange spherical).

**Figure 2** Haematoxylin and eosin stain of the liver biopsy specimen shows diffuse extracellular amyloid deposit in peri-sinusoidal spaces with compression of hepatocytes (black arrow).

la antibody, tuberculin test, and tumour markers were negative. Immunohistochemistry using anti serum amyloid associated (SAA) protein immunoperoxidase staining for secondary amyloidosis was done from the liver biopsy specimen which was also negative. Immunohistochemistry of liver biopsy using anti-kappa and anti-lambda antibody was not done as the serum free light chain assay and serum protein immunofixation electrophoresis was normal. She was managed symptomatically with colchicine and other supportive therapies including intravenous fluids. The patient was followed up for 6 mo. Subsequently she was lost to follow up. Her constitutional symptoms improved marginally on colchicine. But hepatomegaly and altered biochemical parameters did not show any improvement.

## DISCUSSION

Though amyloidosis is considered as a systemic disease, 10%-20% cases can be localised<sup>[4]</sup>. To our knowledge primarily isolated hepatic involvement of liver in amyloidosis has rarely been described in the literature. Though it is possible that the patient has yet exhibited the evidence of systemic disease, hepatic involvement can occur in both primary and secondary

types of amyloidosis (AL/AA). In primary type the characteristic fibrillar protein is a fragment of the variable immunoglobulin light (and/or rarely heavy) chain and in secondary type the protein is the amino acid terminus of the acute phase protein SAA. Secondary amyloidosis with hepatic involvement can be seen in chronic inflammatory disorders and infections including multiple myeloma, tuberculosis, rheumatoid arthritis, familial Mediterranean fever, Crohn's disease, Reiter's syndrome, ankylosing spondylitis, Sjögren's syndrome, dermatomyositis, vasculitis, chronic osteomyelitis, bronchiectasis, cystic fibrosis, systemic lupus erythematosus (SLE)<sup>[4]</sup>, etc. Currently the AA/AL ratio has been 1:17 to 1:38 due to fewer chronic infections and an increasing recognition of AL amyloidosis. Other types of amyloidosis that are rarely seen include dialysis-related amyloidosis with the deposition of  $\beta$ 2-microglobulins, and autosomal dominant systemic amyloidosis, such as familial amyloidotic polyneuropathy with the deposition of genetically variant transthyretin<sup>[5]</sup>.

Hepatic amyloidosis is usually characterised by amyloid deposits in the liver parenchyma along the sinusoids within the spaces of disse or within the blood vessel walls. As a result of extensive compression of hepatocytes by the amyloid deposits there may be atrophy of hepatocyte. More massive infiltration results in enlarged liver with rubber elastic consistency. This results in "lardaceous liver" appearance on cut-surface<sup>[6]</sup>.

The clinical spectrum of hepatic amyloidosis can range from hepatomegaly and borderline abnormal liver function test to more severe form resulting in portal hypertension, hepatic failure and rarely spontaneous rupture<sup>[7]</sup>. Around 70%-80% of the cases have associated nephrotic syndrome, congestive cardiac failure, orthostatic hypotension or peripheral neuropathy. In another series, other frequent findings in cases of hepatic amyloidosis included proteinuria (88%), elevated serum alkaline phosphatase (86%), abnormal serum protein electrophoresis (monoclonal protein or hypogammaglobulinemia, 64%), hyposplenism on the peripheral blood smear (62%), defined by the presence

Figure 3 Apple green birefringence demonstrated by amyloid fibrils on polarizing light microscopy (black arrows in A and B) is in liver biopsy specimen.

of Howell-Jolly bodies; and hepatomegaly (81%) disproportional to the liver enzyme abnormalities<sup>[8]</sup>. The median survival rate in these patients is 9 mo<sup>[7,8]</sup>. Our patient had gross hepatomegaly with constitutional symptoms together with raised alkaline phosphatase but no other associated feature.

Radiological findings of hepatic involvement are non-specific. Pre-contrast and contrast enhanced CT reveals enlarged liver with heterogeneous decrease attenuation with delayed enhancement. There may be focal area of hypo attenuation owing to impaired blood flow due to extensive infiltration by amyloid deposit. Our patient had gross hepatomegaly with tiny foci of parenchymal calcification on pre-contrast CT which is rarely seen<sup>[9]</sup>. Her arterial phase CT shows lack of parenchymal enhancement in liver. Venous phase shows heterogeneous enhancement with diffuse low density areas in liver. Rarely typical hepatic contour characterised by asymmetric and triangular appearance of liver with apex towards falciform ligament may occur owing to selective atrophy of the lateral margins of both the lobes<sup>[10]</sup>.

Immunohistochemistry using anti-kappa and anti-lambda antibodies are useful in immunohistochemical classification and diagnosis of AL type amyloidosis. However it has its own limitations owing to cross reactivity between anti-kappa and anti-lambda antibodies. A study using antibodies against three different regions of immunoglobulin lambda light chain for the immunohistochemical analysis of liver biopsy samples from the cases of immunoglobulin lambda light chain amyloidosis showed that the amyloid deposits may not be homogeneous in the liver and that molecular heterogeneity of amyloid fibril protein or a difference in the mode of deposition results in the histopathological heterogeneity of AL amyloid deposits<sup>[11]</sup>.

Our case represents a diagnostic challenge where specific type of amyloid deposit in liver was difficult to determine. Normal bone marrow examination with normal serum and urine immunofixation electrophoresis ruled out primary amyloidosis. Anti-SAA immunoperoxide staining from liver biopsy was also negative. Hereditary forms of amyloidosis including lysosome form were considered. There was no facility for mass spectroscopic

analysis for varied type of amyloid protein at our centre. There was no evidence of hepatocellular failure or spontaneous rupture. There was no cardiac, renal or nervous system involvement. There was no evidence of tuberculosis, rheumatoid arthritis, SLE, crohns disease, or evidence of other common inflammatory diseases. This case represents need for high level of suspicion to diagnose a case of isolated hepatomegaly due to amyloidosis. There have been case reports of hepatic involvement in amyloidosis including one where the presentation was a liver SOL in the setting of plasma cell dyscrasias, but isolated hepatic involvement is a rare entity<sup>[12]</sup>. In absence of systemic evidence of amyloidosis liver transplant was considered for the patient but she did not have requisite Model for End Stage Liver Disease points to make her eligible candidate. She was managed symptomatically with colchicine and other supportive therapies.

This case represents diagnostic and therapeutic difficulty in managing a case of primary hepatic amyloidosis of undetermined aetiology.

## COMMENTS

### Case characteristics

A middle aged female presented with long-standing abdominal pain with loss of weight without jaundice.

### Clinical diagnosis

On examination her vitals were stable and she had gross hepatomegaly.

### Differential diagnosis

Infiltrative liver disorders (amyloidosis, lymphoma, sarcoidosis), metabolic liver disease (hemochromatosis), autoimmune liver disease.

### Laboratory diagnosis

She had normal alanine and aspartate aminotransferase levels, markedly raised alkaline phosphatase level of 447 U/L (upper normal limit 310 U/L) raised to 1.5 times the upper limit of normal, gamma Glutamyl transferase value of 566 U/L (upper normal limit 45 U/L) raised to 12 times the upper limit of normal and other parameters within normal limit.

### Imaging diagnosis

Computed tomography whole abdomen showed gross hepatomegaly with heterogeneous post contrast enhancement with diffuse low-density areas on

venous phase.

### Pathological diagnosis

Liver biopsy was suggestive of diffuse eosinophilic homogenous material throughout sinusoids with compressed hepatocytes which were Congo red stain positive showing apple green birefringence on polarizing microscopy suggestive of amyloid deposits.

### Treatment

She was managed symptomatically with colchicine and other supportive therapies as there was no definite cause of hepatic amyloidosis that could be found out.

### Related reports

There have been case reports of hepatic involvement in amyloidosis including being presented as a mass in setting of plasma cell dyscrasias, but isolated hepatic involvement is a rare entity published series have described varied presentation of liver involvement in amyloidosis which can range from asymptomatic hepatomegaly to fulminant hepatic failure.

### Term explanations

Amyloidosis is a pathological process that encompasses a spectrum of disease resulting from the extracellular deposition of fibrillar amyloid protein which can involve any organ isolated or in conjunction with other organs and can do so in the form of a focal, tumour-like lesion, or an infiltrative process.

### Experiences and lessons

This case represents diagnostic and therapeutic difficulty in managing a case of isolated hepatic amyloidosis of undetermined aetiology.

### Peer-review

The paper is well written.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Zong-Fang Li, MD, PhD, Director, Head, Professor, Department of General Surgery, the Second Affiliated Hospital, College of Medicine, Xi'an Jiaotong University, Xi'an 710004, Shaanxi Province, China

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

To provide an overview of the properties of human serum albumin (HSA), and to review the evidence for the use of human albumin solution (HAS) in critical illness, sepsis and cirrhosis. A MEDLINE search was performed using the terms "human albumin", "critical illness", "sepsis" and "cirrhosis". The references of retrieved articles were reviewed manually. Studies published between 1980 and 2014 were selected based on quality criteria. Data extraction was performed by all authors. HSA is the main plasma protein contributing greatly to its oncotic pressure. HSA demonstrates important binding properties for endogenous and exogenous toxins, drugs and drug metabolites that account for its anti-oxidant and anti-inflammatory properties. In disease states, hypoalbuminaemia is secondary to decreased HSA production, increased loss or transcapillary leakage into the interstitial space. HSA function can be also altered in disease with reduced albumin binding capacity and increased production of modified isoforms. HAS has been used as volume expander in critical illness, but received criticism due to cost and concerns regarding safety. More recent studies confirmed the safety of HAS, but failed to show any survival benefit compared to the cheaper crystalloid fluids, therefore limiting its use. On the contrary, in cirrhosis there is robust data to support the efficacy of HAS for the prevention of circulatory dysfunction post-large volume paracentesis and in the context of spontaneous bacterial peritonitis, and for the treatment of hepato-renal syndrome and hypervolaemic hyponatraemia. It is likely that not only the oncotic properties of HAS are beneficial in cirrhosis, but also its functional properties, as HAS replaces the dysfunctional HSA. The role of HAS as the resuscitation fluid of choice in critically ill patients with cirrhosis, beyond the established indications for HAS use, should be addressed in future studies.

**Key words:** Human serum albumin; Human albumin

solution; Critical illness; Cirrhosis; Resuscitation fluid; Large-volume paracentesis; Hepatorenal syndrome; Spontaneous bacterial peritonitis

**Core tip:** Human serum albumin has several important functions beyond being the principal protein in plasma. In disease states, albumin levels may not only be low but there may also be functional hypoalbuminaemia. This may explain why human albumin solution is helpful in treating the complications of cirrhosis whereas its role (as a volume expander) in critical illness remains limited. However, in the presence of cirrhosis or acute liver failure the restoration of functional albumin may be beneficial, even in critically ill patients. This still needs to be addressed in clinical trials.

Valerio C, Theodoridou E, Davenport A, Agarwal B. Human albumin solution for patients with cirrhosis and acute on chronic liver failure: Beyond simple volume expansion. *World J Hepatol* 2016; 8(7): 345-354 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i7/345.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i7.345>

## INTRODUCTION

Human serum albumin (HSA) is produced in the liver, and is the main plasma protein fraction responsible for plasma oncotic pressure. Historically, the oncotic property of albumin has been the major determinant of its use in clinical practice. However, it is now clear that albumin is responsible for a number of other important biological functions, and hence should be treated as a drug and not just as a form of fluid used for resuscitation. A close look at the albumin molecule reveals that it consists of three specific domains which act as binding sites for various endogenous and exogenous toxins, and drugs and drug metabolites such that the overall binding capacity of albumin is reflected in its scavenging, antioxidant and anti-inflammatory properties<sup>[1]</sup>. Acute hypoalbuminaemia is common in hospitalised patients resulting from decreased synthesis due to acute organ dysfunction, malnutrition and increased trans-capillary escape due to increased endothelial permeability secondary to systemic inflammation<sup>[2]</sup>. This is particularly noticeable in patients who are chronically hypoalbuminaemic from chronic malnourishment, protein losing nephropathy and enteropathies, and cirrhosis of the liver. In cirrhosis, reduced albumin production (quantitative hypoalbuminaemia) is complicated by an increase in the proportion of irreversibly damaged isoforms (functional hypoalbuminaemia) thus further compromising overall binding capacity<sup>[3]</sup>. While human albumin solution (HAS) are often used for volume expansion and oncotic effect in critically ill patients, their superiority over crystalloid

fluids is not established. In cirrhosis, however, because of the functional dysfunction conferred to the albumin molecule, administration of HAS has been consistently shown to improve circulatory dysfunction, through oncotic but also extra-oncotic mechanisms, and survival. The common indications in this setting include large volume ascitic paracentesis (LVP), type 1 hepatorenal syndrome (HRS), and spontaneous bacterial peritonitis (SBP)<sup>[4]</sup>. The beneficial role of albumin function beyond volume expansion is an evolving field, and further research is required to explore this unique property of albumin in modulating biological functions and disease processes not just in liver disease and sepsis but also in other diseases where albumin dysfunction seems to play a central role in their pathophysiological processes.

The aim of this review is to provide an overview of HSA structure, kinetics and function, and to explore the pathophysiological basis and clinical evidence for the use of HAS in various diseases, particularly in critical illness, sepsis and liver disease. We conducted a medline search for studies published between 1980 and 2014 using the terms "human albumin", "critical illness", "sepsis" and "cirrhosis". Studies were reviewed and selected for their quality and utility in producing this review.

## SYNTHESIS, METABOLISM, DISTRIBUTION AND FUNCTION OF HSA

HSA contributes around 50% of circulating plasma proteins with serum concentrations of 35-50 g/L in healthy subjects. This level reflects the synthesis, metabolism and distribution of HSA, but not its function. HSA synthesis (10-15 g/d) occurs within the hepatocyte from where it is released into the portal tract<sup>[5]</sup>. Synthesis is regulated by the colloid osmotic pressure of the interstitial fluid bathing the hepatocytes<sup>[6]</sup>. The rate of synthesis *in vivo* can increase up to 2.7 fold, provided there is adequate available messenger RNA<sup>[7]</sup>.

Only a minority of total body HSA remains within the bloodstream, with most albumin passing into the interstitial space (Figure 1). Injection of radio-labelled HSA demonstrates trans-capillary escape rate (TCER) of 4.5% per hour<sup>[8]</sup>. In fenestrated capillaries, TCER depends on capillary wall permeability, hydrostatic and oncotic pressure gradients (liver, small intestine, pancreas, bone marrow). In non-fenestrated capillaries, HSA binds to albondin and passes through to the interstitial space. This rate of transfer is increased with long-chain fatty acid binding, cationisation and glycosylation of HSA. Three quarters of extravascular albumin returns to the intravascular space *via* the lymphatic system.

HSA has a half-life of approximately 15 d. Degradation occurs in the liver and kidney, but the majority takes place in the skin and muscle (the main locations of extravascular HSA). Altered or denatured HSA binds to endothelial cell surface receptors; after uptake into intracellular vesicles, fusion with lysosomes results

**Figure 1** Albumin synthesis and distribution. TCER: Trans-capillary escape rate.

in breakdown into free amino acids. The fractional degradation rate of HSA is 3.7% which parallels the rate of synthesis in health.

The classical physiological role of HSA is to maintain colloid oncotic pressure. The high molecular weight of HSA combined with its concentration in blood result in an 80% contribution to the normal plasma oncotic pressure of around 25 mmHg. This direct osmotic effect provides 60% and the net negative charge 40% of the oncotic pressure. The presence of charged residues and the abundance of HSA account for its function as a physiological buffer. HSA is responsible for approximately half of the normal anion gap, and as such decreasing HSA concentration results in a metabolic alkalosis.

## STRUCTURE AND LIGAND BINDING PROPERTIES OF HSA

HSA consists of 585 amino acids with a molecular weight of 66500 Daltons. The globular structure of HSA determined by X-ray crystallography is "heart-shaped" with 17 disulphide bridges cross-linking cysteine residues and uniting the three domains<sup>[9,10]</sup>. These disulphide bridges give HSA strength, but also facilitate conformational changes in response to ligand binding. There is no carbohydrate moiety, but an abundance of charged lysine, arginine, glutamic acid and aspartic acid residues with a free cysteine and tryptophan residue<sup>[11]</sup>. The homologous domains (I, II and III) that make up HSA are in turn constructed from two sub-domains (A and B) that possess 6 and 4  $\alpha$ -helices respectively (Figure 2)<sup>[11]</sup>. Each domain has a binding site with different properties, but nine binding sites for fatty acids have been elucidated with electron magnetic resonance spectroscopy<sup>[11]</sup>. Flexible loops made of proline residues allow movement of subdomains to accommodate ligands. The HSA molecule serves as the transport vehicle for thyroid and steroid hormones, fatty acids, unconjugated bilirubin, and several drugs<sup>[12]</sup>.

Domain I contains the single cysteine residue that is not a part of the structural disulphide bridges<sup>[13]</sup>.

**Figure 2** Human serum albumin structure and binding sites. ROS: Reactive oxygen species; NO: Nitric oxide; SH: Sulfhydryl.

This creates a reactive thiol group which can form inter-molecular bridges and bind with metals, such as copper and iron. Covalent binding with molecules such as D-penicillamine may occur. There is a metal-binding site involving the N-terminus that can neutralize free copper and iron cations restricting catalysis of free radical production<sup>[14]</sup>. HSA contains two further functional cation binding sites, multi-metal binding site A and B<sup>[15]</sup>. The former lies in the interface of domain I and II binding zinc and cadmium. The latter is thought to be a secondary binding site and its location remains uncertain.

There is a single binding site for unconjugated bilirubin in domain I B within a narrow hydrophobic cavity. Usually, there are two fatty acids loaded on an HSA molecule. The long-chain fatty acid binding sites are found in subdomains I B and III B. These sites can also bind bacterial endotoxins so reducing their activity<sup>[16]</sup>.

The hydrophobic cavities in subdomains II A and III A are the principal ligand binding sites for small heterocyclic or aromatic compounds. Subdomain II A has a lone tryptophan residue that limits solvent accessibility. It is one of the principle binding sites of pharmacological agents (*i.e.*, Sudlow site 1) and shows affinity for bulky heterocyclic molecules, including drugs such as warfarin and furosemide<sup>[17]</sup>. Subdomain III A, corresponding to Sudlow site 2, demonstrates greater stereo-selectivity, but is less flexible and binds aromatic molecules, including diazepam and non-steroidal anti-inflammatory drugs<sup>[17]</sup>. The subdomains II A and III A actually face each other, and II A binding can utilise residues in subdomains II B and III A. An important pharmacological consequence of this configuration is that competitive displacement can then occur. Many compounds will also utilise secondary binding sites. Despite modern techniques there are aspects of the

HSA-drug interactions that remain unclear, such as the binding site of digoxin. The ligand binding activity of HSA may also generate a pseudo-enzymatic activity whereby HSA plays an active role in pro-drug modification by hydrolysis.

Most HSA exists with a free redox-active thiol group (due to the cysteine residue in domain I A), referred to as mercaptoalbumin. Due to the relative abundance of HSA this constitutes 80% of available plasma thiols and is a scavenger of many reactive oxygen and nitrogen species<sup>[18]</sup>. Oxidative stress initially converts HSA into the mixed disulfide non-mercaptoalbumin-1 (HNA-1) as reactive oxygen species are scavenged. The quantity of HNA-1 increases with aging<sup>[19]</sup>. HNA-1 can be further oxidised into HNA-2, which is thought to be an irreversibly damaged form. Nitroalbumin, the product of nitric oxide binding to the thiol group, may be a vasodilator and inhibitor of platelet aggregation.

HSA also has a role in clotting, transporting both anti-thrombin and heparin cofactor II, both of which increase the anticoagulant activity of natural heparinoids and exogenous heparins, by inhibiting thrombin generation. Hypoalbuminaemia has been linked to platelet hyper-aggregation in peritoneal dialysis patients<sup>[20]</sup>, and may play a role in the procoagulant tendency reported in acute on chronic liver failure, and with acute kidney injury<sup>[21,22]</sup>. HSA influences several immune pathways and may enhance intracellular protection from inflammation and oxidative stress. In experimental studies HSA inhibits tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) induced upregulation of vascular cell adhesion molecule 1 and nuclear factor- $\kappa$ B activation<sup>[23]</sup>. Intravascular HSA may promote endothelial stability by reducing oxidative stress, dampening inflammation and reducing neutrophil adhesion to endothelial cells. Vascular integrity may be aided by HSA binding in the sub-endothelium reducing endothelial permeability.

Isoforms of HSA as a result of genetic variation do occur but are not typically associated with disease. Exceptions are the variants with high affinity for tri-iodothyronine and levothyroxine, which are responsible for familial dysalbuminemic hypertri-iodothyroninaemia and hyperthyroxinaemia, respectively<sup>[24]</sup>. Patients with these clinical syndromes are euthyroid. Another isoform has been discovered with increased affinity for nitric oxide which has demonstrated anti-bacterial and anti-apoptotic properties.

## HYPOALBUMINAEMIA IN DISEASE

Disease can alter the synthesis, distribution and degradation of HSA. Decreased HSA synthesis occurs in malnutrition and malabsorption as a result of amino acid deficiency, and hypoalbuminaemia is often used as a surrogate of nutritional status<sup>[25]</sup>. In advanced liver disease, hepatocyte dysfunction or loss results in decreased HSA synthesis. HSA is a component of the Child-Pugh-Turcotte score<sup>[26]</sup>, a disease severity score widely used for patients with cirrhosis, although

the more recent model for end-stage liver disease (MELD) does not include HSA<sup>[27]</sup>. Hypoalbuminaemia is common in inflammatory disorders, as HSA synthesis is suppressed by pro-inflammatory cytokines, including interleukin 6 (IL-6) and TNF- $\alpha$ , in the context of the acute phase response<sup>[28]</sup>.

Increased HSA shift into the interstitial space occurs in cases of increased endothelial permeability. Vasodilatation and increased capillary leakage are the hallmarks of severe sepsis, and contribute greatly to multiple organ dysfunction<sup>[29,30]</sup>. Several vasoactive and pro-inflammatory mediators produce vasodilatation and loss of endothelial integrity in sepsis, such as endotoxins, TNF- $\alpha$ , IL-1, IL-6, prostacyclin and nitric oxide, leading to a three-fold increase in HSA TCER<sup>[2]</sup>. This leakage of HSA into the interstitial space is not associated with a concomitant increase in lymphatic return into the intravascular compartment; rather there is increased sequestration in the non-exchangeable sites in the body. Plasma HSA falls faster after a bolus of 20% HAS in patients with sepsis compared with healthy volunteers<sup>[31]</sup>. Furthermore, a reduction in HSA mRNA transcription occurs in the context of the acute phase response, mediated by IL-6 and TNF- $\alpha$ .

## HSA DYSFUNCTION IN CIRRHOSIS

HSA concentration is used as a surrogate of liver function, and hypoalbuminaemia is a common feature in patients with cirrhosis. Recent research has shown that the function of HSA is impaired in patients with cirrhosis (Figure 3)<sup>[32]</sup>. HSA dysfunction may be due to either saturation with bilirubin or allosteric and structural modifications.

A recent study assessed post-transcriptional changes in HSA in patients with cirrhosis and healthy controls<sup>[33]</sup>. Seven isoforms of HSA resulting from post-transcriptional structural modification were identified in patients with cirrhosis, whereas the native unmodified HSA was reduced in the same group compared to controls. The presence of isoforms was associated with the severity of liver disease. The presence of oxidized and N-terminal truncated isoforms was associated with complications such as ascites, renal dysfunction and bacterial infections. The native HSA isoform was associated with greater one-year survival, and was a better predictor of survival than total HSA concentration, supporting the concept of the "effective HSA concentration".

Albumin binding capacity (ABIC) refers to assessment of binding site II by binding of a fluorescent marker (usually dansylsarcosine). ABIC was reduced (< 40%) in 22 patients with cirrhosis and high bilirubin<sup>[34]</sup>, and correlated inversely with the severity of liver disease and short-term mortality. This study showed improved ABIC in patients treated with the Molecular Adsorbents Recirculating System (MARS).

Cobalt binding assays can demonstrate defective metal cation scavenging N-terminal corresponding to ischaemia-modified albumin (IMA). Fatty acid binding

**Figure 3** Impaired albumin function in cirrhosis. ACLF: Acute-on-chronic liver failure; HMA: Mercaptoalbumin; HNA: Non-mercaptalbumin; IMAR: Ischaemia-modified albumin ratio; EPR: Electron paramagnetic resonance; ABiC: Albumin binding capacity.

capacity can be assessed using electron paramagnetic resonance spectroscopy. A study in 34 patients with acute-on-chronic liver failure (ACLF) assessed binding sites associated with main HSA functions using both these methods<sup>[3]</sup>. This study demonstrated impaired HSA ability to transport HSA-bound substances in ACLF. The ratio of IMA to normal HSA (IMAR) was significantly higher in non-survivors compared to survivors. The role of this ratio in novel prognostic scores is currently under investigation. MARS™ treatments did not improve HSA function or IMAR in this study.

Another study assessed the functional status of the HSA thiol moiety by measuring non-oxidized mercaptalbumin, reversibly oxidized HNA-1 and irreversibly oxidized HNA-2 with chromatography according to the redox state of cysteine-34<sup>[35]</sup>. ABiC assessed with dansylsarcosine as ligand was reduced in patients with cirrhosis and was associated with parameters of liver dysfunction. The proportion of oxidised forms was also increased in patients with cirrhosis. The irreversibly damaged HNA-2 form was a strong predictor of 30- and 90-d mortality with predictive accuracy comparable to MELD.

These studies demonstrated impaired HSA function in patients with cirrhosis, which increased with severity of underlying liver disease. Oxidative changes may account for the reduced binding capacity resulting in impaired detoxifying and antioxidant function. Extracorporeal liver support systems, MARS™ and Prometheus™, were developed to remove HSA-bound toxins, such as bilirubin and bile acids, but they are unable to restore HSA function, due to irreversible damage<sup>[36]</sup>. Although initial studies reported some improvement in ABiC with MARS™ treatments, subsequent studies did not show any benefit. Plasma exchange, on the other hand, removes and replaces damaged HSA, and has shown more encouraging clinical outcomes.

Impaired ABiC has been also demonstrated in

**Table 1** Composition of human plasma and different intra-venous fluids

	Human plasma	4% albumin solution	0.9% saline solution	Hartmann's solution
Osmolarity (mOsm/L)	291	250	308	280.6
Sodium (mmol/L)	135-145	148	154	131
Chloride (mmol/L)	94-111	128	154	111
Potassium (mmol/L)	4.5-5.0	0	0	5.4
Calcium (mmol/L)	2.2-2.6	0	0	2
Lactate (mmol/L)	1-2	0	0	29
Octanoate (mmol/L)	0	6.4	0	0

patients with chronic kidney disease, and correlates with the degree of renal dysfunction<sup>[37]</sup>. HSA dysfunction may contribute to the accumulation of HSA-bound uraemic toxins leading to uraemic complications. Renal dysfunction is not uncommon in patients with advanced liver disease, and may further aggravate HSA function. The impact of renal failure on HSA function in ACLF needs to be addressed in future studies.

## HAS COMPOSITION

HAS, produced by plasma fractionation since 1941, has been widely used in clinical practice - despite criticism - mainly for its intravascular volume expansion properties. There are differences that should be taken into consideration between HAS and endogenous HSA, as well as between different HAS formulations. HAS is hypo-osmolar compared to human plasma but with higher sodium and chloride concentrations (Table 1). There may also be differences in oxidation and metal ions among different HAS products, and storage conditions may lead to biochemical changes. These may not be relevant for volume expansion but could modify albumin function. Quantitative analysis of octanoate in HAS showed levels within 20% of the quoted product label value in 132 of 138 HAS tested<sup>[38]</sup>. Octanoate is used as a stabiliser but variations in levels are associated with embryotoxicity. It can also bind to HSA (binding site 1) inducing allostery and displacing compounds, such as non-steroidal anti-inflammatory drugs, at binding site 2<sup>[39,40]</sup>. The stability and binding capacity of different HAS preparations has been investigated for the use of albumin in liver support dialysis systems<sup>[41]</sup>. HAS is available in different concentrations, and experiments in a murine model of endotoxaemia suggest that only albumin at physiological concentrations of 4%, and not 20% HAS, had a protective effect<sup>[42]</sup>.

Recombinant human HAS has shown pharmacokinetic equivalence in studies, but has only been licensed as a pharmacological excipient due to concerns about immunogenic host cell products<sup>[43]</sup>. Industrial manufacture of recombinant HAS is currently not cost-effective. However, the potential production of genetic isoforms of HAS with desirable characteristics, such as antibacterial properties or bilirubin affinity, may expand the utility of recombinant HAS in the future.

## EVIDENCE FOR HAS USE IN CRITICAL ILLNESS AND CIRRHOSIS

### **Critically ill patients**

The utility of HAS in the management of critically ill patients has been a matter of great debate. A Cochrane meta-analysis of 30 clinical trials published in 1998 showed a 6% absolute increase in risk of death with HAS administration compared with crystalloid solutions in patients with hypovolaemia, burns or hypoalbuminaemia<sup>[44]</sup>. However further clinical trials and meta-analyses failed to confirm these findings.

The Saline vs Albumin Fluid Evaluation (SAFE) study was a large double-blind randomised trial comparing 4% HAS with normal saline (NS) fluid resuscitation in approximately 7000 critically ill patients<sup>[45]</sup>. This study did not show any difference in mortality, number of failing organs, length of intensive care unit (ICU) or hospital stay, or need for renal replacement therapy at day 28. In the subgroup of patients with severe sepsis 28-d mortality was lower in the HAS group (30.7%) compared to the NS group (35.3%), but this difference did not reach statistical significance. In multivariate analysis HAS administration was an independent predictor of survival in the same subgroup of patients. In the subgroup of patients with traumatic brain injury, however, mortality at 24 mo was higher in the HAS group (33.2%) compared with 20.4% in the NS group<sup>[46]</sup>.

Another study investigated the administration of 20% HAS in critically ill patients for the first seven days of ICU stay<sup>[47]</sup>. One hundred patients with hypoalbuminaemia were randomized to either 20% HAS or no HAS, with target HSA of 30 g/L. There was significant improvement in organ function, as assessed using the Sequential Organ Failure Assessment score, in the HAS group with a less positive fluid balance. There was, however, no significant difference in 28-d mortality (24% in the HAS vs 30% in the control group) and length of hospital stay.

A subsequent meta-analysis including 38 studies did not show any mortality benefit with HAS administration in critically ill patients with hypovolaemia, burns or hypoalbuminaemia<sup>[48]</sup>. The results of this meta-analysis were greatly influenced by the SAFE study population. A more recent meta-analysis compared colloid vs crystalloid fluid for resuscitation in critically ill patients<sup>[49]</sup>. Twenty four studies that compared HAS with crystalloid fluid were included in the analysis. There was no difference in mortality between the two groups. According to the results of the above meta-analyses, the administration of HAS in critically ill patients cannot be justified in view of the failure to demonstrate survival benefit and the higher cost of HAS.

### **Patients with cirrhosis**

Contrary to the controversial indications for HAS use in critical illness, there is robust evidence to support its use for the treatment or prevention of certain complications

of cirrhosis. Although initially the oncotic properties of HAS were thought to be of great benefit in cirrhosis, the emerging knowledge on the HSA binding properties and the idea of the "effective albumin concentration" shifted interest towards the non-oncotic properties of HAS.

Circulatory dysfunction is a hallmark of cirrhosis. Splanchnic vasodilatation in the arterial circulation, decreased vascular resistance and "effective intravascular blood volume", increased cardiac output and hyperdynamic circulation are the main features of this circulatory dysfunction, and are probably related to overproduction of vasoactive substances, mainly nitric oxide<sup>[50]</sup>. These changes lead to homeostatic activation of the renin-angiotensin system and the sympathetic nervous system, and increased release of antidiuretic hormone, resulting in sodium and water retention. Renal perfusion is reduced due to local vasoconstriction, and glomerular filtration rate decreases. Although HRS is often thought to be a vasomotor nephropathy, there is in addition an inflammatory component, with increased Toll like receptor expression in the renal tubules<sup>[51]</sup>. The use of HAS in cirrhosis has been largely based on its oncotic properties that increase the "effective intravascular blood volume" and improve the circulatory dysfunction. The European Association for the Study of the Liver guidelines suggest administration of HAS in patients with cirrhosis for the following indications<sup>[4]</sup>.

### **LVP to prevent paracentesis-induced circulatory**

**dysfunction:** Diuretic-refractory or diuretic-intolerant ascites occurs in 10% of patients with cirrhosis, and is associated with poor survival. LVP and transjugular intrahepatic portosystemic shunt (TIPS) are the main treatment options for these patients. TIPS not only is more effective in the treatment of refractory ascites compared to LVP, but has been also shown to improve transplant-free survival, as it addresses the underlying portal hypertension<sup>[52]</sup>. However, TIPS is associated with increased incidence of hepatic encephalopathy, thus it is contra-indicated in these patients, as well as in patients with severely impaired liver function or significant cardiac dysfunction<sup>[53]</sup>. TIPS may not be technically feasible in cases with non-compatible vascular anatomy or vascular occlusions.

It is evident that LVP remains the only available treatment option for a proportion of patients with refractory ascites. LVP, however, exacerbates the circulatory dysfunction already present in these patients by accentuating the arteriolar vasodilatation leading to overactivation of the compensatory endogenous neuro-humoral vasoactive systems<sup>[54]</sup>. This paracentesis induced circulatory dysfunction and effective reduction in blood volume may have detrimental effects in cirrhosis including: Rapid re-accumulation of ascites, development of dilutional hyponatraemia, HRS, increased portal pressures and shortened survival<sup>[55]</sup>. A randomised study comparing LVP with or without HAS administration as plasma expander showed that paracentesis without HAS was associated with higher frequency of renal

impairment, higher plasma renin activity and aldosterone concentration, and higher incidence of hyponatraemia<sup>[55]</sup>. Several strategies to prevent post-LVP circulatory dysfunction have been tested including administration of HAS, colloid fluids and vasoconstrictor agents. A meta-analysis including data from 17 randomised trials demonstrated significantly lower incidence of post-LVP circulatory dysfunction with HAS compared to each of the other treatment modalities<sup>[56]</sup>. The incidence of post-LVP hyponatraemia, and mortality were also lower in the HAS group. Current guidelines suggest HAS replacement at a dose of 8 g for every litre of ascitic fluid removed with LVP.

**Treatment of HRS:** HRS type 1 is characterised by progressive renal failure and is associated with increased mortality. Treatment of HRS includes vasoconstrictors (primarily terlipressin, or noradrenaline, or if these are not available then midodrine and octreotide) in combination with HAS. Terlipressin, a vasopressin analogue, is the vasoconstrictor most commonly used. A randomised, double-blind, placebo-controlled trial showed reversal of type 1 HRS in 34% of patients treated with terlipressin and HAS, vs 12% of those treated only with HAS<sup>[57]</sup>. HRS reversal in this study was associated with improved 6-mo survival. These results were confirmed in a randomised study published almost simultaneously by a different research group<sup>[58]</sup>. In this study renal function improved in 44% of patients treated with terlipressin and HAS, but only in 9% of those treated with HAS. Improvement in renal function was again an independent predictor of 3-mo survival.

The efficacy of terlipressin without HAS in treatment of HRS has been also assessed. HRS reversal was achieved in 77% of patients receiving terlipressin and HAS, and in 25% of those receiving terlipressin alone<sup>[59]</sup>. Improvement in arterial pressure and suppression of the renin-angiotensin system was observed only in the combination group, but not in the terlipressin monotherapy group. The recommended dose of HAS in HRS is 1 g/kg of body weight on day 1, followed by 20–40 g/d.

**SBP to prevent renal dysfunction:** One third of patients with SBP, another common complication in patients with cirrhosis and ascites, develop renal dysfunction secondary to rapidly progressive impairment in systemic haemodynamics<sup>[60]</sup>. SBP is also associated with increased mortality, in particular in the subgroup of patients who develop renal impairment. A randomised study assessed renal function and mortality in 126 patients with SBP treated with antibiotics with or without HAS<sup>[61]</sup>. HAS was administered at a dose of 1.5 g/kg of body weight at the time of diagnosis, followed by 1 g/kg of body weight on day 3. Renal impairment developed in 33% in the group treated only with antibiotics, and in 10% in the HAS group, and 3-mo mortality was 41% and 22%, respectively. Following this landmark study, the combination of antibiotics with HAS was established

for the treatment of SBP, and the recommended dose of HAS is that used in the initial study.

The beneficial effect of HAS has also been assessed in patients with cirrhosis and bacterial infections other than SBP<sup>[62]</sup>. A small study showed improvement in circulatory function in patients treated with antibiotics and HAS compared to those treated only with antibiotics, and a trend towards improved renal function, but no difference in 3-mo survival. Unless future studies provide more robust evidence, currently there is not enough evidence to support HAS administration in non-SBP infections.

### **Treatment of hypervolaemic hyponatraemia:**

Hyponatraemia in cirrhosis can be hypovolaemic or hypervolaemic according to extracellular fluid volume status<sup>[63]</sup>. Hypervolaemic or dilutional hyponatraemia is primarily the result of increased secretion of antidiuretic hormone resulting in greater renal water retention compared to sodium<sup>[64]</sup>. Hyponatraemia is a poor prognostic marker associated with high mortality. Treatment options are limited as fluid restriction is rarely effective, and crystalloid fluids are only indicated in hypovolaemic hyponatraemia. Previous studies have shown improvement in serum sodium concentration with HAS administration, most likely related to its volume expansion effect<sup>[65]</sup>, therefore HAS can be used for the treatment of hyponatraemia despite the scarcity of strong evidence. Preliminary reports have shown that increasing solute-free water excretion can improve hyponatraemia by blocking distal renal tubular vasopressin 2 receptors. The efficacy and safety of this class of drugs in patients with cirrhosis are currently under investigation, as too great a loss of water may lead to hypovolaemia and acute renal injury<sup>[66]</sup>.

Finally, the effect of HAS on hepatic encephalopathy has been investigated, with studies failing to show that HAS administration improved hepatic encephalopathy, although it was associated with improved 3-mo survival<sup>[67]</sup>.

### **Critically-ill patients with cirrhosis**

The prognosis for patients with cirrhosis admitted to the ICU is poor with mortality rates of approximately 30% reported in contemporary patient cohorts and up to 80% in older ones<sup>[68]</sup>. Terlipressin and TIPS have improved outcomes, but mortality still remains high. The role of HAS in this setting has not been investigated. The same indications for HAS administration apply to critically-ill patients with cirrhosis in the ICU setting. Beyond the established indications for HAS, however, the question regarding the optimal resuscitation fluid in these patients has not been addressed. HAS administration has been shown to improve circulatory dysfunction and survival in patients with cirrhosis. The use of HAS is limited in critical illness by the absence of survival benefit as demonstrated by the SAFE study and subsequent meta-analyses, and the higher economic cost. We strongly feel that the efficacy of HAS as the primary resuscitation

fluid in critically-ill patients with cirrhosis should be reassessed in prospective randomised studies.

## CONCLUSION

Beyond its well-known oncotic properties, HSA entails important binding capacity for endogenous and exogenous toxins which accounts for its antioxidant and anti-inflammatory properties. HSA concentrations are reduced in several disease states. There is increasing interest in HSA function in disease. In cirrhosis, hypoalbuminaemia is a common feature, but evolving research also suggests that HSA detoxifying function is impaired. The rationale for HAS administration in disease has been largely based on its volume expansion properties. In critical illness, however, fluid resuscitation with HAS has not been found to be superior to crystalloid fluids. In patients with cirrhosis, on the other hand, there are well-acknowledged indications for HAS, namely LVP, HRS and SBP. In critically ill patients with cirrhosis the optimal resuscitation fluid remains unknown. As such, future research should focus on the potential beneficial role of the functional properties of HAS, beyond simple volume expansion.

### Abstract

Indocyanine green (ICG) kinetics (PDR/R15) used to quantitatively assess hepatic function in the perioperative period of major resective surgery and liver

transplantation have been the object of an extensive, updated and critical review. New, non invasive bedside monitors (pulse dye densitometry technology) make this opportunity widely available in clinical practice. After having reviewed basic concepts of hepatic clearance, we analysed the most common indications ICG kinetic parameters have nowadays in clinical practice, focusing in particular on the diagnostic and prognostic role of PDR and R15 in the perioperative period of major liver surgery and liver transplantation. As recently pointed out, even if of extreme interest, ICG clearance parameters have still some limitations, to be considered when using these tests.

**Key words:** Liver function tests; Indocyanine green; Hepatic clearance; Liver surgery; Liver transplantation; Intraabdominal hypertension; Portal hypertension

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Non invasive monitors for indocyanine green (ICG) clearance (PDR and R15) are now available for a rapid assessment of liver function both in the intensive care unit and in major liver surgery. After having reviewed the basic concepts of hepatic clearance, we have analysed the most common indications of ICG kinetic parameters in clinical practice, focusing on the diagnostic and prognostic role of PDR and R15 in the perioperative period of major resective liver surgery and liver transplantation. Since ICG parameters have still some limitations, we will underline the conditions (mainly hyperbilirubinemia and severe peripheral hypoperfusion) able to alter the reliability of these tests.

De Gasperi A, Mazza E, Prosperi M. Indocyanine green kinetics to assess liver function: Ready for a clinical dynamic assessment in major liver surgery? *World J Hepatol* 2016; 8(7): 355-367 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i7/355.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i7.355>

## INTRODUCTION

In modern critical care medicine, extensive and accurate liver function assessment has a relevant place while caring for high risk medical patients or candidates to major liver surgery: At the moment, static and dynamic tests are available<sup>[1-7]</sup>. Static tests, since long included in scores able to quantify acute and chronic (CHILD PUGH, MELD) hepatic dysfunction, assess separately the different functions of the liver and describe the size of the hepatic injury<sup>[1-4]</sup>. On the contrary, information on the functional aspects of the remnant liver after resective surgery or of the quality of the liver graft recovery after transplantation remain elusive. In other words, available to the clinicians is a “frozen” representation of the hepatocytes integrity and of the (residual) metabolic and synthetic capacities (Figure 1).

## STATIC ASSESSMENT OF LIVER FUNCTION

A pivotal role in the amino acids metabolism is played by aspartate aminotransferase (AST) and alanine aminotransferase (ALT). AST, represented at various levels (mainly muscular and cardiac, but not only) are not liver specific and have shorter half life (12-22 h). On the contrary, ALT are liver - specific, have longer half life (30-40 h), are highly expressed in the hepatocytes and largely present in periportal areas. In case of centrilobular hypoxia, ALT show a moderate increase, while in case of acute hepatic injury (acute hepatitis) a significant increase in ALT serum concentration is almost always demonstrated: It is considered a consequence of necrosis or it should be secondary to the increased permeability after a cell membrane damage<sup>[2,3]</sup>. In case of ischemic injury, the AST and ALT peak may reflect the size of liver damage. As above mentioned, AST/ALT increase (longer for ALT, shorter for AST due to the different half life) does not provide information on the functional impairment of the liver nor, by force, of the (residual) hepatic functional reserve<sup>[2,3]</sup>. A rather non-specific marker of ischemic damage to the liver (but not only!) is lactate dehydrogenase (mainly fraction 5). Cholestatic alterations are usually described using gamma glutamyl transferase and alkaline phosphatase.

Plasma Bilirubin concentration reflects phase II metabolism and is the indirect expression of uptake, conjugation and excretion functions of the liver. Early (and perhaps self limiting) phases of ischemic injuries have a moderate impact on the phase II processes, defined as “relatively robust”<sup>[7]</sup>. Among the causes of hyperbilirubinemia (generally speaking due to an increased production or a reduced clearance) relevant are hemolysis, damage of cellular components and reduced intrahepatic bile excretion. One of the main functions of the hepatocytes is protein synthesis. Among synthesized proteins are large part of acute phase proteins, albumin, transport proteins, all the coagulation factors [apart from factor VIII (FVIII) and von Willebrand

factor], antithrombin, anticoagulant proteins (protein C, protein S and protein Z), Plasminogen, alpha 2 plasmin inhibitor, complement, lipoproteins<sup>[2]</sup>. Among coagulation factors, FV and FVII, due to a very short half-life (four to six hours), are included in the Clichy criteria to quantify the synthetic damage of the liver in case of acute liver failure. According to Clichy criteria, in case of acute hepatic failure (so called “fulminant hepatitis”), hepatic encephalopathy grade 3-4 and FV activity below 20% in patients < 30 years (< 30% in patients > 30 years) are the indications for urgent liver transplantation (OLT)<sup>[4]</sup>.

## DYNAMIC ASSESSMENT OF LIVER FUNCTION

Since long, dynamic liver function tests<sup>[2,3]</sup> are considered and used to assess “over time” the liver capacity to metabolize or to eliminate drugs or compounds. Dynamic quantitative liver function tests, unlike conventional (static) tests, rely upon a “quasi” exclusive clearance or metabolism of substances performed by the liver. Being repeatable in a short time span, dynamic tests are able to provide a fast and reliable liver functional evaluation, together with a general prognostic assessment (Figure 1). Indocyanine green (ICG) clearance parameters will be described and discussed in this paper, while Caffeine test, Bromsulphalein clearance, Aminoacid clearance, Galactose elimination capacity, Aminopyridine breath test and Monoethylglycinexylidide formation from lignocaine (MEGX test) are beyond the scope of this review (Figure 1).

### *The hepatic clearance: Matching hepatic perfusion and liver function*

According to the clearance principle<sup>[5]</sup>, hepatic clearance (Cl) is the product of liver extraction capacity (Ex) and liver blood flow (Q):  $Cl = Q \times Ex$ . In general, the dynamic assessment of liver function relies upon this equation: According to the hepatic extraction capacity, the various drugs and compounds are considered at “low” or “high” extraction. Clearance of highly extracted substances approaches hepatic blood flow and is considered an indicator of liver blood flow, extraction rate being limited in case of reduced liver blood flow. Opposite is the case of the clearance of substances at low extraction rate: The clearance of these compounds, not dependent from the hepatic blood flow, becomes a measure of metabolism or elimination processes. A key point of this principle is that the intrinsic hepatic clearance ( $Cl_{int}$ ) becomes a measure of the capacity of the liver to remove substances when blood flow is not limited<sup>[5]</sup>.

## ICG CLEARANCE FOR A DYNAMIC ASSESSMENT OF LIVER FUNCTION

Worldwide, ICG clearance is the most common and easy - to - use test for the perioperative dynamic assessment

**Figure 1** Liver function assessment: Static and dynamic tests (modified from Sakka<sup>[3]</sup>, 2007). AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ICG: Indocyanine green; GGT: Gamma glutamyl transferase.

**Figure 2** Indocyanine green dilution curve. A: First peak; B: Second peak (re-circulation phase); C: Elimination phase (Modified from Vos *et al*<sup>[6]</sup>, 2014). ICG: Indocyanine green;  $C_{icg}$ : ICG blood concentration.

of liver function in case of major liver surgery (resective surgery and liver transplantation) and in the intensive care unit (ICU)<sup>[2,6-8]</sup>. ICG is an inert, water-soluble, fluorescent tricarbocyanine, with a protein binding close to 95% (mainly, alpha1- and beta-lipoproteins and albumin). In healthy individuals, ICG shows a high hepatic extraction rate, usually above 70%. Toxicity is very low, and very rare are the adverse effects, reported in 1/40000 cases. The presence of Iodine in the ICG molecule constitutes a contraindication to its use in case of thyrotoxicosis and iodine allergy (a reaction due to non-immunological histamine release)<sup>[6-8]</sup>. Since the early sixties, ICG elimination kinetics were used to measure blood volume and cardiac output, while in recent years an increased interest exists in using ICG clearance parameters for a dynamic assessment of liver function both in medical and surgical settings<sup>[6,9-11]</sup>. The "standard" determination of ICG clearance ( $ICG_{cl}$ ) relies upon a rather complex *ex vivo* photometric analysis of multiple arterial blood samples obtained in a short time frame (15 min) after the intravenous administration: In spite of being so far the gold standard, it is now used for research purposes only. New bedside, easy to use transcutaneous - non-invasive pulse dye densitometry (PDD) devices able to measure ICG concentrations are on the rise for the use in clinical practice<sup>[1,6,7]</sup>. Among

them are LiMon, (Pulsion Medical System, Germany) and DDG 2001 (Nihon Kohden, Japan): ICG elimination is expressed as ICG plasma disappearance rate ( $ICG_{PDR}$ ) or retention rate at fifteen minutes ( $ICG_{R15}$ ), assessing relative ICG concentration changes (Figure 2).

In hemodynamically stable or unstable ICU patients, in liver transplanted patients and in subjects involved in major liver surgery, good correlation exists between ICG elimination measurements performed with the standard "invasive" method and the PDD technology. In healthy subjects, the intravenous injection of ICG at the dosage of 0.5 mg/kg body weight (BW) generates a plasmatic concentration of 100 mg/mL: In recent experiences, reliable results are also reported with 0.25 mg/kg BW<sup>[3]</sup>. The  $K$  value (rate constant) of the ICG indicator-dilution curve is calculated by both devices applying monoexponential transformation of the ICG concentration and backward dynamic extrapolation of the curve of the elimination phase<sup>[6]</sup>. With appropriate calculations, functional parameters of extreme interest for the dynamic assessment of liver function are thus available.

After intravenous injection, ICG, almost completely bound to proteins, is distributed in the blood within 2 to 3 min: Volume of distribution is very close to plasma volume and half-life is very short (3 to 5 min<sup>[1,3,6]</sup>, longer in case of hepatic dysfunction). Extraction from the blood occurs almost exclusively by the liver, with selective uptake across the sinusoidal plasma membrane by 1 B3 and Na-taurocholate co-transporting polypeptides. ICG is excreted unchanged and almost completely (97%) into the bile in a non-conjugated form, following a two-compartmental model (excretion from the peripheral and not from the central compartment). The absence of metabolism and of enterohepatic recirculation supports the correlation between ICG elimination kinetics and liver function. Sinusoidal uptake (relevant in humans) and canalicular excretion are the two main processes involved in ICG hepatic clearance. The ATP-dependent-export pump multidrug resistance associated protein 2 (MDRP2) and the multi-drug resistance (MDR3)

Figure 3 Schematic representation of indocyanine green kinetics (modified from Imamura *et al.*<sup>[5]</sup>, 2005).

P-glycoprotein are the specific carriers involved in this process, expression of the liver energy status and of the excretory function<sup>[1,3,6,7]</sup>.

Two peaks and one slope (the latter representing the elimination phase, usually lasting 10-20 min) are easily recognizable in the dye disappearance curve<sup>[5]</sup>. Of the two peaks, the first is used for the cardiac output determination, while the second is associated with the recirculation phase (elimination peak). Smaller peaks may follow the first two and are used for the estimation of circulating blood volume<sup>[6]</sup>. According to Imamura *et al.*<sup>[5]</sup>, in the ICG plasma disappearance curve (Figure 3) the initial sharp fall in concentration, (distribution phase, due to the rapid hepatic uptake of ICG from the plasma) is followed by a less steep fall (elimination phase, due to the passage from the liver into the bile). Twenty to 30 min are usually needed for the transition from the distribution to the elimination phase: *K* value (/min) is derived from the first fifteen minutes component of the disappearance curve.

In case of liver dysfunction/disease, a consistent prolongation of ICG half-life is usually recorded, as ICG hepatic clearance depends from both carriers capacity and liver blood flow. In individuals suffering for acute liver injury or steatohepatitis, release of cytokines (mainly tumor necrosis factor alpha and interleukine 6) by the reticuloendothelial cells (mainly Kupffer cells) is able to downregulate the expression of organic anion transporting polypeptide isoforms and sodium-taurocholate co-transporting polypeptide, reducing the hepatic uptake capacity. In contrast, ICG transport capacity is competitively inhibited in case of hyperbilirubinemia<sup>[6-8,10-13]</sup>, due to the same carrier system (ATP - export pump - MDRP2) shared by ICG and bilirubin: In case of hyperbilirubinemia (serum bilirubin > 3 mg/mL), "falsely" reduced ICG clearance values may be recorded due to the carrier competition (*vide infra*)<sup>[6,12,13]</sup>. This could be the case of OLT candidates with preoperative hyperbilirubinemia, in which functional recovery of the newly grafted liver is assessed early after transplant: In this specific context, "falsely" poor results may be found, making the ICG test useless

and possibly misleading (*vide infra*)<sup>[6,7]</sup>. Less common, but indeed not infrequent in the critically ill, is the case of high flow states: False reassuring findings (better than expected) due to "normal or near normal" results might be recorded, masking an altered liver excretory function<sup>[7]</sup>. In the cirrhotic population, measurements of liver blood flow using ICG<sub>CI</sub> are not to be considered completely reliable<sup>[14]</sup>: The hepatic extraction rate in this context is extremely reduced (close to 20%-30%) and ICG<sub>CI</sub> becomes a measure of the uptake clearance (*C<sub>int</sub>*, as demonstrated by Imamura *et al.*<sup>[5]</sup>)<sup>[14]</sup>. Interestingly enough, bile elimination constant was not altered, as reported by Kawasaki *et al.*<sup>[15]</sup>. Using the galactose clearance test to measure liver blood flow, the same AAs were able to demonstrate that in liver cirrhosis a reduced ICG<sub>CI</sub> (reported as ICG<sub>R15</sub>) was dependent from a reduction of both hepatic extraction and hepatic blood flow. Sinusoidal capillarization and intrahepatic shunts, largely represented in cirrhotic patients, are proposed as a possible explanation<sup>[6,15,16]</sup>. In normal conditions, the diffusion of drugs and substances (including proteins) is free between the sinusoids and the hepatocytes: In presence of sinusoid capillarization due to a barrier-limiting factor, it is impaired. ICG, which is highly protein-bound, is particularly prone to this phenomenon. Then, in cirrhotic patients ICG<sub>K</sub> and ICG<sub>R15</sub> (*vide infra*) might reflect not only the degree of sinusoidal capillarization and intrahepatic shunts but, at least in part, also the reduction of hepatic blood flow<sup>[15]</sup>. The logarithmic transformation of the distribution phase of the dye dilution curve is the key passage for the quantitative assessment of ICG removal by the liver cells.

ICG clearance parameters most commonly reported in the literature are<sup>[6,7]</sup>: (1) Plasma disappearance rate - ICG<sub>PDR</sub>; (2) Retention rate at 15 min - ICG<sub>R15</sub>; (3) Disappearance rate constant (or elimination rate constant) (*K* constant) - ICG<sub>K</sub>; and (4) ICG<sub>CI</sub> - ICG clearance.

ICG<sub>PDR</sub> and ICG<sub>R15</sub> are the two kinetic parameters most frequently used in clinical practice for the dynamic assessment of liver function<sup>[6-8,17]</sup> (Table 1, from Vos *et al.*<sup>[6]</sup>, 2014).

**ICG<sub>PDR</sub> - PDR:** Percentage change over time of the reduction of ICG blood concentration starting from a concentration of 100% (> 18% per minute). PDR is automatically calculated according to the time course of the ICG blood concentration using monoexponential transformation of the original ICG concentration curve and backward extrapolation to time point zero. In the critically ill, PDR is an accepted surrogate for clearance, due to the good correlation with ICG<sub>CI</sub> (*r*<sup>2</sup> = 0.77)<sup>[2]</sup>.

$$\text{PDR (\% per minute)} = \ln 2/t_{1/2} \times 100 \text{ or } C_{\text{ICG}}(t) = C_0 \times e^{-k \times t}$$

**ICG<sub>R15</sub> - R15:** The ratio between ICG concentration 15 min after injection and initial concentration (normal 0%-10%).

**Table 1** Quantitative indocyanine green kinetics variables (modified from Vos *et al.*<sup>[6]</sup>, 2014)

Variable	Denomination	Unit	Formula for calculation	Normal value
ICG <sub>PDR</sub>	ICG plasma disappearance rate	% per minute	Backward extrapolation of k, curve fitted as: $C_{ICG}(t) = C_0 \times e^{-k \times t}$	> 18%-24% per minute
ICG <sub>R15</sub>	ICG retention ratio after 15 min	%	$(C_{ICG(15)} / C_{ICG(0)}) \times 100$	< 10%
ICG <sub>t/2</sub>	ICG half life	min	$(\ln 2 \times V_D) / Cl_{ICG}$	3-5
Cl <sub>ICG</sub>	ICG clearance	mL/min per kilogram	$K \times V_D$	6-12

e: Euler's number (approximately 2.718); k: Fractional ICG concentration change per minute; V<sub>D</sub>: ICG volume of distribution; t: Time; C<sub>ICG</sub>(t): ICG concentration at time point t (min); Cl<sub>ICG</sub>: ICG clearance (mL/min per kilogram); ICG: Indocyanine green.

$$R15 (\%) = C_{ICG15} / C_{ICG0} \times 100$$

An initial ICG plasma concentration of 100 mg/mL is usually achieved after the intravenous administration of 0.5 mg/kg BW (considering an average plasma volume of 50 mL/kg). ICG<sub>R15</sub> is calculated transforming the ICG concentration curve to a "point zero" (100%) and then describing the decay (at minute fifteen) as a percentage change per time (% per minute) in a logarithmic graph. ICG<sub>R15</sub> has been widely used as an alternative to ICG<sub>K</sub>, being pharmacologically equivalent<sup>[5]</sup>. It could be considered a surrogate of liver blood flow.

**ICG plasma clearance (500-700 mL/min per square):** Volume of plasma entirely cleared off of ICG per unit time; plasma clearance is dependent on liver function, hepatic blood flow, bile flow (Table 1).

ICG<sub>PDR</sub> and ICG<sub>R15</sub> might be considered the two faces of the same phenomenon. ICG<sub>PDR</sub> quantifies ICG disappearance from the plasma over time (% per minute); ICG<sub>R15</sub> is the amount of the circulating ICG fifteen minutes after the administration (%). However, at variance of ICG<sub>R15</sub>, ICG<sub>PDR</sub> should be associated with ICG uptake by the hepatocytes mass, bile excretion, blood flow - dependent liver metabolism and the energy status<sup>[17]</sup>. Unfortunately, across the various studies the two parameters are used in a different and possibly confounding manner. ICG<sub>R15</sub> is almost always considered for the dynamic assessment of hepatic functional reserve in case of liver resection for hepatocellular carcinoma on cirrhosis (HCC)<sup>[5,8]</sup>; ICG<sub>PDR</sub> and ICG<sub>R15</sub> to assess liver graft function after liver transplantation<sup>[18]</sup>; ICG<sub>PDR</sub> in the critical care setting<sup>[2,17]</sup>.

ICG<sub>PDR</sub> and ICG<sub>R15</sub> are determined using either the high performance liquid chromatography with ultraviolet and fluorescence detection (cumbersome and time consuming methodology) or, as almost always reported nowadays, the modern, non-invasive PDD method (pulse dye densitometry method and spectrophotometry)<sup>[6-8]</sup>. A first "invasive" tool was available in the early nineties with the COLD System (Pulsion Medical System, Germany): ICG<sub>PDR</sub> was measured using an arterial fiberoptic catheter inserted in the femoral artery and connected to the COLD system. The system provided a complete and advanced volumetric hemodynamic profile and the ICG<sub>PDR</sub><sup>[19]</sup>. A non invasive, optical transcutaneous pulse spectrophotometric sensor (PDD

technology) is instead used by LiMON, (Pulsion Medical System, Germany) and DDG 2001, (Nihon Kohden, Japan) analysers<sup>[20-23]</sup>. The system measures ICG concentration determining the relative changes in light absorption by the arterial ICG at two different wave lengths, 805 nm (frequency of the ICG peak absorption) and 905 nm (frequency with no ICG absorption): No interference comes from oxidized or reduced hemoglobin and from bilirubin (peak absorption at 470 nm)<sup>[6,7]</sup>. PDD has been validated both in stable and unstable hemodynamic settings<sup>[18-21]</sup>. Purcell *et al.*<sup>[22]</sup> validated the PDD algorithm comparing ICG<sub>R15</sub> values obtained from direct measurement of blood samples and from LiMON. Stable hemodynamic conditions are imperative for reliable data on liver function<sup>[6,8]</sup>. Systemic or local conditions able to reduce hepatic blood flow (low cardiac output inducing hepatosplanchnic hypoperfusion or hepatic artery thrombosis and abdominal hypertension, respectively) have significant impact on ICG elimination, which is reduced in the above mentioned settings. On the contrary, splanchnic hyperperfusion, increasing ICG extraction, might produce (falsely) high ICG<sub>PDR</sub> readings. In case of liver dysfunction, true pathological ICG<sub>PDR</sub> or ICG<sub>R15</sub> values are present because of a decreased transport from the systemic circulation to the liver (reduced blood flow) and/or a decreased uptake by the hepatocytes from the sinusoids. In the liver transplant setting, for example, conditions able to negatively impact on liver blood flow and/or extraction capacities are hepatic artery thrombosis (HAT), primary graft non function (PGNF), severe early graft dysfunction, severe rejection<sup>[9,10]</sup>.

Altered ICG<sub>PDR</sub> and ICG<sub>R15</sub> might also be reported in case of elevated serum bilirubin levels: In the active transport process into the hepatocytes, competition between bilirubin and ICG for the same carrier "alters" ICG kinetic results. This specific condition could be quite common in the early postoperative period of liver transplantation in patients with pretransplant hyperbilirubinemia: Pathological results should be attributed to ICG/Bilirubin competition for the same carrier (Na Taurocolate-co-transporting peptide) and not necessarily to a graft dysfunction. Since pathological ICG<sub>R15</sub> or ICG<sub>PDR</sub> values might be recorded with serum bilirubin > 3 mg/dL<sup>[6,7]</sup>, extreme caution has to be used when interpreting ICG clearance results in hyperbilirubinemic patients. According to the available studies, a bilirubin

level > 3 mg/dL should be considered the cut-off value. In a series of 76 liver transplanted patients, a higher bilirubin level (6 mg/dL) was found by our group to be the cut-off value able to interfere with ICG kinetics (published in abstract)<sup>[24]</sup>.

ICG<sub>PDR</sub> and ICG<sub>R15</sub> are now used: (1) preoperatively, to assess the liver functional reserve before hepatic resection, particularly in cirrhotic patients<sup>[6,23]</sup>; (2) in the liver transplant setting, either in sequential assessments during the various phases of liver transplantation (rare) or (most often) to dynamically assess the recovery of the graft early after transplantation; and (3) following hepatic resection for a functional evaluation of the remnant liver both in cirrhotic and non cirrhotic patients and after partial hepatectomy (particularly the right hepatectomy) in case of living related liver donation. As above underlined, caution must be used while interpreting the results in case of hyperbilirubinemia<sup>[6,24]</sup>. Last but not least, ICG clearance parameters might be altered in case of repeated administrations if intervals between the sequential ICG injections are too short (less than 30 min): Residual ICG may change the baseline drift<sup>[6]</sup>.

In contemporary clinical liver medicine, a tentative list of indications of ICG kinetic parameters could be the following<sup>[2,6-8]</sup>: (1) Functional definition of the hepatic reserve in cirrhotic and non cirrhotic patients undergoing resective surgery; (2) Morbidity/mortality prediction in the same setting; (3) Functional assessment in cadaveric donors of liver function, particularly in case of extended criteria donors, and in case of living donation (beyond the scope of the review); (4) Non invasive assessment of portal hypertension (PH) and esophageal varices<sup>[25]</sup>; and (5) Early functional assessment of the newly grafted liver.

## THE ROLE OF ICG CLEARANCE KINETICS IN THE PREOPERATIVE ASSESSMENT OF LIVER RESECTION IN CIRRHOTIC PATIENTS

Nowadays, in the clinical management of HCC in cirrhotic and non cirrhotic patients relevant is the role played by the appropriate indication of surgery. Liver resection is considered for cirrhotic patients with compensated hepatic function, as assessed by scores, static or dynamic liver function tests, imaging<sup>[26]</sup>. In 2003, Imamura *et al.*<sup>[27]</sup> were able to report zero mortality in a series of 1056 hepatectomies: However, mortality rates ranging from 2% to 5% (and higher) are still reported by others<sup>[23,26,27]</sup>. Posthepatectomy liver dysfunction or failure remains an extremely feared complication, still reported in up to 30% of the cases: In spite of major innovations in surgical and anesthesiological techniques and in the postoperative care, mortality remains high<sup>[27-30]</sup>. Postoperative liver dysfunction is more frequent in cirrhotic patients who underwent hepatic resection: According to the literature,

major risk factors are inadequate preoperative assessment of liver functional reserve, too "aggressive" resection, perioperative hemorrhagic complications and transfusion needs, postoperative infective complications<sup>[30-35]</sup>.

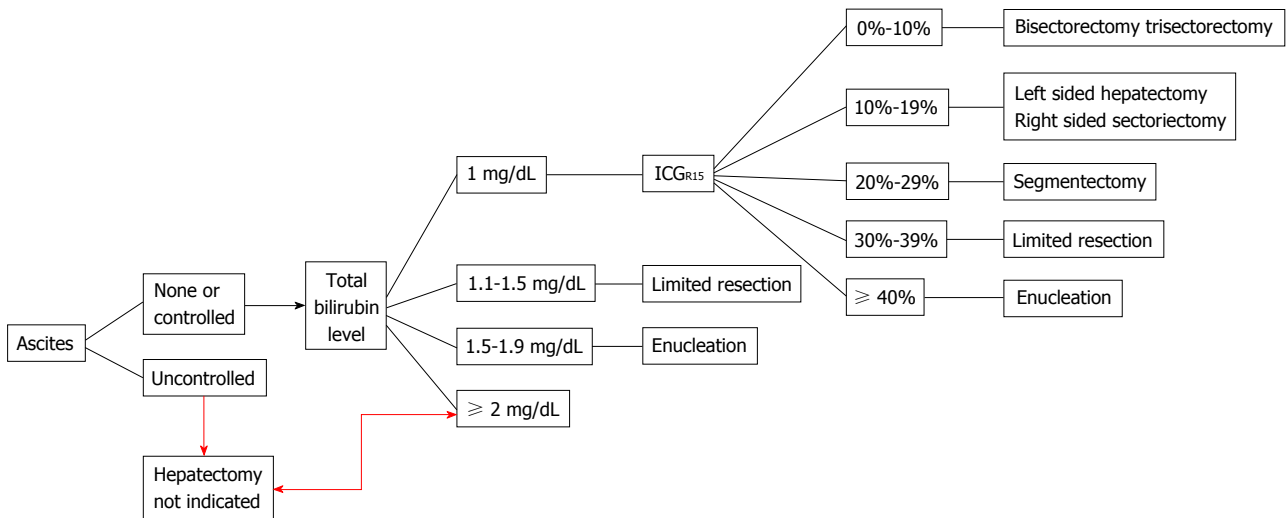

Usually (but not exclusively), indications and extension of resective surgery are tailored according to: (1) presence or absence of ascites and hepatic encephalopathy in the preoperative period; (2) results of conventional static liver function tests (AST/ALT, serum Bilirubin level); (3) imaging (magnetic resonance imaging/magnetic resonance imaging volumetric imaging to predict the remnant hepatic volume); and (4) CTP and MELD scoring systems<sup>[23,33-35]</sup>.

Scores systems widely used in liver medicine for a comprehensive assessment of liver function are CPT and MELD. The CTP score, proposed in 1964 by Child *et al.*<sup>[36]</sup>, and later modified by Pugh (CTP), was created to predict the morbidity/mortality risk of cirrhotic patients with severe PH admitted to shunt surgery<sup>[36,37]</sup>.

Using serum bilirubin, albumin and prothrombin time (PT), (common biochemical parameters, easy to determine in everyday clinical practice) and clinical findings (presence/absence of ascites and encephalopathy), the AAs defined three classes (A, B, C) able to identify the severity of the chronic liver disease. Within the three classes, Pugh *et al.*<sup>[37]</sup> later introduced a score for different values of the biochemical and clinical parameters to identify within the same class (A, B, C) subgroups of patients (A 5-6; B 7- 9; C 10-15) at increasing severity. The CTP score, still quite reliable in predicting mortality after general surgery (roughly, CTP A, 10%; CTP B, up to 30%; CTP C, as high as or above 50%)<sup>[6]</sup>, has some important limitations: Insufficient information on regional assessment of liver function (CTP is by definition a sort of broad classification of the severity of liver disease) and the absence of information on the volume of liver parenchima safely resectable are indeed relevant in the surgical setting<sup>[6,7]</sup>.

In spite of these reported limitations, in the Western surgical school CTP and the degree of PH (often qualitatively defined), together with imaging are often used to assess liver function in the preoperative period. Liver resective surgery should be considered for patients in class A and, limiting the extent of the resection to reduce the risk of postoperative hepatic dysfunction, in well selected Class B patients<sup>[5,27,30]</sup>. Controversial is the use of MELD score or its derivatives (NaMELD and iMELD) in the surgical context. MELD score, based on bilirubin, creatinine and PT as INR, was originally introduced to predict the outcome of patients candidates to transjugular intrahepatic portosystemic shunt procedure. Nowadays, MELD is mainly considered to define the severity of chronic liver disease and its prognosis, to prioritize the liver transplant procedure, to predict survival in liver transplant candidates<sup>[38-40]</sup>. However, reliability of MELD to predict mortality after liver resection is still a matter of debate: major concerns arise from the narrow range (9-14) in which the score

**Figure 4** Makuuchi decisional algorithm to select liver resective procedures in cirrhotic patients according to liver functional reserve (from Imamura *et al.*<sup>[5]</sup>, 2005). ICG<sub>R15</sub>: Indocyanine green retention ratio at 15 min.

**Table 2** Liver damage grading system (Mizuguchi *et al.*<sup>[8]</sup>, 2014, modified)

Parameters	Liver damage grade A	Liver damage grade B	Liver damage grade C
Albumin (g/L)	> 3.5	3.5-3	< 3
Bilirubin (mg/dL)	< 2	2-3	< 3
PT (%)	> 80	50-80	< 50
Ascites	None	Small or controlled	Tense
ICG <sub>R15</sub> (%)	< 15	15-40	> 40

PT: Prothrombin activity; ICG<sub>R15</sub>: Indocyanine green retention ratio at 15 min.

is used. In patients with MELD score > 10, Cucchetti *et al.*<sup>[41]</sup> found a high rate of postoperative liver dysfunction. Hepatic resection is contraindicated in CTP class C patients or in patients whose MELD score is above 14. Instead, in well selected class B patients or in subjects whose MELD score ranges from 9 to 14, the surgical option might be considered: Each single case mandates a thorough preoperative evaluation, including the type of liver resection and its feasibility<sup>[42,43]</sup>.

On the contrary, ICG clearance parameters (mainly ICG<sub>R15</sub>) are since the eighties championed by the Eastern surgical schools<sup>[5,32-34]</sup>: In particular dynamic tests were strongly supported to assess in advance the maximum extent of the resection of the hepatic parenchyma associated with a good functioning remnant liver. In the evidence-based guidelines for the treatment of hepatocellular carcinoma released in Japan in 2009, the use of ICG<sub>R15</sub> was recommended (level of evidence B) for the preoperative assessment of liver function<sup>[43]</sup>. Very recently, ICG<sub>R15</sub> was incorporated in a modified functional evaluation score [Liver Damage Grading System (LDGS)] derived from the CTP classification (Table 2). The Japanese Liver Cancer Study Group of Japan proposed the LDGS, instead of the CTP score, as a more accurate and appropriate tool for the functional

assessment of the hepatic reserve<sup>[8,23]</sup>.

In cirrhotic patients, liver resections should be performed with ICG<sub>R15</sub> < 15%: According to authoritative reports, appropriate candidates for right hepatectomies were patients with ICG<sub>R15</sub> > 10%, whereas left hepatectomies were considered also in surgical candidates with slightly longer ICG<sub>R15</sub> (range 10% to 19%)<sup>[43-45]</sup>. In other series, major liver resections were successfully performed with longer ICG<sub>R15</sub> (range 15% to 20%), if the volume of the residual liver was deemed "sufficient"<sup>[44]</sup>. The role of ICG<sub>R15</sub> in major liver resection became relevant and evident after the publication of the Makuuchi group's experience: Analyzing the results obtained between 1994 and 2002, the AAs were able to report zero mortality in 1056 hepatectomies<sup>[5]</sup>. Three variables were particularly highlighted in the preoperative assessment: (1) ascites (presence or absence); (2) bilirubinemia; and (3) ICG<sub>R15</sub><sup>[5,27]</sup>.

According to the original decisional tree proposed by Imamura *et al.*<sup>[5]</sup>, key points are: (1) contraindication to hepatic resection in presence of uncontrolled ascites or serum bilirubin > 1.9 mg/dL; (2) minor resections possible with serum bilirubin ranging between 1 and 1.9 mg/dL, the lower the bilirubin level, the larger the resection; and (3) according to ICG<sub>R15</sub> intervals different types of hepatic resection possible in case of serum bilirubin < 1.1 mg/dL and no ascites (Figure 4).

Nowadays, preoperative selective portal vein embolization is a challenging option in very well selected subjects candidates to liver resection: An example could be a patient with ICG<sub>R15</sub> 15%-20% whose remnant liver volume after the planned resection is considered "not sufficient". The aim of portal vein embolization is to induce hyperplasia of the hepatic lobules perfused by the contralateral portal vein to increase the volume of the "future remnant" liver<sup>[6,7,46]</sup>. ICG<sub>R15</sub> after embolization correlates with both the volumetric changes and the modification of the liver functional reserve:

It should allow a sort of functional prediction of the remnant liver before resective surgery<sup>[46]</sup>. In the original algorithm proposed by Poon and Fan, hepatic hyperplasia and preservation of "total" liver blood flow were the mainstays of this surgical strategy<sup>[33]</sup>. Definitive implementation of the procedure is still ongoing, even if available results seem promising.

In recent studies, postoperative morbidity [mainly represented by post-hepatectomy liver failure (PHLF)] is reliably predicted by R15 or PDR<sup>[44-47]</sup>. Still under debate is instead the ability of ICG kinetics to correctly predict mortality: The small number of negative events (death) might represent a possible cause<sup>[44,45]</sup>. Using intraoperative ICG<sub>PDR</sub> in a small series of patients, a value of < 9% per minute min predicted postresective liver failure with high sensitivity (88%) and specificity (82%)<sup>[44]</sup>. In another experience, liver failure occurring on postoperative day (POD) 2-5 was predicted by ICG<sub>PDR</sub> < 7% per minute on POD 1<sup>[45]</sup>. Prospectively studying postoperative complications in 100 cirrhotic patients admitted to different liver resections, our group was able to document a significant increase in postresective morbidity associated with ICG<sub>R15</sub> > 40%: Interestingly enough, mortality was not influenced by ICG<sub>R15</sub> (published in abstract)<sup>[47]</sup>.

The most recent intraoperative application of ICG kinetics (ICG<sub>PDR</sub>/ICG<sub>R15</sub>) in major liver surgery was proposed by Thomas *et al*<sup>[48]</sup>: Scope of the study was the definition of reliability of an intraoperative simulation of post-resection liver function. In 20 patients undergoing liver resection, ICG kinetics (LIMON, Pulsion Medical System, Germany) was assessed before and after selective arterial and portal venous inflow trial clamping (TC) of the resected liver segments: The aim was to prevent/avoid PHLF. Similar data were recorded under TC (a significant ICG<sub>PDR</sub> decrease from 16.5% to 10.5% per minute) and after resection (median ICG<sub>PDR</sub> after resection 10.5% per minute). Thomas *et al*<sup>[48]</sup> proposed ICG kinetics as able to reliably simulate post-resection liver function during TC: In their opinion, it might become a useful tool to prevent/avoid PHLF and to reduce hospital length of stay.

In a recent paper, combining the changes of total Bilirubin and INR on POD 1, 3, 5 and 7, Du *et al*<sup>[49]</sup> proposed a definition of postoperative liver failure (PLF). An hepatic damage score (HDs) was built up and used after liver resection to define the degree of the liver metabolic functional impairment (0 = mild; 1 = reversible hepatic "dysfunction"; 2 = fatal hepatic failure). Interestingly enough, in the most compromised patients (HDs = 2) a linear relationship was found between ICG<sub>R15</sub> and the number of the resected segments, possibly identifying preoperative criteria for the most appropriate and safest selection of hepatic resection to reduce PLF<sup>[49]</sup>.

Preoperative pathological ICG<sub>R15</sub> may be wrongly associated with liver dysfunction in case of biliary obstruction. If this is the case, caution should be exerted in interpreting the test results: While the programmed

surgical strategy should not be withheld, further and multimodal investigations are to be considered to adapt/optimize the surgical program<sup>[6]</sup>. In case of hyperbilirubinemia, the South Korean and Japanese surgical schools suggest, as very recently reported by Ge *et al*<sup>[17]</sup>, Tc - galactosyl serum albumin scintigraphy for a more precise functional assessment of the liver. According to the most updated literature, GSA seems to be the ideal agent to predict the volume of hepatocyte mass and its function, due, at least in part, to track the distribution of asialoglycoprotein receptors<sup>[17]</sup>.

## ICG<sub>R15</sub> IN PH: A ROLE AS A NON INVASIVE MARKER?

As above discussed, total liver blood flow and hepatic functional reserve are reflected by ICG<sub>R15</sub>, often used as a prognostic marker in decompensated cirrhotic patients and in candidates to resective liver surgery<sup>[50]</sup>. In cirrhotic patients admitted to resective surgery, preexisting PH and postoperative parenchymal dysfunction are among the most common causes of PHLF. Recently, Lisotti *et al*<sup>[25]</sup> in a cohort of CHILD. A cirrhotic patients with well-preserved liver function evaluated the accuracy of ICG<sub>R15</sub> in reflecting the alteration of hepatic blood flow and, indirectly, the presence and grade of PH and esophageal varices (EV). As comparators, the AAs used hepatic vein pressure gradient and upper gastrointestinal endoscopy, actually the gold standards in this setting. Interestingly enough, Lisotti *et al*<sup>[25]</sup> documented a good performance of ICG<sub>R15</sub> for the diagnosis of both PH and EV. In patients with compensated cirrhosis, ICG<sub>R15</sub> < 6.7% and < 6.9% ruled out clinically significant PH and severe PH respectively, while ICG<sub>R15</sub> < 10% was able to exclude the presence of EV. The AAs concluded for a role of ICG<sub>R15</sub> in identifying patients with advanced liver disease for whom the endoscopic study is warranted.

## ICG KINETICS IN LIVER TRANSPLANT SURGERY

An increased demand of grafts due to the expanded liver transplant (OLT) indications has to face organ shortage, perhaps the most relevant restraint when dealing with solid organ transplant surgery. To expand the donors pool, extended criteria donors and/or suboptimal ("marginal") grafts are ever and ever harvested to match the increasing transplant demand. Early after OLT, the results of conventional "static" liver function tests may raise doubts or uncertainties when used to assess the functional recovery of the liver grafts<sup>[6]</sup>. Recently, few, small single center studies reported on ICG<sub>PDR</sub> to assist and (more objectively support) the decision to harvest livers from suboptimal donors. ICG clearance kinetics, mainly expressed as ICG<sub>PDR</sub> or K constant of elimination, have been used in cadaveric donors before organ harvesting for a quantitative assessment of liver function<sup>[6]</sup>. Unfortunately, the value of ICG<sub>PDR</sub> to assist

graft suitability assessment before harvesting deserves further studies, as values  $< 15\%$  per minute during donor observation were consistently associated with a poor outcome of the graft<sup>[6]</sup>.

ICG kinetics have since long a place in the liver transplant setting. ICG kinetics were recently incorporated in the MELD score for a fine tuning of survival prediction in transplant candidates: As a matter of fact, in candidates whose MELD score ranged from 10 to 30, the ICG-MELD score further improved the prediction performance<sup>[50]</sup>. ICG kinetics into the MELD score add an estimation of liver blood flow, making the new score more accurate than the "simple" MELD and Na MELD in predicting survival in moderate to severe cirrhosis. The role played by hyperbilirubinemia, if present, has of course to be considered. Much more extensively studied is the use of ICG kinetics to predict early perioperative complications and graft and patient survival after OLT. Among the most feared complications in the early postoperative period are HAT and PGNF, conditions which warrant early diagnosis and a timely and appropriate treatment: Urgent retransplantation is mandatory in case of PGNF and very often is the only solution to avoid fatalities in cases of HAT. In the mid nineties, a number of relevant studies<sup>[51-53]</sup> strongly supported the use of ICG clearance parameters for an early assessment of graft function and to predict patient and graft survival. Jalan *et al.*<sup>[51]</sup>, using ICG clearance, correctly predicted both the immediate functional recovery of the new liver and the good graft function three months after OLT when ICG<sub>Cl</sub> on POD 1 was  $> 200$  mL/min. More recently, "low" ICG<sub>PDR</sub> values (5% to 12% per minute) early after OLT were associated with graft malfunction/failure. In the liver transplant setting, the definition of a reproducible and reliable "low" cut-off value is, even if eagerly awaited, still ill - defined: ideally, this value should not be affected by conditions able to create falsely pathological results. Unfortunately, no consensus exists in the literature on this critical point, so far. Faybik *et al.*<sup>[54]</sup>, studying ICG<sub>PDR</sub> using COLD System (Pulsion, Germany) and LiMon (Pulsion, Germany) in a series of patients who underwent OLT found ICG<sub>PDR</sub>  $< 10\%$  per minute as a predictor of postoperative complications. Hori *et al.*<sup>[55]</sup>, using ICG<sub>K</sub> (Nihon Kohden DDG 2001, Japan) in a cohort of thirty patients admitted to living donor liver transplant, assessed graft function daily for the first 14 postoperative days, and then on POD 21 and 28. The early outcome was defined "unfavourable" in case of increased morbidity or mortality. According to this definition, the AAs retrospectively allocated the transplanted patients to two groups, A (favourable outcome, 24 subjects) and B (unfavourable outcome, 6 subjects). ICG<sub>K</sub>  $< 0.180$  on POD 1 correctly predicted the poor outcome of the six patients of group B.

Levesque *et al.*<sup>[56,57]</sup> using LiMON (Pulsion Medical System, Germany) from POD 1 to POD 5 defined an ICG<sub>PDR</sub> value able to predict early postoperative complications. In a first study<sup>[56]</sup>, in a series of 70 consecutive procedures, the transplanted patients were divided

in two groups according to the early outcome: In the group of patients who did well, had immediate good graft function, favourable postoperative course and positive outcome, ICG<sub>PDR</sub> was  $24.4\% \pm 6.8\%$  per minute. Instead, the patients who had postoperative complications were retrospectively subdivided into two subgroups: The first group was composed by subjects who experienced PGNF, HAT, and hemorrhagic or septic shock (early complications); the second included patients who had rejection (late complications). While ICG<sub>PDR</sub> was low ( $8.8\% \pm 4.5\%$  per minute) during the first 5 d in the first subgroup, in the second the ICG<sub>PDR</sub>, initially normal, decreased significantly within 3 to 5 d (ICG<sub>PDR</sub>  $10.3\% \pm 2.5\%$  per minute). Levesque *et al.*<sup>[56]</sup> proposed ICG<sub>PDR</sub>  $< 12.85\%$  per minute as a marker of very early postoperative complications (mainly severe hepatocellular dysfunction, such as PGNF). In a second paper, the same AAs retrospectively reviewing ICG<sub>PDR</sub> in patients who had HAT in the early post OLT period found a significantly lower ICG<sub>PDR</sub> when HAT was documented (range 0.4 to 9.5, mean  $5.8\% \pm 4.3\%$  vs non HAT, range 15.3% to 32.9%, median  $23.8\% \pm 7.4\%$  per minute): ICG<sub>PDR</sub> increased significantly after the revascularization (mean  $15.6\% \pm 3.5\%$  per minute). The AAs concluded defining ICG<sub>PDR</sub> as an interesting diagnostic tool in the early posttransplant period to manage patients suspected for acute HAT<sup>[57]</sup>. The major concern that could be raised on this specific item is the absence of a clear cutoff value in the presence of HAT (see the wide range of ICG<sub>PDR</sub> in the HAT patients). As a matter of fact, this item is quite controversial in the literature. ICG kinetic parameters were used by Olmedilla *et al.*<sup>[58]</sup> at the end of OLT or on POD 1 to assess early graft function. In patients who suffered early severe hepatic dysfunction and had an increased mortality rate, ICG<sub>PDR</sub> was  $< 10.8\%$  per minute. Instead, a favorable outcome was recorded in transplanted patients who had ICG<sub>PDR</sub>  $> 10.8\%$  per minute: In the same study the AAs were also able to document a very high (99%) negative predictive value. In the most recent study coming from the same group, ICG<sub>PDR</sub> and INR were used to build a risk score to predict short term outcome after OLT. Cut-off values were  $\geq 2.2$  for INR (1 point) and  $< 10\%$  per minute for PDR (2 points). The AAs defined four categories (points 0 to 3) in which the risk of early death or retransplantation was described by the score, the higher the score, the higher the risk of adverse outcome (point 0, 4.4%; point 1, 6.5%; points 2, 12%; points 3, 50%). A similar trend was reported also for ICU length of stay and duration of mechanical ventilation. In a validation cohort of 70 patients the score had a good diagnostic performance with sensitivity 60%; specificity 95.5%; positive predictive value (PPV), 66.7%; negative predictive value (NPV) 94.1%. The AAs concluded for a simple and useful tool to be considered for the selection of diagnostic and therapeutic strategies in the early postoperative period<sup>[59]</sup>. Different result were proposed by Escorsell *et al.*<sup>[60]</sup>. In their experience, ICG<sub>PDR</sub> was not a predictor of liver dysfunction and short

term outcome. Using a cut off of 8.8% per minute the AAs subdivided the transplanted patients in two groups (A < 8.8% per minute; B > 8.8% per minute). Interestingly enough, outcome of patients in group A was similar to outcome of patients in group B: Since transplanted patients in group A showed significantly higher bilirubin levels, a false “low” reading of the ICG<sub>PDR</sub> might have occurred. The most probable explanation should be a non proper categorization of a graft as “malfunctioning” because of hyperbilirubinemia and not because of a real dysfunction. Confirmation of this interpretation comes from the reported outcome. Very similar were the results we proposed (in abstract) studying a cohort of 76 consecutive liver transplants<sup>[24]</sup>: ICG<sub>PDR</sub> < 10% per minute was not associated with a poor outcome of the patient and of the graft in the early postoperative period. Interestingly enough, serum bilirubin > 6 mg/dL was always present when ICG<sub>PDR</sub> was < 8% per minute<sup>[24]</sup>. We speculated that in this specific condition (hyperbilirubinemia), ICG<sub>PDR</sub> should be considered, as above underlined, unreliable<sup>[6,7,12,13]</sup>. This point is unfortunately not completely addressed, in our opinion, by Levesque *et al.*<sup>[61]</sup> in the most recent review on this item. The last two studies are, in our opinion, a further strong argument to support the relevant alteration introduced by hyperbilirubinemia, not infrequently observed early after OLT, on ICG kinetics. In both studies, ICG<sub>PDR</sub> falsely predicted an early hepatic dysfunction, not confirmed by the early and medium term outcome of both patients and grafts. Instead, Escorsell *et al.*<sup>[60]</sup> showed a strong correlation between lactate clearance and the functional recovery of the newly grafted livers, further stressing the high PPV of this test: A further confirmation of very similar results we obtained in an earlier study<sup>[62]</sup>. Last but not least, ICG kinetics might be altered by other factors or conditions quite common in the early post transplant period: Among them, the impact of different values of total proteins and hematocrit<sup>[63]</sup>.

Further confirmations for a cautious interpretation of low ICG<sub>PDR</sub> values while assessing liver function both after liver resection and OLT come from a series of recent studies performed with the Maximal Enzymatic Liver Function (LiMax test), a test which relies upon <sup>13</sup>C methacetin metabolism<sup>[64-67]</sup>. In patients who underwent liver resective surgery, Lock *et al.*<sup>[64]</sup> compared ICG<sub>PDR</sub> and Limax to identify patients at risk for postoperative liver failure: Limax showed a better predictive power, once again emphasizing how relevant could be the potential interference of various parameters on the ICG clearance variables.

In a cohort of liver transplant candidates suffering for chronic liver disease, patients who experienced six months liver-related death (primary end point of the study) had, when compared to survivors, significantly lower median Limax values. On the contrary, ICG<sub>PDR</sub> findings were similar in survivors and non survivors. In the same study LIMAX showed a slightly higher NPV (if compared to ICG<sub>PDR</sub> and MELD) when six months risk of

death was considered<sup>[65]</sup>.

Acute liver failure (ALF) is one of the most challenging conditions in liver medicine. Preliminary results on the use of ICG kinetic parameters were recently reported in small series of patients<sup>[7,61,65]</sup>: However hyperbilirubinemia, always present in patients with hyperacute, acute (“fulminant”) or subacute hepatic failure, should impact on ICG elimination kinetics, making problematic at best their interpretation. Lock *et al.*<sup>[67]</sup> recently tested the use of LiMax in ALF. Remarkably, LiMax values, contrary to MELD, were significantly lower in patients who had unfavourable outcome. If confirmed, the AAs concluded for an interesting relevant role of LiMax in ALF in predicting the individual prognosis, possibly supporting in the decision for urgent liver transplant<sup>[67]</sup>.

## CONCLUSION

In recent years reliable and easy-to-use non-invasive bedside analysers using the PDD technology, (LiMon and Nihon Kohden) have boosted the use of ICG kinetic parameters in hepatic surgery and, in general, while caring for the critically ill. Since long, the Eastern surgical schools have supported an extensive application of this technology, particularly when major surgical options are considered in patients affected by hepatocellular carcinoma on liver cirrhosis. The most relevant results, worth to be considered also by the Western surgical community, deal with liver cancer resectability and the potentials for preventing or avoiding postresective hepatic dysfunction/failure. In liver resective surgery, while firm results are available when dealing with morbidity, concern still exists in predicting mortality. In spite of the initial enthusiasms and some very recent results, the use of post OLT ICG kinetics to predict morbidity and mortality are to be considered, at least in our opinion, still under scrutiny. Notwithstanding the results proposed by the most recent publication<sup>[59]</sup>, mixed results or “false pathological findings” (false positives) are present in the literature: To be specifically addressed in the liver transplant setting is the presence of hyperbilirubinemia. In this context, according to ICG<sub>PDR</sub>, newly grafted liver might be falsely classified as severely dysfunctioning or at consistent risk of unfavourable outcome, when opposite is the real final outcome. In spite of the most recent evidence<sup>[59]</sup>, no consensus exists on the cut-off value of PDR/R15 below which a reliable assessment of early graft dysfunction is confidently available. In liver transplanted patients, the negative predictive value of ICG kinetics is indeed relevant: Good graft and patients outcome are almost always associated with “normal” ICG clearance parameters. Into our opinion, in this setting “low” or pathological values are still in a gray zone and caution in interpreting results is needed. As appropriately pointed out by Levesque *et al.*<sup>[61]</sup> when defining severity of complex and evolving diseases, a multistep dynamic approach (instead of single time point static result)

should become the rule. Ending up their review, Vos *et al.*<sup>[6]</sup> proposed a wise and prudent comment on the routine use of IGC kinetics in clinical practice, pushing for further large, prospective, randomized trials: A challenge worth to be considered, particularly in the field of liver transplantation, if gray has to turn to green.

## Abstract

**AIM:** To assess whether reasons for hepatitis C virus (HCV) therapy non-initiation differentially affect racial and ethnic minorities with human immunodeficiency virus (HIV)/HCV co-infection.

**METHODS:** Analysis included co-infected HCV treatment-naïve patients in the University of North Carolina CFAR HIV Clinical Cohort (January 1, 2004 and December 31, 2011). Medical records were abstracted to document non-modifiable medical (*e.g.*, hepatic decompensation, advanced immunosuppression), potentially modifiable medical (*e.g.*, substance abuse, severe depression, psychiatric illness), and non-medical (*e.g.*, personal,

social, and economic factors) reasons for non-initiation. Statistical differences in the prevalence of reasons for non-treatment between racial/ethnic groups were assessed using the two-tailed Fisher's exact test. Three separate regression models were fit for each reason category. Odds ratios and their 95% CIs (Wald's) were computed.

**RESULTS:** One hundred and seventy-one patients with HIV/HCV co-infection within the cohort met study inclusion. The study sample was racially and ethnically diverse; most patients were African-American (74%), followed by Caucasian (19%), and Hispanic/other (7%). The median age was 46 years (interquartile range = 39-50) and most patients were male (74%). Among the 171 patients, reasons for non-treatment were common among all patients, regardless of race/ethnicity (50% with  $\geq 1$  non-modifiable medical reason, 66% with  $\geq 1$  potentially modifiable medical reason, and 66% with  $\geq 1$  non-medical reason). There were no significant differences by race/ethnicity. Compared to Caucasians, African-Americans did not have increased odds of non-modifiable [adjusted odds ratio (aOR) = 1.47, 95%CI: 0.57-3.80], potentially modifiable (aOR = 0.72, 95%CI: 0.25-2.09) or non-medical (aOR = 0.90, 95%CI: 0.32-2.52) reasons for non-initiation.

**CONCLUSION:** Race/ethnicity alone is not predictive of reasons for HCV therapy non-initiation. Targeted interventions are needed to improve access to therapy for all co-infected patients, including minorities.

**Key words:** Human immunodeficiency virus; Hepatitis C virus; Co-infection; Antiviral therapy; Race

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Historically, hepatitis C virus (HCV) treatment rates have been low in patients with human immunodeficiency virus (HIV) co-infection, especially for African-American patients. Identifying the reasons for treatment non-initiation may help improve treatment rates among racially and ethnic minorities. In our study of patients with HIV/HCV coinfection, non-modifiable medical reasons, potentially modifiable medical reasons, and non-medical reasons for non-treatment were common among all patients, regardless of their race/ethnicity. There is a need to recognize and overcome potential treatment barriers in order to improve HCV treatment uptake in this patient population.

Oramasionwu CU, Kashuba ADM, Napravnik S, Wohl DA, Mao L, Adimora AA. Non-initiation of hepatitis C virus antiviral therapy in patients with human immunodeficiency virus/hepatitis C virus co-infection. *World J Hepatol* 2016; 8(7): 368-375 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i7/368.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i7.368>

## INTRODUCTION

Hepatitis C virus (HCV) treatment rates have been low in patients who are co-infected with human immunodeficiency virus (HIV). Up until 2011, when the first direct-acting antivirals (DAAs) became available, only one-third of co-infected patients were deemed eligible to receive HCV therapy, of whom less than one-third initiated HCV treatment<sup>[1-4]</sup>. Of great concern is the proportion of racial and ethnic minorities with co-infection that have not received HCV therapy. Nearly half of United States patients with HIV/HCV co-infection are African-American<sup>[5-7]</sup>. Previous studies involving older HCV regimens [pegylated interferon plus ribavirin (pegIFN-RBV)] reported that African-Americans were less likely than Caucasians to initiate HCV therapy<sup>[6,8,9]</sup>. Of co-infected patients in the HIV Outpatient Study during 1999-2007, African-Americans had a lower likelihood of HCV treatment than Caucasians (HR = 0.3, 95%CI: 0.2-0.6)<sup>[6]</sup>. African-American patients have been shown to not initiate therapy due to presence of IFN-related contraindications or to defer therapy due to lack of symptoms<sup>[10,11]</sup>.

Non-initiation of HCV therapy in co-infected patients is attributed to diverse factors such as patient- and provider-level barriers, perceived risks and benefits of therapy, and patient ineligibility to receive therapy due to medical contraindications<sup>[12]</sup>. Examples of medical conditions that sometimes precluded treatment with older regimens include hepatic decompensation, active injection drug use (IDU), alcohol abuse, severe depression, and advanced HIV-associated immunosuppression<sup>[13-16]</sup>.

Although these treatment-related barriers have been identified in the general co-infected population, scant research has documented their prevalence in co-infected minorities. Some reasons for non-treatment, such as substance abuse, are potentially modifiable. Addressing them could help improve access to HCV therapy in minorities. Despite the clinical promise of the DAAs, it is possible that some of the historical challenges to treating patients with HIV/HCV co-infection are still obstacles to treatment, particularly for minority patients<sup>[1,10,17]</sup>. The objectives of this study were to document reasons for non-treatment with HCV antiviral therapy and to assess how they differentially affect racial and ethnic minorities with HIV/HCV co-infection.

## MATERIALS AND METHODS

### Study design and population

This was a retrospective study of patients with HIV/HCV co-infection enrolled in the University of North Carolina (UNC) Center for AIDS Research HIV Clinical Cohort. This prospective cohort began enrolling patients in 1996 and includes over 4000 HIV-infected patients  $\geq 18$  years of age who receive HIV care at UNC. The cohort,

approved by the UNC Institutional Review Board, has ongoing enrollment and participants provide written informed consent. Data for the cohort are retrieved from two sources. Patient demographic characteristics and laboratory values are retrieved electronically, whereas patient medication histories and comorbid conditions are obtained by standardized and comprehensive electronic medical record reviews.

This study examined patients with HIV and HCV infection who had never received treatment for HCV and who had at least one outpatient clinic visit between January 1, 2004 and December 31, 2011. Patients were included in the study if they had the following: (1) a concomitant diagnosis of HCV based on positive HCV serostatus (as determined by HCV antibody test enzyme-linked immunosorbent assay/enzyme immunoassay); and (2) a positive HCV recombinant immunoblot assay (RIBA) test, detectable HCV RNA or HCV genotype test results. Patients with a history of HCV antiviral therapy were excluded. Anti-HCV therapy was defined as interferon, pegIFN, RBV, telaprevir, or boceprevir. The study period (2004-2011) was selected to best capture the timeframe when combination therapy with pegIFN-RBV was the standard of treatment for most patients with co-infection.

### Measurements

Baseline variables were retrieved from the cohort database and included patient demographics and clinical characteristics at time of HCV diagnosis. Baseline clinical characteristics were measurements taken proximal (allowing a 30-d window) to the date of the first positive HCV test. Demographic variables included age, gender, race/ethnicity (African-American, Caucasian, or Hispanic/other), and insurance coverage (private, public, none, or other). Clinical characteristics included CD4, HIV-1 RNA, HCV RNA, HCV genotype, HIV risk category (risk categories were not mutually exclusive), prior AIDS-defining clinical conditions, and use of highly active antiretroviral therapy (HAART), defined as a combination of three or more antiretroviral drugs. Prior to May 1, 2007, HCV RNA assays were measured in copies/mL, whereas subsequent HCV RNA assays were measured in IU/mL. Results for both assays are presented, where applicable, within the study period.

We reviewed individual medical records to identify reasons cited in the clinic notes by providers for not initiating HCV therapy. Reasons for treatment non-initiation were then categorized as non-modifiable medical reasons, potentially modifiable medical reasons, or non-medical reasons. Non-modifiable medical reasons included death (patients with a poor life expectancy or patients that died before treatment was ever initiated), hepatic decompensation, advanced immunosuppression (CD4 < 200) not controlled by antiretroviral therapy, renal insufficiency, uncontrolled autoimmune conditions, or hematological disease. Potentially modifiable medical reasons included active or recent (within the past six months) IDU/cocaine use, alcohol use, severe depressive

ssion (defined as depression with suicidal ideation), psychiatric illness, or pregnancy/unwillingness to use contraception. Lastly, non-medical reasons included personal factors (e.g., refusal of available therapies, poor adherence to care), social factors (e.g., social instability, homelessness/lack of housing, lack of transportation), and economic factors (e.g., lack of health insurance, prohibitive cost).

### Statistical analysis

Descriptive analyses were conducted on baseline variables, including demographic and clinical characteristics. For each type of reason for non-treatment, the prevalence of the sub-categories by racial/ethnic groups was computed. Statistical differences in the prevalence of reasons for non-treatment between racial/ethnic groups were assessed using the two-tailed Fisher's exact test. For each reason type (non-modifiable medical, potentially modifiable medical, and non-medical), risk factors such as age, gender, race/ethnicity, insurance status, and select HIV clinical characteristics were analyzed using multivariate logistic regression. Three separate regression models were fit for each reason type; the three reason types were the dependent variables in the respective models. Odds ratios and their 95% CIs (Wald's) were computed. All data analyses were conducted using SAS software (version 9.2; SAS Institute Inc., Cary, North Carolina, United States). All statistical analyses were performed by Lu Mao, a trained biostatistician with the UNC CFAR Biostatistics Core.

## RESULTS

### Baseline demographics and clinical characteristics

Within the cohort, 246 patients had a positive HCV serostatus and either a positive HCV RIBA test or detectable HCV RNA at baseline. Of these, 75 patients (30%) were excluded during the chart review process due to lack of HCV genotype results or due to reported history of antiviral therapy. We present results for the 171 patients (70%) that met criteria for this study. Baseline demographic and clinical characteristics are summarized in Table 1. The median age was 46 years [interquartile range (IQR) = 39-50] and most patients were male (74%). The study sample was racially and ethnically diverse; most patients were African-American (74%), followed by Caucasian (19%), and Hispanic/other (7%). This largely reflects the racial/ethnic makeup of the clinical cohort. More than one-third of patients lacked any insurance coverage (37%).

At baseline, patients had a median (IQR) HIV-1 RNA of 4.3 (2.7-5) log<sub>10</sub> copies/mL, a median (IQR) CD4 299 (91-517) cells/ $\mu$ L, and 73% of patients were treated with HAART. Twenty-five patients (15%) had a baseline median (IQR) HCV RNA of 5.8 (5.7, 5.8) log<sub>10</sub> copies/mL (values reported prior to May 1, 2007) and 10 patients (6%) had a baseline median (IQR) HCV RNA of 6.5 (6.2, 6.7) log<sub>10</sub> IU/mL (values reported after May 1, 2007). The most predominant HCV genotype was genotype 1

<sup>1</sup>HIV risk categories were not mutually exclusive; <sup>2</sup>n = 25 patients with RNA reported as copies/mL (prior to May 1, 2007); <sup>3</sup>n = 10 patients with RNA reported as IU/mL (following to May 1, 2007); <sup>4</sup>Genotypes 1 and 2 were both reported in one patient. IQR: Interquartile range; HIV: Human immuno-deficiency virus; HCV: Hepatitis C virus; HAART: Highly active antiretroviral therapy; MSM: Men who have sex with men.

(92%), followed by genotype 2 (5%), genotype 3 (3%), and genotype 4 (< 1%).

### Documented reasons for HCV non-treatment

Reasons for HCV non-treatment did not vary significantly by race/ethnicity (Table 2). Subcategories for each reason type are illustrated in Figure 1. At least one non-modifiable medical reason was documented in approximately half of all patients. Patient death was the most common non-modifiable medical reason in all three racial/ethnic groups, followed by advanced immunosuppression. Two-thirds of patients in each racial/ethnic group had at least one potentially modifiable reason for not initiating therapy (range 66%-69% across racial/ethnic groups); of these, IDU/cocaine use and psychiatric illness was the most common, followed by alcohol use and severe depression. Non-medical reasons were also common in each racial/ethnic group; these were most often due to personal and social reasons, and least commonly due to economic reasons.

### Factors associated with HCV non-treatment

We evaluated age, gender, race/ethnicity, insurance,

HIV-1 RNA, CD4, and prior AIDS-defining clinical conditions as factors independently associated with reasons for not initiating therapy (Table 3). Compared to Caucasian race/ethnicity, African-American race/ethnicity was not associated with having at least one non-modifiable medical reason [adjusted odds ratio (aOR) = 1.47, 95%CI: 0.57-3.80], potentially modifiable medical reason (aOR = 0.72, 95%CI: 0.25-2.09), or non-medical reason (aOR = 0.90, 95%CI: 0.32-2.52).

## DISCUSSION

While low uptake of older HCV antiviral regimens in HIV/HCV co-infected patients, particularly in racial and ethnic minorities, is well-documented in the literature, the reasons for low uptake are less clear<sup>[6,8,16]</sup>. This study evaluated reasons cited by the provider for non-initiation of HCV therapy in a cohort of untreated patients. Patients in our study were predominantly African-American and largely had genotype 1, which is comparable to other studies<sup>[1,18-21]</sup>. Our findings suggest that race/ethnicity alone is not predictive of having at least one reason for not initiating therapy. Rather, a key finding of this study was the high prevalence of multiple reasons for non-treatment, regardless of racial/ethnic group.

Nearly one-third of all patients in this study died without ever receiving HCV therapy. Of note, it cannot be assumed that patients who died would have ever initiated therapy while alive. Advanced immunosuppression (CD4 < 200) was also a common reason for non-treatment in our study. The majority (73%) of patients were on HAART at baseline, yet more than half of all patients had advanced immunosuppression documented as a reason for non-treatment, a finding that has been noted previously. In a study of patients with HIV/HCV co-infection at one of three Los Angeles HIV clinics, HAART use was common (> 90%), yet CD4  $\leq$  200 was independently associated with decreased HCV treatment acceptance (OR = 0.08, 95%CI: 0.01-0.40)<sup>[13]</sup>. Treatment guidelines suggest postponing HCV antiviral therapy in HIV/HCV co-infected patients with CD4 < 200 and recommend HAART initiation to preserve and restore immune function<sup>[22]</sup>. Treatment-related factors such as adherence and regimen appropriateness can influence immune response. CD4 and HIV-1 RNA are indirect, objective measures of these treatment-related factors. However, we only evaluated baseline CD4 and HIV-1 RNA values, which precluded us from drawing inferences about the effects of adherence and regimen appropriateness on immunosuppression and resultant non-initiation of HCV therapy.

As expected, IDU/cocaine use was reported as a potentially modifiable reason for not initiating therapy. Past studies have classified substance abuse as an absolute contraindication to HCV therapy<sup>[23]</sup>. In a recent systematic review evaluating barriers to HCV therapy in HIV/HCV co-infected patients, substance abuse was

aOR: Adjusted odds ratio; HIV: Human immuno-deficiency virus; AIDS: Acquired immune deficiency syndrome.

the most frequently cited barrier<sup>[23]</sup>. However, substance users should not be routinely excluded from treatment, as substance use can fluctuate with time<sup>[24]</sup>. Recent guidelines recommend deferral of treatment if active or ongoing substance abuse is expected to interfere with regimen adherence, and frequent re-evaluation of each patient's adherence to routine medical care, other comorbidities, and potential for reinfection<sup>[15,24]</sup>.

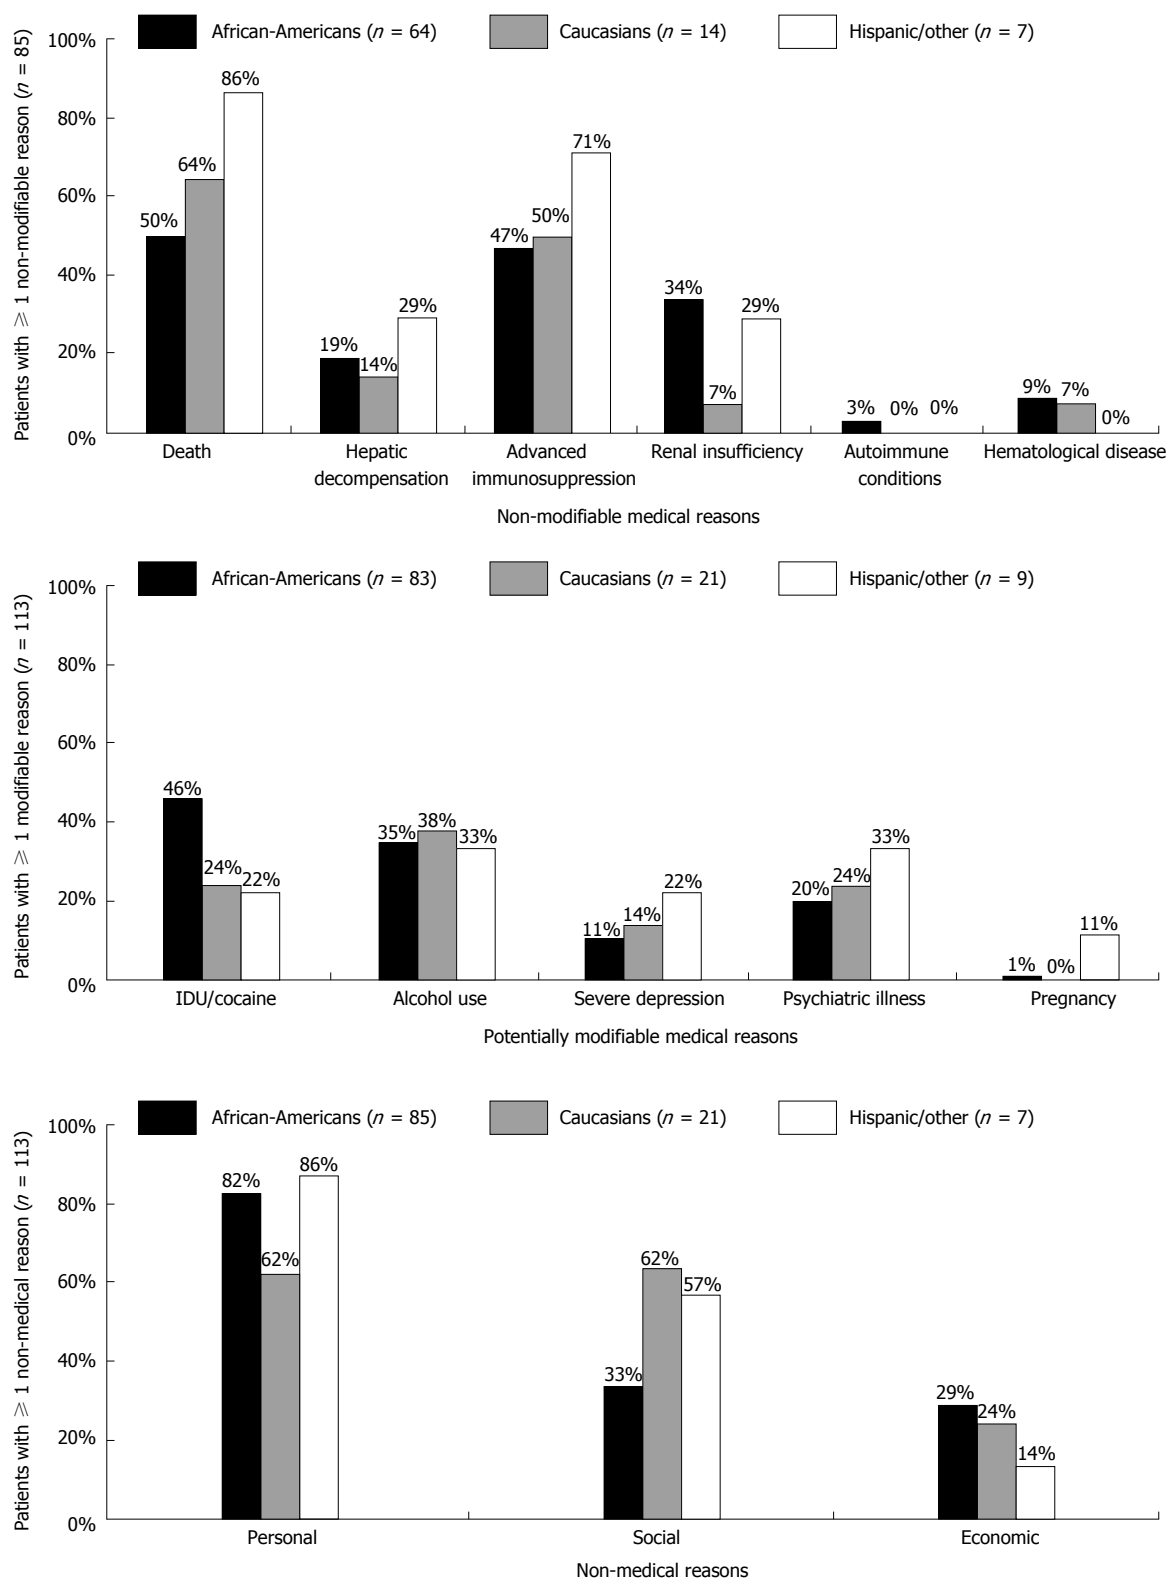

Personal and social factors were commonly reported in all racial/ethnic groups as reasons for not initiating therapy. Engagement in care and adherence are often perceived by the provider as an indicator of treatment readiness and are based on characteristics such as mental health, clinic attendance, substance use, and the patient's attitudes and beliefs about therapy<sup>[25]</sup>. These factors can decrease the likelihood of patient referral for HCV care.

Historically, patients with HIV/HCV, most often African-Americans, have had poor virologic response to HCV therapy<sup>[26-29]</sup>. African-Americans have been shown to be less likely to accept pegIFN-RBV antiviral therapy when it was recommended by their providers<sup>[13]</sup>. It has been suggested that patient awareness of low sustained virologic response (SVR) among African-Americans with genotype 1 may contribute to decisions to refuse therapy<sup>[11]</sup>. The high proportion of personal factors for non-treatment in our study could have also

been attributed to patient refusal of pegIFN-RBV in anticipation of more effective, and ultimately more convenient, therapies. DAA-based therapy demonstrates excellent efficacy in clinical trials; 87% SVR has been attained in African-Americans<sup>[30]</sup>. Nevertheless, some of the reasons for non-treatment identified in the present study are still likely barriers to the DAAs.

Current treatment guidelines acknowledge substance abuse, psychiatric disorders, and lack of access (e.g., cost, insurance, distance to provider) as barriers to current HCV treatment regimens that include DAAs<sup>[31]</sup>. Several strategies are proposed to increase HCV treatment, particularly DAA therapy, in patients with HIV/HCV. At the patient level, pre-treatment education, management of comorbidities and mental health conditions, and harm reduction counseling in individuals with continued substance abuse can be provided through patient referral for specialty services, such as substance abuse treatment and psychiatric therapy<sup>[24]</sup>. Strategies at the provider level include collaborative care models with primary care providers and HCV specialists<sup>[32]</sup>, and co-localization models that combine HCV treatment and care with other primary medical care or substance abuse treatment and social services<sup>[31]</sup>. Systems-level strategies are needed, such as medication patient assistance programs, removal of Medicaid state restrictions regarding substance abuse and HCV therapy,

**Figure 1** Documented reasons for hepatitis C virus non-treatment in patients with human immunodeficiency virus/hepatitis C virus coinfection patients, by race/ethnicity. Patients may have had more than one reason for non-treatment.

decrease prescription prior authorization requirements, and ultimately, to lower DAA drug prices in order to increase treatment access for patients<sup>[33]</sup>.

Our study is subject to limitations. The UNC clinic is a large academic center and may not be representative

of patients receiving care in other clinic settings. All baseline variables were retrieved from the clinical cohort database; however, individual patient records were reviewed to ascertain reasons for non-treatment in the medical record. Some limitations of medical record data

collection include variability in documentation across clinic providers, missing data due to errors that occur during clinic visit narrative dictation and transcription, and lack of specificity for patient information. Listed reasons were based on providers' cited reasons for not initiating HCV therapy. These may differ from patient-reported barriers to care that are specific to racial and ethnic groups, such as medical mistrust<sup>[34]</sup>. As our study was designed to focus on the untreated, we were unable to make any causal associations between documented reasons and why patients were not treated. We did not assess continuity of HAART. Given that advanced immunosuppression greatly contributed to having a non-modifiable medical reason, it is possible that patients who had advanced immunosuppression documented as a reason for non-treatment were maintained on HAART, but did not experience the full clinical benefits of HAART due to regimen adherence, regimen appropriateness, and/or due to inability for some patients to achieve immune reconstitution<sup>[35]</sup>. We did not measure these factors in our study. Lastly, we did not evaluate differences in HCV treatment by race/ethnicity, and were therefore, unable to determine if any treatment disparities exist among patients in the UNC clinic.

In summary, reasons for non-treatment did not differentially affect racial and ethnic minorities co-infected with HIV/HCV. Rather, there was a high prevalence of multiple reasons for non-treatment in patients, regardless of racial/ethnic group. The advent of DAAs has undoubtedly revolutionized HCV care, however, there is still a need to recognize and overcome potential treatment barriers in order to improve treatment uptake and eradicate HCV in this patient population.

The authors would like to thank Oksana Zakharova, Sam Stinnette, Christine Sun, Dan-Thanh Nguyen, Heather Moore, and Joshua Toliver for their assistance with data extraction and data collection for this study.

## COMMENTS

### Background

Historically, hepatitis C virus (HCV) treatment rates have been low in patients with human immunodeficiency virus (HIV) co-infection, especially for African-American patients. Identifying the reasons for treatment non-initiation may help improve treatment rates among racially and ethnic minorities.

### Research frontiers

The authors' findings suggest that race/ethnicity alone is not predictive of having at least one reason for not initiating therapy. Rather, a key finding of this study was the high prevalence of multiple reasons for non-treatment, regardless of racial/ethnic group.

### Innovations and breakthroughs

While low uptake of older HCV antiviral regimens in HIV/HCV co-infected patients, particularly in racial and ethnic minorities, is well documented in the literature, the reasons for low uptake are less clear. This study evaluated reasons cited by the provider for non-initiation of HCV therapy in a cohort of

untreated patients.

## Applications

This study demonstrates that there is a need to recognize and overcome potential treatment barriers in order to improve HCV treatment uptake in this patient population.

## Peer-review

This article is of interest to clinicians that manage patients with HIV/HCV coinfection.

### Abstract

**AIM:** To characterize non-alcoholic fatty liver disease (NAFLD) presentation with esophageal varices.

**METHODS:** We carried out a retrospective cohort study on 258 patients with esophageal varices at a single tertiary referral center. These patients underwent diagnosis of several liver diseases, including: NAFLD-associated cirrhosis, hepatitis B, hepatitis C, Wilson disease, autoimmune liver diseases, and others.

**RESULTS:** Of the 258 patients, 39% of patients exhibited esophageal varices due to NAFLD-associated cirrhosis. Of the 38 (14.7%) patients developed hepatocellular carcinoma during follow-up, 52% were due to hepatitis B, 26% due to hepatitis C and 13.2% due to NAFLD. Of the 258 patients, 50.0% with NAFLD, 33.3% with hepatitis B, 26.3% with hepatitis C, and 58.3% with other diseases were alive at the end of the 5-year period with a significant difference according to the Kaplan-Meier log Rank test ( $P = 0.040$ ). Portal vein thrombosis was detected in 47.5% of patients with NAFLD, in 29% of patients with hepatitis B, in 17% of patients with hepatitis C, and in 62% of patients with other related diseases ( $P < 0.0001$ ).

**CONCLUSION:** Our study showed a proportionally

greater elevation in liver transplant candidacy in patients with NAFLD and portal vein thrombosis. Older patients were more prone to developing cirrhosis, hepatocellular carcinoma and a high mortality rate. However, younger patients exhibited more portal vein thrombosis and gastric varices.

**Key words:** Hepatocellular carcinoma; Non-alcoholic fatty liver disease; Portal vein thrombosis; Esophageal varices

Significant cohort of non-alcoholic fatty liver disease with portal vein thrombosis in transplant waiting list. *World J Hepatol* 2016; 8(7): 376-384 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i7/376.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i7.376>

## INTRODUCTION

Excessive accumulation of fat in hepatocytes in the absence of significant alcohol consumption occurs in up to 30% of adults<sup>[1,2]</sup>. This condition, termed non-alcoholic fatty liver disease (NAFLD), predisposes to non-alcoholic steatohepatitis (NASH), which progresses to cirrhosis and its complications, including hepatocellular carcinoma (HCC)<sup>[2-4]</sup>. Several studies have also reported that in some patients, NAFLD can lead to HCC without transitioning through cirrhosis<sup>[4,5-10]</sup>. Currently, it is estimated that NAFLD is the third leading cause of HCC after hepatitis C and B. Although earlier studies suggested that NAFLD may be less severe and progress slowly in Asian populations, the progression of fibrosis and cirrhosis in patients with NAFLD is no longer believed to differ significantly by ethnicity<sup>[11-13]</sup>.

The prevalence of NASH as a precursor of NAFLD-associated cirrhosis is 3% and 20% in non-obese and obese subjects, respectively<sup>[14]</sup>. The global obesity epidemic has been associated with the increasing burden of NAFLD. It has been estimated that the rising prevalence

of NAFLD will soon lead to large cohorts of patients with decompensated cirrhosis. In this respect, NAFLD is expected to become the leading indication for liver transplantation in the Western world, particularly in the United States. Longitudinal follow-up studies showed an increase in the mortality rate among patients with NAFLD due to hepatic decompensation<sup>[15-19]</sup>. These studies usually included a limited number of patients with short follow-up period and with selected patients such as compensated cirrhosis.

It is possible that risk factors for NAFLD-associated cirrhosis and HCC in Eastern countries differ from those in the West. Thus, we aimed to document the characteristics of patients with NAFLD-associated cirrhosis from Turkey, a European country sharing 97% of its borders with Asia. Relative to other Europeans, the Turkish population exhibits a higher rate of obesity that is comparable to that in the United States. In Turkey, 47.7% of all deaths have been attributed to cardiovascular diseases (most likely cerebrovascular and ischemic heart diseases), which are highly correlated with obesity<sup>[20]</sup>. Overall, 56% of the Turkish population is overweight, especially preobese (body-mass index: 25-29.9 kg/m<sup>2</sup>). This has been attributed in part, to the predominance of non-working women who manifest a higher incidence rate of obesity than their working counterparts (33% vs 14%).

In light of the epidemic spread of obesity in Turkey, and the association of this disease with NAFLD, the current follow-up study evaluated patients with esophageal varices from 2003 at a single tertiary referral liver center, with the aim to investigate the relationship between esophageal varices and NAFLD. The results were compared in terms of the development of portal vein thrombosis (PVT), HCC, survival and mortality. The association between esophageal varices and hepatitis B and hepatitis C was also examined, as these etiologies are also of importance to esophageal varices. According to the World Health Organization, Turkey is one of the countries with intermediate (2%-8%) endemic rate for hepatitis B and less than 2% (1.0%-1.9%) for hepatitis C<sup>[21,22]</sup>.

## MATERIALS AND METHODS

### Retrospective cohort study design

We have kept the records of patients with hepatitis B or C who have been followed prospectively at our hepatology unit and affiliated liver center. Confidentiality of records was maintained according to the guidelines issued by Türkiye Yüksek İhtisas Hospital Institutional Ethics Committee. Data were collected for esophageal varices only at the advanced endoscopy unit. A cohort of patients with esophageal varices from 2003 to 2014 was reviewed. All patients were of Turkish origin and were informed and consented about the investigation and treatment. Eligible patients were  $\geq 18$  years of age and have had esophageal varices diagnosed by upper

gastrointestinal endoscopy examination. They had regular clinical follow-up and endoscopic examinations at our clinic. Efficacy data were based on the last evaluation. Transplanted cases were excluded. The main inclusion criterion was the presence of esophageal varices with or without gastric varices.

Only 258 patients with endoscopically defined high risk varices had reliable data and were included in this study. Each patient was evaluated for fundal varices, PVT, cirrhosis, HCC, and mortality. After the first evaluation, patients were divided into 4 groups: Those with hepatitis B, hepatitis C, NAFLD and others related to autoimmune hepatitis, Wilson Disease, primary biliary cirrhosis, *etc.*

Alcohol history was determined through self-reporting and/or from information provided by family members. History of drug abuse, chronic hepatitis, hypertension, and diabetes was also recorded. Ultrasonographic evaluation of the hepatobiliary system was performed in each patient. Fatty liver was diagnosed by increased echogenicity or increased liver-kidney contrast. NAFLD was diagnosed according to standard criteria<sup>[19]</sup>. Serum serology of hepatitis B surface antigen, anti-hepatitis B surface, anti-hepatitis B core-total and anti-hepatitis C virus (anti-HCV) were measured by enzyme-linked immunosorbent assay. If necessary, liver biopsies were re-evaluated by an experienced pathologist according to established criteria.

The classification system of varices described by Sarin *et al.*<sup>[23]</sup> was used in our endoscopy unit. Accordingly, varices are endoscopically classified as gastroesophageal varices type I (lesser curvature), gastroesophageal varices type II (greater curvature), isolated gastric varices type I (gastric fundus), or isolated gastric varices type II (gastric-excluding the fundus).

### Statistical analysis

Data were coded and recorded electronically using an IBM Statistical Package for the Social Sciences (SPSS; Armonk, NY, United States) for Windows version 17.0 (2007). The  $\chi^2$  and Fisher's exact test was used to compare the groups for the distribution of cirrhosis, PVT, HCC, and mortality. Mean age compared by one-way ANOVA test in four groups and compared by Student's *t*-test between both genders. After the statistically significant ANOVA, we used post-hoc multiple comparison tests Bonferroni in order to identify statistically significant pairs. Kaplan-Meier Log Rank test was used to compare survival in four groups.  $P < 0.05$  was considered statistically significant in all of the tests.

## RESULTS

Primary end-point of the study was to use this cohort of patients with esophageal varices to evaluate the relationship between this disease and several etiologies, including NAFLD (in the presence or absence of cirrhosis), hepatitis B, hepatitis C or other liver-related

diseases. Second end-point was to draw this comparison in terms of PVT, HCC, survival and mortality.

### Etiology

As shown in Table 1, the etiology of the total 258 patients with esophageal varices was attributed to: NAFLD in 39.0% (101 patients), hepatitis B virus in 29.1% (75 patients) and HCV in 11.2% (29 patients). In the rest of the patients (20.5%, 53 patients), the etiology was: Hepatoportal sclerosis in 7.8%, isolated portal vein thrombosis without any other pathology in 4.3%, chronic alcohol consumption in 3.1%, primary sclerosing cholangitis in 1.9%, autoimmune hepatitis in 1.2%, primary biliary cirrhosis in 1.2%, Wilson Disease in 0.8% and chronic pancreatitis in 0.4% of this group of patients.

### Age

As Table 1 reveals, there is no statistical difference in the mean age between groups with NAFLD, hepatitis B and hepatitis C. However, the mean age of patients with these three etiologies (about 60 years) was higher than that in patients with other liver-related diseases (48 years) (Table 1;  $P < 0.0001$ ). The mean age of women with esophageal varices ( $60.4 \pm 14.8$  years, median: 64, and range: 27-90) was higher than that in men ( $53.5 \pm 14.6$ , median: 56; and range: 24-84),  $P < 0.001$ . In terms of etiology, men exhibited a higher percentage of hepatitis B than NAFLD, hepatitis C and others (80% vs 62.4%, 58.6% and 58.5%, respectively,  $P = 0.027$ ) (Table 1).

We also compared and found a difference in the mean age of patients with and without PVT ( $52 \pm 15$  years vs  $58.5 \pm 14.5$  years, respectively,  $P = 0.001$ ), with and without cirrhosis ( $56.3 \pm 15$  years vs  $51.9 \pm 13.8$  years, respectively,  $P < 0.05$ ), with and without HCC ( $62.7 \pm 9.7$  years vs  $54.6 \pm 15.4$  years, respectively,  $P = 0.001$ ) and the mean age of patients that have died and those that are still alive ( $61.1 \pm 13.3$  years vs  $51.8 \pm 15$  years, respectively;  $P < 0.0001$ ). However, there was no difference in the mean age of patients with and without fundic varices ( $54.9 \pm 15.3$  years vs  $56.5 \pm 14.8$  years, respectively,  $P > 0.05$ ).

### PVT

The incidence rate of PVT was 41.9% (being detected in 108 out of 258 patients with esophageal varices) (Table 2). As Figure 1 and Table 2 indicate, PVT was observed in 47.5% of patients with NAFLD, 29.3% of patients with hepatitis B, 17.2% of patients with hepatitis C, and 62.3% of patients with other liver-related diseases ( $P < 0.0001$ ). The incidence of PVT was 36.8% and 42.7% in patients with and without HCC, respectively ( $P > 0.05$ ), 40.4% and 53.6% in patients with and without cirrhosis, respectively ( $P > 0.05$ ), and 56.9% and 29.8% in patients with and without fundic varices, respectively ( $P < 0.0001$ ). Of the 111 patients (43%) that died during the study period, 72 patients (64.9%) had no PVT ( $P = 0.057$ ).

**Figure 1** Incidence of portal vein thrombosis, cirrhosis, and hepatocellular cancer, in addition to mortality rate in patients with non-alcoholic fatty liver disease, hepatitis B, hepatitis C and other liver-related diseases (others). PVT: Portal vein thrombosis; HCC: Hepatocellular cancer; NAFLD: Non-alcoholic fatty liver disease; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

**Table 1** Classification of study groups

	NAFLD	Hepatitis B	Hepatitis C	Others	Total	P value
n (%)	101 (39.0)	75 (29.1)	29 (11.2)	53 (20.5)	258 (100)	
Mean age (median; range of years)	56.4 ± 16.0 (59; 24-83)	57.8 ± 13.3 (58; 24-90)	62.9 ± 12.2 (65; 28-79)	48.1 ± 13.9 (48; 25-81) <sup>b</sup>	55.8 ± 15.0 (58; 24-90)	< 0.0001
% men	62.4%	80.0% <sup>a</sup>	58.6%	58.5%	66.3%	< 0.05

Study groups were classified per etiology: NAFLD, hepatitis B, hepatitis C and others. Mean age in patients with NAFLD, hepatitis B and C that was higher than the mean age of patients with other etiologies (<sup>b</sup> $P < 0.0001$  others *vs* each of NAFLD, hepatitis B and C *vs* other etiologies). Percentage of men with hepatitis B was higher than those with NAFLD, hepatitis C and other etiologies (<sup>a</sup> $P < 0.05$  patients with hepatitis B *vs* NAFLD, hepatitis C and other etiologies). NAFLD: Non-alcoholic fatty liver disease.

**Table 2** Incidence of pathologies and mortality

	Cirrhosis	PVT	HCC	Fundic varices	Mortality
NAFLD	100%	47.5%	5.0% <sup>d</sup>	45.5%	47.5%
Hepatitis B	86.7%	29.3%	26.7%	52.0%	42.7%
Hepatitis C	93.1%	17.2% <sup>b</sup>	34.5%	27.6%	51.7%
Others	69.8% <sup>f</sup>	62.3%	5.7% <sup>d</sup>	43.4%	30.2%
Total	89.1%	41.9%	14.7%	45.0%	43.0%
P value	< 0.0001	< 0.0001	< 0.0001	> 0.05	> 0.05

The distribution of portal vein thrombosis (PVT), cirrhosis, hepatocellular cancer (HCC), fundic varices, and mortality rate in patients with NAFLD, hepatitis B, hepatitis C and other liver-related diseases (others) is shown. <sup>b</sup> $P < 0.0001$ ; <sup>d</sup> $P < 0.0001$ ; and <sup>f</sup> $P < 0.0001$ . Different symbols were used in order to emphasize comparison within each etiology group. NAFLD: Non-alcoholic fatty liver disease.

### Fundic varices

The condition of fundic varices was found in 116 (45%) patients; evenly spread among women and men (46% and 44.4%, respectively,  $P > 0.05$ ). Etiology among patients with fundic varices was as follows: NAFLD in 39.7% (46 patients); hepatitis B in 33.6% (39 patients),

hepatitis C in 6.9% (8 patients) and other diseases in 19.8% (23 patients) ( $P > 0.05$ ). The incidence of fundic varices was 47.4% and 44.5% in patients with and without HCC, respectively ( $P > 0.05$ ), 43.9% and 53.6% in patients with and without cirrhosis, respectively ( $P > 0.05$ ), and 61% and 33% in patients with and without PVT, respectively ( $P < 0.0001$ ). Of the 111 patients (43%) that died during the follow-up study, 70 (63.1%) had no fundic varices ( $P = 0.024$ ). The mortality rate was 35.6% and 51.9% in those with and without fundic varices, respectively ( $P = 0.014$ ).

### HCC

HCC was detected in 14.7% of patients (38 out of 258 total study pool). As shown in Figure 1 and Table 2, the incidence rate of HCC was: 5.0% in patients with NAFLD, 26.7% in patients with hepatitis B, 34.5% in patients with hepatitis C, and 5.7% in other diseases ( $P < 0.0001$ ). Of the 38 patients with HCC, 13% had PVT (Table 3). Moreover, HCC increased the mortality rate in almost all the groups. The mortality rate in hepatitis B group increased from 31% (17/55) in patients with-

**Table 3** Incidence of portal vein thrombosis

	Cirrhosis ( $P > 0.05$ )	HCC ( $P > 0.05$ )	Fundic varices ( $P < 0.0001$ )	Mortality rate ( $P = 0.057$ )
PVT (+)	86% (93 patients)	13% (14 patients)	61% <sup>b</sup> (66 patients)	36.1% (39 patients)
PVT (-)	91% (137 patients)	16% (24 patients)	33% (50 patients)	48.0% (72 patients)

The incidence of portal vein thrombosis (PVT) in patients with cirrhosis, hepatocellular cancer (HCC) and fundic varices are shown. Also reported is the relationship between PVT and the mortality rate. Each of these pathologies and mortality rate was compared in patients with and without PVT. <sup>b</sup> $P < 0.0001$  in the presence *vs* absence of PVT.

**Table 4** Relationship among fundic varices, cirrhosis, hepatocellular cancer, and mortality rate

Fundic varices	Cirrhosis	HCC	Mortality rate
Yes	Yes	Yes	70.6%
		No	28.6%
	No	Yes	100%
No		No	28.6%
	Yes	Yes	85%
		No	23.1%
	No	Yes	No patients in this group
		No	23.1%

HCC: Hepatocellular cancer.

out HCC to 75% (15/20) in patients with HCC ( $P = 0.001$ ). In the group with hepatitis C, the mortality rate increased from 32% (6/19) in patients without HCC to 90% (9/10) in patients with HCC ( $P = 0.005$ ). The mortality rate in NAFLD patients increased from 47.5% during follow-up to 80% after HCC developed.

### Mortality

As shown in Table 4 and Figure 2, 111 (43%) patients died in this study during follow-up. Of the patients, 50.0% with NAFLD, 33.3% with hepatitis B, 26.3% with hepatitis C, and 58.3% with other diseases were alive at the end of the 5-year period with a significant difference according to the Kaplan-Meier log Rank test ( $P = 0.04$ ). Risk for mortality, measured by risk ratio (RR), did not change per gender (RR: male/female = 43.3%/42.5%,  $P > 0.05$ ) or with the occurrence of cirrhosis (RR: 44.8%/28.6%,  $P > 0.05$ ). However, it changed with the existence of fundic varices (RR: 49.3/35.3,  $P = 0.024$  in favor of fundic varices development) and HCC (RR: 78.9%/36.8%,  $P < 0.0001$  in favor of HCC development).

### NAFLD group

Of the 258 patients, 39.0% (101 patients) were diagnosed with NAFLD. The mean age of NAFLD was  $56.4 \pm 16.0$  years and 62% of these patients were men (Table 1). Moreover, 47.5% had PVT, 5.0% had HCC, and 45.5% had fundic varices (Table 2 and Figure 1). The mortality rate was 47.5% during follow-up (Table 2 and Figure 1), but increased to 80% in the presence of HCC.

## DISCUSSION

NAFLD-associated cirrhosis is predicted to rapidly

**Figure 2** Survival functions in patients with non-alcoholic fatty liver disease, hepatitis B, hepatitis C and other liver-related diseases (others). Of the patients, 50.0% with NAFLD, 33.3% with hepatitis B, 26.3% with hepatitis C, and 58.3% with other diseases were alive at the end of the 5-year period with a significant difference according to the Kaplan-Meier log Rank test ( $P = 0.040$ ). NAFLD: Non-alcoholic fatty liver disease; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

become the leading indicator for liver transplant in the Western world<sup>[24,25]</sup>. We herein show that NAFLD-associated cirrhosis is indeed the most common cause of end-stage liver disease at our liver center (Table 2 and Figure 1). By retrospectively evaluating national liver transplant database in the United States, Byrne *et al.*<sup>[26]</sup> and Charlton<sup>[27]</sup> and then, Wong *et al.*<sup>[24,27]</sup> showed a significant increase in the proportion of patients undergoing liver transplant due to NASH. These findings differ from studies carried out in Japan where the rate of seronegative cirrhotic patients was 5%-20%. This finding could be explained by the relatively lower incidence of NASH (1%-3%) by comparison to hepatitis B, hepatitis C and alcoholic liver disease in Japan. Among the cohort of our patients who needed liver transplant, a significantly larger proportion developed decompensated cirrhosis due to NAFLD than hepatitis B or C.

In a prospective longitudinal cohort study, Hui *et al.*<sup>[28]</sup> showed a comparable incidence and survival rate of cirrhosis related to hepatitis C to that related to NASH. Another large multi-center international study compared 247 patients with advanced fibrosis or cirrhosis secondary to NASH to 264 patients with chronic hepatitis C and similar stages of fibrosis<sup>[29]</sup>. In that study, 19.4% of NASH patients developed liver-related

complications and 13.4% either died or underwent liver transplantations during follow-up, as compared to patients with hepatitis C among whom 16.7% developed liver-related complications and 9.4% either died or required transplant surgery. Our observations of higher mortality rates in patients with NAFLD differ from previously reported survival data<sup>[28,30]</sup>. The first study<sup>[28]</sup> that investigated the survival rate in patients with NASH reported a 10-year survival rate of 84%. Then, Sanyal *et al.*<sup>[30]</sup> reported a 10-year mortality rate of 19.1% in patients with NASH cirrhosis as opposed to 4.1% in patients with compensated cirrhosis. Yatsuji *et al.*<sup>[31]</sup> observed a 5-year HCC rate of 11.3% for NASH-associated cirrhosis and 30.5% for HCV cirrhosis; and a 5-year survival rate was 75.2% in NASH-associated cirrhosis and 73.8% in HCV cirrhosis in a study carried out on Japanese patients. Our study found the mortality rate in NAFLD to be 46% during follow-up and 80% after HCC developed. These rates were higher than those in patients with hepatitis in whom mortality rate was 31%-32% in the absence of HCC, and increased to 75% and 90% in patients with hepatitis B and C after HCC developed, respectively. The cohort of this study showed significantly higher mortality in comparison to reports in other ethnic groups. This difference could be due to several factors, such as: (1) The severity of the disease in our cohort that included patients with cirrhosis and esophageal varices; and (2) a higher rate of consumption of diet rich in fat (red meat) and carbohydrates (sweets) in Turkey, as opposed to other countries where fish and white meat (chicken) are more commonly used. Although the role of ethnicity and/or genetics remains controversial, it is possible that the heterogeneity in terms of age, genetic and environmental factors in patients studied in other reports<sup>[1-4,14]</sup> contributes to the difference between their observations and those in the current studies. The observed higher mortality rate in our cohort could in part be attributed to its relative ethnical homogeneity since it basically consists of Caucasian patients from a Turkish origin.

Although NAFLD is a risk factor for HCC, the prevalence rate of HCC in cirrhotic NAFLD has not been well established, despite its reported range of 2.4% to 12.8%<sup>[32]</sup>. Scientists from Sweden described three and five cases of HCC in cohorts of 129 and 256 subjects with NAFLD followed for 13.7 and 21 years, respectively<sup>[33]</sup>. Previous reports indicated that the risk of HCC due to NAFLD is less than the risk resulting from chronic hepatitis C. In a 10-year prospective study, 10 out of 149 American patients with NAFLD-associated cirrhosis developed HCC compared to 25 out of 147 patients with hepatitis C virus-associated cirrhosis<sup>[4]</sup>. A large retrospective cohort study from South Korea evaluated 329 patients with HCC associated with fatty liver disease and demonstrated an increase in NAFLD-related HCC from 3.8% in 2001-2005 to 12.2% in 2006-2010<sup>[34]</sup>. A United States based study evaluated 195 NASH-cirrhosis patients from 2003-2007 with serial

abdominal computed tomography and serum alpha-fetoprotein every 6 mo with a median follow up of 3.2 years<sup>[35]</sup>. Among this cohort for NASH-related cirrhosis patients, 12.8% ( $n = 25$ ) developed HCC with an annual cumulative incidence rate of 2.6%. In a prospective cohort study, Yatsuji *et al.*<sup>[31]</sup> compared 68 patients with NASH-related cirrhosis to 69 age- and sex-matched patients with hepatitis C-related cirrhosis to determine HCC risk. Overall, the 5-year cumulative HCC rate was 11.3% for NASH patients and 30.5% for hepatitis C patients. This lower HCC risk among NAFLD-related cirrhosis patients compared with hepatitis C-related cirrhosis was also confirmed by our study. Our results with 5.0% NAFLD-related HCC with cirrhosis was lower than previously reported with 2.4%-12.8% in patients with NAFLD<sup>[32]</sup>.

The current studies revealed the prevalence of portal vein thrombosis in patients with NAFLD to be significantly higher than in patients with hepatitis B or hepatitis C ( $P < 0.0001$ ). This could be related to the predisposition of patients with NAFLD to developing pro-coagulation and impaired blood flow, as well as a pro-inflammatory state. It is well known that these patients are commonly obese. Obesity is associated with low-grade chronic inflammation and is strongly associated with chronic macrophage accumulation to the hypertrophied adipose tissue<sup>[36-39]</sup>. Adipose tissue macrophages produce proinflammatory cytokines such as tumor necrosis factor- $\alpha$ , interleukin-6, and C-reactive protein. These cytokines alter insulin signaling by protein kinase C  $\theta$ , inhibitor  $\kappa$ B kinase  $\beta$ , suppressors of cytokine signaling and inducible nitric oxide synthase to contribute to insulin resistance. Similarly, increased fat accumulation in liver alters its inflammatory milieu, thus modifying insulin action<sup>[40]</sup>. The metabolic syndrome and NAFLD are also independently associated with both atherosclerosis and endothelial vascular dysfunction, which are related to a prothrombotic state. Thus, increased systemic inflammation and increased procoagulant factor levels associated with insulin resistance could explain the higher prevalence of portal vein thrombosis in our cirrhotic patients with NAFLD.

Englesbe *et al.*<sup>[41]</sup> carried out a retrospective study evaluating the survival of 148 cirrhotic patients with occlusive portal vein thrombosis followed over a large period (1995-2007). The reported rate of death was 54.7%; significantly higher than the 37.2% in patients without portal vein thrombosis. These results are similar to our mortality data that show 65% incidence of death in cirrhotic patients with portal vein thrombosis vs 35% in patients without portal vein thrombosis. Additionally, the incidence of gastric varices was higher in NAFLD associated cirrhosis than other groups in our cohort.

It has also been reported that the incidence of portal vein thrombosis rises to 10%-40% in cirrhotic patients upon developing HCC<sup>[42]</sup>. Consistently, our study showed an elevated incidence of portal vein thrombosis in cirrhotic patients with hepatitis C or B after they developed HCC. In contrast, HCC failed to alter

the incidence of portal vein thrombosis in our cirrhotic patients with NAFLD.

Our studies suggest that increase in NASH-associated cirrhosis would be an indication for orthotopic liver transplantation in Turkey. Increased frequency of NASH-associated cirrhosis with portal vein thrombosis in clinical practice has been a subject of debate among transplant surgeons. Whereas the high incidence of PVT (up to 26%) in patients awaiting liver transplantation constitutes a risk factor for early post-liver transplantation mortality<sup>[43,44]</sup>, PVT is no longer considered an absolute contraindication for transplantation. Unfortunately, we could not reach the records of patients receiving transplant surgery in our studies to be able to assess more concretely the transplantation outcomes in our Turkish patients with NASH-associated cirrhosis and portal vein thrombosis. However, Quillin *et al*<sup>[16]</sup> have recently observed a strong indication for NASH in orthotopic liver transplantation in 2356 patients in the United States<sup>[16]</sup>, despite their older age by comparison to patients with hepatitis C and alcoholic cirrhosis. Whether this is related in part to the potential dominance of Caucasians in that study is unclear, but the study supports an equivalent, if not a more favorable, outcome for orthotopic liver transplantation in patients with fatty liver disease as compared to other common indications for surgery.

In conclusion, our data revealed a proportionally greater rise in liver transplant candidacy due to NAFLD-associated cirrhosis with portal vein thrombosis. The mortality rate of patients with NAFLD-associated cirrhosis did not differ from that in patients with virally caused cirrhosis. We confirmed that NAFLD was the third leading cause of HCC on the transplantation waiting list. Older patients were more prone to developing more cirrhosis, HCC and high mortality rates. However, the younger group had more portal vein thrombosis and fundic varices. These findings should constitute a reliable guideline for evaluating patients at the transplant center and for health policy makers to develop better strategic preventive measures against liver diseases.

## COMMENTS

### Background

Non-alcoholic fatty liver disease (NAFLD) predisposes to non-alcoholic steatohepatitis, which progresses to cirrhosis and hepatocellular carcinoma (HCC).

### Research frontiers

NAFLD-associated cirrhosis is predicted to rapidly become the leading indicator for liver transplant. The mortality rate of patients with NAFLD might differ from that in patients with virally caused cirrhosis.

### Innovations and breakthroughs

The authors' data revealed a proportionally greater rise in liver transplant candidacy due to NAFLD-associated cirrhosis with portal vein thrombosis. This could be related to the predisposition of patients with NAFLD to developing pro-coagulation and impaired blood flow, as well as a pro-inflammatory state. Their observations of higher mortality rates in patients with NAFLD differ from previously reported survival data. Older patients with esophageal varices were

more prone to developing cirrhosis, HCC and a high mortality rate.

### Applications

The authors' data revealed a proportionally greater rise in liver transplant candidacy due to NAFLD-associated cirrhosis with portal vein thrombosis. The underlying cause for this predisposition remains unclear, although both genetic and environmental factors could be implicated. These findings should constitute a reliable guideline to evaluate patients at the transplant center.

### Peer-review

This retrospective study describes NAFLD-related clinical diagnosis over 250 patients in Turkish origin. One unique strength of this study is to show higher risk of portal vein thrombosis and fundic varices, on the other hand, elderlies are more prone to cirrhosis, HCC and high mortality rates.

*World Journal of Hepatology*  
Volume 8 Number 8 March 18, 2016

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Xiao-Ming Fan, MD, PhD, Professor, Department of Gastroenterology, Jinshan Hospital of Fudan University, Shanghai 201508, China

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

The proportion of hepatitis B virus (HBV) previously

exposed patients who receive immunosuppressive treatment is usually very small. However, if these individuals are exposed to potent immunosuppressive compounds, the risk of HBV reactivation (HBVr) increases with the presence of hepatitis B surface antigen (HBsAg) in the serum. Chronic HBsAg carriers have a higher risk than those who have a total IgG anticore as the only marker of resolved/occult HBV disease. The loss of immune control in these patients may result in the reactivation of HBV replication within hepatocytes. Upon reconstitution of the immune system, infected hepatocytes are once again targeted and damaged by immune surveillance in an effort to clear the virus. There are different virological scenarios, and a wide spectrum of associated drugs with specific and stratified risk for the development of HBVr. Some of these agents can trigger a severe degree of hepatocellular damage, including hepatitis, acute liver failure, and even death despite employment of effective antiviral therapies. Currently, HBVr incidence seems to be increasing around the world; a fact mainly related to the incessant appearance of more powerful immunosuppressive drugs launched to the market. Moreover, there is no consensus on the length of prophylactic treatment before the patients are treated with immunosuppressive therapy, and for how long this therapy should be extended once treatment is completed. Therefore, this review article will focus on when to treat, when to monitor, what patients should receive HBV therapy, and what drugs should be selected for each scenario. Lastly, we will update the definition, risk factors, screening, and treatment recommendations based on both current and different HBV management guidelines.

**Key words:** Anti-tumor necrosis factor- $\alpha$  drugs; Acute liver failure; Biologic therapy; Immunosuppressive therapy; Hepatitis B

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Chronic hepatitis B surface antigen carriers have a high risk to develop hepatitis B virus (HBV) reactivation (HBVr) when exposed to immunosuppressive therapy. The loss of immune control in these patients may result in an increase in HBV replication. There is a wide spectrum of associated drugs with specific and stratified risk for the development of HBVr. Currently, HBVr incidence seems to increase worldwide, mainly due to the appearance of more powerful immunosuppressive drugs. This review article focuses on when to treat, when to monitor, what patients should receive HBV therapy, and what drugs should be selected in each scenario. We updated here current HBV management guidelines.

Bessone F, Dirchwolf M. Management of hepatitis B reactivation in immunosuppressed patients: An update on current recommendations. *World J Hepatol* 2016; 8(8): 385-394 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i8/385.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i8.385>

## INTRODUCTION

Hepatitis B virus (HBV) infection is a major public health problem worldwide; roughly, 30% of the world population shows serological evidence of current or past infection<sup>[1]</sup>, and it is largely considered that there are 350 million chronic carriers globally<sup>[2,3]</sup>. Although chronic infection can lead to progressive liver injury, most patients (60%-85%) are asymptomatic, and therefore the infection remains unrecognized until the appearance of signs or symptoms of chronic liver disease/cirrhosis<sup>[4,5]</sup>. Even though a small percentage of patients who were previously in contact with HBV will probably require immunosuppression as treatment of different illnesses (malignant, autoimmune, chronic rheumatic diseases) or to avoid post-transplantation rejection. However, treatment with such agents raises the risk of HBV reactivation (HBVr). This holds particularly true for patients with previously undetected chronic HBV infection, but also for those with resolved or occult infection [hepatitis B surface antigen (HBsAg)-negative, antibody to hepatitis B core antigen (antiHBc)-positive, with or without antibody to hepatitis B surface antigen (antiHBs)-positive serology]<sup>[6-10]</sup>. These events are referred to as HBVr; they were first described 40 years ago as a complication of renal transplantation and cancer chemotherapy. Since then, HBVr has become well recognized in numerous immunosuppression (IS) settings. Despite of that, HBVr due to IS continues to cause severe hepatitis, liver failure, and even death in spite of the availability of effective HBV vaccines, easily available and cheap tests to define patients at risk, and safe and effective antiviral therapies. A more worrisome issue is that the occurrence of this severe clinical event appears to increase around the globe<sup>[11]</sup>; perhaps, this is due to the permanent changing landscape of IS

agents involved, the heterogeneous screening, definition and treatment guidelines, and the multiple available therapeutic options<sup>[12]</sup>. This revision aims to update HBVr definition, risk factors, screening, and treatment recommendations based on the currently published evidence.

## HOST AND VIRAL INTERACTION: HBVR CLINICAL FEATURES

Hepatocellular inflammation and injury in HBV infection is suggested to be directly related to the intensity of host immune response<sup>[13]</sup>. In the initial phase of immune tolerance, infected children have high levels of viral replication, with no associated liver injury. As the immune system matures, the infected person enters a phase of immune clearance, in which the hepatocytes infected with HBV are targeted and damaged, resulting in hepatitis flares. In most individuals, the immune system is eventually able to control viremia, leading to hepatitis B e antigen clearance, suppression of HBV DNA levels, and normalization of liver biochemical test. The immune control phase usually endures; however, in cases of iatrogenic or natural IS, the loss of immune control results in reactivation of HBV replication inside hepatocytes. Upon reconstitution of the immune system, these hepatocytes are once again targeted and damaged by immune surveillance, in an effort to clear the virus<sup>[5,14,15]</sup>. HBVr has been described as a three-phase event (Figure 1). Initially, an increase in HBV DNA levels in an HBsAg positive person, or a reappearance of either HBsAg (seroreversion) or HBV DNA occurs; this period is usually asymptomatic. When the following phase takes place, HBV DNA levels show a sustained increase in viral load, accompanied by concomitant elevations in aminotransferase levels, which may also be associated to the development of severe hepatocellular damage; to note, even acute liver failure and ultimately death may occur. The aforementioned events result from a reconstitution syndrome of the host immune response. Finally, liver damage resolves due to recovery of the immune system strength (spontaneously or as a result of immunosuppressive therapy suspension) or due to the administration of antiviral drugs. This event may result in complete resolution of hepatic inflammation, or in fewer cases, a higher HBV DNA viral load in previously HBsAg positive patients can be observed<sup>[3,14,15]</sup>. Despite the fact that HBVr is usually found in chronically infected patients; it has also been reported in patients with resolved or occult HBV infection (*i.e.*, HBsAg negative, antiHBc positive), since these individuals still have traces of HBV DNA replication in their liver.

The reactivation risk depends on a combination between the degree and duration of IS<sup>[4,16]</sup>. Reactivation of HBV replication during IS can occur in an indirect fashion, through abolition of specific T-cell control, but also in a straightforward manner, when stimulation of a glucocorticoid-responsive element in the HBV

**Figure 1 Hepatitis B reactivation phases.** In the initial phase, there is an increase in HBV DNA levels, usually with an asymptomatic evolution. In the second phase, both ALT and HBV DNA are elevated; symptoms are frequently present, and they may be severe. The third phase is determined by resolution, although HBsAg (if reappeared), or elevated HBV DNA, may persist<sup>[3,17,55]</sup>. IS: Immunosuppression; HBV: Hepatitis B virus; ALT: Alanine aminotransferase; HBsAg: Hepatitis B surface antigen.

genome occurs, leading to up regulation of HBV gene expression<sup>[17]</sup>.

## HBVR DEFINITIONS: A HETEROGENEOUS GROUP

One of the major difficulties assessing the impact of HBVr is the different diagnostic criteria found in the literature<sup>[16]</sup>. Although reports of HBVr and its consequences are not scarce, the data are often difficult to contrast, because of the different definitions used. Some studies consider HBV DNA level elevations<sup>[18]</sup>, some evaluate reappearance of HBsAg<sup>[19]</sup>, and others evaluate episodes of hepatitis syndrome, utilizing different grading (severity) systems<sup>[4]</sup>. Consensus has not been reached, even in the major clinical guidelines; both the European Association for the Study of the Liver (EASL) and Asian Pacific Association for the Study of the Liver (APASL) chronic hepatitis B guidelines, when addressing HBVr, considers HBsAg seroreversion and rise in HBV DNA levels as diagnostic criteria<sup>[20,21]</sup>, whereas the American Association for the Study of Liver Diseases (AASLD) defines HBVr as reappearance of active necro-inflammatory disease of the liver in an individual at an inactive HBsAg carrier state or who was known to have resolved hepatitis B<sup>[5]</sup>. Recently, at the Reactivation of Hepatitis B AASLD meeting held in 2013, the first attempt to establish a standardized nomenclature was made. Reactivation of HBV replication was defined as a marked increase in HBV replication ( $\geq 2$  log increase from baseline levels or a new appearance of HBV DNA to a level of  $\geq 100$  IU/mL) in a person with previously stable or undetectable levels. The types of reactivation were described as reverse HBsAg seroconversion (reappearance of HBsAg), or appearance of HBV DNA in serum in the absence of HBsAg. The severity of reactivation, defined by the presence or absence of jaundice and liver failure; and its outcome (return to baseline status or persistence in an activated state, need for liver transplantation or death) should also be reported<sup>[2,17]</sup>. A universal grading system that also

includes the consequences related to the IS therapy was recently proposed by Visram *et al.*<sup>[4]</sup>, in an additional effort to standardize HBVr grading and its consequences.

## MEDICAL INTERVENTIONS ASSOCIATED WITH HBVR

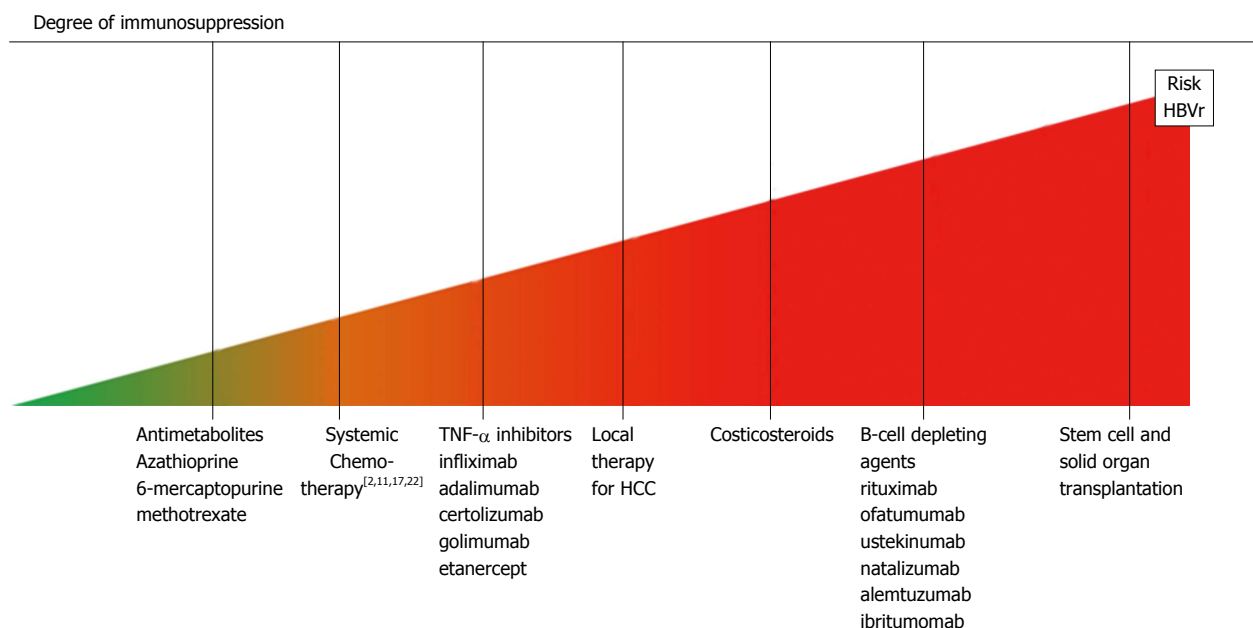

Several agents have been associated with the risk of HBVr, depending on the type and intensity of IS caused by these medical interventions<sup>[2]</sup>. The most relevant ones are described below, and displayed according to the risk of HBVr in Figure 2.

### Antimetabolites

HBVr during IS with low doses of azathioprine or methotrexate, when used as monotherapy, is uncommon<sup>[3,22]</sup>. In a thorough review recently published, no report was found in which azathioprine used alone was documented to cause HBVr<sup>[12]</sup>. Similarly, although several reports associated with methotrexate-induced HBVr are available, most of them involved the concomitant use of other immunomodulators<sup>[22]</sup>. Indeed, this antimetabolite has been in clinical use for more than 50 years, and only a small number of cases have been described in published reports in which HBVr was attributable to this agent when used alone. Based on these findings, they are considered to be drugs with low risk of HBVr<sup>[12,23]</sup>.

### Tumor necrosis factor- $\alpha$ inhibitors

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is a pro-inflammatory and immunoregulatory cytokine involved in the pathogenesis of several inflammatory disorders. The inhibition of TNF- $\alpha$  signaling can lead to increased HBV replication and reactivation<sup>[2,24]</sup>. Anti-TNF- $\alpha$  agents are approved to treat rheumatoid arthritis, intestinal inflammatory diseases and psoriasis; in this context, several (*e.g.*, infliximab, adalimumab, certolizumab, golimumab and etanercept) have been associated with HBVr<sup>[22]</sup>. In a meta-analysis published by Lee *et al.*<sup>[25]</sup> evaluating the risk of HBVr in 468 isolated antiHBc patients with rheumatic conditions treated with different anti-TNF- $\alpha$

**Figure 2** Immunosuppressing agents and related risk of hepatitis B reactivation. HCC: Hepatocellular carcinoma; TNF- $\alpha$ : Tumor necrosis factor- $\alpha$ ; HBVr: Hepatitis B virus reactivation.

(mostly etanercept), HBVr was found in 1.7% of the cases. The same author reported much higher rates of HBVr in HBsAg-positive patients (12.3%) in a similar cohort of rheumatic patients<sup>[26]</sup>. Additionally, several severe HBVr have been communicated, particularly following infliximab administration<sup>[3,27]</sup>. However, it is unclear whether the risk of HBVr is the same with every TNF- $\alpha$  inhibitor. Most cases have been associated with the more potent IS drugs such as infliximab or adalimumab rather than etanercept. Comparative risk assessment between these agents is doubtful when incidence is derived from case report and retrospective rather than well-designed prospective studies. Therefore, a moderate level of confidence can be given to estimation that the risk of HBVr during anti-TNF- $\alpha$  monotherapy is between 1% and 10% in HBsAg carriers, and quite lower in isolated antiHBe<sup>[12]</sup>.

#### Locoregional therapy for hepatocellular carcinoma

Several therapeutic strategies for hepatocellular carcinoma (HCC) have been inferred to cause HBVr<sup>[28,29]</sup>. Transarterial chemoembolization (TACE) has been directly associated with an increased rate of HBVr<sup>[30]</sup>. Even though this procedure has little systemic effect due to the administration of chemotherapeutic agents directly into a branch of the hepatic artery<sup>[2]</sup>, it may cause systemic symptoms if arterio-venous shunts or peritumoral microcirculation are present; this is why host immune system is often compromised. Additionally, anthracyclines (*i.e.*, doxorubicin) are frequently used as part of intra-arterial chemotherapy. In experimental models, anthracyclines have stimulated HBV DNA secretion from HCC cell lines; this mechanism may help to explain the higher risk of HBVr in patients treated with doxorubicin-containing TACE<sup>[12]</sup>. HBVr during radio-

therapy, with or without TACE, has also been examined in several studies<sup>[27,31]</sup>. In a prospective study conducted by Huang evaluating 69 HBV patients with HCC treated with conformal radiotherapy, almost 25% of them suffered HBVr, and 21.7% HBVr induced hepatitis<sup>[32]</sup>. HBVr in patients who underwent HCC surgical resection and local ablation therapy have also been extensively reported<sup>[27,30]</sup>.

#### Corticosteroids

Prednisone is the cornerstone of several chemotherapeutic regimens, and an important agent to induce remission in inflammatory bowel disease<sup>[2]</sup>. This and other corticosteroids have been associated with an increased risk of HBVr (both in monotherapy and especially when combined with other IS drugs)<sup>[22]</sup>. The HBVr is thought to be mediated by abolition of specific T-cell control, and also by direct viral stimulation. The risk of infection has been stratified according to the dosage and time of exposure to the corticosteroid<sup>[33]</sup>. Based on these variables, in a meta-analysis that included every well-documented report on HBVr, a risk stratification score was proposed: HBsAg positive patients who received more than 10 mg/daily of prednisone for 4 wk or longer were included in the high-risk group (> 10% chance of HBVr); HBsAg positive patients that received less than 10 mg/daily of prednisone or HBsAg-negative, antiHBe positive patients that were treated with less than 20 mg/daily of prednisone for less than 4 wk are included in the moderate-risk group (1%-10% risk of HBVr). Finally, antiHBe positive patients treated with less than 10 mg/daily of prednisone for less than 4 wk, and patients with local steroid treatment (such as intra-articular infusion) were included in the low risk group<sup>[12]</sup>. Therefore, corticosteroid use is an independent risk

factor for HBVr<sup>[12,22]</sup>.

### Systemic chemotherapy

This is one of the therapeutic interventions more frequently related with HBVr; not only associated with the degree of immunosuppression but also with the type of malignancy treated<sup>[14,16,34]</sup>. HBsAg-positive chronic carriers with hematologic diseases are at the highest risk of developing HBVr during IS, reaching an incidence of 40%-50%, or even higher, according to different series<sup>[12,27]</sup>. One of the most frequently cited study is related to the risk of HBVr in lymphoma patients, with reactivation rates reaching almost 50%, and an associated mortality of 4%<sup>[14,17,18,22,35]</sup>. Other studies report on an incidence of HBVr in this setting between 24%-67%, and an elevated mortality rate of 4%-41%. One of the reasons for this elevated risk relies on the intensive chemotherapy necessary for lymphoma treatment, especially when most chemotherapies schemes include high doses of steroids and/or rituximab. It may also be due to the rather high prevalence of HBV observed in this cohort of patients<sup>[14,36]</sup>. HBVr has also been described in patients receiving chemotherapy for treatment of solid tumors (*i.e.*, breast, colon and lung cancer)<sup>[21,22,37]</sup>. These patients fall within the intermediate risk category (HBVr chance of 10%-30%). Finally, the low risk group includes patients with gastrointestinal malignancies receiving 5-fluorouracil based therapy<sup>[27]</sup>.

### Biologic antibodies

Rituximab is considered a high-risk factor for HBVr<sup>[38]</sup>. This cytolytic monoclonal antibody is directed against the CD20 antigen of immature and mature B cells; it is used for the treatment of numerous hematological malignancies, severe rheumatic conditions, and (off-label) solid organ transplantation (in the latter scenario, as an adjunctive agent to mitigate humoral allograft response)<sup>[13]</sup>. When combined with standard-of-care chemotherapy for non-Hodgkin's lymphoma, HBVr has been observed in up to 25% of patients with resolved infection; this reactivation may occur even 12 mo after the therapy has been completed; including those patients with isolated antiHBc<sup>[22,39]</sup>. A preliminary analysis of the post marketing data from the Food and Drug Administration (FDA) Adverse Event Reporting System found 109 cases of HBV-related acute liver failure associated with rituximab and ofatumumab (another anti-CD20 monoclonal antibody). They occurred during the 13 years of rituximab and 3 years of ofatumumab commercialization<sup>[17]</sup>. Due to these reports, in the year 2013 a boxed warning was included in the label issued by the FDA for both drugs, describing HBVr resulting in "fulminant hepatitis, hepatic failure and death". This advisement underlines the potential for HBVr especially in chronically infected patients, but also in those who have resolved a previous HBV infection<sup>[13,17]</sup>. Due to these events, all antibodies directed against CD20 have been compelled by the FDA to add HBVr to the boxed

warning; recommending HBV screening tests before initiation of therapy and therapy when positive results are found<sup>[17]</sup>. Other biologic agents, such as specific tyrosine kinase inhibitors imatinib and nilotinib, have been implied in well-documented cases of HBVr; however, newly developed drugs including cytokine and integrin inhibitors such as ustekinumab, natalizumab, alemtuzumab and vedolizumab, have few or no reports of HBVr as yet. Since they all share the same mechanism of action, it is expected for them to convey at least a low to moderate risk of this complication<sup>[12,22]</sup>.

### Stem cell and solid organ transplantation

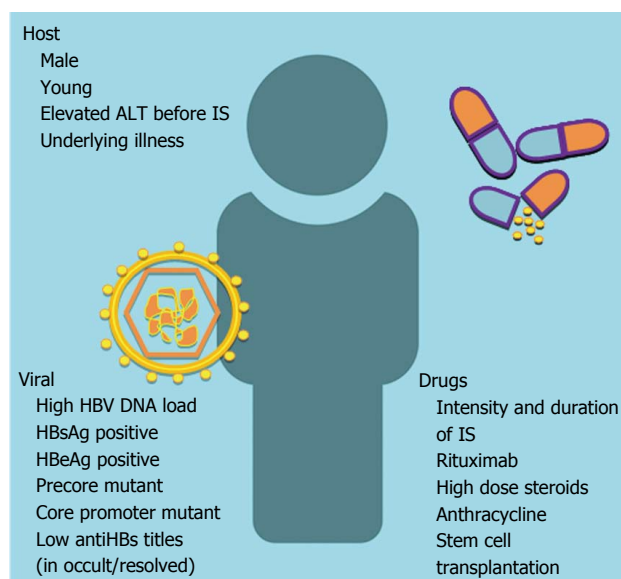

Patients undergoing stem cell/bone marrow transplantation are at the highest HBVr-risk position followed closely by those receiving solid organ transplantation.

Bone marrow/stem cell transplanted patients typically get intense chemotherapy to induce remission of the underlying malignancy, followed by additional chemotherapy and radiation therapy to ablate bone marrow<sup>[17,40]</sup>. The profound IS and loss of pre-existing HBV-specific immunity allows for HBVr in the liver to occur, and the return of active viral replication<sup>[19]</sup>. In this setting, the HBVr rate reaches 50% in both HBsAg-positive and isolated antiHBc-positive patients. In the latter group, antiHBs titles below 10 mIU/mL were a predictor of HBsAg seroreversion<sup>[17]</sup>. Due to the considerable delay in immune system reconstitution that typically occurs in this subset of patients, the risk of seroreversion can endure for several years; furthermore, these patients are prone to develop chronic infection once the virus is reactivated<sup>[19]</sup>. In a retrospective study that evaluated 137 HBsAg negative and antiHBc positive patients who underwent hematopoietic cell transplant patients, the prevalence of HBVr reached 10%, occurring within 9 to 77 mo after transplantation<sup>[40]</sup>.

When considering solid organ transplantation, HBVr risk has been known to reach 50%-90% in HBsAg-positive patients after kidney transplantation. In these cases, reactivation has the potential to cause liver failure, progression to cirrhosis, HCC, and increased liver-related mortality. Other solid transplant recipients (*e.g.*, heart, lung) have been the subject of similar reports<sup>[17]</sup>.

## WHOM TO CHECK: UNIVERSAL SCREENING VS HIGH-RISK PROFILING

The key to prevent HBVr is the timely identification of HBV-infected patients prior to immunosuppressive therapy<sup>[41,42]</sup>. The proportion of patients ignorant of their chronic HBV infection reaches 35% in United States; this proportion is far higher (90%) in the European Union<sup>[4,17]</sup>, whereas in Latin America the figures are unknown. To note, HBV screening is mandatory in high-risk groups in only 15% of the countries located of this region<sup>[43]</sup>. Lack of standardized risk factor assessment, the fact that many patients are not aware (or might not acknowledge)

**Figure 3 Risk factors for hepatitis B reactivation in patients with current/past hepatitis B infection.** ALT: Alanine aminotransferase; HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; IS: Immunosuppression<sup>[2,4,27,56,57]</sup>.

that they have had risk behaviors, and the scarce time dedicated by most physicians to systematically screen their patients for HBV risk factors when they are about to start immunosuppressive therapy worsen the situation<sup>[14,17,44]</sup>. Risk factors for HBV infection are well-known (patients born in areas with intermediate-high HBV prevalence, patients who use intravenous drugs, patients that have had multiple sexual partners, patients with sexually transmitted diseases, etc.)<sup>[5,20]</sup>, but factors associated with HBVr have been less described; these are relevant for the decision and timing of HBV treatment. The most relevant ones are shown in Figure 3.

The combination of several of these risk factors has been suggested to stratify patients into high-, intermediate-, and low-risk for HBVr<sup>[6,12]</sup>. The relevance of risk assessment relies on the screening strategy adopted by the physician. Several HBV diagnostic consensus statements suggest universal screening, including the Centers for Disease Control and Prevention recommendations, as well as the EASL and the APASL guidelines<sup>[6,20]</sup>. The benefits of this approach are not only the identification of every chronically infected HBV patient, but also the recognition of patients previously exposed to the virus, thus eliminating the possibility of missing patients without clearly identified risk factors. The alternative screening strategy involves testing only patients at high risk for HBV infection; these recommendations are endorsed by the AASLD, the American Society of Clinical Oncology, and the National Comprehensive Cancer Network<sup>[6,17,45]</sup>. This targeted approach has been praised in relation to its lower cost, however, it may fail to identify chronic HBV carriers and previously exposed patients, and perhaps more importantly, it has been challenging for physicians to accomplish<sup>[6]</sup>.

**Table 1 Diagnostic tools suggested for hepatitis B screening prior to immunosuppression therapy by different major guidelines**

Recommendations	Hepatitis B screening tests before immunosuppression			
	HBsAg	AntiHBc	HBV DNA	AntiHBs
CDC	Yes	Yes	No	Yes
AASLD	High risk	High risk	No	No
EASL	Yes	Yes	No	No
APASL	Yes	No	No	No
ASCO	High risk	High risk	No	Yes <sup>1</sup>

<sup>1</sup>Only suggested in antiHBc-positive patients. CDC: Center for Disease Control; AASLD: American Association for the Study of Liver Disease; EASL: European Association for the Study of the Liver; APASL: Asian Pacific Association for the Study of the Liver; ASCO: American Society Clinical Oncology; HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; AntiHBc: Antibody to hepatitis B core antigen; AntiHBs: Antibody to hepatitis B surface antigen.

## SCREENING TOOLS: HETEROGENEOUS RECOMMENDATIONS

Currently, there are no universally accepted screening tests adopted into clinical practice. Again, lack of consensus regarding testing for hepatitis B current/resolved infection complicates the picture<sup>[2]</sup>. Recommendations of different serologic testing for HBV screening prior to IS are shown in Table 1. HBsAg testing is endorsed by all major societies without consensus regarding risk evaluation, as already stated<sup>[6]</sup>. AntiHBc is not a required test by the APASL due to the high prevalence of HBV in this region (up to one third of the population)<sup>[46]</sup>. Whether to include antiHBs and HBV DNA testing among antiHBc-positive subjects is still controversial, since it is not based on prospective data<sup>[6,46]</sup>. Finally, regarding the moment for testing, it has been suggested that the major benefit is reached when it is done prior to initiation of therapy<sup>[16,27,47]</sup>.

## TREATMENTS FOR HBVR: SEVERAL MATTERS TO ADDRESS

The rationale for the identification of patients infected by HBV is to allow proper antiviral therapy, if needed, or otherwise to undertake careful monitoring<sup>[17]</sup>. Once again, several decisions have to be made by physicians on this point, some of which have different endorsements according to the consulted guideline. The decision-making stages are the following ones.

### When to treat

Several definitions have been used to classify treatment initiation timing. Treatment prophylaxis refers to antiviral therapy started before or concurrently as the initiation of immunosuppressive therapy, and before aminotransferase or HBV DNA levels rise occurs. On the other hand, in pre-emptive treatments, the occurrence of serum HBV DNA or aminotransferase elevation deter-

**Table 2** Recommendations for treatment and follow-up in different clinical scenarios, according to Asian Pacific Association for the Study of the Liver, American Association for the Study of Liver Disease and European Association for the Study of the Liver guidelines

Recommendations in different clinical scenarios					
	HBsAg (+) HBV DNA $\geq$ 2000 U/mL	HBsAg (+) HBV DNA < 2000 U/mL	HBsAg (-) antiHBc (+)	HBsAg (-) antiHBc (-) antiHBs (-)	HBV-HCC TACE
Action	Treat	Treat	Close mon/treat if HBV DNA (+) or rituximab/stem cell transplant <sup>1</sup>	Vaccination	Treat <sup>3</sup>
Onset	Before IS	Before IS	Before IS	-	Before IS
Duration	6-12 mo (except CI)	6-12 mo (except CI)	6-12 mo	-	-
Drug	Short IS: LAM (LdT) preferred ETV/TDF	Short IS: LAM (LdT) (ETV/TDF)	Short IS: LAM (LdT) (ETV/TDF)	-	LAM (ETV/TDF)
Follow-up	-	-	Every 1-3 mo/treat if HBV DNA (+) <sup>2</sup>	-	-

In HBsAg-positive patients, duration could be determined by CI as in immunocompetent patients. A 12-mo treatment was only endorsed by EASL. Drug selection depends on treatment duration and clinical setting. <sup>1</sup>In isolated antiHBc-positive patients when treated with biologic agents, close follow-up and treatment, if necessary, is suggested by AASLD/APASL; however, EASL proposes that isolated antiHBc-positive patients, if HBV DNA-positive, antiHBs-negative or undergoing rituximab/stem cell transplantation, should be treated with the same strategy as HBsAg positive patients; <sup>2</sup>When monitored, treatment should start when HBV DNA becomes positive, before ALT rise (EASL); <sup>3</sup>Treatment in all HBV-related HCC patients undergoing TACE is suggested by APASL guidelines. CI: Clinical indication; IS: Immunosuppression; HBsAg: Hepatitis B surface antigen; AntiHBc: Hepatitis B core antibody; AntiHBs: Hepatitis B surface antibody; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; TACE: Transarterial chemoembolization; LAM: Lamivudine; ETV: Entecavir; TDF: Tenofovir; LdT: Telbivudine (only listed as an option in AASLD guidelines); AASLD: American Association for the Study of Liver Disease; APASL: Asian Pacific Association for the Study of the Liver; EASL: European Association for the Study of the Liver.

mine the initiation of antivirals (before symptoms, if any, appear)<sup>[17]</sup>. The latter definition has been included in what referred to as “deferred treatment” in more recent publications<sup>[12]</sup>. Regarding HBsAg-positive patients, most treatment guidelines recommend prophylactic treatment; such as the AASLD (initiation of antivirals at the onset of IS), and the APASL guidelines (initiation of antivirals one week prior to chemotherapy)<sup>[5,30]</sup> (Table 2). The EASL mentions the “pre-emptive” treatment strategy, but defines it as antiviral administration during therapy regardless of HBV DNA levels, similar as the aforementioned guidelines<sup>[20]</sup>.

Several studies have compared these starting-point strategies. In the technical review by Perrillo *et al.*<sup>[12]</sup> where results of two randomized controlled trials of antiviral prophylaxis with lamivudine in HBsAg-positive patients undergoing chemotherapy were evaluated, an HBVr rate of 55% was found in the untreated group. There was biochemical evidence of hepatitis in 86% of these patients, which resulted in hepatic failure in 10% of the cohort<sup>[12]</sup>. In a recent meta-analysis published by Zheng *et al.*<sup>[48]</sup> where the efficacy of prophylactic use of lamivudine in HBsAg-positive patients undergoing chemotherapy for breast cancer was evaluated, the rate of HBVr was diminished by 91%, and there was a similar reduction in chemotherapy disruption in the prophylactic lamivudine group. HBsAg-negative and antiHBc-positive patients, when compared with HBsAg-positive patients, appear to have a lower risk of HBVr when exposed to moderate-risk immunosuppressive drugs. This would explain why certain scientific societies such as APASL suggest close monitoring and treatment in this patient’s population only when reactivation occurs<sup>[30]</sup>. In contrast, when high-risk agents such as rituximab are used in isolated antiHBc-positive patients, high rates of reactivation in excess of 10% occur, and antiviral prophylaxis can be expected to result in similar

absolute risk reduction, as described for HBsAg-positive patients<sup>[5,12,30]</sup>.

### Whom to treat and what antiviral to choose

Most guidelines agree on recommendations for HBsAg-positive patients<sup>[49]</sup>. In this group, the choice of antiviral and length of therapy will depend on the clinical status of the HBV infection. When considering HBsAg-positive patients, antiviral therapy should commence in the context of immunosuppression. If the patient has clinical indications for HBV treatment (*i.e.*, HBV DNA > 2000 IU/mL), either tenofovir or entecavir should be chosen, and therapy should be maintained until they reach therapeutic endpoints for chronic hepatitis B. Otherwise, prophylactic therapy could be initiated with lamivudine, although more powerful antiviral could be chosen as well<sup>[5,20,30,50]</sup>. This rule also applies to all HBV-related, HCC patients who are to undergo TACE<sup>[30]</sup>. Lamivudine will only be sufficient in a finite and short-term course of immunosuppressive therapy. Elseways, in those patients with elevated HBV DNA viral load and/or in those receiving prolonged cycles of IS, protection with entecavir or tenofovir is preferred, due to their higher potency and stronger barrier of resistance<sup>[20,51-53]</sup>. Lamivudine resistance increases according to treatment duration, reaching a 10%-20% rate in the first year, and increasing longitudinally with time (especially with high initial HBV DNA viremia). In addition, given that drug-resistant variants are archived and reemerge quickly on re-exposure to the antiviral drug, patients with a history of prior lamivudine or telbivudine treatment would be best treated with tenofovir, as this is the most effective drug for patients with prior resistance. The recommendation of both entecavir and tenofovir are based on the evidence of efficacy of these drugs in treating chronic HBV patients outside the prophylaxis setting, since their utility in the immunosuppressive

scenario has been less studied. There are no studies of tenofovir use, but several cohort studies and a randomized trial using entecavir<sup>[12,54]</sup>. Preliminary results of 121 patients with lymphoma treated with R-CHOP (chemotherapy treatment including rituximab, cyclophosphamide, doxorubicin, vincristine and prednisone) randomized to lamivudine and entecavir prophylaxis, HBVr was seen in 8% of the lamivudine-treated patients and none among the entecavir-treated patients. Recommendations for tenofovir use must be based on anticipated parallel benefits to entecavir, as both drugs are of high antiviral potency and have low risk of resistance with prolonged therapy<sup>[49]</sup>.

There is no consensus regarding the duration of treatment; AASLD and APASL societies suggest 6 mo of maintenance after IS cessation, whereas EASL recommends its extension to 12 mo<sup>[5,20,30]</sup>. Both AASLD and APASL guidelines consider that in HBsAg-negative but antiHBc- and antiHBs-positive patients, and in those with isolated antiHBc, reactivation is infrequent. Therefore these patients should be monitored and antiviral therapy initiated when HBVr occurs<sup>[5,30]</sup>. However, EASL suggests that this subgroup of patients should be tested for HBV DNA, and if present, they should be treated similarly as HBsAg-positive patients. Furthermore in antiHBs negative patients and/or when close monitoring of HBV DNA is not guaranteed, this guideline recommends prophylaxis therapy with antivirals in patients receiving rituximab, bone-marrow or stem-cell transplantation and/or combined regimens for hematological malignancies. The optimal duration of prophylaxis for these indications is unknown<sup>[20]</sup>.

## CONCLUSION

Ambiguity on the nomenclature of HBVr is a major problem that has led to the uncertain estimation of its incidence. A proper standardization of both terminology and definitions are required to reach better estimates of the frequency and associated risk factors of HBVr in different clinical settings. Furthermore, this standard definitions should be employed in safety and efficacy trials for new IS agents.

HBV screening before starting immunosuppressive therapy is a key factor to prevent HBVr. We need consensus on how and when to screen HBV in patients at high risk for HBVr. The call for large, collaborative, population-based studies is eagerly awaited to determine with confidence the efficiency of the HBV screening methods, and the consequent optimal antiviral prophylaxis, aimed to HBVr prevention.

Many HBV-infected patients are unconscious of their disease or risk factors. An appeal from scientific societies for physicians to spend enough time to assess patients for HBV risk factors prior to begin immunosuppression therapy is mandatory.

Finally, to make progress in this field, consensus from major societies composing the scientific hepatology community in the construction of clear guidelines to

define HBVr management (*i.e.*, antiviral selection, treatment onset and duration) and follow-up are essential.

### Abstract

This review focuses on the management of iron meta-

bolism and iron overload experienced in the hereditary condition, human factors engineering (HFE)-associated hemochromatosis. Hemochromatosis refers to a group of genetic diseases that result in iron overload; the major one globally is HFE-associated hemochromatosis. The evolution in understanding of the most common form of hereditary hemochromatosis, being the substitution of cysteine to a tyrosine at position 282 in the *HFE* gene, has been extensively studied. Novel mutations in both *HFE* and non-*HFE* genes have been indicated in this disease which hold significance in its application for the Asia-Pacific region. In conditions with iron overload, the storage of excess iron in various body tissues leads to complications and toxic damage. The most common presenting complaint for this disease is malaise, lethargy and other non-specific symptoms. In order to diagnose hereditary hemochromatosis, there are biochemical, imaging and genetic testing options. Currently, cascade screening of affected families is preferred over population-level screening. The mainstay of treatment is venesection and the appropriate approach to treatment has been consolidated over the years. Recently, the indications for venesection therapy of hemochromatosis have been challenged and are the subject of ongoing research.

**Key words:** Human factors engineering; Iron storage diseases; Genetics; Venesections; Hemochromatosis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The concept of hemochromatosis as a single disease entity has changed to an iron storage disease resulting from several genetic disorders although the final common metabolic pathway is inappropriate iron absorption from the intestine and progressive tissue iron loading. The most common form of the disease is due to a mutation in the human factors engineering gene resulting in cysteine tyrosine substitution at position 282 in the molecule. This mutation is relatively common in populations of northern European extraction but is rare

in other populations. In contrast other rarer forms of hemochromatosis resulting from other mutations in the hepcidin pathway are quite ubiquitous. The main stay of treatment remains venesection although new oral iron-chelating agents show promise.

## INTRODUCTION

The clinical and molecular research surrounding the clinical syndrome of hemochromatosis has been substantial in the last two decades even though it has been recognized in its advanced state for more than 100 years<sup>[1]</sup>. A mutation in the human factors engineering (*HFE*) gene was identified as the cause for more than 90% of cases of classic hemochromatosis<sup>[2]</sup> in most countries except for the Mediterranean region where it is responsible for around 65% of the cases. The genetic cause for hemochromatosis is more common in individuals with a northern European ancestry; however, the clinical manifestation, or incidence of biochemical abnormalities and clinical disease, is not as common in these populations. Although mutations in the *HFE* gene are most common, there are other forms of iron overload caused by mutations in other iron regulatory molecules that present as distinct clinical diseases. Over time, population studies have served the purpose of outlining the risk to an individual with a genetic mutation and the clinical investigations available for assessment and monitoring have improved. The treatment of hemochromatosis is the one aspect of this condition that has evolved the least over the years with phlebotomy still being the main therapy available. However, the treatment has potential for change with increased research on new therapeutic agents under trial. Although the European Association of the Study of Liver (EASL) and the American Association for the Study of Liver Disease have outlined appropriate treatment regimens, recent research have challenged these guidelines suggesting there is a benefit in beginning treatment early for patients with even mildly elevated iron levels but with or without clinical manifestation. According to current guidelines, the threshold of serum ferritin at which to start treatment is currently taken as above the normal range where the normal range for serum ferritin in men is 24-336 µg/L and in women is 11-307 µg/L. The current clinical standard is to maintain the serum ferritin at 50-100 µg/L<sup>[3]</sup>.

## PATHOPHYSIOLOGY

### Iron homeostasis

The role of iron in the body is a crucial one from oxygen

transport in hemoglobin and oxidative phosphorylation to the production of red blood cells and other functions<sup>[4,5]</sup>. In situations with overload, there are consequences in disease and mortality to be discussed later in this paper however the extent of this risk is still debated<sup>[6-9]</sup>. Beginning with iron, when it is consumed, it can enter the body in two forms: Either heme or non-heme<sup>[10,11]</sup>. Heme is mostly commonly ingested as animal protein and non-heme is *via* vegetables. However, there is no mechanism for the excretion of iron which is toxic in overload. Uncontrolled loss (1-2 mg) in menses, bleeding and the sloughing of skin are the only methods for iron removal.

In order to understand iron homeostasis, a discussion regarding the pathway of iron is necessary. Iron is absorbed on the apical surface of enterocytes in the duodenum and proximal small bowel. Non-heme iron can be either ferrous (Fe<sup>2+</sup>) or ferric (Fe<sup>3+</sup>)<sup>[4]</sup>. It is important to note that since ferrous iron is more soluble, it is necessary for ferric iron to be reduced to ferrous iron prior to absorption<sup>[12]</sup>. In order to reduce ferric iron found in non-heme iron to the ferrous state both gastric acidity and duodenal cytochrome B (DCyTB1) have been identified as well as other non-enzymatic pathways<sup>[13,14]</sup>. On the apical surface of enterocytes, the divalent metal transport 1 (DMT1) protein takes in ferrous iron<sup>[14]</sup>. The DMT1 protein also serves to transport manganese and copper (Figure 1).

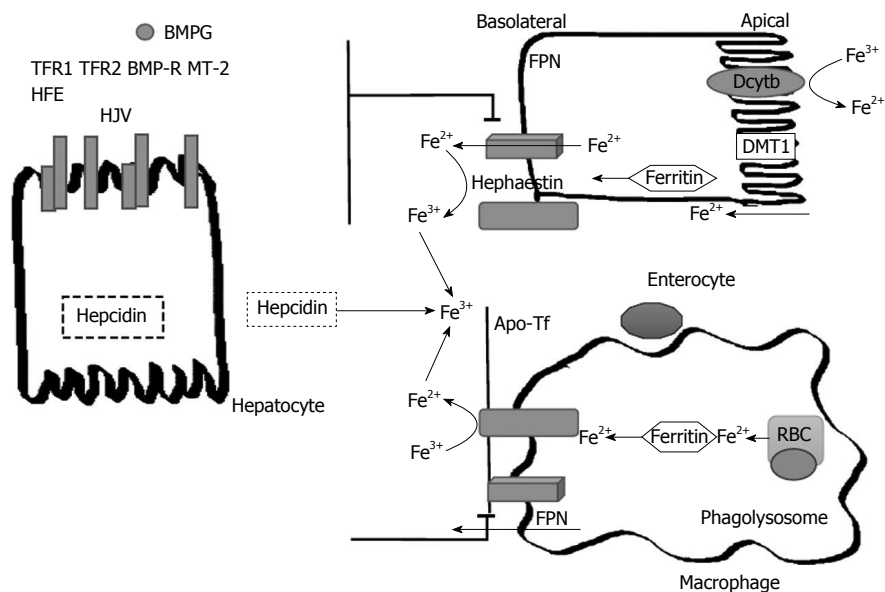

From the enterocyte, iron uptake into tissue is mediated by transferrin receptors (TfR1 and TfR2). In transportation, iron is consistently bound to a molecule due to its ability to form free radicals. Transferrin, the carrier protein for iron binds to the TfR1 and is taken up by endosomes, where transferrin is cleaved and the receptor recycled back to the cell surface<sup>[15]</sup>. In the case of iron overload, excess iron is stored in complexes of hemosiderin or ferritin. Another form of iron storage is hemosiderin which is a by-product of ferritin degradation<sup>[13]</sup>.

On the basal surface of enterocytes, ferroportin (FPN1) is the sole expressed exporter in cells. Iron is released into circulation when FPN1 interacts with ferroxidase and hepcidin. Hephestin next acts to oxidize the iron and the iron is then immediately bound to the transport molecule transferrin (Tf)<sup>[4]</sup>. Another important regulator of iron homeostasis is ferroportin, a protein which acts to export stored iron from enterocytes and other intracellular stores. A small hepatic peptide, hepcidin, negatively regulates ferroportin<sup>[12]</sup> by causing the internalization and degradation of this protein thereby affecting the export of iron. In summary, hepcidin reduces iron uptake and serum iron<sup>[12,16]</sup>. There have been certain factors such as iron, inflammation and oxidative stress that have been demonstrated to have an inhibitory effect on the expression hepcidin. However, hepcidin regulation is not a topic that is completely understood.

### Genetics

Hereditary Hemochromatosis is caused by different

**Figure 1 Pathways of Iron transport and metabolism.** The pathway of iron in enterocytes and macrophages as effected by hepcidin. Dietary non-heme iron is taken into the enterocyte via the DMT1. In order for iron to move across the brush border of the enterocyte via DMT1, it must first be reduced from  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  by DcytB. Once inside of the cell, iron can be sequestered into storage as ferritin or continue along the pathway into circulation. In this process, the iron exporter FPN located on the basolateral surface of enterocytes is responsible for the transport of ferrous iron into circulation. Once iron is in circulation, hephaestin oxidizes the ferrous iron back into the ferric state and then it immediately binds to plasma transferrin. The iron is now able to travel to sites of iron storage or where iron is required. In macrophages, phagolysosomes containing senescent RBC release iron which is also then exported into circulation via ferroportin. Hepcidin, a protein derived from the liver, regulates iron transport in the body by causing the internalization and degradation of FPN transporters on macrophages and the basolateral surface of enterocytes. Hepcidin is regulated based on body iron requirements by signals produced from the interaction between different proteins on hepatocytes. The interaction of the HFE protein and transferrin receptors 1 and 2 (TFR1 and TFR2) and the interaction between bone morphogenic protein (BMP6), hemojuvelin (HJV) and the bone morphogenic protein receptor (BMP-R) and matriptase 2 (MT-2). RBC: Red blood cells; FPN: Ferroportin; DMT1: Divalent metal-ion transporter 1; DcytB: Duodenal cytochrome B; HFE: Human factors engineering.

**Table 1 Classification of iron overload and hemochromatosis**

Genetic iron overload (primary)
Type 1 HFE-associated hemochromatosis
C282Y homozygosity
C282Y/H63D compound heterozygosity
Type 2 juvenile hemochromatosis
2A hemojuvelin mutations
2B hepcidin mutations
Type 3 TFR2-related hemochromatosis
Transferrin receptor 2
Type 4 ferroportin disease
Loss of function mutations, also called type 4A or "M"
Hepcidin resistance mutations, also called type 4B or "H"
Aceruloplasminemia
Ceruloplasmin mutations
A(hypo)transferrinemia
Acquired iron overload (secondary)
Ineffective erythropoiesis
Thalassemia major
Sideroblastic anemia
Chronic hemolytic anemia
Dietary iron overload (African)
Parenteral iron overload (including transfusional overload)

HFE: Human factors engineering.

mutations that alter the regulatory proteins involved in iron homeostasis and hepcidin pathways. The genetic causes for hemochromatosis can be categorized into *HFE* gene mutations and non-*HFE* gene mutations (FPN, TFR HJV)<sup>[2]</sup>. While non-*HFE* gene mutations are not as

common as *HFE* gene mutations, there is an increased proportion of these mutations in non-Northern European populations<sup>[4]</sup>. Therefore, this information is of significance in Asia-Pacific populations<sup>[4]</sup>.

The knowledge and classification of hemochromatosis and other iron overload diseases has become more detailed in the last 2 decades (Table 1). Mutations in the genes encoding HFE, TFR2, hemojuvelin and hepcidin all lead to decreased hepcidin activity and increased iron absorption, resulting in the syndrome of hemochromatosis<sup>[5]</sup>. Mutations in *HFE*, *HJV*, *HAMP*, *TFR2* and *SLC40A1* have been linked to the various types of hemochromatosis<sup>[2,5]</sup>.

#### ***HFE-associated hereditary hemochromatosis***

In Northern European ancestry, an amino acid substitution specifically at position 282 of the HFE protein is the mutation most responsible for iron overload in this population<sup>[5]</sup>. The C282Y substitution is rare outside those of white ethnicity<sup>[17-19]</sup>. *HFE* is tightly linked to the HLA-A locus on chromosome 6p. Persons who are homozygous for the mutation are at increased risk of iron overload and account for 80% to 90% of clinical hereditary hemochromatosis in persons of northern European descent<sup>[6-9]</sup>. Pietrangelo suggest that between 10% and 33% of homozygous patients develop hereditary hemochromatosis<sup>[4,20]</sup>. This suggests that there are other genetic and non-genetic factors in the disease<sup>[21]</sup>.

There have been alternative mutations of HFE identified, primarily H63D and S65C; however, these mutations have not been proven to cause substantial iron overload<sup>[4]</sup>. In order to produce symptomatic disease, a heterozygous mutation is necessary. Since there is an increased prevalence of C282Y, and H63D is more relevant clinically, compound heterozygotes with symptomatic disease are usually C282Y/H63D<sup>[2,22-24]</sup>.

### **Non-HFE associated hereditary hemochromatosis**

Discussion regarding non-HFE associated hemochromatosis is beyond the scope of this paper.

## **CLINICAL MANIFESTATIONS**

Hereditary hemochromatosis is most commonly associated with liver disease including cirrhosis, but the clinical manifestations of iron overload are diverse and involve many other organs. Hemochromatosis is an overall underdiagnosed disease due to the idea that it is a rare condition and also associating diagnosis with clinical features seen in advanced disease such as cirrhosis, diabetes and skin pigmentation<sup>[3]</sup>. Genetic susceptibility for hemochromatosis is seen in approximately one in 250 Caucasians; however, fully expressed disease with end-organ manifestations is seen in fewer than 10% of these individuals<sup>[3]</sup>. Hemochromatosis patients mostly present with non-specific symptoms such as lethargy, arthralgia and weakness<sup>[25,26]</sup>. The other more commonly affected organ systems include liver, heart, pancreas, pituitary, skin and joints. Iron deposition in the conducting bundles and parenchyma of the heart result in cardiac arrhythmias and cardiomyopathy in 2%-19% of symptomatic patients<sup>[27,28]</sup>. Diabetes mellitus (DM) can be seen in up to 60% of symptomatic homozygotes but the rates of DM in asymptomatic patients are comparable to controls<sup>[7,29]</sup>. Endocrine dysfunction can occur as a result of iron deposition in pituitary and parathyroid glands<sup>[27,30]</sup>. Arthropathy is also observed in symptomatic and asymptomatic patients due to calcium pyrophosphate deposition in the articular cartilage, not iron sequestration and primarily involves the 2<sup>nd</sup> and 3<sup>rd</sup> metacarpophalangeal joints<sup>[25,31]</sup>.

## **MANAGEMENT AND TREATMENT**

Treatment for hemochromatosis with venesection (phlebotomy) has remained unchanged over the years<sup>[5]</sup>. Venesection as a treatment has two purposes: Directly reduce serum iron by depleting hemoglobin levels and to replace the depleted circulating serum iron by mobilizing iron stores from tissues. Early intervention, prior to the onset of symptoms, improves patient prognosis<sup>[32]</sup>. Furthermore, venesection in symptomatic individuals improves certain symptoms, such as skin pigmentation, while not having an effect on others such as cirrhosis and arthropathy<sup>[32]</sup>.

According to EASL clinical practice guidelines, the threshold of serum ferritin at which to start treatment is

currently taken as above the normal range. In regards to maintenance, the advocated standard practice is to maintain the serum ferritin at 50-100 µg/L and this is usually achieved with 3-6 mo of venesection<sup>[32]</sup>. It has been identified that the morbidity and mortality related to hereditary hemochromatosis can be greatly reduced by beginning treatment (phlebotomy) before the development of cirrhosis and/or diabetes. As a result of these findings, it is generally recommended that individuals at risk have prompt identification and pre-emptive treatment<sup>[32]</sup>. The pre-emptive treatment should be extended to involve those with homozygous HH that are asymptomatic and have markers of iron overload. Also, individuals with indications or evidence of increased level of hepatic iron should be treated. In summary, the American Association for the Study of Liver Disease recommends that in the absence of indicators suggestive of significant liver disease (alanine aminotransferase, aspartate transaminase elevation), C282Y homozygotes who have an elevated ferritin (but < 1000 µg/L) should proceed to prophylactic phlebotomy without a liver biopsy where target levels of phlebotomy should be a ferritin level of 50-100 µg/L<sup>[3,23,32]</sup>.

Traditionally, it was suggested that serum ferritin be maintained below 50 µg/L, but this has been updated to the range stated. Treatment guidelines also suggest yearly follow-up for the patients whose ferritin levels are at the normal range. This treatment strategy works for types 1-3 hereditary hemochromatosis but patients with type 4a may not tolerate venesection due to the irregular iron export from cells therefore treatment must be intermittent and is more complicated<sup>[32]</sup>.

Generally, 1 unit of blood is understood to contain approximately 200-250 mg of iron but the amount of iron that is removed each venesection can be variable<sup>[3]</sup>. It has been reported that on average, phlebotomy removes around 200-250 mg of iron per session<sup>[33]</sup>. Therefore, treatment must be provided on a personalized and case by case basis for each patient for appropriate venesection intervals and treatment regimens.

Although the treatment has remained the same for many years, there is still debate regarding the appropriate serum ferritin levels for maintenance of hemochromatosis. A recent study conducted by Bardou-Jacquet *et al*<sup>[6]</sup> found that early and sustained iron removal is beneficial as patients with serum ferritin levels between normal and 1000 µg/L, when treated, have reduced cardiovascular and extra-hepatic related mortality rates despite normal liver-related mortality rates. This study suggests that patients with even mild iron overload should be treated which builds on current management guidelines. However, this subject remains controversial.

## **CONCLUSION**

There is a continuing need to study the factors contributing to hemochromatosis due to the variable clinical penetrance of HFE mutations and the worldwide

prevalence of hemochromatosis in the absence of HFE mutations. Hemochromatosis has been divided into HFE-associated hemochromatosis related to mutations affecting iron transport and absorption and also HFE negative hemochromatosis or disease without HFE mutations. There is an incomplete understanding of the reasons for incomplete penetrance of disease phenotype in those with HFE mutations but recent research has revealed the presence of at least one other significant modifying genetic mutation<sup>[34]</sup>. Individuals at risk for hemochromatosis with genetic mutations and with or without symptomatic disease are recommended to pursue treatment at the earliest time possible and prior to any disease as this can help prevent further morbidity and mortality associated with hemochromatosis. Research advancement is opening doors for the management and treatment of iron overload as recent research has begun to develop the importance of treating mild iron overload due to its identified relation with reduced cardiovascular and extrahepatic related mortality rates.

## Abstract

**AIM:** To study the interleukin-1 (IL-1) pathway as a therapeutic target for liver fibrosis *in vitro* and *in vivo* using the ATP-binding cassette transporter b4<sup>-/-</sup> (Abcb4<sup>-/-</sup>) mouse model.

**METHODS:** Female and male Abcb4<sup>-/-</sup> mice from 6 to 13 mo of age were analysed for the degree of cholestasis (liver serum tests), extent of liver fibrosis (hydroxyproline content and Sirius red staining) and tissue-specific activation of signalling pathways such as the IL-1 pathway [quantitative polymerase chain reaction (qPCR)]. For *in vivo* experiments, murine hepatic stellate cells (HSCs) were isolated *via* pronase-collagenase perfusion followed by density gradient centrifugation using female mice. Murine HSCs were stimulated with up to 1 ng/mL IL-1 $\beta$  with or without 2.5  $\mu$ g/mL Anakinra, an IL-1 receptor antagonist, respectively. The proliferation of murine HSCs was assessed *via* the BrdU assay. The toxicity of Anakinra was evaluated *via* the fluorescein diacetate hydrolysis (FDH) assay. *In vivo* 8-wk-old Abcb4<sup>-/-</sup> mice with an already fully established hepatic phenotype were treated with Anakinra (1 mg/kg body-weight daily intraperitoneally) or vehicle and liver injury and liver fibrosis were evaluated *via* serum tests, qPCR, hydroxyproline content and Sirius red staining.

**RESULTS:** Liver fibrosis was less pronounced in males than in female Abcb4<sup>-/-</sup> animals as defined by a lower hydroxyproline content (274  $\pm$  64  $\mu$ g/g *vs* 436  $\pm$  80  $\mu$ g/g liver, respectively;  $n$  = 13-15;  $P$  < 0.001; Mann-Whitney  $U$ -test) and lower mRNA expression of the profibrogenic tissue inhibitor of metalloproteinase-1 (TIMP) (1  $\pm$  0.41 *vs* 0.66  $\pm$  0.33 fold, respectively;  $n$  = 13-15;  $P$  < 0.05; Mann-Whitney  $U$ -test). Reduced liver fibrosis was associated with significantly lower levels of F4/80 mRNA expression (1  $\pm$  0.28 *vs* 0.71  $\pm$  0.41 fold, respectively;  $n$  = 12-15;  $P$  < 0.05; Mann-Whitney  $U$ -test) and significantly lower IL-1 $\beta$  mRNA expression levels (1  $\pm$  0.38 *vs* 0.44  $\pm$  0.26 fold, respectively;  $n$  = 13-15;  $P$  < 0.001; Mann-Whitney  $U$ -test). No gender differences in the serum liver parameters [bilirubin; alanine aminotransferase (ALT); aspartate aminotransferase and alkaline phosphatase (AP)] were found. *In vitro*, the administration of IL-1 $\beta$  resulted in a significant increase in HSC proliferation [0.94  $\pm$  0.72 arbitrary units (A.U.) in untreated controls, 1.12  $\pm$  0.80 A.U. at an IL-1 $\beta$  concentration of 0.1 ng/mL and 1.18  $\pm$  0.73 A.U. at an IL-1 $\beta$  concentration of 1 ng/mL in samples from  $n$  = 6 donor animals;  $P$  < 0.001; analyses of variance (ANOVA)]. Proliferation was reduced significantly by the addition of 2.5  $\mu$ g/mL Anakinra (0.81  $\pm$  0.60 A.U. in untreated controls, 0.92  $\pm$  0.68 A.U. at an IL-1 $\beta$  concentration of 0.1 ng/mL, and 0.91  $\pm$  0.69 A.U. at an IL-1 $\beta$  concentration of 1 ng/mL; in samples from  $n$  = 6 donor animals;  $P$  < 0.001; ANOVA) suggesting an anti-proliferative effect of this clinically approved IL-1 receptor antagonist. The FDH assay showed this dose to be non-toxic in HSCs. *In vivo*, Anakinra had no effect on the hepatic hydroxyproline

content, liver serum tests (ALT and AP) and pro-fibrotic (collagen 1 $\alpha$ 1, collagen 1 $\alpha$ 2, transforming growth factor- $\beta$ , and TIMP-1) and anti-fibrotic [matrix metalloproteinase 2 (MMP2), MMP9 and MMP13] gene expression after 4 wk of treatment. Furthermore, the hepatic IL-1 $\beta$  and F4/80 mRNA expression levels were unaffected by Anakinra treatment.

**CONCLUSION:** IL-1 $\beta$  expression is associated with the degree of liver fibrosis in Abcb4<sup>-/-</sup> mice and promotes HSC proliferation. IL-1 antagonism shows antifibrotic effects *in vitro* but not in Abcb4<sup>-/-</sup> mice.

**Key words:** Cholestasis; Primary sclerosing cholangitis; The ATP-binding cassette transporter b4; Liver fibrosis; Interleukin-1

**Core tip:** Interleukin-1 (IL-1) critically participates in hepatic stellate cells (HSCs) pathophysiology and in the progression of liver injury to fibrosis. We found that fibrosis was more pronounced in female than in male ATP-binding cassette transporter b4<sup>-/-</sup> animals. This fibrosis was associated with higher IL-1 $\beta$  mRNA expression levels. We showed that IL-1 $\beta$  promoted the proliferation of murine HSCs and described an antifibrotic effect of the clinically approved IL-1 receptor antagonist Anakinra *in vitro*. Despite the promising antifibrotic effects *in vitro*, Anakinra failed to improve liver fibrosis in this preclinical primary sclerosing cholangitis model. Its potency in other models of liver injury and fibrosis remains to be determined.

Role of interleukin-1 and its antagonism of hepatic stellate cell proliferation and liver fibrosis in the Abcb4<sup>-/-</sup> mouse model. *World J Hepatol* 2016; 8(8): 401-410 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i8/401.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i8.401>

## INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease that is characterised by obliterative strictures of the intra- and extra-hepatic bile ducts. Because these strictures are associated with inflammation and fibrosis, PSC is supposed to be an immune-mediated liver disease. PSC primarily occurs in young adults and leads to liver cirrhosis with hepatic decompensation and portal hypertension and is frequently associated with malignancy of the biliary tract<sup>[1,2]</sup>. To date, there is no effective therapeutic option to halt disease progression. Thus, liver transplantation in end-stage liver disease is often required. The estimated median time for transplant-free survival may be as

short as 12 to 13 years at tertiary referral centres<sup>[1,3]</sup>. Therefore, new therapeutic targets need to be identified to establish an urgently required effective therapy for PSC.

PSC mainly affects the large bile ducts and causes periductal fibrosis<sup>[4]</sup>. This leads to obliteration of the bile ducts, resulting in impaired bile flow and cholestasis. During chronic cholestatic disease, toxic bile acids accumulate<sup>[5]</sup> and induce cholangio- and hepatocellular apoptosis by specific signalling pathways<sup>[6-8]</sup>. The clinical significance of cholangiocellular and hepatocellular apoptosis in patients with chronic cholestatic disease was recently supported by the detection of serum markers of liver cell apoptosis<sup>[9]</sup>.

Hepatocellular apoptosis is considered a trigger of liver fibrosis *via* the activation of hepatic stellate cells (HSCs)<sup>[10,11]</sup>. This results in the progression to liver fibrosis and cirrhosis in PSC.

HSCs are the major source of hepatic extracellular matrix deposition and crucially participate in the pathogenesis of liver fibrosis<sup>[12-14]</sup>. In addition to other factors, enhanced proliferation of this cell type is thought to be an important profibrotic mechanism<sup>[14]</sup>. In this regard, a recent study found that interleukin-1 $\beta$  (IL-1 $\beta$ ) induces the proliferation of rat HSCs<sup>[15]</sup>. Furthermore, IL-1 was identified as a factor in the progression of liver injury to fibrosis<sup>[16]</sup>. Therefore, we hypothesised that blocking the IL-1 pathway during liver fibrosis might be a therapeutic approach in chronic liver disease.

Anakinra is a clinically approved IL-1 receptor antagonist that is listed for the treatment of rheumatoid arthritis by the European Medicines Agency and the United States Food and Drug Administration. Its implication for the treatment of chronic liver disease and fibrosis has not been investigated thus far.

The ATP-binding cassette transporter b4<sup>-/-</sup> (Abcb4<sup>-/-</sup>) mouse is an established preclinical model for biliary fibrosis and PSC<sup>[17-19]</sup>. Therefore, this model is widely used to study therapeutic strategies for biliary fibrosis and PSC *in vivo*<sup>[20]</sup>.

Here, we tested the proliferative and pro-fibrotic properties of the IL-1 pathway *in vitro*, analysed its contribution to liver fibrosis in the Abcb4<sup>-/-</sup> model *in vivo* and tested the potential protective effects of the clinically approved IL-1 receptor antagonist Anakinra on the development of liver injury and fibrosis in this animal model.

## MATERIALS AND METHODS

### Animals

Animals were obtained from the Jackson Laboratory (United States) and Charles River (Germany). The animal protocol was designed to minimise pain or discomfort to the animals. The animals were housed at a 12/12 h light/dark cycle and were fed *ad libitum*. The animals were kept according to local regulations. The experiments were approved by local authorities. All

ethical, institutional and national guidelines for the care and use of laboratory animals were followed.

### Isolation and culture of primary murine HSCs

The isolation of primary murine HSC from female C57BL/6N wild-type animals was performed by pronase-collagenase perfusion followed by density gradient centrifugation in 13.2% Nycodenz<sup>®</sup> (Axis-Shield PoC, Norway)<sup>[21]</sup>. The cells were plated at a density of 25000 cells/cm<sup>2</sup>. The cells were kept in DMEM containing 10% fetal bovine serum and antibiotics (Sigma, Germany) in a humidified atmosphere with 5% CO<sub>2</sub> and 21% O<sub>2</sub> at 37 °C.

### Toxicity assay

To investigate the potential toxic effects of Anakinra on murine HSCs, we performed the fluorescein diacetate hydrolysis (FDH) assay according to the method of Jones *et al.*<sup>[22]</sup> after stimulation of murine HSCs for 24 h with 25 pg/mL to 2.5  $\mu$ g/mL Anakinra.

### Proliferation assay

The cells were stimulated with vehicle, 0.1 and 1 ng/mL IL-1 $\beta$  for 24 h at day three after isolation. Where indicated, the cells were co-incubated with 2.5  $\mu$ g/mL Anakinra. The proliferation of primary murine HSCs was measured using a BrdU-assay kit (Roche, Germany) according to the manufacturer's instructions.

### In vivo experiments

Available material from female and male Abcb4<sup>-/-</sup> mice was kindly provided by the Research Unit for Experimental and Molecular Hepatology, Graz, Austria (Fickert P and Trauner M). The material from 6- to 13-mo-old animals was studied.

Eight-week old female Abcb4<sup>-/-</sup> (FVB) mice received daily intraperitoneally injections of Anakinra (1 mg/kg body-weight, a dosage used previously for animal studies, corresponding to the recommended dose for the treatment of rheumatoid arthritis<sup>[23]</sup> or NaCl 0.9% as a control for 4 wk, a time period previously shown to be sufficient to identify the modulation of liver fibrosis in this model<sup>[20]</sup>. After narcotisation with isoflurane (Abbott GmbH, Germany), the animals were sacrificed by cervical dislocation.

### Quantitative real-time polymerase chain reaction

Quantitative real-time polymerase chain reaction was performed using a Sybr<sup>®</sup> green system. Glyceraldehyde-3-phosphate dehydrogenase or 18 s were used as housekeeping genes and were normalised against the means of the controls.

### Serum biochemistry

The levels of bilirubin, alkaline phosphatase (AP), aspartate aminotransferase (AST), and alanine aminotransferase (ALT) were analysed using the Cobas Integra 800 analyser (Roche Diagnostics, Germany) or the

Hitachi 917 analyser (Boehringer Mannheim, Germany).

### Quantification of hydroxyproline

The hydroxyproline content was determined according to the method of Edwards *et al.*<sup>[24]</sup>.

### Sirius-red staining

Liver samples were fixed using 4% formaldehyde. After embedding in paraffin, 4- $\mu$ m sections were stained with Sirius red.

### Immunohistochemistry

Ki-67 immunohistochemistry was performed using the polyclonal rabbit anti-Ki-67 antibody (Novocastra, Germany). The ABC system with AEC as a substrate was used for the detection of antibody antigen binding. The number of positively stained cells was counted per mouse in 20 randomly chosen fields at 40-fold magnification.

### Statistical analysis

Statistical calculations were performed using the SPSS 23 software package (IBM, United States). Where appropriate, the differences between groups were verified by the Mann-Whitney *U*-test.

Where appropriate, the analyses of variance (ANOVA) were calculated with the procedure UNIANOVA. The normality and homogeneity of the variances of the residuals were assessed by inspection of residual plots from the UNIANOVA procedure and P-P plots. Furthermore, Levene's test was used to assess the equality of error variances (for details, see also supplemental material). The results are reported as the means  $\pm$  SD. *P*-values less than 0.05 were considered to be statistically significant. The statistical analysis of this study was supported and reviewed by Christoph Glasmacher (Christoph Glasmacher - Biometrics and SAS-Programming for Clinical Research).

## RESULTS

### Gender differences in the liver disease of *Abcb4*<sup>-/-</sup> mice

Hepatic injury and liver fibrosis were evaluated in male and female *Abcb4*<sup>-/-</sup> animals from 6 to 13 mo of age. We found that the hepatic hydroxyproline levels were 37% lower in male animals than in female animals (Figure 1A; 274  $\pm$  64  $\mu$ g/g vs 436  $\pm$  80  $\mu$ g/g liver, respectively; *n* = 13-15; *P* < 0.001; Mann-Whitney *U*-test). Sirius red staining illustrated reduced collagen deposition in male animals (Figure 1B). In accordance with these findings, the livers of male animals showed 34% lower tissue inhibitor of metalloproteinase (TIMP-1) mRNA expression (Figure 1C; 1  $\pm$  0.41 vs 0.66  $\pm$  0.33 fold; *n* = 13-15; *P* < 0.05; Mann-Whitney *U*-test).

The mRNA expression of IL-1 $\beta$  and F4/80 as markers of hepatic-inflammation was 56% (Figure 1C; 1  $\pm$  0.38 vs 0.44  $\pm$  0.26 fold; *n* = 13-15; *P* < 0.001; Mann-Whitney *U*-test) and 29% lower (Figure 1C; 1  $\pm$  0.28 vs 0.71  $\pm$  0.41 fold; *n* = 12-15; *P* < 0.05; Mann-Whitney *U*-test) in the liver tissue of male animals than in the

liver tissue of female animals.

No gender differences were observed regarding the hepatic mRNA expression of collagen 1 $\alpha$ 1, cytokeratin 19 and monocyte chemotactic protein-1; *n* = 13-15; Mann-Whitney *U*-test).

Additionally, no gender differences in serum biochemistry were observed regarding the bilirubin, ALT, AST, and AP levels (data not shown; *n* = 17-21; Mann-Whitney *U*-test). Furthermore, there were no sex differences regarding hepatic mitotic activity in Ki-67 immunohistochemistry (data not shown; *n* = 15; Mann-Whitney *U*-test).

In summary, we identified a lower grade of liver fibrosis in male than in female animals as illustrated by lower hydroxyproline levels and lower hepatic mRNA expression levels of the profibrogenic gene TIMP-1. Furthermore, lower fibrosis in male animals was associated with the reduced mRNA expression of the pro-inflammatory genes IL-1 $\beta$  and F4/80. These findings may support a potential role of the IL-1 pathway in the progression of liver injury to liver fibrosis.

### IL-1 $\beta$ exerts proliferative effects in murine HSCs, while proliferation is reduced by the IL-1 receptor antagonist Anakinra *in vitro*

The importance of IL-1 $\beta$  in stellate cell proliferation was reported previously<sup>[15]</sup>. This work implicates inhibition of the IL-1 pathway as a potential target in the treatment of liver fibrosis. However, blockade of this target by the clinically available IL-1 receptor antagonist Anakinra has not been tested yet regarding HSC pathophysiology and liver fibrosis.

We addressed our *in vitro* experiments to investigate whether Anakinra could inhibit IL-1 $\beta$ -induced HSC proliferation.

In a first step, we evaluated the possible toxicity of Anakinra in primary murine HSCs using the FDH assay. This revealed no toxic effects of Anakinra at the tested doses, including the chosen dose of 2.5  $\mu$ g/mL (data not shown, *n* = 3).

Furthermore, we observed that IL-1 $\beta$  increased the proliferation of murine HSCs [Figure 2A; 0.94  $\pm$  0.72 (arbitrary units) A.U. in untreated controls, 1.12  $\pm$  0.80 A.U. at an IL-1 $\beta$  concentration of 0.1 ng/mL and 1.18  $\pm$  0.73 A.U. at an IL-1 $\beta$  concentration of 1 ng/mL in samples from *n* = 6 donor animals; general effect of IL-1 $\beta$  stimulation *P* < 0.001; control vs 0.1 ng/mL IL-1 $\beta$  *P* < 0.01; control vs 1 ng/mL IL-1 $\beta$  *P* < 0.001; ANOVA]. Due to the sufficient induction of HSC proliferation by IL-1 $\beta$ , the toxicity assay was not required for IL-1 $\beta$ .

Proliferation of murine HSCs was reduced significantly by treatment with 2.5  $\mu$ g/mL Anakinra (Figure 2B; 0.81  $\pm$  0.60 A.U. in untreated controls, 0.92  $\pm$  0.68 A.U. at an IL-1 $\beta$  concentration of 0.1 ng/mL, and 0.91  $\pm$  0.69 A.U. at an IL-1 $\beta$  concentration of 1 ng/mL; in sample from *n* = 6 donor animals; general effect of Anakinra: *P* < 0.001; effect of Anakinra without IL-1 $\beta$  stimulation: *P* < 0.01; effect of Anakinra with 0.1 ng/mL IL-1 $\beta$  stimulation: *P* < 0.01; effect of Anakinra with 1.0

**Figure 1** Gender differences in liver disease in ATP-binding cassette transporter *b4*<sup>-/-</sup> mice. Gender differences in liver fibrosis and liver inflammation were assessed with hydroxyproline measurement, Sirius red staining and quantitative real-time PCR in male and female *Abcb4*<sup>-/-</sup> mice between 6 and 13 mo of age. **A:** The hepatic hydroxyproline content of liver homogenates ( $\mu\text{g/g}$  liver) was lower in male animals than in female animals ( $n = 13-15$ ; <sup>b</sup> $P < 0.001$ ; Mann-Whitney *U*-test); **B:** Sirius-red staining illustrates the gender differences regarding fibrosis in *Abcb4*<sup>-/-</sup> mice. Images were taken from 9- to 10-mo-old animals (original magnification, 10 $\times$ ; bd: bile duct; pv: portal vein); **C:** Gene expression was assessed via quantitative real-time PCR and was normalised for 18 s as a housekeeping gene. Expressions were normalised against the means of female mice. The hepatic IL-1 $\beta$  and F4/80 mRNA expression levels as markers for hepatic inflammation were significantly lower in male *Abcb4*<sup>-/-</sup> mice than in female animals ( $n = 12-15$ ; <sup>b</sup> $P < 0.001$ ; <sup>a</sup> $P < 0.05$ ; Mann-Whitney *U*-test). The mRNA expression levels of the profibrotic gene TIMP-1 were also significantly lower in male *Abcb4*<sup>-/-</sup> mice than in female *Abcb4*<sup>-/-</sup> mice ( $n = 13-15$ ; <sup>a</sup> $P < 0.05$ ; Mann-Whitney *U*-test). PCR: Polymerase chain reaction; TIMP-1: Tissue inhibitor of metalloproteinase-1; *Abcb4*<sup>-/-</sup>: ATP-binding cassette transporter *b4*<sup>-/-</sup>; IL-1: Interleukin-1; CK19: Cytokeratin 19; MCP-1: Monocyte chemotactic protein-1.

ng/mL IL-1 $\beta$  stimulation:  $P < 0.001$ ; ANOVA), indicating a therapeutic effect of Anakinra on the proliferation of murine HSCs and, thereby, on liver fibrosis.

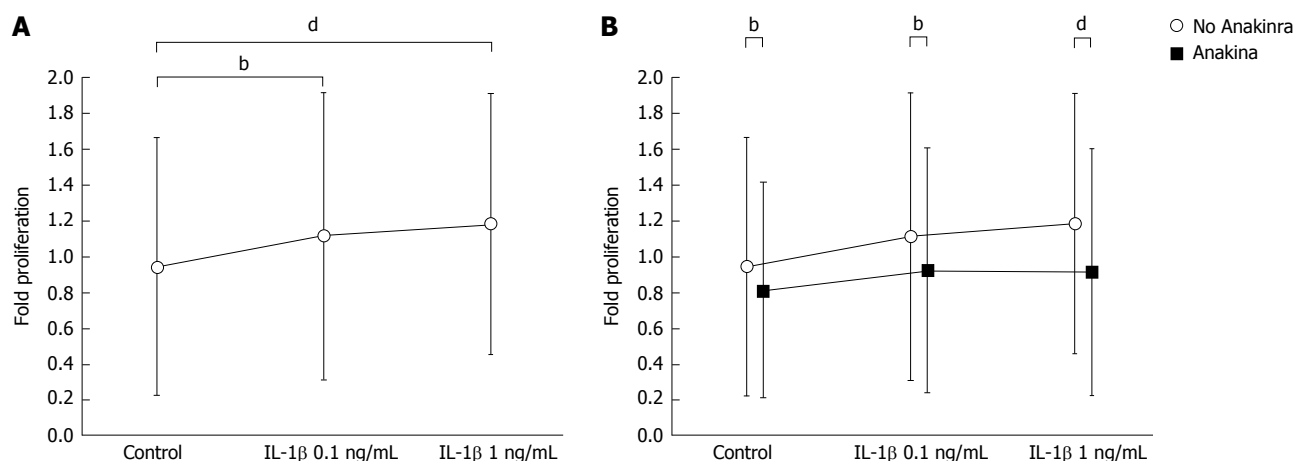

Taken together, Anakinra revealed promising anti-fibrotic effects *in vitro*.

#### **Anakinra has no therapeutic effects in *Abcb4*<sup>-/-</sup> mice**

The association of the degree of liver fibrosis and IL-1 $\beta$  expression in *Abcb4*<sup>-/-</sup> mice together with our *in vitro* data suggest a therapeutic effect of IL-1 antagonism on liver fibrosis *in vivo*. Therefore, we tested the therapeutic effects of Anakinra, a clinically approved

IL-1 receptor antagonist, on biliary fibrosis and hepatic injury in female *Abcb4*<sup>-/-</sup> mice.

The hepatic hydroxyproline levels as a marker of liver fibrosis were lower in untreated Wt animals than in untreated *Abcb4*<sup>-/-</sup> mice (Figure 3A;  $n = 11$ ;  $82 \pm 30 \mu\text{g/g}$  vs  $227 \pm 55 \mu\text{g/g}$  liver;  $P < 0.01$ ; Mann-Whitney *U*-test) but were unaffected by Anakinra treatment (Figure 3A;  $n = 10-11$ ; Mann-Whitney *U*-test). In accordance with this, we found differences regarding the serum parameters ALT (Figure 3A;  $89 \pm 87 \text{ U/L}$  vs  $454 \pm 133 \text{ U/L}$ ;  $n = 8-10$ ;  $P < 0.01$ ; Mann-Whitney *U*-test) and AP (Figure 3A;  $92 \pm 17 \text{ U/L}$  vs  $530 \pm 133 \text{ U/L}$ ;  $n$

**Figure 2** Interleukin-1 $\beta$  exerts proliferative effects in primary murine hepatic stellate cells, while Anakinra reduces hepatic stellate cell proliferation *in vitro*. The effects of IL-1 $\beta$   $\pm$  the IL-1 receptor antagonist Anakinra on the proliferation of murine HSCs were tested *in vitro*. A and B: The effects on HSC proliferation were examined using the BrdU assay after stimulation of cells with vehicle, and IL-1 $\beta$  at 0.1 and 1 ng/mL in the presence and absence of Anakinra (2.5  $\mu$ g/mL), respectively (samples from  $n = 6$  donor animals, <sup>b</sup> $P < 0.01$ ; <sup>d</sup> $P < 0.001$ ; ANOVA). HSC: Hepatic stellate cells; IL-1: Interleukin-1; ANOVA: Analyses of variance.

= 8-10;  $P < 0.01$ ; Mann-Whitney  $U$ -test) between the untreated Wt animals and Abcb4<sup>-/-</sup> mice but no effects of the treatment with Anakinra were observed (Figure 3A;  $n = 10-11$ ; Mann-Whitney  $U$ -test).

In a next step, we performed genetic profiling of fibrosis-related genes. Here, we found no influence of Anakinra on the profile of the profibrotic genes collagen 1 $\alpha$ 1, collagen 1 $\alpha$ 2, tissue growth factor- $\beta$ , and TIMP-1 (Figure 3B;  $n = 10-11$ ; Mann-Whitney  $U$ -test) between the groups.

In line with this finding, Anakinra treatment did not influence the expression of genes encoding the matrix-degrading enzymes matrix metalloproteinases 2, 9, and 13 (Figure 3C;  $n = 10-11$ ; Mann-Whitney  $U$ -test).

The mRNA expression levels of IL-1 $\beta$  and F4/80 as indicators of hepatic inflammation were also unaffected by Anakinra treatment (Figure 3D;  $n = 10-11$ ; Mann-Whitney  $U$ -test).

These missing antifibrotic effects were illustrated by Sirius red staining revealing no differences regarding periportal fibrosis (Figure 3E).

In summary, the *in vivo* administration of Anakinra showed no therapeutic effects on established fibrosis and hepatic injury in Abcb4<sup>-/-</sup> mice.

## DISCUSSION

Few treatment options are available to prevent disease progression to liver fibrosis and cirrhosis in chronic cholestatic liver disease such as PSC. In PSC, the frequently applied bile acid ursodeoxycholic acid (UDCA) failed to demonstrate a positive effect on the clinical outcome<sup>[25]</sup>, despite the beneficial effects of UDCA on serum biochemistry. Consequently, the American Association for the Study of Liver Disease no longer recommends the use of UDCA in PSC<sup>[2]</sup>. The loss of this therapeutic hope aggravates the need for an effective drug to treat PSC.

In the present study, we identified differences in

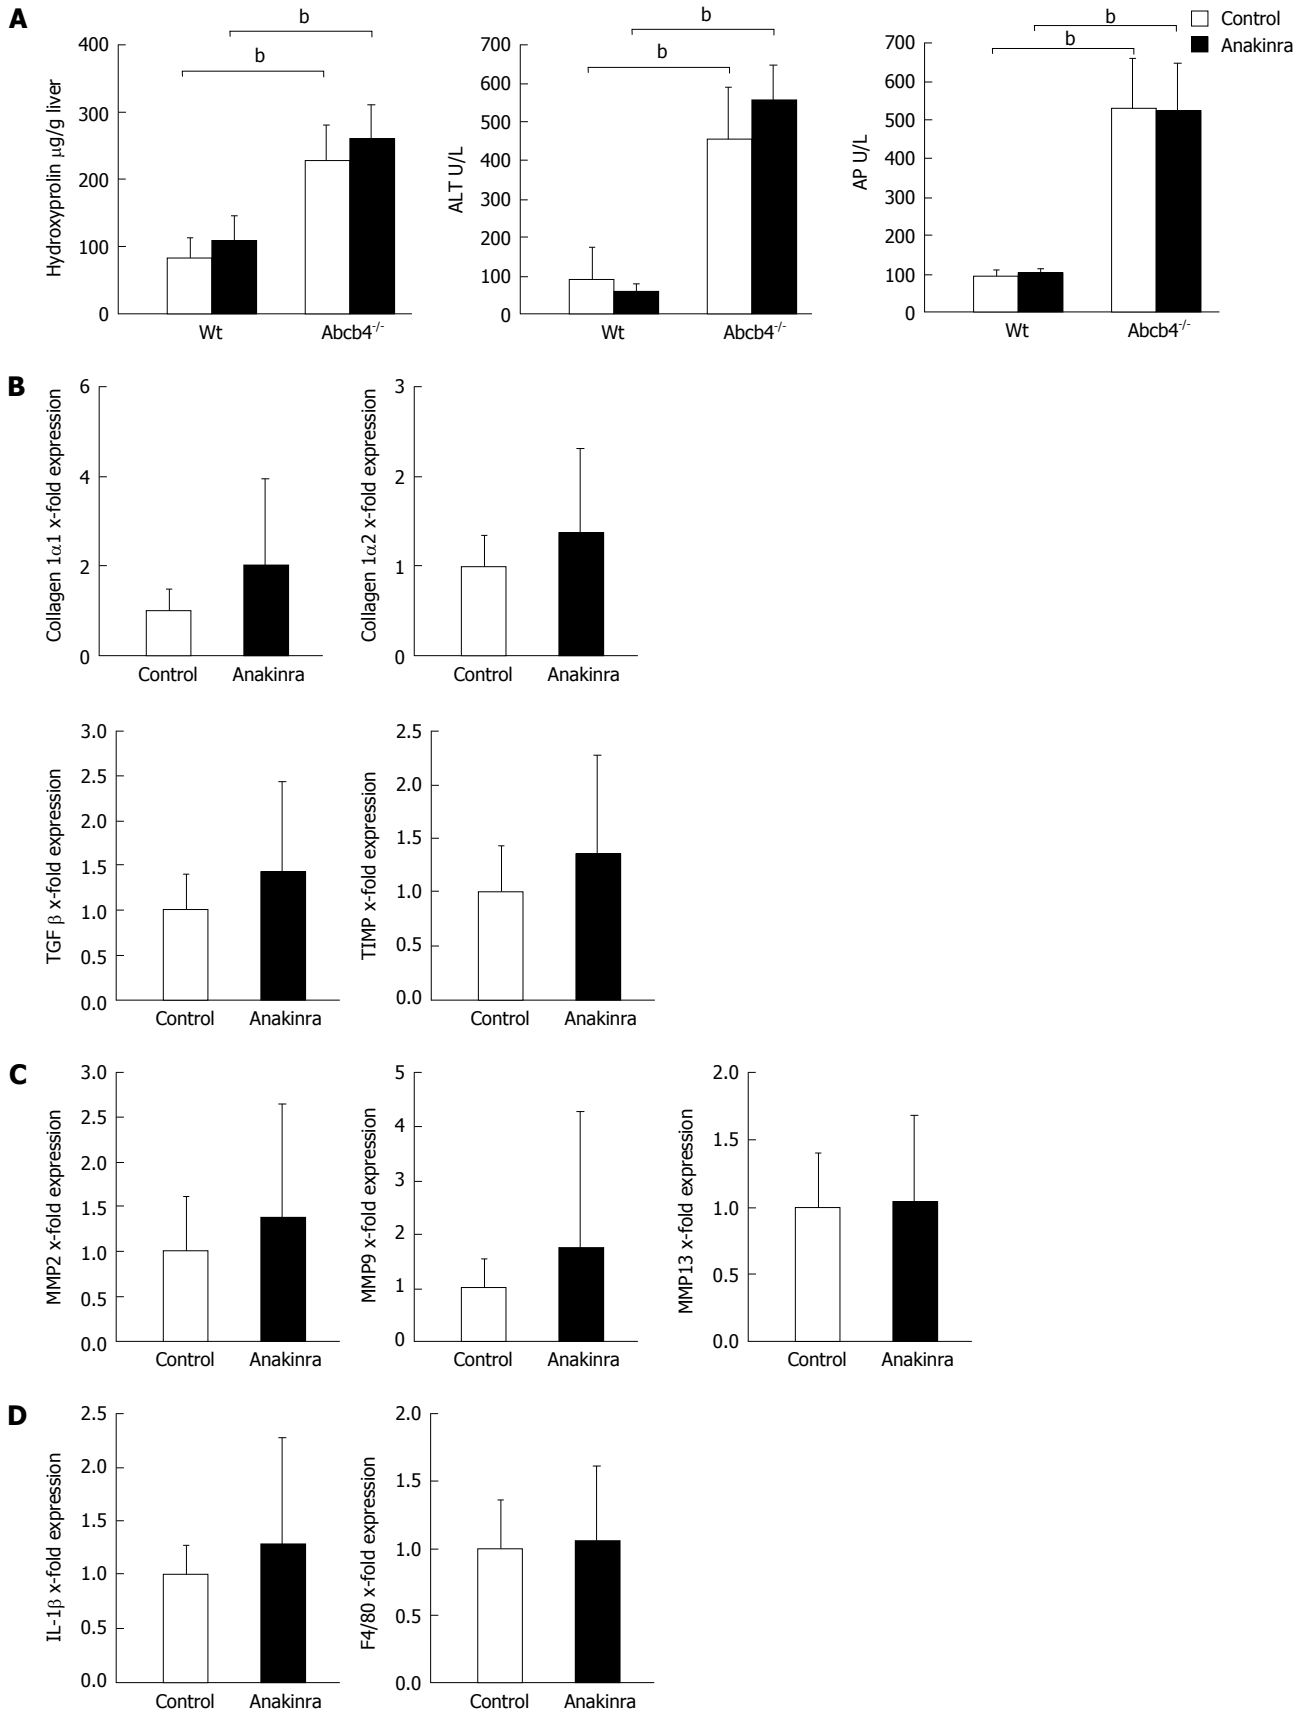

the levels of hepatic fibrosis between female and male Abcb4<sup>-/-</sup> mice. Hepatic fibrosis was more aggravated in female mice as assessed by the determination of the liver hydroxyproline content, a finding that is in line with that of previous studies, which identified a more severe histological phenotype in female animals<sup>[26]</sup>. Here, the pronounced phenotype in females was accompanied by higher mRNA expression levels of IL-1 $\beta$ , F4/80, and TIMP-1.

TIMP is a well-known profibrotic player in the regulation of matrix degradation during fibrogenesis and resolution *via* the inhibition of matrix metalloproteinases<sup>[27]</sup> but also *via* its anti-apoptotic effects on hepatic myofibroblasts<sup>[28,29]</sup>.

Therefore, the different TIMP levels might be a crucial factor for the observed gender differences in the degree of fibrosis. Hepatic inflammation, the role of chemokines, cytokines<sup>[30]</sup> and macrophages in the context of liver fibrosis are broadly discussed<sup>[31]</sup>. Macrophages may produce a wide spectrum of cytokines, including IL-1 $\beta$ , which are relevant for the pro-fibrogenic nature of HSCs<sup>[31-33]</sup>. Therefore, we hypothesised that the higher degree of fibrosis in female Abcb4<sup>-/-</sup> mice may be related to a more pronounced IL-1-driven hepatic inflammation and that the observed TIMP-1 alterations could reflect a consequence of inflammation. Thus, the IL-1 pathway might be a potential therapeutic target in PSC and fibrosis.

Supporting our hypothesis, we found that IL-1 $\beta$  stimulation exerts proliferative effects also on murine HSCs. These findings are in accordance with previously published data in rat HSCs<sup>[15]</sup>. Subsequently, we showed that the HSC proliferation was reduced by applying the clinically approved IL-1 receptor antagonist Anakinra. Because the proliferation of HSCs is a trigger of hepatic fibrosis<sup>[14]</sup>, these effects might be of consequence for disease progression *in vivo*.

In light of recently published data showing that IL-1 receptor antagonism ameliorates inflammasome-

**Figure 3** Anakinra does not reveal therapeutic effects on liver injury in ATP-binding cassette transporter b4<sup>-/-</sup> mice. Eight-week-old female Abcb4<sup>-/-</sup> animals were treated with daily intraperitoneal injections of saline (control) as vehicle or Anakinra (1 mg/kg body-weight) for 4 wk. A: The levels of hepatic hydroxyproline, alanine aminotransferase (ALT), and alkaline phosphatase (AP) were determined as described previously ( $n = 8-11$ ,  $^bP < 0.01$ ; Mann-Whitney *U*-test). Gene expression was assessed via quantitative real-time PCR using glyceraldehyde-3-phosphate dehydrogenase as the housekeeping gene. Data were normalised against the means of the controls (saline); B: No alterations in the profibrotic genes were found [ $n = 10-11$ ; not significant (n.s.); Mann-Whitney *U*-test]; C: No alterations in the antifibrotic genes were found ( $n = 10-11$ ; n.s.; Mann-Whitney *U*-test); D: Anakinra treatment did not result in a significant change in the mRNA expression of the pro-inflammatory gene IL-1 $\beta$  or F4/80 ( $n = 10-11$ , n.s., Mann-Whitney *U*-test); E: The Sirius-red staining illustrates the absence of antifibrotic effects (original magnification 10  $\times$ ). bd: Bile duct; pv: Portal-vein; PCR: Polymerase chain reaction; TIMP: Tissue inhibitor of metalloproteinase; Abcb4<sup>-/-</sup>: ATP-binding cassette transporter b4<sup>-/-</sup>; IL: Interleukin; MMP: Matrix metalloproteinase; TGF: Transforming growth factor.

dependent alcoholic steatohepatitis in mice<sup>[34]</sup>, our *in vitro* findings led us to test the efficacy of medical IL-1 receptor antagonism to prevent liver damage and fibrosis in the Abcb4<sup>-/-</sup> model.

We applied Anakinra at an established dose (1 mg/kg body-weight)<sup>[23]</sup> for 4 wk. This time span has been established to be sufficient to detect the therapeutic effects in the Abcb4<sup>-/-</sup> model<sup>[20,35]</sup>.

However, in the chosen setting, we found no effects on hepatic injury and fibrosis in this study. The serum markers of liver damage and cholestasis, as well as the analysis of liver tissue for fibrotic reaction, were unchanged.

This might be due to the distinctive pathophysiology of fibrosis in the Abcb4<sup>-/-</sup> model. The absence of phospholipids in Abcb4<sup>-/-</sup> mice results in a “toxic bile” constitution that leads to hepatic injury with scarring and obstruction of the biliary tree, finally causing cholestasis<sup>[36]</sup>. It is thought that portal myofibroblasts are primarily affected by the regurgitation of bile in this model<sup>[18]</sup>. These cells seem to rapidly acquire an activated phenotype in the early stages of biliary fibrosis<sup>[37]</sup> and might be the primary effectors of periportal fibrosis, which is the main type of fibrosis in the Abcb4<sup>-/-</sup> mouse<sup>[17,18]</sup>. This is also reflected by the previously observed increasing number in  $\alpha$ -SMA-positive cells per portal field of Abcb4<sup>-/-</sup> over time<sup>[18]</sup>. Our *in vitro* studies revealed the effects on HSCs, possibly might have different characteristics than portal myofibroblasts<sup>[37]</sup>. This could explain the missing transferability of the *in vitro* effects in HSCs on the *in vivo* situation in the Abcb4<sup>-/-</sup> model. Thus, it seems likely that the IL-1-dependent effects may be of pathophysiologic relevance in other types of hepatic fibrosis that are primarily caused by the activation and proliferation of perisinusoidal HSCs, a situation that might be different from cholestatic fibrosis. One might also suspect that

our results suggest that multiple pathways need to be considered for the therapeutic intervention of different types of liver fibrosis.

The observation that conventional immunosuppressive treatment has no therapeutic effect on PSC<sup>[2]</sup> is in accordance with the missing effects of our selective and putatively well-tolerable immunosuppressive approach by inhibition of the IL-1 pathway.

Taken together, this study demonstrated sex differences regarding hepatic inflammation and hepatic fibrosis in the Abcb4<sup>-/-</sup> model. Our *in vitro* experiments suggest the relevance of the IL-1 pathway in HSC proliferation and implicate the therapeutic potential of IL-1 antagonism. However, the treatment with the clinically approved IL-1 receptor antagonist Anakinra did not result in the amelioration of the hepatic phenotype in the Abcb4<sup>-/-</sup> model after 4 wk of treatment. Further studies might identify a therapeutic impact of this pathway in other types of liver fibrosis.

## ACKNOWLEDGMENTS

Parts of this work were presented at the annual meeting of the Bavarian Society for Gastroenterology 2015 in Garmisch-Partenkirchen. The statistical methods of this study were reviewed by Christoph Glasmacher, an external biostatistician (Christoph Glasmacher - Biometrics and SAS-Programming for Clinical Research).

## COMMENTS

### Background

Hepatic stellate cells (HSCs) are the major source of hepatic extracellular matrix deposition and crucially participate in the pathogenesis of liver fibrosis. In addition to other factors, enhanced proliferation of this cell type is thought to be an important profibrotic mechanism. In this regard, a recent study found that interleukin-1 $\beta$  (IL-1) $\beta$  induces the proliferation of rat HSCs. Furthermore, IL-1 was identified as a factor in the progression of liver injury to fibrosis.

Gender differences regarding hepatic injury in ATP-binding cassette transporter b4<sup>+</sup> (Abcb4<sup>+</sup>) mice were reported previously. However, differences in liver fibrosis were not evaluated in detail so far. In this study, the authors describe gender differences regard liver fibrosis in Abcb4<sup>+</sup> animals. Interestingly these findings are associated with coherent alterations of the IL-1 $\beta$  mRNA expression levels. Therefore, they hypothesised that the clinically approved IL-1 receptor antagonist Anakinra could reduce the proliferative effects of IL-1 $\beta$  in HSCs and improve fibrosis in Abcb4<sup>+</sup> mice. They also hypothesised that blocking the IL-1 pathway during liver fibrosis might be a therapeutic approach in this chronic cholestatic liver disease.

### Research frontiers

The proliferative effects of IL-1 $\beta$  on HSCs were described in former studies. However, a therapeutic approach via the clinically approved IL-1 receptor antagonist Anakinra was not investigated thus far regarding its efficacy in liver fibrosis.

### Innovations and breakthroughs

This is the first study to evaluate the efficacy of the clinically approved IL-1 receptor antagonist Anakinra on HSC proliferation *in vitro*. They report on the antiproliferative effects of this agent on HSC proliferation and identified a potential therapeutic approach. Furthermore, this study reported on gender differences regarding liver fibrosis in the Abcb4<sup>+</sup> mouse model.

### Applications

They *in vitro* findings support the importance of the IL-1 pathway in HSC proliferation. The effects of Anakinra on HSC proliferation suggest a therapeutic approach in liver fibrosis.

### Terminology

HSCs are the major source of hepatic extracellular matrix deposition and crucially participate in the pathogenesis of liver fibrosis. The Abcb4<sup>+</sup> mouse model is a preclinical model for primary sclerosing cholangitis and biliary liver fibrosis.

### Peer-review

This paper shows that the IL-1 signaling antagonist Anakinra can influence mouse HSC *in vitro* but not fibrosis in the Abcb4 mouse. Additional novel data is that female mice in this model are more affected than male mice.

## Abstract

**AIM:** To evaluate the efficacy of technical modifications of total hepatic vascular exclusion (THVE) for hepatectomy involving inferior vena cava (IVC).

**METHODS:** Of 301 patients who underwent hepatectomy during the immediate previous 5-year period, 8 (2.7%) required THVE or modified methods of IVC cross-clamping for resection of liver tumors with massive involvement of the IVC. Seven of the patients had diagnosis of colorectal liver metastases and 1 had diagnosis of hepatocellular carcinoma. All tumors involved the IVC, and THVE was unavoidable for combined resection of the IVC in all 8 of the patients. Technical modifications of THVE were applied to minimize the extent and duration of vascular occlusion, thereby reducing the risk of damage.

**RESULTS:** Broad dissection of the space behind the IVC coupled with lifting up of the liver from the retrocaval space was effective for controlling bleeding around the IVC before and during THVE. The procedures facilitate modification of the positioning of the cranial IVC cross-clamp. Switching the cranial IVC cross-clamp from supra- to retrohepatic IVC or to the confluence of hepatic vein decreased duration of the THVE while restoring hepatic blood flow or systemic circulation *via* the IVC. Oblique cranial IVC cross-clamping avoided ischemia of the remnant hemi-liver. With these technical

modifications, the mean duration of THVE was  $13.4 \pm 8.4$  min, which was extremely shorter than that previously reported in the literature. Recovery of liver function was smooth and uneventful for all 8 patients. There was no case of mortality, re-operation, or severe complication (*i.e.*, Clavien-Dindo grade of III or more).

**CONCLUSION:** The retrocaval liver lifting maneuver and modifications of cranial cross-clamping were useful for minimizing duration of THVE.

**Key words:** Total hepatic vascular exclusion; Retrocaval liver lifting maneuver; Oblique clamping; Switching the clamp; Hepatectomy

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Total hepatic vascular exclusion (THVE) is needed for resection of liver tumors involving inferior vena cava (IVC). Because THVE has a high risk of morbidity, compared to inflow occlusion alone, its duration should be shortened. The technical modifications reported here minimized the risk of damage of THVE. Specifically, the procedures include the retrocaval liver lifting maneuver, switching of the cranial IVC cross-clamp, and oblique IVC cross-clamping. For the 8 patients retrospectively assessed, the duration of THVE was  $13.4 \pm 8.4$  min, which was remarkably shorter than that reported previously. Postoperative recovery was smooth for all patients, without severe complications.

## INTRODUCTION

Despite recent advances in liver surgery, resection for tumors involving inferior vena cava (IVC) is still challenging<sup>[1-4]</sup>. This situation requires total hepatic vascular exclusion (THVE) for combined resection of the IVC. The THVE method was developed to control bleeding during hepatic parenchymal transection<sup>[5,6]</sup>; however, it is technically complicated and may cause profound liver damage and circulatory instability, and as a result inflow occlusion *via* Pringle's maneuver is more frequently used to control bleeding during usual hepatectomy, rather than THVE<sup>[7]</sup>. While THVE can effectively limit blood loss during hepatic parenchymal transection, especially that from hepatic veins<sup>[8,9]</sup>, its related rates of morbidity and mortality after hepatectomy for tumors involving IVC have been quite high<sup>[10,11]</sup>. Novel strategies to reduce the risk of damage and complications of THVE will benefit clinical practice and

patient outcome.

Long occlusion time is one of the most significant hazards of operative morbidity and mortality after hepatectomy with THVE<sup>[2]</sup>. There is no doubt about the importance of minimizing duration of THVE to reduce ischemic damage of the liver. Different from the procedure of portal triad clamping applied alone, addition of THVE necessitates taking into account both hepatic ischemia and instability of systemic circulation, including renal congestion. Selective hepatic vascular exclusion with hepatic venous occlusion preserving IVC flow is an alternative of THVE in usual hepatectomy<sup>[12,13]</sup>, but the method cannot be used for tumors involving IVC. Reports describing technical modifications aimed at minimizing hazards of THVE are available in the publicly available literature, but they are small in number<sup>[8,14]</sup>. Herein, we describe some technical modifications of THVE that were applied to patients in our hospital and which were found by retrospective analysis to have successfully minimized the duration and the extent of vascular occlusion. The purpose of reporting these results is to share these methods with clinicians and researchers in the field of hepatology so as to help reduce the rates of disastrous events during hepatectomy requiring THVE.

## MATERIALS AND METHODS

### Patients

From January 2010 to April 2015, 301 patients underwent hepatectomy at our hospital. Patients who underwent hepatectomy with THVE or modified THVE with IVC cross-clamping were selected for retrospective analysis, and those patients who had required only a small portion of the IVC to be resected without cross-clamping of the IVC were excluded from the study. A total of 8 patients (2.7% of the 301 hepatectomized patients) fit the criteria for inclusion, namely tumors involving IVC and treatment by combined resection of the IVC.

### Preoperative evaluation for indication of THVE

For all 8 patients, tumor status had been evaluated using three-phase contrast-enhanced computed tomography (CT). Contrast-enhanced magnetic resonance imaging (MRI) and/or (<sup>18</sup>F)-fluoro-D-glucose positron emission tomography had been performed in addition as necessary. The indication of THVE during hepatectomy was massive tumor involvement of IVC or tumor involvement of major hepatic vein extending to its confluence on IVC. Tumors that had been deemed as necessitating resection by side clamping of the IVC were excluded from the indication of THVE. THVE was not used merely for controlling bleeding from the parenchymal transection plane.

### Standard THVE procedures

By dissecting the coronary ligament around the suprahepatic IVC just below the diaphragm, the outer wall

**Table 1** Surgical procedures

Case No.	Diagnosis	No. of tumor	Size of the largest tumor, cm	THVE and modifications	THVE duration, min	Hepatectomy	Vascular reconstruction procedures	Outcome
1	HCC	1	20.0	Standard with switching <sup>1</sup>	5	Extended right hepatectomy	Direct suture of IVC	Alive without disease, 60 mo postoperative
2	Liver metastasis	1	20.0	Standard with switching <sup>1</sup>	9	Extended right hepatectomy	IMV patch for HV, Direct suture of IVC	Alive with disease, 17 mo postoperative
3	Liver metastasis	2	9.0	Standard with switching <sup>1</sup>	23	Extended right hepatectomy	IMV patch for HV and IVC	Alive with disease, 10 mo postoperative
4	Liver metastasis	1	6.0	Oblique <sup>2</sup> (right)	26	Right hepatectomy	IMV patch graft for IVC	Died of disease, 27 mo postoperative
5	Liver metastasis	4	2.5	Oblique <sup>2</sup> (right)	20	Partial resection	IMV patch graft for IVC and HV	Alive without disease, 15 mo postoperative
6	Liver metastasis	10	18.0	Oblique <sup>2</sup> (right)	7	Right hepatectomy, partial resection	Direct suture of IVC	Died of disease, 8 mo postoperative
7	Liver metastasis	15	5.5	Oblique <sup>2</sup> (right)	7	Extended anterior sectionectomy, partial resection	Direct suture of IVC	Died of disease, 9 mo postoperative
8	Liver metastasis	9	5.5	Oblique <sup>2</sup> (left)	10	Segmentectomy, partial resection	Direct suture of IVC and HVs	Alive without disease, 13 mo postoperative

<sup>1</sup>Switching the cross-clamp; <sup>2</sup>Oblique cross-clamping. IMV: Inferior mesenteric vein; IVC: Inferior vena cava; HVs: Hepatic veins; THVE: Total hepatic vascular exclusion.

of the IVC was made visible. Ligation and division of infradiaphragmatic veins had been made as necessary. For all 8 patients, the attachment between the liver and diaphragm was dissected, and the dorsal space of the suprahepatic IVC was dissected. Subsequently, the suprahepatic IVC was encircled gently and taped in preparation for cranial cross-clamping of the IVC. The infrahepatic IVC was also dissected circumferentially and encircled in preparation for caudal cross-clamping. Principally, THVE was not applied before completion of hepatic parenchymal transection. The final step of resection involved clamping of the caudal and cranial IVC prior to the resection and reconstruction of the involved IVC *via* THVE.

#### Other surgical procedures

The abdomen was opened *via* J-shape incision that included upper median and right oblique incisions. Tumor status and the relation between the tumors and major intrahepatic vasculature were confirmed by intraoperative ultrasonography. The liver was mobilized to the extent necessary for the planned surgery. The hepatic parenchyma was transected using the clamp-crushing method. Thin vessel branches were burned by electrocautery or soft coagulation devices. Thicker branches were ligated and divided. Intermittent Pringle's maneuver was applied routinely during the hepatic parenchymal transection using a 15-min/5-min period of clamping and release.

#### Evaluation of operative morbidity and mortality

The recorded postoperative complications were classified according to severity by using the Clavien-Dindo criteria (grades I - V). Hepatic failure was defined as serum level of total bilirubin > 5.0 mg/dL (equal to 85.5  $\mu$ mol/L) at postoperative day 5 or later. Operative mortality was defined as all in-hospital deaths and death

within 90 d after surgery.

#### Follow-up schedule and adjuvant chemotherapy

Follow-up after discharge involved CT or MRI evaluation every 4-6 mo and blood testing and physical examination every 1-6 mo for a total period of 5 years after the last intervention.

#### Statistical analysis

All numerical values were calculated as mean and SD or median and range.

## RESULTS

The 8 patients included in this analysis consisted of 6 men and 2 women, with median age of 72-years-old (range: 36-78 years). Seven of the patients had a diagnosis of colorectal liver metastases and 1 had a diagnosis of hepatocellular carcinoma (Table 1). The mean diameter of the total resected tumors was  $10.8 \pm 7.3$  cm. All patients had tumors involving the IVC, with or without confluence of the hepatic veins as shown in Figure 1.

The surgical procedures used for all 8 patients are listed in Table 1. For all, the initial surgical step was broad dissection of the space behind the IVC, after which the liver was lifted up by the surgeon's left hand to move it from the retrocaval space in order to control bleeding before and during THVE (retrocaval liver lifting maneuver). Standard THVE was applied to 3 patients (cases 1-3), for which the cranial cross-clamp for THVE was switched from the suprahepatic to retrohepatic levels or to the confluence of the major hepatic vein to shorten the duration of THVE (switching the cross-clamp). For the remaining 5 patients (cases 4-8), total ischemia of the whole liver was avoided by applying the

**Figure 1** Abdominal computed tomography scan images of cases 1-4. A: Case 1: Lumen of the IVC compressed by a huge right liver tumor with expansive growth; B: Case 2: A large right liver tumor involving the right aspect of the IVC and the confluence of middle and left hepatic veins; C: Case 3: Two tumors were present, a right liver tumor involving the right portal vein and the portal vein bifurcation, and another tumor occupying the cranial part of segments 4 and 8 and involving the left aspect of the trunk of the middle and left hepatic veins; D: Case 4: A tumor involving the right dorsal aspect of the IVC and its confluence of the right hepatic vein. IVC: Inferior vena cava.

cranial clamp obliquely to maintain the hepatic venous outflow of the liver remnant (oblique cross-clamping). Detailed descriptions of these techniques are provided below.

### Technical modifications for THVE

**Retrocaval liver lifting maneuver:** The liver cannot be detached from the IVC when the tumor involves the IVC. Instead, the retrocaval space behind the hepatic IVC should be dissected broadly to facilitate performance of standard or modified THVE (Figure 2A and B). In all 8 patients of this study, the IVC was compressed ventrally and the liver was lifted up from the retrocaval space by the surgeon's left hand (Figure 2C and D). This maneuver was quite useful for controlling bleeding during transection of the hepatic parenchyma near the IVC. With the help of this maneuver parenchymal transection can be completed safely before applying THVE, as shown in Figure 2D. The THVE procedure was applied at the last step of the combined resection and reconstruction of IVC, with the involved part of the IVC excised en-bloc with the liver specimen (Figure 2E). Theoretically, no bleeding should come from the IVC under THVE, but a significant amount of backflow bleeding often comes from the cut orifice of IVC during THVE. For all 8 patients in this study, compressing the IVC upward from the retrocaval space, by means of

the surgeon's left hand, was effective for controlling backflow bleeding from the cut orifice of the IVC under THVE (Figure 2E).

**Switching the cross-clamp:** Standard THVE cannot be avoided for combined resection of IVC involving the major hepatic vein of the liver remnant, as was performed in case 3 of this study (Figure 3A). After removal of the specimen and completion of the repair of the IVC under standard THVE, the position of the cranial IVC cross-clamp was switched from the suprahepatic IVC to the IVC confluence of the resected hepatic vein to be reconstructed (Figure 3C). Then, the IVC blood flow was restored to stabilize systemic hemodynamics.

Another surgical situation in this study involved switching of the cross-clamp of the suprahepatic IVC to the retrohepatic level, as performed in case 1. The tumor status is shown in Figure 1A. At the first step of this intervention, standard THVE was applied for resection of large hepatocellular carcinoma that involved retrohepatic IVC massively. Both the tumor and the involved wall of the IVC were resected under standard THVE. After repairing the IVC defect around the confluence of the hepatic vein, the suprahepatic IVC cross-clamp was switched to the level just below the hepatic vein confluence. Then, the portal triad occlusion was released to restore the blood flow of the liver remnant, after which

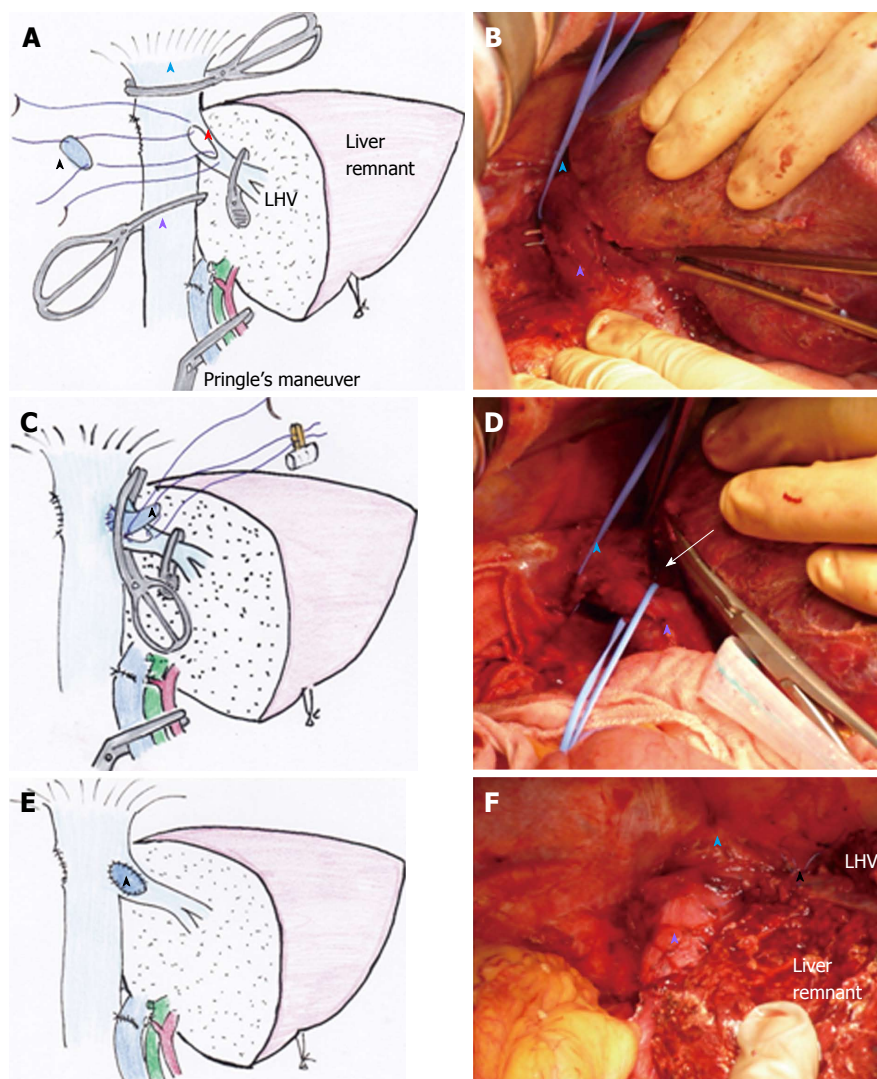

**Figure 2 Retrocaval liver lifting maneuver, performed in case 2.** A (illustration) and B (intraoperative image): The retrocaval space (arrow) was dissected broadly from the right lateral view toward the inner aspect of Spiegel's lobe (black arrowhead), after which the supra- and infrahepatic IVC were taped to prepare cross-clamping for THVE (blue arrowhead and purple arrowhead); C (illustration) and D (intraoperative image): The index and middle fingers of the surgeon's left hand were placed into the dissected retrocaval space, and the IVC was compressed ventrally to control bleeding around the IVC during deep parenchymal transection, after which the thumb finger of the surgeon's left hand was used to spread the transection plane of the liver (C, which also shows the tumor status); D: Hepatic parenchymal transection is completed, except for the IVC involved site, before applying THVE; E (illustration) and F (intraoperative image): The liver specimen was excised along with the involved IVC and LHV wall (red arrowheads), and the backflow bleeding from the cut orifice of IVC was controlled by pinching the IVC using the surgeon's left hand from its placement in the retrocaval space; F shows the view after reconstruction of IVC and LHV. See Figure 1B for tumor status. IVC: Inferior vena cava; LHV: Left hepatic vein; THVE: Total hepatic vascular exclusion.

the retrohepatic IVC was repaired without prolonging the ischemic time of the liver.

**Oblique cranial cross-clamping:** When the space between the right and middle hepatic veins is free from involvement, venous drainage of the residual liver can be preserved during vascular exclusion by applying the cranial cross-clamping obliquely (Figure 4A). For this purpose, the retrocaval space must be dissected sufficiently in advance, same as shown in Figure 2A. Prior to this step, hepatic parenchymal transection had been completed to facilitate visualization of the anterior aspect of the hepatic IVC (Figure 4A and B). In the next step,

the vascular clamp was inserted behind the IVC obliquely, preserving the outflow orifice of the hepatic vein of the liver remnant (Figure 4A and B). By applying this modification of the THVE procedure, ischemic damage was avoided, as was intestinal congestion. In patients of this study for whom the right liver tumor involved the IVC massively around the orifice of right hepatic vein (RHV) (as in cases 4-7), the cranial IVC cross-clamp was applied from the right cranial side to the left caudal side of the IVC to allow venous drainage of the trunk of middle and left hepatic veins (MHV + LHV) (Figure 4A). In patients of this study for whom the left liver tumor involved the trunk of MHV + LHV (as in case 8), the

**Figure 3 Switching the cross-clamp, performed in case 3.** A (illustration) and B (intraoperative image): The right liver and involved right wall of the LHV and a part of the IVC wall had been resected en-bloc under standard THVE (red star indicates the orifice of resected IVC and LHV), before which the suprahepatic IVC was taped (blue arrowhead, blue tape), and the caudal cross-clamp was placed just under the confluence of LHV to the retrocaval space that had been already dissected (B). The defect of the confluence of the IVC and LHV was to be reconstructed by using an IMV patch graft (black arrowhead); C (illustration) and D (intraoperative image): After suturing the IMV patch graft to the IVC part of the defect, the IVC cross-clamps were removed and the clamp was switched to the confluence of the LHV to restore the systemic circulation via the IVC. The space for switching the clamp was spread by the caudal blue tape (white arrow in D); E (illustration) and F (intraoperative image): The view after reconstruction is shown. See Figure 1C for tumor status. IMV: Inferior mesenteric vein; IVC: Inferior vena cava; LHV: Left hepatic vein; THVE: Total hepatic vascular exclusion.

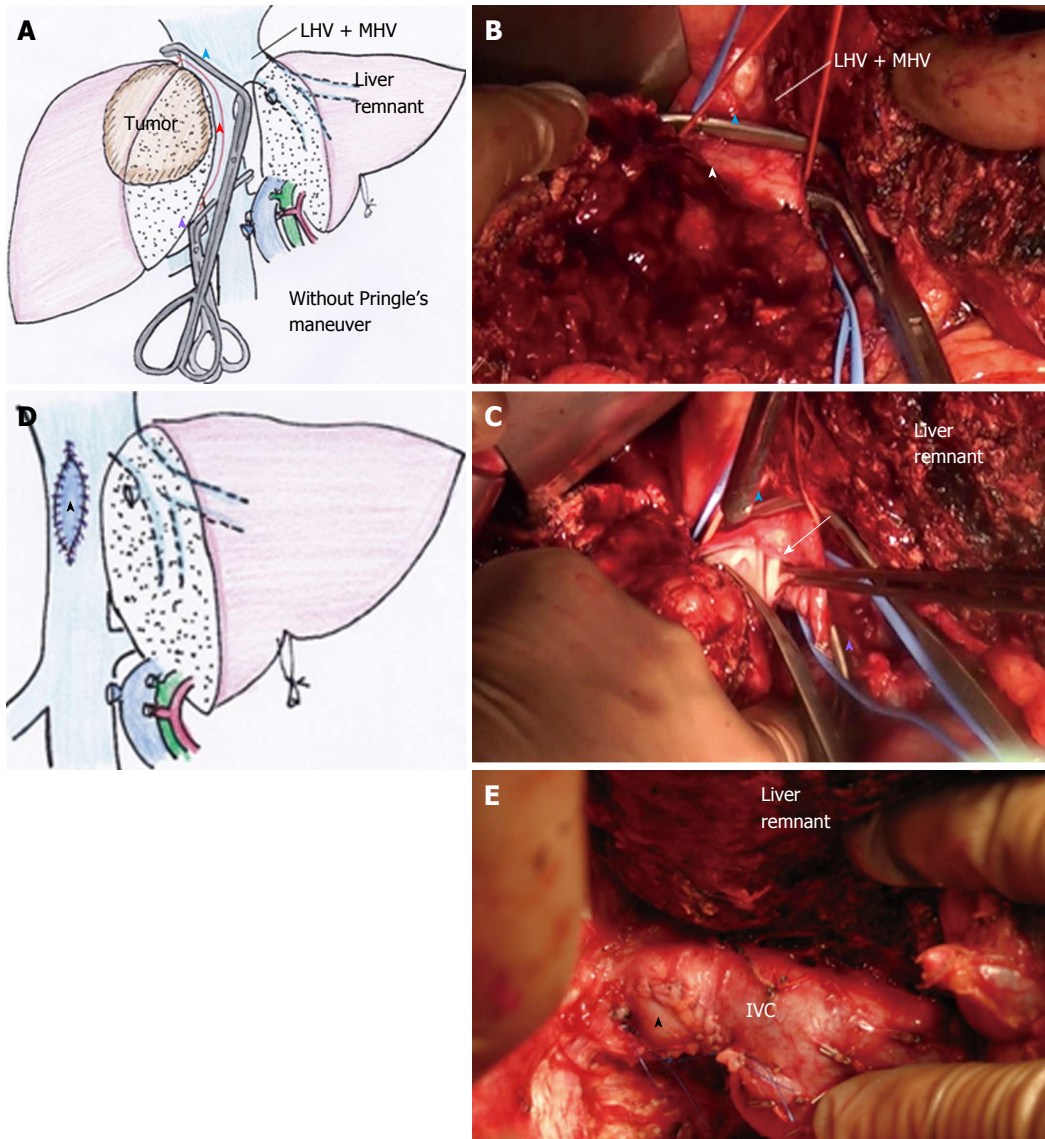

clamp was applied from the left cranial line to the right caudal line to preserve the outflow of the RHV. In the 5 patients who represented these two special situations, the THVE duration presented in Table 1 equates to the occlusion time of oblique cross-clamping of the IVC.

#### Operative parameters and postoperative course

The mean values of the operative parameters for the total 8 patients in this study are presented in Table 2. In no case did the THVE time exceed 30 min. Results from biochemical liver function tests and prothrombin time indicated the smooth recovery of liver function during the first postoperative week. In no case did the maximum serum total bilirubin level exceed 5 mg/mL, and no patient developed liver failure. For all of the

patients, the serum total bilirubin levels gradually decreased during the first postoperative week to below 2 mg/mL (equal to 34.2  $\mu$ mol/L) by day 7. No patient showed a prothrombin time less than 50% at any time during the postoperative period. In addition, no patient experienced a complication of Clavien-Dindo grade III or higher and there was no case of operative mortality. The postoperative complications that occurred included leg edema, pleural effusion, refractory ascites, and wound infection ( $n = 1$  each). No patient required reoperation, subsequent surgical or radiological interventions, or management in the intensive care unit, and all patients were discharged within a month after the surgery. All of the reconstructed vessels remained patent through the end of follow-up.

**Figure 4 Oblique cranial cross-clamping, performed in case 4.** A (illustration) and B (intraoperative image): The trunk of LHV + MHV was free from tumor involvement, while the right aspect of the IVC was involved extensively (red arrowhead). After completion of hepatic parenchymal transection, the cranial IVC cross-clamp (blue arrowhead) was applied obliquely between the tumor-involved IVC and the trunk of LHV + MHV preserving outflow of the LHV + MHV trunk, which was possible because the retrocaval space had been dissected sufficiently. Then, the involved IVC wall (white arrowhead in B) and the liver was resected *en-bloc* under modified THVE; C (intraoperative image): The involved IVC wall was cut away with scissors (arrow) between the oblique cranial (blue arrowhead) and caudal (purple arrowhead) cross-clamps; D (illustration) and E (intraoperative image): The large cut orifice of IVC was reconstructed with IMV patch graft (black arrowhead). See Figure 1D for tumor status. IMV: Inferior mesenteric vein; IVC: Inferior vena cava; LHV: Left hepatic vein; THVE: Total hepatic vascular exclusion.

### Survival

All patients returned to usual active life after discharge. The 1-year survival rate was 71%. Individual outcomes for each patient are presented in Table 1. At the date of this report, case 1 was alive without disease (5 years after surgery) and cases 6 and 7 presented with early multiple tumor recurrence in the liver remnant and died of rapid progression at 8 and 9 mo respectively.

### DISCUSSION

Liver tumors involving IVC or its junction of major hepatic veins represent situations in which THVE is needed for curative resection. Such surgery is fraught

with challenges, including unstable systemic circulation, ischemic damage of the liver and high risk of morbidity. Minimizing the duration and extent of exclusion is key to increasing the safety of THVE<sup>[2]</sup>. To this end, the present study highlights the feasibility of three technical modifications of THVE. The techniques include: (1) retrocaval liver lifting maneuver; (2) switching the cross-clamp; and (3) oblique cranial cross-clamping, which minimized duration of THVE and ischemic damage of the liver. It is noteworthy that application of these modified techniques minimized occlusion time; in addition, recovery of liver function was smooth, no severe complication developed, and operative mortality was not experienced. These operative results are quite favorable,

**Table 2** Operative parameters and postoperative course of 8 patients

Parameters	Values or number of patients
Operation time	482 ± 108 min

particularly when compared to those reported by other studies<sup>[1-3,8,10,11]</sup>.

To date, only a limited number of studies of THVE for resection of liver tumors involving IVC are present in the publicly available literature, probably because the number of experiences in individual institutes has been small. The most distinctive features of the present study are the extremely short duration of THVE and favorable recovery after surgery. While the mean durations of THVE were 29 min to 78 min in the reports from very experienced institutes<sup>[1,2,7,8]</sup>, the mean THVE duration in the present study was only 13.4 ± 8.4 min. The mortality rates of hepatectomy with IVC resection were 4.5% to 25% in the previous reports<sup>[1-4,8,10,11,15]</sup>. In particular, the morbidity and mortality rates were quite high when standard THVE was applied frequently, even when hypothermic perfusion was used to attenuate the ischemic liver damage. In the previous reports, the major causes of mortality were liver failure and sepsis<sup>[1,3,4,8,11]</sup>, both of which are likely to be relevant to ischemic injury of the liver and intestinal congestion since they may facilitate bacterial translocation. Of course, simple comparison to the present case series is not possible due to the differences in severity of tumor status and underlying conditions. Nevertheless, minimized duration of THVE might have contributed to the favorable postoperative course in the present study.

Hand manipulation of the IVC from the broadly dissected retrocaval space is a unique method to decrease bleeding around the IVC. This procedure is also essential

as a preparation for modifying the THVE procedure to improve its safety. When the tumor involves the IVC, the liver cannot be freed from the IVC and Belghiti's liver hanging maneuver is not possible (and is rather a contraindication)<sup>[16]</sup>. In such a situation, wide dissection of the retrocaval space makes subsequent procedures safer. Lifting-up the liver by hand from the retrocaval space proved quite useful to control bleeding from the hepatic parenchyma near the IVC and backflow bleeding from the cut orifice of the IVC during THVE. Although no bleeding is supposed to come from the IVC under THVE theoretically, significant amount of backflow bleeding, which occurs frequently, serves to disrupt and complicate the vascular reconstruction procedure of IVC. Sources of such backflow bleeding are lumbar veins, short hepatic veins, or small venous branches that extend into the major hepatic veins. Even with portal triad occlusion by Pringle's maneuver, blood flow into the liver from the diaphragm or lesser omentum can exist. Compressing the IVC by hand, from the retrocaval space, was shown in the present study to be quite useful and the only way to control backflow bleeding during THVE.

The damage associated with THVE includes both systemic circulatory instability (due to absence of venous return *via* the IVC) and total cessation of hepatic blood flow. These conditions cause congestion of the kidney and intestine, which may explain why the damage and morbidity after THVE is much higher than that experienced after inflow occlusion alone<sup>[7]</sup>. In the current study, when the cranial IVC cross-clamp was switched from the supra- to the retrohepatic IVC (as performed in case 1), blood flow of the liver remnant was restored, thereby shortening the ischemic time of the liver remnant and intestine. When the clamp was switched to the confluence of hepatic vein of the liver remnant (as performed in case 3), IVC blood flow was restored, thereby resolving the systemic circulatory instability and renal congestion.

Oblique cranial IVC clamping is an option of standard THVE to avoid ischemic damage of the liver remnant as well as intestinal congestion; yet, this technique has not been precisely described in the literature. Even in the series of patients in this study with tumors with massive IVC involvement, the hepatic vein of the liver remnant side was free from involvement in many of the cases, and this is reported in other studies as well<sup>[1,8]</sup>. Such a situation is good indication for oblique cross-clamping. Sufficient dissection of the retrocaval space and completion of hepatic parenchymal transection in advance are essential for application of this method.

The timing of applying THVE may be one of the most important issues underlying its efficacy and safety. In most of the studies reported in the literature, THVE was applied during both parenchymal transection and combined resection/reconstruction of IVC<sup>[1,7,8]</sup>. This might be one of the reasons for the characteristic long occlusion time in the studies previous to ours. The primary policy of our hospital, however, is to make

every effort to minimize the duration of THVE. Because the retrocaval liver lifting maneuver makes it possible to complete the hepatic parenchymal transection without much bleeding, THVE was applied at the final step only for IVC resection and reconstruction. We believe that its success depends primarily on the procedures that had been applied prior to the application of THVE, including sufficient dissection of the retrocaval space and smooth completion of the hepatic parenchymal transection.

The small number of included patients may be a limitation of the present study. In general, the number of patients requiring THVE for hepatectomy with IVC reconstruction is rather small for a single institute, such as ours, as reflected in the previous studies<sup>[1-4,10,11,15]</sup>. The accumulated literature on this topic includes no reports that provide a definitive description of modified procedures of THVE, especially the retrocaval liver lifting maneuver and oblique cranial cross-clamping that are described here for the first time. These techniques can be strategies to decrease the risk of disastrous bleeding and ischemic liver damage. Sharing these data with other surgeons will serve to increase the safety and feasibility of surgery for liver tumors involving IVC.

In conclusion, the retrocaval liver lifting maneuver and modifications of IVC cross-clamping are useful to attenuate damage related to THVE. The knowledge and techniques that have arisen from the current analysis of our case series may help to improve the surgical techniques and outcomes for advanced liver tumors involving IVC.

## COMMENTS

### Background

Total hepatic vascular exclusion (THVE) is needed during hepatectomy for liver tumors involving inferior vena cava (IVC). However, THVE carries a much greater risk than inflow occlusion alone.

### Research frontiers

The authors performed technical modifications that shortened the duration of THVE, thereby reducing the risk of damage.

### Innovations and breakthroughs

The technical modifications described in this study for THVE included the retrocaval liver lifting maneuver, switching of the cranial IVC cross-clamp, and oblique cranial IVC cross-clamping. With these techniques, the mean duration of THVE was shortened remarkably, compared to that reported in the past literature. Moreover, postoperative recovery of liver function was smooth without any severe complications.

### Applications

The retrocaval liver lifting maneuver and modifications of cranial cross-clamping minimized the duration of THVE. Thus, these techniques might help to decrease risk of liver damage and increase likelihood of favorable postoperative courses in patients who undergo hepatectomy requiring THVE.

### Terminology

THVE is a method to control bleeding during hepatectomy by occluding both inflow and outflow of the liver. THVE is required especially for resection of liver tumors involving IVC.

## Peer-review

The authors suggest some technical modifications of the THVE. The study is clearly planned and correctly managed. The technical details of the three variations are clearly explained as well as the figures.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Fan Zhu, PhD, Professor, Department of Medical Microbiology, Medical School of Wuhan University, Wuhan 430072, Hubei Province, China

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

## Abstract

Hepatocellular carcinoma (HCC) is the leading cause of deaths in cirrhotic patients and the third cause of cancer related deaths. Most HCC are associated with

well known underlying risk factors, in fact, HCC arise in cirrhotic patients in up to 90% of cases, mainly due to chronic viral hepatitis and alcohol abuse. The worldwide prevention strategies are conducted to avoid the infection of new subjects and to minimize the risk of liver disease progression in infected patients. HCC is a condition which lends itself to surveillance as at-risk individuals can readily be identified. The American and European guidelines recommended implementation of surveillance programs with ultrasound every six months in patient at-risk for developing HCC. The diagnosis of HCC can be based on non-invasive criteria (only in cirrhotic patient) or pathology. Accurately staging patients is essential to oncology practice. The ideal tumour staging system in HCC needs to account for both tumour characteristics and liver function. Treatment allocation is based on several factors: Liver function, size and number of tumours, macrovascular invasion or extrahepatic spread. The recommendations in terms of selection for different treatment strategies must be based on evidence-based data. Resection, liver transplant and interventional radiology treatment are mainstays of HCC therapy and achieve the best outcomes in well-selected candidates. Chemoembolization is the most widely used treatment for unresectable HCC or progression after curative treatment. Finally, in patients with advanced HCC with preserved liver function, sorafenib is the only approved systemic drug that has demonstrated a survival benefit and is the standard of care in this group of patients.

**Key words:** Hepatocellular carcinoma; Surveillance; Staging system; Radiofrequency ablation; Liver surgery; Liver transplant; Transarterial chemoembolization

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Liver cancer is the fifth leading cause of cancer worldwide, and the third-leading cause of cancer death. Although some risk factors have been classically associated with development of hepatocellular carcinoma (HCC), in the last years, also, some protective factors

have been described, like coffee drink, and drugs like statins and beta-blockers. The current European Association for the Study of Liver and American Association for the Study of Liver Diseases guidelines recommended the barcelona clinic liver cancer classification as staging system for prognosis prediction and treatment allocation. The therapeutic approach in patients with HCC depends on factors such as liver function, tumour extension and comorbidities existence. Available treatments are: Surgical treatments, percutaneous ablation, chemoembolization, radioembolization and systemic treatment.

Pascual S, Herrera I, Irurzun J. New advances in hepatocellular carcinoma. *World J Hepatol* 2016; 8(9): 421-438. Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i9/421.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i9.421>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the leading cancer in the world. It is an important health problem especially in high incidence areas. Nowadays the global incidence is still growing, but with the development of hepatitis B vaccine and the new therapies in hepatitis C virus (HCV), a gradual decline in the incidence is expected in the next decades. Another important issue is the high mortality of the patients with this tumour. In spite of well established surveillance programs in patients with chronic liver disease, most tumours are diagnosed in intermediate-advanced stage, and only palliative measured can be applied.

In the next pages we will review the risk factors associated with the development of HCC, the new advances in diagnosis imaging, the main prognosis classification and finally the therapeutic approach.

## EPIDEMIOLOGY

Liver cancer is the fifth-leading cause of cancer diagnosed in men worldwide<sup>[1]</sup>, and the seventh cause of cancer in women, representing about 7% of the total number of cancer diagnoses. Globally, liver cancer is the third-leading cause of cancer death, after lung and stomach<sup>[2,3]</sup>. The annual incidence of HCC is similar to the deaths per year that it generates, which point out the aggressiveness of this disease<sup>[1]</sup>.

The HCC incidence increases progressively with advancing age in population with a peak at the age of 70-year-old<sup>[4]</sup>. In Chinese and black African population, mainly infected with hepatitis B virus (HBV), the patient are younger, and in Sub-Saharan Africa (an area with a high incidence of HBV infection) can appear in the third decade of life<sup>[5,6]</sup>.

The incidence of HCC is highest in men, with a male to female ratio of 2.4 and this difference is even higher in populations with a high incidence of HCC, with an

average of 3.7 to 1<sup>[3]</sup>. The differences in the geographical distribution of HCC reflects the differences in exposure to the hepatitis viruses and different environmental pathogens, so the incidence is highest in East Asia, Sub-Saharan Africa and Melanesia, with 85% of the total number of cases<sup>[2,3]</sup>, while in most industrialized countries the incidence is low, except in the South of Europe<sup>[7]</sup>. Globally there is a growing incidence of the number cases of HCC, even in United States and Europe, mainly due to the high number of people infected with the virus of HCV in these areas<sup>[3]</sup>. The universal vaccination against HBV in children born after 1980 in some endemic countries has decrease the rate of HCC in children and it is expected a reduction of the incidence of this tumour in the future in these areas<sup>[8,9]</sup>.

## ETIOLOGY AND RISK FACTORS

Multiple risk factors have been associated with the development of HCC, being the most frequent chronic viral hepatitis (B and C), alcohol abuse, and exposure to aflatoxins, however, this can occur in people without any known risk factor<sup>[10]</sup>.

Geographically in Africa and East Asia, the most frequently risk factor associated with HCC is chronic HBV infection, while in Western countries, HCV infection is the main risk factor<sup>[2]</sup>. Overall 54% of cases could be attributed to HBV infection, 31% to HCV infection and 15% to other causes. Cirrhosis is the main risk factor for the development of HCC and about 30%-35% of all cirrhotic patients will develop HCC in the course of their disease, which may be due to chronic viral hepatitis, alcohol, hereditary metabolic diseases, or autoimmune and non-alcoholic fatty liver disease<sup>[11]</sup>. It is estimated that the annual risk of developing HCC in the cirrhotic patients is between 1%-8% according to the aetiology<sup>[12]</sup>. The risk of developing HCC increases progressively in male patients, with advanced age, low platelet count, and oesophageal varices<sup>[13]</sup>, as well as it has also been associated with increasing pressure portal<sup>[14]</sup>, or with the degree of liver stiffness measured with transient elastography<sup>[15-17]</sup>.

### Viral hepatitis

HBV and HCV Chronic infection are the main risk factor for the development of HCC<sup>[18-21]</sup>. The higher prevalence of HBV infection occurs in China, Southeast Asia and Sub-Saharan Africa<sup>[8,21]</sup>. Globally, it is estimated that 54% of all liver cancers are attributable to HBV infection<sup>[22]</sup>. The prevalence of HCV infection is higher in Egypt, Japan and the South of Italy<sup>[21]</sup>.

The development of HCC associated with HBV infection usually occurs in patients with cirrhosis, but it can appear in patients without cirrhosis<sup>[5,23-28]</sup>. So screening for HCC will be recommended in this group of patients. Some risk factors for the development of HCC have been identified in patients with chronic HBV infection: The presence of hepatitis virus e antigen (as an indicator of viral replication)<sup>[28]</sup>, high viral load<sup>[29]</sup>,

genotype C (which is the most prevalent in Asia)<sup>[30]</sup> and infection in early childhood or perinatal period<sup>[31-33]</sup>. Several studies have demonstrated that the treatment of chronic HBV hepatitis with interferon or nucleotide analogues (suppressing viral load) reduces the relative risk of developing HCC<sup>[31,34-43]</sup>, but these benefits have not been observed in patients who develop resistance to the treatment. Some studies suggest that patients co-infected by HBV and HCV have greater risk of developing HCC<sup>[44-46]</sup>.

There is a very well known association between HCV chronic infection and the development of HCC, in fact, the risk of developing HCC in these patients increase between 20 and 30 times<sup>[21,47-49]</sup>. In very few cases it may occur in patients with HCV infection and lower grades of hepatic fibrosis<sup>[13,50]</sup>. High viral loads and HCV genotype 1b infection have been associated with higher risk of HCC occurrence<sup>[51]</sup>. The levels of inflammatory markers of oxidative stress are higher in patients infected with HCV and HCC<sup>[52]</sup> and the immune response can be another cofactor in the progression from cirrhosis to HCC in HCV infected patient<sup>[53]</sup>. In patients with HCV infection who achieve sustained viral response after treatment, there is a decrease in the risk of HCC<sup>[54,55]</sup>. The universal analysis of blood donations for anti-HCV has resulted in a substantial decrease in the number of cases of hepatitis C in blood donors and the use of needles and disposable syringes and other changes in medical procedures have substantially reduced new infections by HCV. As well as HCV and HBV co-infection may increase the risk of developing cirrhosis and HCC<sup>[56]</sup>, the HIV infection appears to be a cofactor that increases the risk of developing HCC in cirrhotic patients with viral hepatitis<sup>[57]</sup>.

### **Schistosomiasis**

The infection by trematode in blood is endemic in tropical areas of Africa, the Caribbean, Asia, and South America. The species of *Schistosoma japonicum*, already identified as possible human carcinogen, has been associated with risk of developing HCC in infected by HBV and HCV patients<sup>[58,59]</sup>.

### **Toxins**

The ingestion of food contaminated with aflatoxin B1 (fungi *Aspergillus flavus* and *Aspergillus parasiticus*), which can be found at staple foods of tropical and subtropical areas, is a co-factor of risk in the development of HCC, especially in some regions of Africa and Asia, associated with infection by HBV<sup>[60,61]</sup>. Several studies have shown increased HCC mortality in some rural Chinese areas associated with drinking water potentially contaminated with toxins of some algae (microcystins), with hepatotoxic effect<sup>[62,63]</sup>. Other studies have established a relationship between the consumption of betel nut, very common in Asia, with an increasing risk of developing cirrhosis and HCC<sup>[64,65]</sup>.

Many studies have associated chronic alcohol consumption with the development of liver cirrhosis and

HCC<sup>[66-72]</sup>, although quantity of alcohol ingestion and duration of consumption that supposes a significant risk for developing HCC is unknown. It has been described a relationship between genetic polymorphisms of the enzymes involved in the metabolic pathway of ethanol and increased risk of HCC in excessive drinkers. An increased risk of HCC in heavy alcohol drinkers has been associated to the polymorphism of the aldehyde dehydrogenase and the dysfunction of the enzyme Glutathion S-transferase<sup>[73,74]</sup>. Some studies have established that smoking is a significant co-factor in the development of HCC<sup>[66,75,76]</sup>.

### **Diabetes mellitus and obesity**

The obesity, diabetes and dyslipidemia have also been identified as cofactors of risk in the development of HCC, although the pathophysiological mechanisms have not been clarified. It is believed that the deposit of fat in the liver could alter some metabolic functions in patients with diabetes mellitus<sup>[77,78]</sup>. In these patients, liver steatosis can lead to a nonalcoholic fatty hepatitis, whose pathogenesis is unclear but it have been related to chronic inflammation, oxidative stress, insulin resistance and lipotoxicity, constituting a cofactor for the development of liver cirrhosis and HCC<sup>[79-82]</sup>.

The metabolic syndrome, which is defined by the presence of central obesity, dyslipemia, hypertension, and impaired glucose metabolism, has also been associated with an increased risk of developing HCC<sup>[83]</sup>.

### **Other causes of cirrhosis**

Patients with hemochromatosis may develop HCC by up 45% cases, according to some studies, iron overload can lead to the development of cirrhosis and HCC in these patients<sup>[84]</sup>. The protein alpha-1-antitrypsin deficiency is a documented risk factor in the development of cirrhosis and HCC that also could be without cirrhosis<sup>[85]</sup>. Occasionally, patients with cirrhosis secondary to Wilson's disease, autoimmune hepatitis or primary biliary cirrhosis can develop HCC<sup>[86-88]</sup>. Several studies suggest that porphyria may increase the risk of developing HCC, even in patients without cirrhosis<sup>[89-97]</sup>.

### **Other factors**

A meta-analysis showed an increase of significant risk of any primary liver cancer, and also of HCC in patients with cholelithiasis<sup>[98]</sup>. The oral contraceptive (OC) consumption has been rarely associated with the emergence of benign tumours of the liver in young women, like hepatic haemangioma, focal nodular hyperplasia and specially hepatocellular adenoma<sup>[99]</sup>. Some cases of malignant transformation of liver adenomas in women taking OC have been described<sup>[100,101]</sup>, but subsequent studies did not corroborate these results<sup>[102]</sup>. Some studies have suggested that the excessive consumption of saturated fats and meat may increase the risk of HCC<sup>[103,104]</sup>. Although others authors have not found this association<sup>[105]</sup>. Nitrogenous compounds (used in smoked fish, cheeses, bacon, sausages and other foods)

may increase the risk of liver disease and cancer<sup>[106]</sup>.

In an American study, individuals with a family history of first degree with liver cancer, had up to four times more likely to develop liver cancer than the general population, suggesting that certain shared genetic and environmental factors would influence the risk of developing liver cancer<sup>[107]</sup>. There is some evidence that there might be an association between a polymorphism of the gene of epidermal growth factor and the risk of developing HCC, although these data require further investigation<sup>[108-115]</sup>.

## PROTECTIVE FACTORS

### Statins

The use of statins has been associated with a decrease in the risk of developing HCC<sup>[116,117]</sup>. In a meta-analysis, including 10 studies, the risk of developing HCC was lower in people taking statins<sup>[118]</sup>.

### Beta-blockers

A recent retrospective, observational study establishes the hypothesis that treatment with propranolol may reduce the risk of HCC in cirrhotic patients<sup>[119]</sup>.

### Diet

The consumption of fish, vegetables and omega-3 fatty acids has been associated with a lower risk of developing HCC in different studies<sup>[107,120,121]</sup>. Similarly, the increased consumption of vitamin E has also been associated with lower risk of HCC rate<sup>[122]</sup>. The Mediterranean diet, characterized by high consumption of vegetables, olive oil and cereals, with moderate wine consumption and fish, and low consumption of meat, is associated with a lower risk of HCC<sup>[123]</sup>.

### Coffee

There are several studies that have associated coffee consumption with a reduced risk of liver cancer including HCC. In a recent meta-analysis, taking more than two cups of coffee a day reduces risk of liver cancer of up to 43%, which could be related to its antioxidant effect<sup>[124-126]</sup>.

## SURVEILLANCE

Surveillance is cost effective in high risk cirrhotic patient, with an expected annual incidence of HCC exceeding 1%-5% per year, and in some cases of non-cirrhotic patients with HBV chronic infection. The problem is that most of the studies of surveillance of HCC in chronic liver disease have been developed in endemic Asian countries with high incidence of HBV infection. In fact, the only prospective study has been developed in China, exclusively in patients with HBV infection. In this study, the mortality related to HCC was lower in patients under HCC surveillance<sup>[127]</sup>. Other retrospective studies conducted in Europe and America also have showed a better prognosis in patients diagnosed in

surveillance programs<sup>[128-130]</sup>. Both, European American and Asian guidelines recommended that patient with high risk of developing HCC should be entered into surveillance programs. This should be performed using ultrasonography every six months<sup>[131-133]</sup>.

## DIAGNOSIS OF HCC

According to the latest consensus conferences and practice guidelines, nowadays, to get to a definitive diagnosis of HCC, will not be necessary to perform a liver biopsy if the tumour is higher than 1 cm in diameter and the typical imaging features are present in a contrast enhanced study [dynamic computed tomography (CT) scan or magnetic resonance (MR)]. Thus, to properly documented the existence of HCC is required that the tumour enhances more intensely in the arterial phase than the surrounding liver and less than the surrounding liver in the venous phase. But these rules are only applicable if the patient has well diagnosed cirrhosis or a HBV chronic hepatitis. In any other cases (patient with typical lesion but without liver disease or patient with atypical lesion and cirrhosis), a liver biopsy must be performed to establish the diagnosis. The serum alphafetoprotein level has no longer be used for diagnosis of HCC, because is insufficiently sensitive or specific for use as a surveillance assay<sup>[130,131]</sup>.

In order to reduce the variability in liver lesion interpretation and standardize the report from CT and MR information, the American College of Radiology has developed a new classification: Liver Imaging-Reporting and Data System (LI-RADS). The LI-RADS assigns imaging findings to one of five categories, allowing radiologist to stratify individual observations according to the level of concern HCC. So LR-1 is an observation definitively benign and LR-5 is definitively HCC. The intermediate stages correlates with probably benign (LR-2), intermediate possibility of being HCC (LR-3) and probably HCC (LR-4) according to radiological features, lesion diameter and contrast enhanced behaviour<sup>[134]</sup>. As has been described recently, the nodules both LI-RADS category 4 and category 5 have high specificity for HCC diagnosis, and in addition, a relevant proportion of lesions categorized as LI-RADS category 2 and 3 could be HCC and a liver biopsy should be recommended in such patients<sup>[135]</sup>. A consensus is necessary between different organizations in order to optimize reporting of CT and MR imaging features in the patients at risk for HCC<sup>[136]</sup>.

## STAGING

The main prognosis predictors of survival in patients with HCC are: Liver function, tumour burden (size and number of HCC nodules, vascular invasion), serum alpha-fetoprotein level and performance status. Nowadays, there is no universally adopted staging system for HCC. The most widely and accepted staging system in oncology, the classification of malignant tumours

**Table 1** Factors included in each staging system

Staging system	Size	Nodules	Met	PVT	AFP	CH	Alb	Bil	ALP	Ascites	PS
TNM	Yes	Yes	Yes	No	No	No	No	No	No	No	No
Okuda	Yes	No	No	No	No	No	Yes	Yes	No	Yes	No
CLIP	Yes	No	No	Yes	Yes	Yes	No	No	No	No	No
FRENCH	No	No	No	Yes	Yes	No	No	Yes	Yes	No	Yes
BCLC	Yes	Yes	Yes	Yes	No	Yes	No	Yes	No	No	Yes
JIS	Yes	Yes	Yes	No	No	Yes	No	No	No	No	No
CUPI	Yes	Yes	Yes	No	Yes	No	No	Yes	Yes	Yes	No

Met: Metastasis; PVT: Portal vein thrombosis; AFP: Alfafetoproteina; Alb: Albumin; Bil: Bilirubin; ALP: Alkaline phosphatase; PS: Performance status; CLIP: Cancer of the Liver Italian Program; BCLC: Barcelona clinic liver cancer classification; CUPI: Chinese University Prognosis Index; JIS: The Japan Integrated Staging; TNM: Classification of malignant tumours; FRENCH: French classification of hepatocellular carcinomas; CH: Child-Pugh.

(TNM), has been adapted for HCC by the American Joint Committee on Cancer. Currently, the United Network for Organ Sharing, the organ allocation administration in United States of America, allocates donors organs for liver transplantation for the treatment of HCC based on the revised TNM classification. The problem of this system is that it does not incorporate any measure of liver function reserve, which is critical in HCC. Prognosis for HCC is impacted by local spread and hepatic dysfunction, and any staging system in HCC should include parameters that represent both aspects because an advanced liver disease can contraindicate any therapeutic approach as much as an advanced and extended HCC. The first staging system specifically designed for HCC was the Okuda classification<sup>[137]</sup>, but other staging systems have been described in the last decades: Cancer of the Liver Italian Program<sup>[138]</sup>, French classification<sup>[139]</sup>, Barcelona clinic liver cancer classification (BCLC)<sup>[140]</sup>, Chinese University Prognosis Index<sup>[141]</sup>, the Japan Integrated Staging<sup>[142]</sup>, which has been redefined including biomarkers and the Taipei Integrated Scoring System, based on total tumour volume<sup>[143]</sup>. In Table 1 are represents the parameters included in these staging system. Some of these classifications have been externally validated in separated groups.

The current European Association for the Study of Liver (EASL)-EORTC GP guidelines and the American Association for the Study of Liver Diseases (AASLD) guidelines endorse the BCLC classification and recommend the use of this staging system for prognosis prediction and treatment allocation<sup>[132,133]</sup>. The BCLC classification divides HCC patients in five stages, from (0, A, B, C, D) according to pre-established prognosis variables: Size and number of nodules, vascular invasion, performance status and Child-Pugh stage. The five stages are: 0 very early stage, A early, B intermediate, C advanced and D terminal and each stage represents the first approach to the evaluation of the patients with expected prognosis and initial treatment option to be considered. Early stage patients may be treated with potential curative treatment: Percutaneous ablation, surgery or liver transplant (LT). Intermediate stage patients may be treated with chemoembolization, advanced stages may be treated with systemic therapy (sorafenib) and in terminal patients only best supportive approach

can be applied. But, as in all recommendations, the final treatment indication should take into account a detail evaluation of additional characteristics of the patients that imply a personalized decision making. So, a young patient with Child C and a small tumour should be considered for LT, not for best supportive care.

## TREATMENT

The therapeutic approach in patients with HCC depends on several factors such as liver function, size and number of nodules, tumour extension, age and comorbidities existence. Currently, available treatments can be divided into surgical treatments (resection or transplantation), percutaneous ablation (Chemistry: Acid ethanol acetic or thermal: Microwave, laser, radiofrequency and cryoablation), chemoembolization, radioembolization and systemic treatment. The goal of curative treatments should be to obtain a complete response, according to modified RECIST radiological criteria<sup>[144,145]</sup>. The recommendation of selection for different treatment strategies are based on evidence-based data and local experience and capacities. Is advisable that any decision of treatment should be adopted by multidisciplinary HCC teams including hepatologist, oncologist, surgeons, radiologist and interventional radiologist. Properly allocate each treatment in each case is a crucial decision and is mandatory to warrant a good results in terms of survival, treatment morbidity and mortality and recurrence.

### Surgery

As in any tumour, the surgical resection should be the first option to be considered in patients with HCC. The problem is the limitation that supposes the presence of liver cirrhosis, hypertension portal, coagulopathy, or hepatic dysfunction associated, that may contraindicate any surgery and resection of the tumour. The results of surgery to make appropriate estimated that survival at 5 years should reach 60% and 5 years tumour recurrence 70%, peri-operative mortality must be 2%-3% and less than 10% of transfusion requirements. Anatomic resection aiming 2 cm margins provides better results and survival but only could be applied in patients with preserved liver function. Adequate selection of patients for surgery involves a correct assessment of liver

**Table 2** Reported 5-year overall survival and recurrence in patients undergoing liver transplant for hepatocellular carcinoma within Milan criteria

Ref.	n	5-yr overall survival	5-yr recurrence
Mazzaferro <i>et al</i> <sup>[155]</sup>	48	74%	8%
Bismuth <i>et al</i> <sup>[149]</sup>	45	74%	11%
Llovet <i>et al</i> <sup>[147]</sup>	79	75%	4%
Jonas <i>et al</i> <sup>[151]</sup>	120	71%	15%
Yao <i>et al</i> <sup>[158]</sup>	64	72%	6.5%
Marsh <i>et al</i> <sup>[153]</sup>	248	67%	3.6%
Herrero <i>et al</i> <sup>[154]</sup>	47	70%	8.5%
Mazzaferro <i>et al</i> <sup>[155]</sup>	444	73%	4.3%

function, using Model End Stage Liver Disease punctuation, Child-Pugh class or more sophisticated estimation with the measurement of indocyanine green retention rate or hepatic venous pressure gradient (HVPG). Portal hypertension is an independent prognosis factor in patients undergoing resection and the extensive assessment is recommended before surgery using the component of portal hypertension: Platelet counts, splenomegaly, esophageal varices, and/or HVPG. In practice, BCLC recommendation is to avoid surgery in patient with advanced liver insufficiency, hypertension portal or high bilirubin<sup>[146]</sup>.

If the patient is properly selected, with preserved liver function and no clinically significant portal hypertension, the next step is to evaluate tumour extension: Size and number of nodules, vascular invasion and presence of microsatellites. Tumour size, multinodularity and vascular invasion, are well known predictors of recurrence and survival. Characteristically, microscopic vascular invasion is related to tumour size and involves 20% of tumours of 2 cm, 30%-60% of tumours 2-5 cm and up to 60%-90% of tumours up to 5 cm<sup>[147]</sup>. With all of this in mind, hepatic resection should be considered for small solitary tumours (and multifocal only if technically possible) with adequate hepatic function. In BCLC staging system, surgery is reserved for patient in the very/early stage, with well preserved liver function and a single tumour less than 2 cm, without portal hypertension and normal bilirubin.

## LT

Since Mazzaferro described the Milan criteria in 1996 (solitary tumour less than 50 mm in diameter or less than 3 tumours, and 30 mm in diameter each one, in the absence of extrahepatic vascular spread), numerous studies have validated the results of the initial study, both in terms of 5-year survival and recurrence of the tumour (Table 2)<sup>[148-155]</sup>. This study also allowed that transplantation became a feasible option for treatment in these patients, and also showed that to achieve acceptable rates of survival (*i.e.*, similar to that of the patients transplanted without HCC), the size and number of tumour should be limited. The situation of treatment of HCC has changed dramatically in the last decades. A better knowledge about the tumour behaviour, impro-

vement in surgical techniques and radiological therapies together with a better selection of potential candidates to each treatment have allowed to improve the survival of patients with HCC. The optimisation of the criteria as well as the management of patient already listed for LT remains a source of debate. Important questions, like the expansion of eligibility criteria for LT beyond Milan criteria, the role of down-staging as a bridge to LT or the possible need of adjuvant therapies in patient in waiting list in order to avoid tumour progression and eventual drop-out, are still unresolved.

## Expanded criteria for LT

Alternative eligibility criteria beyond Milan criteria have been proposed, and some of them have been incorporated into clinical practice. The main aim of all these new approaches is to permit the fair allocation of liver graft between more potential recipient with similar survival and tumour recurrences. Having in mind the recognised predictors of recurrence (size and number of nodules, presence of bi-lobar disease, tumour differentiation and presence of micro or macro vascular invasion or tumour satellites), some groups have proposed different expensive criteria. In fact, the limitation of some of the studies have been the used of pathological examination of the explants to determine the tumour burden (data that obviously is only disposable after the LT) instead of radiological staging, as it is showed in Table 3<sup>[155-162]</sup>. This fact, hinders the correct interpretation of the results a consequently the clinical application of the results. The University of California, San Francisco criteria constitutes a well recognised extension to Milan criteria and have been applied in clinical practice<sup>[151]</sup>. First published in 2001, demonstrated that patients with a single tumour less 65 mm in diameter, or 2-3 tumours each with less 45 mm diameter, with a total tumour diameter less than 80 mm, had similar survival than patients inside Milan criteria<sup>[155]</sup>. Subsequent studies (both prospective and retrospective) have reported favourable results with expanded criteria. A recent retrospective and multicentre study by Mazzaferro *et al*<sup>[155]</sup>, have been performed introducing "up to seven" criteria: the sum of the number of tumour nodules and the diameter of the largest nodule (in centimetres) being less than 7<sup>[154]</sup>. These results have been externally validated in an independent cohort<sup>[162,163]</sup>. The international consensus conference for liver transplantation for HCC recommended to consider the LT in patients with HCC inside Milan criteria and only a modest expansion of the number of potential candidates may be considered outside Milan criteria<sup>[164]</sup>.

## Downstaging

Another important question is the role of downstaging in patients with HCC exceeding Milan criteria, using locoregional therapies: Radiofrequency ablation (RFA), transarterial chemoembolization (TACE), transarterial radioembolization or surgery. The objective of these therapies should be to decrease tumour size or number

**Table 3** Summary of the characteristics of the published studies including patients within Milan criteria or with expanded criteria

Ref.	Patients MC/EC	HCC criteria	Staging method	Design	5-yr survival (%) MC/EC
Yao <i>et al</i> <sup>[158]</sup> UCSF criteria	46/14	1 < 6 cm 2-3 > 4, 5 cm Sum diameter < 8 cm	Explant	Retro	72

Guiteau <i>et al</i> <sup>[161]</sup>	363/82	1 < 6 cm 2-3 < 5 cm Sum diameter 9 cm	Rx	Pros	73/71 (3-yr)

Staging method: Pre LT with radiological features (Rx) or post LT according to histopathological features (Explant). Study design: retrospective (Retros), prospective (Pros). MC: Milan criteria; EC: Expanded criteria; LT: Liver transplant; UCSF: University of California, San Francisco; HCC: Hepatocellular carcinoma.

of tumours in order to achieve a pre-established locally criteria acceptable for LT. Some of the studies have reported successfully results with this strategy achieving 5 years survival similar to that of patients with HCC who meet Milan criteria without requiring downstaging<sup>[165,166]</sup>. Nevertheless, there are some unresolved issues. The defined upper limit for size and number of nodules eligibility for downstaging and the possible role of alpha-fetoprotein has not been well defined. The assessment of adequate response is variable in the different reports, although the recommendation should be to consider the amount of available tumour according to modified RECIST criteria. Otherwise, the acceptable criteria previously defined as successful downstaging in each study, has been different, as well as the observation period recommended after the tumour has been downstaged, before considering for LT. The recommendation of Consensus Conference was that LT may be considered after successful downstaging, without evidence for preferring a specific locoregional therapy and using criteria including size and number of viable tumour<sup>[164]</sup>.

### Interventional radiology treatment

HCC is the tumour that takes the greatest advantage from interventional radiology therapies for several reasons: Not only surgical difficulties in cirrhotic patients, but also ablative and endovascular treatments have demonstrated high response rates and survival benefits.

Among all chemical ablative treatments, percutaneous ethanol injection (PEI) has a widespread use, although it has more difficulties to treat encapsulated tumours against other substances as acetic acid. PEI

has been the most used ablative therapy until 1999<sup>[167]</sup>, but it has been disregarded after the emergence of more sophisticated techniques. Despite it has also evolved with multi-pronged needles that minimize some PEI disadvantages as the need of multiple sessions<sup>[168]</sup>, they have a limited use and nowadays PEI use is reserved for the treatment of HCC < 2 cm with unfavorable RFA locations (Figure 1).

Among 2000-2010 numerous cohort studies and some randomized control trials (RCTs) and meta-analysis<sup>[169]</sup> demonstrated that RFA gets better control of the disease compared to PEI. It has the ability to create bigger necrosis, including a peripheral ring to the tumour, and therefore higher complete necrotic rates - even sustained necrosis - particularly in tumours < 3 cm, where ablation is more effective.

Initial complete response has demonstrated a positive impact on survival, although there still will be high recurrence rates, comparable to surgical resection. HCC usually appears in the setting of underlying chronic hepatic disease and this conditioned the appearance of new nodules, but there are also same segment recurrence nodules as a result of the growth of small peritumoral satellites or vascular microinvasion out of the ablated zone.

There are some researches<sup>[170,171]</sup> with specimen from surgery, about the distance of microsatellites depending on tumour size that come to the conclusion that a reasonable limit of RFA is 2, 5-3 cm in order to create a security margin of 5 mm. This makes us use RFA needles 1 or 2 numbers of ablation greater than the tumour diameter. Other strategies to increase the

**Figure 1 Ethanol injection treatment for hepatocellular carcinoma.** A: Very early hepatocellular carcinoma pre-percutaneous ethanol injection treatment (Arterial phase); B: Very early hepatocellular carcinoma pre-percutaneous ethanol injection treatment (Portal phase); C: Percutaneous ethanol injection procedure (Ultrasound guidance fine needle puncture); D: Percutaneous ethanol injection procedure (Ethanol aggregation after ultrasound guidance percutaneous ethanol injection); E: Computed tomography control arterial phase after 1 year (Sustained complete response).

ablation zone are overlapping techniques or multi-pronged needles, but their clinical use is difficult and not widespread.

RFA creates a complete necrosis area with a predictable diameter, whenever is not affected by nearby medium-large-sized vessels that could condition the perfusion-mediated tissue cooling, known as the heat sink effect. This limitation and the presence of non-treated microsatellites make up their main theoretical limitations, but there are also others that limit their clinical use: Ultrasound visualization of the nodule within liver parenchyma (difficult at fatty liver, macronodular cirrhosis, VIII segment nodules...) and the risk of damage of nearby organs (yuxtahilar, gallbladder, stomach, duodenum, large intestine). This potential damage contraindicates RFA if we are not able to isolate them with sterile water instillation (spacing technique). Last,

sub capsular tumours are not good indication of RFA due to the risk of tumoral seeding.

BCLC protocol last review<sup>[140]</sup> considered RFA as the first therapy at HCC < 2 cm, when a patient is not candidate to LT. This stage is also known as very early stage 0 or carcinoma *in situ*. RFA is also considered an alternative curative treatment at early stage (A) (single or 3 nodules  $\leq$  3 cm), with survival benefit up to 70%.

Microwave ablation is emerging as an alternative to RFA with several advantages. It is able to induce greater intratumoral temperature and bigger ablation area during less time than RFA. Thus, it is less dependent from tissue impedance and less influenced by heat-sink effect. Nowadays, it has less scientific evidence than RFA and there is lack of comparative papers between both techniques, but it seems logical to use it at HCC nearby to large hepatic vessels.

Irreversible electroporation is the technique more expensive, less used in clinical practice and with less evidence, although it is not affected by heat-sink effect and it doesn't damage adjacent structures. Therefore, its use seems useful to treat complex location lesions<sup>[144,172]</sup>.

TACE has been established by a meta-analysis of RCTs<sup>[173]</sup> as the standard of care for nonsurgical patients with large or multinodular noninvasive HCC isolated to the liver and with preserved liver function, known as intermediate stage HCC.

It is frequently used to control tumour progression (palliative treatment) as primary therapy or while waiting for liver transplantation, but some considerations has to be remarked. Intermediate stage is actually a heterogeneous group of patients and TACE benefit should be assessed in subgroups of patients as it has already been remarked<sup>[174]</sup>. Moreover, large series treated by TACE reported patients with single nodule stage A HCC<sup>[175,176]</sup>.

This would be justified by the recent concept of treatment stage migration: If a subject in a given stage is not candidate to the recommended treatment, we should consider the treatment of the more advance stage<sup>[140]</sup>. In our experience more than 1/3 of patient candidates to RFA, due to ablation difficulties, were treated by TACE (Figure 2), as has also been remarked in the literature<sup>[177]</sup>.

Thus, early stage HCCs have been treated with TACE with reported maintained complete responses and it has been suggested to include TACE as an alternative curative intention therapy (stage A), in selected patients and performed with a concrete technique<sup>[178]</sup>.

TACE technique is an interesting underestimate debate. There are different accepted techniques to perform endovascular HCC treatments with no enough evidence to determine the best option and this implies huge difficulties to standardize the results. Bland embolization or simple chemoinfusion have evolved to combined techniques of intra-arterial chemotherapy followed by ischemic changes after intra-arterial embolic materials (TACE).

Conventional TACE involves the selective injection of a chemotherapeutic agent (usually Doxorubicine) emulsified in a viscous carrier (lipiodol), followed by embolic material into the feeding arteries of the tumour.

It has been the most common way to perform TACE since the beginning of the century-validated with level 1 of evidence<sup>[173]</sup> - and is still acceptable with widespread use, above all in eastern countries. There are different ways to perform it regarding on how to mix lipiodol and contrast, being more or less selective and types of lipiodol aggregation. The optimal way should include filling of the "rear door of the tumour", *i.e.*, small portal drainage veins<sup>[179]</sup>.

An alternative way to perform TACE is widespread in the clinical practice, known as drug-eluting beads-TACE (DEB-TACE). It concerns performed microspheres loaded with chemotherapeutic agents which allows the delivery of large amounts of drugs to the tumour for a prolonged

period of time (improve antitumoral efficacy), thereby decreasing plasma levels of the chemotherapeutic agent and potentially systemic effects (better tolerance).

A prospective multi-institutional RCT (Precision V)<sup>[178]</sup> demonstrated significant better tolerance compared to cTACE, but only improved response in advanced disease (Child-Pugh B). Later several cohort studies and some RCTs favors DEB-TACE vs cTACE in response rates and survival, but nowadays it is a usual debate in HCC symposiums because more evidence is needed to evaluate the two modalities of TACE. Actually, DEB-TACE has implemented in the clinical practice of western countries based on some clear rationale: Maximize drug delivery, long lasting effect/slow and sustained release, tumour effect vs systemic side effects and better reproducibility.

Technical recommendations to perform it have been published to improve its efficacy, helping reproducibility and constitute clear working tendencies<sup>[180-182]</sup>: (1) Must use microcatheter with super-selective injection at feeding arteries; (2) Use angio-CT system technology for tumour targeting; (3) Mix beads with contrast 3-4:1 to increase visibility; (4) Avoid complete stasis (endpoint near stasis); (5) Inject slowly (1 mL/min) trying to introduce as much Doxorubicin as possible inside the tumour (maximum 150 mg); (6) Use of small size microspheres to increase penetrability. At present 100-300  $\mu$ m are recommended, but the use of smaller beads (M1 70-150  $\mu$ m) - commonly used at treating liver metastasis- is being evaluated in clinical trials. Many working groups have introduced them in their protocols, particularly with small size HCCs and they are extremely promising thanks to their bigger penetrability<sup>[183]</sup>; and (7) - Repeat TACE in 2-4 wk, if needed, to get initial complete response, which is being related to survival benefit<sup>[184]</sup>.

Ablative therapies and chemoembolization form the interventional treatments recommended by BCLC staging and treatment strategy, with simplicity as one of its known advantages. Other classifications as Japanese guidelines<sup>[185]</sup> stands for suggest other treatment options together with first line therapies in different stages or subgroups of them.

The huge variability of patients with HCC makes necessary to create a tailored approach that nowadays it is an undeniable clinical tendency<sup>[186]</sup>. We should adjust to each patient the most suitable treatment for its particular case, after a multidisciplinary assessment. The combination of locoregional therapies sometimes offers this maximal flexibility. This approach seems to be particularly valuable in patients with multifocal disease and nodules > 3 cm.

Among combine therapies, there are more experience with the combination of TACE and RFA (TACE first). Therefore, perfusion tissue is reduced and heat loss by perfusion mediated tissue cooling is minimized making possible larger ablation zone with wider safety margin<sup>[187]</sup>. Thus, sometimes downstaging is possible, above all with HCC 3-5 cm.

**Figure 2** Transarterial chemoembolization for hepatocellular carcinoma. A: Four centimeter hepatocellular carcinoma S-IV. Arterial and venous phase computed tomography; B: First transarterial chemoembolization procedure; C: Small residual foci after 1 transarterial chemoembolization; D: Second transarterial chemoembolization; E: Complete response after 2 transarterial chemoembolization.

In the recent years, several groups perform RFA followed by TACE (RFA first). This way, TACE acts over a transitional zone with sub lethal hyperthermia and increase vascular permeability. This forms an increase delivery, uptake and susceptibility to chemotherapeutics ideal to treat microsatellites outside RFA zone<sup>[188]</sup>.

Radioembolization is an alternative to TACE with less evidence and minor applicability. It needs to join interventional radiology and nuclear medicine units, which is restricted to only a few hospitals. Besides, technically is more complex than TACE and require an anatomical previous vascular map, because many times is necessary to embolize the arteries that communicate the target liver places with other adjacent organs as gallbladder or stomach that could be damaged.

Although is not included in the BCLC recommended treatments, it would be indicated in stage B HCC as an alternative to TACE and some stage C HCC with portal thrombosis that is not a contraindication of this technique. Some working groups consider it a first option in tumour > 5 cm or when > 4 nodules are present<sup>[174]</sup>. Ongoing RCTs are needed to unequivocally confirm the survival benefit provided by transarterial radioembolization in many cohort studies.

### Sorafenib

Sorafenib is a small molecule that inhibits tumour-cell proliferation, tumour angiogenesis and it is a multi-tyrosine kinase inhibitor and nowadays is the only drug that have demonstrated survival benefits in patients with advanced HCC. The initial phase II and phase III studies showed positive results with better survival in patients treated with sorafenib. The benefit of sorafenib was to increase the median survival from 7.9 mo in the placebo group to 10.7 mo in the sorafenib group. In addition, sorafenib showed a significant benefit in terms of time to progression, but objective responses rates were low<sup>[189]</sup>. These results were corroborated in other phase III study conducted in Asia<sup>[190]</sup>. This drug is only indicated in patients with preserved liver function and advanced disease not susceptible of other therapies and in this group of patients have an acceptable safety profile with manageable adverse events. The initial results were very promising because it was the first time that a systemic therapy demonstrated benefits effects in patients with HCC. Two subsequent trials, the Space (Sorafenib or placebo in combination with TACE for intermediate-stage HCC)<sup>[191]</sup> and the Storm (Sorafenib or placebo after resection or ablation to prevent recurrence of HCC)<sup>[192]</sup> have failed to demonstrated efficacy of sorafenib as adjuvant in combination with locally therapies. In the next years, new novel drugs, with a slightly different profile in terms of targets and intensity, have been tried both in first-line and second-line therapy. Until now, none of these drugs (sunitinib, brivanib, linifanib and combination of erlotinib and sorafenib) have proven to be better than sorafenib in first-line trials, in terms of survival. Second-line trails with brivanib, everolimus

and ramucirumab have also failed to show benefits compared with placebo.

The EASL and AASLD recommend the use of sorafenib in patients with HCC advanced stage and preserved liver function.

## CONCLUSION

HCC is a tumour with high incidence in patients with liver cirrhosis and is currently the leading cause of death in this group of patients. It is expected a decreases in incidence in the coming decades due to better management of patients infected with HBV and HCV. The vaccination against hepatitis B, the extended use of antiviral drugs with a high genetic barrier, which remain at undetectable viral load levels and the higher rate of sustained viral response in patients with chronic HCV with the new generation of antiviral drugs will reduce the incidence of this tumour in the future. On the other hand, increasingly numbers of studies have identified protective factors such as treatment with beta-blockers or statins, and perhaps in the future the use of some of these drugs will be recommended in selected cirrhotic patients. On the other hand, the improvement in the quality of imaging techniques allows establishing a diagnosis without histological confirmation in a high percentage of patients. New radiologic classifications, although promising, need more studies to be accepted universally. Once confirmed the diagnosis, the staging of the tumour allows us to decide the best therapeutic approach. Although several prognostic classifications have been described, the BCLC classification has been supported by American and European clinical practice guidelines. In addition, it allows deciding the best therapy according to the stage. The mainstays of treatment of HCC are surgery, radiological approach and systemic drugs. Since it is the treatment of choice to better outcomes in terms of survival, the indications of liver transplantation are in constant review. The expanded criteria and the downstaging have helped to expand the number of patients who are eligible for this option, with acceptable survival and recurrence after the transplant. On the other hand, the percutaneous ablative techniques have obtained good results in terms of response and survival, similar to surgical resection, in selected cases. In patients at intermediate stages, chemoembolization with particles has improved the results against the conventional chemoembolization with a similar rate of adverse effects. Sorafenib is the only systemic drug that has demonstrated survival benefits in advanced-stage patients and therefore remains the standard of care in this group. So far, any drug has shown survival benefits in second-line therapy after progression with sorafenib.

### Abstract

Thirty years have passed since the first report of portal vein embolization (PVE), and this procedure is widely adopted as a preoperative treatment procedure for patients with a small future liver remnant (FLR). PVE has been shown to be useful in patients with hepatocellular carcinoma (HCC) and chronic liver disease.

However, special caution is needed when PVE is applied prior to subsequent major hepatic resection in cases with cirrhotic livers, and volumetric analysis of the liver segments in addition to evaluation of the liver functional reserve before PVE is mandatory in such cases. Advances in the embolic material and selection of the treatment approach, and combined use of PVE and transcatheter arterial embolization/chemoembolization have yielded improved outcomes after PVE and major hepatic resections. A novel procedure termed the associating liver partition and portal vein ligation for staged hepatectomy has been gaining attention because of the rapid hypertrophy of the FLR observed in patients undergoing this procedure, however, application of this technique in HCC patients requires special caution, as it has been shown to be associated with a high morbidity and mortality even in cases with essentially healthy livers.

**Core tip:** Preoperative portal vein embolization (PVE) has been developed to secure the safety of a major hepatic resection by inducing the hypertrophy of the future liver remnant. PVE has been shown to be useful for patients with hepatocellular carcinoma and chronic liver disease. However, the indications should be carefully judged based on the volumetric analysis and evaluation of the liver functional reserve. Recently, a novel technique called the associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) has been introduced to gain a rapid hypertrophy of the future liver remnant; however, at present, data supporting ALPPS in hepatocellular carcinoma with

cirrhosis are still very weak.

## INTRODUCTION

Currently, hepatic resection is the treatment of choice for large hepatocellular carcinomas (HCC), colorectal liver metastases (CLM) and hilar cholangiocarcinomas, and extensive liver resection is often required in patients with these malignancies. Preoperative portal vein embolization (PVE), which induces atrophy of the liver segments to be resected and hypertrophy of the future liver remnant (FLR), has been introduced in an attempt to expand the indications for major (the resection of 3 or more Couinaud segments<sup>[1]</sup>) hepatic resection and prevent postoperative liver insufficiency. Thirty years have passed since the first report of PVE by Makuuchi *et al.*<sup>[2]</sup>, and the usefulness of PVE is currently widely accepted. However, the beneficial effect of preoperative PVE may be impaired in patients with chronic liver disease, especially liver cirrhosis<sup>[3]</sup>, and caution is required when PVE is applied in patients with large HCCs and underlying liver cirrhosis. In such patients, volumetric analysis of the liver segments in addition to evaluation of the liver functional reserve is mandatory<sup>[4]</sup>. On the other hand, some European groups have recently advocated the usefulness of a new procedure termed the associating liver partition and portal vein ligation for staged hepatectomy (ALPPS)<sup>[5]</sup>, as this procedure has been shown to induce rapid hypertrophy of the FLR within a short interval<sup>[6]</sup>. However, application of ALPPS to HCC patients with underlying liver cirrhosis is debatable from the point of view of the safety. In this manuscript, we have reviewed the recent advances in preoperative PVE and other procedures aimed at increasing the FLR.

## HISTORY OF PVE

In the first report, Makuuchi *et al.*<sup>[7]</sup> applied preoperative PVE for patients with hilar cholangiocarcinoma. They stated that the purposes of PVE were: (1) to initiate compensatory hypertrophy of the FLR; and (2) to avoid a sudden increase of the portal venous pressure during and after the surgery<sup>[7]</sup>. The second goal is especially important in HCC patients with portal hypertension, where PVE may serve as a preoperative "tolerance test"; if the FLR cannot tolerate the higher portal pressure induced by PVE, sufficient hypertrophy of the FLR cannot be expected. Two approaches were used for PVE: Transileocolic portal embolization (TIPE) *via* laparotomy under general anesthesia, and percutaneous transhepatic portal embolization (PTPE) using a puncture technique

with ultrasonic guidance under local anesthesia. The embolic material consisted of a mixture of absorbable gelatin powder, contrast material, and antibiotics.

Kinoshita *et al.*<sup>[8]</sup> performed selective PVE (THPE), wherein they used a contralateral approach to occlude the portal vein branch bearing the HCC tumor. The aim of selective PVE was to enhance the effect of transcatheter arterial embolization (TAE) and the accompanying hypertrophy of the nonembolized segments. They used gelatin sponge, thrombin mixed with glucose, or an adhesive mixture of fibrin with contrast material as the embolic material.

Subsequently, the indication of preoperative PVE was expanded to other liver tumors, including CLM and HCC without cirrhosis. Among patients with CLM, PVE is indicated in patients with: (1) small multiple lesions of the right lobe; or (2) a small solitary tumor located adjacent to the hilum of the liver<sup>[9,10]</sup>. Reports dealing with PVE for HCC with underlying cirrhosis or chronic hepatitis were at first mainly small patient series from Asian countries, while documentations of large patient series have appeared after the year 2000<sup>[11-18]</sup>. The indications for PVE in cases of HCC is determined by the relationship between the liver functional reserve and the volumetric ratio of the FLR to the total liver volume. In general, major hepatic resection is contraindicated in Child-Pugh class B or C patients; these patients are therefore also not suitable candidates for PVE. In addition, Child-Pugh class A patients should undergo assessment by the indocyanine green retention rate at 15 min (ICG-R15). An ICG-R15 value of > 20% is generally considered as a contraindication for major hepatic resection and therefore also for PVE (Figure 1)<sup>[4]</sup>.

## MODIFICATION OF PVE

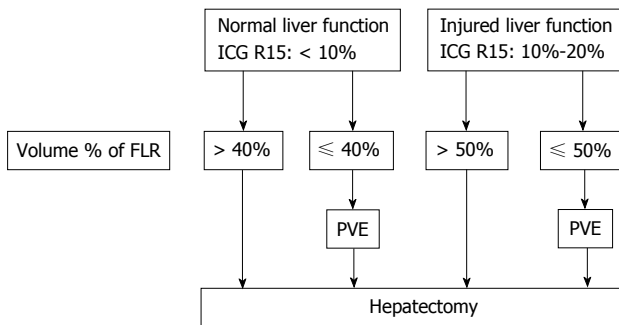

### Approach

Several approaches have been advocated for PVE, which can be mainly categorized as TIPE or PTPE; the PTPE approach is further subdivided into an ipsilateral approach and a contralateral approach. TIPE is a safe approach; complete portography can be achieved using this approach, and insertion of the catheter into the segmental portal branches is relatively easy; however, it requires general anesthesia and laparotomy, and carries the risk of post-PVE bowel obstruction.

PTPE can be performed under local anesthesia, and is therefore considered to be a less invasive procedure; however, the possible risk of hemorrhage/subcapsular hematoma or peritonitis cannot be ignored, and if the contralateral approach is selected, injury to the vessels in the FLR may make the subsequent liver resection impossible. A meta-analysis showed that despite the absence of any significant difference in the rate of major complications between TIPE and PTPE, the rate for minor complications was significantly higher for PTPE<sup>[19]</sup>.

Nagino *et al.*<sup>[20]</sup> recommended the ipsilateral approach occluded the right anterior and posterior portal branches using different types of catheters. This technique is

**Figure 1** Indications of portal vein embolization for patients with hepatocellular carcinoma. PVE: Portal vein embolization; FLR: Future liver remnant; ICG R15: Indocyanine green retention ratio at 15 min.

advantageous from the standpoint of safety, as the portal branch of the resected segments is punctured. Currently, PTPE using the ipsilateral approach, although the most technically demanding, is the most popularly used approach; however, the optimal approach must be selected according to the tumor location and past history of laparotomy.

#### Segment 4 embolization

When a more extended hepatic resection, such as right trisegmentectomy, is needed, embolization of the segment 4 portal branch in addition to the right portal vein branch may yield additional beneficial effects<sup>[21]</sup>. Embolization of the segment 4 branch is easy when the ipsilateral PTPE approach or TIPE is used. Two previous reports have confirmed the additional beneficial effect of embolization of the segment 4 portal branch on segment 2 + 3 hypertrophy, however, both reports dealt with non-injured livers, and no data are available for patients with underlying liver cirrhosis<sup>[22,23]</sup>.

#### Embolic material

A number of embolic materials have been used for PVE, including gelatin sponge, gelatin powder, thrombin, fibrin glue, polyvinyl alcohol particles, absolute ethanol, cyanoacrylate, absolute ethanol, small spherical particles, and metallic coils<sup>[19]</sup>. The ideal agent would be the one that would lead to rapid, reproducible, and substantial functional hypertrophy of the FLR in the majority of patients without producing significant toxicity or adverse events. Currently, a combination of absolute ethanol and microcoils is widely used for HCC patients, as these agents have been shown to induce a greater degree of hypertrophy of the FLR as compared with other embolic materials<sup>[24]</sup>. However, there have been no randomized controlled trials to compare the efficiency of the embolic materials.

## BASIC ASPECTS OF PVE

#### Liver regeneration after PVE

The mechanism of liver hypertrophy/regeneration after PVE has been widely studied using animal models or in clinical settings. Several experimental results imply

that the mechanism of liver regeneration after PVE/portal vein ligation (PVL) is different from that after hepatectomy, as indicated by the different response to follistatin<sup>[25]</sup>. The difference is fundamentally attributed to maintained or enhanced arterial blood flow to the embolized liver segments after PVE, or the presence *per se* of the embolized segments, and the atrophying embolized liver segments are supposed to retain their specific functions. In addition, negative regulators of hepatocytes proliferation (such as transforming growth factor- $\beta$  and interleukin-1 $\beta$ ) are strongly expressed in the embolized segments. These factors in the embolized segments may modify the whole process of regeneration after PVE, although no definitive conclusions have been made yet<sup>[26]</sup>.

#### Enhancement of the effect of PVE

Various factors have been shown to influence the effect of PVE: Age, gender, body mass index, nutrition status, previous chemotherapy, diabetes mellitus, *etc*<sup>[26]</sup>. It has been shown that liver regeneration is impaired in chronically diseased livers<sup>[3]</sup>. Sugawara *et al*<sup>[14]</sup> have examined the clinical factors associated with liver hypertrophy after PVE in HCC patients, and have found that the hypertrophic effect was significantly enhanced when PVE was combined with TAE. Recently, Beppu *et al*<sup>[27]</sup> have shown a favorable effect of branched-chain amino acid supplementation on functional liver regeneration after PVE.

## CLINICAL IMPLICATIONS OF PVE

#### Clinical outcomes after PVE and major hepatic resection

Clinically, the percent increase in the volume of the FLR in cirrhotic livers within the first 2-3 wk after PVE is reported to be in the range of 5% to 10%<sup>[10-12]</sup>, and the hypertrophy ratio of the FLR has also been reported to be approximately 1.3 to 1.5<sup>[10,11,13]</sup>. Others have reported a rate of hypertrophy in cirrhotic livers of 9 cm<sup>2</sup>/d at 2 wk<sup>[14]</sup>. These figures are significantly smaller than those reported in non-cirrhotic livers<sup>[14-17]</sup>. Nevertheless, most previous reports have documented the safety of the PVE procedure and of subsequent major hepatic resection even in cases with a cirrhotic liver<sup>[28-32]</sup>.

Previous reports have documented satisfactory long-term results after PVE and subsequent major hepatic resection for HCC (Table 1)<sup>[11-18]</sup>. The reported 5-year survival rates range from 44% to 72%, and the reported 5-year disease-free survival rates range from 21% to 56%. These figures are comparable to those after major hepatic resections for HCC without PVE. It may be deduced that PVE does not have any adverse effect on the risk of oncogenesis (*i.e.*, intrahepatic HCC recurrence or development of new primary lesions) in the FLR after hepatic resection.

PVE also has significance as a preoperative "tolerance test". Indeed, if the liver cannot tolerate PVE, sufficient hypertrophy of the FLR cannot be expected, and a subsequent major hepatic resection is precluded. In

PVE: Portal vein embolization; TACE: Transcatheter arterial chemoembolization.

addition to the volumetric increase of the FLR, the kinetic growth rate (speed of increase in the volume of the FLR) has also been shown to be a predictor of the morbidity and mortality after subsequent major hepatic resections<sup>[33]</sup>.

### Tumor growth after PVE

On the other hand, tumors in the nonembolized liver segments have been reported to grow more rapidly than tumors in the embolized segments. Alternatively, tumors in the nonembolized segments show an enhanced rate of progression as compared to their natural history. This possible underlying mechanisms for this observation are that: (1) the increased arterial blood supply to the nonembolized liver segments after PVE can promote tumor growth; and (2) the cytokines associated with the atrophy-hypertrophy complex can also promote the progression of tumors. Several previous reports have addressed this issue. Despite some conflicting results, accumulating evidence suggests an adverse effect of PVE on tumor growth<sup>[34-38]</sup>, although most previous studies investigating the risk of tumor growth after PVE have dealt with patients having colorectal liver metastases.

Tumor growth after PVE, especially tumor growth in the nonembolized FLR and/or extrahepatic tumor progression, may preclude curative resection. Indeed, a recent meta-analysis reported that about 15% of patients could not undergo curative resection after PVE, and about a half of these patients showed severe tumor progression or extrahepatic tumor spread<sup>[19]</sup>.

### Sequential transcatheter arterial chemoembolization and PVE and two-staged hepatectomy

As mentioned above, the risk of tumor growth after PVE may counteract the beneficial effect of PVE. Therefore, measures to prevent tumor growth during the waiting period before hepatectomy should be considered.

Our group has employed combined transcatheter arterial chemoembolization (TACE) with PVE as a preoperative treatment in HCC patients. The antitumor effect of TACE in cases of HCC has been reported previously<sup>[39]</sup>. TACE is also useful for embolizing the arterio-portal shunts in the tumor. Thus, the combination

of TACE plus PVE before planned major hepatic resection may strengthen the effect of PVE while simultaneously preventing tumor progression. Our study showed satisfactory short- and long-term outcomes after sequential preoperative TACE and PVE in 17 patients with HCC<sup>[15]</sup>. During the waiting period after PVE, tumor progression, as evaluated by measurements of the tumor volume, serum alpha-fetoprotein level, and plasma des- $\gamma$ -carboxy prothrombin level, was significantly suppressed.

Another European group compared 18 patients who underwent sequential preoperative TACE and PVE with 18 patients who underwent PVE alone prior to hepatic resection<sup>[16]</sup>. All the patients underwent a right hepatectomy 4-8 wk after the PVE. They found that the degree of hypertrophy of the FLR was greater in the TACE + PVE group, and that the recurrence-free survival period was also significantly longer in the TACE + PVE group than that in the PVE alone group.

A potential concern of sequential TACE and PVE is infarction or necrosis of the non-cancerous liver parenchyma. Our previous results showed, however, that necrosis of the non-cancerous liver parenchyma in the resected specimens was minimal. Possibly, recanalization of the hepatic artery abrogates the possible adverse effect of dual embolization.

Two-stage hepatectomy with preoperative PVE can also be applied in patients with metastatic liver tumors<sup>[40]</sup>. The tumors in the FLR are removed by limited resections as the first step, PVE is performed as the second step, and finally, the major hepatic resection is carried out as the third and final step. This strategy is fascinating, but is rarely performed in HCC patients as the surgical indications for bilobar multiple HCC are extremely limited.

## ALTERNATIVES TO PVE

### PVE vs PVL vs ALPPS

In general, PVL at the right branch is believed to induce canalization of the intrahepatic communications of the peripheral portal branches within a few days, therefore, PVE is considered to be more efficient as compared to PVL. However, a meta-analysis has shown only a borderline difference in the increase of the FLR volume

after PVE and PVL. The morbidity and mortality of the two procedures are similar<sup>[41]</sup>.

Recently, European groups have reported a novel approach to rapid liver regeneration in patients scheduled for extended right hepatectomy. This procedure, termed ALPPS, consists of right portal ligation and in situ splitting of the liver parenchyma on the right side of the umbilical portion of the portal vein. Schnitzbauer *et al.*<sup>[5]</sup>, who published the first report of this procedure, reported a marked and rapid hypertrophy of about 75% of the left lateral lobe within a median of 9 d. This growth rate has been reported to be 11 times higher as compared to that after PVE/PVL, and comparable to that in donors after living donor liver transplantation<sup>[42]</sup>. The mechanisms of the apparent profound hepatic growth of the FLR after ALPPS are unknown, although probably this noteworthy phenomenon may be attributable to an abrupt of the arterial blood flow between the two parts of the liver. The same group and others also documented that ALPPS significantly improved the chance of curative resection for initially unresectable liver tumors as compared to conventional PVE/PVL<sup>[6,43]</sup>.

The concern about this procedure, however, is the high morbidity and mortality rates associated with it<sup>[44,45]</sup>. The reported 90-d mortality after ALPPS is 15%, while that after PVE/PVL is 6%, and the odds ratio for perioperative death was 2.7-fold higher in the patients who underwent ALPPS<sup>[6]</sup>. In addition, a high recurrence rate within a short follow-up period has also been reported<sup>[46]</sup>. Based on these observations, Shindoh *et al.*<sup>[47]</sup> concluded that PVE (right portal branch plus segment 4) and interval surgery remain the standard for patients with small FLRs.

Is ALPPS applicable to HCC patients with cirrhosis? The ALPPS series included some patients with HCC (about 10% of the patients), and some recent papers have documented that ALPPS can be safely performed in HCC patients with cirrhosis; however, no detailed data are available because of the small number of patients<sup>[5,6,48]</sup>. Currently, the indications of ALPPS for HCC patients are extremely limited and each patient should be carefully examined as to his/her suitability to undergo ALPPS.

### Radioembolization

Our group has applied a combination of preoperative TACE and PVE to prevent tumor progression during the waiting period before surgery. An alternative to this strategy is radioembolization, which treats the tumor in the embolized lobe along with induction of contralateral hypertrophy. An increase in the size of the non-embolized lobe by 42% after radioembolization has been reported in cirrhotic livers<sup>[49]</sup>. A comparison of PVE and radioembolization in non-cirrhotic livers has shown that PVE induces a greater degree of hypertrophy of the FLR than that radioembolization<sup>[50]</sup>. Nevertheless, this novel procedure is promising, as it enables both embolization and treatment of the tumor(s) in a single step.

## CONCLUSION

Much basic and clinical evidence associated with PVE has been accumulated, however, especially for cases of HCC with underlying liver cirrhosis or chronic hepatitis, the available clinical data are limited. Development of safe and reliable novel approaches that can be used in combination with PVE to induce rapid hypertrophy of FLR, which can be applied even to chronically diseased livers, is needed.

### Abstract

Incidentally found focal liver lesions are a common

finding and a reason for referral to hepatobiliary service. They are often discovered in patients with history of liver cirrhosis, colorectal cancer, incidentally during work up for abdominal pain or in a trauma setting. Specific points should be considered during history taking such as risk factors of liver cirrhosis; hepatitis, alcohol consumption, substance exposure or use of oral contraceptive pills and metabolic syndromes. Full blood count, liver function test and tumor markers can act as a guide to minimize the differential diagnosis and to categorize the degree of liver disease. Imaging should start with B-mode ultrasound. If available, contrast enhanced ultrasound is a feasible, safe, cost effective option and increases the ability to reach a diagnosis. Contrast enhanced computed tomography should be considered next. It is more accurate in diagnosis and better to study anatomy for possible operation. Contrast enhanced magnetic resonance is the gold standard with the highest sensitivity. If doubt still remains, the options are biopsy or surgical excision.

**Key words:** Focal liver lesions; B-mode ultrasound; Ultrasound; Magnetic resonance; Fine needle biopsy; Computed tomography

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Focal liver lesions are being found more commonly, which may need further investigations. History and physical examination is essential part of work up. Blood work is an important adjunct in the patient's journey. There are different modalities of imaging (B-mode ultrasound, contrast enhanced ultrasound, contrast enhanced computed tomography and contrast enhanced magnetic resonance); each has advantages and disadvantages. The decision of biopsy or surgery is kept for the treating team.

## INTRODUCTION

Focal liver lesions (FLLs) are a common reason for consultation to a hepatobiliary service, they often need further work up, and investigations. They are often discovered in patients with a cirrhotic liver or colorectal cancer but can be found incidentally during work up for abdominal pain and sometimes in the trauma setting.

Incidental liver lesions are being found more commonly due to advancement in imaging modalities. In some reports, incidental FLLs were found in up to 33% of radiological studies. In autopsy cases, it reached more than 50%<sup>[1,2]</sup>.

Unfortunately, there is no clear pathway for work up and with a wide differential diagnosis; these lesions may need multiple imaging modalities to characterize whether they are benign or malignant.

A cornerstone in evaluating these patients is history and physical examination. A deferential diagnosis of metastasis vs hepatocellular carcinoma (HCC) should be considered for patients with family history of previous malignancies or chronic liver diseases. However, in a healthy population without significant medical background, the differential diagnosis should include wider possibilities, both benign and malignant.

Different modalities are being used to reach a definitive diagnosis. These include: B-mode ultrasound (B-US), contrast enhanced ultrasound (C-US), elastography, contrast enhanced computed tomography (C-CT) scan and contrast enhanced magnetic resonance (C-MR) imaging. Due to the lack of guidelines, most institutions are using all available modalities to establish a diagnosis, which is time consuming, uncomfortable, and not cost effective.

## HISTORY AND PHYSICAL EXAMINATION

Specific points should be taken in consideration as a part of history taking; risk factors for liver cirrhosis like hepatitis and alcohol consumption, exposure to substances known to cause liver lesions, use of the oral contraceptive pill should be elucidated especially in childbearing aged women. Obesity and metabolic syndromes and diabetes are know pathognomic factors for non alcoholic fatty liver disease which is know to increase hepatocellular cancer<sup>[3]</sup>. Patients with a previous cancer should raise the suspicion of a liver metastatic lesion. A family history of malignancy should also be clarified<sup>[4]</sup>. A history of fever and travel should raise the suspicion of infective process.

During physical examination of the patient-jaundice, cachexia, palpable masses, palpable lymph nodes and stigmata of liver disease - should be looked for (Table 1)<sup>[4]</sup>.

The differential diagnosis of a liver lesion is wide, and

can be benign requiring no treatment or an advanced malignant condition beyond cure. The list can be minimized with a careful clinical, chemical and radiological assessment (Table 2).

## BLOOD WORKS

When requesting blood investigation for patients with FLL the results should answer three essential points.

The general condition of the patient; using a full blood count, renal profile, liver function test and albumin level.

The assessment of liver status using the above with the addition of a coagulation profile. These will help obtain a Childs-Pugh score and can be determinant in planning proper management plan.

Tumor markers such as carcinoembryonic antigen (CEA), alpha-feto protein (AFP) and cancer antigen 19-9 (CA19-9) should be requested. A high-level of CEA should raise the possibilities of metastatic colorectal cancer. HCC and cholangiocarcinoma could have raised level of AFP and CA19-9 respectively. An elevated AFP (over 400 ng/mL) may confirm the diagnosis if combined with the addition of two confirmatory imaging techniques<sup>[5]</sup>.

## B-US

The limitation of any type of ultrasonography (USS) (B-mode or contrast enhanced) is the visualization of the whole liver. When the whole liver can be seen USS is a very useful screening test but in certain patients views of parts of the liver can be very limited which limits the usefulness of the investigation.

B-US is one of the most commonly used modalities to investigate the liver and can help to diagnose different pathology. In patients presenting with liver disease, abdominal pain and jaundice a B-US is usually requested. In the Focused Assessment with Sonography for Trauma examination, liver lesions are found in approximately 12 of every 1000 patients examined<sup>[6]</sup>. B-US is also recommended in the surveillance for patients at a high risk of developing HCC<sup>[7,8]</sup>.

The role of B-US in the diagnosing FLLs in a healthy patient is limited to a few diagnoses, of which hemangioma is the most common. Haematomas, hydatid cysts, and abscesses can be conveniently identified using B-US alone. The diagnosis of other FLLs with B-US alone is more challenging and rarely possible.

The use of pulsed and color Doppler USS is limited to focal nodular hyperplasia (FNH) in which the central artery with radial distribution is a characteristic element present in approximately 80% of cases<sup>[9]</sup>.

## C-US

There are two main types of contrast used with ultrasound, micro-bubbles (MBs) and Sonazoid. MBs can be

**Table 1 Clinical signs in-patients with liver disease**

General	Compensated	Decompensated
Jaundice	Xanthelasma	Disorientation
Fever	Parotid enlargement	Drowsiness
Loss of body hair	Spider naevi	Coma
	Gynecomastia	Hepatic flap
	Large or small liver	Fetor hepaticus
	Splenomegaly	Ascites
	Clubbing	Dilated veins on abdominal wall
	Liver palms	Oedema
	Dupuytren's contracture	
	Xanthoma	
	Scratch marks	
	Testicular atrophy	
	Purpura	
	Pigmented ulcers	

defined within different vascular phases: Arterial, portal and the delayed venous phase and are very useful in the detection of malignancies. Sonazoid is approved only in Japan and has an extra post-vascular phase (also called the Kupffer phase), MBs become phagocytosed by Kupffer cells and hence there is no post vascular phase when MBs are used.

Malignancies are characterized by hypo enhancement in the portal and venous phases as well as in the post-vascular phase, making their detection with C-US possible. C-US has been shown to be a reliable imaging technique for follow-up of metastatic liver disease with an accuracy of 91% compared to CT scan and MR imaging<sup>[10]</sup>.

In imaging of HCCs C-US is more complicated. Well-differentiated HCC lesions are iso enhancing in late phases in 51% of cases only, meaning that other imaging modalities are required<sup>[11]</sup>.

The use of USS contrast agents has radically changed the approach to the characterization of FLLs. C-US allows the classification of the majority of FLLs with a high diagnostic accuracy. The typical pattern of FLLs has been well described in the European Federation of Societies for Ultrasound in Medicine and Biology guidelines for C-US, originally published in 2004, updated in 2008, and soon to be updated again<sup>[12,13]</sup>.

Excluding simple cysts (without enhancement in all phases), benign FLLs are generally characterized by an iso echoic pattern in the portal and late phases; because of the persistence of USS contrast agents in the sinusoidal space. In contrast, the washout of these agents in late phases is characteristic of malignant lesions.

Hervé Trillaud confirmed the superior results of real-time C-US for FLLs characterization, compared to that of unenhanced ultrasound. Furthermore, it was demonstrated that the diagnostic accuracy of SonoVue®-enhanced ultrasound was better in comparison to C-CT and C-MR<sup>[14]</sup>.

Hohmann *et al.*<sup>[15]</sup> using MBs agents in C-US with a long-lasting late phase, showed no significant difference in lesion detection compared with C-MR imaging.

**Table 2 Common differential diagnosis of focal liver lesions**

Benign lesions	Malignant lesions
Cystic lesion (5%-14%)	Metastasis (14.4)
Simple, infectious, pre malignant	Cystic lesions (8%)
Hemangioma (2%-20%)	Hepatocellular carcinoma (2%-6%)
Hepatic adenoma (3%)	Cholangiocarcinoma (2%)
Biliary hamartoma (1.5%)	Lymphoma
Regenerative nodule (11%)	Sarcoma

## ELASTOGRAPHY

Real-time (RT) elastography is a technique that can estimate the strain modules from radiofrequency signals in response to external compression and provide an estimation of tissue elasticity. This technique has been studied for the characterization of nodules in superficial structures such as the breast, thyroid, and prostate. Few studies are available concerning its application to the liver, particularly for the evaluation of liver fibrosis. Apart from its use for characterization, RT elastography has been studied for the detection of liver nodules in animal models and during surgery<sup>[16,17]</sup>. In the latter setting, it has been demonstrated to have a higher diagnostic accuracy than B-mode intraoperative USS in detecting lesions surrounded by a heterogeneous background or with an iso echoic pattern (96% vs 89%). Nevertheless, its role in the detection of FLLs is yet to be definitively assessed.

## C-CT SCAN

C-CT scan is one of the essential imaging studies of FLL. The protocol and ability to acquire a multiphasic study is paramount in characterizing liver lesions. Triphasic images are the method of choice, which give a significant improvement in the result compared to single-phase studies<sup>[18]</sup>. The ability for three-dimensional reconstruction helps in assessing the vascular anatomy, the liver and tumor volumes. It also provides a good screening tool to the rest of the abdomen as well as to stage a malignant pathology. Differentiation between benign and malignant conditions is based on the degree of uptake of the contrast agent at different phases of the study. For example, hepatocellular cancer has an early uptake of contrast in the arterial phase with an early washout in the portal and delayed phases (Figure 1)<sup>[8]</sup>. One of the limitations of C-CT is the large dose of radiation given to the patient and the nephrotoxic effect of the iodine contrast that limit its use in patients with renal impairment.

## C-MR SCAN

C-MR is the best modality for FLLs assessment, in both primary and metastatic malignancy. C-MR represents the current technique of choice in this setting since it is free of ionizing radiation as well as demonstrating a high contrast resolution using several sequences and different

**Figure 1** Contrast enhanced computed tomography images of hepatocellular carcinoma. A 55 years old male, diabetic, presented with upper abdominal pain (arrows shows the lesion in different phases with clear washout at the venous phase).

types of contrast media. The commonly used contrast media are gadolinium-chelates, which have an extra-cellular hepatic distribution which help in differentiating liver lesions and obtaining angiography. Other types of contrast agent have an intra-cellular distribution such as ferrumoxides and hence help to detect liver parenchymal lesions<sup>[19-21]</sup>. There is general agreement about the superiority of C-MR with extra-cellular contrast medium compared to the baseline study without contrast or with other types of contrast<sup>[22-26]</sup>.

Primovist (Gd-EOB-DTPA) is a biphasic hepatobiliary magnetic resonance contrast agent. Dynamic C-MR imaging can be performed with the Gd-based extracellular contrast agents where the hemodynamic characteristics of the lesion can be studied. Following that, the hepatobiliary phase can be obtained when the contrast agents are excreted in both renal and biliary systems. Obtaining hepatobiliary phase can provide histological as well as functional information about lesions which might improve the diagnostic accuracy of FLLs<sup>[27]</sup>. Gd-EOB-DTPA-enhanced MR can provide useful information to help characterizing benign and malignant focal lesions and not only to detect them (Figure 2)<sup>[28]</sup>.

Soussan *et al*<sup>[29]</sup> reported that using gadolinium-based C-MR gives a diagnostic accuracy of 52%-66% for incidentally found solid liver lesions compared to 52%-53% with C-US.

Chung *et al*<sup>[30]</sup> demonstrated that Gd-EOB-DTPA-enhanced MR is more accurate to differentiate between benign and malignant lesions and more specific to diagnosis FNH and focal eosinophilic infiltration. Both

dynamic C-CT and Gd-EOB-DTPA-enhanced MR had similar high diagnostic accuracy for hemangiomas and HCCs, whereas other relatively uncommon lesions such as inflammatory myofibroblastic tumor, embryonal sarcoma or schwannoma are rarely diagnosed accurately on both modalities<sup>[30]</sup>.

An advantage of C-MR is lack of ionizing radiation and the ability to use in renal impairment patients. It also provides a better characterization of liver lesions compared to other modalities. A drawback is the high cost and the longer procedure duration<sup>[30]</sup>.

## BIOPSY VS SURGERY

Radiological imaging, tumor markers and other information gathered through the assessment process are often diagnostic, and therefore biopsy is rarely needed. Biopsy increases risks of bleeding and needle-track seeding. Biopsy of hepatic adenomas, FNH, and hemangioma has an increased risk of bleeding<sup>[31]</sup>. It has been reported that biopsy of HCCs are associated with a significant risk of needle-track seeding (1.6%-5%)<sup>[4,32,33]</sup>.

A group of investigators studied 160 patients with FLLs. Preoperative fine needle biopsy was not performed. After surgery, 98% of preoperative diagnosis was confirmed histologically<sup>[34]</sup>.

In rare cases imaging might not be conclusive, and hence, a surgical resection for definitive diagnosis might be needed. Resection will confirm the diagnosis, prevent progression of premalignant conditions and will reduce the risk of bleeding or seeding if biopsy were done.

**Figure 2** Contrast enhanced magnetic resonance images of focal nodular hyperplasia. A 30 years old female, medically free, had abdominal pain; ultrasonography showed gallstones and liver lesion (arrows shows the lesion with the characteristic central scar of FNH).

Other indication for surgery is resectable lesion, which has been characterized on imaging, and a diagnosis has been made.

Fine-needle liver biopsy of FLLs is generally reserved for patients who are not surgical candidates and can be done at the same time of non-surgical treatments such as radiofrequency ablation or trans arterial chemoembolization.

## CONCLUSION

Incidentally found FLLs should be thoroughly assessed using history and physical examination in association with blood tests as the starting point to formulate a differential diagnosis. Imaging modalities should be used wisely to save cost but to get the highest sensitivity possible. Ultrasound is fast, feasible, safe, cost effective and if combined with contrast, has an increased sensitivity in reaching the diagnosis but C-CT has a greater accuracy in diagnosis, is more widely applicable (less influenced by body morphology) and is helpful to study liver anatomy. C-MR is the modality of choice with the highest sensitivity. Biopsy should be reserved for questionable lesions where surgery is not an option.

### Abstract

**AIM:** To achieve an evidence-based conclusion regarding the safety and efficacy of telbivudine during pregnancy.

**METHODS:** A pooled analysis of data from a literature search reported 1739 pregnancy outcomes (1673 live births) from 1725 non-overlapping pregnant women treated with telbivudine. The prevalence of live birth defects (3.6/1000) was similar to that of the non-antiviral controls (3.0/1000) and not increased as compared with overall prevalence (14.5 to 60/1000). No target organ toxicity was identified. The prevalence of spontaneous abortion in pregnant women treated with telbivudine (4.2/1000) was not increased compared with the overall prevalence (16/1000). The mother-to-child transmission rate was significantly reduced in pregnant women treated with telbivudine (0.70%) compared to those treated with the non-antiviral controls (11.9%;  $P < 0.0001$ ) or compared to the historical rates of hepatitis B virus (HBV)-infected population without antiviral treatment (10%-15%).

**RESULTS:** Cumulatively 489 pregnancy cases have been reported in the telbivudine pharmacovigilance database (with a cut-off date 31 August 2014), of those, 308 had known pregnancy outcomes with 249 cases of live births (239 cases of live birth without congenital anomaly and 10 cases of live birth with congenital anomaly). In the latest antiretroviral pregnancy registry report (1 January 1989 through 31 January 2015) of 27 patients exposed to telbivudine during pregnancy (18, 6 and 3 during first, second and third trimester, respectively) 19 live births were reported and there were no cases of birth defects reported.

**CONCLUSION:** Telbivudine treatment during pregnancy presents a favorable safety profile without increased rates of live birth defects, spontaneous abortion or elective termination, or fetal/neonatal toxicity. Exposure to telbivudine in the first, second and third trimester of pregnancy has been shown to significantly reduce the risk of HBV transmission from mother to child on the basis of standard immune prophylaxis procedure.

**Key words:** Telbivudine; Hepatitis B virus; Pregnancy; Mother-to-child transmission; Vertical transmission

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The data from literatures, pharmacovigilance reports on telbivudine exposure and antiretroviral pregnancy registry during pregnancy in women with hepatitis B virus (HBV) infection showed no increased rates of live birth defects, spontaneous abortion or elective termination. No fetal/neonatal toxicity was reported during telbivudine treatment. Telbivudine exposure in the second and/or third trimesters of pregnancy has been shown to reduce the risk of HBV transmission from mother to child if administered in addition to hepatitis B immunoglobulin and HBV vaccination with a favorable safety profile.

Piratvisuth T, Han GR, Pol S, Dong Y, Trylesinski A. Comprehensive review of telbivudine in pregnant women with chronic hepatitis B. *World J Hepatol* 2016; 8(9): 452-460 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i9/452.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i9.452>

## INTRODUCTION

Chronic hepatitis B (CHB) infection is a major public health problem. Perinatal or childhood transmission of hepatitis B virus (HBV) commonly leads to chronic hepatitis which causes necroinflammation and progression of fibrosis resulting in higher risk of developing cirrhosis and hepatocellular carcinoma<sup>[1]</sup>. Over 50% of CHB carriers in endemic areas acquired their infection perinatally<sup>[2,3]</sup>. In the absence of prevention, infants born to hepatitis B e antigen (HBeAg) positive mothers have a 40%-90% risk of acquiring CHB *via* vertical

transmission<sup>[4]</sup>. In addition, 15%-90% of infected infants develop chronic infection (according to the HBeAg status of the mother), compared with < 5% of patients who acquire infection during adulthood<sup>[5-7]</sup>.

It was reported that 42.1% of infants born to HBsAg-positive mothers globally acquired HBV infection perinatally, because those infants did not receive any active or passive immunoprophylaxis for HBV. In contrast only 2.9% of infants who received immunoprophylaxis acquired HBV infection perinatally<sup>[8]</sup>. HBV perinatal transmission or mother-to-child transmission (MTCT) is considered to occur mainly at delivery. Therefore, standard immunoprophylaxis procedures to prevent perinatal transmission are recommended<sup>[9]</sup>. This standard procedure is based on the combination of passive and active immunization with hepatitis B immunoglobulin (HBIG) and HBV vaccination. However, immunoprophylaxis may not be effective in a proportion of newborns from highly viremic mothers (serum HBV DNA > 10<sup>6-7</sup> IU/mL) who are mostly HBeAg positive, who carry a > 10% risk of vertical HBV transmission despite efficient HBIG and vaccination<sup>[10]</sup>. The vaccine failure cases were reported in previous studies<sup>[11-13]</sup>. There was an earlier report from Mayotte, a French territory in Africa, that newborns who had received complete and timely sero-vaccination had a low immunoprophylaxis failure rate (3%)<sup>[14]</sup>.

Antiviral therapy administered to HBV carrier mothers during pregnancy plus appropriate immunoprophylaxis to newborns have been suggested to effectively prevent MTCT by reducing maternal HBV DNA levels and developing passive immunization in newborns. The European Association for the Study of the Liver (EASL) guidelines recommend the use of a nucleos(t)ide analogue to reduce viral loads in pregnant women who are hepatitis B surface antigen (HBsAg) positive and have high HBV DNA levels (> 10<sup>6-7</sup> IU/mL) to enhance the effectiveness of HBIG and vaccination<sup>[15,16]</sup>. Pregnant women with cirrhosis have an increased risk of developing maternal complications, significant perinatal complications, and poor pregnancy outcomes<sup>[9]</sup>. Therefore, it is often recommended that woman of child-bearing age with advanced fibrosis or cirrhosis should be treated with nucleos(t)ide analogues and that their treatment regimen must be maintained during a future pregnancy<sup>[13]</sup>.

No anti-HBV therapies are currently approved for the prevention of MTCT in pregnancy. Each antiviral has been assigned by the Food and Drug Administration (FDA) to one pregnancy drug class based on preclinical evaluation of the potential teratogenicity. Of the seven antiviral drugs for CHB currently available, alpha interferons and pegylated alpha interferons have anti-proliferative actions and are contraindicated during pregnancy<sup>[15]</sup>. Of the currently approved five oral nucleos(t)ide analogues, tenofovir and telbivudine belong to pregnancy category B (animal reproduction studies have failed to demonstrate a risk to the fetus and studies in pregnant women failed to demonstrate a risk to the fetus), while the other three

**Table 1 Food and drug administration pregnancy categories for hepatitis B virus antiviral therapy<sup>[15]</sup>**

Pregnancy category	definition	HBV therapy categorization
A	Adequate and well controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters)	None
B	Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women or animal studies that have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester	Telbivudine; Tenofovir
C	Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well controlled studies in humans, but potential benefits might warrant use of the drug in pregnant women despite potential risks	Lamivudine; Entecavir; Adefovir
D	There is positive evidence of human fetus risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits might warrant use of the drug in pregnant women despite potential risks	None
X	Studies in animals or humans have demonstrated fetus abnormalities, and/or there is positive evidence of human fetus risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits	Interferon

drugs, lamivudine, adefovir and entecavir, belong to pregnancy category C (animal reproduction studies have shown an adverse effect on the fetus and no adequate or well controlled studies in humans)<sup>[15]</sup> (Table 1). Of the aforementioned drugs, there are limited data on treating HBV infection during pregnancy. A prospective randomized controlled trial of tenofovir in HBV infected mothers have been reported<sup>[17]</sup>. Treatment with lamivudine in late pregnancy has shown reduced mother-to-infant transmission but drug resistance is a potential concern<sup>[15]</sup>.

Telbivudine has shown no carcinogenicity, teratogenicity, mutagenicity or mitochondrial toxicity in pre-clinical studies. Telbivudine has demonstrated greater antiviral and clinical efficacy than lamivudine in CHB patients<sup>[18-20]</sup>. In a prospective cohort study, telbivudine showed better preventive effect in reducing perinatal transmission when used in early trimesters of pregnancy than latter in pregnancy. There were no complications or severe adverse events observed in telbivudine-treated mothers or infants<sup>[21]</sup>. Another study showed that telbivudine treatment in chronic HBV-infected mothers was effective in blocking the MTCT of HBV and growth and development of the children were normal<sup>[22]</sup>. As recommended by EASL and the Asian-Pacific Association for the Study of the Liver guidelines, telbivudine is listed as one of the preferred drugs to be used for the prevention of MTCT in the last trimester of pregnancy in HBsAg-positive women with high levels of viremia (serum HBV DNA > 10<sup>6-7</sup> IU/mL)<sup>[15,23]</sup>.

Here we present a summary of the information available on the safety and efficacy of telbivudine when used during pregnancy. This analysis was based on scientific literature, and analysis of a Novartis pharmacovigilance database and a public Antiretroviral Pregnancy Registry. The objective of this analysis was to achieve an evidence-based conclusion regarding the safety and efficacy of telbivudine use in HBV infected pregnant mothers and to confirm the observations from telbivudine preclinical studies.

## MATERIALS AND METHODS

### Preclinical studies

Several preclinical studies of reproductive and developmental toxicity have been conducted with telbivudine to assess its potential adverse effects on fertility, general reproductive performance, development of the conceptus, gestation, birth and post-natal performance (Novartis; data on file). An overview of these studies conducted is summarized in Table 2.

### Clinical studies

Programmed searches were conducted in literature databases for an extensive literature review. The cut-off periods were set as no starting limit till May 2015. Databases included BIOSIS Previews, EBM Reviews (Cochrane Database of Systematic Reviews, ACP Journal Club, Database of Abstracts of Reviews of Effects, Cochrane Central Register of Controlled Trials, Cochrane Methodology Register, Health Technology Assessment, and NHS Economic Evaluation Database), Embase, International Pharmaceutical Abstracts, MEDLINE (including in-process and other non-indexed citations, MEDLINE Daily Update, and OLDMEDLINE). The search strategy included the following keywords in all fields using different combinations with the Boolean operators OR and AND: "telbivudine" or equivalent names ("2' deoxy beta thymidine", "beta thymidine", "epavudine", "LdT 600", "NV 02B", "NV02B", "Sebivo" or "Tyzeka"); pregnant or pregnancy; hepatitis. Another search was conducted in Chinese databases to review Chinese literatures in the following Chinese databases: Wanfang Med Online (med.wanfangdata.com) and China Knowledge Resource Integrated Database (www.cnki.net). Keywords for search in Chinese databases included "telbivudine", "gestation", "pregnancy", "intrauterine infection", "mother-to-child transmission" and "vertical transmission".

A consistent methodology was used when reviewing each paper. The main criterion for selecting a publication

**Table 2** Reproductive and developmental toxicity with telbivudine

Study type	Route of administration	Species	No. of animals	Doses (mg/kg per day)	Treatment	Reference
Rat studies						
Fertility, reproduction, developmental	Oral gavage	Sprague Dawley rats	25 males 25 females	0, 100, 500, 1000	Males: -28 AC to DG 17 Females: -15 AC to DG 17	Study 1314-001
Fertility	Oral gavage	Sprague Dawley rats	25 males 25 females	0, 1000, 2000	Males: -28 AC to DG 13	Study 1314-005
Fertility	Oral gavage	Sprague Dawley rats	25 males 25 females	0, 2000	Females: -15 AC to DG 7	Study 1314-006
Peri/postnatal	Oral gavage	Sprague Dawley rats	25 females	0, 100, 250, 1000	Females: DG 7 to DL 20	Study 1314-003
Rabbit study						
Developmental	Oral gavage	New Zealand White rabbits	20 females	0, 50, 250, 1000	Females: DG 6-18	Study 1314-002

AC: Ante coitum; DG: Gestation day; DL: Lactation day.

was completeness of safety data ("adequate safety information" was defined as including both pregnancy and pregnancy/infant outcome to address the safety profile of telbivudine use in pregnancy) and non-overlapping cases. For articles reported more than once by the same author, the corresponding author was contacted for clarification of the case details. Systemic reviews or meta-analysis were not included in this analysis. Studies with non-overlapping data and safety information were selected and analyzed. All pregnant women who were treated with telbivudine during the period of pregnancy and were reported with a pregnancy outcome were included in the analysis of this review. All those pregnancies without a pregnancy outcome reported or lost to follow up were excluded from this review.

### Pharmacovigilance database

Pregnancy cases from Novartis pharmacovigilance database were collected with a cut-off date of 31 August 2014. Data collected prospectively (acquired prior to the knowledge of the pregnancy outcome or prior to the detection of a congenital malformation at prenatal examination (e.g., fetal ultrasound or serum markers) were separated from data collected retrospectively (acquired after the outcome of the pregnancy was known or after the detection of a congenital malformation on prenatal test). Only safety data were collected from the cases; data on perinatal and intrauterine information was not adequately collected.

### Antiretroviral pregnancy registry

The Antiretroviral Pregnancy Registry (APR; [www.APRRegistry.com](http://www.APRRegistry.com)) is designed to collect and evaluate data on the outcomes of pregnancies exposed to antiretroviral products. It has been actively collecting relevant data since January 2003 and telbivudine has been included in the list of evaluated drugs. An interim analysis report is issued online semi-annually including data from 1 January 1989 through the latest period. The interim report contains analyses of voluntary prospective reports (i.e., reports made to the Registry prior to the outcome of pregnancy being known) of prenatal exposures. Additionally, data from retrospective reports are collected,

but the outcomes are reviewed and evaluated separately. The present analysis was based on the latest available APR Interim Report<sup>[24]</sup> (1 January 1989 through 31 January 2015)

### Endpoints assessment and variables of analysis

The following endpoints were selected in pregnant women with HBV infection: Pregnancy outcome and efficacy of preventing MTCT.

According to the Committee for Medicinal Products for Human Use (CHMP) 2005 guidelines on the exposure to medicinal products during pregnancy, "pregnancy outcome" is defined as the end products of pregnancy, which include three main categories: (1) fetal death; (2) termination of pregnancy; and (3) live birth<sup>[25]</sup>.

Fetal death (intrauterine death or *in utero* death) is defined as death prior to complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of pregnancy; the death is indicated by the fact that after such separation the fetus does not show any evidence of life [World Health Organization (WHO) International Classification of Diseases (ICD) 10]. There are 2 types of fetal death: (1) early fetal death (before 22 completed weeks of gestation) comprises ectopic pregnancy (extra-uterine pregnancy or early fetal death most often in the Fallopian tube) and miscarriage (spontaneous abortion or molar pregnancy); and (2) late fetal death (after 22 completed weeks of gestation) is known as stillbirth.

Termination of pregnancy (induced abortion or elective abortion) is artificial interruption of pregnancy.

Live birth is the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of pregnancy, which breathes or shows any evidence of life after separation (WHO ICD 10).

The same guidelines also defined the variables used to measure prevalence of birth defects<sup>[25]</sup>: (1) live birth prevalence rate = (number of cases among live born infants/total number of live born infants) × 1000; (2) birth prevalence rate = [number of cases among live and stillborn infants/total number of (live + still) born infants] × 1000; and (3) Total prevalence rate = (number of cases among live births, stillborn and terminated pregnancies)/(number of live births, stillbirths and

terminated pregnancies)  $\times 1000$ .

The efficacy variable is the rate of MTCT, which is conservatively defined as evidence of HBV infection (detectable HBV DNA or detectable HBsAg) at the age of 6-12 mo or older in the source literature references.

## RESULTS

### Preclinical studies

Studies in pregnant rats (Study 7245-112) and rabbits (Study GVA00010) showed that telbivudine crosses the placenta. Developmental toxicity studies in rats (Study 1314-001) and rabbits (Study 1314-002) at doses up to 1000 mg/kg per day and with exposure levels 6- to 37-times higher indicated that telbivudine was not a developmental toxin in either species (Table 2). Similarly, the high doses (1000 mg/kg per day) given to rats during the peri- and post-natal developmental periods showed no evidence of post-natal developmental toxicity or change in behavior (Study 1314-003). Based on these findings, it is concluded that telbivudine is not teratogenic and has shown no adverse effects in developing embryos and fetuses, as well as in pre- and postnatal development. Telbivudine use is considered to pose a negligible risk to fetus during pregnancy.

### Clinical studies from literature search

**Characteristics of the selected cases:** A total of 18 publications with non-overlapping data and safety information were identified through the literature search, in which 1725 mothers were treated with telbivudine during pregnancy period. These 1725 non-overlapping pregnancy cases were all prospective cases where mothers were exposed to telbivudine during different trimester of pregnancy. The 18 selected publications are listed in Table 3.

**MTCT rate:** Based on the literature review, MTCT rate of telbivudine treatment during pregnancy with the

standard immunoprophylaxis procedure was reported to be 0.70% (11/1572; Table 4). Of the 11 infants with MTCT, 8 mothers started telbivudine treatment from 3<sup>rd</sup> trimester and 3 mothers started from 1<sup>st</sup> trimester. Of the 11 infants with MTCT, 6 mothers had  $> 6 \log$  copies/mL HBV DNA prior to telbivudine treatment, 2 mothers had  $> 5 \log$  copies/mL and 2 mothers had  $> 3 \log$  copies/mL HBV DNA. There was no report on HBV DNA level for 1 mother.

Of the 18 selected literature references, 14 had a non-antiviral control group. The MTCT rate in the non-antiviral treatment group was 11.9% (124/1041; Table 4). The MTCT rate calculated in telbivudine treated patients (0.70%) was significantly lower vs MTCT rate calculated in patients from non-antiviral control group (11.9%) ( $P < 0.0001$ , Fisher's exact test).

**Rates of birth defects:** A total of 1739 pregnancy outcomes were reported from 1725 pregnancies (Figure 1). The safety outcomes of infants in terms of rates of birth defects were calculated according to the three definitions of the CHMP guidelines<sup>[25]</sup>.

Of the 1673 live births, a total of 6 infants had birth defects (3 infants with ankyloglossia, cutaneous hemangioma, and vaginal canal leak<sup>[22]</sup>; 1 infant with unilateral cleft palate<sup>[26]</sup>; 2 infants with a congenital cleft lip, palate and ear accessories<sup>[27,28]</sup>). Of the 6 infants with birth defects, 4 were born to mothers starting telbivudine treatment in 1<sup>st</sup> trimester and 2 were born to a mother starting telbivudine treatment in 2<sup>nd</sup> or 3<sup>rd</sup> trimester. The "live birth prevalence rate" was  $6/1673 = 3.6/1000$  which was not significantly different from the non-antiviral control ( $3.0/1000$ ) ( $P = 1.0000$ ) (Table 4). Since no stillbirth was reported, the "birth prevalence rate" was same as the "live birth prevalence rate"  $6/1673 = 3.6/1000$ , which was not significantly different from the non-antiviral control ( $3.0/1000$ ) ( $P = 1.0000$ ). The "total prevalence rate" of birth defects with telbivudine exposure was  $7/1674 = 4.2/1000$  (Table

**Table 4** Summary of prevalence rates of birth defects, abortion and perinatal transmission rates with telbivudine exposure during pregnancy in literature studies

	Events ( <i>n</i> )	Population ( <i>N</i> )	Rate in telbivudine treated patients ( <i>n/N</i> )	Non-antiviral treatment control in literature studies	Background rates in overall population (prevalence based on surveillance reports)
Birth defects: Live birth prevalence	6	1673	3.6/1000 <sup>a</sup>	3.0/1000	14.5-60/1000 <sup>1</sup>
Birth defects: Birth prevalence	6	1673	3.6/1000 <sup>a</sup>	3.0/1000	NA
Birth defects: Total prevalence	7	1674	4.2/1000 <sup>b</sup>	3.0/1000	NA
Spontaneous abortion	7	1682	4.2/1000	NA	16/1000 <sup>2</sup>
Elective termination	1	1682	0.6/1000	NA	230/1000 <sup>3</sup>
MTCT	11	1572	0.70% (11/1572) <sup>d</sup>	11.9% (124/1041)	10%-15% <sup>4</sup>

<sup>1</sup>EUROCAT data<sup>[48]</sup>; MACDP data<sup>[49]</sup>; Christianson *et al*<sup>[50]</sup> (2006); Dai *et al*<sup>[54]</sup> (2011); <sup>2</sup>US CDC data<sup>[51]</sup>; <sup>3</sup>WHO data<sup>[52]</sup>; <sup>4</sup>Historical data from HBV-infected population without antiviral treatment<sup>[10-12]</sup>. <sup>a</sup>*P* = 1.0000 *vs* non-antiviral treatment control in the same literature studies (Fisher's exact test); <sup>b</sup>*P* = 0.7502 *vs* non-antiviral treatment control in the same literature studies (Fisher's exact test); <sup>d</sup>*P* < 0.0001 *vs* non-antiviral treatment control in the same literature studies (Fisher's exact test). NA: Not available; MTCT: Mother-to-child transmission.

**Figure 1** Analysis of the pregnancy outcomes from non-overlapping literature references. <sup>1</sup>1734 pregnancy outcomes from 1721 pregnancy mothers due to multiple births.

4), which was not significantly different from the non-antiviral control (3.0/1000) (*P* = 0.7502).

**Pharmacovigilance database:** A total of 489 cumulative pregnancy cases have been reported in the telbivudine pharmacovigilance database (with a cut-off date 31 August 2014). Of the 489 cases, 308 had known pregnancy outcomes with 249 cases of live births (239 cases of live birth without congenital anomaly and 10 cases of live birth with "congenital anomaly" including medical conditions that were not birth defects). Of these 10 cases, 6 cases were considered with congenital birth defects (one case each of hypertrophic pyloric stenosis, cryptorchism, atrial septal defect, syndactyly, hemangioma, and congenital heart disease). Of these 6 cases, 3 had telbivudine exposure during the first trimester.

Fifty-nine cases were reported with the following situations: Ectopic pregnancy (*n* = 2), spontaneous abortion (*n* = 11), intrauterine death (*n* = 3), neonatal death (*n* = 1), elective termination with fetal defects (*n* = 5) and elective termination without fetal defects or unknown (*n* = 37).

**Antiretroviral pregnancy registry:** Based on the cumulative current APR report (1 January 1989 through 31 January 2015), a total of 17332 evaluable prospective cases treated with anti-retroviral drugs during pregnancy period [most with human immunodeficiency virus (HIV) infection] were included in the primary analysis. Of the 8602 birth outcomes with a 1<sup>st</sup> trimester exposure to an antiretroviral drug, there were 219 reports of birth defects. Of the 9026 birth outcomes in the combined second and/or third trimester exposure to antiretroviral drugs, 249 were reported birth defects. Of 27 patients who were exposed to telbivudine during pregnancy (18, 6 and 3 during first, second and third trimester, respectively), 19 live births were reported and there were no cases of birth defects reported.

## DISCUSSION

The prevention of vertical transmission of HBV from mothers to their infants, while limiting toxicity is the key for treating pregnant women with HBV infection and is a significant unmet medical need. Telbivudine, classified as a FDA pregnancy category B drug, is listed

as one of the preferred drugs and may be used for the prevention of MTCT in the last trimester of pregnancy in HBsAg-positive women with high levels of viremia (serum HBV DNA  $> 10^{6-7}$  IU/mL)<sup>[15,23]</sup>. Preclinical studies have demonstrated that telbivudine is not teratogenic and has not shown any adverse effects in developing embryos and fetuses, as well as in pre- and postnatal development. However, certain other antiviral drugs are associated with some potential teratogenic risks during fetal development. A French long-term perinatal cohort study in HIV-infected mothers reported the risks of lamivudine exposure during pregnancies as it causes birth defects in children<sup>[29]</sup>. In the present analysis, based on a systematic literature review of clinical studies, the total prevalence rate of live birth defects in telbivudine-treated pregnancies was not significantly different as compared to the non-antiviral controls in the same literature studies or did not increase as compared to overall prevalence. In the six cases that were reported with congenital anomalies, no particular organ toxicity emerged. Three infants were reported with ankyloglossia, cutaneous hemangioma, and vaginal canal leak; 1 infant with unilateral cleft palate; 2 infants with a congenital cleft lip, palate and ear accessories. The reported prevalence of accessory auricle (0.06%) in this study was not higher than in studies from China (0.3%)<sup>[30]</sup>, Taiwan (0.2%)<sup>[31]</sup>, or Turkey (0.47%-0.7%)<sup>[32,33]</sup>. The reported prevalence of cleft lip and palate (0.12%) in this study was similar to those rates reported in studies performed in China (0.13%)<sup>[34]</sup>, in United States (cleftlip with or without palate 0.114% or cleft palate without cleft lip 0.109%)<sup>[35]</sup>.

The present analysis provides evidence that telbivudine usage in pregnant women in all pregnancy trimesters is generally safe and efficacious, which is in accordance with the EASL guidelines<sup>[15]</sup>. Moreover, at least 297 mothers with telbivudine exposure during 1<sup>st</sup> trimester were included in our study. Of note, 4/6 infants with birth defects were born to mothers who were exposed to telbivudine in the 1<sup>st</sup> trimester; and 8/11 infants with MTCT were born to mothers who were exposed to telbivudine in the 3<sup>rd</sup> trimester of pregnancy. Accordingly, the starting trimester of telbivudine treatment should be a balanced decision considering the maternal HBV DNA load and the need of minimizing risk of birth defects to achieve a best efficacy and safety outcome.

The pharmacovigilance database setting is different from clinical trials in terms of nature, objective or data completeness. In a clinical trial setting, all pregnancy cases treated with telbivudine are required to be collected either prospectively or retrospectively according to a predefined protocol. In contrast, pharmacovigilance database is an observational setting which is targeted to collect adverse event cases reported from all sources and physicians (or consumers) are trained to report cases when any "adverse" event occurs. However, pregnancy is usually not regarded by physicians and consumer as an "adverse" event. As a result, a majority of pregnancy cases with normal outcomes are not reported to the pharmacovigilance database, but those with unfavorable

pregnancy or infants' outcome are more likely to be regarded as "adverse" events and reported. In other words, pregnancy cases with normal outcomes are either under-reported by physicians or cannot be sufficiently collected in the current safety database settings. Therefore, in this review, data from the pharmacovigilance database was cited as another source of data, and it was not pooled with data from literature studies to calculate the prevalence rates of birth defects.

Several recent reviews on telbivudine use in pregnancy have reported results of pregnancy outcomes and prevention of HBV transmission, which were consistent with our results. A meta-analysis of telbivudine use in pregnancy (two randomized controlled trials and four non-randomized controlled trials) analyzed 306 mothers who received telbivudine treatment (vs no treatment,  $n = 270$ ). After a follow-up of 6-12 mo after delivery, HBV DNA positive rates were 0.9% in the telbivudine group vs 14.6% in the control group<sup>[36]</sup>.

In another review of 8 studies, a total of 663 infants born to telbivudine-treated mothers had significantly lower rates of HBsAg positivity and HBV DNA positivity measured post-partum at 6 mo (OR = 0.06,  $P < 0.00001$ ; OR = 0.05,  $P = 0.0003$ ) and 12 mo (OR = 0.13,  $P = 0.007$ ; OR = 0.08,  $P = 0.001$ ) vs the non-treatment control<sup>[37]</sup>.

Although the mechanism of MTCT of HBV is not yet fully elucidated, there are three proposed mechanisms (intrauterine transmission, transmission during delivery and post-partum transmission)<sup>[9]</sup>. Maternal serum HBV DNA level has been identified as the most important independent risk factor for MTCT<sup>[15]</sup>.

A majority of patients in our analysis had HBeAg-positive CHB and high HBV DNA levels prior to treatment with HBV DNA levels and HBeAg status being evenly matched between the telbivudine-treated patient and control groups. Telbivudine use during pregnancy resulted in a low rate of MTCT at 0.70% despite high HBV DNA levels at baseline. The MTCT rate in the non-antiviral control groups of the 14 literature references was 11.9%, which was similar to the rates reported in previous literature references (10%-15%)<sup>[10,11]</sup>. These results from 18 different studies with 1725 pregnancies indicate that the overall blocking of vertical transmission is 99.3% (MTCT 0.70%). Of the 18 literature studies, 15 studies did not report antiviral resistance associated with telbivudine treatment; 3 studies had reported a resistance rate of 1.2%, 2.3% or 6.5%.

A limitation of the analysis is the follow-up period in literature references which was a maximum of 12 mo for most of infants; therefore, long-term effects on such infants remain to be assessed.

In conclusion, the data from literatures, post-marketing pharmacovigilance reports on telbivudine exposure and APR during pregnancy in women with HBV infection showed no increased rates of live birth defects, spontaneous abortion or elective termination. No fetal/neonatal toxicity was reported during telbivudine treatment. The favorable safety profile observed from telbivudine reproductive and developmental preclinical

studies have been confirmed in various clinical settings. Importantly, based on the evidences from more than 1700 of HBV infected mothers reported from literature, telbivudine exposure in pregnancy has been shown to reduce the risk of HBV transmission from mother to child if administered in addition to HBIG and HBV vaccination with a favorable safety profile.

## ACKNOWLEDGMENTS

The authors wish to thank Rajeeb Ghosh from Novartis Healthcare for editorial assistance in the development of this manuscript.

## COMMENTS

### Background

Currently, no anti-hepatitis B virus (HBV) therapies are approved for the prevention of mother-to-child transmission (MTCT) of HBV during pregnancy. In this comprehensive review, data were collected from the published literature, a pharmacovigilance database and an ongoing public registry antiretroviral pregnancy registry (APR).

### Research frontiers

Here the authors present a summary of the information available on the safety and efficacy of telbivudine when used during pregnancy. This analysis was based on scientific literature, and analysis of a Novartis pharmacovigilance database and a public APR.

### Innovations and breakthroughs

The favorable safety profile observed from telbivudine reproductive and developmental preclinical studies have been confirmed in various clinical settings. Importantly, based on the evidences from more than 1700 of HBV infected mothers reported from literature, telbivudine exposure in pregnancy has been shown to reduce the risk of HBV transmission from mother to child if administered in addition to hepatitis B immunoglobulin and HBV vaccination with a favorable safety profile.

### Peer-review

This is a very interesting study on the safety of telbivudine administration in pregnancy and its efficacy in preventing MTCT of HBV infection. The data are well analysed and written and the conclusions are useful particularly for the hepatitis B e antigen positive mothers with high viral loads.

## Contents

*World Journal of Hepatology*  
Volume 8 Number 10 April 8, 2016

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Young-Hwa Chung, MD, PhD, Professor, Department of Gastroenterology, University of Ulsan College of Medicine, Asan Medical Center, Seoul 138-736, South Korea

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning arrhythmia, heart failure, vascular disease, stroke, hypertension, prevention and epidemiology, dyslipidemia and metabolic disorders, cardiac imaging, pediatrics, nursing, and health promotion. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Biliary complications are common after living donor liver transplant (LDLT) although with advancements in surgical understanding and techniques, the incidence is decreasing. Biliary strictures are more common than leaks. Endoscopic retrograde cholangiopancreatography (ERCP) is the first line modality of treatment of post

LDLT biliary strictures with a technical success rate of 75%-80%. Most of ERCP failures are successfully treated by percutaneous transhepatic biliary drainage (PTBD) and rendezvous technique. A minority of patients may require surgical correction. ERCP for these strictures is technically more challenging than routine as well post deceased donor strictures. Biliary strictures may increase the morbidity of a liver transplant recipient, but the mortality is similar to those with or without strictures. Post transplant strictures are short segment and soft, requiring only a few session of ERCP before complete dilatation. Long-term outcome of patients with biliary stricture is similar to those without stricture. With the introduction of new generation cholangioscopes, ERCP success rate may increase, obviating the need for PTBD and surgery in these patients.

**Key words:** Living donor liver transplant; Biliary complications; Biliary strictures; Endoscopic retrograde cholangiopancreatography; Percutaneous transhepatic biliary drainage

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Biliary complications are the Achilles heel of liver transplantation and are more common in live related liver transplant than cadaver liver transplant. Endoscopic retrograde cholangiopancreatography along with percutaneous transhepatic biliary drainage is successful in managing more than 90% of biliary complications after liver transplant. Although strictures increase morbidity after liver transplant, the mortality rates are not influenced by biliary strictures. This review provides diagnostic approach and management algorithm of these biliary structures in the setting of right lobe liver transplant.

Wadhawan M, Kumar A. Management issues in post living donor liver transplant biliary strictures. *World J Hepatol* 2016;

8(10): 461-470 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i10/461.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i10.461>

## INTRODUCTION

Liver transplantation has become a well-established treatment for end stage liver disease<sup>[1]</sup>. Living donor liver transplant (LDLT) is still the predominant form for transplantation in eastern part of the world including India. Biliary leaks and strictures are still recognized as the most common complications after LDLT. Biliary complications after orthotopic liver transplantation (OLT) are evaluated and treated by endoscopy; only a few require percutaneous interventions. Surgical intervention is necessary only in treatment failures as a backup option<sup>[2]</sup>. Non-anastomotic stricture (NAS) are uncommon and difficult to treat with endoscopic retrograde cholangiopancreatography (ERCP)/percutaneous transhepatic biliary drainage (PTBD). NAS's often require re-transplant as the only effective treatment option. This review will focus on the diagnosis and management of anastomotic biliary strictures (ABS) after LDLT.

## MAGNITUDE OF THE PROBLEM AND CONTRIBUTING FACTORS

Incidence of biliary complications after liver transplantation has been variably reported between 5%-40% (Table 1). The incidence is higher after LDLT compared to deceased donor liver transplant (DDLTL)<sup>[3]</sup>. Over last 3 decades the reported incidence of bile leaks as well strictures is decreasing (Table 1)<sup>[4-15]</sup>. This can be ascribed to better understanding of the technical causes leading to biliary complications.

Although the cause of biliary complications is mainly technical, various factors have been implicated in the development of these complications. Overview of the possible contributory factors and role of each has been listed in Table 2<sup>[12,14-22]</sup>.

In LDLT the anastomosis is made between right anterior and posterior ducts of the donor with the common hepatic duct of the recipient. The various types of anastomoses are shown in Figure 1. There could be one anastomosis if common trunk of right hepatic duct is available (Figure 2) or there could be two or more anastomoses (Figure 3). Usually, in case of double duct anastomosis, native right anterior and right posterior are used to anastomose to donor ducts. If the two ducts are close together, sometimes ductoplasty with single recipient duct is done (Figure 4). In rare circumstances, surgeons have used cystic duct for anastomosis to one of the ducts of the donor. In our own experience, the use of cystic duct for anastomosis leads to stricture formation in almost all cases (unpublished data). Once the stricture develops in cystic duct anastomosis, it is technically almost impossible to handle with endoscopy

**Table 1 Evolution of post living donor liver transplant biliary complications with the changing time**

Ref.	Year	Country	n	Follow-up (mo)	Leaks	Strictures
Sugawara <i>et al</i> <sup>[4]</sup>	2003	Japan	92	45	20.6%	9.7%

Kim <i>et al</i> <sup>[12]</sup>	2010	South Korea	22	51.3	0%	9.1%
Wadhawan <i>et al</i> <sup>[14]</sup>	2013	India	65	28	8.8%	10.3%
Mizuno <i>et al</i> <sup>[13]</sup>	2014	Japan	108	58.4	5.6%	13.9%
Vij <i>et al</i> <sup>[15]</sup>	2015	India	127	9.32	0.7%	0%

(Figures 5 and 6). At our center, we have abandoned using cystic duct of the recipient for ductal anastomosis.

## DIAGNOSIS

Biliary complications related to anastomosis could be leaks or strictures. The diagnosis of biliary complications is made on the basis of clinical symptoms (jaundice, itching, bilious drainage, and cholangitis), deranged liver function tests (LFT), and/or radiologic imaging. Imaging plays a very important role in diagnosis as well management of biliary problems. Ultrasonography (USG), magnetic resonance cholangiopancreatography (MRCP), hepatobiliary scintigraphy (HBS) as well as computerized tomogram (CT) have an important role in diagnosis and management of biliary problems.

The timeline for biliary complications after transplant is shown in Figure 7<sup>[23]</sup>.

Most bile leaks would present early after transplant (within first few weeks), almost all would manifest in 3 mo<sup>[23]</sup>. Leaks presenting early after transplants are usually diagnosed clinically by the presence of bile in the drains. Sometimes, even early bile leaks may be tricky to diagnose as many patients produce large amount of peritoneal fluid for a few days after transplant, thus diluting the bile. On the other hand, late leaks may present after drain removal with pain abdomen and fever with or without jaundice and septicemia. Role of static imaging (USG, CT, MRCP) in diagnosis of leaks is mainly to diagnose collections. However, HBS may be useful to diagnose subclinical leaks (cut surface leaks after LDLT, minor leaks from anastomotic site not apparent on drain)<sup>[24]</sup>. Minor bile leaks may have minimal derangement of LFT's, any fever with pain abdomen should raise a suspicion of bile leak. Any undiagnosed sepsis in post-operative setting, should raise the suspicion of bile leak and all efforts should be made to diagnose it.

Biliary strictures usually present later than leaks but within first year after transplant<sup>[23]</sup>. The most common

**Table 2 Overview of factors contributing to biliary complications**

Ref.	Year	Factor	Inference
Dalgic <i>et al</i> <sup>[16]</sup>	2005	Corner sparing sutures	Decreased incidence of complications
Castaldo <i>et al</i> <sup>[17]</sup>	2007	Continuous <i>vs</i> interrupted sutures	No difference in two techniques
Soejima <i>et al</i> <sup>[18]</sup>	2008	Hilar dissection to preserve blood supply	Decreased incidence of complications
Lin <i>et al</i> <sup>[19]</sup>	2009	Microsurgical biliary reconstruction	Decreased incidence of complications
Kim <i>et al</i> <sup>[12]</sup>	2010	Telescopic reconstruction of bile duct	Decreased incidence of complications
Chok <i>et al</i> <sup>[20]</sup>	2011	CIT and acute cellular rejection	Higher biliary complications with increased CIT Acute cellular rejection predicted biliary strictures
Horster <i>et al</i> <sup>[21]</sup>	2013	HCV infection as etiology	Higher incidence of biliary complications in patients with HCV infection and higher viral load
Wadhawan <i>et al</i> <sup>[14]</sup>	2013	Type of anastomosis	Higher incidence of biliary complications in double duct and cystic duct anastomosis
Mathur <i>et al</i> <sup>[22]</sup>	2015	Internal biliary stenting	No difference in complications with or without stenting
Vij <i>et al</i> <sup>[15]</sup>	2015	Corner sparing sutures Bile duct mucosal eversion	Decreased incidence of biliary complications

CIT: Cold ischemia time; HCV: Hepatitis C virus.

**Figure 1 Types of biliary anastomoses and corresponding biliary reconstructions**<sup>[54]</sup>. A: Single duct anastomosis; B: Double duct - minimum distance between two donor ducts, requires ductoplasty with recipient CBD; C: Double duct - two donor duct are far away, requires two separate duct anastomosis or a hepaticojejunostomy; D: Single duct to duct reconstruction; E: Double duct to duct reconstruction using right and left hepatic ducts; F: Double duct to duct reconstruction using cystic and CHD; G: Mixed type using duct to duct and hepaticojejunostomy. CHD: Common hepatic duct; CBD: Common bile duct.

presenting symptoms of stricture is itching with or without jaundice. LFT reveal a cholestatic pattern; bilirubin rise may be late in the course after LDLT. Less commonly, cholangitis may be the presentation of a biliary stricture. The first investigation in such cases is ultrasound of the abdomen. The presence of ductal dilatation has a high positive predictive value for the diagnosis of a stricture<sup>[25]</sup>. However, ductal dilatation is not prominent in many cases after LDLT. Absence of ductal dilatation has been previously reported to be an unreliable indicator of adequate biliary drainage<sup>[26]</sup>. It has been shown that donor bile ducts do not respond to the distal obstruction by same extent of dilatation as the non transplant liver<sup>[27]</sup>. MRCP has a sensitivity and specificity of 85%-90% in diagnosing biliary strictures after transplant<sup>[28,29]</sup>. The phenomenon of limited dilatation of donor ducts further underestimates the diagnosis of strictures on MRCP imaging. Specific criteria have

been proposed for diagnosis on MRCP imaging<sup>[30]</sup>. The variables that need to be studied in MRCP include type of anastomosis, length of stricture, length of common stump proximal to the anastomosis and differential diameters of recipient and donor ducts, *etc.* These help in the diagnosis as well as planning of endoscopic treatment.

Acute cellular rejection is an important differential when we have graft dysfunction. In fact rejection has been shown to be associated with stricture<sup>[21]</sup>. In our own experience, in the presence of ductal dilatation patients should be first taken for biliary decompression and if graft dysfunction persists, they should be treated for rejection. In the absence of dilatation, a liver biopsy may help in diagnosing the predominant cause of graft dysfunction.

HBS has been used in diagnosing the biliary obstruction with variable results<sup>[31,32]</sup>. It has a high positive predictive value but low sensitivity and specificity. Hence it is not widely used in the diagnosis of strictures.

Despite the fact that diagnostic ERCP is on its way out, it still remains an important modality to diagnose and confirm suspected biliary strictures after transplant. Sometimes in doubtful cases, a direct cholangiography [ERCP, percutaneous transhepatic cholangiography (PTC)] is required for the diagnosis. Thus direct cholangiography is the gold standard not only in establishing the diagnosis but also in allowing therapeutic intervention in the same setting. ERCP being less invasive with lower complication rates, is the modality of choice and is preferred over PTC<sup>[2,14]</sup>.

## MANAGEMENT

Biliary strictures can be managed by either endoscopic access (ERCP) or by percutaneous access (PTBD). All over the world, ERCP is the treatment of choice for management of biliary strictures after LDLT and is preferred over PTBD. Only one trial has compared the two modalities head to head<sup>[33]</sup>. The results of this study showed similar success and complication rates for

**Figure 2 Anastomotic stricture - single duct anastomosis.** A: Magnetic resonance cholangiopancreatography shows stricture at the anastomotic site of a single duct anastomosis; B: Endoscopic retrograde cholangiopancreatography (ERCP) in the same patient shows the stricture; C: ERCP in same patient shows guide wire negotiated across the stricture.

**Figure 3 Anastomotic stricture - double duct anastomosis.** A: Magnetic resonance cholangiopancreatography image shows stricture across both RASD as well as RPSD ductal anastomosis; B: Endoscopic retrograde cholangiopancreatography (ERCP) image shows guide wire negotiated across RPSD in this patient; C: ERCP image shows guidewire negotiated across RASD in this patient.

**Figure 4 Anastomotic stricture - ductoplasty.** A: Magnetic resonance cholangiopancreatography image of a ductoplasty of RASD and RPSD to common hepatic duct; B: Endoscopic retrograde cholangiopancreatography (ERCP) image shows stricture at ductoplasty site; C: ERCP image shows guide wire across one ductal system.

both approach. However, the number of interventions required was higher in the percutaneous arm. Despite sparse comparative data, ERCP is the preferred approach with PTBD being reserved for rescue in cases of failed ERCP/stenting. PTBD is considered more invasive, with a higher incidence of complications like hemorrhage, bile leak from entry site and need to keep an external stent that is liable to be displaced inadvertently.

#### **Definitions of stricture and endoscopic outcomes**

Classical definition of anastomotic biliary stricture on cholangiography is a dominant narrowing at the anastomotic site without effective drainage of the contrast material<sup>[34]</sup>. However, the diagnosis of stricture is nowadays made on MR cholangiography rather than direct cholangiography. The parameters to be studied on MRCP examination include the presence and location of

**Table 3 Definitions**

Term	Definition
Anastomotic biliary stricture	ERCP/PTC - Dominant narrowing at the anastomotic site without effective drainage of the contrast material MRCP - More than 50% reduction in anastomotic diameter compared to intrahepatic duct
Successful initial endoscopic outcome	Stricture negotiated with stent with continuous improvement in liver functions
Successful long-term endoscopic outcome	Persistent patency of the anastomotic site on cholangiography after stent removal (anastomotic site > 80% of intrahepatic ductal diameter)
Initial endoscopic treatment failure	Inability to negotiate the stricture on ERCP
Endoscopic treatment failure	Persistence of the stricture after 12 mo of therapy
Persistent ABS	Visible stricture on cholangiography after stent removal, measuring less than 80% of the diameter of the intrahepatic duct or hindering effective drainage of contrast medium
Recurrence of stricture	Biochemical derangement with ERCP documented recurrence of stricture after initial success

ERCP: Endoscopic retrograde cholangiopancreatography; PTC: Percutaneous transhepatic cholangiography; ABS: Anastomotic biliary strictures; MRCP: Magnetic resonance cholangiopancreatography.

**Figure 5** Anastomotic stricture - cystic duct anastomosis (endoscopic retrograde cholangiopancreatography failed, patient underwent percutaneous transhepatic biliary drainage).

**Figure 6** Cystic duct anastomosis after dilatation. This patient developed stricture again and underwent a hepaticojejunostomy.

**Figure 7** Timeline of biliary complications after transplant.

any strictures, upstream duct dilatation, the diameter of the ducts proximal to the anastomotic site (donor duct), distal to the anastomotic site (recipient duct) (Table 3).

ABS is diagnosed when the diameter of the anastomosis is less than 50% of the proximal (donor) bile duct<sup>[35]</sup>. If ABS is diagnosed, the length and diameter of the stricture is recorded. Also to be noted is the size discrepancy as well as angulation between donor and recipient ducts<sup>[34]</sup>. The percent stenosis is calculated as the difference between the donor duct diameter and the stricture diameter, divided by the donor duct

diameter. In case of multiple duct anastomoses, details of each anastomosis have to be recorded as it has implications on number of stents to be placed. Also in case of a single duct anastomosis, the possibility of stricture extending intrahepatic is to be considered (this can convert a single duct anastomosis similar to double duct thus mandating more than one stent). Although more than 50% change in diameter of anastomosis to intrahepatic (donor duct) is taken as suggestive of stricture, this has not been validated in any of the trials. There are no studies comparing the relative diameters in asymptomatic individuals compared to those with biochemical derangements.

Successful initial endoscopic outcome is defined as the continuous improvement in LFT. Successful long-term endoscopic outcome refers to persistent patency of the anastomotic site on cholangiography after stent removal. The biliary anastomosis is considered patent on cholangiography when the narrowest diameter at the anastomosis is greater than 80% of the upstream intrahepatic (donor) duct diameter, and spontaneous emptying of contrast medium is seen on fluoroscopy<sup>[2]</sup>. Initial endoscopic treatment failure is defined as inability to negotiate the stricture on ERCP<sup>[14]</sup>. Endoscopic treatment failure is defined as persistence of the stricture after 12 mo of therapy. A persistent ABS is defined as a visible stricture on cholangiography after stent

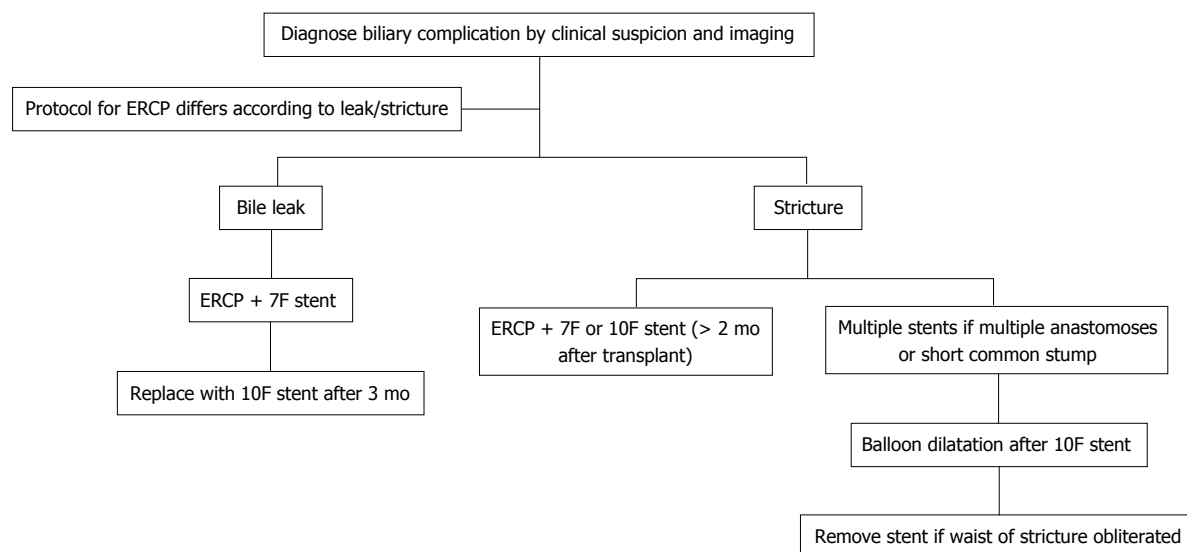

Figure 8 Protocol for endoscopic intervention (please see text also). ERCP: Endoscopic retrograde cholangiopancreatography.

removal, measuring less than 80% of the diameter of the intrahepatic duct or hindering effective drainage of contrast medium. Recurrence of stricture is defined as biochemical derangement with ERCP documented recurrence of stricture after initial success.

### Timing of intervention

There is no data available on the timing of intervention after development of biliary stricture. There is a fear of disrupting the anastomosis if ERCP is done early (first few weeks). However, there is no published data to substantiate that fear. In our own center, we tend to delay ERCP for at least 3 wk. Also we feel that early biliary leaks may merit surgery than ERCP.

The success rate also depends on the time gap between the transplant to the presentation of biliary stricture. We have found that strictures that present early have a higher rate of successful outcome after ERCP. This is probably explained by the fact that early strictures are often soft involving short segment and hence are easily negotiable on ERCP. Those presenting late (generally in such cases there is a lag period between onset of symptoms and time of presentation) often have very tight strictures, making the negotiation of stricture difficult. The rate of salvage PTBD as well requirement of surgical intervention is higher in these cases.

### Protocol of endoscopic intervention

The intervention protocols vary between institutions. Most centers would only stent the stricture after initial sphincterotomy at the first ERCP. Balloon dilatation is usually done in subsequent ERCP's. But there are institutions where balloon dilatation is carried out at the first ERCP itself<sup>[36]</sup>. Usually after the initial ERCP, stents are replaced every 3 mo with larger stents. Stents placed for longer time are more likely to get blocked predisposing to cholangitis<sup>[37-39]</sup>. Use of multiple

stents has shown better long-term success than single stents<sup>[40,41]</sup>.

There are 4 published trials comparing stenting alone vs stenting and balloon dilatation. Three of these are in post DDLT biliary strictures and only one was in LDLT patients<sup>[42]</sup>. This trial showed better long-term outcomes with a combination of both strategies compared to either alone.

The protocol we follow at our center is described as follows (Figure 8)<sup>[14]</sup>. The initial stenting is done with 7F/10F plastic stent depending on the timing of presentation after transplant. We use 7F stents initially for those with biliary leak in addition to stricture, and in those presenting very early after transplant (within 2 mo). Patients presenting after 2 mo of transplant usually undergo either a 10F stent (single duct anastomosis) or two 7F stents (double duct anastomosis). We always place stents across all anastomoses even if only one has a stricture as we feel stenting only one duct may block the other biliary system leading to cholangitis. We use the same strategy of stenting both anterior and posterior duct in a single duct anastomosis if the common duct of donor is small. We do not use balloon dilatation in first ERCP for the fear of anastomotic disruption. The stents are usually exchanged after 3 mo. We perform balloon dilatation with 6 mm or 10 mm biliary dilatation balloon (depending on the size of intrahepatic ducts) during second ERCP. The stents are removed if the waist of stricture is completely obliterated. Each patient requires about 2-3 stent exchanges over 6-12 mo. This is quite less than what is seen in other cases of benign biliary strictures (Iatrogenic post cholecystectomy and strictures associated with chronic pancreatitis). This could be due to the fact that these patients are on immunosuppression and thus do not have significant fibrosis.

The success rate of ERCP in post LDLT biliary strictures has been reported between 60%-75%<sup>[9,14,41-45]</sup>.

**Figure 9 Balloon dilatation of biliary stricture.** A: Endoscopic retrograde cholangiopancreatography (ERCP) images show stricture at the anastomotic site; B: ERCP image showing balloon dilatation of the stricture; C: Successful obliteration of the waist of stricture after balloon dilatation.

This is lower than reported success rate for post DDLT strictures (80%-90%)<sup>[3]</sup>. The reasons for lower success in LDLT strictures are multiple and will be discussed in detail in technical challenges section.

There are reports of use of covered self-expandable metal stents (SEMS) in treatment of biliary leaks and strictures after transplant. However, most of the data is in post DDLT strictures<sup>[46,47]</sup>. The smaller size of donor liver ducts as well as very short common duct stump and discrepancy between recipient and donor duct size make it unsuitable for use in LDLT strictures. Moreover, using a fully covered stent in LDLT strictures will compromise the patency of the contralateral duct. We do not use SEMS in post LDLT strictures.

### Technical challenges

The ERCP procedure is much more challenging in post LDLT compared to DDLT recipient. The anastomosis is much higher and peripheral making the access difficult<sup>[44]</sup>. There is also a size discrepancy between donor and recipient ducts adding to the difficulty. The role of ischemia element at the anastomotic site often leads to the stricture extending intrahepatic, hence often converting single duct anastomosis akin to double duct anastomosis (separation of anterior and posterior segments of the donor liver)<sup>[48]</sup>. The hypertrophy of the partial liver in LDLT often creates a sharp angulation between donor and recipient ducts. This angulation when complicated by a stricture often leads to a very difficult situation less amenable to successful endoscopic treatment<sup>[49]</sup>. Kyoto group has described a similar anomaly as crane neck deformity, in which the biliary anastomosis is located at a point that is far below the highest portion of the recipient duct<sup>[43]</sup>. This is particularly difficult to negotiate with ERCP, but salvage PTBD is often successful in such cases.

A peculiar problem arises when strictures are associated with leaks also. In this scenario, the guide wire repeatedly slips preferentially into the leak area without negotiating the stricture (path of least resistance). In such cases also, ERCP is often unsuccessful and PTBD is required.

Newer techniques like cholangioscopy (spyglass)

have been described in LDLT for traversing difficult strictures<sup>[50,51]</sup>. However in our limited experience of three cases, we did not find it of any additional benefit. We found that limited visibility and steering ability of the currently available devices is the major problem hindering the usefulness. With the improving technology and introduction of better cholangioscopes, this may help in negotiating difficult strictures.

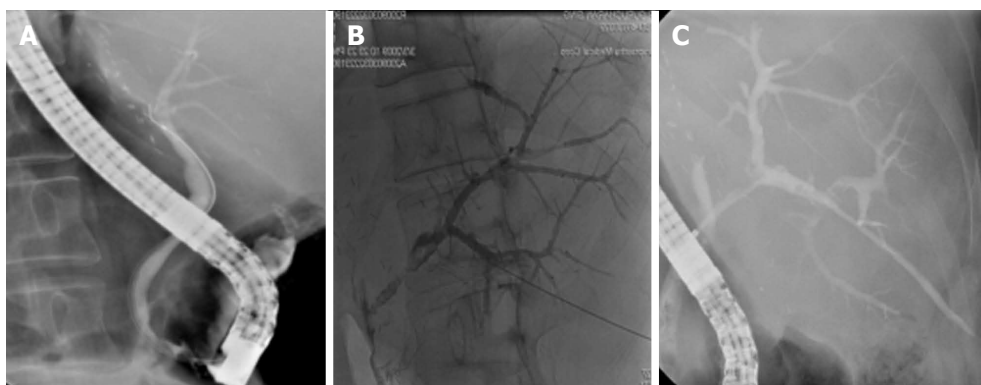

Another novel technique using magnets to traverse difficult biliary strictures after LDLT has been described<sup>[52,53]</sup>. This was initially described in LDLT from Korea by Jang *et al*<sup>[52]</sup>. Subsequently, a through the scope magnet has been used by turkey group with very good results. A similar technique with use of EUS-ERCP interface has also been successfully used to repair biliary anastomosis after LDLT<sup>[54]</sup>. Ersoz *et al*<sup>[55]</sup> described a novel technique using standard balloon to negotiate S shaped difficult strictures. With further refinement of these technique, it may help prevent surgery in difficult to negotiate biliary strictures after LDLT.

### Long-term outcomes

Long-term data after removal of stents is sparse. The only published paper which discusses long-term outcome, reported a stent free status in 42.5% of patients at a median follow-up of 33 mo<sup>[38]</sup>. In our own experience, 90% of the patients after balloon dilatation are free of stents at a median of 1 year after initial ERCP (Figure 9). The recurrence rate after stent removal is around 20% at a median follow-up of 30 mo after last balloon dilatation (unpublished data). Most patients who have recurrence of stricture after balloon dilatation are successfully treated by repeat ERCP only<sup>[33]</sup>.

### Failure of endoscopic treatment

The failure rate of endoscopic management in LDLT strictures varies from 25%-40% in various studies. The reasons for higher failure rate compared to DDLT have been discussed in technical considerations section. Patients who fail ERCP are usually successfully managed by PTBD. We at our center always do a rendezvous ERC procedure after a successful PTBD (Figure 10)<sup>[14]</sup>. Stenting *via* PTC route has been described but is not

**Figure 10 Rendezvous procedure.** A: Endoscopic retrograde cholangiopancreatography opacified only RASD; B: RPTBD accessed via percutaneous transhepatic biliary drainage; C: Rendezvous procedure being performed.

widely practiced as it entails dilatation of liver tract of PTBD<sup>[33]</sup>. In our series the technical success rate of ERCP was 75%, majority of the failures were managed by PTBD (combined success rate of 91%). However, in small number of patients, where both ERCP and PTBD fail (about 9%), surgical intervention in the form of hepaticojejunostomy is required<sup>[14]</sup>.

### Complications

Complication rates after ERCP have been variably reported between 10%-24%<sup>[14,32,39-44]</sup>. Due to altered duodenal anatomy (upper abdominal surgery), the approach to the papilla becomes difficult as after any other upper abdominal surgery. The incidence of complications including pancreatitis rates are similar as in non-transplant ERCP's. We have seen proximal migration of plastic stents in significant number of patients. Removal of these becomes quite difficult. To avoid that, we have started using single pigtail stents.

### Biliary complications and graft survival

Most of the biliary strictures are now managed successfully with non-surgical approach (ERCP or PTBD). The success rate of these interventions is very high with minimum morbidity and almost no mortality. At least two trials have analyzed the effect of biliary complications on graft survival in LDLT<sup>[14,37]</sup>. Both concluded that there is no effect of biliary complications on patient or graft survival. However, both these trials had analyzed strictures in relation to mortality. We believe that if the data on bile leaks is analyzed separately, the results may be different as bile leaks predispose to sepsis and graft dysfunction early after liver transplant.

### Future directions

Biliary strictures are the commonest complication of liver transplant both OLT and LDLT. Despite that there is no consensus on numerous management issues in it. We need more evidence to show what is the best protocol, i.e., only balloon or balloon dilatation plus stent, how many stents, for how long. Natural history of treated biliary strictures needs to be further studied. Newer

devices to facilitate difficult stricture cannulation during endoscopy need to be developed. Digital spyglass may be one such modality. Any bad/favorable prognostic signs for endoscopic treatment need to be defined. Above all more effort is required to refine the surgical techniques to avoid these strictures.

## CONCLUSION

Biliary complications are common after LDLT, strictures seen more commonly than leaks. With refining surgical skills and better understanding of factors predisposing to biliary strictures, the incidence of biliary complications is decreasing. ERCP is the first line modality of treatment of post LDLT biliary strictures with a technical success rate of 75%-80%. Most of ERCP failures are successfully handled by PTBD. A minority of patients may require surgical correction. ERCP for post LDLT strictures is technically more challenging than routine ERCP's as well post DDLT strictures ERCP's. With the introduction of new generation cholangioscopes, ERCP success rate may increase, obviating the need for PTBD and surgery in the management.

### Abstract

Hepatocellular carcinoma (HCC) is a common malignancy and now the second commonest global cause of cancer death. HCC tumorigenesis is relatively silent and patients experience late symptomatic presentation. As the option for curative treatments is limited to early stage cancers, diagnosis in non-symptomatic individuals is crucial. International guidelines advise regular surveillance of high-risk populations but the current tools lack sufficient sensitivity for early stage tumors on the background of a cirrhotic nodular liver. A number of novel biomarkers have now been suggested in the literature, which may reinforce the current surveillance methods. In addition, recent metabolomic and proteomic discoveries have established specific metabolite expressions in HCC, according to Warburg's phenomenon of altered energy metabolism. With clinical validation, a simple and non-invasive test from the serum or urine may be performed to diagnose HCC, particularly benefiting low resource regions where the burden of HCC is highest.

**Key words:** Hepatocellular carcinoma; Biomarker; Metabonomics; Warburg hypothesis; Serum; Plasma; Urine

**Core tip:** Many independent authors have utilized

quantitative techniques, such as  $^1\text{H}$  nuclear magnetic resonance and mass spectrometry to discover novel biomarkers to aid early diagnosis, following the removal of alpha fetoprotein from international surveillance guidelines. However, relatively little effort has been directed to translate these findings to the clinical setting. hepatocellular carcinoma (HCC) is a global issue and the vast majority of the burden is placed upon resource-limited regions, where presentations are late and management techniques for advanced tumors are unavailable. Early identification through a simple serum or urinary investigation, therefore, may be a pivotal step in addressing the global burden of HCC.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth commonest malignancy and arises most frequently in patients with cirrhosis<sup>[1]</sup>. The global distribution of HCC is disproportionate, being most common in areas where chronic hepatitis B virus (HBV) infection is highly prevalent (Figure 1). However, HCC is an increasing problem in the western world, due to migration from HBV-endemic regions, hepatitis C virus (HCV) infection, alcoholic cirrhosis and non-alcoholic steatohepatitis, related to the obesity epidemics<sup>[2,3]</sup> (Figure 2).

Curative treatments, such as hepatic resection and orthotopic liver transplant, offer good prognosis, but are limited to early HCC<sup>[4]</sup>. In developing countries, medical advice is often sought late, resulting in delayed, end-stage presentation. More than two-thirds of HCC patients in the developed world are diagnosed at advanced stages<sup>[5]</sup>. The high global incidence and late presentation of HCC make it the second global cause of cancer-related mortality with 1.6 million global deaths, annually<sup>[6]</sup>. The key and as yet, unmet need is to identify small tumors, amenable to curable treatments, in an otherwise nodular cirrhotic liver parenchyma.

Improved surveillance of populations at-risk by adding a sensitive biomarker investigation to complement current imaging studies has the potential to detect tumors at an early stage, when curative interventions can be implemented. Furthermore, designing a simple and accessible investigative test for a set of HCC biomarkers may not only improve diagnosis and management of liver cancer, but pioneer proteomic or metabonomic diagnosis for other diseases in developing countries, where technical and human resources are limited.

## PATHOGENIC MECHANISMS WITH METABOLIC IMPLICATIONS

### *Altered tumor metabolism*

There is increasing evidence that altered metabolism in tumor cells is both a cause and effect of carcinogenesis. Tumor cells require increased amounts of energy and substrates for *de novo* synthesis of nucleotides, lipids, and proteins for rapid proliferation. Otto Warburg, in the 1920s, pioneered the theory of altered tumor metabolism. Recent evidence both supports and disputes his original conclusions.

### *“Warburg effect” and glycolysis*

In 1924, Warburg, through placing a section of rat carcinoma in nitrogen-saturated Ringer’s solution (to simulate anaerobic conditions), observed that the tumor could be transplanted to a live donor if sugar was included in the Ringer’s solution, but not if the solution was left plain<sup>[7]</sup>. Following this work, Warburg discovered that even in the presence of oxygen, cancer cells preferentially metabolize glucose by glycolysis as oppose to oxidative phosphorylation, a vastly more inefficient route for energy production. He hypothesized that the increase in glycolysis under normal oxygen conditions arose from a deficiency in the mitochondrial oxidative phosphorylation<sup>[8]</sup> (Figure 3). He thus established that tumor cells take up glucose at high rates to fuel heightened glycolysis. Indeed, it is upon this basis that tumors can be identified with glucose-labeled positron emission tomography<sup>[9]</sup>. Glycolysis generates adenosine triphosphate (ATP) with lower efficiency, but at a faster rate than oxidative phosphorylation, which may be of benefit for rapidly dividing cells. The role of mitochondria in tumor cells is contentious. Primary defects in oxidative phosphorylation (which occurs within the mitochondrial membrane) have been invoked to explain the Warburg phenomenon because tumor mitochondria are often small, lack cristae and are deficient in the  $\beta$ -F1 subunit of the ATPase<sup>[10,11]</sup>. However, many groups have demonstrated that tumor cell mitochondria are actually functional and even Warburg admitted that despite their high glycolysis rate, oxygen consumption by cancer cells is not diminished<sup>[12]</sup>. Furthermore, HCC is a highly vascular tumor that, certainly in the early stages, is likely to be adequately supplied with oxygenated blood. Importantly, glycolysis also provides intermediates for the pentose phosphate pathway and subsequent biosynthesis of nucleic acids. Which of these functions heightened glycolysis serves is, as yet, unresolved.

There is now some consensus that the major role of heightened glycolysis in tumor cells is to provide substrates to the pentose phosphate pathway for nucleotide synthesis, rather than energy provision in the form of ATP<sup>[12,13]</sup>. In essence, the tumor is maximizing production of cellular constituents for proliferation at the expense of energy production.

## MOLECULAR EFFECTORS AND TUMOUR METABOLISM

Several oncogenes and tumor suppressor genes have been implicated in altered tumor metabolism. Sequential mutations are common in HCC and two effectors in particular, hypoxia inducible factor 1 (HIF 1) and p53, may be responsible for some of the metabolic changes arising in HCC.

### HIF

HIF 1 is a heterodimeric protein complex transcription factor that is activated by hypoxic, inflammatory, metabolic and oxidative stress<sup>[10,12,14]</sup>. The HIF 1 heterodimeric complex (HIF 1 $\alpha$  + HIF 1 $\beta$ ) is stabilized at low oxygen levels, but degraded by the proteasome in normoxic conditions. The HIF 1 heterodimer stimulates glycolysis by increasing the expression of pro-glycolytic uptake enzymes and transport molecules, such as glucose transporter 1 (GLUT 1) and hexokinase<sup>[12]</sup>. HIF 1 $\beta$  deficient hepatoma cells grown as solid tumors in mice were found to have reduced rates of growth and glycolytic intermediates compared to wild type hepatoma cells<sup>[15]</sup>. It would therefore appear that HIF 1 may play a central role in the Warburg model. However, HIF 1 is only stable in hypoxic conditions and Warburg's model describes heightened glycolysis in normoxic conditions.

Only a minority of cancers display aberrant HIF 1 function in normoxia, such as renal cell carcinoma<sup>[16]</sup>. The role of HIF 1 in HCC is still under investigation but a number of recent studies, mostly in animal models, have observed high HIF 1 activity and its downstream counterparts, such as GLUT1, in hepatoma cells<sup>[17-19]</sup>. Recent studies have also identified association between HIF 1 and the prognosis of HCC, where HIF 1 $\alpha$  levels have been found to be significantly raised in HCC, compared to benign liver disease<sup>[19]</sup>. Furthermore, it appears that HIF 1 inhibition may be a potential target of therapeutic benefit in HCC by down-regulating its role in tumorigenesis. There have been several proposals to incorporate HIF 1 inhibition as adjunct to the current treatment pathways, but further investigations are required before its clinical application<sup>[20]</sup>.

### p53

Tumor suppressor genes, such as p53, have also been implicated in alterations in metabolism. Inactivation of p53 can cause the Warburg phenomenon. p53 positively regulates the expression of the protein synthesis of cytochrome C oxidase 2, which is required for the assembly of the oxidative phosphorylation enzyme, cytochrome C oxidase<sup>[21]</sup> and also negatively regulates phosphoglycerate mutase, a key glycolytic enzyme<sup>[22]</sup>. In addition, p53 transcriptionally activates TP53-induced

**Figure 4** “Angiogenic switch” in hepatocellular carcinoma. VEGF: Vascular endothelial growth factor; HCC: Hepatocellular carcinoma; HIF 1: Hypoxia inducible factor 1.

glycolysis and apoptosis regulator an inhibitor of phosphofructokinase activity which in turn lowers the level of fructose 1,6-bisphosphate which acts as an allosteric activator of glycolytic enzymes<sup>[23]</sup>.

These examples illustrate the evidence that genetic alteration through tumor-driven mutation can affect metabolism. It is likely that many genes and proteins are involved in altered tumor metabolism, with a few taking a lead role.

## METABOLITE EFFECTS ON CARCINOGENESIS

Metabolites can affect carcinogenesis and may not be mere by-products of cellular reactions. Lactate, thought to be a “waste” product of glycolysis, may be such a signal. Lactate may stimulate HIF 1 independently of hypoxia<sup>[24]</sup> and may condition the tumor environment and suppress anticancer immune effectors<sup>[10,25,26]</sup>. HIF 1 can also be stimulated by the buildup of tricarboxylic acid (TCA) cycle intermediates, fumarate and succinate. This is evidenced through tumorigenic germline mutations of TCA cycle enzymes fumarate hydratase and succinate dehydrogenase, resulting in an accumulation of fumarate and succinate which competitively inhibit the  $\alpha$ -ketoglutarate-dependent HIF 1 $\alpha$  prolyl hydroxylase, the enzyme that targets HIF 1 for destruction<sup>[27]</sup>. Through high-throughput liquid-and-gas-chromatography-based mass spectrometry of urine and plasma from patients with prostate carcinoma, Sreekumar *et al.*<sup>[28]</sup> identified sarcosine, a metabolite derivative of glycine, as a marker of the cancer. Furthermore, exogenous addition of sarcosine to tumor cells, or knockdown of sarcosine degrading enzymes, caused a shift of benign prostatic cells into a malignant phenotype.

## OTHER PATHOGENIC MECHANISMS

Genetic profiling studies of HCC tissue have shown several genes to be disrupted through somatic mutations, chromosomal disruption and epigenetic aberration through methylation abnormalities including *p53*, *Rb1*,  *$\beta$ -catenin*, *CMYC* and *survivin*. The Wnt- $\beta$  catenin pathway is the most commonly disrupted pathway,

usually as a result of mutations in *CTNNB1*, *AXIN1* genes, *CDH1* epigenetic silencing and changes in expression of Wnt receptors from the Frizzles family<sup>[29]</sup>. Activation of the pathway induces translocation of  $\beta$ -catenin into the nucleus where it regulates specific oncogenes such as *CMYC* and *CCND1*. An initial somatic mutation in an oncogene or tumor suppressor gene is likely to generate a clonal expansion of cells which then have the potential, through further “proliferation advantageous” mutations and chromosomal disruptions, to develop into pre-neoplastic lesions. These lesions, often < 1 cm, have been identified in patients with cirrhosis and have been sub-classified into low or high grade dysplastic nodules<sup>[30]</sup>. The former carry a low risk and the latter a very high risk, of malignant transformation.

### “Angiogenic switch”

Dysplastic nodules are often hypoechoic on ultrasound imaging and derive their blood supply from the portal vein. These nodules may, less frequently, appear as either hyperechoic or isoechoic. Established HCC displays typical arterial phase uptake on contrast imaging. At a critical point, an “angiogenic switch” is activated which stimulates arterial neo-vascularization of the nodule and development of an established HCC (Figure 4). Japanese groups have identified this as a critical moment before which total cure with resection is likely and after which prognosis deteriorates rapidly<sup>[31]</sup>. Certain factors may contribute to “neo-angiogenesis” of HCCs. Vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) have been implicated as angiogenesis modulators. HCC cell lines may produce VEGF by themselves and increased concentration of VEGF in the serum of patients with HCC has been correlated with outcome after surgical resection<sup>[32,33]</sup>. HIF 1, a factor commonly expressed in HCC and heavily influential upon cellular metabolism, has been shown to induce expression of VEGF. A number of oncogenes have also been implicated in angiogenesis such as *ras* and *myc*<sup>[34]</sup>.

It has been shown that chemotherapeutics active against HCC such as the multikinase inhibitor, sorafenib, exert their effects through inhibition of pro-angiogenic factors such as VEGF and PDGF, establishing neo-

**Table 1 Comparison of nuclear magnetic resonance and mass spectrometry**

NMR: Nuclear magnetic resonance; MS: Mass spectrometry.

angiogenesis as a major therapeutic target in HCC<sup>[30]</sup>. With the onset of neo-angiogenesis, there is likely to be a rapid change in the metabolism of tumor cells and also the surrounding stroma<sup>[35]</sup>. The importance of the interaction between tumor and stromal cells is becoming increasingly recognized. Vizan *et al.*<sup>[36]</sup>, studied the metabolic adaption of endothelial cells, to stimulation by VEGF and fibroblast growth factor. Glycogen synthesis, the pentose cycle and glycolytic pathways were shown to be essential for endothelial cell proliferation and inhibition of these pathways decreased endothelial cell viability and migration<sup>[36]</sup>. The interaction of cellular metabolism and neo-angiogenesis is therefore crucial to tumor development.

## CURRENT SURVEILLANCE AND DIAGNOSIS

HCC is likely to originate from hepatic stem cells<sup>[37]</sup>, with internal and external stimuli, such as viral DNA integration, inflammation and fibrosis, likely inducing alterations in tumor originator cells leading to apoptosis, cell proliferation, dysplasia and eventually, neoplasia<sup>[34]</sup>. The global alteration of metabolites that arise during, or as a consequence of tumorigenesis, then, may measure both the presence and the severity of disease.

Unfortunately, HCC surveillance lacks reliable biomarkers. Serum alpha fetoprotein (AFP) historically has been the most used biomarker. However, not all HCCs secrete AFP. Furthermore, it may be elevated in chronic liver disease in the absence of HCC<sup>[38]</sup>, and its use is no longer recommended by international authorities. Ultrasonography (US) at 6 monthly intervals is the currently recommended screening and surveillance modality for patients with established liver cirrhosis<sup>[39]</sup>. Diagnosis is based on the fact that HCCs are highly arterialized, in contrast to the remainder of the liver. The most recent American Association for the Study of Liver Disease guidelines require the presence of features typical of HCC (arterial hypervascularity and venous phase washout) in just one imaging modality for lesions > 1 cm<sup>[39]</sup>. Previous guidelines suggested that diagnosis was made by the confirmation of two contrast-enhanced imaging modalities (contrast-enhanced ultrasound, computed tomography or magnetic resonance imaging) with characteristic features or one imaging modality suggestive of HCC with an AFP level of > 400 ng/mL<sup>[40]</sup>.

Diagnostic imaging techniques for HCC require a combination of equipment availability, infrastructural support and technicians to perform and interpret the results, which unsurprisingly, are limited in the majority of developing regions with high HCC burden. Alternative solutions to HCC diagnosis, therefore, are urgently required, as AFP measurement lacks sensitivity and specificity. An acceptable alternative requires the diagnostics to be quick, inexpensive, accessible and adequately sensitive and specific to the disease. Blood and urine tests are extremely simple methods of investigation, which are widely utilized in developing regions. For example, designing a urine dipstick test that can quantify and score the severity of HCC from a set of candidate biomarkers may significantly reduce cancer-related morbidity and mortality, and revolutionize the surveillance process in developing regions.

## METABOLIC PROFILING TO FIND BIOMARKERS

Metabolic profiling is a general term encompassing "metabonomics", which is the study of global metabolic responses to physiological, drug and disease stimuli<sup>[41]</sup> and "metabolomics", which aims to characterize and quantify all the small molecules in biofluid samples<sup>[42]</sup>. The most commonly used methods of metabolite characterization are proton nuclear magnetic resonance (<sup>1</sup>H NMR) spectroscopy and mass spectrometry (MS). These techniques are complimentary and each has advantages and disadvantages (Table 1). Sensitivity of MS is high, with some forms of gas chromatography (GC)-MS reaching femtomolar levels, but samples are degraded during the run and metabolite identification can be challenging<sup>[43,44]</sup>. Nuclear magnetic resonance spectroscopy displays lower sensitivity (nano to millimolar), but samples remain intact and NMR spectral profiles have been extensively categorized making metabolite identification more straightforward<sup>[37-39]</sup>.

## PROTON NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

Nuclear magnetic resonance is based on the behavior of nuclei subjected to a magnetic field. Hydrogen is the most abundant element in living organisms and using high power magnetic fields of *in vitro* samples, high-resolution metabolic NMR spectra can be obtained with clearly defined metabolite peaks of small mobile molecules (< 2 kDa). Comprehensive metabolic profiles have been generated from biofluids, including urine<sup>[45,46]</sup>, serum<sup>[47-50]</sup>, bile<sup>[51]</sup> and intact tissue<sup>[52]</sup>.

## MASS SPECTROMETRY

Mass spectrometry has been utilized for metabolic profiling since the 1970s<sup>[53]</sup>. Metabolites, or their constituent fragments, are detected and distinguished

by their molecular weight and ionic charge. Owing to their complex nature, biological fluids require separation prior to mass spectrometric analysis to achieve detection of as many metabolites as possible. The most common separation methods are GC or liquid chromatography (LC). Gas chromatography requires extensive sample pre-treatment and derivatization steps. In contrast, LC requires minimal sample preparation and is immediately amenable to biofluid analysis. Ultra performance LC utilizes separation columns with much smaller particle size packing material (1.4–1.7  $\mu\text{m}$ ) than traditional columns, permitting the injection of liquids at pressures exceeding 10000 psi, thus allowing for improved metabolite resolution. Once ionized, the particles are detected usually by a time-of-flight analyzer, which allows the detection of analytes over the range of  $m/z$  50–1000 Da.

## CLINICAL APPLICATION OF BIOMARKERS

The development and progression of HCC underscores complex molecular and metabolic interactions, involving several stages of disease over a prolonged period of time. A single reliable biomarker to assess both presence and severity of disease, such as it was for AFP, is likely to be unfeasible in this setting. Therefore, a panel that reliably assesses HCC tumorigenesis from a selection of candidate biomarkers may be better suited to tackle the situation. The candidate biomarkers must show adequate sensitivity and specificity by validation-based experiments, and demonstrate diagnostic synergism when individual biomarker results are combined. Such a new biomarker panel must then be assessed in comparison studies for the current diagnostic methods, such as US and biopsy, for different disease states of HCC, and its utility in surveillance protocols must then be considered, particularly in the developing world context. Biomarkers are also heterogeneous in their quantification and analysis, as different equipment and techniques are utilized. This practical issue must be addressed with thorough cost-benefit analyses that compare biomarker analysis to the local investigative methods.

## SERUM MARKERS OF HCC

### Serum AFP

Serum AFP is the most widely used marker of HCC. It is a fetal glycoprotein, which is synthesized *in utero* by the embryonic liver, cells of the vitelline sac and the fetal intestinal tract. Serum AFP is usually undetectable in healthy adults<sup>[54]</sup>. The production of AFP by HCC cells has been seen as confirmation that the tumor arises from hepatic stem cells as a form of maturation arrest, akin to an embryonic state<sup>[55]</sup>. Not all HCCs secrete AFP and its diagnostic accuracy is variable. A meta-analysis of AFP for HCC surveillance found that it displayed a sensitivity of 39% to 65% and a specificity of 76% to 94% for tumor diagnosis<sup>[56]</sup>. The cut-off level of AFP was important in determining the diagnostic power.

A cut-off of 20 ng/mL resulted in a sensitivity of 64% and specificity of 91%<sup>[57]</sup>, while a cut-off of 400 ng/mL resulted in a sensitivity of 17% and specificity of 99%<sup>[58]</sup>. Values of over 400 ng/mL are generally considered diagnostic of HCC, although only about 20% of patients with HCC display values this high. Furthermore, patients with chronic viral hepatitis may display a raised AFP during viral flares without the presence of HCC. In a study of 290 Chinese patients with chronic HBV, 44 were found to have elevated serum AFP levels (> 20 ng/mL) and only six (13%) had HCC. The remaining 38 had elevated serum AFP, either due to viral flares or due to unknown causes<sup>[59]</sup>. Trevisani *et al.*<sup>[58]</sup> also observed that an AFP elevation in non-infected patients could be more indicative of HCC when compared to infected patients.

### Lens culinaris agglutinin-reactive AFP

Lens culinaris agglutinin-reactive AFP (AFP-L3) is a glycoform variant of AFP and is expressed as a percentage of the total AFP level. It can be detected in the serum of approximately one third of patients with small HCCs (< 3 cm) where cut-off levels of 10% to 15% are used. At higher cut-off levels of > 15%, AFP-L3 displays a sensitivity of 75% to 96.9% and specificity of 90% to 92%<sup>[60,61]</sup>. The usefulness of this marker is limited as studies have only been conducted in East Asian populations in whom AFP levels are already raised.

### Des gamma carboxyprothrombin

Des gamma carboxyprothrombin (DCP) is an abnormal prothrombin protein and is also known as prothrombin induced by vitamin K absence II. It is produced as a result of an acquired defect in the post-translational carboxylation of the prothrombin precursor in malignant cells, the gene responsible being gamma-carboxylase<sup>[62]</sup>. In several large studies, serum DCP was found to display poor diagnostic sensitivity (48% to 62%), but good specificity (81% to 98%) for HCC<sup>[62,63]</sup>. A study comparing the performance characteristics of AFP, DCP and lens culinaris agglutinin-reactive AFP in the diagnosis of HCC observed that DCP was significantly better than the other markers in differentiating HCC from cirrhosis, with a sensitivity of 86% and a specificity of 93%<sup>[64]</sup>. There are conflicting reports, however, with a study by Nakamura *et al.*<sup>[65]</sup> reporting that the efficacy of DCP was lower than that of AFP in the diagnosis of small tumors, although higher than AFP for large tumors.

### Alpha-L-fucosidase

Alpha-L-fucosidase (AFU) is a glycosidase found in cellular lysosomes and increased activity is found in the serum of patients with HCC. Studies of its diagnostic accuracy have displayed high sensitivity (82%) and specificity (70.7%–85.4%)<sup>[66–68]</sup>. A comparative study of AFP and AFU in an Egyptian cohort found AFU to have a higher sensitivity (81.8% vs 68.2%) but lower specificity (55% vs 75%) with a combined AFP + AFU sensitivity of 88.6%<sup>[69]</sup>. Unfortunately, AFU has been

**Table 2 Diagnostic performance of serum markers of hepatocellular carcinoma**

Serum marker	Sensitivity	Specificity
AFP	39%-65%	79%-94%
AFP-L3	75%-97%	90%-92%
DCP	48%-62%	81%-98%
AFU	82%	71%-85%
AFP-L3 + DCP	85%	98%

AFP: Alpha fetoprotein; AFP-L3: Lens culinaris agglutinin-reactive AFP; DCP: Des-gamma-carboxy prothrombin; AFU: Alpha-L-fucosidase.

found to be elevated in other tumors and is therefore not specific to HCC. The diagnostic performance of these serum markers is outlined in Table 2.

### Glypican-3

Glypican-3 (GPC3) is a heparin sulfate proteoglycan and has been shown to be capable of promoting the proliferation of tumor cells by modulating Wnt pathways and affecting cellular adhesion. As a tumor marker, GPC3 expression has been shown to be elevated in HCC tissue and in serum of 40% to 53% of patients with HCC<sup>[69]</sup>.

### Vascular endothelial growth factor

VEGF is a homodimeric cytokine associated with tumor neovascularization. HCC is often diagnosed by imaging evidence of a highly vascularized mass in the liver, and HCC patients have been shown to have increased expressions of VEGF compared to those with normal liver tissues<sup>[70]</sup>. Furthermore, two previous studies have shown mortality in HCC increases with over-expression of VEGF<sup>[71,72]</sup>.

### Interleukin-8

Interleukin-8 (IL-8) is a multifunctional CXC chemokine, which may exert numerous effects on tumor proliferation, angiogenesis and migration. High serum IL-8 has been indicated in HCC patients compared to healthy controls, and its levels correlate to tumor size, absence of tumor capsule, presence of venous invasion, advanced pathological tumor-node-metastasis staging, and poorer disease-free survival<sup>[73,74]</sup>.

### Transforming growth factor-beta 1

Transforming growth factor-beta 1 (TGF- $\beta$ 1) is a negative autocrine growth factor that regulates cell proliferation and differentiation. Comparison studies against AFP (200 ng/mL) have shown TGF- $\beta$ 1 to have higher sensitivity at 68% (800 pg/mL cut-off), and a specificity of 95%<sup>[75]</sup>. Raised TGF- $\beta$ 1 also detected 23% of HCC patients with normal serum AFP<sup>[76]</sup>.

### Tumor-specific growth factor

Tumor-specific growth factor (TSGF) is released by malignant tumors, and has been shown to correlate with tumor growth and surrounding vascularization.

Therefore, it is reasonable to suggest that TSGF could be a potential biomarker that may be used for HCC grading in populations around the world. TSGF has been approved for use by the Chinese government following study results that showed a sensitivity of 82% in HCC diagnosis at the cut-off of 62 U/mL<sup>[77]</sup>.

### Squamous cell carcinoma antigen

Squamous cell carcinoma antigen is part of a family of serine protease inhibitors, or serpins, and has been utilized to diagnose a variety of squamous cell carcinomas<sup>[78]</sup>. It has also been found to have a diagnostic role in HCC, where the sensitivity and specificity were 77.6% and 84%, respectively<sup>[79]</sup>.

### Heat shock proteins

Another potential biomarker for HCC are heat shock proteins (HSP), which are cellular molecules that are expressed under non-specific stress stimuli, including carcinogenesis<sup>[80]</sup>. In particular, HSP70 has been identified as a potentially sensitive marker to differentiate early HCC from precancerous lesions<sup>[81]</sup>.

### Serum metabolites

Metabolic profiling using proteomic techniques mentioned above, such as *in vitro* proton <sup>1</sup>H NMR spectroscopy<sup>[49,82-85]</sup> and MS<sup>[85-99]</sup> have been incorporated to identify a specific metabolic pattern that may be utilized for identifying HCC. Lysophosphatidylcholines (LPC) have been reported in several studies to be significantly decreased in HCC sera compared to healthy controls<sup>[88,89,91-93,96-98]</sup>. LPCs have been described in endothelial cell migration<sup>[100]</sup>, which may contribute to the hypervascularized state in HCC. Two LPCs in particular, LPC 16:0 and LPC 18:0, were significantly altered in HCC compared to cirrhotic patients<sup>[91-93,97]</sup>. Morita *et al.*<sup>[101]</sup> confirmed the overexpression of LPC acyltransferase 1 (LPCAT1) which converts LPC C16:0 to phosphatidylcholine 18:1. The up-regulation of LPCAT1 could be the reason for the reduction in LPC C16:0. A careful interpretation is required, as expression of LPC species has been found to be significantly different between hepatic compensation and decompensation. Free fatty acid (FFA) species have been markedly different in HCC groups compared with control groups, but study results have been conflicting, perhaps due to patient heterogeneity regarding age, gender, ethnicity, diets and existing comorbidities<sup>[91,93-95,97,98,102]</sup>. The European Prospective Investigation into Cancer and Nutrition study additionally described an extensive interaction between HCC and modifiable lifestyle factors in a large European cohort<sup>[85]</sup>, and FFA levels have been linked to the severity of liver disease and disease etiology<sup>[103]</sup>. FFA species that have been identified include FFA C16:0, C18:0, C20:4 and C24:1.

Metabolites of energy production were broadly altered in HCC, particularly concerning products of beta-oxidation and other alternative metabolic pathways<sup>[49,82-84]</sup>. This may point to Warburg's phenomenon in HCC tumor-

rigenesis, where a shift of oxidative glucose metabolism to anaerobic glycolysis takes place to contribute a higher rate of energy production in tumor cells<sup>[8]</sup>. The increase in very low density lipoprotein, as seen in Gao *et al.*<sup>[49]</sup> study, may explain the global lipid mobilization for the lipolytic pathway. Studies have also identified a rise in ketone bodies, such as acetone and beta-hydroxybutyrate, which are formed as by-products of beta-oxidation<sup>[84]</sup>. Furthermore, components of the normal TCA cycle such as 2-oxoglutarate, succinate and glycerol also were significantly altered in HCC groups against controls<sup>[49,102,103]</sup>. The elevation of 2-oxoglutarate may be a consequence from a decreased mitochondrial respiration. Overall, the observed effect of reduced TCA, increased beta-oxidation and increased ketone bodies suggest a heightened alternative metabolic response in tumorigenesis.

Elevated levels of serum bile acids, such as glycochenodeoxycholic acid, glycocholic acid, deoxycholic acid and cholic acid, have long been recognized in many hepatobiliary diseases<sup>[104]</sup>. A study by Chen *et al.*<sup>[105]</sup> identified cirrhotic patients have significantly higher levels of bile acids than those without. Interestingly, levels are significantly different even when comparing compensated against decompensated cirrhosis. It is no surprise that HCC metabonomic studies have identified elevated bile acids in HCC patients when compared to the healthy population<sup>[91-94,96-98,102]</sup>. Bile acids may have a role in tumorigenesis, as reports have described their involvement in glucidic metabolism and acting as signaling molecules<sup>[106,107]</sup>. However, the studies have not controlled for possible confounding factors such as the compensation/decompensation profile, or the prandial state of patients, where certain bile acids are elevated after food intake<sup>[108]</sup>, and therefore, bile acids would not be suitable HCC biomarkers until specific studies are performed to address this issue.

## URINARY MARKERS OF HCC

For a urinary biomarker to be widely applicable three central attributes are necessary. First, the biomarker, if produced pre-renally, needs to be small enough and of the correct ionic charge to be filtered by the renal glomerulus and not re-absorbed by the tubules. Therefore, it has to be roughly less than 20 kDa in atomic weight. Second, the marker should be specific to the cancer in question and not secondary to the effects of cancer on general physiology. Finally, the marker should be secreted in adequate amounts for accurate, repeatable detection in early disease. Large, complex proteins are unlikely to enter the urinary stream, so are not candidates for urinary biomarkers.

### Nucleosides

Studies in the 1970s observed elevated levels of the methylated purines 7-methylguanine, 1-methylguanine, *N*-dimethylguanine, 1-methylhypoxanthine and adenine in the urine of patients with HCC. In 1976, it was found

that urine levels of cyclic guanosine 3':5' monophosphate (cGMP) were elevated in rats with transplanted liver and renal tumors<sup>[109]</sup>. In 1982, Dusheiko *et al.*<sup>[110]</sup>, found parallels in human studies, observing elevated urinary cGMP levels in patients with HCC. In the same study, cGMP was also elevated in the urine of patients with liver disease and other non-HCC tumors, reducing the specificity of the marker considerably.

In 1986, Tamura *et al.*<sup>[111]</sup> observed that urinary levels of pseudouridine, a C-glycoside isomer of the nucleoside uridine, to be elevated in patients with HCC. When combined with serum AFP, sensitivity for HCC detection was 83%. Disappointingly, this marker was also non-specific and found to be similarly elevated in patients with other malignancies such as non-Hodgkin's lymphoma. In a Taiwanese patient study, it was observed that the urinary nucleosides adenosine, cytidine and inosine were elevated in patients with HCC<sup>[112]</sup>. When combined with serum AFP, sensitivity for tumor diagnosis was 80%. The study was flawed in that controls consisted of healthy patients with no liver disease and ideally the finding should have been confirmed in comparison to a group of patients with cirrhosis.

### TGF $\alpha$ and $\beta$

TGF $\alpha$  and  $\beta$  have both been detected in the urine of patients with HCC. The first report was from 1990, observing elevated TGF $\alpha$  levels in urine<sup>[113]</sup>. In 1991, a TGF-related protein was found in HCC patient urine and this was confirmed as TGF $\beta$ 1 in 1997 by the same group<sup>[114,115]</sup>. In these studies, TGF $\beta$ 1 correlated with prognosis and survival. A functional link was attractive as TGFs are known to stimulate non-transformed cells reversibly to grow as colonies *in vitro*.

### Neopterin

In 1998, a study performed in Japan found neopterin, a protein now known to be released from macrophages following inflammatory stimulation, to be elevated in the urine of patients with advanced HCC<sup>[116,117]</sup>. Similar to other potential markers, neopterin has since been shown to be elevated in a number of malignancies and pro-inflammatory conditions such as human immunodeficiency virus related disease, reducing its validity as a specific marker for HCC<sup>[118]</sup>.

### Polyamines

The polyamines, organic compounds containing two or more amine groups, include putrescine, spermine, and spermidine. Their exact cellular role is unclear but they are required for cellular proliferation. Putrescine acts on *S*-adenosylmethionine (SAME), a methylating molecule, to produce spermine which in turn acts on further SAME molecules to produce spermidine<sup>[119]</sup>. Antonello *et al.*<sup>[120]</sup> reported increased urinary levels of free and acetylated polyamines using HCC patients compared to healthy controls and patients with cirrhosis, although the sensitivity of these markers was found not to be high enough for early tumor detection.

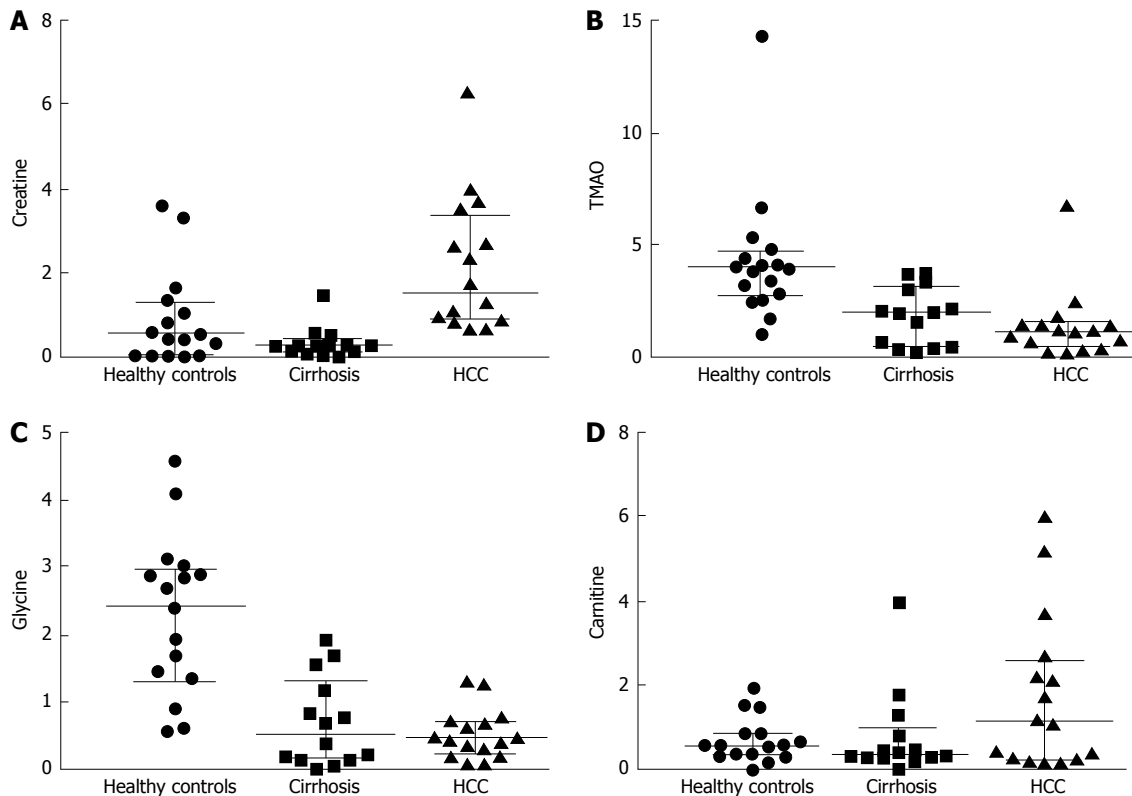

Figure 5 Univariate analysis of discriminatory urinary variables from an Egyptian cohort, comparing values from healthy controls, cirrhosis group and hepatocellular carcinoma group. Discriminatory variable A: Creatine; B: Trimethylamine N-oxide (TMAO); C: Glycine; D: Carnitine. Adapted from Shariff *et al*<sup>[125]</sup>. HCC: Hepatocellular carcinoma.

### Urinary trypsin inhibitor

Urinary trypsin inhibitor (UTI) is a 25 kDa protein thought to be produced by hepatocytes. In 2004, an enzyme-linked immunosorbent assay-based study observed that urinary UTI was elevated in patients with HCC, albeit not significantly when compared to patients with cirrhosis<sup>[121]</sup>. Follow-up studies have found correlations with severity of liver disease and patient prognosis in general, but not specifically with HCC<sup>[122]</sup>.

### Soluble urinary metabolites

Recently, Chen *et al*<sup>[102]</sup> analyzed the serum and urine from 82 patients with HCC and compared these profiles to patients with benign liver tumors and healthy volunteers. Forty three serum and 31 urine metabolites were differentially present in samples of patients with HCC. These included bile acids, free fatty acids, inosine and histidine.

Wu *et al*<sup>[103]</sup> reported a urinary GC-MS study of 20 HCC patients which identified a marker panel of 18 metabolites discriminating HCC and healthy Chinese controls. This panel included octanedioic acid, glycine and hypoxanthine. In the same year, Chen *et al*<sup>[123]</sup> utilized mass spectroscopy techniques with hydrophilic interaction chromatography and reverse phase liquid chromatography in a comparison of 21 urine samples of patients with HCC to 24 healthy volunteer samples. In this set, hypoxanthine, creatinine, betaine, carnitine, acetylcarnitine, leucylproline and phenylacetylglutamine

were altered between groups.

The most recent studies of urinary HCC metabolites to date have been performed within the African populations in Nigeria, Egypt and Gambia<sup>[124-126]</sup>. These studies compared the profiles of HCC with cohorts with cirrhosis without HCC, and healthy control, allowing further differentiation and insight into the metabolic difference in HCC tumorigenesis (Figure 5). Urinary creatinine was lowered in all three African cohorts. Urinary creatinine excretion has been associated with muscle mass<sup>[127]</sup>, and the results seen in the studies may reflect cancer cachexia rather than a specific marker for HCC.

Urinary carnitine levels were also elevated in HCC compared to cirrhosis in all three African groups. Carnitine is a hydrophilic compound, mainly absorbed from the diet and in part synthesized by the body. It is an essential compound for mitochondrial transport of long-chain fatty acids from the cytosol for beta-oxidation. Well-functioning kidneys efficiently reabsorb carnitine, a high urinary level inferring excess carnitine ingestion, biosynthesis or poor reabsorption. Increased urinary acylcarnitines have previously been reported in specific FFA oxidation disturbances and after intense exercise<sup>[128]</sup>. In the context of HCC, Shariff *et al*<sup>[125]</sup> hypothesized its elevation may be explained by increased metabolic activity and high cell-turnover, causing carnitine overproduction to fuel beta-oxidation and rapid energy production<sup>[127]</sup>.

Urinary creatine levels were significantly elevated in

the Egyptian cohort with HCC, but were non-significantly elevated in the Nigerian compared to the respective cirrhosis groups<sup>[124,125]</sup>. Creatine is a nitrogenous organic acid, synthesized mainly in the liver by its constituent parts arginine, glycine and methionine. It has a direct function in cellular energy transport, interacting directly with ATP to produce phosphocreatine and adenosine diphosphate. It is likely that the heightened cell turnover increases cellular energy transport demand, and subsequently raises creatine levels.

Dimethylglycine (DMG), choline, and trimethylamine-N-oxide (TMAO) are metabolites involved in choline intermediary metabolism. Urinary DMG and choline were elevated but a lower concentration of TMAO was noted in the Gambian population. Overexpression of choline has been well established in a series of different tumors. TMAO is typically formed by bacterial degradation of choline, it is likely that this alteration reflects dysregulation of intestinal microbiota, as suggested by Ladeb *et al.*<sup>[126]</sup>. The metabolic alterations that have been observed may be explained by the Warburg phenomenon and its preferential glucose metabolism *via* anaerobic glycolysis.

Urinary glycine levels were reduced in the Egyptian population, but have been unreported in the other studies<sup>[125]</sup>. Glycine's normal cell function involves the methylation of DNA. Its reduction in HCC may be explained by the widely noted phenomenon of hypomethylation within the tumorigenic process. In addition, the Nigerian and Egyptian studies have seen an increase in creatine, as mentioned above. Glycine is a molecular constituent of creatine, which is upregulated in the high cell turnover environment of HCC, which may also explain the decline in glycine observed from the Egyptian study<sup>[124,125]</sup>.

## CONCLUSION

This review provides an overview of HCC pathogenesis and from it, a large selection of potential biomarkers that correlate to the complex molecular and metabolic interaction in its tumorigenesis. HCC is a significant global health issue, which primarily affects countries where there is an infrastructural limitation on community-based surveillance for early disease, and therapeutic options in later stages of tumor presentation. Various diagnostic techniques that have been successfully utilized in developed countries, such as US surveillance, cannot be introduced in resource-limited regions where their application is fundamentally unsuitable. In the current absence of a simple and effective diagnostic investigation in those regions, we highlight the need for research progression in designing clinical diagnostic techniques that may be cheaply and effectively administered. In particular, we emphasize the potential of metabolomics identification of candidate metabolites through the development of a simple urine dipstick, which may be easily performed even in the lowest-income settings.

In considering biomarker application, there must be a careful and a realistic consideration as to the hetero-

geneous metabolic profiles of varying ethnic groups. It is unlikely that a single panel of metabolites that have adequate sensitivity and specificity in the developed population would be appropriate for the developing world population. Previous research has shown that there are clear racial differences in the diagnostic value of AFP, where a minority of Asian, Eurapoid, and Hispanic patients with HCV-related HCC had a normal AFP (18%), close to half the African American patients had a normal AFP level (43%), and furthermore, there was an observed difference between underlying etiology of liver disease, where HCV-related HCC had a stronger association with raised AFP, compared to HBV-related HCC<sup>[129]</sup>. The clear etiological, dietary, genetic and environmental factors that differ between populations suggest the need for specific metabolomic studies, or at least validation studies, in the very regions of the world where better diagnostics or screening tools are required.

To address the pressing issue of identifying novel biomarkers that are sensitive, practically applied, and ethnically specific, the most recent African urinary studies may present the most relevant biomarkers, which can be translated to a simple urine dipstick test<sup>[124-126]</sup>. The significant metabolites include urinary creatine, carnitine and creatinine, among others. Again, these metabolites reflect the molecular changes that happen as part of Warburg's hypothesis of altered energy metabolism. The close fit of the results to the hypothesis should encourage researchers to study the molecular pathway closer in relation to HCC.

In conclusion, success in the field of proteomics and metabolomics will ultimately depend on its clinical application, and this requires a greater emphasis on validation-based experiments of early HCC identification.

### Abstract

Hepatocellular carcinoma (HCC) is etiologically linked with hepatitis B virus (HBV) and is the leading cause of death amongst 80% of HBV patients. Among HBV affected patients, genetic factors are also involved in modifying the risk factors of HCC. However, the genetic factors that regulate progression to HCC still remain to be determined. In this review, we discuss several single nucleotide polymorphisms (SNPs) which were reportedly associated with increased or reduced risk of HCC occurrence in patients with chronic HBV infection such as cyclooxygenase (COX)-2 expression specifically at COX-2 -1195G/A in Chinese, Turkish and Egyptian populations, tumor necrosis factor  $\alpha$  and the three most commonly studied SNPs: PAT-/+, Lys939Gln (A33512C, rs2228001) and Ala499Val (C21151T, rs2228000). In genome-wide association studies, strong associations have also been found at loci 1p36.22, 11q22.3, 6p21 (rs1419881, rs3997872, rs7453920 and rs7768538), 8p12 (rs2275959 and rs37821974) and 22q11.21. The genes implicated in these studies include *HLA-DQB2*, *HLA-DQA1*, *TCF19*, *HLA-C*, *UBE2L3*, *LTL*, *FDX1*, *MICA*, *UBE4B* and *PG*. The SNPs found to be associated with the above-mentioned genes still require validation in association studies in order to be considered good prognostic candidates for HCC. Screening of these polymorphisms is very beneficial in clinical experiments to stratify the higher or lower risk for HCC and may help in designing effective and efficient HCC surveillance programs for chronic HBV-infected patients if further genetic vulnerabilities are detected.

**Core tip:** In this review, we discuss various common associations between hepatitis B virus (HBV) and host polymorphisms. These single nucleotide polymorphisms which have been found to be associated with various genes still require validation in association studies in order to be considered good prognostic candidates for hepatocellular carcinoma (HCC). Screening of these polymorphisms is very beneficial in clinical experiments to stratify the higher or lower risk for HCC and may help in designing effective and efficient HCC surveillance programs for chronic HBV-infected patients if further genetic vulnerabilities are detected.

## HEPATITIS B VIRUS

Hepatitis B virus (HBV) infection is the third most common cause of cancer-related deaths in relation to hepatocellular carcinoma (HCC) with a high incidence in Asian countries. HCC is responsible for approximately 660000 deaths worldwide each year and 85%-90% of these deaths are due to primary liver cancers<sup>[1]</sup>. It is recognized that these cancers are mainly due to HBV infection with 60% of HCC cases seropositive for this virus<sup>[2]</sup>. Many risk factors including viral factors (e.g., genomic mutations, genotypes, HBV-DNA levels), host factors and unhealthy lifestyles all contribute to the development of liver diseases<sup>[3]</sup>.

Both epigenetic and genetic factors play a role in the malignant transformation of liver cells<sup>[4]</sup>. Multiple cellular signaling genes are enhanced by the incorporation of HBV into the host's genome which promotes transactivation of HBx protein<sup>[5]</sup>. This process activates/inactivates suppressor genes (e.g., *p53*), oncogenic genes (e.g., *c-fos* and *c-myc*), induces loss of heterozygosity and activates transcriptional factors [e.g., nuclear factor kappa-B (NF-κB) and AP-1]<sup>[6]</sup>.

However, underlying disease and the duration of severity vary significantly between each phase. Moreover, clinical progression varies between patients. Liver injuries in patients with HBV infection are thought to be the outcome of the host's immune responses against HBV. For example, cytotoxic T lymphocyte-mediated, an HLA-class I antigen-restricted, response to the HBV antigen expressed on hepatocytes results in necrosis and apoptosis<sup>[7]</sup>.

Several genome wide association studies have identified candidate single nucleotide polymorphisms

(SNPs) by comparing the SNPs present in HCC patients and those present in asymptomatic HBV carriers<sup>[8]</sup>. Therefore, to specifically evaluate genetic factors, it is vital that the controls and patients are well matched regarding these factors to identify the correct SNP. The results of many studies suggest that several SNPs are associated with HBV clearance and persistent infection. Functional analyses are necessary to confirm these results<sup>[6,7]</sup>. In this review, we discuss several SNPs which are reportedly associated with increased or reduced risk of HCC occurrence in patients with chronic HBV infection<sup>[9]</sup>.

## INFLAMMATORY GENETIC POLYMORPHISM

It has been reported previously that SNPs can affect disease progression after HBV infection. Cytokines, such as tumor necrosis factor-α (TNFα) and interleukin (IL)-10, have a significant role in regulating viral infection. Genetic variation of these cytokines is linked with the outcome of HBV infection<sup>[10-16]</sup>.

Several studies have shown that genetic polymorphisms in multiple genes such as *TP53*<sup>[17]</sup>, *IL-6*<sup>[18]</sup>, and DNA repair genes<sup>[19]</sup>, are associated with the development of chronic HBC infection, progression of the infection and increased risk of HCC. These may serve as biomarkers in identifying HCC risk<sup>[20]</sup>. However, these studies were predominantly performed in HBV-positive populations or populations with a high infection rate.

Genetic variation in tumor suppressor genes or oncogenes is capable of altering gene function and, consequently, may contribute to the development of cancer. Significant research has been conducted to investigate the association between polymorphisms in tumor suppressor genes and oncogenes and the risk of HCC; however, the results are controversial.

## ASSOCIATIONS BETWEEN HBV AND THE HOST POLYMORPHISM

### Cyclooxygenase-2

Cyclooxygenase-2 (COX-2) is involved in many cellular functions, including inflammation, inhibition of apoptosis, carcinogenesis, angiogenesis, invasion and metastasis<sup>[21,22]</sup>. COX-2 is overexpressed in many cancers including HCC, indicating that there is an association between COX-2 expression and the development of cancer<sup>[23,24]</sup>. Selective COX-2 inhibitors have been shown to suppress the growth of HCC cells *in vitro* and *in vivo*<sup>[25]</sup>. A polymorphism in the promoter region of the COX-2 gene could functionally upregulate the transcriptional activity of COX-2, indicating a possible mechanism by which COX-2 may contribute to genetic susceptibility to HCC<sup>[21]</sup>. Several studies have reported that COX-2 point mutations including -1195G/A, -765G/C and +8473T/C were correlated with liver diseases and

HBV-related HCC<sup>[26]</sup>. COX-2-765G/C is related to the risk of skin, esophageal, colorectal, breast and gastric cancers<sup>[27-29]</sup>. With regard to HCC, contradictory and inconclusive results were found. Some studies have reported a correlation between COX-2-765G/C and HBV-related HCC risk<sup>[30-32]</sup>, but other studies reported that no such correlation exists<sup>[26,33,34]</sup>. It has been reported that these inconsistent results were possibly due to limited sample sizes and ethnic variation in those studies. COX-2 + 8473T/C is associated with oral and breast cancers<sup>[35,36]</sup>, but is not associated with HCC<sup>[37]</sup>. A recent meta-analysis by Chen *et al.*<sup>[26]</sup> on Chinese, Turkish and Egyptian populations, concluded that COX-2-1195G/A may be associated with HCC risk, but not COX-2-765G/C or COX-2 + 847T/C.

### ***IL-1alpha and 1beta***

IL-1 $\alpha$  is a potent pro-inflammatory cytokine and has many different biological functions, including cell survival, proliferation, and anti-apoptosis<sup>[38,39]</sup>. IL-1 $\beta$  is also reported to inhibit interferon-induced antiviral activity<sup>[40]</sup> and is assumed to be closely associated with the pathogenesis of chronic hepatitis C. Several polymorphisms of the *IL-1* gene that are thought to affect IL-1 $\beta$  production have been reported<sup>[41]</sup>. -31T SNPs of IL-1 $\beta$  have been shown to enhance IL-1 $\beta$  transcriptional activity<sup>[42]</sup> and several studies reported that -511C/-31T is a risk factor for the development of cancer and liver diseases<sup>[43-45]</sup>. Wang *et al.*<sup>[41]</sup> showed that IL-1 $\beta$ -31 polymorphism was associated with HCC, after controlling for other confounding clinical parameters.

### ***E-cadherin (CDH1)***

E-cadherin is a transmembrane protein that mediates cell-cell adhesion and is expressed in most normal epithelial cells. Downregulation of E-cadherin may lead to a loss of E-cadherin-mediated adhesion, resulting in increased susceptibility to tumor development and is associated with poor prognosis in various carcinomas including HCC<sup>[45-52]</sup>. In addition, HBV and HCV reduce E-cadherin expression and promote tumor recurrence in HCC patients. One of the mechanisms that have been proposed for reduced E-cadherin expression is SNPs in the promoter region of the *CDH1* gene. CDH1-160 C/A and -347G/GA polymorphisms result in the downregulation of E-cadherin protein and is associated with cancer susceptibility<sup>[53]</sup>. Several studies demonstrated that CDH1-347 SNPs are significantly associated with HCC risk<sup>[52,54-57]</sup>. However, the correlation between CDH1-160 SNPs showed conflicting results. Some studies<sup>[58,59]</sup> have shown that CDH1-160 SNP carriers have an increased risk of prostate and bladder cancer, while others showed that it was not associated with the development of prostate, HCC, colorectal or gastric cancer<sup>[60]</sup>.

### ***Peroxisome proliferator-activated receptor gamma***

Peroxisome proliferator-activated receptor gamma

(PPAR $\gamma$ ) is a hormone receptor, present in adipose tissue and plays a critical role in the regulation of fatty acid storage and glucose metabolism<sup>[61]</sup>. PPAR $\gamma$  has been shown to be associated with type 2 diabetes mellitus (T2DM)<sup>[62]</sup>. PPAR $\gamma$  contains two isoforms, PPAR $\gamma$ 1 and PPAR $\gamma$ 2 and several variants in the *PPAR $\gamma$*  gene have been identified<sup>[63]</sup>. The A allele of PPAR $\gamma$ 2 is associated with a significant decrease in the development of T2DM<sup>[64]</sup>. The relationship between PPAR and HCC is not clear. Although experimental studies have shown that PPAR may have a role in HCC<sup>[65,66]</sup>, the implications of these findings are unclear. Koytak *et al.*<sup>[66]</sup> investigated the effect of the PPAR $\alpha$  L162V polymorphism on clinical outcome in a patient with HCC caused by hepatitis viruses. They concluded that there was a relationship between the PPAR $\alpha$  L162V polymorphism and HBV-induced HCC and was associated with advanced HCC. This polymorphism was shown to enhance PPAR $\alpha$  transcriptional activity and is associated with lipid abnormalities and an increased body mass index<sup>[67-70]</sup>.

### ***TNF $\alpha$ -inducible protein 3***

TNF $\alpha$ -inducible protein 3 (TNF $\alpha$ IP3), a cytoplasmic zinc finger protein with ubiquitin-modifying activity, has been shown to inhibit NF- $\kappa$ B activity and TNF-mediated apoptosis<sup>[71-74]</sup>. TNF $\alpha$ IP3 polymorphisms have been linked to inflammatory, autoimmune and malignant diseases. A recent study reported that there was no association between TNF $\alpha$ IP3 rs2230926 polymorphism and susceptibility to chronic HBV infection or the progression of HBV-related diseases<sup>[75]</sup>.

### ***Cytotoxic T lymphocyte-associated factor 4***

Cytotoxic T lymphocyte-associated factor 4 (CTLA-4) is a protein receptor expressed in T cells and it functions as a negative regulator of the immune system. Several *CTLA-4* gene polymorphisms have been identified including -318C>T, A49G and CT60<sup>[76]</sup>. CTLA-4 polymorphisms are associated with several autoimmune diseases, including thyroid and liver diseases<sup>[77,78]</sup>. It has been shown that SNPs in CTLA-4 may be associated with HBV progression and viral persistence<sup>[79]</sup>. CTLA-4 SNPs can be used as a marker for predicting treatment outcome in chronic HCV-infected patients<sup>[80-82]</sup>.

### ***TNF $\alpha$***

TNF $\alpha$  is a multifunctional cytokine that regulates the inflammatory reaction and has an important role in the development and progression of a number of diseases, including liver disease<sup>[83,84]</sup>. It has been suggested that genetic polymorphisms of TNF $\alpha$  may contribute to the pathogenesis of liver diseases, infectious diseases and inflammatory disorders<sup>[43,85]</sup>. For example, TNF $\alpha$  SNPs affect TNF $\alpha$  production leading to a greater risk of HCC. The polymorphism at site -1031T/C, -863C/A, -857C/T, -376, -308G/A and -238G/A of the TNF $\alpha$  promoter is associated with the outcome of HBV infection and disease progression<sup>[86-89]</sup>.

### IL-10

IL-10 is an important anti-inflammatory cytokine produced in macrophages. Three SNPs in the *IL-10* gene promoter, at -1082, -819 and -592, are associated with IL-10 production and secretion by peripheral blood monocytes. It has been shown that IL-10-592 A/C polymorphism was associated with susceptibility to HBV infection<sup>[90]</sup>.

### Glutathione S-transferases

The glutathione S-transferases (GSTs) enzymes play an important role in maintaining the cellular defense mechanism against the effects of reactive oxygen species and various exogenous toxins, and have been shown to be overexpressed in several cancers<sup>[91,92]</sup>. Deletion polymorphism of *GST* genes results in diminished enzyme activity leading to the insufficient defense of cells from metabolites and free radicals, elevated concentration of endogenous mutagens and a high risk of various tumors, including HCC<sup>[93-96]</sup>. GSTs polymorphisms have been shown to be associated with colorectal cancer, lung cancer, squamous cell carcinoma of the head and neck, HBV-related HCC, and various urogenital and gastrointestinal disorders<sup>[97-99]</sup>. For example, meta-analyses have shown that GSTM1, GSP1 and GSTT1 are associated with an increased risk of HCC<sup>[100,101]</sup>.

### Epidermal growth factor

Epidermal growth factor (EGF) and its respective receptor (EGFR) signaling are important regulators of proliferation and the pathogenesis of many human carcinomas<sup>[102,103]</sup>. Upon ligand binding, the two EGFR domains undergo trans-autophosphorylation at specific tyrosine residues<sup>[104]</sup>. These phosphotyrosines are recognized by Src homology 2 domain containing proteins<sup>[105]</sup> and activate a diverse signaling network that includes the RAS/extracellular signal-regulated kinase pathway<sup>[106]</sup>, the phosphatidylinositol 3-kinase pathway<sup>[107]</sup> and the Janus kinase/Signal transducer and activator of transcription pathway<sup>[108]</sup>.

Activation of EGF has also been shown to be required for hepatocyte growth during liver regeneration<sup>[109]</sup>. In addition, many viruses such as Epstein Barr virus and HBV can tweak EGF receptor expression in their favor<sup>[110-112]</sup>. The role of EGF polymorphism has been explored in numerous meta-analyses<sup>[113-116]</sup> and was shown to be highly associated with susceptibility to HCC<sup>[117]</sup>. Prominent among these is the EGF + 61A > G transversion (rs4444903) which was shown to regulate expression of the *EGF* gene<sup>[118,119]</sup>. This SNP is found in the 5' untranslated regions of the *EGF* gene and was shown in cell lines to enhance the stability of EGF mRNA<sup>[119]</sup>. The G/G allele is associated with higher serum levels of EGF compared with the A/A allele<sup>[119,120]</sup>. Numerous follow-up studies have validated the positive association between this G/G and G/A genotype with HCC in diverse genetic populations<sup>[117,121-123]</sup> and thus can be considered a good prognostic marker for the

genetically susceptible population.

### Murine double minute 2

Murine double minute 2 (MDM2) is a ubiquitin ligase that controls the turnover rate of an important tumor suppressor, p53, which is deleted or mutated in 50% of all human tumors<sup>[124]</sup>. P53 is also referred to as the guardian of the genome because it can activate DNA repair pathways<sup>[125]</sup>, arrest cell cycle at the G1/S regulation checkpoint<sup>[126]</sup> or initiate apoptosis if the damage cannot be repaired<sup>[127]</sup>. All these important networks converge in the active form of p53, which is kept in check by MDM2. The addition of ubiquitin subunits to critical lysine residues transfers the active p53 to 26S proteasome for degradation along with MDM2<sup>[128,129]</sup>. In addition, the binding of MDM2 can block p53-mediated transactivation functions<sup>[130]</sup>. The activity of MDM2 protein is equally important in regulating this DNA repair-cell cycle-apoptosis nexus and variation in the expression levels of this protein was shown to have serious consequences in cells or organisms<sup>[131]</sup>. Bond *et al.*<sup>[132]</sup> showed that the SNP 309T > G (rs 2279744) located in the promoter region of MDM2 can enhance the transcriptional levels of this protein and subsequent perturbation of p53 functions in the cell. This T > G mutation is thought to generate a binding site on the MDM2 promoter for Sp1 transcription factor<sup>[133]</sup> and thus enhances the levels of MDM2 protein in the cell.

The positive association between this SNP 309T > G (rs 2279744) in the *MDM2* gene and HCC was shown by numerous ethnic-based studies<sup>[134-136]</sup> and meta-analyses<sup>[137,138]</sup>. This epidemiological finding together with functional assays of MDM2 levels point to the relevance of MDM2 SNP 309T > G polymorphism as an important player in susceptibility to HCC development.

### T cell immunoglobulin mucin-3

T cell immunoglobulin mucin-3 (TIM3) negatively regulates the autoimmune and allergic responses and has been linked to T cell dysfunction associated with HBV-related HCC<sup>[139]</sup>. The 280 aa mature TIM3 is selectively expressed on CD4<sup>+</sup> Th1 and CD8<sup>+</sup> Tc1 cells, but not on CD4<sup>+</sup> Th2 cells<sup>[140]</sup>. It interacts with its ligand galectin-9 and drives death Th1 T cells<sup>[141,142]</sup>. Blocking TIM3-mediated signaling restores dysfunctional CD4 and CD8<sup>+</sup> T cell-specific adaptive immune responses<sup>[143]</sup>. TIM3 is upregulated on CD4 and CD8<sup>+</sup> T cells in chronic HBV infected individuals<sup>[144]</sup>.

Numerous potential SNPs (-1541C/T, -1516G/T, -882C/T, -574G/T and +4259T/G) in TIM3 have been tested for their association with chronic HBV and HCC<sup>[145]</sup>. TIM3-1516 G/T (rs10053538) polymorphism has been shown to predispose individuals to cirrhosis and/or HCC<sup>[146,147]</sup>. One study reported that TIM3 SNPs do not have a functional effect<sup>[148]</sup>, whereas others have reported a significant effect of these TIM3 polymorphic variants<sup>[149]</sup>. Further studies are needed to determine the functional relevance of this polymorphism.

**Xeroderma pigmentosum complementation group C**

Xeroderma pigmentosum complementation group C (XPC) protein along with seven other core members (ERCC1, XPA, XPB, XPD, XPE, XPF and XPG) constitutes the nucleotide excision repair pathway (NER). This pathway is required for the repair of DNA damage including pyrimidine dimers, photo products, chemical adducts and cross-links<sup>[150,151]</sup>. XPC requires an association with HR23B in order to recognize damaged DNA<sup>[152]</sup>. The protein HR23B is a human homolog of *Saccharomyces cerevisiae* RAD23 and binding of XPC-HR23B to a DNA lesion unwinds the helix<sup>[153]</sup>. The XPA protein can then bind and the whole repair machinery of the NER can be recruited onto the damaged base.

Many studies have investigated the association between XPC sequence variants and cancer risk<sup>[154-158]</sup>. The three most commonly studied SNPs in the literature are: PAT-/+<sup>[159]</sup>, Lys939Gln (A33512C, rs2228001)<sup>[155]</sup> and Ala499Val (C21151T, rs2228000)<sup>[160]</sup>. The poly (AT) insertion/deletion polymorphism (PAT) is located on intron 9 and has been shown to be linked to head and neck cancer risk<sup>[161]</sup> and to lung cancer<sup>[162]</sup>, but no studies have found an association with HCC risk. The XPC codon Lys939Gln alleles, on the other hand, significantly increased HCC risk<sup>[163,164]</sup>. The Ala499Val variant homozygous genotype is a risk factor for bladder cancer<sup>[158]</sup>, but has not been studied for HCC.

**IL-16**

IL-16 is a pro-inflammatory cytokine and was initially called lymphocyte chemoattractant factor<sup>[165]</sup>. It can activate a diverse set of immune cells such as CD4<sup>+</sup> T cells, monocytes, macrophages, eosinophils and dendritic cells<sup>[166-169]</sup>. In addition to inducing activation and chemotaxis of immune cells, IL-16 can upregulate the IL-2 receptor<sup>[170]</sup> and HLA-DR4 expression<sup>[171]</sup>. Upon CD4 receptor binding, IL-16 signaling increases intracellular calcium and inositol triphosphate, and translocation of protein kinase C from the cytosol to the plasma membrane<sup>[172,173]</sup>. Moreover, IL-16 can stimulate the production of further pro-inflammatory mediators including IL-1 $\beta$ , IL-6, IL-15 and TNF $\alpha$ , *e.g.*, by monocytes<sup>[174]</sup> thereby initiating and/or sustaining the inflammatory response.

Genetic polymorphisms in IL-16 have recently been reported and shown to affect susceptibility to a range of cancers including colorectal, gastric and prostate cancer and nasopharyngeal carcinoma<sup>[175-178]</sup>. Data regarding HCC and IL-16 polymorphisms are scarce in the literature and only two studies were found to have assessed three SNPs (rs11556218T > G, rs4778889T > C, and rs4072111C > T)<sup>[179]</sup>. In the study by Li *et al.*<sup>[180]</sup>, no association with HCC was found for all three SNPs (rs11556218T/G *P* = 0.511, rs4072111C/T *P* = 0.308 and rs4778889T/C *P* = 0.070). The other study by Thomas *et al.*<sup>[178]</sup> did not include HCC patients. However, this study did include chronic hepatitis B patients who showed a positive association between rs11556218T

> G, a negative association between rs4778889T > C and a positive association between rs4072111C > T polymorphisms and patient susceptibility to chronic hepatitis B infection<sup>[179]</sup>.

**Genome-wide association studies**

Numerous genome-wide association studies (GWAS) have been carried out with chronic HBV and HCC patients to identify novel susceptible loci contributing to disease<sup>[6,181-186]</sup>. Of these, strong associations were found at 1p36.22, 11q22.3, 6p21 (rs1419881, rs3997872, rs7453920 and rs7768538), 8p12 (rs2275959 and rs37821974) and 22q11.21. The genes implicated in these studies include HLA-DQB2, HLA-DQA1, transcription factor 19 (TCF19), HLA-C, ubiquitin-conjugating enzyme E2 (UBE2L3), LTL, ferredoxin 1 (FDX1), MICA, UBE4B and PG.

HLA-DQ is an MHC class II cell surface receptor found on antigen presenting cells, whereas HLA-C is an MHC class I receptor expressed by all cells. TCF19, as the name suggests, is an important transcription factor during cell cycle G1/S transition<sup>[187]</sup>. UBE2L3 is a typical E2 ligase that accepts ubiquitin from the E1 complex and transfers it to targeted proteins<sup>[188]</sup>. Leukocyte telomere length (LTL) has been associated with the risk of developing many malignancies<sup>[189]</sup> and LTL-related SNPs are potential targets for such GWAS studies. FDX1 is a gene that codes for a small iron-sulfur protein that transfers electrons from NADPH through ferredoxin reductase to mitochondrial cytochrome P450<sup>[190]</sup>. In addition, it is involved in steroid, vitamin D, and bile acid metabolism<sup>[191]</sup>.

These SNPs found to be associated with the above-mentioned genes still require validation in association studies in order to be considered good prognostic candidates for HCC.

**Tumor growth factor beta**

Tumor growth factor beta (TGF $\beta$ ) is a tumor suppressor gene located on chromosome 19q13.1-13.39. The protein TGF $\beta$  is involved in pleiotropic biological processes such as cell growth<sup>[192]</sup>, differentiation<sup>[193]</sup>, extracellular matrix synthesis<sup>[194]</sup>, hematopoiesis<sup>[195]</sup>, angiogenesis<sup>[196]</sup>, and cellular apoptosis<sup>[197]</sup>. TGF $\beta$ 1 is one of TGF $\beta$  isoforms and is upregulated in HCC tissues correlating with the carcinogenesis and prognosis of HCC<sup>[198,199]</sup>. TGF $\beta$ 1 also suppresses HBV replication by reducing hepatocyte nuclear factor-4- $\alpha$ <sup>[200]</sup>. Thus, the relevance of this cytokine and its single nucleotide polymorphism in HBV-associated HCC is of paramount importance.

Seven TGF $\beta$ 1 polymorphisms have been described in the literature, of which three lie in the upstream region of the gene at positions -988C > A, -800G > A, and -509C > T, one insertion in a nontranslated region at position +72C, two in exon 1 (Leu10Pro and Arg25Pro); and 1 in exon 5 (Thr263Ile)<sup>[201]</sup>. Numerous studies have investigated the association between these

COX-2: Cyclooxygenase-2; IL-1 $\alpha$ ,  $\beta$ : Interleukin-1 $\alpha$ ,  $\beta$ ; CDH1: Cadherin 1; PPAR $\gamma$ : Peroxisome proliferator-activated receptor  $\gamma$ ; TNFAIP3: Tumor necrosis factor alpha-induced protein 3; TNF $\alpha$ : Tumor necrosis factor  $\alpha$ ; GST: Glutathione S transferase; EGF: Epidermal growth factor; MDM2: Mouse double minute 2 homolog; TIM3: T-cell immunoglobulin 3; XPC: Xeroderma pigmentosum; TGF $\beta$ 1: Transforming growth factor beta 1.

SNPs and HCC<sup>[202-205]</sup>. There are contrasting reports with some studies reporting a positive association between -509C > T (rs1800469) and HCC risk<sup>[206]</sup>, whereas another study reported a weak or no association<sup>[204]</sup>. In addition, the Arg25Pro change at +915G/C (rs1800471) was not correlated with HCC risk<sup>[207]</sup>. The mutation in codon 10 (Leu > Pro) was very strongly correlated with HCC according to one study<sup>[208]</sup>. There is still limited information regarding other polymorphisms of TGF $\beta$ 1 and further studies are required to draw firm conclusions on their association with HCC. Table 1 lists the polymorphic genes and their contribution to HCC.

## DISCUSSION

In this article, we discuss the association between the HBV genotype and its mutations in the development of liver cancer and the possibility that individuals with inherited genetic mutations have a hereditary predisposition for HBV-related HCC. Such individuals can inherit a germ-line mutation in one allele of the gene; somatic mutation of the second allele facilitates tumor progression. Although the inherited germ-line mutation may not be adequate to affect tumor development, it is likely that HBV proteins also induce many alterations in the genome. Analysis of the whole transcriptome in these individuals with genetic predisposition would be a useful indicator. It is now well understood that host genetic differences significantly influence susceptibility

and resistance to HBV infection and the development of liver cancer, thus it is important to identify these genotype-phenotype associations for better treatment of the disease (Figure 1). Genome-wide sequencing studies have identified numerous germline mutations associated with liver cancer predisposition and large numbers of somatic alterations. It is difficult to assess the difference between background and HBV-related mutations as HBV infection plays an important role in the development of host genetic mutations, due to impairment in the DNA repair process. To elucidate the role of HBV-related genetic variations, researchers have used traditional biological methods to identify genetic mutations. More recently, advanced techniques such as next generation sequencing technology have been used to identify key mutations involved in the development of HCC. Important HCC-associated mutations have been found in key regulatory genes including COX-2, IL-1 $\alpha$  and  $\beta$ , E-cadherin (CDH1), PPAR $\gamma$ , TNF $\alpha$ IP3, CTLA-4, TNF $\alpha$ , IL-10, GSTM1/GSTT1 Deletion Oxidative stress, EGF, MDM2, TIM3), XPC, IL-16, TGF $\beta$ , 1p36.22, 11q22.3, 6p21, 8p12 and 22q11.21 candidate SNPs in GWAS. The association between each locus and the outcome of liver disease is discussed in detail in this article.

Based on these findings, we predict that advanced sequence analysis of host genome will provide us with a better understanding of the viral and host genetic factors involved in the development of HCC. Further studies are needed to evaluate and understand the role

### Abstract

**AIM:** To identify plasma analytes using metabolomics that correlate with the diagnosis and severity of liver disease in patients with alcoholic hepatitis (AH).

**METHODS:** We prospectively recruited patients with cirrhosis from AH ( $n = 23$ ) and those with cirrhosis with acute decompensation (AD) from etiologies other than alcohol ( $n = 25$ ). We used mass spectrometry to identify 29 metabolic compounds in plasma samples from fasted subjects. A receiver operating characteristics analysis was performed to assess the utility of biomarkers in distinguishing acute AH from alcoholic cirrhosis. Logistic regression analysis was performed to build a predictive model for AH based on clinical characteristics. A survival analysis was used to construct Kaplan Meier curves

evaluating transplant-free survival.

**RESULTS:** A comparison of model for end-stage liver disease (MELD)-adjusted metabolomics levels between cirrhosis patients who had AD or AH showed that patients with AH had significantly higher levels of betaine, and lower creatinine, phenylalanine, homocitrulline, citrulline, tyrosine, octenoyl-carnitine, and symmetric dimethylarginine. When considering combined levels, betaine and citrulline were highly accurate predictors for differentiation between AH and AD (area under receiver operating characteristics curve = 0.84). The plasma levels of carnitine [0.54 (0.18, 0.91);  $P = 0.005$ ], homocitrulline [0.66 (0.34, 0.99);  $P < 0.001$ ] and pentanoyl-carnitine [0.53 (0.16, 0.90);  $P = 0.007$ ] correlated with MELD scores in patients diagnosed with AH. Increased levels of many biomarkers (carnitine  $P = 0.005$ , butyrobetaine  $P = 0.32$ , homocitrulline  $P = 0.002$ , leucine  $P = 0.027$ , valine  $P = 0.024$ , phenylalanine  $P = 0.037$ , tyrosine  $P = 0.012$ , acetyl-carnitine  $P = 0.006$ , propionyl-carnitine  $P = 0.03$ , butyryl-carnitine  $P = 0.03$ , trimethyl-lisine  $P = 0.034$ , pentanoyl-carnitine  $P = 0.03$ , hexanoyl-carnitine  $P = 0.026$ ) were associated with increased mortality in patients with AH.

**CONCLUSION:** Metabolomics plasma analyte levels might be used to diagnose of AH or help predict patient prognoses.

**Key words:** Metabolomics; Biomarkers; Liver disease; Model for end-stage liver disease; Cirrhosis; Alcoholic hepatitis; Liver biopsy

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The model for end-stage liver disease score, which is commonly used to predict outcomes in patients who have liver disease, is far from perfect. We report results from a study that uses metabolomics biomarkers as a means for assessing diagnosis and prognosis in patients who have liver disease. Plasma analytes from fasted subjects have provided information regarding 3 and 6 mo transplant free survival. This study is one of the first to employ the novel metabolomics approach as it relates to patient outcomes. These results can pave the way for future research that can enhance the way we assess patients with liver disease.

## INTRODUCTION

Generally, clinical assessment is sufficient to generate

a diagnosis of alcoholic hepatitis (AH). However, sole dependence on clinical signs and symptoms is not specific, and further confirmation is usually needed. Thus, the gold standard for the diagnosis of AH is liver biopsy. Liver biopsy is considered an expensive and invasive procedure, and 1%-5% of patients require post-procedural hospitalization<sup>[1]</sup>. In addition, sampling error and inter-observer variability contribute to the limitations of liver biopsy as a procedure<sup>[1]</sup>. Therefore, it behooves practitioners to utilize alternative non-invasive tools to diagnose AH. Hanounieh *et al*<sup>[1]</sup> have shown promise in the possibility of analyzing volatile compounds in breath samples as a useful diagnostic test in patients with AH. Consequently, a rapid, non-invasive, accurate, and precise test would greatly benefit AH diagnosis.

Furthermore, prognosis of AH is determined by several scoring systems, including the model for end-stage liver disease (MELD), which is primarily based on serum lab values and is one of the chief parameters in evaluation of long-term outcome and qualification for liver transplant. While the MELD score can detect short-term survival in patients with AH with good accuracy, its prediction of long-term survival is still debated<sup>[2]</sup>. Palaniyappan *et al*<sup>[2]</sup> evaluated several scoring systems and their ability to predict long-term outcome of AH and concluded that all scoring systems were uniformly poor in predicting long term survival beyond six months. In addition, the cut-off value for the MELD score in detecting severe AH has not been agreed upon, with various studies employing different values<sup>[2]</sup>. Therefore, MELD score may not accurately reflect the risk of death in some groups of patients with liver disease such as AH awaiting liver transplantation.

Metabolomics was originally defined as the detailed qualitative and quantitative analysis of the metabolites present in complex biological samples<sup>[3]</sup>. Metabolites are both the intermediate and end result of all the biological processes taking place in a cell, tissue, or organism, thereby serving as the most proximal reporters of the body's response to a disease process or drug therapy<sup>[4]</sup>. By identifying and quantifying metabolites, one can gather a picture of the genetic variations and environmental influences (such as diet, lifestyle, drug use, and toxicological exposure) in a biological specimen. In more recent years physicians have been exploring the potential of metabolite profiling in providing diagnostic and prognostic information for many diseases, such as AH. For example, Rachakonda *et al*<sup>[5]</sup> demonstrated *via* metabolomics profiling that specific biomarkers could be used to determine disease prognosis in patients with severe AH. Thus, the potential of utilizing biomarkers in diagnosis of liver disease, assessing liver disease severity, and determining long-term survival in patients with AH is worth investigating; further exploration is warranted as there is limited information on this subject. Herein, we used a targeted metabolomics approach to identify plasma analytes that may provide improved diagnostic and prognostic value in patients with alcoholic hepatitis and end-stage liver disease.

## MATERIALS AND METHODS

### Patients

We recruited patients with liver cirrhosis awaiting liver transplantation from a single tertiary care center. The study population was divided between those with AH with cirrhosis ( $n = 25$ ) and those with acute decompensated (AD) cirrhosis from etiologies other than alcohol ( $n = 23$ ). The diagnosis of AH with cirrhosis was based on clinical and laboratory features: A patient with a history of heavy alcohol use, exclusion of other causes of liver disease, elevated aspartate aminotransferase that remained under  $< 300$  IU/mL, a ratio of aspartate aminotransferase (AST) level to alanine aminotransferase (ALT) level that is  $> 2$ , total serum bilirubin level of  $> 5$  mg/dL, an elevated international normalized ratio, and neutrophilia. Significant alcohol intake was defined as a consumption of  $> 2$  drinks daily or  $> 6$  drinks daily on weekends for the past 5 years. We used the definition of the American Association for the Study of Liver Disease guidelines of what constitutes a standard drink: 12 g of alcohol with range 9.3-13.2 g.

The diagnosis of liver cirrhosis was based on the histologic features of cirrhosis on liver biopsy and/or a composite of clinical signs and findings of cirrhosis provided by laboratory tests, endoscopy, and radiologic imaging. AH was defined by the acute development of one major complication of liver disease including acute kidney injury, ascites, encephalopathy, or gastrointestinal hemorrhage secondary to gastrointestinal varices or portal hypertensive gastropathy and enteropathy. Hepatic encephalopathy was assessed by a single individual using Conn score and asterix grade. Acute kidney injury was defined as an abrupt (arbitrarily set at 48 h) reduction in kidney function manifested by an absolute increase in serum creatinine of 0.3 mg/dL or more, equivalent to a percentage increase in serum creatinine of 50% or more (1.5-fold from baseline)<sup>[6]</sup>.

Among patients with acute decompensated liver cirrhosis, only those who remained abstinent from alcohol use for at least 6 mo before admission were included, whereas all patients with AH were (by definition) actively abusing alcohol before admission. The data was collected at the time of diagnosis and admission with alcoholic hepatitis - subjects were not drinking alcohol following admission. We also excluded all individuals with ongoing tobacco use. Patients with liver cancer or other malignancies were excluded, as were those with prior history of transplantation.

### Data collection

Mass spectrometry identified and measured 29 metabolomics compounds related to amino acid and intermediary metabolism in plasma samples from fasted subjects. Samples and associated clinical data were collected from fasting subjects undergoing community health screens. All subjects gave written informed consent and the Institutional Review Board of the Cleve-

land Clinic approved all study protocols.

### Quantification of plasma analytes by liquid chromatography/mass spectrometry/mass spectrometry

Stable isotope dilution liquid chromatography/mass spectrometry (MS)/MS was used to quantify plasma analytes. Four volumes of methanol containing isotope-labeled internal standards was added to one volume of plasma for protein precipitation. After centrifugation, supernatant was analyzed by injection onto a silica column that was interfaced with an atmospheric pressure ionization 4000 Q-TRAP mass spectrometer (AB SCIEX, Framingham, MA)<sup>[7]</sup>. A discontinuous gradient was generated to resolve analytes by mixing 0.1% propanoic acid in water with 0.1% acetic acid in methanol<sup>[7]</sup>. Analytes and the isotope-labeled internal standards were monitored in positive multiple reaction monitoring MS mode using characteristic precursor-product ion transitions (Table 1). Parameters for ion monitoring were optimized for each analyte. Various concentrations of analytes were spiked into a control plasma sample to prepare calibration curves for quantification of analytes.

### Statistical analysis

Data are presented as mean  $\pm$  SD, median (25<sup>th</sup>, 75<sup>th</sup> percentiles) or  $n$  (%). Univariable analysis was performed to compare clinical characteristics and biomarker levels between the two groups. Analysis of variance or the non-parametric Kruskal-Wallis test were used to assess differences in continuous variables and Pearson's  $\chi^2$  tests or Fisher's exact tests were used for categorical factors. Analysis of covariance was used to assess differences in biomarker levels while adjusting for MELD; the logarithm of each compound was modeled as the outcome variable with group and MELD as the independent variables. Receiver operating characteristics (ROC) analysis was performed to assess the utility of biomarkers in distinguishing acute alcoholic hepatitis from alcoholic cirrhosis; the area under the ROC curves [area under receiver operating characteristics curve (AUC)] and corresponding 95%CI are presented.

We used various statistical analyses to compare clinical characteristics and plasma levels of compounds among groups and to test the correlation between levels of compounds and severity of liver disease. Correlations between 0.0-0.3 are considered low, between 0.3-0.5 are considered moderate, and between 0.5-0.7 are considered high, and between 0.7-1.0 are considered very high. Spearman's correlation coefficients were also used to assess correlations between biomarkers and severity of liver disease for each group separately. Finally, logistic regression analysis was performed to build a predictive model for AH.

Lastly, a survival analysis was done to evaluate transplant-free survival. Kaplan-Meier product-limit estimates were used to assess transplant-free survival. Follow-up time was defined as time from sample collection to death and subjects were censored at time of

orthotopic liver transplantation (OLT), if applicable, or last follow-up visit. Cox regression was used to assess associations between biomarker levels and transplant-free survival. In addition, inverse probability of censoring weighting estimation of cumulative/dynamic time-dependent ROC curve was used to assess the role of novel biomarkers in prediction of 3 and 6-mo LT-free survival<sup>[8,9]</sup>. Each marker was compared to the MELD score and markers with AUC of at least 0.70 were further assessed to see if any of these improved prediction of survival in combination with MELD. A  $P < 0.05$  was considered statistically significant. A 95%CI encompassing 0.5 was considered to indicate no significant predictive value. SAS (version 9.2, the SAS Institute, Cary, NC) and R (version 3.0.3, the R Foundation for Statistical Computing) were used to perform all analyses. The statistical methods of this study were reviewed by

Rocio Lopez from the Cleveland Clinic Foundation.

## RESULTS

### Baseline characteristics

Table 2 presents a summary of patient demographic and clinical characteristics. A total of 45 subjects were included in the analysis. The average age was  $53 \pm 10$  years, 54% were male, and 75% were Caucasian. The mean MELD score was  $18.0 \pm 9.3$ . MELD score was comparable between subjects with AH and those with AD.

### Metabolomics biomarkers of alcoholic hepatitis

Table 3 presents a summary of MELD-adjusted biomarker levels in the two study groups. Betaine, creatinine, homocitrulline and citrulline, tyrosine, phenylalanine, octenoyl carnitine, and symmetric dimethylarginine (SDMA) were significantly higher in patients with AH compared to those with AD.

Table 4 presents AUC data using ROC analysis, where values greater than 0.7 are strongly predictive for differentiation between AH and AD. Citrulline, betaine, and tyrosine were all notable for their values in differentiating AH from AD. Using a combination of citrulline and betaine provided the greatest AUC, at 0.835 with a 95%CI between 0.747 and 0.978. Other significant biomarkers include homocitrulline, SDMA, octenoyl-carnitine, creatinine, and phenylalanine. The remaining biomarkers were insignificant.

Table 5 presents the correlations between biomarkers and liver disease severity for alcoholic hepatitis. There was moderate to strong correlation between several biomarkers and both MELD and Maddrey's scores. Correlations between 0.0-0.3 are considered trivial/low, 0.3-0.5 are considered moderate, 0.5-0.7 are considered high and 0.7-1.0 are considered very high/strong.

The objective of this study was to detect patterns in biomarkers or hypothesis generation. In addition, adjustments for multiple comparisons are typically somewhat conservative and it would be possible to miss many potential associations that should be further explored. Holm-Bonferroni adjustment is quite conservative when the number of tests is large or the tests are not independent<sup>[10]</sup>. Despite this, we performed the Holm-Bonferroni adjustment to provide a more complete set of data (Table 6). In this case only citrulline, phenylalanine, and homocitrulline remain significantly different between the groups.

### Metabolomics biomarkers of severity of liver disease

Patients were followed over 12.5 (P25, P75: 4.3, 14.1) mo during which three subjects received a liver transplant and a total of 24% of subjects expired. As seen in Figure 1, tyrosine was strongly associated with transplant-free survival outcome in patients with liver cirrhosis [AUC for 3-mo OLT-free survival AUC = 0.91 (0.74-1.0)]. Combined MELD scores and tyrosine levels provided the best accuracy for 3-mo transplant-

**Figure 1 Tyrosine predicts 3-mo liver transplant-free survival in patients with end-stage liver disease.** Results are presented as AUC (P25, P75). AUC: Area under receiver operating characteristics curve; OLT: Orthotopic liver transplantation; MELD: Model for end-stage liver disease.

**Figure 2 Tyrosine predicts 6-mo liver transplant-free survival in patients with end-stage liver disease.** AUC: Area under receiver operating characteristics curve; OLT: Orthotopic liver transplantation; MELD: Model for end-stage liver disease.

free survival AUC = 0.92 (0.76-1.0). Evidently these biomarkers can be used to predict OLT-free survival with reasonable sensitivity and specificity.

Figure 2 shows the same analysis with similar results, except for 6-mo OLT-free survival. MELD provided an AUC of 0.77, tyrosine provided an AUC of 0.90, and MELD and tyrosine together provided an AUC of 0.89.

Tyrosine alone as well as tyrosine in combination with MELD provided better AUC values than MELD alone, suggesting its utility in predicting OLT-free survival.

A multivariable Cox regression analysis was used to adjust for MELD, the most important predictor of mortality, and tyrosine remained significantly associated with mortality [HR = 1.02 (1.01, 1.04) for a one unit

Values presented as mean (95%CI) and P-values obtained from analysis of covariance. The natural logarithm of each biomarker was modeled as the outcome variable with disease group and MELD as the independent variables. <sup>a</sup>P < 0.05, <sup>b</sup>P < 0.01. ADMA: Asymmetric dimethylarginine; SDMA: Symmetric dimethylarginine; MMA: Monomethylarginine; TMAO: Trimethylamine N-oxide.

increase in tyrosine; *P* = 0.002]. In Figures 1 and 2 it can also be seen that tyrosine performs better than MELD for prediction of 3- and 6-mo mortality, and the combination of MELD and tyrosine (in a multivariable analysis) performs more or less the same as the compound by itself.

Time-dependent ROC analysis (Table 7) shows that phenylalanine [AUC = 0.77 (0.56, 0.97)], carnitine [AUC = 0.73 (0.53, 0.93)], asymmetric dimethylarginine (ADMA) [AUC = 0.72 (0.49, 0.96)] and monomethylarginine (MMA) [AUC = 0.71 (0.47, 0.94)] all provide excellent predictive value for transplant-free survival in patients with liver cirrhosis, but there was no evidence to suggest that they were significantly better than MELD.

## DISCUSSION

The purpose of this study was two-fold. First, the utility of metabolomics as an un-invasive diagnostic tool for AH was assessed. The diagnosis of AH is usually a clinical one, based on severe liver dysfunction in the context of excessive alcohol consumption, excluding other causes of acute and chronic liver disease (CLD)<sup>[1]</sup>. However, this method of diagnosis is not steadfast, as some studies that have included a liver biopsy in all patients with clinically suspected AH have shown histologic confirmation in only

70%-80% of patients<sup>[1]</sup>. Thus, liver biopsy remains the gold standard in diagnosing AH patients; however it is invasive, expensive, and burdensome for the patient. The utilization of metabolic biomarkers as an alternative, objective, un-invasive diagnostic tool is promising.

Our results demonstrated that AH patients have a specific metabolome that can be employed for diagnostic purposes. AH patients had higher levels of betaine, and lower levels of creatinine, citrulline, homocitrulline, tyrosine, phenylalanine, octenoyl-carnitine, and SDMA. Most importantly, betaine and citrulline provided excellent prediction accuracy in distinguishing AH from AD. Figure 3 shows the sensitivity and specificity of citrulline and betaine for diagnosis and acute decompensation from non-alcohol-related etiologies. Alcohol consumption in patients with alcoholic liver disease results in bacterial overgrowth and increases gut permeability and translocation of bacteria-derived lipopolysaccharides from the gut to the liver<sup>[1]</sup>. This could explain the altered levels of amino acids in these patients.

Betaine is a molecule involved in transmethylation reactions in biological systems. S-adenosylmethionine (SAM), a critical methylating agent, is crucial to maintaining the integrity of the liver. One important function of SAM is its conversion of phosphatidylethanolamine to phosphatidylcholine, the latter of which constitutes lipoproteins involved in transporting fat away from the

**Table 4** Utility of biomarkers in differentiating cirrhosis with alcoholic hepatitis from cirrhosis with acute decompensation from etiologies other than alcohol: Receiver operating characteristics analysis

Ornithine	0.351 (0.186, 0.517)

AUC: Area under receiver operating characteristics curve; ADMA: Asymmetric dimethylarginine; SDMA: Symmetric dimethylarginine; MMA: Monomethylarginine; TMAO: Trimethylamine N-oxide.

liver, thereby preventing hepatic fat infiltration and subsequent liver injury<sup>[11]</sup>. Betaine plays a significant role in this pathway as a methylating agent in the liver. Betaine transfers a methyl group to homocysteine *via* betaine-homocysteine methyl transferase (BHMT) in order to form methionine, which then goes on to form SAM and methylate biological molecules to protect the liver. Thus, betaine is protective against harmful fatty deposits in the liver due to alcohol abuse. While acute alcohol ingestion induces BHMT activity so that SAM levels can remain physiologically normal, chronic alcohol abuse leads to diminished SAM levels due to exhaustion of this system<sup>[11]</sup>. Consequently, this lead to increased betaine levels in the serum of AH patients, as the hepatocytes cannot compensate and regenerate SAM *via* the BHMT pathway. Furthermore, other studies have shown that dietary supplementation with betaine generated increased SAM in the liver and protected against ethanol-induced steatosis in rats<sup>[12]</sup>. However, with chronic alcohol abuse and dysfunction of the BHMT pathway, betaine cannot be metabolized.

Citrulline, in particular, is a biomarker of intestinal

**Figure 3** Citrulline and betaine serve as diagnostic biomarkers in patients with alcoholic hepatitis. AUC: Area under receiver operating characteristics curve.

functionality<sup>[13]</sup>. Consequently, changes in intestinal flora due to liver disease can lead to imbalances in citrulline. Furthermore, it has been demonstrated that portal hypertension secondary to cirrhosis stimulates nitric oxide synthase (NOS)<sup>[14]</sup>. NOS converts arginine and oxygen into citrulline and nitric oxide (NO), resulting in vasodilation and increased blood flow. Pârvu *et al*<sup>[13]</sup> found that CLD patients had an increased serum citrulline concentration, indicating increased NO production to counter the mechanisms of portal hypertension<sup>[1]</sup>. Therefore, it makes sense that acute exacerbations of liver function seen in AH patients would deplete citrulline stores in an effort to produce NO and increase blood flow to an acute on chronic liver injury.

The second goal of this study was to assess the utility of metabolomics as a marker for the prognosis of liver disease. One particularly noteworthy result is the association between tyrosine and transplant-free survival outcome in patients with liver cirrhosis. The MELD score and tyrosine level, considered together, provided the greatest sensitivity and specificity for predicting 3-mo transplant-free survival. Tyrosine and phenylalanine are aromatic amino acids whose metabolism can become impaired as a consequence of liver injury, as the enzymes that metabolize these compounds are produced by the liver. Concentrations of aromatic amino acids are increased in patients with chronic liver disease who experience an acute inflammatory event such as acute alcoholic hepatitis, gastrointestinal bleeding, infection, or encephalopathy<sup>[15]</sup>. Liver cirrhosis with a superimposed liver injury will lead to systemic inflammation resulting in elevated tyrosine levels. Systemic inflammation in the context of acute on chronic liver failure exacerbates the patient's health through the release of various pro-inflammatory cytokines<sup>[15]</sup>. Therefore, plasma tyrosine levels can be used to estimate the degree and severity of this inflammation, and provide novel information on prognosis and outcome.

Values presented as mean (95%CI) and *P*-values obtained from analysis of covariance. The natural logarithm of each biomarker was modeled as the outcome variable with disease group and MELD as the independent variables. A superscript of a indicates <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01. rho: Spearman's correlation; MELD: Model for end-stage liver disease; ADMA: Asymmetric dimethylarginine; SDMA: Symmetric dimethylarginine; MMA: Monomethylarginine; TMAO: Trimethylamine N-oxide.

Other analytes such as phenylalanine, carnitine, ADMA, and MMA were all found to be accurate predictors of transplant-free survival in patients with liver cirrhosis. It should be noted that there was no evidence to suggest that tyrosine, phenylalanine, carnitine, ADMA, and MMA were significantly better than MELD. However, despite the lack of statistical significance, in terms of the AUC even a small jump of 0.01-0.02 is promising as it denotes clinical significance. This study was an exploratory analysis designed to assess usefulness of metabolites and given the small sample size of 45 patients, no strong conclusions can be reached. However, the promising results of this study indicate the need for future studies with larger sample sizes to evaluate and corroborate the usefulness of these analytes in predicting transplant-free survival. Future studies can also explore more complex combinations of metabolites in predicting OLT-free survival. More data can help determine if plasma analytes are superior or inferior to the MELD score, or if they should be used in combination with the MELD score as a prognostic tool.

Limitations of this study include the small number

of patients in the sample size. Furthermore, no power calculations were done to determine optimum sample size. Given no power calculations and a small sample size, we are only capable of generating sufficient power for large differences and the false negative rate may be high. Further research must validate the findings from this study utilizing larger patient populations. Another limitation was the lack of control group in this study. A control group is an essential part of any experiment that seeks to find a significant difference among populations. While this project had no control group, other research has corroborated the results from this study with control groups<sup>[7]</sup>. Lastly, this study was limited in that liver biopsy was not performed in all patients to confirm the diagnosis of AH; it was only performed in a subset of patients. One final limitation of this study is the lack of biopsy confirmation of AH as a diagnosis. Since liver biopsy is considered the gold standard in diagnosing AH, it cannot be said with absolute certainty that all patients were diagnosed with AH. Further research in this area might involve standardized biopsy evaluation alongside metabolomic correlations to liver disease.

**Table 6** Model for end-stage liver disease-adjusted average biomarker levels

Biomarker ( $\mu\text{mol/L}$ )	Alcoholic cirrhosis ( $n = 23$ )	Alcoholic hepatitis ( $n = 25$ )	Holm-bonferroni corrected $P$ -value
Citrulline	40.2 (33.2, 48.6)	23.7 (19.7, 28.5)	0.009 <sup>b</sup>

ADMA: Asymmetric dimethylarginine; SDMA: Symmetric dimethylarginine; MMA: Monomethylarginine; TMAO: Trimethylamine N-oxide.

**Table 7** Utility of biomarkers in predicting transplant-free survival

Biomarker ( $\mu\text{mol/L}$ )	3-mo survival AUC (95%CI)	6-mo survival AUC (95%CI)
MELD	0.82 (0.69, 0.95)	0.77 (0.62, 0.92)
Tyrosine	0.91 (0.74, 1.0)	0.89 (0.74, 1.0)
Phenylalanine	0.77 (0.56, 0.97)	0.79 (0.61, 0.98)
Carnitine	0.73 (0.53, 0.93)	0.74 (0.56, 0.93)
ADMA	0.72 (0.49, 0.96)	0.70 (0.48, 0.92)
MMA	0.71 (0.47, 0.94)	0.70 (0.49, 0.91)

AUC: Area under receiver operating characteristics curve; MELD: Model for end-stage liver disease; ADMA: Asymmetric dimethylarginine; MMA: Monomethylarginine.

This is the first study that profiles plasma metabolites in patients with AH and CLD. Investigation of the human metabolome in disease states can be very useful in generating diagnostic markers and understanding the pathophysiology of those disease states. However, this study is limited in its relatively small sample size. Future larger studies are needed to confirm the diagnostic value of biomarkers in AH and CLD.

Metabolomics plasma analyte levels could help diagnose AH and determine the prognosis of patients

with liver cirrhosis awaiting liver transplantation. Specifically, combined citrulline and betaine plasma levels yield a highly sensitive and specific discriminatory test of AH vs AD. Tyrosine, in combination with MELD score, provides even greater sensitivity and specificity for predicting 3 mo OLT-free survival than the MELD score on its own.

In conclusion, metabolomics plasma analyte levels could aid in diagnosing AH or in determining potential patient prognosis.

## COMMENTS

### Background

Liver biopsy remains the gold standard for the diagnosis of alcoholic hepatitis (AH). Herein, the authors use a novel metabolomics approach to identify plasma analytes that may correlate with the diagnosis of AH and the severity of liver disease in patients with AH.

### Research frontiers

Metabolomics represents the analysis of metabolites present in biological samples. By identifying and quantifying metabolites, one can gather a picture of the genetic variations and environmental influences (such as diet, lifestyle, drug use, and toxicological exposure) in a biological specimen. The authors use metabolomics to assess prognostic and diagnostic factors in patients with liver disease with the hopes of developing more accurate measures of patient

outcomes.

### Innovations and breakthroughs

In this study, several metabolites were found to be associated with survival in patients with liver disease.

### Applications

These findings could potentially be used to develop more robust measures to provide a diagnosis and prognosis in patients with liver disease. The model for end-stage liver disease score and liver biopsy, which are currently used, are imperfect; a less invasive and more accurate measure is needed.

### Peer-review

This is a very important paper and presents impact on health system. It is very well elaborated.

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Feng Wu, MD, PhD, Professor, Nuffield Department of Surgical Sciences, University of Oxford, Oxford, Oxford OX3 7LE, United Kingdom

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Hepatitis C virus (HCV) infection is still a major health problem throughout the world. HCV patients living in rural areas are less fortunate than their counterparts residing in populous urbanized regions. The lack of medical resources and properly trained medical personnel in rural regions make it especially burdensome for HCV patients seeking treatment. Dr. Sanjeev Arora at the University of New Mexico Health Sciences Center took initiative to resolve the issue at hand by developing a model named Project Extension for Community Health Outcomes (ECHO). ECHO connects primary care providers (PCPs), usually family medicine physicians, in local communities with specialists. ECHO providers test the efficacy of treatment given using the ECHO model vs that at academic medical centers. The ECHO model has produced promising results such that the sustained virologic response rates for both types of sites were near-equivalent. Show Me ECHO was adapted from Project ECHO to train PCPs in Missouri and equip them with the tools and skills to properly treat and diagnose HCV in a timely manner. This healthcare model can be implemented for treating other common infections and chronic diseases. Telemedicine is the direction healthcare is headed for the next several decades. It has potential to be applied in developing countries to alleviate agony and despair resulting from limited resources and lack of access to expert medical care.

**Key words:** Hepatitis C; Treatment; Community; Health care; Outcome; Rural; Primary care; Extension for Community Health Outcomes

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** The American Association for the Study of Liver

Diseases recommends Project Extension for Community Health Outcomes (ECHO). Project ECHO aims to move the knowledge not the patients. By bringing expertise to primary care physicians, patients from rural and underserved communities will benefit by alleviating the struggle associated with travel and appointment delays. The framework of this project can be used to manage other diseases that require specialty physician care that may not be feasible. Telemedicine represents the future of healthcare, its success will substantially reshape the healthcare delivery in developing countries and is pivotal for geographically isolated and underserved populations.

Tahan V, Almashhrawi A, Kahveci AM, Mutrux R, Ibdah JA. Extension for Community Health Outcomes-hepatitis C: Small steps carve big footprints in the allocation of scarce resources for hepatitis C virus treatment to remote developing areas. *World J Hepatol* 2016; 8(11): 509-512 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i11/509.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i11.509>

## INTRODUCTION

Hepatitis C virus (HCV) infection and its complications are still a major health problem throughout the world. There are roughly 4 million persons with a seropositive test for HCV in the United States, many of whom are even not aware of the disease and many of those who know are in a medical quandary with regards on how to access treatment<sup>[1]</sup>. Incredible progress has been achieved regarding HCV treatment in the past decade, highlighted by an increase in HCV cure rates.

Access to proper HCV treatment and care has truly become a hurdle for millions of patients housed in rural settings because of the uneven distribution of trained medical personnel and resources to select urbanized cities. As a result, patients in rural and remote areas often find themselves at the mercy of HCV because of the shortage of medical resources at their disposal. Oftentimes, these patients have no other option but visit nearby primary care providers (PCPs) in small clinics. However, PCPs are only equipped to address basic healthcare needs which mean HCV patients are subject to subpar treatment at best<sup>[2,3]</sup>.

## WHAT IS PROJECT EXTENSION FOR COMMUNITY HEALTHCARE OUTCOMES?

The University of New Mexico Health Sciences Center (UNMHSC) launched the Extension for Community Healthcare Outcomes (ECHO) model in 2003 in response to the external circumstances that burdened many rural HCV patients from successfully being treated. Dr. Sanjeev Arora, a distinguished Professor of Medicine, Division of Gastroenterology, at the UNMHSC, is the

director and founder of Project ECHO. He pioneered a new high-speed approach for providing expert healthcare to patients. Dr. Arora was distraught with the reality that there is a prevalent shortage of resources; there are thousands of HCV patients needing quality care and treatment. He chose to be proactive to instill necessary change that was long overdue. Coupled with the rapid technological advancements of the time, telemedicine progressed and ECHO was born<sup>[3,4]</sup> and has been proven to be effective<sup>[5-7]</sup>.

The purpose of the ECHO model is to establish a working network of PCPs, psychiatrists, pharmacists, infectious disease specialists, and other healthcare professionals that can collaborate and exchange information such as patient lab results and treatment plans (Figure 1). Through a video conferencing platform, the teams are given an opportunity to inform each other of their own personal experiences and challenges to better serve the interests of HCV patients in the long run. These sessions, called Knowledge Networks, allow PCPs to acquire the critical skills necessary in treating geographically isolated HCV patients<sup>[8]</sup>.

## HIT OR MISS?

Arora *et al*<sup>[8]</sup> set up an experimental model to test HCV treatment efficacy of their newly inaugurated ECHO program. They hypothesized that any success they have had with treating patients at academic medical centers would be mirrored in remote clinics employing the ECHO model. The parameter used to measure efficacy of treatment is sustained virologic response (SVR). After a patient completes therapy, he/she is evaluated for a period of 6 mo. If the HCV does not reappear during this time, the patient has achieved SVR<sup>[8]</sup>.

Originally, 519 patients enrolled in the study from both the ECHO sites and University HCV clinics. Of these 519, 407 remained relevant for the overall SVR rates in the study. HCV patients who got at least one dose of HCV treatment were included in the analysis. Any patient without follow-up data was considered as treatment failure<sup>[5]</sup>. The patient count was 261 and 146 at the ECHO sites and University HCV clinics, respectively. Some more patients were also discontinued from the study for not meeting specified health targets. The overall SVR was 152/261 (58.2%) and 84/146 (57.5%) for ECHO sites and the University of New Mexico HCV clinic, respectively. Therefore, the magnitude of this success supports what Arora *et al*<sup>[8]</sup> had hypothesized early on about HCV treatment using the ECHO model. As a result, the number of ECHO sites drastically increased to around 300 nowadays<sup>[8]</sup>. Currently, each center is collecting the SVR data on new and more effective interferon free HCV treatment to compare the outcomes.

## NEW MEXICO TO MISSOURI

Missouri residents amount to a little over 6 million

Figure 1 Extension for Community Health Outcomes Model. ECHO: Extension for Community Health Outcomes.

people. About one-fourth of all Missourians inhabit rural areas of the state<sup>[9]</sup>. Missouri residents that belong to the underserved areas of the state are oftentimes disconnected from their specialty care providers because of geographic barriers. As mentioned before, the pool of health care resources is often concentrated in large metropolitan cities, which subsequently attracts many specialty care providers to these populous areas<sup>[3]</sup>. According to the Bureau of Health Professions, about 20% to 25% people in Missouri live in a rural community. However, the percentage of physicians caring for these communities are roughly 9% of all physicians in Missouri with a notable shortage of specialists<sup>[10]</sup>.

## TARGETS OF SHOW ME ECHO MODEL

Show Me ECHO, an adaptation of the University of New Mexico School of Medicine's ECHO model, was instigated with a similar purpose: To promote accessible and affordable quality care for HCV patients in disadvantaged underserved and rural populations in Missouri with an aim to move the knowledge not the patients<sup>[6]</sup>.

Show Me ECHO model in Missouri also echoes developing PCPs expertise. By educating and empowering PCPs, it will be possible to screen, diagnose, and treat HCV in a timely fashion in remote and underserved areas. The use of telemedicine surely has that potential to bridge the gap between specialists and PCPs through an exchange of knowledge and treatment protocols which can improve the patient experience for generations to come. In addition to all of this, a health surveillance system is essential to ensure fluid interactions between patients and healthcare providers. One of Show Me ECHO project goals is to create a link between the Missouri Department of Health, Senior Services, and the Missouri Primary Care Association so that HCV cases are accurately recorded. Thus, a sound health surveillance system across Missouri will advance the timeliness of diagnosis and treatment.

## IMPLICATIONS OF ECHO

The American Association for the Study of Liver Diseases recommends Project ECHO because of its success in treating HCV patients amid the adversities experienced initially by both patients and healthcare professionals<sup>[7]</sup>. Indeed, the benefits of Project ECHO

are paramount and not limited to successful SVR rates. By bringing expertise to PCPs, patients from rural and underserved communities will benefit by alleviating the struggle associated with travel and appointment delays. Additionally, community-based health centers, rather than university clinics, are usually more suitable for rural HCV patients because PCPs are often more cognizant of their local community. Visiting the same PCP for HCV treatment reduces tensions between both patients and healthcare providers, allowing for optimal coordination in a familiar setting<sup>[8]</sup>. Without Project ECHO, many HCV treatments would have been stymied. Show Me ECHO is on track as well to produce promising results.

ECHO model is a great Segway into healthcare in developing countries. The possibilities for introducing Project ECHO in those countries are immense because healthcare is presumably hindered by the lack of appropriate expert medical care. Telemedicine can leverage the aid and significantly alleviate the patients' sufferings.

Project ECHO is a great template for the medical field to actively embrace because of its potential to allocate specialized care needed for disadvantaged HCV patients in developing countries. The framework of this project can be used to manage other diseases that require specialty physician care that may not be feasible. Telemedicine represents the future of healthcare, its success will substantially reshape the health care delivery in developing countries and is pivotal for geographically isolated and underserved populations.

### Abstract

Hepatocellular carcinoma (HCC) is the main common primary tumour of the liver and it is usually associated with cirrhosis. The barcelona clinic liver cancer (BCLC)

classification has been approved as guidance for HCC treatment algorithms by the European Association for the Study of Liver and the American Association for the Study of Liver Disease. According to this algorithm, hepatic resection should be performed only in patients with small single tumours of 2-3 cm without signs of portal hypertension (PHT) or hyperbilirubinemia. BCLC classification has been criticised and many studies have shown that multiple tumors and large tumors, as wide as those with macrovascular infiltration and PHT, could benefit from liver resection. Consequently, treatment guidelines should be revised and patients with intermediate/advanced stage HCC, when technically resectable, should receive the opportunity to be treated with radical surgical treatment. Nevertheless, the surgical treatment of HCC on cirrhosis is complex: The goal to be oncologically radical has always to be balanced with the necessity to minimize organ damage. The aim of this review was to analyze when and how liver resection could be indicated beyond BCLC indication. In particular, the role of multidisciplinary approach to assure a proper indication, of the intraoperative ultrasound for intraoperative restaging and resection guidance and of laparoscopy to minimize surgical trauma have been enhanced.

**Key words:** Hepatocellular carcinoma; Liver surgery; Hepatic resection; Multiple hepatocellular carcinoma; Cirrhosis; Barcelona clinic liver cancer; Multidisciplinary approach; Intraoperative ultrasound; Laparoscopy; Portal hypertension

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the main common primary tumour of the liver, representing approximately 85%-90% of primary hepatic malignancies; it is ranked as the fifth and seventh most common cancer respectively in males and females, and represents the third leading cause of neoplasm-related deaths worldwide<sup>[1,2]</sup>. HCC is usually associated with cirrhosis, whose major causes could be identified in viral and alcoholic liver disease, although recent epidemiological data highlighted the increasing etiological role of obesity, diabetes and metabolic syndrome in liver oncogenesis<sup>[3]</sup>. The treatment of HCC set on cirrhosis is complex: The aim to be oncologically radical has always to be balanced with the necessity to minimize organ damage. In this sense liver transplantation is considered the gold standard treatment, because offers the possibility to treat simultaneously the liver cancer and the damaged organ; on the other hand organ shortage led to the development of restricted indication to liver transplantation, addressing many patients to receive local therapies<sup>[4]</sup>. In literature, several HCC staging systems based on tumour's features and liver function have been developed and proposed to guide the therapeutic decisions in such patients; among all the barcelona clinic liver cancer (BCLC) classification (Figure 1) has been approved as guidance for HCC treatment algorithms by the European Association for the Study of Liver (EASL) and the American Association for the Study of Liver Disease (AASLD), combining independent prognostic predictors like the background liver status, patient's performance status and tumor morphological features, and showing a reliable capacity to categorize patients with different prognosis in order to provide recommendations regarding therapeutic options. The BCLC flow chart recommends curative treatments for HCC in very early- or early-stage (stage 0-A), trans-arterial chemoembolization for intermediate-stage disease (stage B), sorafenib administration for advanced stage HCC (stage C), and supportive care for end stage HCC (stage D)<sup>[5,6]</sup>. BCLC indication to liver resection seems to be markedly limiting. On contrary, other

authors have shown that surgical resection can offer good short- and long-term outcomes even in presence of portal hypertension (PHT), multinodular disease, large nodules or even HCC with macrovascular invasion<sup>[7-9]</sup>; thus the BCLC classification has been criticised because some patients who may benefit from surgical treatment are excluded from curative resection and these findings have encouraged many experts to disregard the EASL/AASLD therapeutic recommendations<sup>[6-8]</sup>.

The aim of this review was to analyze when and how liver resection could be indicated beyond BCLC indications.

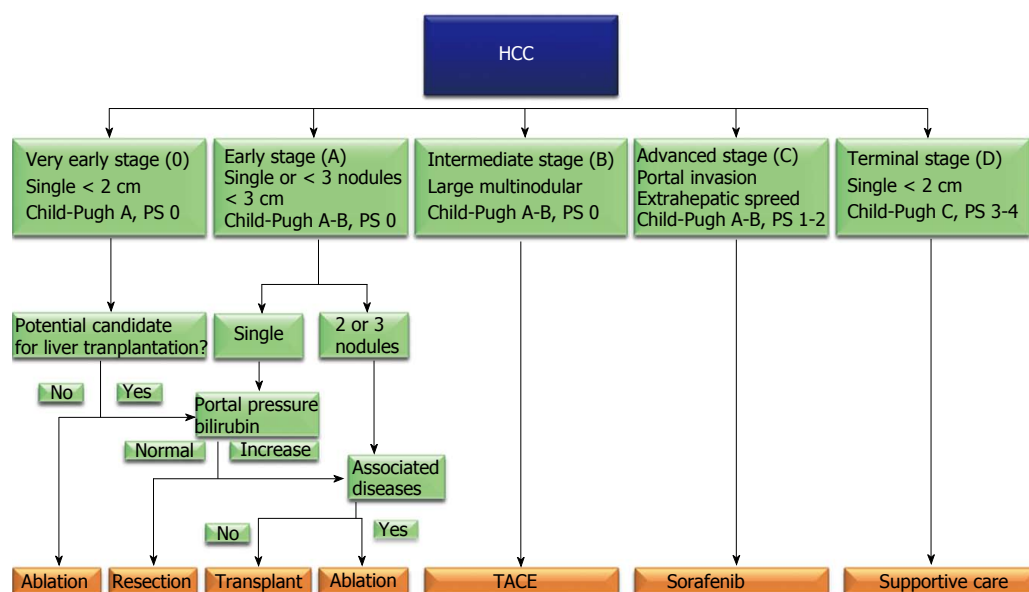

## DISCUSSION

### **Liver resection beyond BCLC classification: When?**

Historically hepatic resection has been performed with caution to HCC patients because of concerns about morbidity and mortality rates. However, recent improvements in surgical technique and perioperative care have improved hepatic resections outcomes with consequent extension of indications to surgical procedures. In this sense some high volume surgical liver unit recently reported hospital mortality less than 2%<sup>[10]</sup>. According to BCLC algorithm, liver resection would be indicated only in patients with single tumours of 2-3 cm in diameter without PHT or increased bilirubinemia<sup>[6]</sup> (Figure 1). BCLC classification has been criticised because it excludes many patients who could benefit from curative resection. PHT, large tumor size, multifocal presentation and vascular invasion are well recognized risk factors for post-operative morbidity and mortality and for poor long-term prognosis, but should not be considered contraindication to surgical treatments.

### **LARGE HCC (> 5 cm)**

BCLC algorithm suggests hepatic resection only in presence of small HCC (< 5 cm). On contrary, several authors have recently reported that liver resection can offer good short- and long-term outcomes even in patients with HCC > 5 cm. Main concerns related to restricted surgical indication in patients with large HCC take into account the increased rates of presence of satellite nodules, increased rate of distant metastases and of vascular invasion those are related to increasing tumour size and represent important prognostic factors for poor survival. Furthermore patients with large HCC (> 5 cm) may necessitate a major hepatectomy, which is considered a high-risk procedure especially in HCC set on cirrhosis<sup>[11,12]</sup>. Anyway radical liver resection can be considered a valuable option in patients with large HCC<sup>[13]</sup>. Large surgical series recently published reported a significant rate (up to 36%) of large HCC surgically treated with good results<sup>[14]</sup>. In this sense, it's remarkable that in literature there are many studies reporting cases of liver resection for HCC > 8-10 cm with good results even considering the poor prognostic results of the main alternative for such BCLC stage B HCC represented

**Figure 1** Barcelona clinic liver cancer algorithm for treatment of hepatocellular carcinoma<sup>[9]</sup>. HCC: Hepatocellular carcinoma; TACE: Transarterial chemo-embolization.

by transarterial chemo-embolization (TACE). Zhong *et al.*<sup>[15]</sup> comparing liver resection to TACE in a wide cohort of patients with large HCC in BCLC B stage (mean size 8.8 cm) showed that tumor resection offers better 5-year overall survival than TACE (41% and 18%, respectively). Proper identification and multidisciplinary discussion of risk factors for surgical morbidity and mortality in such patients (including presence of vascular invasion, cirrhosis, high level of alpha-fetoprotein and the presence of multiple lesions<sup>[16]</sup>) is critical for patients' selection and to obtain good outcomes.

## MULTIPLE HCC

Treatment guidelines do not recommend hepatic resection for multifocal HCC. Liver resection in presence of multiple HCC is still controversial; anyway it has been recognized a survival benefit for patients with a number of HCC  $\leq 3$  and lesions less than 3 cm in diameter (according to Milan criteria)<sup>[17]</sup>. Multifocal presentation is well recognized independent prognostic factor for early recurrence and poor prognosis<sup>[18]</sup>. Anyway recent prospective studies showed that hepatic resection in patients with BCLC stage B HCC is well tolerated and related to a low mortality rate, acceptable morbidity and significant survival benefits<sup>[4]</sup>. Surgical resection yielded better results than TACE in patients with multiple HCCs of the same stage; Zhong *et al.*<sup>[19]</sup> analyzed outcomes of patients with more and less of 3 HCC tumors who underwent liver resection or TACE. Survival was significantly higher in the surgery subgroup at 1 year (90% vs 59%), 3 years (52% vs 11%), and 5 years (33% vs 6%).

## PORTAL VEIN HYPERTENSION

PHT is considered a contraindication for liver resection

according to the EASL and AASLD published guidelines for HCC management. PHT may increase the risk of peri-operative haemorrhage, impair liver regeneration, and increase the risk of liver failure. Recent advances in surgical techniques and peri-operative care for patients with cirrhosis have reduced the number of cirrhosis-related complications and deaths. Several authors demonstrated that patients with and without PHT had similar morbidity (28%-39% vs 21%-32.2%) and 90-d mortality (2%-2.1% vs 3.1%-6%). The overall survival at 1, 3 and 5 years is similar or slightly longer in patients without portal vein hypertension (respectively 85%-96%, 67%-80% and 50%-65%) compared to patients with PHT (respectively 83%-90%, 59%-67% and 45%-48%), these results appear significant and encouraging, considering that liver resection, with exclusion of liver transplantation, represent the best choice of radical cure<sup>[20-22]</sup>. Patients with PHT should be carefully selected for surgery, but PHT should not be considered a contraindication to liver resection.

## MACROVASCULAR INFILTRATION

According to the EASL and AASLD guidelines for management of HCC, patients with macrovascular infiltration are considered in advanced stage (stage C) and should be treated only with chemotherapy (Sorafenib). Presence of macrovascular invasion is related to an increased risk of metastases and is a well known predictor of poor survival<sup>[23]</sup>. The median survival for untreated patients with macrovascular portal or major hepatic vein infiltration is 3-5 mo and median survival for such patients treated with sorafenib is 6 mo<sup>[18,24]</sup>. Selected patients with macrovascular infiltration who underwent liver resection for HCC can achieve longer overall survival, 46%-49% and 11.2%-38% respectively

at 3 and 5 years with acceptable morbidity and mortality rate (under 3%-5%)<sup>[13,14,25]</sup>. Consequently the surgical resection should be considered when planning the treatment's strategy for such patients and formally included together with other treatment modalities for the cure of BCLC stage C patients.

#### ***Liver resection beyond BCLC classification: How?***

Patients suffering from cirrhosis are at increased risk of developing significant postoperative complications including ascites, lung infection or pleural effusion, transient encephalopathy, kidney failure, portal vein thrombosis and bleeding due to primary haemostasis dysfunction<sup>[26,27]</sup>. In order to reduce mortality and morbidity after liver surgery in patients with cirrhosis, surgeons have developed meticulous selection criteria to guide surgical indication in such patients. For all these reasons the decision to submit a cirrhotic patient to a liver resection is complex. It is of paramount importance that pre-operative evaluation of cirrhotic patients with hepatocellular carcinoma would be performed by a multidisciplinary team, in order to match different point of view and possible therapeutic approach. Furthermore, some technical aspects of liver resection should be enhanced discussing the approach to patients with an advanced stage HCC.

### **THE ROLE OF MULTIDISCIPLINARY APPROACH**

HCC has different presentations those are compounded by the status of liver disease, and the multiple treatment options available make choosing the first line of treatment for a given patient a difficult task. Management of HCC patients should be undertaken by a multidisciplinary team including all the specialties those have a role in the treatment of such patients; if this kind of approach should represent the standard for the treatment of every patient with HCC, the importance of the sharing of indication in disagreement with BCLC algorithm is even increased. Studies those have shown a decrease in morbidity and mortality after liver resection for HCC also showed the importance of a multidisciplinary approach<sup>[28-31]</sup>. Patients in intermediate/advanced stages should be carefully selected for the best treatment according to the stage of the disease, to the presence of cirrhosis, to the age of patient, to general condition and comorbidity. A team of surgeon, oncologist, hepatologist, radiologist and interventional radiologist, anesthesiologist and pathologist should evaluate the best treatment for each of these patients, in order to perform a tailored treatment that could include more than one approach. BCLC indication to liver resection should be less restrictive; on the other hand the importance of patients' selection must be considered and great efforts are needed to establish selection criteria to be included in the treatment algorithm.

### **THE ROLE OF INTRAOPERATIVE ULTRASOUND**

Intra-operative ultrasound (IOUS) is still considered the most accurate diagnostic technique for detecting focal liver lesions in hepatocellular carcinoma. The main advantages related to an extensive use of ultrasounds in liver surgery for HCC on cirrhosis concerns the intra-operative re-staging and the possibility to perform echo-guided surgical procedures. IOUS may detect additional nodules compared with pre-operative imaging in 33%-41% of patients undergoing liver resection for HCC<sup>[32,33]</sup>. The removal of new nodules after this early diagnosis may increase the BCLC stage of patients but also contribute to perform a more complete treatment and improve choice of cure. Moreover intra-operative echo guidance, allowing to perform a parenchyma-sparing anatomical hepatic surgery in respect of principles of oncologic radicality, is an invaluable tool to engage surgical procedure in intermediate/advanced-stage patients<sup>[34]</sup>. The use of ultrasound guidance is mandatory for planning the surgical strategy, decide the exact resection plane during the parenchymal transection in order to respect the surrounding vessels and biliary structures. Main concerns related to the restricted indication to liver surgery following BCLC indication regards the possibility of increased peri-operative mortality and morbidity and the poor chance of radical cure and prolonged survival in patients with intermediate/advanced HCC. IOUS, minimizing the extension of the parenchyma removed in respect of oncological radicality and offering a re-staging and a consequent more radical treatment, represents an invaluable tool in the perspective of expansion of surgical indication beyond BCLC recommendations. The extensive use of ultrasound in liver surgery together with technological improvements in recent years allowed *per se* an expansion of surgical indication in advanced HCC: The possibility to detect intra-operatively connecting veins between adjacent hepatic veins allows to perform radical limited liver resection even in patients with major hepatic vein invasion, in order to reduce the rate of major resection and its consequent increased morbidity and mortality<sup>[35,36]</sup>. Anatomic liver resection is usually performed because of HCC spreading along the nourishing portal venous branch and consequent growth of satellite nodules within the same anatomical segment. Thus, anatomic resection allows removal of the known tumor, as well as of potential undetectable satellite metastases; the advantages of anatomic resection can be maximized in particular in large HCC which are frequently surrounded by satellite lesions<sup>[37,38]</sup>. IOUS is of paramount importance to guide and assure an anatomic liver resection, either with traditional puncture technique of the portal branch feeding the tumor, either by means of recently introduced compression technique or other methods as trans-hepatic balloon catheter or CEIOUS portography combined with indigo carmine dye injection<sup>[39-43]</sup>. In a recent meta-analysis Chen *et*

*al*<sup>[44]</sup> analyzed outcomes of 833 patients underwent anatomic liver resection for HCC and 670 patients underwent non-anatomic resection for the same disease. The surgical margin *per se* does not represent a main aspect, because an anatomic resection (segmentectomy or sub-segmentectomy) can be considered adequate even in presence of a narrow margin; the advantages related to limited anatomic resection can be maximized to perform multiple limited resection in multiple HCC, in order to assure local radical tumor removal with a parenchyma sparing policy<sup>[44]</sup>. There are several methods up to now available to perform an anatomic (segmental or subsegmental) US-guided liver resection: Puncture technique proposed by Makuuchi *et al*<sup>[40]</sup>, insertion of a balloon catheter transhepatically to occlude the feeding portal branch<sup>[41]</sup> and ultrasound-guided finger compression technique<sup>[43]</sup>.

## THE ROLE OF LAPAROSCOPY

Laparoscopic surgery for liver tumors requires skilled surgeons and specific technological instruments. Moreover its indications have not been still clearly defined; for such reasons it has not been widely performed even if its employment is progressively expanding. The main concern about the use of laparoscopic technique for malignancies is the risk of inadequate tumor resection; positive margin is a well known prognostic factor for poor survival in surgery for HCC, in this perspective intra-operative ultrasound should be considered an indispensable tool to achieve a safe and effective liver resection. Anyway according to several meta-analyses comparing open vs laparoscopic liver resections for HCC, laparoscopic liver resection is considered a safe procedure with comparable overall and recurrence-free survival rates<sup>[45-47]</sup>. Laparoscopic approach might improve the postoperative course of cirrhotic patients, because limited mobilization of the liver reduces parenchymal trauma, nonexposure of intestinal viscera restricts fluid requirements and decreased the formation of ascites<sup>[26,48]</sup>. In a recent study Kanazawa *et al*<sup>[26]</sup> compared outcomes of cirrhotic patients underwent laparoscopic and laparotomic liver resection; the two groups was not different by age, sex, stage of cirrhosis, number and size of lesions. In this study the incidence of intractable ascites was significantly higher in the laparotomy group than in the laparoscopy group (71% vs 11%). Furthermore the use of laparoscopy in cirrhotic patients may allow the preservation of wall portosystemic shunts, and in some cases the integrity of round ligament, which can contain collateral vessels. This can result in a lower increase of post-operative PHT and risk of bleeding<sup>[26]</sup>. Laparoscopic liver resection is associated with less total and major morbidity, shorter hospital stay and lower rate of post-operative early readmissions or number of outpatient clinic appointments compared with open counterpart<sup>[49,50]</sup>. The above mentioned advantages of laparoscopic approach can be crucial in the perspective of expansion

of surgical indication to patients with HCC beyond BCLC indications. In particular patients with PHT or multinodular disease can benefit of a minimally invasive treatment, which can include also combined laparoscopic resection and ablation of multiple HCC in the perspective of a tailored treatment<sup>[51,52]</sup>. Surgical resection has shown better results in terms of disease free and overall long term survival compared to laparoscopic ablation. Nevertheless, in the treatment of HCC not suitable for liver transplantation or not eligible for resection because of severe PHT and not manageable by percutaneous approach for tumor size or location, laparoscopic ablation should be considered as a valuable choice since it proved to be a safe and effective technique, as it permits to treat lesions with low-morbidity-rate<sup>[51]</sup>. Laparoscopic approach is also useful to avoid unnecessary laparotomy in patients who show unresectable not previously diagnosed lesions (36% of patients with HCC with surgical indication)<sup>[53]</sup>. Several authors showed that laparoscopic liver resections can be technically performed regardless tumor size and location, but important reviews have recognized that it can be considered more safe and feasible for lesions located on left lateral (segments II and III) and anterior right (III, VI) segments<sup>[45-47]</sup>. For this reason the position of lesions is an essential element to establishing the indication to surgical resection for advanced HCC. In order to minimize postoperative complications in fragile patients, the possibility of laparoscopic liver resections is a decisive element in the decision-making process of the best treatment of patients with HCC.

## CONCLUSION

According to BCLC classification hepatic resection should be performed only in patients with small single tumours of 2-3 cm without signs of PHT or hyperbilirubinemia. By contrast many studies have shown that surgical resection can lead to good short and long-term survival in patients with PHT and with multinodular, large or macrovascular invasive HCC. The treatment of these patients is complex, surgery should only be performed in selected patients and a multidisciplinary team is necessary to choose the best treatment for each patient. Intra-operative ultrasound and laparoscopy are necessary tools in a modern liver unit, especially for cirrhotic patients.

BCLC indication should be expanded and redefined: BCLC algorithm should take into account the survival benefit of surgical resection in selected patients with HCC in B-C stages and should discuss the invaluable role of IOUS and the potential role of laparoscopy with the aim to standardize the surgical management. After the recognition that ablative treatment in HCC  $\leq 2$  cm offer the same survival benefit than surgical removal and consequently can be considered the treatment of choice for such patients<sup>[54]</sup>, it should be recognized that surgical treatment offers the best choice of prolonged survival even to selected patients with intermediate/advanced

stage HCC.

### Abstract

**AIM:** To investigate if echocardiographic and hemodynamic determinations obtained at the time of transjugular intrahepatic portosystemic shunt (TIPS) can provide prognostic information that will enhance risk

stratification of patients.

**METHODS:** We reviewed medical records of 467 patients who underwent TIPS between July 2003 and December 2011 at our institution. We recorded information regarding patient demographics, underlying liver disease, indication for TIPS, baseline laboratory values, hemodynamic determinations at the time of TIPS, and echocardiographic measurements both before and after TIPS. We recorded patient comorbidities that may affect hemodynamic and echocardiographic determinations. We also calculated Model for End-stage Liver Disease (MELD) score and Child Turcotte Pugh (CTP) class. The following pre- and post-TIPS echocardiographic determinations were recorded: Left ventricular ejection fraction, right ventricular (RV) systolic pressure, subjective RV dilation, and subjective RV function. We recorded the following hemodynamic measurements: Right atrial (RA) pressure before and after TIPS, inferior vena cava pressure before and after TIPS, free hepatic vein pressure, portal vein pressure before and after TIPS, and hepatic venous pressure gradient (HVPG).

**RESULTS:** We reviewed 418 patients with portal hypertension undergoing TIPS. RA pressure increased by a mean  $\pm$  SD of  $4.8 \pm 3.9$  mmHg ( $P < 0.001$ ), HVPG decreased by  $6.8 \pm 3.5$  mmHg ( $P < 0.001$ ). In multivariate linear regression analysis, a higher MELD score, lower platelet count, splenectomy and a higher portal vein pressure were independent predictors of higher RA pressure ( $R = 0.55$ ). Three variables predicted 3-mo mortality after TIPS in a multivariate analysis: Age, MELD score, and CTP grade C. Change in the RA pressure after TIPS predicted long-term mortality (per 1 mmHg change, HR = 1.03, 95%CI: 1.01-1.06,  $P < 0.012$ ).

**CONCLUSION:** RA pressure increased immediately after TIPS particularly in patients with worse liver function, portal hypertension, emergent TIPS placement and history of splenectomy. The increase in RA pressure after TIPS was associated with increased mortality. Age, splenectomy, MELD score and CTP grade were independent predictors of long-term mortality after TIPS.

**Key words:** Transjugular intrahepatic portosystemic shunt; Transjugular portosystemic shunts; Right atrial pressure; Outcomes; Mortality

**Core tip:** Transjugular intrahepatic portosystemic shunt (TIPS) is a procedure accompanied by morbidity and mortality. We hypothesize that echocardiographic and hemodynamic determinations obtained at the time of TIPS can provide prognostic information that will enhance risk stratification of patients. We measured echocardiographic and hemodynamic variables before

and immediately after the TIPS procedure in a large cohort of patients at our institution. Our findings corroborate previous literature stating that right atrial pressure increased after TIPS. Our study demonstrates several predictors of long-term mortality after TIPS, such as age, splenectomy, and Model for End-stage Liver Disease score; this data can help assess the risk for patients undergoing TIPS.

## INTRODUCTION

Transjugular intrahepatic portosystemic shunt (TIPS) is a procedure performed to treat complications of portal hypertension such as bleeding esophageal varices, refractory ascites and hepatic hydrothorax<sup>[1-3]</sup>. The placement of a covered stent creates an anastomosis between the hypertensive portal vein and the inferior vena cava *via* the hepatic vein; this non-surgically decompresses the portal pressure. Although TIPS is minimally invasive, patients with advanced liver disease-particularly those with comorbidities-can have complications related to the procedure. The Model of End-stage Liver Disease (MELD) score was originally conceived to determine survival outcomes in patients receiving TIPS. In their original study, Malinchoc *et al*<sup>[4]</sup> created a model utilizing serum bilirubin, serum creatinine, international normalized ratio (INR), and cause of underlying liver disease, all of which were used to predict three-month mortality in patients undergoing TIPS. In today's practice, the MELD score is primarily used to determine the extent of liver failure and subsequent placement on organ transplant waiting lists in addition to predicting risk and mortality of TIPS placement. However, there remains a limited amount of data available that can ascertain which variables convey a higher risk of complications from TIPS.

TIPS is a procedure that should be employed meticulously, as it can be accompanied by morbidity and mortality. Existing literature has elucidated variables that are traditionally associated with a poor outcome after TIPS, which include increasing age, male gender, high Child-Turcotte-Pugh (CTP) score, high MELD score, urgent placement of TIPS for uncontrolled variceal hemorrhage, renal dysfunction, ascites, and pre-existing hepatic encephalopathy<sup>[5-10]</sup>. However, there is a dearth of studies assessing the prognostic value of echocardiographic and hemodynamic determinations at the time of TIPS.

Liver cirrhosis is characterized by a hyperdynamic circulation, with an increased cardiac preload and a decreased cardiac afterload; this pre-existing hemody-

dynamic stress in cirrhotic patients may be worsened after TIPS placement. After TIPS placement, there is a rapid increase in blood flow from the splanchnic circulation to both the right heart and pulmonary circulation<sup>[11-13]</sup>. This increase in volume can precipitate right ventricular (RV) failure and pulmonary hypertension<sup>[13,14]</sup>. The pulmonary pressures may increase, particularly if the vasculature cannot vasodilate to accommodate the increase in cardiac output. In addition, TIPS permits more direct delivery of vasoactive and neurohumoral mediators, which are normally cleared by the liver, to the pulmonary circulation<sup>[5,14]</sup>. This higher load of vasoactive mediators may increase the RV afterload<sup>[14]</sup>. Due to these hemodynamic changes, it has been recommended that the TIPS procedure be considered with caution in patients with limited cardiac reserve<sup>[11,14]</sup>. While there are no clinical studies that identify a single RA pressure measurement that constitutes an absolute threshold above which TIPS should not be performed, intervention should be reconsidered or performed cautiously when right atrial (RA) pressure is greater than 20 mmHg; furthermore, a pulmonary arterial pressure greater than 45 mmHg may contraindicate TIPS placement.

Evidently, TIPS is not suitable for every patient that presents with portal hypertension, and contraindications must be ruled out prior to stent placement. Further research is indispensable to optimizing patient selection in order to achieve maximum survival benefits. We hypothesize that the echocardiographic and hemodynamic determinations obtained at the time of TIPS can provide prognostic information that will enhance risk stratification of patients for this procedure. We particularly sought to assess whether RA pressure could provide prognostic information, given that a higher RA pressure may reflect a higher intravascular volume and a degree of systolic/diastolic RV dysfunction, conditions that could worsen after TIPS placement. We tested our hypothesis in a large number of patients who underwent TIPS placement at the Cleveland Clinic.

## MATERIALS AND METHODS

This retrospective study received approval from the Cleveland Clinic Institutional Review Board (study number: 12-579). Written informed consent was waived. We reviewed the medical records of 467 patients who underwent TIPS placement between July 2003 and December 2011. Patients were identified using the billing codes for TIPS. Subjects were excluded from the analyses if they underwent liver transplantation before TIPS, TIPS placement was unsuccessful, or if the initial TIPS procedure was performed at an outside facility. Forty-nine patients met exclusion criteria and were thus excluded from analysis.

We recorded information regarding patient demographics, underlying liver disease, indication for TIPS, baseline laboratory values (albumin, bilirubin, INR, creatinine, and platelets), hemodynamic determinations at the time of TIPS, and echocardiographic measure-

ments both before and after TIPS. We also recorded patient comorbidities that may affect hemodynamic and echocardiographic determinations, including arterial hypertension, cardiac heart failure, heart valvular disease, chronic obstructive pulmonary disease, interstitial lung disease, scleroderma, splenectomy, sarcoidosis, sleep apnea, hypothyroidism, chronic kidney disease on hemodialysis, human immunodeficiency virus status, and cocaine use. In addition, we calculated MELD score and CTP class.

We recorded the following pre-TIPS echocardiographic determinations: Left ventricular ejection fraction (LVEF), RV systolic pressure (RVSP), subjective RV dilation, and subjective RV function. We recorded the following hemodynamic measurements: RA pressure before and after TIPS, inferior vena cava pressure before and after TIPS, free hepatic vein pressure, portal vein pressure before and after TIPS, and hepatic venous pressure gradient (HVPG). RV and pulmonary artery pressures were not routinely measured. It should be noted that all variables collected after TIPS were measured immediately after the procedure was performed. We also collected information regarding the type, diameter and length of the stent placed.

We recorded the following post-TIPS echocardiographic determinations: LVEF, RVSP, subjective RV dilation and function.

### TIPS technique

The TIPS procedure was performed according to previously described techniques, with modifications as needed<sup>[15]</sup>. After instillation of local anesthesia, the internal jugular vein was cannulated under direct ultrasound guidance and an introducer was placed. Through the introducer, an angled catheter was advanced into the RA and the pressure was recorded. The catheter was then maneuvered into the right hepatic vein. A long sheath was advanced to the proximal right hepatic vein, followed by a Fogarty balloon. Wedged and free hepatic vein pressures are not routinely collected during the TIPS procedure; these values are usually known from prior transjugular liver biopsy procedures performed on these patients. Carbon dioxide was injected as the contrast agent while digital images were obtained in an attempt to opacify the portal venous system. A parenchymal tract was created from the right hepatic vein to the right portal vein using a sheathed modified Colapinto needle. Alternatively, the TIPS procedure was performed with the modified Rosch-Uchida set. The kit used depends on the preference of the physician performing the procedure. A catheter was advanced into the portal vein and an initial pressure measurement was obtained. Nonionic contrast material was injected in order to display the anatomy and confirm the entry site. The parenchymal tract was then dilated and a stent was placed with the goal of obtaining an HVPG < 12 mmHg for patients with GI bleeding. There is no defined HVPG for patients with ascites; too low of a gradient puts these patients at risk for hepatic encephalopathy. At our institution, we aim to obtain an

<sup>1</sup>Other etiologies of portal hypertension include hepatitis B virus, autoimmune hepatitis, alpha-1 anti-trypsin deficiency, Budd Chiari syndrome, hemochromatosis, Wilson's disease, sarcoidosis, cystic fibrosis, biliary atresia, portal vein thrombosis, nodular regenerative hyperplasia, veno-occlusive disease and Caroli's disease; <sup>2</sup>Other indications for TIPS include hepatorenal syndrome, portal hypertensive gastropathy, superior mesenteric vein thrombosis, splenomegaly and the need to decrease the portal pressure prior to a surgical intervention. COPD: Chronic obstructive pulmonary disease; HIV: Human immunodeficiency virus; ILD: Interstitial lung disease; HCV: Hepatitis C virus; TIPS: Transjugular portosystemic shunt; INR: International normalized ratio.

HVPG around 7-8 mmHg, but this is not absolute and is adjusted to the clinical circumstances such as LFTs and the presence of encephalopathy pre-TIPS. The majority of our TIPS procedures are performed for control of ascites. A final angiogram was used to confirm good flow through the TIPS. In addition, the RA pressure and portal vein pressure were measured again immediately after the TIPS procedure was completed.

### Statistical analysis

Means and SD are provided for continuous variables, while numbers of patients with percentages are given for categorical variables. Hemodynamic variables before and after TIPS were compared using paired *t*-test. Binary logistic regression was used to identify variables that predict 3-mo mortality and results are reported as odds

ratio with 95%CI. We evaluated the association between RA pressure and other variables with univariate linear regression. We tested the relationship between survival and variables of interest with Cox proportional-hazards modeling adjusted for age and gender. The start point for the analysis was the date of the TIPS and the end of follow-up was marked by the patient's death or the end of study in December 2011. Patients were censored at the time of orthotopic liver transplant (OLT). Factors associated with survival in the univariate analysis (*P* value < 0.05) were entered into a multivariate model (forward selection). Results are expressed as hazard ratios (HRs) with the corresponding 95%CI. Predictors with HRs > 1 are associated with a higher risk for the outcome tested. We constructed receiver operating characteristic (ROC) curves to determine the sensitivity and specificity of different cutoffs of RA pressure and estimated RVSP for discriminating patients who died during follow-up. All *P* values reported are two tailed and *P*-values < 0.05 were considered significant. The statistical analyses were performed using SPSS version 17 (SPSS, Inc, Chicago, IL) and MedCalc, version 14.12.0 (Ostend, Belgium). The statistical methods of this study were reviewed by Dr. Adriano Tonelli from the Cleveland Clinic Foundation.

## RESULTS

### Patient characteristics

We included 418 patients with portal hypertension in the study. The mean  $\pm$  SD age was 55.8  $\pm$  11.6 years and 242 patients (57.9%) were male. The primary causes of portal hypertension were cryptogenic and non-alcoholic steatohepatitis (NASH) induced cirrhosis [*n* = 132 (31.6%)], alcohol induced liver disease [*n* = 105 (25.1%)] and hepatitis C virus [*n* = 105 (25.1%)]. Less common etiologies for portal hypertension and comorbidities are listed in Table 1.

Indications for TIPS included gastrointestinal bleeding [*n* = 182 (43.5%)], refractory ascites [*n* = 157 (37.6%)], hepatic hydrothorax [*n* = 51 (12.2%)] and other causes [*n* = 28 (6.7%)] (Table 1). A total of 113 (27.8%) TIPS procedures were done emergently. Laboratory evaluations of patients before TIPS (*n* = 416) are as follows (mean  $\pm$  SD): Serum albumin (g/dL) 2.9  $\pm$  0.7, serum bilirubin (mg/dL) 3.0  $\pm$  5.4, INR 1.3  $\pm$  0.4, serum creatinine (mg/dL) 1.3  $\pm$  1.1, platelets (K/ $\mu$ L) 115.3  $\pm$  77.6. MELD score pre-TIPS revealed a mean  $\pm$  SD of 13.3  $\pm$  6.9. Meanwhile, CTP classes A, B and C were present in 46 (11.5%), 224 (55.9%) and 131 patients (31.3%), respectively. The mean  $\pm$  SD diameter of the stent placed was 9.9  $\pm$  1 mm.

### Echocardiographic and invasive hemodynamic determinations

Among the 301 patients who had echocardiography data available, 224 patients (74%) had estimates of the RVSP, which demonstrated a mean  $\pm$  SD of 31.9  $\pm$  10.9 mmHg. Only 11 patients (3.7%) out of 294 in whom

**Table 2** Multivariate linear regression model with right atrial pressure as dependent variable

Model	$\beta$	Standard error	P-value
Constant	-2.21	1.01	0.03 <sup>a</sup>
MELD score	0.19	0.03	< 0.001 <sup>b</sup>
Platelet count (K/ $\mu$ L)	-0.01	0.01	0.004 <sup>b</sup>
Portal vein pressure (mmHg)	0.30	0.03	< 0.001 <sup>b</sup>
Splenectomy	4.69	1.97	0.02

R = 0.55, R<sup>2</sup> = 0.3, adjusted R<sup>2</sup> = 0.29. <sup>a</sup>P < 0.05; <sup>b</sup>P < 0.01. MELD: Model for End stage Liver Disease.

the RV function was evaluated had mild or moderate RV dysfunction prior to TIPS placement. There were several notable hemodynamic changes that occurred immediately after TIPS. The RA pressure increased by a mean  $\pm$  SD of 4.8  $\pm$  3.9 mmHg ( $P$  < 0.001). The HVPG decreased by a mean  $\pm$  SD of 6.8  $\pm$  3.5 mmHg ( $P$  < 0.001). However, this was at the expense of a reduction in the portal vein pressure, which decreased by a mean  $\pm$  SD of 11.7  $\pm$  5.6 mmHg ( $P$  < 0.001). Finally, the RVSP measured by echocardiography ( $n$  = 109) increased by 7.4  $\pm$  2.6 mmHg ( $P$  < 0.001).

#### Factors associated with RA pressure before TIPS

We found several factors to be associated with elevated RA pressure prior to TIPS placement, including MELD score ( $R$  = 0.36,  $P$  < 0.001), serum bilirubin ( $R$  = 0.29,  $P$  < 0.001), INR ( $R$  = 0.26,  $P$  < 0.001), serum creatinine ( $R$  = 0.26,  $P$  < 0.001), platelets ( $R$  = -0.18,  $P$  < 0.001) and portal vein pressure ( $R$  = 0.46,  $P$  < 0.001). Elevated RA Pressure before TIPS is directly related to severity of the patient's underlying liver disease. Moreover, splenectomy ( $R$  = 0.11,  $P$  = 0.03) and emergent TIPS placement ( $R$  = 0.24,  $P$  < 0.001) were associated with higher RA pressure in univariate linear regression analysis. RA pressure was not significantly different among the major etiologies of portal hypertension (ETOH, chronic hepatitis, NASH or others). In patients in whom TIPS were placed for acute variceal bleeding the RA before TIPS was higher (7.8  $\pm$  5.9 mmHg) than TIPS placed for ascites (6.0  $\pm$  3.9 mmHg,  $P$  = 0.001). Similarly, RA pressure after TIPS was higher in patients who received TIPS for acute variceal bleeding (12.4  $\pm$  6.5 mmHg vs 10.9  $\pm$  4.0 mmHg,  $P$  = 0.01) instead of ascites.

In multivariate linear regression analysis, a higher MELD score, lower platelet count, splenectomy and a higher portal vein pressure were independent predictors of higher RA pressure ( $R$  = 0.55,  $P$  < 0.001) (Table 2). Adding the etiology of portal hypertension and/or the reason for TIPS as variables did not affect the model. RA pressure was not found to be associated with RVSP or RV function obtained with echocardiography.

#### Predictors of 3-mo survival after TIPS

A total of 97 (24.7%) patients died within the 3-mo period after TIPS. Twenty-six patients underwent OLT during this time frame and were excluded from this

<sup>a</sup>P < 0.05; <sup>b</sup>P < 0.01. CKD: Chronic kidney disease; CTP: Child Turcotte Pugh; HD: Hemodialysis; MELD: Model for End stage Liver Disease; OR: Odds ratio; RA: Right atrium; RVSP: Right ventricular systolic pressure; TIPS: Transjugular portosystemic pressure.

analysis. Table 3 shows variables that predicted mortality at 3-mo in a univariate binary logistic regression. Etiology of portal hypertension and reason for TIPS were not significant predictors of this outcome. Only three variables remained predictors of 3-mo mortality after TIPS in a multivariate binary analysis. These included age (per 1 year, OR = 1.04, 95%CI: 1.02-1.08,  $P$  = 0.003), MELD score (per 1 unit, OR = 1.14, 95%CI: 1.08-1.19,  $P$  < 0.001) and CTP grade C (compared to A, OR = 4.75, 95%CI: 1.02-22.17,  $P$  < 0.001).

#### Predictors of long-term survival after TIPS

Patients were followed for a median (interquartile range) of 26.7 (2-45) mon. A total of 68 (16.3%) patients underwent OLT after TIPS. Of the remaining patients, 261 (74.6%) patients died before transplantation during follow-up. Median survival after TIPS was 26 mo (95%CI: 17-33) (Figure 1). Table 4 shows several variables that predicted long-term mortality post TIPS in a univariate Cox survival analysis. Etiology of portal hypertension or reason for TIPS was non-significant predictors of long-term mortality in our cohort. Table 5 shows significant predictors of long-term mortality after TIPS (age, splenectomy, MELD score, CTP groups B and C) according to a multivariate analysis that excluded echocardiographic parameters. When echocardiographic parameters were factored into the model, MELD score (per 1 unit, HR = 1.05, 95%CI: 1.02-1.08,  $P$  < 0.001) and RV function (per increase in 1 degree of severity, HR = 2.24, 95%CI: 1.34-3.74,  $P$  < 0.002) were significant predictors of long-term mortality. Of the hemodynamic determinations studied, only the change in the RA pressure after TIPS predicted long-term mortality (per 1 mmHg change, HR = 1.03, 95%CI: 1.01-1.06,  $P$  < 0.012).

#### Receiver operating characteristic analysis for RA pressure and RVSP

variables mortality at 3-mo (excluding liver transplant) and mortality or liver transplant at one year. The first variable tested was RA pressure measure by right heart catheterization immediately before TIPS. The area under the curve (AUC) for 3-mo mortality was 0.63 (95%CI: 0.58-0.68,  $P < 0.001$ ) (Figure 2A) with an optimal cut-off by Youden index of  $> 9$  mmHg (sensitivity of 41.3%, specificity of 80.5%). In addition, RA pressure  $> 14$  mmHg had a sensitivity of 14.1% and specificity of 95.7%. The AUC for mortality or liver transplant at one year was 0.58 (95%CI: 0.53-0.64,  $P = 0.009$ ) and a RA pressure of  $> 9$  mmHg showed a sensitivity of 18.1% and specificity of 66.4% in predicting this outcome.

An ROC curve testing a second variable, RVSP estimated by echocardiography, was also constructed. The AUC for 3-mo mortality was 0.60 (95%CI: 0.53-0.67,  $P = 0.04$ ) (Figure 2B) with a Youden index of  $> 29$  mmHg (sensitivity of 67.4 % and specificity of 50.6%). At a cut-off  $> 40$  mmHg, the sensitivity was 28.3% and specificity was 88.0%. Moreover, at a cut-off  $> 50$  mmHg, the sensitivity was 10.9% and specificity was 95.6% for predicting 3-mo mortality. The AUC predicting mortality or liver transplant at one year for RVSP was 0.58 (0.51-0.65,  $P = 0.047$ ) with a Youden index of  $> 29$  mmHg (sensitivity of 41.8% and specificity of 42.0%). At a cut-off  $> 40$  mmHg, the sensitivity was 10.0% and specificity was 79.0% and

at a cut-off  $> 50$  mmHg, the sensitivity was 3.60% and specificity was 91.4%.

A Kaplan-Meier analysis was performed, and three-month survival after TIPS based on RA pressure  $> 9$  mmHg vs  $\leq 9$  mmHg and estimated RVSP pressure  $> 40$  mmHg vs  $\leq 40$  mmHg is presented in Figure 3.

## DISCUSSION

We analyzed a large cohort of patients with portal hypertension who underwent TIPS for a variety of reasons, chiefly to assess hemodynamic variables before and after TIPS as potential predictors for mortality. We found an increase in RA pressure and a decrease in portal vein pressure after TIPS. The increase in RA pressure immediately after TIPS was associated with worsening liver function, portal hypertension, emergent TIPS placement and history of splenectomy. Of all the hemodynamic variables measured at the time TIPS, the increase in RA pressure after TIPS was associated with increased long-term mortality and a RA pressure  $> 9$  mmHg before TIPS predicted 3- and 12-mo mortality with specificity of 81% and 66%, respectively. It is important to note that in our models, the etiology of portal hypertension and the reasons for placing TIPS had no impact on short- or long-term survival.

Other studies examined the hemodynamic changes before and after TIPS. Kovács *et al*<sup>[16]</sup> assessed the short-

**Figure 2 Receiver operating characteristic curves for three-month mortality.** We tested the variables right atrium pressure before TIPS (A) and estimated RVSP by echocardiography pre TIPS (B). RVSP: Right ventricular systolic pressure; TIPS: Transjugular portosystemic shunt; RA: Right atrium.

**Figure 3 Kaplan-Meier analysis of three-month survival after transjugular portosystemic shunts.** A: Stratified by RA pressure > 9 mmHg vs ≤ 9 mmHg; B: Stratified by estimated RVSP pressure > 40 mmHg vs ≤ 40 mmHg. The separation in survival curves in both panels is particularly noted during the first month. *P* values are provided by log-rank test. RVSP: Right ventricular systolic pressure; RA: Right atrium.

term hemodynamic and cardiac magnetic resonance imaging changes after TIPS in 11 patients with liver cirrhosis and intractable esophageal varices or refractory ascites. They concluded that the amount of shunted blood after TIPS was more than the preload reserve of the right and left ventricle, and this was manifested by the significant increase of the pulmonary capillary wedge pressure and persistent enlargement of the left and right atria. Van der Linden *et al.*<sup>[14]</sup> studied the short and mid-term hemodynamic changes after TIPS in 16 sedated biopsy proven cirrhotic patients. They noted an increase in the mean pulmonary artery pressure (PAP), cardiac index, and RA pressure after TIPS. After a transient balloon occlusion of the shunt, they measured these hemodynamics variables once again. Interestingly, all hemodynamic determinations returned to baseline except for the mean PAP, which remained significantly elevated. This hemodynamic change persisted after one month, suggesting that the increase in pulmonary

pressure after TIPS is not only due to volume overload but also due to neurohumoral changes. This is consistent with findings from previous studies that evaluated the hemodynamic changes after TIPS placement<sup>[11,17]</sup>.

Azoulay *et al.*<sup>[11]</sup> investigated 12 cirrhotic patients who underwent the TIPS procedure due to refractory ascites or refractory esophageal variceal bleeding. Hemodynamics were measured before TIPS, at 30 min, and one month after TIPS. Significant changes recorded included the decrease in the HVPG from  $15 \pm 3$  to  $7 \pm 3$  mmHg at 30 min after TIPS, and the subsequent decrease to  $8 \pm 3$  mmHg at one month. The cardiac index increased from  $4.5 \pm 1.3$  to  $5.7 \pm 1.5$  at 30 min after TIPS and subsequently to  $7.4 \pm 1.4$  L/(min·m<sup>2</sup>) at one month. Colombato *et al.*<sup>[17]</sup> studied in 15 cirrhotic patients the systemic, splanchnic and pulmonary hemodynamics before TIPS, at 15-30 min and at two months after TIPS. Immediately after TIPS, the cardiac index increased by 32% and at two months the increase

was attenuated but remained significantly elevated. In our study, the only hemodynamic variable measured that significantly predicted long-term mortality after TIPS was RA pressure. It is worth noting that our cohort was much larger: 418 patients in our study vs 15 patients in Colombato *et al.*<sup>[17]</sup>'s study.

Mortality after TIPS continues to be elevated despite better selection of patients and improvements in the technical aspects of the procedure. In fact, the overall 30-d mortality ranges between 3% and 44%; meanwhile the one year mortality varies from 11% to 58%. The mortality is greater in high risk patients, in whom it can be as high as 90% within a few weeks after the procedure<sup>[5,6,18,19]</sup>. In our study, we observed a 3-mo and 12-mo mortality after TIPS (censored by liver transplant) of 23.6% and 40.3%, respectively. Given this high mortality rate, it is advantageous to identify predictors of short- and long-term mortality in patients considered for TIPS. Variables previously reported to adversely impact outcomes after TIPS include age<sup>[19,20]</sup>, gender, need for emergent TIPS, encephalopathy<sup>[6]</sup>, ascites, variceal hemorrhage<sup>[6]</sup>, CTP class C<sup>[10,20]</sup>, MELD score, bilirubin > 3<sup>[6,21]</sup>, INR<sup>[21]</sup>, creatinine, alanine aminotransferase > 100 IU/L<sup>[6]</sup>, sodium level<sup>[10]</sup>, albumin<sup>[21]</sup> and portosystemic gradient.

Our study yielded results that corroborate the aforementioned literature. In our study, both echocardiographic (RVSP) and hemodynamic (RA and portal vein pressures both before and after TIPS) variables were predictors of 3-mo survival after TIPS. However, the effect of these determinations became non-significant when adjusting for age, MELD score and CTP grade. Interestingly, a large number of variables impacted long-term survival. Those with independent value included age, MELD score, CTP grade, splenectomy and RV function. We also noted that the higher MELD score and CTP grade impacts adversely the short and long-term prognosis after TIPS. These findings have been described in the literature as predictors of short and long term mortality after TIPS creation in cirrhotic patients<sup>[5,10,20]</sup>. Parvinian *et al.*<sup>[19]</sup> evaluated the specificity of RA pressure in predicting mortality after TIPS at 30- and 90-d in a series of 125 patients. They demonstrated 30-d mortality of 18% and 90-d mortality of 28%. According to univariate analysis, baseline RA pressure and final RA pressure were significantly associated with survival at 30- and 90-d, in addition to Child-Pugh score and MELD score. As in our study, multivariate analysis did not include RA pressure as an independent predictor of mortality at 90-d, supporting these results in a large patient cohort.

In this study, we particularly focused on the prognostic importance of hemodynamic and echocardiographic determinations. Patients with advanced cirrhosis and portal hypertension can develop cardiomyopathy with left ventricular diastolic dysfunction<sup>[21]</sup>, hyperdynamic state, volume overload, and less commonly portopulmonary hypertension; these conditions can be aggravated with the insertion of TIPS<sup>[14,17,22-24]</sup>. The placement of TIPS rapidly increases the RV preload and afterload, which

can lead to overt heart failure, pulmonary hypertension and death<sup>[11,14,16,22-37]</sup>. RA pressure obtained before TIPS could be of value in clinical practice; physicians may elect to abort a TIPS procedure based on this hemodynamic parameter.

Our study has limitations that include the: (1) retrospective collection of data; (2) the lack of data on cardiac output, pulmonary artery and pulmonary capillary wedge pressures which are determinations not routinely obtained at the time of TIPS; and (3) echocardiographic determinations were not done at the time of TIPS. The nature of our patient cohort also poses some limitations. Despite these limitations this study presents data on a large number of TIPS procedures performed during the course of eight years. It describes factors that affect short (3-mo) and long-term prognosis. Most importantly, we found that an important factor with predictive value is RA pressure, which increases after TIPS most prominently in patients with more severe liver disease.

RA pressure increased immediately after TIPS particularly in patients with worse liver function, portal hypertension, emergent TIPS placement and history of splenectomy. The increase in RA pressure after TIPS was associated with increased mortality. Age, splenectomy, MELD score and CTP grade were independent predictors of long-term mortality after TIPS.

## ACKNOWLEDGMENTS

We would like to thank the interventional radiology laboratory personnel for their outstanding work. We are indebted to Jennie Newman licensed practical nurse for her invaluable assistance in this project.

## COMMENTS

### Background

Transjugular intrahepatic portosystemic shunt (TIPS) is a procedure that can be accompanied by morbidity and mortality. There is a lack of studies assessing the prognostic value of echocardiographic and hemodynamic determinations at the time of TIPS. The hypothesis that the echocardiographic and hemodynamic determinations obtained at the time of TIPS can provide prognostic information that will enhance risk stratification of patients for this procedure.

### Research frontiers

Risk stratification of patients with liver disease who are undergoing TIPS is imperfect. It is evident that a number of hemodynamic changes occur after the procedure; their effect on patient outcomes still warrants investigation. The authors examine echocardiographic and hemodynamic variables in this cohort of patients in order to glean information regarding survival and outcomes in patients undergoing TIPS. Furthermore, through a multivariate analysis they also investigate other variables that may significantly influence patient outcomes. This will help to optimize patient benefit from the TIPS procedure.

### Innovations and breakthroughs

In their study, they found that right atrial pressure increased immediately after TIPS particularly in patients with worse liver function, portal hypertension, emergent TIPS placement and history of splenectomy. The increase in right atrial pressure after TIPS was associated with increased mortality. Age, splenectomy, Model of End-stage Liver Disease score and Child Turcotte Pugh

grade were independent predictors of long-term mortality after TIPS.

## Applications

These findings could be used to enhance patient selection for TIPS.

## Peer-review

This retrospective study is important clinical value to select the patients for TIPS and evaluate the prognosis for patients who underwent TIPS placement.

### Abstract

Crigler Najjar syndrome is associated with indirect hyperbilirubinemia due to a deficiency of enzyme Uridine Di Phospho Glucuronosyl Transferase (UDPGT). Presented here is a case of a female in the first trimester of pregnancy, who was diagnosed to have type 2 Crigler Najjar syndrome. We also discuss the management of this rare disease especially in pregnancy. Unconjugated bilirubin can cross the placental barrier causing neurological damage in the newborn. Patient was carefully monitored during pregnancy and treatment with phenobarbitone in low doses was adjusted such that the serum bilirubin levels were below 10 mg/dL. Crigler Najjar syndrome being rare needs to be diagnosed early in pregnancy to avoid adverse fetal outcomes. Phenobarbitone being an inducer of enzyme UDPGT is used as the first line of treatment and is not teratogenic in the low doses used. Treatment protocol followed was on the basis of previous reported cases and successful perinatal outcome was achieved.

**Key words:** Crigler Najjar type 2; Phenobarbitone; Folic acid; Pregnancy; Kernicterus

**Core tip:** Crigler Najjar syndrome type 2 is a rare disorder causing indirect hyperbilirubinemia. In pregnancy placental crossing of unconjugated bilirubin can cause high bilirubin levels in the fetus with low Uridine Di Phospho Glucuronosyl Transferase activity causing permanent neurological impairment in the newborn. Hence timely diagnosis and treatment with low dose phenobarbitone is required.

## INTRODUCTION

Crigler Najjar type 2 is a rare condition with an incidence of 1 per 1000000 births. There is no predilection to any race or sex. Being an autosomal recessive disorder consanguineous marriage is a risk factor. Uridine Di Phospho Glucuronosyl Transferase (UDPGT) level in the liver is less than 10% of normal. The serum bilirubin ranges from 3-20 mg/dL. Patients usually present with jaundice in the first year of life but can sometimes occur even in the third decade. Acute increase in bilirubin levels can occur during fasting or illness. DNA analysis of *UDPGT* gene shows mutation in exon 1  $\times$  1-5. Expression analysis of the gene shows residual activity<sup>[1]</sup>. Greater than 25% fall in bilirubin levels after treatment with phenobarbitone distinguishes it from Crigler Najjar type 1.

Levels of bilirubin can be elevated due to the stress of pregnancy. The placenta is an ineffective barrier for unconjugated bilirubin and can result in high bilirubin levels in the neonate causing kernicterus and sometimes even death<sup>[2]</sup>.

Proper identification of the condition and timely treatment with phenobarbitone can avoid morbidity and mortality in the neonate<sup>[3]</sup>.

## CASE REPORT

A female patient of age 24 years had a history of jaundice since childhood. She came to us in her first trimester of pregnancy because her jaundice had increased since the previous 2 wk. Patient had unconjugated hyperbilirubinemia with normal liver enzymes. Tests for viral hepatitis, autoimmune liver disease and Wilson's disease were negative. Abdominal ultrasound including a selective hepatobiliary scan did not show any abnormalities. The *UDT1A1* gene was studied for the TATA sequence. The result was negative; Gilbert's syndrome was thus ruled out. Total bilirubin at 12 wk of gestation was 6.85 mg/dL with indirect bilirubin being 6.14 mg/dL and albumin of 4 g/dL. Her liver enzymes were normal. A dose of 30 mg/d of phenobarbitone was started for the patient. Her serum bilirubin and albumin levels were measured at weekly intervals for the first month and then monthly. Her liver enzymes were also measured simultaneously. We diagnosed the patient to be a case of Crigler Najjar type 2 based on: (1) history of hyperbilirubinemia since childhood; and (2) response to phenobarbitone. A congenital anomaly scan at 20 wk showed no fetal abnormalities. Through her pregnancy, bilirubin levels were maintained in the range of 4 to 8 mg/dL. Figure 1 shows readings of the patient's bilirubin levels taken throughout pregnancy. Total bilirubin was measured at 4.92 mg/dL at time of delivery, which was completed at the normal full term. At the same time, indirect bilirubin was 3.78 mg/dL. Bilirubin levels in the

neonate were normal. As a result, no treatment of any form was required.

## DISCUSSION

Crigler Najjar syndrome is a rare autosomal recessive condition with an incidence of 1 in 1000000 births. Pregnancy in Crigler Najjar syndrome type 2 has been reported only in 6 cases so far (type 1-4 type 2-6 cases)<sup>[4]</sup>.

Our patient was a case of Crigler Najjar type 2 where serum bilirubin usually does not exceed 10 mg/dL. However pregnancy being a stressful condition the bilirubin levels can increase to more than 10 mg/dL. We had monitored the patient's bilirubin levels, serum albumin and liver enzymes at monthly intervals.

Crigler-Najjar disease type 2 seems to pose no unique maternal risk during pregnancy. The fetus seems to be resistant to elevated maternal unconjugated bilirubin, but the neonate may require therapy for hyperbilirubinemia<sup>[5]</sup>. Unconjugated bilirubin crosses the placental barrier to cause high levels of bilirubin in the fetus resulting in neurological damage or even death<sup>[6]</sup>. There is no fixed level of bilirubin at which neurological damage occurs but a proposed level above 10 mg/dL has been suggested<sup>[4]</sup>. In a study by Holstein *et al*<sup>[7]</sup>, maternal bilirubin levels between 4.2 and 8.9 maintained by treatment with phototherapy/phenobarbitone resulted in a normal neonate.

Pinkie *et al*<sup>[8]</sup> observed that a maternal bilirubin of 10.8 mg/dL at delivery necessitated treatment with exchange transfusions and phototherapy. We had started our patient on low dose phenobarbitone (30 mg daily) and we were able to maintain bilirubin levels less than 10 mg/dL. Phenobarbitone is known to be teratogenic causing facial dysmorphism and mental retardation. However this is seen only at high doses of 750-1500 mg/d and has not been observed at enzyme inducing doses of 60 mg/d<sup>[3]</sup>.

It has been recommended that an acute increase in bilirubin should be treated with phototherapy and albumin. If patient is already on phototherapy then duration of phototherapy should be increased to 24 h. If neurological toxicity develops then plasmapheresis should be done. However our patient had maintained bilirubin levels with phenobarbitone alone.

The newborn was born without jaundice and did not require any treatment. Bilirubin levels over 10 mg/dL is an indication for phototherapy in term infants without risk factors 4 mg/dL in infants with high risk for kernicterus (preterm, low birth weight)<sup>[9]</sup>. A follow-up of the infant is required for at least 18 mo<sup>[10]</sup>. A study by Taylor *et al*<sup>[11]</sup> showed that an untreated maternal level of 20 mg/dL resulted in a normal infant at birth but the child developed quadriplegia at 18 mo of age. Hence we propose that the standard guidelines for the management of pregnancy in Crigler najjar syndrome type 2 should be followed<sup>[9]</sup>: (1) Genetic counselling before becoming pregnant; (2) Folic acid at a dose of 10 mg during pregnancy; (3) Maternal bilirubin serum

**Figure 1** Monitoring of bilirubin levels throughout pregnancy.

levels should be below 10 mg/dL; (4) Phenobarbitone at low dose of 60 mg/d; (5) Avoid drugs that increase unbound, unconjugated bilirubin like sulfonamides, salicylates, furosemide, ampicillin, and ceftriaxone; and (6) Neurologic follow-up of the newborn including hearing disorders (brainstem evoked potentials).

## COMMENTS

### Case characteristics

Pregnant female with jaundice.

### Clinical diagnosis

Icterus with negative abdominal findings.

### Differential diagnosis

Viral hepatitis, auto-immune hepatitis, Wilson's disease, hyperbilirubinemias, biliary pathology.

### Laboratory diagnosis

Indirect hyperbilirubinemia with normal liver enzymes.

### Imaging diagnosis

Normal hepatobiliary scan.

### Treatment

Phenobarbitone 30-60 mg once daily.

### Experiences and lessons

Suspicion for indirect hyperbilirubinemias for patients presenting with jaundice

and management of Crigler Najjar syndrome in pregnancy with low dose Phenobarbitone.

## Peer-review

Short, clear and well written manuscript. A rare disease that should be of interest to the Journal readers.

## Contents

Three issues per month Volume 8 Number 12 April 28, 2016

### TOPIC HIGHLIGHT

- 533 Incidence, risk factors and outcomes of *de novo* malignancies post liver transplantation  
*Mukthinuthalapati PK, Gotur R, Ghabril M*

### REVIEW

- 545 Hepatitis C virus and neurological damage  
*Mathew S, Faheem M, Ibrahim SM, Iqbal W, Rauff B, Fatima K, Qadri I*

### MINIREVIEWS

- 557 Antiviral therapy for hepatitis C: Has anything changed for pregnant/lactating women?  
*Spera AM, Kamal Eldin T, Tosone G, Orlando R*

### ORIGINAL ARTICLE

#### Retrospective Study

- 566 Predictors of fifty days in-hospital mortality in decompensated cirrhosis patients with spontaneous bacterial peritonitis  
*Bal CK, Daman R, Bhatia V*

## Contents

*World Journal of Hepatology*  
Volume 8 Number 12 April 28, 2016

### ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Dr. Jih Ru Hwu, BSc, FRSC, PhD, President, Academic Fellow, Editor, Professor, Research Fellow, Department of Chemistry, National Tsing Hua University, Hsinchu 30013, Taiwan

### AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

### INDEXING/ ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### FLYLEAF

I-IV Editorial Board

### EDITORS FOR THIS ISSUE

### Abstract

Liver transplantation (LT) is associated with a 2 to

7 fold higher, age and gender adjusted, risk of *de novo* malignancy. The overall incidence of *de novo* malignancy post LT ranges from 2.2% to 26%, and 5 and 10 years incidence rates are estimated at 10% to 14.6% and 20% to 32%, respectively. The main risk factors for *de novo* malignancy include immunosuppression with impaired immunosurveillance, and a number of patient factors which include; age, latent oncogenic viral infections, tobacco and alcohol use history, and underlying liver disease. The most common cancers after LT are non-melanoma skin cancers, accounting for approximately 37% of *de novo* malignancies, with a noted increase in the ratio of squamous to basal cell cancers. While these types of skin cancer do not impact patient survival, post-transplant lymphoproliferative disorders and solid organ cancer, accounting for 25% and 48% of malignancies, are associated with increased mortality. Patients developing these types of cancer are diagnosed at more advanced stages, and their cancers behave more aggressively compared with the general population. Patients undergoing LT for primary sclerosing cholangitis (particularly with inflammatory bowel disease) and alcoholic liver disease have high rates of malignancies compared with patients undergoing LT for other indications. These populations are at particular risk for gastrointestinal and aerodigestive cancers respectively. Counseling smoking cessation, skin protection from sun exposure and routine clinical follow-up are the current approach in practice. There are no standardized surveillance protocol, but available data suggests that regimented surveillance strategies are needed and capable of yielding cancer diagnosis at earlier stages with better resulting survival. Evidence-based strategies are needed to guide optimal surveillance and safe minimization of immunosuppression.

**Key words:** Liver transplant; Immunosuppression; Risk; Outcomes; Malignancy

**Core tip:** The risk of new cancers is significantly increased after liver transplantation (LT), and is driven by patient factors, oncogenic viruses and lifelong immunosuppression. *De novo* malignancy is a major risk factor for mortality after LT, equaling the risk of cardiovascular disease or infectious diseases. The risk of *de novo* malignancies may be reduced by attention to patient risk factors and minimization of immunosuppression when possible. Ultimately rigorous surveillance is needed to allow for early diagnosis and attenuation of mortality risk.

## INTRODUCTION

Liver transplantation (LT) is the definitive therapy for decompensated end-stage liver disease regardless of etiology. During the past 2 decades, the outcomes of LT have steadily improved as a result of more widespread expertise, better surgical techniques and more effective and better tolerated immunosuppressive agents. The growing number of LT recipients and improving survival rates place particular importance on the factors that jeopardize long term survival. Inherent to this population is the need for lifelong immunosuppression, which is associated with some broad categories of risk for morbidity and mortality. These include infection, cardiovascular risks, renal injury and cancer. When studied in patients surviving the early post LT period, *de novo* malignancy emerges as the leading category of immunosuppression associated long term mortality risk, accounting for approximately 21% to 25% of deaths<sup>[1,2]</sup>. This review summarizes current knowledge of *de novo* malignancy post LT including; epidemiology, pathogenesis, disease burden, clinical implications, preventive and surveillance considerations, while emphasizing risk factors and outcomes.

## INCIDENCE

Multiple studies report widely varying incidence rates of *de novo* malignancy post LT, along with considerable variations in associated risks, cancer types and outcomes. The incidence of *de novo* malignancies in relatively large cohorts (subjectively defined as more than 150 patients) is summarized in Table 1, the last row of which contains the means of the respective variables. These include single center experiences<sup>[3-7]</sup>, registry based studies<sup>[8-11]</sup>, and the majority are retrospective with few exceptions<sup>[12]</sup>. Variability in *de novo* malignancy

incidence rates reflect actual differences (based on differing cohort characteristics and risks) and artificial differences (based on differing methodologies and study design). The factors impacting actual differences in cancers types and their incidence may include age, gender, racial and geographical considerations, as well as the predominant underlying liver diseases and their associated comorbidities. Whereas artificial heterogeneity may be less apparent, yet could arise from variability in the: (1) definitions of *de novo* malignancy, *e.g.*, not all include non-melanoma skin cancers; (2) designated time threshold for of exclusion of cancers that are likely pre-existing before LT; (3) method of identification of malignancies, *e.g.*, in-center chart review vs utilization of cancer registries; (4) surveillance protocols and frequency of clinical follow up at study centers (critical for in-center reporting of cancer cases); (5) duration of follow up post LT since cancer incidence increases with time<sup>[8,13]</sup>; and (6) in the case of standardized incidence ratio (SIR) calculations, the control population used and type of cancers captured by the respective registries. In this review, we have described incidence rates of cancers and as well as the SIR where possible, as it allows age and gender adjusted risk analysis. SIR is calculated as the ratio of observed incidence in a cohort to the expected incidence in the population (hence has no unit).

Cancer registry data used to calculate expected age and gender adjusted incidence rates for SIR estimation doesn't capture non-melanoma skin cancers (NMSCs). Therefore SIR analyses succinctly reflect the risk of more life-threatening types of cancer. Interestingly, purely registry based analyses yield higher SIR values for *de novo* malignancy post LT, ranging from 2.2 to 4.9<sup>[10,14-16]</sup>, than 1.4 to 3.1<sup>[2,9,11,17,18]</sup> of single and multi-center studies. The reasons for this are unclear but could reflect differing approaches to immunosuppression given the reporting bias for higher transplant volume centers.

## RISK FACTORS FOR *DE NOVO* MALIGNANCY

The risk factors for the development of *de novo* malignancy after LT are not fully understood, but it is likely that patient, transplant and environmental factors interact to shape that risk.

### *Immunosuppression related risk*

Over the past few decades, a better understanding of the role of the immune system in preventing malignancy in immunocompetent individuals helped establish the concept of immunosurveillance<sup>[19]</sup>. Transplant recipients receive lifelong immunosuppression with chronic impairment of immunosurveillance, which promotes proliferation and survival of malignant cellular clones. Though immunosuppressive drug dose intensity likely contributes to cancer risk, the evidence for this is

<sup>1</sup>Excluding non-melanoma skin cancers; <sup>2</sup>Excluding post-transplant lymphoproliferative disorder; <sup>3</sup>Excluding basal cell skin cancer; <sup>4</sup>Median or mean ± SD. SIR: Standardized incidence ratio.

indirect. Comparative studies indicate a lower SIR for *de novo* malignancies in LT (2.2) recipients compared with heart (2.5) or lung (3.6) recipients who typically require higher intensity of immunosuppression<sup>[16,20]</sup>. A higher rate of hepatocellular carcinoma recurrence has been described with higher trough levels of the calcineurin inhibitors (CNI), tacrolimus and cyclosporine, particularly in the early post LT period<sup>[21,22]</sup>. Calcineurin inhibitors inhibit T-lymphocyte cell mediated immunity, and may also increase the risk of malignancy by increasing synthesis of growth factors, *e.g.*, transforming growth factor- $\beta$ , interleukin-6 and vascular endothelial growth factor in tumor cells, and impair DNA repair, thereby enhancing tumor growth, metastasis and angiogenesis<sup>[23]</sup>. The duration of immunosuppression also likely increases risk of malignancy, with increased incidence reported in recipients who were immunosuppressed before LT<sup>[9]</sup>.

The choice of immunosuppressive drug is a potentially modifiable cancer risk factor. Cyclosporine initially, and tacrolimus subsequently, have been and remain the mainstay of long term immunosuppression in LT over the last few decades. Even though some studies have shown higher carcinogenic risk with tacrolimus<sup>[7,24]</sup>, and others with cyclosporine based protocols<sup>[2,25-27]</sup>, there is no accepted cancer risk advantage for either agent<sup>[3,28]</sup>. A more practical concern in choice of immunosuppressant relates to the class of mammalian target of rapamycin (mTOR) inhibitors, sirolimus and everolimus, though these agents are used mainly in renal sparing regimens. The putative

**Table 2** A listing on known oncogenic viruses and the malignancies associated with them

Oncogenic virus	Associated malignancy
EBV	PTLD
Human papilloma virus	Cervical, skin, oropharynx, anal
Human T-cell lymphotropic virus type 1	Adult T cell leukemia
Kaposi's sarcoma-associated herpesvirus	KS, primary effusion lymphoma, castleman's disease
HBV	HCC
HCV	HCC, PTLD <sup>1</sup>

<sup>1</sup>Role controversial. HCC: Hepatocellular carcinoma; EBV: Epstein-Barr virus; PTLD: Post transplant lymphoproliferative disorder; KS: Kaposi's sarcoma; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

anti-proliferative properties of mTOR inhibition include inhibition of cellular growth, proliferation, metabolism and angiogenesis<sup>[29]</sup>. Though there is no prospective randomized controlled study data currently, a number of retrospective studies have described lower rates of hepatocellular carcinoma (HCC) recurrence<sup>[30,31]</sup>, and *de novo* malignancies<sup>[32,33]</sup> with mTOR inhibitors post LT and renal transplantation<sup>[34]</sup>. A meta-analysis of retrospective studies has shown that mTOR inhibitor, sirolimus, is of value in preventing recurrence and increasing survival in those transplanted for HCC<sup>[35]</sup>.

The post LT cancer risk related to anti-metabolites has been described for azathioprine in one study, with an odds ratio (OR = 3.8, 95%CI: 1.7-8.6,  $P = 0.004$ )<sup>[36]</sup>. Whereas mycophenolate mofetil has been shown to have anti-tumor properties in animal studies<sup>[37]</sup>, and was associated with a trend towards lower risk of non-skin *de novo* malignancies post renal transplant in a large United States, and European/Canadian registry based study<sup>[38]</sup>. In a recent study of solid organ transplant, mycophenolate mofetil use was associated with lower risk of proximal colon cancer<sup>[39]</sup>.

Immunosuppression induction with anti-lymphocyte antibodies or anti-thymocyte globulin was associated with increased of skin cancer in one study<sup>[9]</sup>, however that risk was not seen in larger series using anti-thymocyte globulin induction<sup>[2,28]</sup>. Rejection episodes also did not alter the risk of malignancy in LT recipients<sup>[5,6,12,40]</sup>. These data suggest that higher levels of immunosuppression in the short term do not increase the long term risk of cancer.

Immunosuppression also increases the cancer risk related to latent oncogenic virus infections (Table 2)<sup>[41]</sup>. Oncogenic virus associated tumors may be more immunogenic than those related to other factors, and may regress once immunosuppression is stopped or minimized<sup>[42]</sup>. This provides the rationale for a decrease in immunosuppression as the first line intervention for some virus related cancers, such post-transplant lymphoproliferative disorder (PTLD), particularly when associated with Epstein-barr virus (EBV) viremia<sup>[43]</sup>.

### Recipient related factors

The association of specific patient factors with cancer risk are organized and elaborated on below.

**Age:** Advanced age is a well described risk factor for *de novo* malignancy<sup>[2,7,8,12,44,45]</sup>, although this is not a universal finding<sup>[25,28]</sup>. This suggests that other factors may supersede age in cancer risk, though some caveats are notable with the extremes of age. For example the SIR for early PTLD was high (18.1) in pediatric LT recipients in one study<sup>[9]</sup>, with a similar observation in another study<sup>[10]</sup>. In another study, LT recipients older than 60 had > 2 fold higher 5-year incidence of new cancers (> 40%) compared to younger LT recipients (< 20%), largely due to non-skin cancers, with significantly higher cancer related mortality<sup>[46]</sup>.

**Gender and race:** There is conflicting data on the relative risk of *de novo* malignancy according to gender, with slightly higher SIR of cancers in females in one registry study<sup>[14]</sup>, and in males in another<sup>[45]</sup>, limiting any meaningful conclusion. Although skin cancer risk would be expected to differ according to race, there is limited data of cancer risk in relation to race. Non-Caucasian race was associated with a higher hazard ratio (HR = 2.5, 95%CI: 1.3-4.3) for non-skin cancers in one study, but the small size of that subgroup was limiting<sup>[2]</sup>.

**Indication for LT:** Patients who receive LT for certain indications are more prone to some malignancies. Patients with primary sclerosing cholangitis (PSC) in a United States multicenter prospective observational study had the highest cumulative incidence of non-skin cancer of 5.5%, 10.4%, and 21.9% at 1, 5, and 10 years, respectively<sup>[12]</sup>. Patients with PSC and inflammatory bowel disease (IBD) and an intact colon at the time of LT were at increased risk of gastrointestinal (colon) malignancy (HR = 2.34, 95%CI: 1.02-5.38)<sup>[12]</sup>, which may not be surprising given the association of PSC and IBD with colon cancer risk. However, patients with PSC also exhibited an increased risk for PTLD, skin malignancies and solid organ malignancies<sup>[12]</sup>. A high cancer risk for LT recipients with PSC was also observed in an Italian study, though cancer types were not specified<sup>[47]</sup>. The reasons for generalized cancer risk are unclear, but may reflect immunosuppression before LT, and possibly vitamin D deficiency which may promote malignancy<sup>[48]</sup>.

**Alcohol use history and smoking:** Many studies have described the carcinogenic properties of alcohol and smoking in immunocompetent individuals<sup>[49,50]</sup>. Alcoholic liver disease (ALD) is associated with increased cancer risk post LT<sup>[7,12,36,45,51-54]</sup>. Synergy between the carcinogenic effects of alcohol and smoking is well described<sup>[55,56]</sup>. Smokers were more likely to have alcoholic liver disease than non-smokers (35% vs 13%,

**Table 3** A summary of ranges of reported overall incidence rates and standardized incidence ratios of a number of cancer types following liver transplantation<sup>[2-5,7-12,14-16,28,36,47,66,110,118-120]</sup>

	Incidence (%)	SIR
Skin cancers		
Represent 24%-54% of all cancers, average 37%		
Overall (non-melanoma)	0.9-11.6	2.1-70, average 24
Squamous cell cancer	0.6-15.3	Not reported
Basal cell cancer	0.6-10.6	Not reported
KS	0.2-1.4	128-144
Melanoma	0.2-3.9	4.4
Post-transplant lymphoproliferative disorders		
Represent 4%-57% of all cancers, average 25%		
Overall	0.5-2.9	3.9-21, average 12
Hodgkin's lymphoma	0.001-0.4	8.2-8.9
Non-Hodgkin's lymphoma	0.8-3.7	3.5-37.3
Solid organ cancers		
Represent 24%-75% of all cancers, average 48%		
Overall	1.4-7.5	1.4-3.1, average 2.3
Lip	1.8	14-24.8
Oropharyngeal	1.7-1.9	7-10
Lung	0.6-2.4	1.4-2.0
Stomach	0.2-0.7	0.5-3.7
Colorectal	0.5-1.1	1.4-4.9
Breast (in females)	0.2-0.6	0.6-1.6 <sup>1</sup>
Cervix (in females)	0.7-1.4	1.3-5.7
Prostate (in males)	0.2-1.8	0.6-1.6 <sup>1</sup>

<sup>1</sup>The SIR was not found to be significantly higher for transplant recipients compared with the reference population. Of note, studies often reported either incidence rate or SIR, but rarely both values. SIR: Standardized incidence ratio; KS: Kaposi's sarcoma.

$P = 0.008$ ) in one study<sup>[56]</sup>, and patients transplanted for ALD were more likely to be smokers (82% vs 45%,  $P = 0.001$ ) and smoked more cigarettes per day ( $27 \pm 15$  vs  $16 \pm 11$ ,  $P = 0.001$ ) in another<sup>[54]</sup>. A United Kingdom registry study reported a higher SIR (3.16) of *de novo* malignancy for ALD compared to all other LT indications (1.99)<sup>[45]</sup>. In the immunocompetent population, there is evidence that the increased risk of cancer due to alcohol abuse could be reversed by abstinence<sup>[57]</sup>. However, this effect may be delayed by a more than a decade<sup>[58]</sup>, with cancer risk carried through post LT.

**History of cancer prior to LT:** A history of cancer prior to LT was not associated with its recurrence after LT<sup>[8,25]</sup>. However, LT for HCC has been associated with an increased risk of *de novo* malignancy<sup>[7,44]</sup>. An increased incidence of non-skin cancers in patients with a history of non-liver cancer prior to LT (30.8% vs 8.3%,  $P = 0.001$ ) has also been described, where it was additionally an independent predictor of non-skin *de novo* malignancies (HR = 2.5, 95%CI: 1.3-4.9,  $P = 0.005$ )<sup>[2]</sup>. This association is supported by data from renal transplantation studies<sup>[34,59,60]</sup>. Therefore, a prior history of cancer may reflect a patient's composite (genetic and epigenetic) risk of malignancy.

## SITE SPECIFIC *DE NOVO* MALIGNANCIES

The risk of *de novo* malignancy is variable across a range of tumor types, as reported by cancer registry

studies. These cancers are commonly grouped according to three broad categories including; skin cancers, PTLD and solid organ cancers. The risks of specific tumors post LT are summarized in Table 3.

### Skin cancers

Skin malignancy, typically NMSC, is the most common malignancy after LT<sup>[2,7,9,12,40,61]</sup>. These include squamous cell cancer (SCC), basal cell cancer (BCC) and Kaposi's sarcoma (KS). Ultraviolet radiation is an important risk factor in the pathogenesis of skin malignancies, and exerts a field cancerization mutagenic effect in exposed areas of the skin<sup>[62-65]</sup>. In a prospective study of LT recipients with comprehensive dermatology follow-up, only total pre transplant sun burden and skin characteristics were found to be the risk factors for NMSC<sup>[66]</sup>. The relative risk of cutaneous malignancies in this cohort was found to be 20 fold higher than the general population. Conversely studies from Iran, South Korea and China described no to very low incidence rates of skin cancer, likely due to the prevalent skin types<sup>[67-69]</sup>. In organ transplant recipients, SCC is more common than BCC, in contrast to the general population<sup>[44,70]</sup>. Additionally, while SCC and BCC are easily surveyed and resected, SCC can behave more aggressively in LT recipients<sup>[70,71]</sup>. In general though, LT recipients with SCC and BCC have similar survival to patients not developing *de novo* malignancies post LT<sup>[2,40]</sup>.

Immunosuppression with CNIs and azathioprine is a significant risk factor for NMSC<sup>[72-76]</sup>, but it is likely

the degree of immunosuppression that represents the main risk rather than the choice of agent<sup>[62,77,78]</sup>. However, there is mounting evidence that mTOR inhibitors have protective effect against NMSC due to their aforementioned anti-proliferative properties<sup>[72,77]</sup>, especially in renal transplant recipients. In a randomized trial, converting renal transplant recipients with NMSC from CNI to sirolimus based immunosuppression was associated with a reduced risk of subsequent NMSC (relative risk 0.56, 95%CI: 0.32-0.98) and longer recurrence free interval (15 mo vs 7 mo,  $P = 0.02$ )<sup>[79]</sup>. However, similar evidence in LT recipients is currently lacking.

Kaposi's sarcoma is related to human herpes virus-8 (HHV-8) and occurs only in immunocompromised individuals. The incidence of KS after LT reflects the prevalence of HHV-8 (also known as Kaposi's sarcoma-associated herpes virus), with high rates reported in the Mediterranean region<sup>[80,81]</sup>. Not surprisingly the highest rates and SIR (commonly > 100) for KS post LT are reported in Italian transplant series<sup>[11,17,47]</sup>.

### Post-transplant lymphoproliferative disorders

The term PTLD encompasses a broad spectrum of lymphoproliferative disorders observed in the immunocompromised solid organ transplant recipients. It is the second most common malignancy in LT recipients, and is notable in its wide age distribution, extending to the very young<sup>[14]</sup>. The rate of PTLD is lower in the liver compared to other solid organ recipients<sup>[82]</sup>, likely due to lower immunosuppression levels needed to prevent liver allograft rejection, and possibly a smaller number of donor lymphocytes in the graft<sup>[83]</sup>. The other factor driving PTLD risk is EBV infection, with associated PTLD generally occurring earlier, in the first 12 to 18 mo, after LT and involving younger patients<sup>[82,84]</sup>. Infection with EBV and immunosuppression appear to play crucial roles in the pathogenesis of PTLD. EBV mismatch between donor and recipient of LT increases the risk of PTLD by 70 fold<sup>[85,86]</sup>. Primary infection with EBV after LT also increases the risk significantly<sup>[87]</sup>. Primary EBV or latent (of virus within B cells) infection can stimulate B cell proliferation and transformation<sup>[88]</sup>. EBV associated PTLD occurs three times more frequently in pediatric patients<sup>[87,89]</sup>. This is likely a reflection of the EBV negative status of pediatric recipient, whereas EBV infects 90% of the adults worldwide<sup>[90]</sup>.

Another important phenotype of PTLD develops later post LT in the absence of EBV infection involves older recipients and carries a worse prognosis<sup>[82]</sup>. The pathogenesis of EBV negative PTLD is uncertain<sup>[91]</sup>, but some risk factors were described in a study of 480 adult LT recipient PTLD in France, where 16 developed PTLD<sup>[92]</sup>. These were age above 50, LT for hepatitis C virus (HCV) or alcoholic cirrhosis, and the use of anti-lymphocyte antibodies such as muromonab, the latter reported by others<sup>[82,87]</sup>. The use of anti-thymocyte globulins in LT for HCV cirrhosis augmented PTLD risk in another study (27% for HCV vs 6.4% for non-HCV

cases,  $P = 0.08$ )<sup>[93]</sup>. When compared to lymphomas in the immunocompetent population, PTLD are more likely to exhibit extra-nodal involvement, high-grade and poor outcomes<sup>[94]</sup>. Factors which confer a poor prognosis with PTLD are; high grade or stage at diagnosis<sup>[43]</sup>, T cell disease<sup>[95]</sup>, central nervous system and bone marrow involvement<sup>[96,97]</sup>, poor performance status<sup>[98]</sup>, higher number of extra-nodal sites<sup>[98]</sup>, and EBV negative disease<sup>[43,85,99]</sup>.

### Solid organ cancers

Like PTLD, this category of *de novo* malignancy carries significant risk of mortality post LT, but is a term loosely used to group a wide range of tumor types and organ involved. Some characteristics of risk are evident in relation to subgroups of solid organ cancers, including aerodigestive, gastrointestinal, genitourinary and gynecologic systems.

### Aerodigestive cancers

Aerodigestive cancers are associated with smoking and alcohol use, and arise from the tissues of the aerodigestive tract, which include the respiratory tract and the upper part of the digestive tract (including the lips, mouth, tongue, nose, throat, vocal cords, and part of the esophagus and windpipe). These are largely reported as head and neck cancers and lung cancer post LT.

A meta-analysis of studies examining head and neck cancer after LT found an overall SIR of 3.8 (95%CI: 2.7-4.9)<sup>[100]</sup>. They develop at mean post LT intervals that range from 34 to 61 mo<sup>[3-5,92,101]</sup>. Liver transplant recipients with a history of tobacco use and ALD are at high risk for developing head and neck cancers<sup>[7,12,102]</sup>, and in some studies only developed in patients with a history of ALD<sup>[6,103]</sup>.

In a large study encompassing all solid organ transplants in the United States, the SIR for lung cancer after LT was found to be 1.95 (95%CI: 1.74-2.19)<sup>[14]</sup>. Lung cancer develops at mean post LT intervals ranging from 42 to 50 mo<sup>[3,5,28,61,101]</sup>. The main risk factors for lung cancer, similar to the general population, in LT recipients was smoking<sup>[2,7,12,54]</sup>. Those transplanted for ALD also had increased risk of lung cancer compared to those transplanted for other causes (4.3% vs 0.7%,  $P < 0.001$ ), though tobacco use which prevalent in this population may confound these observations<sup>[7,12,54]</sup>. Post LT lung cancer is commonly diagnosed in advanced stages<sup>[3,5,54]</sup>, suggesting the need for diligent surveillance programs in the high risk population (smokers and those transplanted for ALD). It remains unclear how long tobacco and alcohol related cancer risk persist following cessation.

### Gastrointestinal cancers

The most common gastrointestinal cancer seen in solid organ transplant recipients is colon cancer<sup>[14]</sup>. The SIR for colon cancer in LT recipients ranges from 1.4 to as high 27.3 in subsets of high risk patients with PSC<sup>[16,17,45]</sup>.

Patients receiving LT for PSC are at particularly high risk for colon cancer, due to the association with IBD<sup>[12,45,104-106]</sup>. In the study by Watt *et al.*<sup>[12]</sup> PSC alone (HR = 1.9,  $P = 0.12$ ) was not a risk factor for gastrointestinal malignancy, whereas patients with PSC, IBD and intact colons had a significant cancer risk (HR = 3.51, 95%CI: 1.48-8.36,  $P = 0.005$ ). Colon cancer was more common in LT recipients with ulcerative colitis (SIR = 27.3 vs 3.5), than those without it, particularly in patients older than 40 (SIR = 4.8 vs 1 in younger patients)<sup>[45]</sup>. Longer duration of IBD and more extensive colonic involvement increase the risk for colorectal cancer in LT recipients with PSC<sup>[104-106]</sup>. Colorectal cancer develops at a younger age in LT recipients compared with the general population, and has a worse prognosis<sup>[107,108]</sup>. A relatively high incidence of colon and stomach cancer have been reported in a South Korean study<sup>[67]</sup>, with otherwise relatively low (2.2%-2.3%) *de novo* malignancy incidence rates reported in East Asian studies<sup>[67,69]</sup>.

### Genitourinary and gynecologic cancers

Registry studies indicate an increased SIR of some (cervical, vulvar, bladder and kidney) but not all genitourinary or gender-specific (breast, prostate, uterine, ovarian) cancers following solid organ transplant<sup>[10,14-17,45]</sup>. In the largest of these, there was a slightly lower SIR for breast and prostate cancer in transplant recipients<sup>[14]</sup>. Cervical cancer risk was significantly elevated in one series (SIR = 30.7)<sup>[17]</sup>, and other human papilloma virus related cancers (vulvar, vaginal, anal, penile) all appear to have higher SIR (range 2.4-7.6) relative to the general population<sup>[14]</sup>. Bladder cancer risk is increased in a number of studies, with a range of SIR value from 1.5 to 2.4<sup>[14-16]</sup>, and were noted to develop late (10 years) post LT in one cohort<sup>[47]</sup>.

## SURVIVAL AFTER *DE NOVO* NON-SKIN CANCERS

In a comparison of patients from a solid organ transplant cancer registry with a general population from the Surveillance, Epidemiology, and End Results database, transplant patients were more likely to be diagnosed with American Joint Commission on Cancer stage > 2 cancers, and worse cancer-specific survival<sup>[109]</sup>. The relative risk of cancer-related mortality compared to the general population was 2.9 (95%CI: 1.59-5.11)<sup>[7]</sup>. In a large single center study *de novo* malignancy, excluding NMSC, was a leading category of mortality risk (14.2%), along with infections (15%), disease recurrence (13%) and cardiovascular (9%) complications<sup>[2]</sup>. Patient survival rates at 1.3 and 5 years after diagnosis of *de novo* malignancy were 55%, 36%, and 27% compared with 100%, 100% and 67% for patients with only NMSC,  $P = 0.001$ , respectively<sup>[2]</sup>. Similarly, *de novo* malignancy excluding NMSC was associated with an increased risk of mortality [HR = 4.9 (95%CI: 1.67-14.2),  $P = 0.003$ ] in another large series<sup>[40]</sup>, and probability of death after

diagnosis was 40% at 1 year, and 55% at 5 years, respectively<sup>[12]</sup>.

There is considerable variability in reported survival after PTLD, with median survival as low as 2 mo (95%CI: 0.3-3.5 mo) in one study<sup>[36]</sup>, likely as a result of heterogeneity in risk characteristics of PTLD<sup>[95]</sup>. Longer median survival intervals (27 mo to 35 mo) are noted in other LT series<sup>[12,14]</sup>, with reported 1 and 5 year survival rates of 56% and 46%, respectively<sup>[82]</sup>. Pediatric LT recipients with PTLD appear to have better outcomes, with median survival of 8.2 years and reported 10 years survival rates of 59%<sup>[85,96]</sup>, and no reported mortality in some series<sup>[94]</sup>. Advanced stage, Burkitt or Burkitt-like PTLD, and c-myc translocations indicated poor prognosis and short survival in pediatric PTLD<sup>[96]</sup>.

The reported site-specific cancer survival rates for the aforementioned solid organ cancer categories are: Oropharyngeal cancer 1 and 5 year survival of 43% to 78% and 56% respectively, lung cancer 1 and 5 year survival of 41% to 43% and 16% respectively, gastrointestinal cancers 1 and 5 year survival of 67% to 80% and 52% respectively, and genitourinary cancers 1 and 5 year survival of 79%-100% and 71% respectively<sup>[3,12]</sup>.

## SURVEILLANCE

The increased risk and mortality associated with *de novo* malignancies underlines the need for surveillance strategies to detect tumors at earlier stages, allow more effective treatments, and improve survival. However, there are no standardized surveillance protocols for LT recipients at present. Routine follow up visits alone were only capable of detecting 12% of the non-skin cancers in one series, and annual visits resulted in identifying half of all malignancies in another<sup>[8,9]</sup>. Poor compliance with surveillance protocols was also cited as a limitation in a study where active surveillance identified only 3 of 28 non-skin cancers<sup>[7]</sup>. These data further highlight the need for regimented surveillance strategies in this regard.

In a compelling study, the incidence and outcome of *de novo* malignancy were compared before and after institution of an intensified surveillance protocol which included: Annual chest and abdominal computerized tomography (CT), urological, gynecological (pap smear and mammography) and dermatological examination, and colonoscopies every 5 years<sup>[18]</sup>. With a historical surveillance program consisting of annual chest radiographs and abdominal ultrasounds serving as the reference comparator, the detection rate for *de novo* malignancies increased from 4.9% to 13% with intensified surveillance ( $P = 0.001$ ), fewer tumors were diagnosed at stage III or IV (46% vs 75%), and median survival following a diagnosis of non-skin cancer increased from 1.2 to 3.3 years ( $P = 0.001$ )<sup>[18]</sup>.

At another center, a similarly multifaceted surveillance protocol that included: (1) urinalysis, chest radiographs and abdominal ultrasounds performed every

6 mo in the first year post LT and annually thereafter; (2) mammography every two years; (3) colonoscopy every 7-10 years if no adenomas were detected; and (4) in patients with smoking history, an annual otolaryngological evaluation and low dose CT of the chest after 2006<sup>[110]</sup>. Patients that were diagnosed with *de novo* malignancy through active surveillance had better survival (all were alive after 25 mo of follow up) compared with patients diagnosed with symptomatic disease or incidentally (median survival of 13.5 mo) ( $P = 0.002$ )<sup>[110]</sup>. The use of annual low dose chest CT in LT recipients with more than 10 pack years of cumulative smoking history led to a diagnosis of early stage lung cancer in 12% of patients<sup>[111]</sup>.

Additionally, special populations amongst LT recipient and the specialized surveillance strategies that are or may be warranted for them include those with: (1) underlying PSC and IBD, or IBD alone of more than 8-10 years duration with annual surveillance colonoscopy; (2) a history of human papilloma virus infection with annual pap smear in females, and annual genital and anal pap/scraping in both genders; and (3) patients from the Mediterranean region with testing of HHV-8 titers due to increased prevalence and association with risk of KS<sup>[112]</sup>.

## PREVENTATIVE MEASURES

Smoking is a major risk factor for cancer, especially nasopharyngeal cancers and lung cancer, as well cardiovascular disease related mortality<sup>[56]</sup>, and smoking cessation should be counseled as early as possible. Regular application of broad spectrum sunscreen (SPF > 50, with high-UVA absorption) over sun-exposed areas in solid organ transplant recipients, in conjunction with counseling of excessive sun exposure avoidance, reduced the risk of actinic keratosis, invasive SCC and BCC from developing in a prospective case control study in solid organ transplant recipients<sup>[113]</sup>. Protective clothing has also been shown to protect against UV radiation<sup>[114]</sup>. The minimization of immunosuppression without risking graft rejection is limited by the lack of accurate markers of over or under immunosuppression, but would likely to attenuate the risk of *de novo* malignancy in LT recipient. There is also insufficient evidence to guide the routine use of mTOR inhibitors in at risk patients, but those studies are ongoing<sup>[115-120]</sup>.

## CONCLUSION

Liver transplant recipients are at increased risk of cancer when compared to the general population, and the most commonly encountered cancers are NMSC, PTLT, and aerodigestive. They are due mainly due to the effects of immunosuppression and latent oncogenic viruses prevalent in the population. Important risk factors for development of *de novo* malignancy include age, degree of immunosuppression, history of smoking and alcohol abuse and transplantation for PSC and ALD. *De novo* malignancies, excluding NMSC, represent a major risk

category for post LT mortality. There are no standardized surveillance protocols for *de novo* malignancy post LT, but available evidence supports adoption of some consistent surveillance strategies. Minimization of immunosuppression and attention and counseling related to other risk factors in LT recipients may reduce an individual's risk of developing cancers post LT, but more evidence is needed to optimize care.

### Abstract

Chronic hepatitis C virus (HCV) infection exhibits a wide range of extrahepatic complications, affecting various organs in the human body. Numerous HCV patients suffer neurological manifestations, ranging from cognitive impairment to peripheral neuropathy. Overexpression of the host immune response leads to the production of immune complexes, cryoglobulins, as well as auto-antibodies, which is a major pathogenic mechanism responsible for nervous system dysfunction. Alternatively circulating inflammatory cytokines and chemokines and HCV replication in neurons is another factor that severely affects the nervous system. Furthermore, HCV infection causes both sensory and motor peripheral neuropathy in the mixed cryoglobulinemia as well as known as an important risk aspect for stroke. These extrahepatic manifestations are the reason behind underlying hepatic encephalopathy and chronic liver disease. The brain is an apt location for HCV replication, where the HCV virus may directly wield neurotoxicity. Other mechanisms that takes place by chronic HCV infection due the pathogenesis of neuropsychiatric disorders includes derangement of metabolic pathways of infected cells, autoimmune disorders, systemic or cerebral inflammation and alterations in neurotransmitter circuits. HCV and its pathogenic role is suggested by enhancement of psychiatric and neurological symptoms in patients attaining a sustained virologic response followed by treatment with interferon; however, further studies are required to fully assess the impact of HCV infection and its specific antiviral targets associated with neuropsychiatric disorders.

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** There is high prevalence rate of neuropsychiatric ailments with respect to patients infected with chronic hepatitis C virus (HCV). Brain inflammatory disorders, cerebrovascular disease peripheral neuropathy, psychiatric disturbs and cognitive symptoms are the complex clinical signs which occurs when infected by chronic HCV infection. HCV prompts psychiatric and neurological symptoms through numerous pathways with imprecise mechanisms, which includes neurotransmitter and metabolic pathway imbalance, immune-mediated responses and direct brain neurotoxicity inflammation. Awareness of HCV-associated neuropsychiatric disorders and its pathogenic mechanisms is vital to understand the clinical manifestations and to introduce an applicable treatment.

## INTRODUCTION

Hepatitis C virus (HCV) with a prevalence rate of 2.8% globally, affects around 185 million people<sup>[1]</sup>. Targeting mainly liver parenchymal cells (hepatocytes), HCV causes severe hepatitis, cirrhosis that could lead to hepatocellular carcinoma if left unattended. It may affect other organs too<sup>[2]</sup>. The association of hepatitis with insulin resistance and diabetes type 2 is well documented. Nevertheless it has also been correlated to various other organs like eye, gut, kidney, thyroid and cardiovascular complications leading to rheumatic diseases, neuropathology, and dermatological complications<sup>[3-8]</sup>. Hence, it could be considered a systemic complication, due to its ability to use cellular machinery for replication regardless of the organ<sup>[9]</sup>. How HCV is correlated with extrahepatic complications is poorly understood. Nevertheless, chronic infections are characterized by hepatic and systemic inflammation through activation of several signaling pathways and through their effect of release of various cytokines and augmented oxidative stress<sup>[10]</sup>. HCV infection could directly or indirectly cause systemic inflammations by inducing immunological response to the disease and metabolic imbalance.

The correlation of HCV disease covers a wide spectrum of clinical manifestations therefore it necessitates the importance of understanding the disease in this context, clinically, to overcome these manifestations in a more robust way. It is reported that chronic HCV infection

has been associated with neurological as well as psychiatric conditions in upto about 50% of the cases<sup>[11]</sup>. Major HCV related neurological ailments comprise of autoimmune disorders, cerebrovascular events, myelitis, encephalopathy, encephalomyelitis, and cognitive impairment; psychiatric disorders include, anxiety depression, and fatigue<sup>[12,13]</sup>. All the aforementioned complications that are manifested by HCV infection, regardless of the severity of disease<sup>[14]</sup>. There seems to be a lack of knowledge about how hepatitis is linked to numerous complications though it's certain that the brain can be a suitable site for viral replication<sup>[15]</sup>. Nevertheless sequence analysis of HCV residing in liver and brain show variability suggesting an evolutionary path that a virus may embark on to be able to infest the central nervous system (CNS)<sup>[14,16]</sup>.

## CNS INVOLVEMENT IN HCV INFECTION

HCV infection has been correlated to numerous neurological disorders ranging from meningeal to encephalic inflammation and leukoencephalitis<sup>[17,18]</sup>.

Clinically a wide range of complications have been associated with HCV infection, ranging from encephalomyelitis to loss of neurons though sphincter impairment, spastic quadriparesis and sensory dominate the clinically know complication<sup>[17]</sup>. Finding the viral genome in brain during postmortem signifies the correlation of disease with neurological pathology. HCV related transverse myelitis and neuronal malfunction has been well documented<sup>[19-22]</sup>.

Severe demyelination in addition to the infiltration of parenchyma and perivascular T cells has been linked to HCV infection by examining spinal cord biopsy. The commencement of the disease is indicated by acute partial transverse and myelopathy transverse myelitis, or else by sensory ataxia or spastic paraplegia. Recurrence and multi-segmental spinal involvement are commonly reported. A patient with no sign of virus but positive for anti-HCV antibodies postulates an immune mediated response leading to neurological complications.

Chronic HCV has also been associated with severe encephalomyelitis<sup>[23,24]</sup>. Magnetic resonance imaging (MRI) reports point toward CNS injuries in the cerebral and cerebellar white matter. Clinically, dysfunctional psychomotors, consciousness, hemianopsia, urinary retention, hemiparesis and other neurological defects are documented. HCV has been proposed to prompt demyelination *via* an immune-mediated response. These findings proposed that in cases with acute disseminated encephalomyelitis the likelihood of HCV infection increases<sup>[11]</sup>.

## NEUROPHYSIOLOGICAL SYMPTOMS

Around 50% HCV infection patients complain of neuropsychiatric symptoms, brain fog, fatigue, and also show quality of life impairment upto some extent, regardless liver disease severity<sup>[25]</sup>. During the onset of the disease

HCV patients report complications like, fatigue, malaise, maintaining attention and forgetfulness. In a study on 37 HCV infected patients without other complications by McAndrews *et al.*<sup>[26]</sup>, verbal learning impairment and lack of attention were observed. A correlation of cognitive impairment and fatigue with HCV infection was observed in half of the patients observed in a study conducted by Weissenborn *et al.*<sup>[27]</sup>, comparing neuropsychological functioning of HCV positive patients with normal liver function; though in another study by Montagnese *et al.*<sup>[28]</sup>, an exceptionally high incidence of fast ( $\beta$ -dominated) electroencephalograms was documented.

## REPLICATION OF HCV IN BRAIN

HCV, though primarily infecting the liver, is frequently associated with CNS abnormalities<sup>[27]</sup>. Neurocognitive defects in chronic HCV infection independent of hepatic encephalopathy is increasingly reported in several studies<sup>[10,26,29]</sup>. It is however unclear if the CNS itself supports the viral replication. A recent study has shown the expression of HCV receptors in the brain microvascular endothelial cells. Interestingly, the microvascular endothelia are the only cells in the neuronal pool to bear the receptors for HCV<sup>[30]</sup>. Microvascular endothelial cells, that form integral components of blood brain barrier (BBB), are thus assumed to play critical role in the transit of HCV into CNS<sup>[30]</sup>.

Quantification of HCV RNA in the brain, liver and plasma have shown a 1000-10000 fold lower load in brain compared to the liver. The HCV RNA was detected in a minimum of one region of the brain of four HCV infected subjects, independent of human immunodeficiency virus (HIV) co-infection status. The viral RNA quantities from the brain and liver - however significantly varied between clinical samples, which may be due to a higher postmortem interval resulting in the degradation of RNA in some sample<sup>[30]</sup>. The E1 and 5' untranslated region sequences of HCV also varies between the liver, brain and plasma, further reinforcing the hypothesis of HCV replication and involvement in the brain<sup>[31-33]</sup>.

Visualizing the hepatocytes expressing HCV antigen is difficult due to the low cellular viral<sup>[34,35]</sup>. Based on the relatively low HCV RNA content in brain to the liver, detection of HCV antigen in the brain is extremely challenging, and existing imaging methodologies are not sensitive enough to detect the cells of CNS that are infected by the virus<sup>[29]</sup>.

Prior studies have shown the presence of HCV RNA in microglia and astrocytes that were also isolated by laser capture microdissection<sup>[36,37]</sup>. Another study has shown that two independently derived brain endothelial cell lines (hCMEC/D3 and HBMEC) facilitate the entry and replication of the virus. Antibodies specific for CD81, SR-BI, and claudin-1 inhibited the infection, demonstrating a common receptor dependent entry pathway for hepatocytes and hepatoma-derived cell lines<sup>[30,38,39]</sup>. All these studies have shown that the viral entry may not

be limited to hepatocytes. mRNA and protein profile database have shown the expression of CD81, SR-BI, and claudin-1 in epithelial and endothelial cells derived from various tissues<sup>[40,41]</sup> strongly suggesting that HCV infection may be supported by extrahepatically<sup>[29]</sup>. Besides, the entry of HCV into the brain endothelial cells, its replication has also been observed. The HCV infected hCMEC/D3 cells release lower level of virus that can potentially infect hepatoma cells, thereby spreading infection which was CD81 dependent.

Studies have also shown that ApoE plays important role in the infection of brain endothelial cell<sup>[42,43]</sup>. This is evident by the neutralization of HCV infection in hCME/D3 cells by ApoE antibodies, while only partially neutralized Huh 7 further, underlining its role in exacerbation of infection in the hCME/D3 cells<sup>[30]</sup>.

The tight junction between endothelial cells forming the BBB restricts the exchange of substances between the blood and CNS. Moreover, the receptor-mediated efflux transport systems further restrict the entry of hydrophilic molecules into the brain<sup>[44]</sup>. The presence of multidrug resistance proteins such as the P glycoprotein in the BBB provide a protective niche for the replication of virus by restricting the access of antiviral drugs in patients treated for HCV infection<sup>[45]</sup>. Studies have also shown the inhibition of HCV replication through antiviral agents targeting NS3 protease and NS5B polymerase enzymes *in vitro*<sup>[30]</sup>.

Disruption of BBB result in enhanced access of pathogens such as the HIV and west Nile virus into the CNS<sup>[46,47]</sup>. Infection of hCMEC/D3 is associated with enhanced HCV RNA and antigen expression as confirmed by TUNEL staining with increased permeability to FD-70 a paracellular permeability marker.

In conclusion, it was observed that the brain microvascular endothelium, expressing the major viral receptors essentially contribute to the CNS infection of HCV. Specific brain endothelial cell lines have been identified to support the entry and replication of HCV in the brain that may be controlled by antibodies specific for HCV receptor-such as interferon and antiviral agents.

Low level release of virus by HCV-infected hCMEC/D3 cells with cytotoxic properties supports a model in which the BBB provides - an ideal extrahepatic environment for infection, implying a direct role of HCV to induce neuropathology<sup>[30]</sup>.

## MECHANISMS CONTRIBUTING TO NEUROLOGICAL DYSFUNCTION

HCV could lead to various CNS complications ranging from cerebrovascular events to autoimmune syndromes. Acute cerebrovascular events which includes transient ischemic attacks, ischemic stroke and lacunar syndromes have been reported in patients suffering with HCV<sup>[13,48,49]</sup>. Occurrence of occlusive vasculopathy as well the vasculitis is also the well-known events<sup>[50,51]</sup>. Isolated CNS vasculitis could lead to the narrowing of

cerebral arteries<sup>[52]</sup>. In few of the patients, the CNS ischemic changes might be possible in the setting of an anti-phospholipid associated syndrome or it might be associated with the anti-neutrophil cytoplasmic antibodies<sup>[53]</sup>. A recent study has shown the HCV-metabolic syndrome association with an evidence that HCV infection is a great risk factor for an enhanced thickness in the carotid wall and plaque formation, thus is a major contributory factor of cerebrovascular mortality specifically in the patients who have higher levels of HCV-RNA<sup>[54]</sup>.

Encephalopathic syndromes that have been clinically characterized by confusion, altered consciousness, cognitive impairment, dysphagia, and dysarthria are linked with the diffuse involvement of white matter in HCV patients with cryoglobulins and/or circulating anticardiolipin antibodies. The patients suffering with these syndromes have also shown small lesions in the sub-cortical regions and periventricular white matter. Additionally, alterations in severe and diffuse infra and supratentorial white matter that could cause vasculitis have been observed in patients with coincidental systemic vasculitis. Another study has shown that a CNS vasculitis-induced ischemic damage in a patient that also suffering with mixed cryoglobulins (MC), peripheral neuropathy, and relapsing multiinfarct encephalopathy<sup>[55]</sup>. The neuropathological examination of this patient has shown multiple ischemic lesions (0.5-3 mm in diameter) in the white matter of cerebral hemispheres, cerebellum, parenchymal infiltration, and an accumulation of the lymphocytes around small vessels. Further study has also shown the incidence of vasculitis-induced ischemic changes in a patient that was suffering with chronic HCV, MC, and sensory neuropathy<sup>[56]</sup>.

Besides the encephalopathic syndromes, cognitive decline that has been clinically characterized by an impaired attention, visual constructive, and spatial functions have been associated with an enhanced occurrence of periventricular white matter high intensity signals (WMHISs) on T2-weighted MRI<sup>[56]</sup>. The patients have shown a relationship between CG level and number of impaired cognitive functions whereas no correlation was observed with systemic manifestations of CG, including peripheral neuropathy. A variation in the WMHIS has shown vessel disease that could lead to chronic hypo-perfusion of white matter and local alterations of blood-brain barrier<sup>[57]</sup>. Spectrum of CNS syndromes encountered in HCV patients is not restricted to the foregoing vasculitic and vasculopathic forms but also causes inflammatory disorders such as an acute encephalitis, meningoradiculitis and encephalomyelitis. Studies have also shown the patients suffering with leuko-encephalitis and perivascular T-cell infiltration in association with HCV genome<sup>[18]</sup> or fatal progressive encephalomyelitic syndromes<sup>[17]</sup>. Another study has shown a patient suffering with an acute disseminated encephalomyelitis, an autoimmune post-infectious CNS disease that has been developed after HCV-infection

which supports the role of cellular immune-mediated mechanisms in CNS complications of HCV infection<sup>[24]</sup>.

Most of the patients with chronic HCV-infection complain of fatigue, poor memory and impaired concentration. Fatigue, mood alterations and cognitive dysfunction has shown a disturbed social and physical activity of the patients. Few of the HCV patients with severe fatigue also complain of sleep disturbances, restless leg syndrome, muscle and joint pain, and depression. A recent study of 53 HCV-positive patients with neuropsychiatric has shown an increase choline and myo-inositol concentrations in the basal ganglia and white matter, and an increase in the concentration of creatinine, N-acetyl-aspartate (NAA), and N-acetyl-aspartyl-glutamate in basal ganglia<sup>[58]</sup>, these findings are consistent with the HCV-induced chronic cellular inflammation. Another study revealed an increased ratio of choline/creatine (Cho/Cr) in the basal ganglia as well as the frontal white matter of HCV infected patients through magnetic resonance spectroscopy<sup>[59]</sup>. Further findings have shown<sup>[60]</sup> a lower level of NAA/Cr ratio in the frontal grey matter of HCV-patients without any change in the Cho/Cr ratio. Both findings have suggested the occurrence of an increased cell membrane turnover and reduced neuronal function<sup>[27]</sup>. Use of ondansetron which is a competitive antagonist of serotonin receptors has ameliorated fatigue in HCV infected patient. Also, the placebo controlled randomized study of thirty six HCV infected patients have shown an improved fatigue and depression scores with ondansetron<sup>[61]</sup>. These studies have shown an important role of serotonergic pathway dysfunction that causes fatigue, reduced level of serum tryptophan, and a reduced synthesis of serotonin<sup>[62,63]</sup>. Moreover, findings of fifteen HCV infected patients reporting neuropsychiatric symptoms was carried out through different neuropsychological tests including 18F-fluoro-desoxy-glucose, serotonin, and positron emission tomography. The results have shown significant decrease in striatal and midbrain dopamine availability and decrease metabolism in limbic, parietal, frontal, and temporal cortices. These findings further confirmed significant role for defective dopaminergic transmission in causing cognitive impairment in the HCV<sup>[64]</sup>. The HCV infection has also been linked with myopathy and a few cases of non-inflammatory and inflammatory myopathies were reported. The clinical features of HCV associated myopathies ranging from progressive weakness to relapsing forms, mild increase in muscle enzymes, and moderate weakness. In non-inflammatory myopathies, pathological features include vacuolar changes<sup>[65]</sup> and necrotizing myopathy<sup>[66]</sup> with slow or progressive proximal weakness, and selective atrophy of type 2 fibers in relapsing myopathy. Study has showed the oxidative mitochondrial damage in a patient with severe ptosis, generalized weakness, diplopia and respiratory involvement, and ultra-structural changes of mitochondrial shape, and cristae<sup>[67]</sup>. Additional findings have showed that HCV promotes tumor necrosis factor -

mediated apoptosis in myocytes<sup>[68]</sup>.

## CRYOGLOBULINEMIA

Cryoglobulins are immunoglobulins in nature. They are able to clump together at temperatures below 37 °C<sup>[69,70]</sup> causing organ damage chiefly through two main pathways, vascular sludging (Hyperviscosity syndrome, associated with type I cryoglobulinaemia) or immune-mediated (Vasculitis, associated with mixed cryoglobulinemia)<sup>[70]</sup>. Causes of cryoglobulinaemia range from, infections, autoimmune disorders and malignancy though the main culprit is HCV<sup>[70]</sup>. Our understanding of cryoglobulinaemia advocate successive antiviral therapy in conjunction with targeted therapy rather than following a monotherapeutic<sup>[71,72]</sup>.

While our understanding of the disease progression still has loop holes, chronic immune stimulation/lymph proliferation due to increased cryoglobulins production, formation of complex by cryoglobulins or their antigens and their inadequate clearance are considered to be three main causative factors of cryoglobulinemia.

## TYPES OF CRYOGLOBULINEMIA

Type I cryoglobulinemia is characterized by monoclonal globulins produced during lymphoproliferative disease. These Igs precipitate during exposure to cold, leading to inflammatory vasculitis and vessel obstruction.

Types II and III cryoglobulinemia is associated with increased production of cryoglobulins by proliferative B-cells clones<sup>[72,73]</sup>. Chronic HCV infection may trigger hyperactivation of B-cells causing infection *via* CD81, a cell surface protein<sup>[74,75]</sup>.

## HCV IN CRYOGLOBULINEMIA

Detection of HCV in 1989<sup>[76]</sup> significantly changed the course of scientific research from fundamental to HCV-oriented cryoglobulinaemia<sup>[77]</sup>. Ferri *et al*<sup>[78]</sup> detected circulating HCV-RNA in almost 90% of subjects with mixed cryoglobulinemia, though subsequent analyses by other groups discovered wider ecological. HBV is found to be associated with mixed cryoglobulinemia whereas HCV is primarily correlated with type II cryoglobulinaemia<sup>[79]</sup>. HIV infected patients have low percentage (7%-17%) of cryoglobulinemia but rises to almost 65% in patients coinfecting with HCV<sup>[78]</sup> that can be reduced by anti-retroviral therapies<sup>[79]</sup>. Apart from viral infections the disease has also been associated with a wide range of other infectious.

HCV infection is an important model to understand the mechanisms that lie behind cryoglobulinaemic etiology. HCV lympho-tropism is the first step in B-cell hyper proliferation, regardless of cryoglobulinaemia<sup>[78,80]</sup>. E2 an HCV envelope protein interacts with the major extracellular loop of tetraspanin CD81, a signaling protein expressed by hepatocytes, B and T lymphocytes<sup>[74]</sup>. This interaction purportedly triggers prolonged

B-cell stimulation<sup>[81]</sup>. B-cell clones are found in peripheral blood, bone marrow, and liver HCV patients, predominantly those with type II cryoglobulinaemia. These B-cell clones produce monoclonal IgM with an idiotype, WA that works as a cross-linker, this binds to immunoglobulins directed towards HCV core protein. Precipitates from HCV-related cryoglobulinaemia patients comprise of HCV core proteins and RNA, this means the immune system forms cryoglobulins during chronic HCV infection<sup>[82]</sup>.

## PERIPHERAL NEUROPATHY

Peripheral neuropathy (PN) is a complication secondary to large number of common diseases such as diabetes, thyroid disorders, renal failure, vitamin deficiency and treatments, including viral infection. Degradation of sensory or motor axons commonly occurs which disrupts the effective communication between the central and peripheral nervous system<sup>[83]</sup>. Clinically, PN manifests itself as motor impairment largely resulting in weakness, sensory defects such as numbness, paresthesia, hyperalgesia/allodynia and pain or more severe autonomic dysfunction leading to organ failures. Patients may present with multiple symptoms of varying severity, making it highly heterogeneous, which in turn depends on the underlying trigger<sup>[84]</sup>. Degeneration of axon, vascular occlusion and inflammation<sup>[84]</sup> with perivascular trafficking of mononuclear cells are essential pathologic features of the debilitating condition<sup>[85]</sup>. Demyelization and absence of axonal fascicular differentiation is also reported.

Forty percent to seventy-five percent patients positive for HCV, present with symptomatic PN, being more prominent with HCV associated cryoglobulinemia (CG)<sup>[86]</sup>. Although presence of serum cryoglobulins is a prognostic marker of severe manifestation of PN, symptoms may be reported even in its absence, underlying a direct role of the virus in precipitating the disease<sup>[87]</sup>. Yoon *et al*<sup>[88]</sup> reported 43.5% prevalence of PN in the absence of CG based on clinical and electrophysiological examination of HCV infected patients.

Involvement of peripheral nervous system in HCV infection is variable depending upon age, duration of infection, CG and other comorbidities<sup>[12,88]</sup>. Twenty-six percent to eighty-six percent HCV patients positive for CG present with clinical/electrophysiological PN. Pathogenesis of HCV associated PN is indirect and mostly inflammatory, as the virus itself does not invade the nerve and muscle tissues. Mechanisms proposed to explain the neurologic manifestation of the virus include the vascular deposition of HCV RNA containing CG, direct viral invasion and perivascular inflammation<sup>[89]</sup>.

HCV associated neurologic impairments range from sensory axonopathy to mononeuritis multiplex. Sensory or motor impairment of one or more distal nerves is most frequent, that tends to become symmetric causing loss of sensation and weakness<sup>[90]</sup>. Prevalence of sensory and motor neuropathy with HCV was found to be

9% and 10% respectively<sup>[91]</sup>. Sensory predominant symmetrical polyneuropathy involves perivascular infiltration of lymphocytes and monocytes of small sized vessels. Mononeuritis multiplex, involving one or two non-contiguous nerves, has a more systemic effect and involves inflammation of medium sized vessels with myriad of inflammatory cells accompanied with vascular necrosis that is asymmetric<sup>[92]</sup>. Asymmetrical sensory neuropathies may be large or small fiber. Demyelinating polyneuropathy and polyradiculoneuropathy is less frequently encountered with HCV infection. Pure motor neuropathies and autonomic neuropathies are rare in HCV<sup>[12]</sup>.

Abd El-Kader *et al.*<sup>[93]</sup> estimated the prevalence of PN in patients with HCV related liver disorders based on complete neurologic examination and nerve conduction study<sup>[93]</sup>. Of the 50 subjects included in the study, 22% had sensory abnormalities, 18% had motor impairment while 10% had a combination of both. Furthermore, PN was found unrelated to serum vitamin B12 levels and severity of disease. Distal sensory loss of pain and reflexes may observe on neurologic examination in otherwise asymptomatic patients.

Biasiotta *et al.*<sup>[90]</sup> characterized the clinical and neurological features of HCV related neuropathies. Sixty-eight percent (47 out of 69) of patients were diagnosed with peripheral neuropathy with 45 exhibiting a predominantly sensory, distal symmetric polyneuropathy while 2 showing mononeuropathy multiplex. Thermal pain sensitivity was specifically linked to pure small fiber neuropathy while sensory abnormalities observed in both mononeuropathy multiplex and mixed fiber, distal symmetric polyneuropathy.

PN can be considered a manifestation of HCV induced CG<sup>[86]</sup>. Abnormal immunoglobulin, reversibly precipitating at low temperatures, *i.e.*, 4 degrees, with marked rheumatoid factor activity are produced by B cells, form immune complexes that obstruct vessels and trigger vascular inflammation<sup>[90]</sup>. IgG and IgM are primarily implicated to precipitate HCV associated PN either by their direct binding to myelin inducing an erosive immune attack or as lymphocytic irritant within the vasa nervorum resulting in vasculitis. In one study antibodies against myelin associated glycoprotein were identified to induce the immune trigger<sup>[93]</sup>. Such demyelinating association is rare with an occurrence of 5 per 10000. Anti MAG neuropathy is clinically characterized with sensory ataxia with motor involvement and hand tremor intention involving large nerve fibers<sup>[94]</sup>.

## PSYCHIATRIC DISORDERS IN HCV-INFECTED PATIENTS

HCV like HIV is among the few known infections that cause psychiatric disorders<sup>[95]</sup>. Illicit drug injection (IDU) is a major factor for HCV infection<sup>[96]</sup>. IDU is common among patients who have personality disorders besides alcoholism, illicit sexual behavior and mood

disorders<sup>[97-99]</sup>. Alcohol is predominantly associated with increased prevalence of anti-HCV antibody. Synergy between alcohol and HCV aggravates liver disease and lessens the effectiveness of interferon (IFN) treatment. IFN $\alpha$  is increasingly being used to treat HCV because of its effectiveness though it can induce a variable number of psychiatric disorders like acute confusional state, depressive and agitated manic episode<sup>[100]</sup>. Up to 70% of HCV patients treated with IFN may develop depression<sup>[96]</sup>. This could be attributed to numerous pathophysiological complication that are associated with IFN treatment including distorted monoamine metabolism<sup>[96]</sup>, increase in apoptosis, BDNF reduction, and altered hypothalamus-pituitary-adrenal axis function<sup>[100]</sup>. In one study observing the neurological implication of IFN in conjunction with ribavirin treatment the authors found 1/4 of all the patients developed major depressive disorder (MDD). Higher interleukin 6 concentrations in serum, history of psychiatric condition, depression and low educational level considerably increases the incidence of MDD during antiviral therapy<sup>[101]</sup>. Symptoms of neuro-vegetative depression start to occur early during treatment though cognitive symptoms start in a span of 4 wk of IFN treatment<sup>[96]</sup>. Depression, anxiety, and cognitive impairments can be treated through serotonergic antidepressants, while neuro-vegetative symptoms like loss of appetite, fatigue, sexual impairment, and psychosomatic symptoms are not much responsive to treatment by SSRIs<sup>[102]</sup>. Hence serotonin-norepinephrine reuptake inhibitors, bupropion, methylphenidate or modafinil are used to address neuro-vegetative disorders<sup>[100]</sup>. Confusional state induced by IFN $\alpha$  is associated with psychomotor retardation, disorientation, Parkinsonism, and psychosis in addition to induction of manic disorder. In case of acute mania mood stabilization and antidepressants are administered<sup>[100]</sup>. HCV patients with MDD or bipolar symptoms are more prone to psychiatric disorders as compared to patients with no psychiatric illnesses during treatment with IFN<sup>[96]</sup>. It's not just IFN but HCV itself might be associated with mood disorder. This can be in part linked to factors such as high-risk behavior, stigma and drug abuse. Nevertheless, evidence suggests the association some HCV genotypes such as 3a are related to risk of depression<sup>[103]</sup>. Neuronal invasion by HCV is another factor that could lead to mental distortion<sup>[103-105]</sup>.

## ANTIVIRAL TREATMENT

HCV related CG is clinically challenging. Use of immunosuppressive agents such as glucocorticoids and cytotoxic drugs is not recommended to manage CG induced severe neuropathic pain, because of the ensuing viral infection. Interestingly, antiviral agents considerably improve symptoms, underlining pathogenic role of virus in precipitating the secondary symptoms. Targeting the underlying viral infection is thus a reasonable strategy to treat HCV associated CG symptoms, although the response produced would be slow. Additionally, anti-

ral therapy suppresses B cell proliferation in the bone marrow, thereby controlling CG in more than one way. However, achieving a sustained virologic response is critical for the success of these therapies<sup>[86]</sup>. Immunosuppression prior to induction of antiviral therapy can be considered in patients with severe symptoms to obtain a reasonable and timely therapeutic response. Ideally, a combination of immunosuppressive and an anti-viral agent is highly desirable that can directly act on the proliferating B cells while simultaneously wiping out the etiologic trigger, *i.e.*, the virus<sup>[106]</sup>.

IFN $\alpha$  is a cytokine produced by cells that primarily modulates the immune response during viral infections<sup>[83]</sup>. Interferon in combination with other drugs is an essential component of HCV therapy. Therapeutic utility of IFN lies in their ability to decrease virus replication rate, inhibit lymphocyte proliferation, Ig synthesis with enhanced immune complex competency and macrophage activity<sup>[86]</sup>.

IFN $\alpha$  monotherapy, although active against virus, was associated with heightened autoimmunity<sup>[107]</sup>. Thus, the IFN $\alpha$  itself is assumed to brew the pathogenic inflammatory environment for neuropathy *via* immune mediated myelin degradation and vessel occlusion causing nerve ischemia, in the absence of CG. Despite its increased high autoimmune titer, IFN $\alpha$  forms the core of HCV therapy. Peg IFN $\alpha$ -ribavirin is clinically, virological, immunologically superior to IFN $\alpha$ -ribavirin and is recommended in mild to severe cryovas with HCV. Moreover, it was associated with shorter duration of therapy, less frequent side effects and deaths producing, sustained virologic response in 60% patients<sup>[84]</sup>. Therapeutic success of the combination varies between 48%-88% depending upon the HCV genotype. Reduction of neuropathic pain in HCV positive patients was observed from 65.2% to 22.1% after peg IFN and ribavirin therapy<sup>[108]</sup>. Chronic inflammatory demyelinating polyneuropathy, reported in a minority of HCV infected population, was significantly corrected with IFN $\alpha$  and ribavirin therapy, although a few studies have classified it as a side effect of IFN $\alpha$ <sup>[109]</sup>. In that case, intravenous Ig administration and plasma exchange were effective for management of PN. The efficacy of ribavirin in reducing PN is attributed to its viral clearance, decreasing inflammation, circulating cryoglobulins and anti MAG antibodies<sup>[83]</sup>.

In patients not responding to antiviral therapy, addition of protease inhibitors telaprevir/boceprevir significantly enhanced the clinical outcome. Potency of the triple antiviral therapy was comprehensively described by Saadoun *et al.*<sup>[110]</sup>. In a cohort with genotype 1 HCV and CG. Patients randomly received either telaprevir/boceprevir with peg IFN $\alpha$ /ribavirin for 48 wk and were followed up to 6 mo after treatment. Of the 56.6% patients included in the study with peripheral neuropathy, 47% showed improvement after treatment as clinically assessed by the neuropathy total symptom score. The study further highlighted the clinic considerations for the success of the triple antiviral

therapy.

Successes of these trials have driven the direct use antiviral agents to reduce cryoglobulinemia and related symptoms associated with HCV. The NS3/4A inhibitor simeprevir and the NS5B inhibitor sofosbuvir have recently been approved, for their nearly absolute sustained virologic response 95% with minimum toxicities<sup>[106]</sup>. The magnified therapeutic response is due to their shortened courses of combination IFN free therapy.

Rituximab, a CD 20 monoclonal antibody, directly acts by arresting cryoglobulins production and its subsequent pathogenic cascade<sup>[108]</sup>. Rituximab monotherapy is thus highly relevant in treating cryovas emergencies such as neuropathic pain<sup>[111]</sup>. However its sole efficacy in reducing PN has not been satisfactorily assessed. In one study, 36% patients showed a subsidy in peripheral neuropath with rituximab administration.

Studies have reported higher efficacy and safety of rituximab against the conventional immunosuppressive agent's, *i.e.*, glucocorticoids, azathioprine and cyclophosphamide to treat cryovas. An early clinical remission of cryovas with rituximab therapy was reported in patients with HCV, who did not show improvement with previous antiviral treatment<sup>[111-113]</sup>. Patients with liver cirrhosis, not eligible for antiviral treatment, also showed improvement with rituximab therapy, with enhanced protidosynthetic and ascites activity of the liver.

Rituximab monotherapy effectively alleviated MC symptoms in about 71.4%-84% HCV patients<sup>[111,112]</sup>. Rituximab given in combination peg IFN $\alpha$ -ribavirin was evaluated in patients with severe HCV-cryo, resistant to IFN $\alpha$  combination therapy. Of the 16 patients enrolled, 15 showed marked clinical improvement with 10 complete responders. Efficacy and safety of peg IFN $\alpha$ /ribavirin with and without rituximab was evaluated in two separate studies. Rituximab with the antiviral regimen produced earlier clinical remission<sup>[114-116]</sup>.

Recently, low dose of interleukin 2 (IL2) has emerged as a promising approach based on the presence of defective regulatory T cells in HCV-cryo. CD4<sup>+</sup> CD25<sup>+</sup> Fox P3<sup>+</sup> T cells are assumed to be responsible for disease refractoriness, after the complete resolution of HCV and vasculitis<sup>[117,118]</sup>. These are regulatory cells that control the autoimmune response of the body and their deficiency during viral infection account for the expansion of holistic B cells. Efficacy of low dose IL2 in patients with refractory HCV-cryo was assessed in a prospective open labeled phase I / II a trial wherein IL2 increased the percentage of the regulatory T cells while decreasing the B cells<sup>[119-121]</sup>.

## DISCUSSION

Antiviral treatment should be the first line treatment for managing mild to moderate vascular and neurologic symptoms. Symptoms usually recede with an optimum sustained virologic response. Rituximab therapy should be opted for patients with severe exacerbations of secondary symptoms. Plasmapheresis may be required

before placing patients on the antiviral therapy. Patients on IFN therapy should be monitored as IFN therapy may aggravate the symptoms. Corticosteroids may be used for temporary relief of minor inflammatory pain. Immunosuppressant should be the last resort opted in patients not responding to antiviral treatment/refractory disease.

## CONCLUSION

Age and duration of HCV infection are the major clinical determinants of PN. Furthermore, it was found that duration of HCV infection and not the presence of cryoglobulins, was related to PN. Clinically, Neuropathic pain with HCV should be approached with a multimodal approach, with the prime objective being reducing the viral load, that automatically resolves secondary symptoms. Treatment should be strategized based on the severity of the disease and patients response. Addition of steroids, tricyclic antidepressants, local anesthetics and opioids may be required to the standard antiviral therapy, in case of acute pain attacks. Persistence or relapse of neurologic symptoms despite viral clearance may be indicative of other seeding conditions.

### Abstract

Hepatitis C virus (HCV) affects about 3% of the world's

population, with the highest prevalence in individuals under 40. The prevalence in pregnant women varies with geographical distribution (highest in developing countries). Prevalence also increases in sub-populations of women at high risk for blood-transmitted infections. HCV infection in pregnancy represents a non-negligible problem. However, most of the past antiviral regimens cannot be routinely offered to pregnant or breastfeeding women because of their side effects. We briefly reviewed the issue of treatment of HCV infection in pregnant/breastfeeding women focusing on the effects of the new direct-acting antivirals on fertility, pregnancy and lactation in animal studies and on the potential risk for humans based on the pharmacokinetic properties of each drug. Currently, all new therapy regimens are contraindicated in this setting because of lack of sufficient safety information and adequate measures of contraception are still routinely recommended for female patients of childbearing potential.

**Key words:** Hepatitis C virus infection; Breastfeeding woman; Antiviral therapy; Pregnancy category; Direct-acting antivirals

**Core tip:** Until recently, the only drugs available for the treatment of hepatitis C virus infection had a well-documented teratogenic effect limiting their use in childbearing women. Recently, new generation drugs, designated the direct-acting antivirals have been approved. There are no studies available describing their effects on pregnant and lactating women. We here will try to analyze their pharmacokinetic properties and data from animal studies to try to predict their potential use pregnancy.

## INTRODUCTION

Hepatitis C virus (HCV) infection is a major public health problem that affects more than 150 million people (about 3% of the world's population), most of whom are unaware of their infection<sup>[1,2]</sup>. The prevalence of HCV infection is between 0.5%-2% in most European countries and in the United States, in which 5-10 million and almost 4 million people, respectively, are affected, most of whom are in the fourth decade of life<sup>[1,3-5]</sup>. Differently, the prevalence of HCV infection exceeds 10% in some developing countries (especially in Africa, Asia and South America)<sup>[1]</sup>. One of the modes of HCV transmission is vertical transmission. Rates of vertical transmission of HCV infection range between 2%-10%<sup>[4]</sup>. Although HCV infection acquired at birth may resolve spontaneously, about 25000 to 50000 of children become chronically infected<sup>[4-7]</sup>. The prevalence of HCV infection in children is very low in Europe and the United States (0.05%-0.36%)<sup>[8]</sup>, and increases to between 1.8% and 5.8% in Egypt (which has the highest prevalence of pediatric HCV infection), Sub-Saharan Africa, Mongolia and the Amazon Basin<sup>[8]</sup>. Consequently, birth to an infected mother is one of most frequent routes of infection, and is comparable to injection drug use, unsafe medical practices and high-risk sexual practices<sup>[1]</sup>.

Acute HCV infection, asymptomatic in most cases, can progress to chronic hepatitis in more than half the patients. Chronic hepatitis C is associated with progression to fibrosis, which leads to liver cirrhosis in about 10% to 20% of patients within 20-30 years. Lastly, from about 1%-5% of cirrhotic patients can develop hepatocellular carcinoma each year<sup>[2]</sup>. Currently, HCV-related liver cirrhosis is the major cause of liver transplantation in developed countries<sup>[1,2]</sup>. Notwithstanding the decline in the number of cases of acute HCV infection, the burden of liver cirrhosis, hepatocellular carcinoma and HCV-related death remains high due to the existence of a reservoir of infected patients<sup>[1,3]</sup>.

The epidemiology of hepatitis C infection might change radically in the next few years thanks to antiviral therapies that result in viral clearance in terms of sustained virologic response (SVR), namely undetectable HCV RNA 12 wk (SVR12) or SVR24 after treatment completion. HCV infection is cured in more than 99% of patients who achieve an SVR. Generally, liver disease can be cured only in non-cirrhotic patients<sup>[2]</sup>.

The effect of maternal viremia on vertical transmission and on the rate of spontaneous resolution of the acquired infection among newborns is not well defined. However, mothers with undetectable plasma HCV RNA levels rarely transmit HCV by the vertical

route<sup>[4]</sup>. Therefore, it seems reasonable to assume that treatment to decrease viremia in pregnant women with chronic HCV may result in lower rates of vertical HCV transmission.

Until 2011, the standard-of-care therapy for HCV infection, which was based on the association of pegylated interferon (PEG-IFN) and Ribavirin, resulted in an SVR in only 40%-80% of patients depending on HCV genotype (lower for genotypes 1 and 4 than for genotypes 2 and 3)<sup>[2]</sup>. In 2011, new antiviral drugs, namely, direct-acting antivirals (DAAs), became available. These drugs act mainly by targeting the non-structural HCV proteases NS3-4A and NS5A or by inhibiting RNA-dependent RNA polymerase, and are thus referred to as protease inhibitors and inhibitors of HCV RNA-dependent RNA polymerase, respectively<sup>[2]</sup>. Each of these DAAs can be used as a component of combination regimens (with or without PEG-IFN and Ribavirin) and result in SVR rates as high as 60%-100%<sup>[2]</sup>. The SVR rate depends on the DAA used, the HCV genotype, pre-existing amino acid substitutions (that might confer resistance to some DAAs) and the severity of liver disease<sup>[2]</sup>. These new regimens could change both the epidemiology and the natural progression of hepatitis C.

Here we discuss the potential use, in pregnant and breastfeeding women, of the antiviral therapies (including DAAs) licensed for the treatment of chronic C hepatitis. We also examine the adverse effects of anti-HCV drugs on fertility, pregnancy and lactation (in particular, embryo toxic and teratogenic effects). In this context, no antiviral therapy has yet been approved for use in childbearing women, and therefore little is known about the effects of anti-HCV drugs on pregnancy and lactation in this population. Consequently, our discussion and conclusions are based principally on data derived from animal studies<sup>[9-15]</sup>.

## ANTIVIRAL THERAPY OF HEPATITIS C IN CHILDBEARING WOMEN

Hepatitis C infection in pregnant and breastfeeding women is not a negligible problem. About 1%-8% of pregnant women have markers of HCV infection, and the prevalence is lower in western/northern countries than in Eastern/Southern countries<sup>[11,15]</sup>. Since, HCV infection is usually asymptomatic, most infected women are unaware of their status and may be diagnosed with chronic C hepatitis incidentally when undergoing serological tests during pregnancy or before delivery. For example, in Italy, free-of-charge screening for HCV, HBV and the human immunodeficiency virus, is routinely offered to all pregnant women from the 33<sup>rd</sup> to the 37<sup>th</sup> week of gestation<sup>[16]</sup> and reveals many cases of previously undiagnosed chronic C hepatitis. Notably, the number of HCV-infected childbearing women is expected to increase with the increase in the migratory flow from developing countries to Western/Northern countries. As mentioned above, the vertical transmission

of HCV infection is now one of most frequent routes of transmission<sup>[1]</sup>. Consequently, eradication of the virus in pregnant women and women of childbearing age is the main target in the prevention and control of HCV infection<sup>[4]</sup>. Problems related to the treatment of HCV infection in pregnant and breastfeeding women are not rare. In a developed country such as the United States, pregnancy is the third most common contraindication to treatment and delayed treatment onset in about 2% of more than 45000 HCV-infected patients<sup>[17]</sup>. In addition, in the same study about 1.3% of women undergoing antiviral therapy for HCV became pregnant during therapy<sup>[17]</sup>. Thus, the problem is not only whether or not to start treatment in a pregnant and/or breastfeeding woman, but also how to manage a woman who becomes pregnant during antiviral therapy.

### ***The past of antiviral therapy: PEG-IFN/Ribavirin and PEG-IFN/Ribavirin plus first-generation DAAs***

For many years, the two cornerstones of the standard-of-care treatment of HCV infection were IFN and Ribavirin, both of which have side-effects and contraindications that limited their use in the setting of pregnant/breastfeeding patients<sup>[18,19]</sup>. IFN- $\alpha$  is a protein released in response to viral infections. It binds to specific receptors on the cell surface thereby promoting a complex cascade of protein-protein interactions that rapidly activate gene transcription. IFN-stimulated genes regulate many biologic effects (*i.e.*, inhibition of viral replication in infected cells, inhibition of cell proliferation and immunomodulation). The United States Food and Drug Administration (FDA) classified the first pharmacological formulation of IFN- $\alpha$  in Pregnancy Category C since the molecule had an abortifacient effect in animals (rhesus monkeys) during the early/middle fetal period of organogenesis and late fetal development<sup>[20,21]</sup>. The drug may also impair fertility; in fact, menstrual cycle irregularities, namely, prolonged or shortened menstrual periods and erratic bleeding, have been observed in nonhuman primates, and menstrual rhythm normalized upon treatment discontinuation<sup>[22]</sup>. Decreased serum estradiol and progesterone concentrations have been reported in women treated with human leukocyte IFN although no mutagenic effect or toxicity has been reported<sup>[22]</sup>. Given the species-specificity of IFN, effects in animals are unlikely to be predictive of those in humans<sup>[20,21]</sup>. Nevertheless, in clinical practice, IFN- $\alpha$  is widely used in most pregnant women affected by essential thrombocythemia to prevent or reduce the risk of thrombocythemia-related fetal loss<sup>[22]</sup>. The risk of major malformation, miscarriage, stillbirth or preterm delivery does not seem to be significantly higher in this setting than in the general population<sup>[22]</sup>.

Also the pegylated formulation of IFN- $\alpha$  (PEG-IFN- $\alpha$ ) should be assumed to have abortifacient potential despite the lack of well-controlled studies in pregnant women<sup>[23,24]</sup>. Apart from the potential risks for the fetus, a major concern is the risk of serious IFN-related adverse effects on the patient's psychological status,

namely exacerbation of postpartum depression<sup>[18]</sup>. Therefore, pregnant candidates for PEG-IFN treatment should undergo psychiatric evaluation. The degree of IFN excretion in human milk is unknown. However, given the potential risk of serious adverse reactions to the drug in nursing infants, IFN is contraindicated in children below the age of 2 years<sup>[20,21,23,24]</sup>. The decision whether to discontinue nursing and to initiate antiviral therapy depends solely on whether or not the progression of maternal liver disease must be immediately blocked. Given its low SVR rate (< 30%), PEG-IFN mono-therapy has been widely used in recent years in association with Ribavirin<sup>[25]</sup>. The combination of PEG-IFN and Ribavirin increased the SVR24 to 40% in North America and to 50% in western Europe in patients infected with HCV genotype 1<sup>[25]</sup>. Even better results were obtained in patients with genotypes 2, 3, 5 and 6: The best SVR was achieved in patients with genotype 2 (up to 80% SVR)<sup>[25]</sup>. The results of combined treatment in genotype 4 patients are the same as those obtained in genotype 1 patients or slightly better<sup>[25]</sup>.

Ribavirin is a guanosine analog nucleotide inhibitor that acts by interrupting viral RNA synthesis and viral mRNA capping. It is a prodrug that, when metabolized (into purine RNA nucleotides), interferes with RNA metabolism required for viral replication<sup>[26,27]</sup>. The mechanism underlying this effect is unknown. The FDA classified Ribavirin in Pregnancy Category X<sup>[26,27]</sup> because of its embryocidal and teratogenic effects in animals<sup>[26-28]</sup>. The fetal malformations reported in animal studies include abnormalities of the skull, palate, eye, jaw, limbs, skeleton and gastrointestinal tract<sup>[26-28]</sup>. Therefore, Ribavirin is absolutely contraindicated for both HCV-infected childbearing women and HCV-infected male partners of pregnant women unless they take effective contraceptive measures. In addition, since Ribavirin-induced spermatogenic abnormalities (cell toxicity, mutagenicity and a decreased epididymal sperm count) reverted only 4-8 mo after treatment withdrawal in all animal species studied<sup>[29,30]</sup>, women are advised to avoid pregnancy for at least 6 mo after partners of men taking Ribavirin treatment<sup>[26,27]</sup>.

Between 2003 and 2009, the United States Ribavirin Registry collected the data of 118 babies born to mothers exposed to the drug (49 direct and 69 indirect exposures) during pregnancy: Only six cases of birth defects were reported (torticollis, hypospadias, polydactyly, neonatal teeth, glucose-6-phosphate dehydrogenase deficiency, ventricular septal defect, and cyst of the fourth ventricle of the brain)<sup>[28]</sup>. Despite the low rate of birth defects, it seems reasonable not to encourage or support the use of Ribavirin in pregnant women, and, moreover, to recommend that women avoid pregnancy during Ribavirin treatment.

In conclusion, because of its low SVR rate unless combined with Ribavirin, PEG-IFN should not be administered in childbearing women even though it has not been reported to have abortifacient and/or teratogenic effects.

**Table 1** Main pharmacokinetic properties of the new direct-acting antivirals

Drug	Molecular weight	Effect of food on absorption	Cytochrome P450 enzymes interaction			Binding to plasma protein	Half-life
			Enzyme	Effect of the drug on the enzyme	Effect of the enzyme on the drug		
Sofosbuvir	529.45 Da	Increased absorption, slower rate	NO	None	None	85%	0.5 h/26 h <sup>1</sup>
Simeprevir	749.93 Da	Increased absorption, slower rate	CYP3A4	Inhibitor	Alter AUC	> 99.9%	10-41 h
Daclatasvir	738.98 Da	Decreased absorption <sup>2</sup>	CYP3A4	Weak inducer	Alter AUC	> 99%	12-15 h
Ledipasvir	888.9 Da	No effect	CYP3A4	Weak inducer	None	> 99.8%	47 h
Viekirax	Ombitasvir 894.1	Increased absorption	CYP3A4	Inhibitor	Alter AUC	99.9%	21-25 h
	Paritaprevir 765.8 Da					98.6%	5.5 h
	Ritonavir 720.9 Da					99%	4 h
Dasabuvir	493.5 Da	Increased absorption	CYP3A4	Inducer	None	99.5% (94.5% <sup>3</sup> )	6 h
			CYP2C8	None	Alter AUC

			CYP3A4	Inducer	None		

<sup>1</sup>GS-331007 metabolite; <sup>2</sup>Following a high-fat meal; <sup>3</sup>Dasabuvir M1 metabolite. AUC: Area under the curve; NO: Not metabolized by P450 enzymes; CYP: Cytochrome.

The year 2011 saw the advent of DAAs that target essential components of the HCV life cycle. The first-generation DAAs were the protease inhibitors boceprevir and telaprevir, which were indicated mainly for the treatment of chronic hepatitis C patients infected by genotype 1 virus. Boceprevir is an inhibitor of HCV NS3/4A protease, an enzyme required for the proteolytic cleavage of HCV-encoded polyprotein into mature forms of the non-structural proteins NS4A, NS4B, NS5A and NS5B. Telaprevir is an NS3-4A protease inhibitor that competes with NS5A/5B for its substrate-binding site. The FDA classified both these first-generation DAAs in Pregnancy Category B<sup>[31,32]</sup>. In fact, neither boceprevir nor telaprevir negatively affected fetal development in animals (mice, rats and rabbits). Consequently, in the absence of well-controlled human studies, "no evidence of risk in humans" has been supposed. Nevertheless, the major limitation to the use of these drugs is that they must be administered in association with PEG-IFN and Ribavirin as part of a triple-therapy regimen. Consequently, both boceprevir and telaprevir are contraindicated during pregnancy and adequate contraceptive measures are strongly recommended for both childbearing women and their male sexual partners throughout treatment duration and up to 6 mo after withdrawal<sup>[31,32]</sup>. Lastly, the excretion of protease inhibitors into human breast milk remains to be clarified; the levels of these drugs in the milk of lactating rats can be higher than those observed in maternal blood<sup>[31,32]</sup>.

### Second-generation DAAs

The second-generation DAAs, which became available in 2015, and their principal pharmacokinetic properties are listed in Table 1. Pharmacokinetic data are not complete for all second-generation DAAs. In the absence of data on their properties and effects on pregnant and lactating human females, clinicians can only try to predict the effect that pregnancy-associated physiological changes may have on the peak plasma dose, drug metabolism, and the ability of the drug to cross the placental barrier and/or enter into the mother's milk. Generally, drugs

that are more likely to cross the placenta are lipids or weak acids with a molecular weight below 500 Da, are poorly bound to plasma proteins and have a long half-life. The concentration of the drug in breast milk, and therefore its potential effect on the newborn, depends on dosage, rate of absorption in the maternal circulation, maternal drug metabolism and the time from drug administration to breastfeeding<sup>[33,34]</sup>. In the following section we will briefly review the data on the pharmacokinetics and teratogenicity in animals of the DAAs currently available to try to identify the ones that could potentially be used in childbearing women.

Sofosbuvir (Sovaldi®) is a pangenotypic nucleotide prodrug converted by hepatocytes into its active form that acts by competitively inhibiting the HCV NS5B polymerase active site and thus blocking viral RNA synthesis. It is indicated for the treatment of chronic hepatitis C as a component of a combination antiviral regimen. Neither the area under the curve (AUC) nor the product's absorption changes when the drug is taken with food, which suggests that the prolonged gastric emptying observed in pregnancy would not affect absorption of the drug or the time-to-peak plasma dose. Sofosbuvir is readily available after oral administration, and undergoes extensive first pass metabolism. Gender does not appear to significantly affect its pharmacokinetics<sup>[35]</sup>. Since P450 enzymes do not seem to be involved in metabolizing Sofosbuvir, increased activity of these enzymes in pregnancy is unlikely to affect its plasma concentration. On the other hand, Sofosbuvir has strong affinity for the P-glycoprotein efflux protein (Table 1). The drug is eliminated as GS-331007 in urine. The glomerular filtration rate usually increases during pregnancy and consequently renal drug elimination is generally greater than elimination in the non-pregnant state; however, it is unclear whether this process could alter the plasma concentration of Sofosbuvir to the point of requiring dose adjustment to attain a clinical response. Similarly, it is unclear whether the drug could cross the placental barrier. In studies conducted on animals (rats and rabbits), Sofosbuvir

**Table 2** Effect of new direct-acting antivirals in pregnancy and Food and Drug Administration Pregnancy Categories

Drug		Embryotoxicity and/or teratogenicity <sup>1</sup>	Dose-escalation <sup>2</sup>	Transfer across placenta	Transfer into milk	FDA Pregnancy Category <sup>3</sup>

metabolites crossed the placenta and entered the milk of lactating animals. However, this process did not appear to significantly affect the viability or the development of embryos or fetuses<sup>[34,35]</sup>. Little is known regarding the use of Sofosbuvir in pregnant women. The outcomes of less than 300 pregnancies are mentioned in the product characteristics reports of the European Medical Agency, but no data about those outcomes are available on the Pubmed database. The FDA classified Sofosbuvir in Pregnancy Category B when used alone or with Ledipasvir, and in Pregnancy Category X when used in combination with Ribavirin. The latter combination is strongly contraindicated during pregnancy and adequate contraceptive measures are highly recommended for both childbearing women and their male sexual partners throughout treatment duration and up to 6 mo after treatment withdrawal (Table 2)<sup>[36]</sup>.

Simeprevir (Olysio®) is a specific NS3/4A HCV serine protease inhibitor that interrupts the processing of the HCV-encoded polypeptide thereby blocking the HCV viral life cycle. Simeprevir is considered a second-generation HCV protease inhibitor because its binding affinity and specificity for NS3/4A is higher than that of first-generation protease inhibitors that have a linear structure. It has been approved as part of combination regimens with PEG-IFN and Ribavirin or with Sofosbuvir for the treatment of chronic hepatitis C genotype 1 infection in adults. When Simeprevir is taken with food, its absorption is delayed so that its bioavailability reaches 62% (Table 1). It is therefore possible that the prolongation of gastric emptying observed in pregnancy may also affect absorption and the time-to-peak plasma dose of Simeprevir. After its absorption, Simeprevir undergoes first-pass metabolism by the P450 cytochrome enzymes, mainly the CYP3A4 system (Table 1). It is also a substrate of the P-glycoprotein drug transporters. Plasma levels of Simeprevir change significantly when administered with inducers or inhibitors of CYP3A4. Plasma exposure of simeprevir is greatly affected also by the state of the liver, and there may be an increase of up to 5-fold in the AUC depending on the degree of hepatic impairment. Therefore, the increased activity of the P450 enzymes in pregnancy, and the possible physiopathological changes that may

affect the liver of pregnant women may affect the plasma concentration of Simeprevir. Metabolites of Simeprevir are mainly eliminated *via* biliary excretion. Gender did not appear to have a clinically relevant role on the pharmacokinetics of Simeprevir.

As yet, there are no data concerning the passage of Simeprevir across the human placenta (Table 2), however, animal studies established that the drug is transferred across the placenta, and that it exerts teratogenic effects on the foetal skeletal system, namely supernumerary ribs and delayed ossification at exposures 4-fold higher than those observed at the recommended dose (Table 2). Moreover, Simeprevir can be excreted in the milk of lactating animals. The drug is classified in FDA Pregnancy Category C when administered alone, and Pregnancy Category X when used in combination with Ribavirin<sup>[37-39]</sup>.

Daclatasvir (Daklinza®) inhibits the NS5A protein (Table 1), and appears to act on viral replication, and on the assembly and secretion stages of the viral life cycle, thereby causing a rapid decline in both intra- and extracellular levels of HCV RNA. It is the first NS5A complex inhibitor approved for use in the European Union as part of combined regimens with Sofosbuvir, Ribavirin and PEG-IFN for the treatment of chronic HCV infection in adults. Oral clearance (CL/F) of Daclatasvir is significantly lower in women than in men<sup>[40]</sup>. However, this gender difference does not appear to be clinically relevant. It remains unclear whether the documented non-significant gender difference in oral clearance, and the expected changes in drug bioavailability and clearance in the pregnant state may, together, significantly affect Daclatasvir exposure in pregnant women.

Daclatasvir is a substrate of P-glycoprotein and is metabolized by the CYP3A4 enzyme (Table 1). Dose adjustments are recommended when it is administered with strong inducers of this class of cytochrome enzymes. It is therefore likely that the increased activity of the P450 enzymes in pregnancy would affect the plasma concentration of Daclatasvir.

Daclatasvir is primarily excreted unchanged through the biliary route. Overall, based on its chemical characteristics, it is unlikely that Daclatasvir could cross the materno-fetal circulation at therapeutic doses. However,

Daclatasvir was found to cross the placenta in a study conducted in rats and rabbits<sup>[40]</sup> (Table 2). In the latter study, there was a decrease in the gestational weight of mothers exposed to the drug. Daclatasvir exerted an embryotoxic and teratogenic effect at exposures 4-fold to 16-fold higher than the clinical AUC exposure, and the potential toxic exposure was exponentially greater with the increase in the animals' body surface area<sup>[40]</sup>. In other studies, Daclatasvir was excreted in the milk of lactating animals at concentrations 1.7- to 2-fold higher than maternal plasma concentrations<sup>[40,41-43]</sup>. Daclatasvir has recently received FDA approval for marketing in the United States. At the time of writing this article, it has not been included in a Pregnancy Category.

Ledipasvir is available in a combined formulation with Sofosbuvir called Harvoni. Harvoni is administered alone or in combination with Ribavirin in patients with chronic hepatitis C infection<sup>[2]</sup>. Ledipasvir acts on the replication, assembly and secretion phases of HCV by inhibiting HCV NS5A phosphoprotein<sup>[44]</sup>. Based on the limited data available, Ledipasvir acts only on genotypes 1, 3 and 4. It is gradually absorbed after oral administration; the AUC does not appear to be affected when the drug is administered with meals. Moreover, Ledipasvir does not appear to undergo significant first pass and/or pre-excretory metabolism and it is mainly excreted unchanged through the biliary route, in faeces. Like Sofosbuvir, Ledipasvir is not metabolized by the P450 enzymes. It is therefore unlikely that increased activity of these enzymes in pregnancy affects its plasma concentration. Slow oxidative metabolism of Ledipasvir into M19 has been demonstrated *in vivo*, although the mechanism underlying this process is unknown. However, it is not possible to make any assumption regarding changes in this particular metabolic route in pregnant women. Both the AUC and C-max of Ledipasvir appear to be greater in females than in males, but this difference has not been considered clinically significant by the regulating authorities<sup>[44]</sup> (Table 1).

Studies conducted with animals showed that Ledipasvir crosses the placenta and is excreted in the milk of lactating animals. In non pregnant animals, the number of corpora lutea and implantation sites were decreased with a 6-fold increase in exposure, while in pregnant animals the effects on offspring, *i.e.*, mainly alterations in body weight, were observed at a concentration 4-fold higher than the recommended clinical dosage<sup>[44]</sup>. The FDA categorized Ledipasvir in the Pregnancy Category B when used with Sofosbuvir without Ribavirin<sup>[42-44]</sup> (Table 2).

Viekirax<sup>®</sup> is a combination formulation composed of three pharmacologically active substances, namely Ombitasvir, Paritaprevir and Ritonavir. The combination acts on different steps of the HCV lifecycle: Ombitasvir inhibits HCV NS5A and Paritaprevir inhibits HCV NS3/4A, while Ritonavir, which does not directly affect HCV, acts as a booster of Paritaprevir through its inhibitory effect on CYP3A. Viekirax is indicated only in combination with Ribavirin and/or Dasabuvir (see below) for the treatment

of chronic hepatitis C in adults. The combination reaches T-max 4-5 h after oral administration and requires up to 12 d of dosing to reach steady state<sup>[45,46]</sup>. Exposures of the individual components are affected by drug-to-drug interactions, even with the other components of Viekirax and with Dasabuvir. Food also significantly affects Viekirax absorption. In fact, absorption of the drug is much lower when administered in the fasting state. All three components are highly-bound to plasma proteins and undergo extensive hepatic metabolism. Notably, Paritaprevir is predominantly metabolized by CYP3A4, and therefore requires boosting with Ritonavir, which is also metabolized by the same enzyme. The components of the combination have different half-lives: Ombitasvir has the longest half-life, around 21-25 h and is mainly excreted by the biliary route. Paritaprevir and Ritonavir have a mean half-life of 5.5 and 4 h, respectively and are excreted mainly in faeces with only a small proportion being eliminated renally (8.8% for Paritaprevir and 11.3% for Ritonavir). Since exposures of the three individual components of Viekirax do not seem to vary significantly irrespectively of the degree of renal impairment, therefore renal elimination does not appear to be significant. Exposure of all the three active components of Viekirax is related to gender. In fact, concentrations of Ombitasvir and Paritaprevir were found to be 0.5- and 1-fold higher, respectively in women<sup>[47]</sup>. Moreover, exposure of Ombitasvir was found to be related to body weights. Body weight also affects Ombitasvir exposure but not Paritaprevir exposure (Table 1).

Both Ombitasvir and Paritaprevir/Ritonavir caused malformations in the eyes and teeth of animals at exposures 4-fold higher than the AUC. In the case of Paritaprevir/Ritonavir, an exposure 32/8-fold higher than those observed at the recommended dose resulted in malformation in the offspring of animals, again involving the eyes. Passage of Ombitasvir and Paritaprevir metabolites in the milk of lactating animals, and to a lesser extent through the placenta, has been demonstrated, but no effect was observed in lactating pups. The FDA categorized Viekirax in Pregnancy Category B<sup>[45-47]</sup> (Table 2).

Dasabuvir (Exviera<sup>®</sup>) is a non-nucleoside inhibitor of the HCV RNA-dependent RNA polymerase. It is indicated for the treatment of chronic hepatitis C infection in adults only in combination with Viekirax, thereby forming the "Viekira pak". Dasabuvir reaches T-max 4-5 h after oral administration. Viekira pak reaches steady state after 12 d of dosing. Like Viekirax, Dasabuvir must be administered with food. In fact, taken with food, its exposure is 30% higher than in the fasting state. It is metabolised by the P450 enzymes, namely CYP2C8 and to a lesser extent by CYP3A. Its metabolites are mainly eliminated through the biliary route. Exposure is 30% higher in women than in men. Also Dasabuvir exposure is affected by body weight and by impairment of renal and hepatic functions, albeit not in a clinically significant way (Table 1).

At doses of Dasabuvir 48-fold higher than the maximum recommended dose, Dasabuvir did not cause any embryocidal and/or teratogenic effects in animals<sup>[47]</sup>. The drug was excreted in the milk of lactating animals probably by the breast cancer resistance protein efflux transporter of which Dasabuvir is a substrate. However, the drug did not affect nursing pups. The FDA categorized Dasabuvir in Pregnancy Category B<sup>[45,46,48]</sup> (Table 2).

## CONCLUSION

Given the lack of human studies, no DAA has yet been approved for use in pregnancy or during breast feeding. Consequently, we have reviewed the features of the DAAs approved for treatment of chronic HCV infection in adults in the attempt to identify the most promising candidates, in terms of pharmacokinetic profile and adverse effects, for use in pregnancy or during breast feeding. Sofosbuvir appears to have a favourable pharmacokinetic profile and animal studies indicate that it may be safe during pregnancy. Thus, Sofosbuvir, used in Ribavirin-free regimens, may become the drug of choice for women of childbearing age affected by HCV infection. On the contrary, Simeprevir is not suitable for use in pregnant or breast-feeding women, because its AUC and half-life are greatly affected by liver performance and by drug-drug interactions. Moreover, Simeprevir was associated with teratogenic effects in animals at doses only 4-fold higher than recommended doses. Ledipasvir has a highly favourable pharmacokinetic profile, and too moreover was safe in animal embryos and fetuses. Consequently, its combined formulation with Sofosbuvir (Harvoni), appears to be a good choice in women of child-bearing potential. Daclatasvir, based on its pharmacokinetic profile, appears to have a wide safety margin when used at therapeutic levels. It also appears that dosages may have to be increased in pregnant women. However, in contrast to its expected safety, it was found to cross the placenta and exert a teratogenic effect in animals. It is still awaiting FDA pregnancy categorization.

Although the Ombitasvir/Paritaprevir/Ritonavir combination is in FDA Pregnancy Category B, the pharmacokinetic profile of the individual components, namely absorption and affinity for P450 enzymes, suggest a potential for variability in AUC exposures with the physiological changes of pregnancy to the point that dose adjustment may be required. Furthermore, the components of the combination exerted a teratogenic effect on animals. Lastly, given its indication for use in combination with Ribavirin, it would not be suitable for women of childbearing potential. Dasabuvir is supposed to be relatively safe in pregnancy based on its pharmacokinetic profile and animal studies.

Until very recently infection with HCV genotype 2 would have posed a further treatment challenge in infected pregnant women, because all the recommended regimens for its treatment included Ribavirin. Even

though Italian authorities have very recently approved the use of Daclatasvir for the treatment of adult patients chronically infected by HCV genotype 2 in Ribavirin-free regimen associated with Sofosbuvir<sup>[49]</sup>, a safety data on pregnant women are lacking.

In conclusion, second-generation anti-HCV DAAs have revolutionized the standard of care and prognosis of patients suffering from chronic hepatitis C infection, however, childbearing women cannot benefit from this advance. As concluded by other authors<sup>[4]</sup>, despite promising safety profiles, there are no approved therapies to prevent vertical HCV transmission. Therefore the only achievable goal seems to be universal screening of fertile women to identify and treat those with HCV infection before they become pregnant.

Lastly, it would be useful to create a registry similar to the Ribavirin Pregnancy Registry in order to monitor the effect of the second-generation DAAs on women who become pregnant during therapy, in terms of outcome on both the mother and the product of conception.

## Abstract

**AIM:** To determine the predictors of 50 d in-hospital mortality in decompensated cirrhosis patients with spontaneous bacterial peritonitis (SBP).

**METHODS:** Two hundred and eighteen patients admitted to an intensive care unit in a tertiary care hospital between June 2013 and June 2014 with the diagnosis of SBP (during hospitalization) and cirrhosis were retrospectively analysed. SBP was diagnosed by abdominal paracentesis in the presence of polymorphonuclear cell count  $\geq 250$  cells/mm<sup>3</sup> in the peritoneal fluid. Student's *t* test, multivariate logistic regression, cox proportional hazard ratio (HR), receiver operating characteristics (ROC) curves and Kaplan-Meier survival analysis were utilized for statistical analysis. Predictive abilities of several variables identified by multivariate analysis were compared using the area under ROC curve.  $P < 0.05$  were considered statistical significant.

**RESULTS:** The 50 d in-hospital mortality rate attributable to SBP is 43.11% ( $n = 94$ ). Median survival duration for those who died was 9 d. In univariate analysis acute kidney injury (AKI), hepatic encephalopathy, septic shock, serum bilirubin, international normalized ratio, aspartate transaminase, and model for end-stage liver disease - sodium (MELD-Na) were significantly associated with in - hospital mortality in patients with SBP ( $P \leq 0.001$ ). Multivariate cox

proportional regression analysis showed AKI (HR = 2.16, 95%CI: 1.36-3.42,  $P = 0.001$ ) septic shock (HR = 1.73, 95%CI: 1.05-2.83,  $P = 0.029$ ) MELD-Na (HR = 1.06, 95%CI: 1.02-1.09,  $P \leq 0.001$ ) was significantly associated with 50 d in-hospital mortality. The prognostic accuracy for AKI, MELD-Na and septic shock was 77%, 74% and 71% respectively associated with 50 d in-hospital mortality in SBP patients.

**CONCLUSION:** AKI, MELD-Na and septic shock were predictors of 50 d in-hospital mortality in decompensated cirrhosis patients with SBP.

**Key words:** Decompensated cirrhosis; Acute kidney injury; Model for end-stage liver disease sodium; Septic shock; Spontaneous bacterial peritonitis

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Spontaneous bacterial peritonitis (SBP) is associated with poor prognosis especially with in-hospital patients. The mortality rate ranges from 20%-40%. The model for end-stage liver disease (MELD) has been suggested as a predictor of the in-hospital mortality in patients with SBP. However, the role of other predictors has not been established. The goal of this study is to identify other prognostic factors for mortality in decompensated cirrhotic patients with SBP and to evaluate the predictive power of acute kidney injury, MELD-sodium and septic shock.

Bal CK, Daman R, Bhatia V. Predictors of fifty days in-hospital mortality in decompensated cirrhosis patients with spontaneous bacterial peritonitis. *World J Hepatol* 2016; 8(12): 566-572 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i12/566.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i12.566>

## INTRODUCTION

Spontaneous bacterial peritonitis (SBP) is defined as acute infection of ascitic fluid without any identifiable surgically treatable intra-abdominal source<sup>[1]</sup>. SBP is a major complication of decompensated cirrhosis with ascites<sup>[2]</sup>. The SBP is diagnosed by abdominal paracentesis with an elevated ascitic fluid neutrophil count ( $\geq 250$  cells/mm<sup>3</sup>) and/or a positive ascitic fluid culture. In up to 60% cases, gram-negative bacteria (*Escherichia coli* or *Klebsiella pneumonia*) are most prevalent organism involved<sup>[3]</sup>. In about 25% of the cases, gram-positive bacteria (mainly *Streptococcus species* and *Enterococci*) are involved<sup>[3]</sup>. The prevalence of SBP is up to 30% in hospitalized cirrhotic patients with ascites<sup>[4]</sup>. Despite intensive management, the in-hospital mortality remains between 20%-40%<sup>[5]</sup>. Model for end-stage liver disease (MELD) scores have been investigated with their predictive accuracy; however it is vulnerable to variations in laboratory measurements, making their utili-

zation in prediction of SBP related in-hospital mortality affected<sup>[6,7]</sup>. In addition, decompensated cirrhotics with major complication like SBP may have low MELD scores with high mortality<sup>[7]</sup>. Acute kidney injury (AKI) is common in patients with decompensated cirrhosis with ascites. AKI in cirrhosis was diagnosed by AKI network (AKIN) based on serum creatinine/urine output. AKI can be used to predict mortality in decompensated cirrhotic with ascites<sup>[8]</sup>. SBP-associated septic shock carries significant mortality in cirrhosis<sup>[9]</sup>. Thus this study aimed to have a comprehensive approach to determine possible prognostic factors predicting SBP related in-hospital mortality, compare the predictive power of AKI, MELD-sodium (MELD-Na), and septic shock and to identify the best cut-off point of MELD-Na scores to predict 50 d in-hospital mortality.

## MATERIALS AND METHODS

### Patients

Medical records of 218 adult patients admitted to hepatology intensive care unit (ICU) of the Institute of Liver and Biliary Sciences, New Delhi between June 2013 and June 2014 with the diagnosis of SBP (during hospitalization) and cirrhosis were reviewed. The study was approved by the Institutional Ethics Committee and the guidelines of Helsinki declaration were followed<sup>[10]</sup>. The Ethics Committee waived the requirement for the consent for data analysis.

The diagnosis of cirrhosis was based on clinical, laboratory and imaging findings. SBP was diagnosed by abdominal paracentesis in the presence of neutrophil count  $\geq 250$  cells/mm<sup>3</sup> in the ascitic fluid and the absence of the secondary features suggestive of secondary bacterial peritonitis<sup>[11]</sup>. We also required a positive culture.

Patient charts were retrospectively reviewed. Data include patient demographics, etiology, severity of liver disease, laboratory values, co-existing medical diagnoses (diabetes mellitus, hepatocellular carcinoma), medication use, organ failure, ascitic fluid analysis results, duration of ICU stay, and patient outcome. In the case of culture-positive infections, all microorganisms and their antibiotic susceptibility patterns were recorded. Most patients admitted to the ICU were referred after a variable antibiotic exposure; prior systemic or non-absorbable antibiotic data could not be collected.

The laboratory parameters [bilirubin, creatinine levels and international normalized ratio (INR)] at admission to intensive care unit were used to calculate MELD-Na score using the UNOS Internet site<sup>[12]</sup>. As a protocol, all patients admitted/transferred to the ICU with ascites, underwent an ascitic fluid analysis within 24 h of admission, in the absence of severe coagulopathy. Ascitic fluid was sent for albumin and cell count with differential and cultured by inoculation of 10 mL of ascitic fluid in blood culture bottles. Paired blood culture samples were also collected at admission in all patients. Antibiotic choice varied from patient to patient, and no standard first-line

drugs were used. The choice of antibiotic was decided based on previous antibiotic exposure of the patient before development of SBP, whether the patient was on quinolone prophylaxis, and physician discretion based on the perceived severity of patient illness. The antibiotic use was narrowed and modified as per the gram-stain and antibiotic sensitivity results. No patient underwent fluid restriction or hypertonic saline for management of dilution hyponatremia.

Renal dysfunction was defined by AKIN criteria<sup>[8]</sup> and managed by albumin infusions and intravenous terlipressin, with dose titrated as per response and tolerance. Intravenous albumin was used in all patients, with a minimal daily dose of 20 g and increased to up to 60 g/d<sup>[13]</sup>, titrated by clinical monitoring and hourly urine output. We did not stratify renal dysfunction into hepatorenal syndrome (HRS), and non-HRS. However, any cause of secondary renal dysfunction was actively investigated, with urine sediment, 24-h urine protein excretion, and bedside-renal ultrasound. All patients were evaluated daily by a nephrologist. Hepatic encephalopathy was treated with oral and rectal lactulose and rifaximin. No patient received neomycin. We suspected secondary peritonitis in patients with inadequate response to therapy, severe abdominal tenderness or when multiple organisms were identified in the ascitic fluid. These patients underwent a non-contrast computed tomography (CT) scan of abdomen.

American College of Chest Physicians/Society of Critical Care Medicine consensus conference criteria were used to diagnose septic shock<sup>[14]</sup>.

### Exclusion criteria

Patients with cirrhosis and ascites fluid polymorphonuclear cell (PMN) < 250 cells/mm<sup>3</sup>. Patients admitted from the community with SBP. Patients presented with ascites unrelated to cirrhosis. Patients with variceal haemorrhage advanced malignancy and human immunodeficiency virus.

### Statistical analysis

Stata version 14 for Windows was used for analysis. All the variables were normally distributed with equal variance. The continuous variables were described as mean  $\pm$  SD. The means of continuous variables were compared using student's *t* test. Categorical variables were described as proportions. The means of categorical variables were compared with logistics regression. Multivariate logistics regression was employed to analyse statistically significant variables. Cox proportional hazard model was used to analyse the hazard rates of the predictors adjusted by age and gender. The predictive accuracy of the prognostic variables like MELD-Na, AKI and septic shock was measured using receiver operating characteristics (ROC) curves. The best cut-off point for MELD-Na was created using acceptable sensitivity and specificity in the ROC analysis to determine 50 d in-hospital mortality risk. For each predictor variable, sensitivity, specificity, positive predictive value (PPV),

negative predictive values (NPV), positive likelihood ratio (+LR) and negative LR (-LR) were calculated to fit into the prognostic model. Two tailed *P* value < 0.05 was considered statistically significant. The power of the study was set at 80%. STROBE checklist for retrospective analysis was performed.

## RESULTS

Total of 218 patients with decompensated cirrhosis with ascites and SBP were included in the study. Two hundred and eleven (97%) patients were diagnosed with SBP for the first time and only 7 patients (0.03%) had previous episodes (more than once). The 50 d in-hospital mortality rate was 43.11% (*n* = 94). Median survival duration for those who died was 9 d. In univariate analysis AKI, hepatic encephalopathy, septic shock, total leucocyte count, serum bilirubin, INR, aspartate transaminase (SGOT), and MELD-Na were significantly associated with in-hospital mortality in patients with SBP (Table 1).

The baseline characteristics of the demographics, etiology, clinical and laboratory data is shown in Table 1. Mean age was 49.90  $\pm$  12.52 years and the male was predominant (83%). Most common etiology of liver cirrhosis was ethanol-induced (45.87%) followed by crypto/non-alcoholic fatty liver disease-NAFLD (28.9%). Hepatitis C virus related cirrhosis constitute only 11% in this study. A total of 109 subjects (50.0%) had hepatic encephalopathy with 59 deaths (62.77%), *P* = 0.001. Overall, 99 patients (45.11%) had AKI in hospitalized patients out of which 64 died (68.09%), *P* < 0.001. Compared with survivors the deceased had a higher proportion of septic shock (25.53% vs 3.23%), *P* < 0.001. Total leukocyte counts, bilirubin, INR, SGOT were significantly higher in the patients who died compared to the survivors. Mean MELD-Na score was higher among the deaths comparing to the survivors (30.59  $\pm$  6.62 vs 25.21  $\pm$  7.44) with statistical significance (*P* < 0.001). Child-Turcotte-Pugh (CTP) (B/C) score was not different among the groups. The mean CTP scores were high with mean 10.72 (SD: 1.82).

On multivariate regression analysis, AKI (*P* = 0.001), septic shock (*P* = 0.029), MELD-Na (*P* < 0.001) were found to be independent predictors of 50 d in-hospital mortality in patients with SBP (Table 2). Cox proportional hazard model showed the hazard ratio (HR) of AKI was 2.16 (95%CI: 1.36-3.42), septic shock (HR = 1.73, 95%CI: 1.05-2.83) and MELD-Na (HR = 1.1, 95%CI: 1.02-1.21). ROC curve for AKI, septic shock and MELD-Na had better prognostic accuracy for 50 d in-hospital mortality in patients with SBP (Figure 1). AKI had highest area under the curve (AUC) 0.77 (95%CI: 0.71-0.83), followed by MELD-Na (AUC: 0.74, 95%CI: 0.69-0.79), septic shock (AUC: 0.71, 95%CI: 0.65-0.77). Table 3 reports the sensitivity, specificity, PPV, NPV, +LR and -LR for these predictors. The cut off for MELD-Na derived from the ROC with the best ability to predict 50 d in-hospital mortality in decompensated cirrhotic patient with SBP was 28, with sensitivity 92.9%, specificity 60.3%, and NPV of 97.9%. The Kaplan-Meier

## DISCUSSION

The prevalence of SBP in outpatients has been reported to be 1.5%-3.5%<sup>[15]</sup>. Among in-patients the prevalence is around 10%<sup>[15]</sup>. Half of the episodes of SBP are acquired during hospitalization. In the present observational study SBP related 50 d in-hospital mortality in decompensated cirrhosis was 43%. Of total 94 cases, 93 patients with SBP (99%) died on or before 50<sup>th</sup> d of hospitalisation.

This study assessed different prognostic factors which can be used to predict mortality in hospitalized patient with SBP and corroborates that hepatic encephalopathy, total leukocyte count, serum bilirubin, SGOT, INR and child pugh score significantly associated with mortality<sup>[5,7,16]</sup>. The MELD score shows promise as a means for risk - stratifying patients with SBP including those waiting for liver transplantation<sup>[7]</sup>. Certain limitations of MELD model<sup>[17]</sup> prompted us to include MELD-Na as hyponatremia is a well-known predictor of death in cirrhotic patients. Isolated creatinine is inaccurate measurement of renal failure in decompensated

liver cirrhosis due to significant reduction in creatinine production in liver and muscle wasting<sup>[18]</sup>. We found AKI, MELD-Na and septic shock to be the important predictors of mortality. We did not incorporate other independent variables like total leukocyte count, serum bilirubin, INR since these were the components in the present predictive model like MELD-Na and septic shock.

In this study AKI has the single best predictive ability (AUC: 0.77) followed by MELD-Na (AUC: 0.74) and septic shock (AUC: 0.71). In addition, we identified MELD-Na cut-off 28 with sensitivity 92.9% and NPV of 97.9%. The hazard ratio of mortality for patients with AKI was significantly higher 2.16 (95%CI: 1.36-3.42) compared to septic shock (HR = 1.73, 95%CI: 1.05-2.83) and MELD-Na (HR = 1.06, 95%CI: 1.02-1.09). Kaplan-Meier survival analysis showed AKI, MELD-Na, and septic shock as predictors for the 50 d in-hospital mortality in decompensated patients with SBP. It can help in the further improvement of the quality of care of hospitalized SBP patients with reduction of their short-term mortality. The cut-off for MELD-Na can be applied to prioritize high-risk patients

upon hospital admission who would benefit by expectant management.

Diagnosis of SBP is based on the demonstration of an absolute number of PMNs in ascitic fluid equal to or greater than 250/mm<sup>3</sup>. However, the best specificity for diagnosis has been reported with a cut-off of 500 PMN/mm<sup>3</sup>. It is unclear whether a positive culture in the absence of elevated ascitic fluid PMN count (bacteriascites), requires antibiotic therapy. In these cases, some guidelines recommend antibiotic treatment only if the patient shows signs of infection<sup>[18]</sup>. Ascitic fluid culture is positive in 40% of all cases. The most common isolates include GNB, usually *Escherichia coli* and Gram-positive cocci (mainly *Streptococcus* species and *Enterococci*)<sup>[3]</sup>. Gram negative organism infections predominate in community acquired and gram-positive organisms in nosocomial infections<sup>[3]</sup>. Recommended first-line antibiotics for treatment of SBP include third generation cephalosporins (mainly Cefotaxime), Amoxicillin-Clavulanic acid, ciprofloxacin, and ofloxacin<sup>[19]</sup>, with an expected resolution rate of over 90%. These guidelines from the western medicine acknowledge the increasing problem of antibiotic resistance<sup>[20]</sup> and recommend coverage for resistant organisms if there is no evidence of infection resolution at repeat ascitic fluid analysis at 48 h. Resistant infections are usually caused by *Enterococcus faecium* and extended-spectrum  $\beta$ -lactamase-producing *Enterobacteriaceae*, which are resistant to the current recommended empirical antibiotic therapy<sup>[21]</sup>. These findings led to the suggestion that nosocomial SBP should be treated with carbapenems or with tigecycline<sup>[22]</sup>. We included only patients with hospital-acquired SBP because most of the present ICU admissions include transferred patients already hospitalised, with a variable but consistent antibiotic exposure. Only a minority of our patients are admitted directly from the community, and usually to the wards and not to the ICU. These patients would be expected to have a higher prevalence of resistant infections. A hospital-acquired infection was an independent predictor of death, likely due to a higher rate of multidrug resistance (resistance to third-generation cephalosporin)<sup>[23]</sup>.

This study has certain strengths and limitations. The results clearly show AKI has greater predictive ability than septic shock and MELD-Na as far as 50 d in-hospital mortality in SBP patient is concerned. This study did not account for the stages of ascites. We didn't stratify our patients according to different stages of AKI as per AKIN criteria. We didn't consider HRS into account in this study. We didn't evaluate the antibiotic resistance in SBP patients who are culture positive at the baseline. We included only nosocomial acquired SBP. Most of our patients presented with advanced decompensated liver cirrhosis at the time of SBP diagnosis. The advanced liver cirrhosis was assessed by lower serum albumin, high serum bilirubin and INR values. This study is a single centre study, these findings needed to be supplemented by multicentre prospective studies.

## COMMENTS

### Background

Spontaneous bacterial peritonitis (SBP) is associated with poor prognosis especially in-hospital patients. The mortality rate ranges from 20%-40%. The model for end-stage liver disease (MELD) has been suggested as a predictor of the in-hospital mortality in patients with SBP. The authors' goal is to identify other prognostic factors for mortality in decompensated cirrhotic patients with SBP and to evaluate the predictive power of acute kidney injury (AKI), MELD-sodium (MELD-Na) and septic shock to predict mortality.

### Research frontiers

The prognostic factors for mortality with SBP patients in liver cirrhosis are important in determining the management. MELD has been considered as an important predictive factor. But it's not clear about role of other prognostic factors.

### Innovations and breakthroughs

In this study, 50 d in-hospital mortality rate attributable to SBP is 43.11%. receiver operating characteristic (ROC) curve, Kaplan Meier survival analysis was useful tool in predicting 50 d in-hospital mortality in SBP with liver cirrhosis. Multivariate cox proportional regression analysis showed AKI [hazrd ratio (HR) = 2.16, 95%CI: 1.36-3.42,  $P = 0.001$ ] septic shock (HR = 1.73, 95%CI: 1.05-2.83,  $P = 0.029$ ) MELD-Na (HR = 1.06, 95%CI: 1.02-1.09,  $P \leq 0.001$ ) were significantly associated with 50 d in-hospital mortality. The prognostic accuracy for AKI, MELD-Na and septic shock was 77%, 74% and 71% respectively.

### Applications

Liver transplant is potentially only curative therapeutic option with long term result in patients with decompensated cirrhosis and SBP. The cost of liver transplant and the shortages of the liver donor is a point of concern. The findings of this study can be used as a strategic approach in advanced liver cirrhosis patients on hospital admission that would benefit from intensive management where liver transplant is not a plausible option. It can help in the further improvement of the quality of care of hospitalized SBP patients with reduction of their short-term mortality. The cut-off for MELD-Na can be used to stratify high-risk patients on hospital admission who would benefit by intensive management.

### Terminology

The ROC analysis is a graphical plot in statistical methods to create a cut off value for the predictors. The graph is plotted with true positive value against false positive value. The accuracy of cut off value is interpenetrated by the area under curve (AUC) in ROC curve. AUC = 1 is gold standard, 0.9-1 = excellent, 0.8-0.9 = good, 0.7-0.8 = fair, 0.6-0.7 = poor,  $\leq 0.5$  = fail. Kaplan-Meier survival curve is a time to event analysis of series of events over a period of time recorded in horizontal and declining horizontal steps. When a person withdraws from the study (censored), lost follow up, or died there will be a sudden drop in the curve. HR: It's a ratio of hazard rates. It is the probability of an event in the study group or population at a particular time. HRs are used in time to event analysis.

### Peer-review

This is a retrospective study to analyze predictors of 50 d in-hospital mortality in decompensated cirrhosis patients with spontaneous bacterial peritonitis. The authors review the medical records of 218 adults admitted with SBP in period of one year, to identify factors related to mortality. The article is very well described; it was properly planned and conducted.

Editorial Board Member of *World Journal of Hepatology*, Yong Zhang, MD, PhD, Associate Professor, Attending Doctor, Department of Surgical Oncology, First Hospital of Xi'an Jiaotong University, Xi'an 710061, Shaanxi Province, China

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Hepatocellular carcinoma (HCC) is the most common type of liver cancer. The main risk factors for HCC are alcoholism, hepatitis B virus, hepatitis C virus, nonalcoholic steatohepatitis, obesity, type 2 diabetes, cirrhosis, aflatoxin, hemochromatosis, Wilson's disease and hemophilia. Occupational exposure to chemicals is another risk factor for HCC. Often the relationship between occupational risk and HCC is unclear and the reports are fragmented and inconsistent. This review aims to summarize the current knowledge regarding the association of infective and non-infective occupational risk exposure and HCC in order to encourage further research and draw attention to this global occupational public health problem.

**Key words:** Hepatocellular carcinoma; Autophagy; Epigenetic events; Hepatitis B virus; Hepatitis C virus; Occupational exposure; Chemical agents; Mitophagy;

Arsenic; Cadmium

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Hepatocellular carcinoma (HCC) is the fifth most common human cancer. This review summarizes current knowledge regarding the occupational risk factors of HCC. In particular, we underline not only the infective but also non-infective occupational risk exposure, including chemical agents and toxic metabolites which are a major cause of liver damage.

Rapisarda V, Loreto C, Malaguarnera M, Ardiri A, Proiti M, Rigano G, Frazzetto E, Ruggeri MI, Malaguarnera G, Bertino N, Malaguarnera M, Catania VE, Di Carlo I, Toro A, Bertino E, Mangano D, Bertino G. Hepatocellular carcinoma and the risk of occupational exposure. *World J Hepatol* 2016; 8(13): 573-590 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i13/573.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i13.573>

## INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) is increasing worldwide. There are geographical areas with a high prevalence, as in Asia and Africa, and death from HCC has increased in the United States and Europe<sup>[1-5]</sup>.

Aflatoxin<sup>[6]</sup>, alcohol intake<sup>[7]</sup>, hepatitis B virus (HBV)<sup>[4]</sup>, hepatitis C virus (HCV) infection<sup>[5]</sup> and oral contraception<sup>[8,9]</sup> are known risk factors for HCC, whereas cigarette smoke, anabolic steroids and insulin resistance are suspected to be contributing factors<sup>[10-16]</sup>.

The relationship between occupational risk and HCC is often unclear and the reports are fragmented and inconsistent<sup>[17-19]</sup>; however, it is very commonly reported that vinyl chloride monomer (VCM) induced angiosarcoma of the liver<sup>[20]</sup>.

HCC mortality, assessed by standardized mortality ratio, has been reported in different categories of workers: Building and chemical workers, painters, subjects exposed to solvents and workers in the textile industry have often been reported to be at high risk for HCC<sup>[21-30]</sup>. However, such studies have often failed to identify a single agent responsible for the heightened HCC risk. There have been few investigations of occupational exposure and liver cancer. A number of factors and confounders have precluded drawing firm conclusions<sup>[31]</sup>.

The possible associations between the risk of infection and non-infectious occupational hazards and HCC will be discussed, in the hope of drawing attention to this global public health problem.

## REVIEW METHOD

The PubMed, Scopus and Web of Science databases were searched using the following keywords: "HCC", "occupational exposure", "chemical agents", "arsenic",

"cadmium", "HBV", "HCV", "molecular hepatocarcinogenesis", "molecular immunological targets", "autophagy", "mitophagy" and "epigenetic events". Published data at the International Agency for Research on Cancer (IARC) were consulted.

## INFECTIVE RISK FACTORS FOR HCC

Infection is one of the main contributors to cancer development<sup>[32]</sup>. There are 11 biological agents classified as IARC group 1 carcinogens<sup>[33,34]</sup>. HBV, HCV and AFB1 are responsible for HCC development<sup>[35]</sup>. The vast majority of the global cancer burden attributable to infection occurs in less developed regions (Table 1).

## HEPATITIS INFECTIONS

Infection with HBV and HCV can be through parenteral or unapparent transmission<sup>[36-42]</sup>.

### Occupational exposure to hepatitis B

The risk of hepatitis from needlestick injury from an hepatitis B envelope antigen positive (HBsAg+) source is 22%-31%, whereas the risk of contracting clinical hepatitis from a needlestick injury involving an hepatitis B surface antigen positive (HBsAg+), eAg- source is 1%-6%. Post-exposure prophylaxis (PEP), including HBIG and the HBV vaccine, is believed to be 85%-95% effective. HBV vaccine or HBIG alone is thought to be 70%-75% effective<sup>[43-45]</sup>.

### Occupational exposure to hepatitis C

The risk of HCV transmission from percutaneous exposure is approximately 2%. HCV is rarely transmitted from mucous membrane exposure to blood (both documented cases have been when the source patient was human immunodeficiency virus/HCV co-infected) and it has never been documented following blood exposure to intact or non-intact skin. There is no known PEP for HCV exposure. According to a European case-control study, assessment of the risk of transmission after occupational HCV exposure should take into account the injury severity, device involved and the HCV RNA status of the source patient<sup>[46-50]</sup>.

## DEVELOPMENT OF HCC IN CHRONIC HBV INFECTION

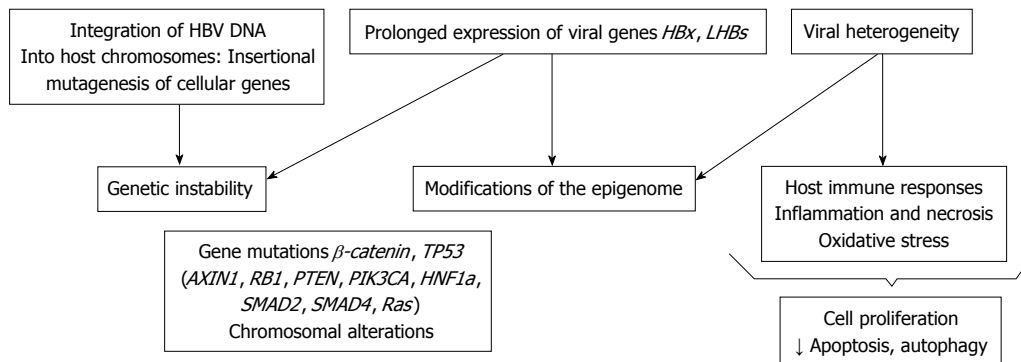

Chronic HBV infection has a causal role in HCC development<sup>[36]</sup> since it promotes carcinogenesis through liver injury (necrosis and inflammation) and cirrhosis development (fibrosis and regeneration)<sup>[41,43-45]</sup>. Moreover, HBV and HCV co-infection causes a higher than 50-fold risk compared to HCC<sup>[51-54]</sup>.

Risk factors for liver cancer in HBV patients include: (1) host-related risk factors: Older age, Asian ethnicity, male sex, alcohol intake and advanced liver disease<sup>[55-57]</sup>; (2) viral risk factors: HBV genotype C, mutations of pre-S, enhancer-H, core promoter, HCV or hepatitis

**Table 1** Hepatocellular carcinoma and occupational exposure to infective agents

Risk agent	CAS No.	Occupational exposure	IARC class
Infective risk			
HBV	-	Health care workers <sup>[4,38,41,44]</sup> , waste operators <sup>[38,44]</sup>	Group 1 <sup>[34]</sup>
HCV	-	Health care workers <sup>[38,39,61]</sup>	Group 1 <sup>[34]</sup>
Aflatoxin B1	1162-65-8	Paper mill and sugar factory; poultry production; rice mill; waste management; swine industry; agri-food industry; wheat handling; textile manufacturing <sup>[77,78,87-91,93,96]</sup>	Group 1 <sup>[76]</sup>

IARC: International Agency for Research on Cancer; CAS No.: Chemical abstract service number; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

**Figure 1** Pathogenesis of hepatitis B virus-related hepatocellular carcinoma. HBV: Hepatitis B virus.

Delta virus infection and PC/BCP HBV variants<sup>[45,58]</sup>; and (3) risk factors related to host-virus interaction: Cirrhosis, high HBV-DNA serum levels, prolonged HBeAg positivity, prolonged HBsAg positivity and high HBsAg serum levels<sup>[59-62]</sup>.

Lastly, the HCC risk factors in chronic HBV infection are different and the pathogenesis is characterized by the combined action of different alterations involving genetic, epigenetic and immunological factors<sup>[63-71]</sup> (Figure 1).

## DEVELOPMENT OF HCC IN CHRONIC HCV INFECTION

The mechanism by which HCV causes HCC is not wholly clear. It has been suggested that HCV proteins have direct oncogenic properties<sup>[5]</sup>. Chronic HCV infection leads to cirrhosis in 10%-20% of patients of whom 1%-5% develop liver cancer<sup>[5]</sup>. Central tumor suppressor genes and a number of proto-oncogenes, such as retinoblastoma tumor suppressor (*Rb*) and *P53*, have been suggested as targets of direct alteration by HCV proteins; the wnt/ $\beta$ -catenin and transforming growth factor- $\beta$  pathways may also be directly affected<sup>[5]</sup>.

Moreover, chronic infection, necrosis and cell regeneration, fibrosis and cirrhosis are, together with the direct mechanisms, the high risk factors for HCC. Finally, HBV or HCV chronic infection has immunomodulatory and immunosuppressive effects<sup>[71-73]</sup>.

## AFLATOXINS

The aflatoxins are metabolic products of certain fungi, *Aspergillus flavus* and *parasiticus* that develop in cereals

(maize), oilseeds (groundnuts) and dried fruit and are chemicals of the furanocoumarins type. To date, we have isolated 17 aflatoxins and 5 are relevant to dissemination and toxicity. High exposure concentrations cause acute hepatitis. Chronic exposure causes the development of liver cancer. This could be caused by the aflatoxin ability to determine the mutation of the p53 tumor suppressor gene, which in normal conditions induces the apoptosis processes<sup>[74-77]</sup>.

The risk of HCC increases when the exposure occurs in the presence of HBV infection, as occurs in the Chinese population<sup>[78-96]</sup>.

## NON-INFECTIVE RISK FACTORS FOR HEPATOCELLULAR CARCINOMA

A wide range of occupational activities may involve worker exposure to a variety of chemical agents. The liver is the main organ involved in metabolism and in toxicokinetics of a xenobiotic. However, it is frequently also a target organ because of its blood supply and the many metabolic and excretory processes in which it has a role. Adverse effects of chemical exposure involving the liver (hepatotoxicity) comprise hepatocellular damage, cholestatic injury, fatty liver, granulomatous disease, cirrhosis and malignancies, including HCC. A variety of chemicals comprising VCM, organic solvents, chlorinated pesticides and arsenic exert adverse effects on the liver<sup>[97]</sup> (Tables 2 and 3).

## VCM AND POLYVINYL CHLORIDE

VCM, chemical abstract service number (CAS No.

BZD and dyes metabolized to BZD	92-87-5	Dye production and use; clinical laboratories <sup>[220,247]</sup>	Group 1 <sup>[76]</sup>

<sup>1</sup>Not all of them are to be referred to group 1. VCM: Vinyl chloride monomer; TCE: Trichloroethylene; PCE: Perchloroethylene; DDT: 1,1,1-Trichloro-2,2-bis (p-chlorophenyl)-ethane; TCDD: 2,3,7,8-Tetrachlorodibenzo-p-dioxin; PeCDF: 2,3,4,7,8-Pentachlorodibenzofuran; PCB: Polychlorinated biphenyls; PBB: Polybrominated biphenyls; O-toluidine: Ortho-toluidine; MOCA: 4,4'-Methylene bis (2-chlorobenzeneamine); 4-ABP: 4-aminobiphenyl; BZD: Benzidine; IARC: International Agency for Research on Cancer; CAS No.: Chemical abstract service number.

**Table 3 Hepatocellular carcinoma and occupational exposure to metals**

Risk agent	CAS No.	Occupational exposure	IARC class
Non-infective risk			
As	7440-38-2	Timber manufacturing; pesticide use; As extraction industry; lead processing; pharmaceutical industry; glass industry; leather preservatives; antifouling paints; agrochemical production; microelectronics and optical industries; non-ferrous metal smelters; coal-fired power plants <sup>[254-258]</sup>	Group 1 <sup>[263]</sup>
Cd	7440-43-9	Cd mining; manufacturing of Cd-containing ores and products; Ni-Cd battery manufacturing, Cd alloy production <sup>[275,277,278]</sup>	Group 1 <sup>[263]</sup>

As: Arsenic; Cd: Cadmium; IARC: International Agency for Research on Cancer; CAS No.: Chemical abstract service number.

75-01-4), is a chlorinated organic compound. VCM is found in cigarette smoke and is mainly used in the production of polymer polyvinyl chloride (PVC). VCM is rapidly absorbed after inhalation and is primarily metabolized by the liver.

Since PVC is harmless in its polymeric form, workers handling the finished goods are not at risk of exposure. The risk phases are those in which the workers are in contact with the material when still in the monomeric state. Many epidemiological studies have demonstrated the high prevalence of exposure to VCM in those working with the chemical. Thiodiglycolic acid is the main VCM metabolite detected in the urine of occupationally exposed subjects.

It has been shown in both human and animal models that VCM is able to induce liver angiosarcoma and HCC<sup>[98-104]</sup>.

Maroni *et al.*<sup>[105]</sup> reported the hepatotoxicity of VCM and other studies have shown the capacity of VCM to

induce specific gene mutations in the liver<sup>[105-117]</sup>.

Various European and Italian studies have reported the apparent association between the amount and timing of exposure to VCM and development of HCC in those exposed<sup>[118-120]</sup>.

## ORGANIC SOLVENTS

Organic solvents are substances that contain carbon and are capable of dissolving or dispersing one or more other substances. Millions of workers are exposed to organic solvents contained in products such as varnishes, adhesives, glues, plastics, textiles, printing inks, agricultural products and pharmaceuticals.

Many organic solvents are recognized by NIOSH as carcinogens (carbon tetrachloride, benzene and trichloroethylene), reproductive hazards and neurotoxins. Among the organic solvents, trichloroethylene (TCE) and perchloroethylene (PCE) have been reported to be

capable of promoting cancer in humans<sup>[121,122]</sup>.

TCE (CAS 06/01/79) has been associated with a high prevalence of liver tumors in exposed workers. Although the hepatic metabolism of this solvent is known, the molecular alterations that cause liver cancer are not completely known<sup>[123-127]</sup>.

It is hypothesized that TCE may be involved in various mechanisms, such as the reduction of programmed cell apoptosis and the uncontrolled proliferation induced by peroxisome activated receptor (PPAR). In fact, it has been proved that TCE is able to bind PPAR<sup>[128-132]</sup>.

*RAD51* is a eukaryote gene. The protein encoded by this gene is a member of the RAD51 protein family which assists in the repair of DNA. TCE binds the *RAD51*, consequently alters the DNA repair and can cause a certain degree of genomic instability.

Finally, it was reported that TCE can cause hypomethylation of DNA and hyperexpression of oncogenes (e.g., *MYC* and *JUG*), responsible for uncontrolled cell proliferation<sup>[133-137]</sup>.

A high prevalence of liver cancer was found in animal models exposed to PCE (CAS 127-18-4)<sup>[138,139]</sup>.

Porru *et al.*<sup>[140]</sup> showed that, in workers chronically exposed to organic solvents (toluene and xylene), there is an increased risk of HCC and that the risk is time-dependent.

## PESTICIDES

Pesticides are widely used in agriculture to get the best quality products and appearance. Farmers and many workers in the agro-food chain are exposed to these substances as well as consumers who eat agricultural products that are not properly cleaned and decontaminated.

Among these substances, 1,1,1-trichloro-2,2-bis (p-chlorophenyl)-ethane (DDT) and its metabolite 1,1-dichloro-2,2-bis (p-chlorophenyl)-ethylene (DDE) have been extensively studied. DDT was used both in agriculture and for environmental disinfection until its use was later forbidden in both America and Europe because of its toxic effects on humans. However, in Africa and many parts of Asia it is currently used to control diseases delivered by an insect as a vector (e.g., Leishmaniasis, malaria).

In humans, DDT contamination occurs through contact with the skin, mucous membranes and inhalation. After DDT absorption, it is distributed to all organs and a portion will be stored in fatty tissues, especially if the exposure was massive<sup>[141-146]</sup>.

Many insecticides, including DDT, were reported to be responsible for leading the development of HCC<sup>[147-152]</sup>. This occurs through different mechanisms not yet completely understood. Moreover, DDT has an estrogenic effect, while DDE has anti-androgenic effects. DDT may also interfere with the *CYP3A1* gene involved in the inflammatory and immune responses in the liver.

Probably none of these mechanisms is individually able to result in HCC but the simultaneous presence of these alterations may lead to the development of liver cancer. Furthermore, the presence of important cofactors, such as HBV, HCV and AFB1, amplifies the risk in exposed populations<sup>[152-158]</sup>.

## N-NITROSAMINES

Nitrosamines are carcinogenic chemical compounds produced when nitrite, a preservative added to certain foods (fish, fish byproducts, certain types of meat, cheese products, beer), combines with amino acids in the stomach. Nitrosamines can be also found in latex products and tobacco smoke. Moreover, nitrosamines are produced in research laboratories, in rubber and tyre manufacturing processes and may be found as contaminants in the final rubber product. Some nitrosamines have been found to be effective for a variety of purposes, including antimicrobial (No. 11) or chemotherapeutic agents (Nos. 5 and 9) in conjunction with others, herbicides (Nos. 5 and 6), additives to soluble and synthetic metalworking fluids (No. 3), solvents or gasoline and lubricant additives (No. 4), antioxidants, stabilizers in plastics, fiber industry solvents and copolymer softeners, and to increase dielectric constants in condensers. Contamination can occur with skin contact and by ingestion and/or inhalation.

Nitrosamines are carcinogenic and are implicated in nasopharyngeal, esophageal, stomach, liver and urinary bladder cancers<sup>[159]</sup>.

From 1981 to 1991, the United States - National Toxicology Program conducted several investigations to characterize and assess the toxicological potential and carcinogenic activity of N-nitrosamines in laboratory animals (rats and mice). The results were reported in the second (1981) (N-nitrosamines: 2-7, 9-15) and sixth (1991) (N-nitrosamines: 1-8) annual report on carcinogens<sup>[159-163]</sup>.

In environmental surveys of some European rubber factories, de Vocht *et al.*<sup>[164]</sup> found the average N-nitrosamine levels well below the regulatory limits in force but high accidental exposures have still occurred. In fact, they detected high levels of urinary N-nitrosamines in exposed workers<sup>[162,164-166]</sup>. Recent studies have reported a correlation between exposure to N-nitrosamines and HCC which might be due to the shortening of telomeres among workers in the rubber industry. Telomeres are critical to maintaining the integrity of chromosomes and telomere length abnormalities are associated with carcinogenesis<sup>[163,165,167-169]</sup>.

## DIOXINS AND DIOXIN-LIKE COMPOUNDS

The dioxins and dioxin-like compounds are a class of heterocyclic organic compounds whose molecular structure fundamentally consists of a ring of six atoms, four carbon and two oxygen atoms; dioxin in the strict

sense is differently stable and comes in two different positional isomers. Commonly referred to dioxins are also compounds derived from furan, in particular dibenzofurans. Therefore, part of the dioxin-like compounds are polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans and among them, the most toxic is 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). It has been shown that compounds of the family of dioxins are formed during the initial stage of the waste combustion when combustion generates gaseous HCl in the presence of catalysts, such as copper and iron. Organic chlorine, which is bound to organic compounds of polymers such as PVC, is mainly responsible for the formation of compounds belonging to the family of dioxins. Dioxins are generated even in the absence of combustion, for example in bleaching paper and tissues with chlorine.

About 90% of human dioxin, except for cases of exposure to specific sources such as industrial plants and incinerators, takes place through food (in particular the fat of animals exposed to dioxin) and not directly by air. The phenomenon of bioaccumulation is very important, *i.e.*, the possibility that dioxin enters into the human food chain from plants, through herbivores, carnivores and finally humans<sup>[170-176]</sup>. Dioxins are classified as definitely carcinogenic and are in the IARC group 1 carcinogenics for humans.

The National Institute for Occupational Safety and Health (NIOSH) has classified TCDD as an occupational carcinogen that can cause space-occupying liver lesions, both non-neoplastic and neoplastic, such as in HCC<sup>[177-181]</sup>.

Many studies have indicated that the carcinogenic capacity of TCDD may be due to the interaction between TCDD and the aryl hydrocarbon receptor (AhR). This receptor is implicated in several xenobiotic metabolisms but there is evidence that AhR is able to control other genes, some of which have a pro-oncogenic capacity<sup>[182-184]</sup>. The TCDD is an important AhR agonist and is therefore able to induce and enhance HCC development and diffusion<sup>[184]</sup>.

## POLYCHLORINATED BIPHENYLS

Polychlorinated biphenyls (PCB) are synthetic chlorinated aromatic hydrocarbons, chemically stable and therefore persistent environmental contaminants. The contamination occurs by skin contact or inhalation, which also allows the possibility of developing vapors for equipment containing PCB overheating<sup>[185]</sup>.

Studies in animal models have shown that these chemical compounds can cause chronic hepatitis as well as cancers, such as HCC and cholangiocarcinoma, especially if there is high exposure and a prolonged time. However, there is little data on liver injury in humans. In one case, exposure to olive oil accidentally contaminated with PCB resulted in death from hepatic cirrhosis. Other studies in workers exposed to the PCB have reported an increased incidence of liver tumors<sup>[185-188]</sup>.

Some possible mechanisms by which PCB can cause cancer have been assumed: Reactive oxygen species (ROS) is produced through the enzymatic oxidation or autooxidation of PCB; PCB determines the increased expression of genes responsible for inflammation and apoptosis in the liver; and PCB has "toxic" effects on certain genes, such as the loss of part of a chromosome and chromosome breakage<sup>[189-199]</sup>. ROS are also able to reduce telomerase activity which can determine telomere shortening. The contribution of all or part of these alterations may facilitate the onset of tumors and more specifically HCC<sup>[200-205]</sup>. At present we have no conclusive data on the relationship between PCBs and HCC and further studies will be needed to establish the causal link. However, the evidence reported by animal model studies have made it possible to classify PCB in IARC group 1<sup>[206,207]</sup>.

## POLYBROMINATED BIPHENYLS

Polybrominated biphenyls are polyhalogenated derivatives of a biphenyl core<sup>[208]</sup> that are chemically stable and therefore persistent environmental contaminants. Whereas they were widely used just a few years ago, they are now subject to restrictive rules that limit their use in the European Union (Restriction of Hazardous Substances Directive).

Contamination can occur through skin contact, inhalation and ingestion<sup>[209-212]</sup>. Based on data obtained from animal research, PDDs are considered potential human carcinogens and can result in hematological, digestive system and liver malignancies. The pathogenic mechanisms by which they can result in PDD cancer are similar to those described for PCB which allows them to be defined as "probably carcinogenic for humans" (group 2A)<sup>[207]</sup>.

## CHLORAL AND CHLORAL HYDRATE

Chloral (or trichloroacetaldehyde) is a chemical compound with the formula  $C_2HCl_3O$  and CAS (chemical abstracts service) 75-87-6. Chloral is produced by the chlorination of ethanol and is also produced as an intermediate in the synthesis of various products, for example DDT. Chloral is used for production of chloral hydrate (formula  $C_2H_3Cl_3O_2$  and CAS No. 302-17-0).

Chloral hydrate is an ingredient used in Hoyer's solution<sup>[213-216]</sup>. In mouse studies, oral administration of chloral in water induced liver nodules as well as hyperplastic nodules and HCC after 92 wk. Significant increases in HCC incidence were seen in treated mice surviving 104 wk<sup>[217,218]</sup>. Some studies indicate that chloral hydrate is able to produce genomic alterations, such as chromosomal aberrations, loss of cell apoptosis and rupture of the gap junction. There are limited studies on carcinogenicity in humans. However, thanks to evidence in animal studies, chloral and chloral hydrate are currently classified in group A2<sup>[216-219]</sup>.

## ORTHO-TOLUIDINE

Ortho-toluidine (O-toluidine) (CAS No. 95-53-4) is used in the chemical and rubber industry and is found in some colorants, herbicides and pesticides. O-toluidine can be an environmental contaminant if in the water used for irrigation of the cultivated fields. It has also been found in tobacco cigarettes. In animal models, O-toluidine caused bladder cancer and its exposure increased the incidence of HCC. Its carcinogenic power is probably due to the ability to determine the formation of DNA adducts, causing damage to the DNA structure. Therefore, O-toluidine is classified in group A<sup>[220-229]</sup>.

## 4,4'-METHYLENE BIS (2-CHLOROBENZENAMINE)

4,4'-Methylene bis (2-chlorobenzylamine) (MOCA) (CAS No. 101-14-4), used in the rubber industry, can be absorbed through the skin in workers, while population exposure occurs by ingestion of vegetables grown in contaminated soil. The ingestion or subcutaneous injection of MOCA in rats results in an increased incidence of HCC and lung cancer<sup>[230-232]</sup>. MOCA has a documented detrimental effect on the genome; in fact, it is able to determine chromatin alterations and deletions<sup>[76,233]</sup>. MOCA is classified in IARC group 1.

## 4-AMINOBIHENYL

4-aminobiphenyl (4-ABP) is used in the rubber industry as an antioxidant and a dye and is also found in cigarettes. It is classified in IARC group 1<sup>[76]</sup>. In rats, 4-ABP ingestion causes bladder cancer, angiosarcoma and HCC; subcutaneous or intraperitoneal exposure determines a high incidence of HCC<sup>[234]</sup>. The metabolism of 4-ABP determines the formation of N-hydroxyl ABP which is a mutagen. 4-ABP can form a DNA adduct. In human liver tissue, higher 4-ABP-DNA levels were observed in HCC cases compared with controls<sup>[235-241]</sup>. Although there was a dose-related increase in 4-ABP DNA (cigarettes smoked/day) and an association with mutant p53 protein expression in bladder cancers, there are currently no reports of p53 or other specific gene mutations caused by exposure to PAH or 4-ABP in HCC<sup>[242-244]</sup>.

## BENZIDINE AND DYES METABOLIZED TO BENZIDINE

In the past, benzidine (BZD) (CAS No. 92-87-5) and dyes metabolized to benzidine have been widely used in the production of dyes. Their use is currently banned in the United States and Europe. However, the use of products containing these substances may expose people to health risks<sup>[245-248]</sup>. Epidemiological data on the risk of tumors in humans are limited, but the ingestion of BZD in rats increases the incidence of HCC<sup>[249-252]</sup>.

BZD and dyes metabolized to BZD are classified in group 1 carcinogens<sup>[76]</sup>.

## ARSENIC

Arsenic (As) (CAS 7440-38-2) is widespread in nature and, combined with other elements, forms very toxic inorganic compounds that can pollute the water and contaminate the population. The workers in mechanical industries are exposed to the risk of illness from dyes, chemicals and glass<sup>[253-258]</sup>.

After oral intake and gastrointestinal absorption, it is metabolized in the liver where it is conjugated with glutathione and methylated<sup>[259,260]</sup>. The chronic exposure to small amounts produces chronic liver disease, cirrhosis and HCC.

In the 2004 IARC monograph, the result of inorganic As in HCC formation was called "limited". In contrast, more recent data from animal models have shown the possibility of a strong bond with liver tumor formation<sup>[261-268]</sup>.

Various carcinogenic mechanisms, genetic and epigenetic, have been proposed: DNA methylation, oxidative damage, genomic instability and reduction of programmed cell death<sup>[269-274]</sup>.

## CADMIUM

Cadmium (Cd) (CAS No. 7440-43-9) is a chemical element used as an anti-corrosion coating and a pigment. It is combined with lithium in rechargeable batteries and is also in cigarette tobacco. In fact, a cigarette contains about 2.0 µg Cd, of which 10.2% is transferred to the smoke<sup>[275]</sup>. Cd in the blood and body of smokers are typically double those found in non-smokers<sup>[276]</sup>. Burning municipal waste leads to inhalation of Cd. Workers in the metal and plastic product industry and workers involved in the construction of solar panels are exposed to Cd<sup>[277,278]</sup>.

In 2011, Cd production was estimated to be 600 metric tons in United States. Most of the Cd produced today is obtained from zinc and products recovered from spent Ni-Cd batteries. China, South Korea and Japan are the leading producers, followed by North America<sup>[278]</sup>. According to OSHA estimates, 300000 workers are exposed to Cd in the United States. Cd found in food and cigarette smoke accumulates in the liver, kidney and pancreas. Liver concentrations increase with age, peaking at 40-60 years.

Based on epidemiological data, the IARC states that there is no evidence of unequivocal carcinogenic effects of Cd<sup>[278-282]</sup>.

However, many animal studies have demonstrated the ability of Cd to determine various tumors, including HCC. This risk is dose and time-dependent and it is conditioned on the exposure mode. Oxidative stress, DNA methylation, the failure of DNA repair, activation of oncogenes, uncontrolled cell growth and the loss of apoptosis are among the mechanisms hypothesized by

researchers<sup>[283-286]</sup>. Interestingly, Sabolić *et al.*<sup>[287]</sup> have shown that the Cd can be internalized in the Kupffer cells which begin to produce cytokines, some of these are indicated as cofactors in the development of HCC.

Some studies have reported that chronic exposure to Cd increases the risk of tumors in humans<sup>[288-290]</sup>. However, large epidemiological studies are necessary to demonstrate whether long term Cd contamination is responsible for HCC development in humans, as in animal models.

## DISCUSSION

Workplace risk prevention and safety rely chiefly on eliminating the risk itself (primary prevention) and, when it is not technically feasible, measures have to be enacted to reduce risk to a minimum<sup>[291]</sup>.

When chemical agents are involved, primary prevention entails replacing a toxic agent with a non-toxic one. However, some mutagenic/carcinogenic agents can be produced in synthetic processes as intermediates or waste products<sup>[292]</sup>. As regards biological agents, it is critical to distinguish deliberate introduction of an agent into the working cycle, as in research centers, from the potential exposure resulting from its unwanted presence, as in the case of health care workers. Whereas the biological agent can be replaced in the former case, other measures have to be enacted in the latter<sup>[293]</sup>.

When risk assessment determines the existence of a healthy risk, adequate risk control systems have to be implemented. Such systems are divided into general and personal protection devices (PPD). The former include adoption of technical and procedural measures, for instance the reduction of environmental pollutants, whereas PPD largely consist of devices worn by workers (*e.g.*, masks, gloves), preventing direct contact with vapors, fumes and/or potentially contaminated material, *e.g.*, biological fluids<sup>[294]</sup>. Biological risk prevention may involve mandatory vaccine prophylaxis, as in the case of HBV infection. Moreover, the fast pace of advances in vaccine development and protection equipment and devices requires continuous re-assessment of workplace protection systems<sup>[295,296]</sup>.

In workplaces where risks are documented, safety procedures must be instituted in accordance with national guidelines. In case of flaws or deficiencies in such guidelines, those in charge of workplace safety are required to refer to the guidelines of internationally recognized organizations such as the Centers for Disease Control and Prevention, American Conference of Industrial Hygienists, NIOSH, *etc.*

The employer and occupational physician have key roles in preventing occupational risk and diseases. The occupational physician, besides carrying out biological monitoring and health surveillance (secondary prevention), is responsible for promoting workplace health<sup>[291]</sup>.

As regards HCC prevention, all exposed workers should have HBV vaccination. In addition, campaigns

against smoking and alcohol drinking should be organized, providing an explicit warning that these factors may contribute to the development of liver cancer<sup>[10-12,101]</sup>.

Development and progression of HCC is still not a completely known multistage process. Genetic, epigenetic and immunological factors probably contribute to the development of HCC<sup>[7,11,13,37,38,50,51,101,297,298]</sup>.

## CONCLUSION

In conclusion, the precancerous milieu of chronic liver disease is characterized by neo-angiogenesis, inflammation with ROS production and fibrosis. Synchronous events occurring in this setting also include hypoxia, oxidative stress, apoptosis, mitophagy and autophagy<sup>[299-302]</sup>.

Autophagy shows a double face in HCC. While autophagy helps to prevent tumorigenesis, it is also used by the cancer cells for survival against apoptosis by traditional chemotherapeutic drugs<sup>[303,304]</sup>. Initially, autophagy functions as a tumor suppressor and later, when HCC has developed, the autophagy may contribute to its growth<sup>[303,305]</sup>.

Microbes have evolved mechanisms to evade and exploit autophagy and both HBV and HCV use autophagy for their own survival<sup>[306]</sup>. Studies have shown that autophagy enhances viral replication at most steps of HBV replication and that autophagy proteins are likely to be factors for the initial steps of HCV replication<sup>[307,308]</sup>. In tumor cells with defects in apoptosis, autophagy allows prolonged survival.

## Future directions

All these mechanisms are still being studied in order to provide new therapeutic approaches to HCC<sup>[309]</sup>. Despite the progress achieved in understanding the cancer process and the impact of this knowledge on treatment, primary prevention remains the most effective approach to reduce cancer mortality in both developed and developing countries for the near future<sup>[9,37,38,50,51,56,309]</sup>.

### Abstract

Hepatocellular carcinoma (HCC) is the sixth most common cancer worldwide, with an increasing diffusion in Europe and the United States. The management of such a cancer is continuously progressing and the objective of this paper is to evaluate innovation in the surgical treatment of HCC. In this review, we will analyze the modern concept of preoperative management, the role of laparoscopic and robotic surgery, the intraoperative use of three dimensional models and augmented reality, as well as the potential application of fluorescence.

**Key words:** Hepatocellular carcinoma; Liver resection; Hepatectomy; New perspectives; Innovative surgical approaches

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide, with at least 1 million new cases each year<sup>[1]</sup>. Even if liver transplantation remains the ideal treatment, hepatic resection remains the only curative treatment for HCC. Considering the early experience of liver resection for HCC in the 1980s, results were discouraging, with a mortality rate in the range of 10% and a considerable morbidity. Improvements in patient selection, early diagnosis, preoperative and postoperative management, surgical technique and development of new technologies have allowed to obtain a lower mortality and morbidity, achieving 0% in certain high-volume centers. The development of laparoscopic and robotic surgery, associated with the application of new technologies in patient care and progress in the medical treatment of HCC, represent a modern era challenge to optimize the management of HCC with the objective of improving overall and disease-free survival. The aim of this article is to describe all innovations in the surgical treatment of HCC.

## ADVANCES IN THE ASSESSMENT AND PLANNING OF SURGICAL TREATMENT

The onset of HCC in a normal liver is an extremely rare situation. It is associated with the presence of pathological liver, and cirrhosis in most cases (80%). The presence of a pathological liver requires a comprehensive study of liver function and patient condition, in order to prevent any postoperative liver failure which occurs in approximately 8% of patients after major hepatic resections<sup>[2]</sup>. The preoperative planning of a surgical procedure has improved the safety of liver resection in cirrhotic patients. The introduction of the concept of

future remnant liver (FRL)<sup>[3]</sup> as a predictor of liver failure has contributed to the development of the concept of liver volumetry. In case of pathological liver, FRL was usually set at 50% of functional liver to prevent any postoperative liver failure<sup>[3]</sup>. The necessity to calculate liver volumetry has increased the diffusion of three-dimensional (3D) surgical planning software<sup>[4]</sup>, with the double function of simulating surgery and calculating liver volumes. Even if conventional 2D images [magnetic resonance imaging (MRI) or computed tomography (CT)-scanning] reveal all the required information concerning tumors, major vessels and the biliary tract, surgeons could come across difficulties in perceiving the relationships of these structures before surgery, and during surgical planning. This platform allows to explore hepatic veins and portal triads from the hepatic pedicle up to segmental branches, allowing to evaluate spatial relationships with the tumor. This software allows to identify the vascular territory supplied by isolated vessels, allowing to simulate anatomical segmentectomy and easy planning of major and minor hepatectomies<sup>[5]</sup>. Many software tools are now available to create a 3D model, offering a visualized model of patient organs and pathologies.

## PORTAL VEIN EMBOLIZATION AND STEM CELLS APPLICATION

As previously mentioned, any hepatic resection must guarantee volume of FRL to prevent postoperative liver failure. In case of cirrhotic liver, the most common scenario in the presence of HCC, namely a portion of 40% to 50% of FRL, should be guaranteed so that liver function should not be affected. In case of insufficient FRL, portal vein embolization was suggested by Makuuchi *et al*<sup>[6]</sup> in 1990, in order to stimulate liver hypertrophy before surgery. This hypertrophy usually requires 4 to 6 wk, but in some cases, more time could be necessary, especially in case of pathological parenchyma. However, during this period, the tumor could continue its progression, and the patient could well become inoperable. One possibility to reduce this risk is to obtain a quicker hypertrophy, reducing the time between portal vein embolization and hepatectomy. Several studies have suggested that stem cells could have an important role in the process of tissue regeneration<sup>[7]</sup>. In case of acute or chronic liver suffering, stem cells can be stimulated from bone marrow. Among them, a subpopulation of cells (CD133<sup>+</sup>) have been recognized as potentially involved in liver regeneration after portal embolization, with encouraging results in some case series, demonstrating an augmented capacity of liver parenchyma regeneration<sup>[7-11]</sup>.

## 3D PRINT OF LIVER MODELS

Based on the data acquired by CT-scan which provide 2D information on geometrical measurements of tumors,

portal vein, hepatic vein and liver parenchyma, a 3D software edited model has been elaborated. 3D printing is a procedure which creates a solid 3D object based on a previous digital model. It is obtained *via* a 3D printer, which lays down thin layers of material in order to form a perfect 3D replica of the computer model. Initially developed to plan living donor liver transplantation<sup>[12]</sup>, an application is currently being found for it in liver surgery<sup>[13]</sup>. The main objective for the development of this physical liver model is to overcome the limitation of conventional 3D models and 2D images such as the absence of reliable liver surface markers, the difficult appreciation of depth, and difficulties in identifying liver segmentation as well as the relationships between vascular and biliary structures. Another advantage is the possibility to use the 3D-printed model during liver surgery, packing the prototype into a sterilized nylon bag<sup>[14]</sup>, which allows to adjust the model to the surgical situation and the surgical field in order to obtain a better understanding.

## REAL-TIME IMAGE FUSION FOR RADIOFREQUENCY ABLATION

Radiofrequency is currently considered an important support for the surgical treatment of HCC or in some cases it is considered an alternative to surgical resection<sup>[15]</sup>. This treatment is highly operator-dependent, especially for targeting, monitoring and controlling, as well as in cases of very small lesions in a pathological parenchyma. The development of a real-time image fusion system is based on the fusion of real-time sonograms with images previously obtained on CT-scan or MR<sup>[15-23]</sup>. To obtain this image fusion, a probe is equipped with a magnetic sensor, which generates a magnetic field interfaced with previously stored images. This fusion could lead to the detection of small HCCs, with an extremely high tumor-targeting success rate of 90% to 100%<sup>[21-23]</sup>. Such encouraging results could improve the performance of RFA treatment for nodules, which could not be revealed by means of sonography. The development of this tool associated with a needle tracking system could be used to assess the efficiency of RFA, hence allowing for a 3D evaluation of the treated zone.

## LAPAROSCOPIC SURGERY FOR HCC

Hepatic surgery still represents one of the most challenging and technical procedures requiring considerable experience. Despite such difficulties, some pioneers in laparoscopic surgery described the first laparoscopic liver resection in 1993<sup>[24]</sup>. Initially considered a standard procedure for patients with a single and subcapsular lesion of less than 5 cm, located in the left liver or in the anterior sectors of the right liver, it currently represents a valid alternative to open surgery for major hepatectomies, as it is considered a safe and feasible

procedure for the treatment of malignant lesions<sup>[25]</sup>. Even if the diffusion of this minimally invasive approach has rapidly gained consensus, laparoscopic resection of pathological livers was considered contraindicated due to the quality of parenchyma and condition of patients. A continuous progression of surgical devices over the last decades has improved the diffusion and safety of these complex procedures. The development of an ultrasonic scalpel (Ultracision™, Ethicon Endosurgery, Cincinnati, OH, United States) allows for a bloodless dissection of liver parenchyma. The ultrasonic dissector (Dissectron, Satelec, Mérignac, France) allows to divide and identify pedicles before being divided and clipped. Large vascular elements were divided after being secured with Hem-o-lok™ clips. Hemostasis and biliostasis of small elements were performed using saline-assisted bipolar electrocautery. Automatic vascular staplers allow for a safer and quick division and suture of large vascular structures, thereby reducing technical difficulties of manual suturing of large vessels. A crucial role during laparoscopic hepatic resection is the one played by ultrasonography, as it is used to localize hepatic veins and portal pedicles, allowing for a continuous control during parenchymal transection to check for safety margins. All these improvements, associated with the enhanced postoperative management of patients and augmented surgical skills have allowed the development of laparoscopic liver resection on cirrhosis, becoming a gold standard for treatment of HCC<sup>[26]</sup>. Despite a strong association with augmented mortality and morbidity as compared to hepatic resection on non-pathological livers, liver resection guarantees several advantages, especially in the postoperative period<sup>[27-30]</sup>, reducing blood loss, postoperative pain, abdominal wall infection, length of stay, and facilitating the surgical operation in case of future liver transplantation<sup>[31,32]</sup> due to a reduction of adhesions. As for non-pathological livers, and this is also true for HCC on cirrhosis, major hepatectomies, even associated with vascular resection<sup>[33]</sup>, are feasible with similar morbidity and mortality rates<sup>[34]</sup>.

## ROBOTIC SURGERY FOR HCC

The development and diffusion of the da Vinci™ robotic surgical system (Intuitive Surgical, Inc., Sunnyvale, CA, United States) have introduced a novel approach in general surgery with an enormous potentiality of integration. The system is made up of a patient-site with four robotic operating arms and a surgeon-site equipped with a stereoscopic 3D camera. Using the robot, this system allows to replicate human hand movements with precise downscaling. As laparoscopy had reached a standardization in hepatobiliary surgery, difficult procedures could benefit from the integrated function of robotic surgery. The aim of robotic surgery is to improve clinical outcome. The two main limitations of laparoscopic surgery (visual and ergonomic limitations) have been totally overcome by the robotic system, allowing to perform advanced procedures with safety.

Precise dissections could be achieved, due to the possibility of using articulated systems with seven degrees of freedom and advanced 3D views. Major limitations of robotic surgery include operating costs and lack of haptic feedback. Once this limitation is overcome, the diffusion will be faster, and more cases will be described in the literature. Currently, regarding HCC, few case series<sup>[35-39]</sup> are available and about 500 cases are described in the literature for liver malignant conditions. No benefits have been described as compared to laparoscopic surgery in terms of morbidity, mortality, and oncological results<sup>[35,38]</sup>. This is probably due to the shortage of series and of patients and will require further studies.

## ROBOTIC AND DEVELOPMENT OF AUGMENTED REALITY

The advent of robotic surgery has allowed the integration of the da Vinci™ robotic surgical system using virtual reality. During the surgical procedure, the 3D model reconstruction could be superimposed with real-time model mobilization, with the possibility to selectively view biliary structures, portal veins, the arterial system, hepatic veins, and lesions. This fusion is defined as augmented reality. This technique, initially described by Pessaux *et al.*<sup>[40]</sup>, use different skin landmarks associated with intra-abdominal landmarks to obtain a computer-assisted fusion of the 3D model with a real-time stereoscopic image of the operative field obtained via the 3D robotic camera. The superimposed image was used as a guide for the surgeon who, with the possibility to increase and decrease the transparency of the virtual model, could easily identify vascular structures as well as the correct localization of the lesion in order to obtain oncological resection margins. This modern era principle has found an application in other fields of surgery<sup>[40-44]</sup>, with an extremely interesting application of the lesion initially detected on CT-scan or MRI but impossible to detect preoperatively with ultrasound, called missing lesions<sup>[45]</sup>. This superimposition of 3D model reconstruction of the first bi-dimensional imaging in which the lesion was available allows the robotic image to guide resection of the liver segment in which the lesion is supposed to be located, hence allowing to achieve satisfying oncological margins.

## MINIMALLY INVASIVE APPLICATION OF FLUORESCENCE

Indocyanine green (ICG) is a non-toxic, non-radioactive and highly safe fluorophore with the capacity to appear green when excited by light in the near infrared spectrum. Historically used to predict liver failure<sup>[46]</sup>, its elimination from blood depends on hepatic blood flow. Cellular uptake and biliary excretion are measured using the ICG-plasma disappearance rate (ICG-PDR). In case of augmented values of ICG-PDR<sup>[46,47]</sup>, major

hepatectomies could be contraindicated to prevent postoperative liver failure. Considering the integration of a fluorescence camera in the robotic da Vinci™ system and laparoscopic camera, fluorescence could be integrated in operative strategies during hepatectomies. Arteries and veins are the first structures to be visualized after venous injection of ICG (5-60 s), and this could allow for an easier recognition of anatomical variations and identification of structures in the hepatic hilum. After vascular capitation, approximately 45 to 60 min after injection, ICG accumulates in the liver and is secreted in the bile. This application could be valuable to prevent complications during difficult cholecystectomies<sup>[48]</sup>, as it could allow to identify bile duct and cystic duct. In the future, it could well reduce the interest in using a perioperative cholangiogram, thereby reducing the exposure of patients to radiation.

Concerning the identification of liver neoplastic tissue, hemodynamic, metabolic and biliary excretion of ICG allow for the identification of tumoral parenchyma<sup>[49]</sup>. Poorly differentiated HCCs are characterized by a low capitation of the lesion with a fluorescent rim, due to a perilesional alteration of biliary excretion<sup>[50]</sup>. Well-differentiated HCCs have an intense fluorescent pattern<sup>[50]</sup>. This finding, as demonstrated for colorectal cancer liver metastasis, could allow to detect undetected lesions with previous conventional preoperative imaging<sup>[51]</sup>, with a potentially significant impact on disease-free survival<sup>[52]</sup>.

## CONCLUSION

HCC still represent a challenge for the surgeon of the next era. Considering the rapid evolution and quick technological progress applied to surgery, additional solutions will be put forward to achieve lower morbidity and mortality rates, guaranteeing a more precise resection, which will offer better oncological results. This progress, associated with progress in diagnosis<sup>[53]</sup>, advances in medical treatment, and an improvement of radiology and oncology will ensure a better future for our patients.

### Abstract

**AIM:** To identify factors that influence long-term liver function following radiofrequency ablation (RFA) in patients with viral hepatitis-related hepatocellular carcinoma.

**METHODS:** A total of 123 patients with hepatitis B virus- or hepatitis C virus-related hepatocellular carcinoma (HCC) ( $n = 12$  and  $n = 111$ , respectively) were enrolled. Cumulative rates of worsening Child-Pugh (CP) scores (defined as a 2-point increase) were examined.

**RESULTS:** CP score worsening was confirmed in 22 patients over a mean follow-up period of  $43.8 \pm 26.3$  mo. Multivariate analysis identified CP class, platelet count, and aspartate aminotransferase levels as significant predictors of a worsening CP score ( $P = 0.000$ ,  $P = 0.011$  and  $P = 0.024$ , respectively). In contrast, repeated RFA was not identified as a risk factor for liver function deterioration.

**CONCLUSION:** Long-term liver function following RFA was dependent on liver functional reserve, the degree

of fibrosis present, and the activity of the hepatitis condition for this cohort. Therefore, in order to maintain liver function for an extended period following RFA, suppression of viral hepatitis activity is important even after the treatment of HCC.

**Key words:** Radiofrequency ablation; Hepatocellular carcinoma; Liver function; Hepatitis B; Hepatitis C

Risk factors for deterioration of long-term liver function after radiofrequency ablation therapy. *World J Hepatol* 2016; 8(13): 597-604 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i13/597.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i13.597>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant neoplasms worldwide<sup>[1]</sup> and most cases of HCC involve patients infected with hepatitis B virus (HBV) or hepatitis C virus (HCV)<sup>[2-4]</sup>. Radiofrequency ablation (RFA) is currently recognized as an effective local treatment for HCC<sup>[5,6]</sup> and has been shown to be a relatively low risk procedure<sup>[7-9]</sup>. However, deterioration of liver function has been observed during the long-term follow-up of these patients<sup>[10-12]</sup>. Therefore, the risk factors that contribute to deterioration of liver function need to be identified. Although a few reports have investigated changes in long-term liver function following RFA<sup>[10-12]</sup>, long-term liver function in patients with viral hepatitis-related HCC is still uncertain. The goal of this study was to identify risk factors for liver function deterioration in patients with HCC and viral hepatitis.

## MATERIALS AND METHODS

### Patients

This retrospective cohort study was based on data obtained from a prospective database maintained by

the Oita University and Oita Medical Center. Between January 2002 and December 2010, 479 patients underwent percutaneous RFA for HCC at these two institutions. This study was conducted according to the ethical guidelines of the 1975 Declaration of Helsinki and approved by the Ethics Committee of Oita University and Oita Medical Center.

A diagnosis of HCC was based on vascular findings obtained by dynamic computed tomography (CT) using early arterial uptake followed by washout in the porto-venous and equilibrium phase. For patients with an uncertain diagnosis, a fine-needle biopsy was performed. Prior to RFA, patients with hyper vascular tumors underwent transarterial chemoembolization. All ablations were performed with a single needle electrode (COVIDIEN, Cool-tip RF Ablation System, Ireland). Furthermore, all RFA procedures were performed percutaneously with ultrasound guidance, and diazepam and pentazocine were routinely administered prior to insertion of the electrode. If necessary, physiological saline was infused into the chest or abdominal cavity to induce artificial pleural effusion or ascites to avoid injury to adjacent organs, or to facilitate visualization of the tumor. Effects of RFA were confirmed by dynamic CT three days after treatment. If the ablated margin was insufficient, additional ablation was performed until a sufficient ablated margin was obtained.

Inclusion criteria for patient selection in the present study included: (1) HCC occurring due to HBV- or HCV-related chronic liver disease; (2) first occurrence of HCC; (3) the presence of up to four nodules per patient, with each nodule having a diameter less than 5 cm; and (4) the presence of tumors only in the liver, with complete necrosis achieved by treatment with RFA. Of the 479 patients treated for HCC, 356 patients were excluded from this study due to: Non-B or non-C HCC ( $n = 77$ ), recurrent HCC ( $n = 80$ ), complete necrosis was not obtained ( $n = 4$ ), advanced HCC ( $n = 33$ ), simultaneous other malignancies ( $n = 8$ ), nephrotic syndrome or advanced chronic kidney disease ( $n = 7$ ), portal thrombus ( $n = 3$ ), chronic debilitating disease ( $n = 1$ ), poor food intake ( $n = 2$ ), breakthrough hepatitis by resistant HBV ( $n = 2$ ), treatment with warfarin ( $n = 3$ ), received albumin around the same time as RFA treatment ( $n = 1$ ), started interferon (IFN) therapy up to 1 year after RFA treatment ( $n = 17$ ), uncontrollable progression of HCC up to 1 year after RFA treatment ( $n = 4$ ), death due to other disease within 1 year ( $n = 2$ ), documents not stored by the electronic system ( $n = 75$ ), a follow-up period less than one year ( $n = 27$ ), and treatment with a nucleoside analog within six months of RFA treatment ( $n = 10$ ). The latter was included based on reports that significant improvement in liver function had been observed within six months of lamivudine treatment for decompensated cirrhotic HBV patients<sup>[13,14]</sup>. Although it was also reported that albumin levels increased during the first two years of IFN treatment for chronic hepatitis C patients with sustained virological response (SVR)<sup>[15]</sup>, none of the patients in the current cohort met this

**Table 1 Patient characteristics (*n* = 123) at the start of the follow-up period**

Gender (male/female)	71/52
Age (yr)	69.7 ± 8.0
Hepatitis (HBV/HCV)	12/111
CP score (5/6/7/8)	79/22/15/7
CP class (A/B/C)	102/21/0
Size of tumor (mm)	20.6 ± 7.7
No. of tumor(s) (1/2/3/4)	78/30/13/2
Total bilirubin (mg/dL)	0.97 ± 0.4
Albumin (g/dL)	3.7 ± 0.6
Prothrombin time (%)	90.5 ± 15
Platelet count (10 <sup>4</sup> /μL)	11.1 ± 5.0
AST (IU/L)	58.2 ± 32.1
ALT (IU/L)	53.0 ± 39.7
Hepatitis condition RVH group/CAH group	13/110
Prior TACE with TACE/without TACE	110/13

criterion.

For the resulting 123 patients enrolled in this study, two groups were established in order to examine the influence of viral hepatitis activity. The first group included nine HBV patients who achieved complete remission of hepatitis (defined as a normal range of transaminase levels) by treatment with an oral nucleoside such as lamivudine, adefovir, or entecavir, two patients with non-active HBV, and four HCV patients who received IFN therapy and achieved a SVR. This group was referred to as the remission of viral hepatitis (RVH) group. The second group consisted of one HBV patient and 107 HCV patients with active hepatitis, and this group was referred to as the chronic active hepatitis (CAH) group.

#### Follow-up periods

The starting point for observation was the first day that patients underwent RFA. Follow-up periods concluded when recurrent HCC(s) were no longer able to be controlled with RFA. In addition, follow-up periods were ended when liver function was found to be deteriorating due to another disease, when treatment with IFN was initiated, when treatment with a nucleoside analog was initiated, when recurrent tumors were treated by surgery, or when a thrombus formed in the portal vein. During the follow-up period, abdominal CT or ultrasonography was performed every four months and blood assays were performed monthly.

#### Statistical analysis

All quantitative variables are presented as the mean ± SD. The endpoint used was a 2-point increase in Child-Pugh (CP) scoring. The cumulative rate of worsening CP scores (defined as a 2-point increase) was also calculated, and cumulative proportion curves were generated using the Kaplan-Meier method. Independent

factors that influenced a worsening CP score were identified by univariate and multivariate analysis using Cox's proportional hazards model. A *P*-value less than 0.05 was considered statistically significant. All statistical analyses were performed using the IBM SPSS Statistics version 20.0 for Windows.

## RESULTS

#### Patient profiles

A total of 123 patients (71 males, 52 females) with HBV infection (*n* = 12) or HCV infection (*n* = 111) were enrolled in this study. Additional characteristics of this cohort are provided in Table 1. Of the HBV patients, 9/12 were treated with nucleoside analogs [lamivudine (*n* = 1), lamivudine plus adefovir dipivoxil (*n* = 4), and entecavir (*n* = 4)] at least six months prior to RFA therapy. There were also two patients with non-active HBV carriers, and one HBV patient had an active case of hepatitis at the time of RFA. Of the HCV patients, 4/111 achieved a post-SVR state with IFN therapy. The CP class A group consisted of 102 patients which included: An active HBV carrier (*n* = 1), inactive HBV carriers that did not receive nucleoside analog treatment (*n* = 2), inactive HBV carriers that received nucleoside analog treatment (*n* = 8), patients with active hepatitis C (*n* = 87), and SVR patients with hepatitis C (*n* = 4). The CP class B group included an inactive HBV carrier who received nucleoside analog treatment (*n* = 1), and active hepatitis C patients (*n* = 20). During the follow-up period, the frequency of RFA treatment for recurrent tumors included a single treatment (*n* = 32), two treatments (*n* = 23), three treatments (*n* = 9), four treatments (*n* = 5), five treatments (*n* = 3), and six treatments (*n* = 2). There were 49 patients that did not receive any RFA treatment.

#### Liver function after RFA treatment

The follow-up period was ended for patients of this cohort due to: Loss of local control of tumor progression with RFA (*n* = 21), death or worsening of liver function due to another disease or accident (*n* = 7), induction of IFN therapy for HCV infection (*n* = 5), surgical treatment for recurrent tumors (*n* = 1), emergence of a portal thrombus (*n* = 1), and administration of a nucleoside analog for HBV infection (*n* = 1). In the latter case, a patient with HBV was enrolled in the CAH group since he initially refused treatment with entecavir. However, 12 mo later he consented to receive entecavir as a treatment, and consequently, the follow-up period for this case ended after 12 mo.

A worsening CP score was confirmed for 22 patients during a mean follow-up period of 43.8 ± 26.3 mo. Moreover, the 1-, 2-, 3-, 5- and 7-year cumulative rates for worsening CP scores calculated according to the Kaplan-Meier method were 2.4%, 6.9%, 10.0%, 19.3% and 33.2%, respectively (Figure 1). The variables listed in Table 1, as well as the frequency of RFA for

Frequency of RFA treatments for recurrent HCC ( $\geq 2$ <i>vs</i> < 2)	1.51	0.64-3.53	0.344

AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; TACE: Transarterial chemoembolization; CP: Child-Pugh; RFA: Radiofrequency ablation; HCC: Hepatocellular carcinoma.

**Table 3** Multivariate analysis to identify risk factors that contributed to a worsening Child-Pugh scores following radiofrequency ablation ( $n = 123$ )

Variable	HR	95%CI	P-value
CP class (B <i>vs</i> A)	5.07	2.13-12.1	0.000
Platelet count ( $10^4/\mu\text{L}$ ) (< 10 <i>vs</i> $\geq 10$ )	3.83	1.36-10.8	0.011
AST (IU/L) ( $\geq 40$ <i>vs</i> < 40)	7.01	1.30-37.9	0.024
ALT (IU/L) ( $\geq 35$ <i>vs</i> < 35)	1.21	0.35-4.19	0.761

A worsening Child-Pugh (CP) scores was defined as a 2 point increase. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

recurrent HCC, were selected as factors for analysis using Cox's proportional hazards model. In contrast, the type of infection (HBV or HCV), and the presence of an active hepatitis condition (RVH or CAH), were excluded from this analysis, since none of the patients in HBV or RVH group exhibited at least a two point increase in CP scores during the follow-up period. Risk factors that were found to contribute to worsening CP scores following RFA are listed in Tables 2 and 3. In a univariate analysis performed, CP class, total bilirubin, albumin, prothrombin time, platelet count, levels of aspartate aminotransferase (AST), and levels of alanine aminotransferase were found to be associated with a worsening CP score (Table 2). Accordingly, these factors were selected for multivariate analysis. Frequency of RFA treatments for recurrent HCC was not found to be associated with deterioration of long-term liver function. Since total CP class, bilirubin, albumin, and prothrombin time are factors that indicate liver function, CP class was selected as a factor representative of these variables. In the multivariate analysis performed, CP class, platelet count, and AST were identified as significant predictors of a worsening CP score (Table 3) ( $P = 0.000$ ,  $P = 0.011$  and  $P = 0.024$ , respectively). Cumulative rates of

**Figure 1** Cumulative rate of worsening Child-Pugh scores (defined as a 2-point increase) for all patients. The 1-, 2-, 3-, 5- and 7-year cumulative rates for worsening CP scores calculated according to the Kaplan-Meier method were 2.4%, 6.9%, 10.0%, 19.3% and 33.2%, respectively. CP: Child-Pugh.

worsening CP scores were generated using the Kaplan-Meier method and are shown in Figure 2.

Subpopulational analyses were also performed with respect to HBV, HCV, RVH and CAH. For the HBV group ( $n = 12$ , mean follow-up period:  $64.0 \pm 28.7$  mo, CP class A ( $n = 11$ ), CP class B ( $n = 1$ ), CAH ( $n = 1$ ), RVH ( $n = 11$ ), platelet count:  $(10.4 \pm 4.3) \times 10^4/\mu\text{L}$ , AST:  $26.3 \pm 5.4$  IU/L, frequency of RFA treatment after initial treatment (0/1/2/3 times): 4/6/1/1 patients, respectively), none of the patients exhibited deterioration of long-term liver function.

For the HCV group [ $n = 111$ , mean follow-up period:  $41.6 \pm 25.2$  mo, CP class A ( $n = 91$ ), CP class B ( $n = 20$ ), CAH ( $n = 107$ ), RVH ( $n = 4$ ), platelet count:  $(11.1 \pm 5.1) \times 10^4/\mu\text{L}$ , AST:  $61.6 \pm 31.9$  IU/L, frequency of RFA treatment after initial treatment (0/1/2/3/4/5/6 times): 45/26/22/8/5/3/2 patients, respectively], CP class and platelet count were both identified as significant predictors of worsening CP scores in the multivariate analysis performed ( $P = 0.000$  and  $P = 0.009$ , respectively) (Table 4). None of the patients in the SVR group ( $n = 4$ ) exhibited worsening of CP scores.

For the RVH group [ $n = 15$ , mean follow-up period:  $65.4 \pm 28.0$  mo, HBV ( $n = 11$ ), HCV ( $n = 4$ ), CP class A ( $n = 14$ ), CP class B ( $n = 1$ ), platelet count:  $(11.7 \pm 5.1) \times 10^4/\mu\text{L}$ , AST:  $25.7 \pm 5.1$  IU/L, frequency of RFA treatment after initial treatment (0/1/2/3 times): 8/6/0/1 patients, respectively], none of the patients exhibited worsening CP scores.

For the CAH group [ $n = 108$ , mean follow-up period:  $40.8 \pm 24.7$  mo, HBV ( $n = 1$ ), HCV ( $n = 107$ ), CP class A ( $n = 88$ ), CP class B ( $n = 20$ ), platelet count:  $(11.0 \pm 5.0) \times 10^4/\mu\text{L}$ , AST:  $62.7 \pm 31.6$ , frequency of RFA treatment after initial treatment (0/1/2/3/4/5/6 times): 41/26/23/8/5/3/2 patients, respectively], CP class B and patients with a platelet count  $< 10 \times 10^4/\mu\text{L}$  were associated with CP worsening ( $P = 0.000$  and  $P = 0.010$ , respectively).

**Figure 2** Comparison of cumulative rate of worsening Child-Pugh scores (defined as a 2-point increase) according to the Kaplan-Meier method.  $P$ -values were calculated using a log-rank test. Analysis according to: A: CP class: A ( $n = 102$ ) and B ( $n = 21$ ); B: Platelet count:  $< 10 \times 10^4/\mu\text{L}$  ( $n = 54$ ) and  $\geq 10 \times 10^4/\mu\text{L}$  ( $n = 69$ ); C: AST levels:  $< 40 \text{ IU/L}$  ( $n = 39$ ) and  $\geq 40 \text{ IU/L}$  ( $n = 84$ ). CP: Child-Pugh; AST: Aspartate aminotransferase.

**Table 4** Multivariate analysis of risk factors that contributed to a worsening Child-Pugh scores following radiofrequency ablation for hepatitis C virus patients ( $n = 111$ )

Variable	HR	95%CI	P-value
CP class (B vs A)	4.90	2.05-11.7	0.000
Platelet count ( $10^4/\mu\text{L}$ ) ( $< 10$ vs $\geq 10$ )	3.96	1.40-11.2	0.009
AST (IU/L) ( $\geq 40$ vs $< 40$ )	5.25	0.98-28.0	0.052
ALT (IU/L) ( $\geq 35$ vs $< 35$ )	1.11	0.33-3.73	0.865

A worsening Child-Pugh (CP) score was defined as a 2 point increase. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

## DISCUSSION

Treatment of HCC generally involves a surgical approach and/or a non-surgical approach. In the latter case, transarterial embolization, radiation therapy, chemotherapy, and local puncture therapy are the main options available. While percutaneous ethanol injection therapy<sup>[16]</sup> is a type of local puncture therapy that has been performed since the 1980s, local ablative therapy such as microwave coagulation therapy<sup>[17]</sup> and RFA therapy were subsequently developed. Currently, RFA is the main form of local puncture therapy administered

due to its ability to provide local control of HCC. The less invasive approach of RFA also represents a key advantage of RFA over surgical resection. However, since the recurrence rate of HCC following radical treatment is generally high, repeated RFA treatments are often needed. There have been reports that the application of repeated RFA for the treatment of recurrent tumors can increase the chances of long-term survival<sup>[8,9,18]</sup>.

A few reports have referred to the influence of RFA on liver function. For example, Koda *et al.*<sup>[10]</sup> reported that liver function in patients with low pre-treatment CP scores transiently deteriorated within the first month of observation, while patients with high pre-treatment CP scores exhibited a greater extent of deterioration over a longer term of observation, approximately 6 mo. In a study by Kuroda *et al.*<sup>[11]</sup>, changes in liver function were monitored one year after RFA, and it was observed that a CP score of 9 or higher represented a major risk factor for aggravation of liver function following RFA. Furthermore, in another report by Yokoyama *et al.*<sup>[12]</sup>, the influence of RFA treatments on long-term liver function was investigated. Approximately 15% of CP class A or CP class B patients were observed to progress to CP class C five years after RFA treatment. However, the factors that influence on long-term liver function in

patients with viral hepatitis-related HCC following RFA is still uncertain. There are various factors that may contribute to changes in liver function. Since tumor progression is an obvious factor that aggravates the liver function of HCC patients, the current analyses were performed with patients where tumor progression could be excluded. Based on the analyses performed, CP class B patients, patients with a platelet count  $< 10 \times 10^4/\mu\text{L}$ , and patients with AST levels  $\geq 40$  IU/L, were found to be significantly associated with a worsening of liver function after RFA. These results suggest that worsening of long-term liver function after RFA is dependent on liver function, the degree of fibrosis present, and the activity of a patient's hepatitis condition. However, repeated RFA was not found to be a factor that aggravates long-term liver function.

None of the RVH patients exhibited CP worsening, thereby suggesting that liver function can be maintained in RVH patients if HCC is controlled. This result also suggests that short-term functional damage of the liver that is caused by RFA does not influence long-term liver function. However, since almost all of the RVH patients in the present study belonged to the CP class A group, additional studies are needed to clarify whether long-term liver function is affected following RFA for RVH patients with poor liver function.

Nucleoside analogs such as lamivudine or entecavir are used to treat active cases of hepatitis B by inhibiting DNA synthesis with termination of the nascent proviral DNA chain. As a result, levels of both serum HBV-DNA and transaminase concentrations are rapidly reduced. When viral suppression is prolonged, this can result in histological improvement, including regression of fibrosis<sup>[19-22]</sup>, and in patients with HBV-related HCC, liver function has improved<sup>[23-26]</sup>. For hepatitis C patients, IFN therapy has previously been the only treatment found to reduce levels of virus. For example, peginterferon plus ribavirin treatment has been a standard therapy for HCV infection until recently when telaprevir or simeprevir combined therapy was shown to improve the efficacy of IFN therapy<sup>[27,28]</sup>. However, since many cases of HCV-related HCC involved elderly patients, or a cirrhotic liver, there were many patients who could not receive radical treatment for HCV when HCC was detected. Other direct-acting antiviral agents have recently been investigated, and these have been found to increase SVR ratios<sup>[29,30]</sup>. Correspondingly, it is possible for HCC patients who are difficult to treat with IFN to be treated with IFN-free therapies.

While liver resection and RFA are still the standard treatments for many HCC patients, the long-term effects of surgical resection vs RFA remain controversial<sup>[31-33]</sup>. Thus, when many patients of HCV-related HCC become able to be treated with IFN-free therapies, this issue may be re-evaluated. In addition, further studies are needed to evaluate treatment modalities with respect to coexisting hepatitis conditions.

In conclusion, the results of the present study

indicate that long-term liver function following RFA is dependent on functional reserve of the liver, the degree of fibrosis present, and hepatitis activity. Since viral eradication or suppression is currently the most effective method to improve these factors, anti-viral therapy is important even after the treatment of HCC.

## COMMENTS

### Background

There are only a few reports that have examined liver function following radiofrequency ablation (RFA). In particular, long-term liver function following RFA in patients with viral hepatitis-related hepatocellular carcinoma (HCC) has not been well studied.

### Research frontiers

In the present study, long-term liver function in patients with viral hepatitis-related HCC that underwent RFA was found to be dependent on the functional reserve of the liver, the degree of fibrosis, and hepatitis activity.

### Innovations and breakthroughs

In previous studies, liver functional reserve at the time of RFA treatment was identified as a risk factor for liver function deterioration following RFA. Here, the authors demonstrate that the degree of liver fibrosis and hepatitis activity are also associated with deterioration of liver function following RFA.

### Applications

The strong and safe treatment regimen for patients with hepatitis B or hepatitis C that the authors have developed has the potential to maintain liver function following RFA treatment of patients with viral hepatitis-related HCC.

### Peer-review

This is a very well done study, it demonstrates that RFA seems to be a well tolerated therapy without relationship with deterioration of liver function.

### Abstract

Recurrence rate of hepatocellular carcinoma remains quite high even after surgery, and no postoperative therapies have been definitively shown to prevent hepatocellular carcinoma recurrence. A previous study showed that therapy with nucleos(t)ide analogues given to such patients after surgery significantly improved survival. However, many questions still exist about the usage of nucleos(t)ide analogues for patients with hepatocellular carcinoma after surgery.

**Key words:** Antiviral therapy; Hepatocellular carcinoma; Hepatitis B virus; Unanswered question

**Core tip:** Some important points about the usage of nucleos(t)ide analogues for patients with hepatocellular carcinoma after surgery in clinic were pointed out.

### TO THE EDITOR

Recurrence rate of hepatocellular carcinoma (HCC) remains quite high even after curative resection or radiofrequency ablation (RFA), and no adjuvant thera-

pies have been definitively shown to prevent HCC recurrence<sup>[1,2]</sup>. A previous study showed that therapy with nucleos(t)ide analogues (NAs) given to HCC patients after resection significantly improved survival<sup>[3]</sup>. Whether the same holds for HCC patients after RFA was unclear until Lee *et al*<sup>[4]</sup> reported their important findings that postoperative NA therapy significantly reduced 2-year recurrence rate. The authors supported their conclusions using multivariate analysis and propensity score matching. These results provide by far the strongest evidence that postoperative NA therapy can benefit patients with hepatitis B virus (HBV)-associated HCC. At the same time, methodological limitations in that study raise several important questions that must be addressed in future work.

Several of these limitations are acknowledged by Lee *et al*<sup>[4]</sup> in their report. They did not take into account possible confounding effects due to differences in baseline viral load, HBeAg, liver function, or type of treatment after recurrence. In addition, their focus on recurrence rate as the most important outcome and the relatively short (2-year) follow-up prevented them from clarifying how NA therapy provided clinical benefit. NA therapy is not thought to directly affect tumor growth. Rather, it is thought to act in the short term by reducing the risk of HBV reactivation and improving liver function. Lee *et al*<sup>[4]</sup> did not measure these outcomes in their study, making it impossible to examine how NA therapy reduced the recurrence rate. NA therapy is also thought to act in the long term by: (1) suppressing viral replication, which might reduce the risk of *de novo* HBV-related HCC development; and (2) reducing chronic inflammation in the remnant liver, thereby improving hepatic functional reserve after surgery and improving the patient's treatment options. Lee *et al*<sup>[4]</sup> could not observe these mechanisms because they stopped follow-up at 2 years. As a result, Lee *et al*<sup>[4]</sup> were able to measure only early recurrence, not late recurrence, which occurs at least 2 years after surgery or RFA. The 2-year cut-off also prevented the authors from measuring overall survival, a key outcome for establishing the efficacy of any treatment.

The results of Lee *et al*<sup>[4]</sup> argue strongly for the therapeutic potential of postoperative NA therapy for patients with HBV-related HCC, but they fall short of definitively establishing the therapy as effective. To close this evidence gap, we recommend that future studies address the following questions<sup>[5]</sup>: (1) Do all patients with HBV-related HCC benefit from postoperative NA therapy? What are the indications for NA therapy? Should these indications include preoperative liver function and viral load? We note that most patients in the study by Lee *et al*<sup>[4]</sup> had early-stage tumors (< 3 cm) and cirrhosis. Also, all the patients in the former

randomized controlled trial were all with relatively early-stage tumors<sup>[3]</sup>. In addition, almost all patients enrolled in previous studies had Child-Pugh A liver function<sup>[3,4,6,7]</sup>. So, further studies should investigate the benefit of NA therapy for patients with Child-Pugh B or C liver function. Last but not least, is NA therapy valuable for those with serum HBV DNA less than 500 copies/mL? (2) Which NA drug(s) are the most effective and safest? Lamivudine is the first antiviral drug. Although it suppresses the virus quickly, the frequency of drug resistance is too high. Other NA drugs include adefovir dipivoxil, entecavir, and tenofovir; (3) When is the optimal time to initiate NA therapy, and how long should it last? Nowadays, doctors and patients increasingly attach importance to the phenomenon of HBV reactivation. Therefore, NA therapy should be started before surgery. One of the purposes of NA therapy is to prevent tumor recurrence. Less than two years of therapy may be not enough; and (4) Are there benefits and risks to adding a second NA drug or continuing monotherapy? Many studies reported that combined therapy with two or more NA drugs were suitable for chronic hepatitis B. However, it is unknown for patients with HCC after surgery.

Addressing these questions will be essential for defining the NA treatment regimens most likely to provide clinical benefit, as well as for identifying the most suitable patient populations.

## ABOUT COVER

Editorial Board Member of *World Journal of Hepatology*, Dr. C Ganesh Pai, MD, Professor, Department of Gastroenterology and Hepatology, Kasturba Medical College, Manipal, Karnataka 576104, India

## AIM AND SCOPE

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/  
ABSTRACTING

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

### Abstract

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors in China. The Barcelona

Clinic Liver Cancer (BCLC) staging system is regarded as the gold standard staging system for HCC, classifying HCC as early, intermediate, or advanced. For intermediate HCC, trans-catheter arterial chemoembolization (TACE) is recommended as the optimal strategy by the BCLC guideline. This review investigates whether liver resection is better than TACE for intermediate HCC. Based on published studies, we compare the survival benefits and complications of liver resection and TACE for intermediate HCC. We also compare the survival benefits of liver resection in early and intermediate HCC. We find that liver resection can achieve better or at least comparable survival outcomes compared with TACE for intermediate HCC; however, we do not observe a significant difference between liver resection and TACE in terms of safety and morbidity. We conclude that liver resection may improve the short- and long-term survival of carefully selected intermediate HCC patients, and the procedure may be safely performed in the management of intermediate HCC.

**Key words:** Trans-catheter arterial chemoembolization; Intermediate hepatocellular carcinoma; Liver resection; Prognostic factor

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most common cause of cancer related death in the world<sup>[1]</sup>. In China, where about 120 million people are positive for hepatitis B surface antigen, HCC accounts for 300000 deaths every year<sup>[2]</sup>. It is a great challenge for clinicians to cure HCC. In order to provide standardized treatment for HCC, numerous HCC staging systems have been proposed in recent decades, including the tumor-node-metastasis (TNM) system, the Okuda system, the Barcelona Clinic Liver Cancer (BCLC) system, the Cancer of the Liver Italian Program (CLIP), the Vienna classification, the Chinese University Prognostic Index, the Japan Integrated Staging score, and the Tokyo staging system<sup>[3]</sup>. All of these staging systems rely mainly on three variables: Tumor characteristics, liver function, and general status. The TNM system is one of the oldest; however, the complexity of its variables has limited its application. The most widely adopted systems for staging HCC are the CLIP and the BCLC system (endorsed by European Association for the Study of the Liver and the American Association For the Study of the Liver)<sup>[4]</sup>. At present, the BCLC system is regarded as the optimal staging system to predict prognosis and guide treatment of HCC<sup>[5]</sup>.

The BCLC system was proposed by Llovet *et al*<sup>[6]</sup> in 1999, and validated extensively in 2002, 2005, and 2010<sup>[7,8]</sup>. Based on the BCLC grading system, the corresponding recommended treatment for each stage is stratified. Curative treatment is advocated for early HCC (defined as a single tumor less than 5 cm in diameter, or up to three tumors less than 3 cm in diameter), such as surgery, radiofrequency ablation, and liver transplantation. For intermediate HCC (a single tumor more than 5 cm in diameter; two to three tumors of which at least one is more than 3 cm in diameter; or more than 3 tumors of any diameter), trans-catheter arterial chemoembolization (TACE) is recommended as the standardized treatment<sup>[9-11]</sup>. A large proportion of patients in China are classified at diagnosis with intermediate or advanced HCC (any tumor with radiologically evident and histologically proven macro-vascular invasion, spread to lymph nodes and/or distant metastases). Therefore, only a minority of Chinese patients are eligible for radical resection or other curative treatments.

Controversy over the optimal treatment for intermediate HCC has emerged in recent years, as some evidence has suggested that due to the heterogeneity of individuals in liver function and tumor size, patients

with intermediate HCC may not all derive the same benefit from TACE. TACE cannot induce complete tumor necrosis, especially when large nodules are encountered. As the mortality and morbidity of liver resection are decreasing worldwide, surgery has been considered in some treatment models<sup>[12-14]</sup>. One study at Fudan University Hospital endorsed surgical resection for intermediate HCC<sup>[15]</sup>.

This review summarizes research on the role of liver resection in the management of intermediate HCC. Through comparison of liver resection and TACE, we seek to determine an optimal treatment for intermediate HCC.

## LIVER RESECTION VS TACE FOR INTERMEDIATE HCC

The current treatment algorithm recommends TACE as the standard treatment for intermediate HCC based on two randomized controlled trials<sup>[16,17]</sup>. However, patients with intermediate HCC vary widely in tumor size, tumor volume, overall health, and other factors, and so derive different benefit from TACE. In recent years, many studies have validated the BCLC treatment recommendation<sup>[7,18-23]</sup>. Liver resection has been widely performed in patients with intermediate HCC, and many investigators have argued that liver resection is as safe as TACE for intermediate HCC and provides better survival outcomes in selected patients<sup>[24-31]</sup>. Several centers have proposed their own criteria for judging which intermediate HCC patients are most likely to benefit from liver resection; Zhang *et al*<sup>[32]</sup> proposed that intermediate HCC cases with the following features should be considered for radical resection: Large or very large solitary tumor with swelling outward, clear border or pseudo-capsule, and less than 30% of the liver destroyed or more than 50% of hepatic hypertrophy; or multiple tumors limited to one segment or lobe. The authors also pointed out that confinement of tumors to one segment or lobe is not an absolute indication, considering that surgical outcomes could be affected by multi-center distribution and the relationship between lesions and major vessels.

Wang *et al*<sup>[24]</sup> reported that the median overall survival of patients with intermediate HCC after liver resection was significantly higher than that after TACE. Additionally, the 1-, 3- and 5-year survival rates in the liver resection group were also significantly higher than those in the TACE group. The study found that liver resection provided the best survival outcomes for patients with early and intermediate HCC. In accordance with these findings, several studies found similar survival benefits of liver resection in the management of intermediate HCC<sup>[24-31]</sup>. Another group of investigators performed a propensity score study which enrolled patients with intermediate and advanced HCC, and observed survival benefits of liver resection by total analysis and propensity-matched analysis<sup>[29]</sup>. In addition,

they conducted a subgroup analysis to detect whether patients with liver resection had better survival rates than those with TACE, and survival benefits were observed in subgroup analysis by tumor size, tumor number, macro-vascular invasion, and portal hypertension. Given that the heterogeneity of survival rates among different study cohorts, the highest and lowest 5-year survival rates were 63% and 37%, respectively. Due to the variation in regions and characteristics of enrolled patients and surveillance techniques in different centers, the survival rate might differ for these two procedures in different populations, and we cannot recommend that liver resection be the preferred treatment for intermediate HCC in all cases. However, we observed a similar linear trend of survival benefits of liver resection in the studies we examined (Table 1).

Several studies examined the complications and mortality rates of each treatment modality. Two groups of investigators observed that the incidence of complications in patients with liver resection was significantly higher than that in patients with TACE<sup>[27,29]</sup>. Hsu *et al*<sup>[27]</sup> noted that the liver resection group had a higher incidence of acute liver failure and biliary duct injury

than did the TACE group. However, the incidence of fever was lower in the resection group. Studies reached inconsistent findings about the mortality rates associated with each treatment strategy. Hsu *et al*<sup>[27]</sup> observed a higher mortality rate in the resection group than in the TACE group, which was contradicted by several other studies<sup>[26,29]</sup>. This could perhaps be explained by the fact that the proportion of patients aged < 65 years differed between the liver resection group and the TACE group, which likely biased the analysis of mortality. As we know, elements associated with the mortality of patients with HCC include liver function, surgical procedures, and age<sup>[33,34]</sup>. If the demographic characteristics of patients in different groups are not comparable, we cannot perform a reliable analysis of mortality and complications. Studies providing data related to complications of liver resection and TACE are summarized in Table 1.

## LIVER RESECTION IN PATIENTS WITH EARLY AND INTERMEDIATE HCC

The corresponding treatment recommendation for early HCC is a curative strategy such as liver resection, liver

transplantation, or radiofrequency ablation. Many multi-center studies with large sample sizes have validated liver resection for early HCC<sup>[35-37]</sup>. Generally, patients with intermediate HCC are not candidates for radical resection based on the BCLC treatment algorithm. However, in recent decades, the question of whether liver resection is indicated for intermediate HCC has been debated worldwide. Ng *et al.*<sup>[38]</sup> found the 5-year survival rate to be 39% for intermediate HCC treated by liver resection, which was fairly acceptable. They advocated to perform liver resection in patients with intermediate HCC, and they also demonstrated that liver resection in carefully selected intermediate HCC patients could be as safe as in early HCC patients. Recently, numerous studies have demonstrated that liver resection for intermediate HCC can achieve comparable survival outcomes as in early HCC<sup>[18,24,39,40]</sup>. Nevertheless, a group of investigators reported survival benefits of liver resection for early HCC<sup>[41]</sup>. This 10-center study found that disease free survival and overall survival after liver resection were significantly higher for early HCC than for intermediate HCC, but the survival outcomes of liver resection for intermediate HCC were still acceptable, with 5-year survival rate estimated at 57%. They classified the patients receiving liver resection into three groups: BCLC A, BCLC B and BCLC C. The demographic characteristics of the BCLC A and BCLC B groups were not comparable, as both tumor number and average tumor size were lower in the BCLC A group, which may have biased the analysis of survival outcomes. Furthermore, surgical procedures differed significantly between these two groups, with a higher proportion of patients with minor resection in the BCLC A group than in the BCLC B group. Despite the survival advantages in the BCLC A group, the BCLC B group also achieved favorable short- and long-term survival outcomes, in accordance with other findings<sup>[35,42,43]</sup>.

Regarding complications and mortality of liver resection for early and intermediate HCC, two groups of investigators did not observe differences in mortality and morbidity between patients with early and intermediate HCC after liver resection<sup>[38,44]</sup>. Yamashita *et al.*<sup>[42]</sup> reported that the mortality and morbidity of patients with intermediate HCC receiving liver resection were 3.8% and 24.5%, respectively, which were higher than those in other investigations. The very large tumors (> 10 cm in diameter) of patients in the Yamashita *et al.*<sup>[42]</sup> study may explain the higher mortality and morbidity of this study compared with others. Recent studies comparing liver resection in early and intermediate HCC are presented in Table 2.

A high incidence of recurrence affects the survival rate of patients with HCC after liver resection, and recurrence rate has been identified as an independent prognostic factor for long-term survival<sup>[45]</sup>. Ng *et al.*<sup>[38]</sup> reported a higher incidence of intrahepatic recurrence after liver resection in intermediate HCC, but found no difference in the extra-hepatic recurrence of patients with early and intermediate HCC after liver resection.

Torzilli *et al.*<sup>[44]</sup> conducted a prospective cohort study in 2008, which did not find significant differences in either intrahepatic or extra-hepatic recurrence between patients with early and intermediate HCC receiving liver resection. Another study reported that the estimated 1-, 2-, 3- and 5-year recurrence rates of patients with intermediate HCC after liver resection were 44.2%, 54.5%, 60.6% and 68.1%, respectively<sup>[43]</sup>. Variables that help predict the risk of HCC recurrence are serum albumin level, microscopic vascular invasion, multi-nodularity, and advanced Edmondson stage<sup>[46]</sup>. Multi-nodularity and serum albumin level were identified as independent factors of recurrence by Chang *et al.*<sup>[43]</sup>. Given that the incidence of HCC recurrence is fairly high, routine surveillance by computed tomography scan or magnetic resonance imaging is strongly recommended for patients with intermediate HCC after resection<sup>[47,48]</sup>.

## PROGNOSTIC FACTORS OF SURVIVAL

Benefits of liver resection are tightly associated with numerous variables, such as liver function, tumor size, and tumor number. Investigators have identified several important variables correlated with survival outcomes of patients with intermediate HCC after liver resection (Table 3). Overall survival is one critical endpoint for the prognosis of patients. One group of investigators found that 8 of 16 variables analyzed had a significant prognostic influence on overall survival by univariate analysis, of which, only 5 variables showed significant prognostic influence by multivariate analysis<sup>[38]</sup>, and they determined that patients without any prognostic risk factors had a higher 5-year survival rate than those with one or more prognostic risk factors. Another group of investigators identified serum albumin level, ICG-15R, tumor capsule, portal hypertension, and other measures as risk markers (variables in different studies related to overall survival are presented in Table 3). Many studies have found that tumor number is a key factor in predicting overall survival<sup>[41,49-51]</sup>, and it is a critical variable in different HCC staging systems. Incomplete radical resection and postoperative recurrence are closely associated with tumor number.

The Child-Pugh grade is another prognostic factor for overall survival that has been clarified by several studies<sup>[26,35]</sup>. To our knowledge, the Child-Pugh grading is the most widely used system for evaluating liver function. Since liver resection, particularly extensive liver resection, can lead to liver failure in patients with insufficient liver volume, preoperative assessment of liver function will undoubtedly improve the intra-operative safety and postoperative survival rate. Specifically, T4 status of HCC stage was reported to be a prognostic factor of overall survival with a hazard ratio of 5.12 by a liver cancer study group in Japan<sup>[42]</sup>. However, as this variable is based on tumor size, tumor number, and macro-vascular invasion, we do not classify it as an independent variable for overall survival.

Disease-free survival was another key endpoint in

prognosis analysis of patients with malignant neoplasms. Microvascular invasion and Child-Pugh class B were two independent factors for disease-free survival in patients with single large or huge HCC<sup>[39]</sup>. It is known that HCC patients with major vascular invasion have a poor survival rate and high incidence of recurrence<sup>[52]</sup>. Single large or huge HCC is normally located adjacent to biliary ducts or vessels, making vascular invasion more probable. Alpha-fetoprotein level greater than 400 ng/mL is a significant

prognostic risk factor for disease-free survival by multivariate analysis. However, previous studies have demonstrated that minor proportions of patients with HCC do not present with up-regulation of alpha-feto-protein, which makes the surveillance of onset and recurrence of HCC challenging<sup>[53-55]</sup>. Variables in different studies related to overall survival are presented in Table 3.

## CONCLUSION

According to the current BCLC treatment guideline, TACE is recommended as the optimal treatment strategy for intermediate HCC. However, the patients with HCC in Asia distribute among BCLC A, BCLC B, and

BCLC C, despite advances in surveillance of HCC in recent years, and a large proportion of patients in Asia present as BCLC B or C when diagnosed. According to the recommendations by the BCLC guideline, these patients cannot benefit from surgical resection. Our review investigated whether liver resection is in fact a viable treatment for intermediate HCC patients.

We found that liver resection could achieve better or at least comparable survival outcomes compared with TACE for intermediate HCC. As for the safety and morbidity, controversy remains. Nevertheless, with advances in surgical equipment and perioperative management, we expect that survival benefits for intermediate HCC after liver resection will improve in the future.

In addition, we examined the outcomes of liver resection in patients with BCLC A and BCLC B. With two exceptions, most studies demonstrated that liver resection offers comparable survival benefits in intermediate HCC and early HCC<sup>[38,41]</sup>. We conclude that liver resection may improve the short- and long-term survival of intermediate HCC when patients are carefully selected and it may be safely performed in the management of intermediate HCC. However, multi-center randomized controlled trials are needed to clarify which patients are most likely to benefit from liver resection. We identified several key prognostic risk factors for overall survival and disease-free survival. We noted that patients without any prognostic risk factors achieved better short- and long-term survival than those with one or more prognostic risk factors, which indicates that careful selection of patients is critical for satisfactory outcomes in intermediate HCC patients undergoing liver resection.

Controversy remains surrounding liver resection for the management of intermediate HCC. Surgical procedures have been proposed by some treatment algorithms, and even patients beyond the Milan criteria have been selected for liver transplantation<sup>[56-58]</sup>. However, more evidence is needed about whether the indications should be expanded for liver resection for intermediate HCC.

## Abstract

**AIM:** To investigate the combined diagnostic accuracy of acoustic radiation force impulse (ARFI), aspartate aminotransferase to platelet ratio index (APRI) and Forns index for a non-invasive assessment of liver fibrosis in patients with chronic hepatitis B (CHB).

**METHODS:** In this prospective study, 206 patients had CHB with liver fibrosis stages F0-F4 classified by METAVIR and 40 were healthy volunteers were

measured by ARFI, APRI and Forns index separately or combined as indicated.

**RESULTS:** ARFI, APRI or Forns index demonstrated a significant correlation with the histological stage (all  $P < 0.001$ ). According to the AUROC of ARFI and APRI for evaluating fibrotic stages more than F2, ARFI showed an enhanced diagnostic accuracy than APRI ( $P < 0.05$ ). The combined measurement of ARFI and APRI exhibited better accuracy than ARFI alone when evaluating  $\geq$  F2 fibrotic stage ( $Z = 2.77$ ,  $P = 0.006$ ). Combination of ARFI, APRI and Forns index did not obviously improve the diagnostic accuracy compared to the combination of ARFI and APRI ( $Z = 0.958$ ,  $P = 0.338$ ).

**CONCLUSION:** ARFI + APRI showed enhanced diagnostic accuracy than ARFI or APRI alone for significant liver fibrosis and ARFI + APRI + Forns index shows the same effect with ARFI + APRI.

**Key words:** Acoustic radiation force impulse; Aspartate aminotransferase to platelet ratio index; Forns index; Hepatitis B virus; Non-invasive diagnosis

**Core tip:** Chronic hepatitis B (CHB) is a major health problem in a lot of countries all over the world, particularly in China. An accurate staging of liver fibrosis is critical for prognosticating this disease. However, although it is still the golden standard, liver biopsy is hindered by its inherent drawbacks in clinical applications. In this study, we demonstrated that non-invasive methods, including acoustic radiation force impulse (ARFI), aspartate aminotransferase to platelet ratio index (APRI) and Forns index showed significant correlations with the histological staging results from liver biopsy. The combined measurement of ARFI and APRI had the best diagnostic accuracy, which provided an ideal and convenient non-invasive diagnostic method for the detection of hepatic fibrosis of CHB patients in clinical practice.

Dong CF, Xiao J, Shan LB, Li HY, Xiong YJ, Yang GL, Liu J, Yao SM, Li SX, Le XH, Yuan J, Zhou BP, Tipoe GL, Liu YX. Combined acoustic radiation force impulse, aminotransferase to platelet ratio index and Forns index assessment for hepatic fibrosis grading in hepatitis B. *World J Hepatol* 2016; 8(14): 616-624 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i14/616.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i14.616>

of progressing to liver cirrhosis<sup>[1]</sup>. Unlike cirrhosis, hepatic fibrosis is reversible at its early stage when proper clinical therapeutic interventions are applied<sup>[2]</sup>. Therefore, an accurate staging of liver fibrosis is critical for prognosticating this disease. To date, the gold standard for staging hepatic fibrosis is still the liver biopsy, which cannot be routinely performed because of its inherent limitations, such as pain, bleeding, inaccurate staging from sampling error, and variability of biopsy interpretation<sup>[3]</sup>. During the past decades, considerable efforts have been invested in developing non-invasive methods of assessments, which may provide accurate evaluation of liver fibrosis comparable to liver biopsy. Indeed, these non-invasive methods have several advantages such as high safety margin, simple, convenient, reproducible, and inexpensive.

Acoustic radiation force impulse (ARFI) is a new quantitative assessment method of estimating tissue stiffness through measurement of shear wave velocity (SWV, measured in m/s). Its quantitative representation is named as virtual touch tissue quantification, which gives an objective numerical evaluation of the tissue stiffness<sup>[4-6]</sup>. ARFI imaging offers a quantitative assessment of the hepatic parenchyma elasticity to non-invasively grade and stage hepatic fibrosis. It has been used to diagnose hepatic fibrosis of patients with CHB<sup>[7]</sup>, hepatitis C<sup>[8]</sup>, cirrhosis<sup>[9]</sup>, and non-alcoholic fatty liver disease (NAFLD)<sup>[10]</sup>. In addition, ARFI is often performed with serum liver functions tests [e.g., alanine aminotransferase (ALT), aspartate aminotransferase (AST), total proteins, and albumin] to generate better prediction and evaluation of liver fibrosis<sup>[11]</sup>. Among these, AST platelet ratio (APRI) is a serum hepatic function test which has been proposed as a non-invasive tool for the assessment of liver fibrosis in CHB<sup>[12]</sup> or chronic hepatitis C<sup>[13]</sup>. Another important serum test is Forns index method, which uses simple obtained parameters including age, gamma-glutamyltransferase (GGT), cholesterol, and platelet count (PLT), but it requires a relatively complicated calculation<sup>[14]</sup>. One of the advantages of APRI and Forns index over the other non-invasive tests is that they are based on readily available blood tests and simple to use. Although these strategies have been widely applied in the past decade for hepatitis C evaluation<sup>[15,16]</sup>, their accuracy for CHB grading are still not comparable with liver biopsy. Therefore, a combined use of these non-invasive methods may be another promising and practical diagnostic application in CHB patients. In the current study, we aimed to compare the accuracy among ARFI, APRI, Forns index and their combinations for non-invasive diagnosis grading and prognosis of human CHB-induced hepatic fibrosis.

## INTRODUCTION

Chronic liver injury, such as chronic hepatitis B (CHB), may cause inflammation and necrosis of hepatocytes, leading to hepatic fibrosis. It is a long-term pathological change with certain possibility (about 20%)

## MATERIALS AND METHODS

### Subjects of study

This prospective study was approved by the ethical committee of Shenzhen Third People's Hospital. All study procedures and methods were in accordance with

the approved guidelines. All patients in this study were fully informed about the research protocol including the data handling and the privacy of personal data. After this procedure, patients signed the written consent. A total of 246 subjects were consecutively enrolled in this study, including 206 CHB subjects and 40 healthy subjects. These 206 CHB cases were selected from 245 CHB patients diagnosed by liver biopsy in Shenzhen Third People's Hospital, from May 2011 to December 2014. Of the 206 CHB patients, there were 39 female cases (18.9%) and 167 male cases (81.1%). Inclusion criteria are: (1) patients must be 18-65 years old; (2) with hepatitis B surface antigen positive for more than 6 mo; (3) without receiving antiviral treatment before this study; (4) ALT and AST were  $< 2 \times$  upper limit of normal (ULN) in the past 6 mo; (5)  $18.5 <$  body mass index (BMI)  $< 31.0$ ; (6) length of liver biopsy tissue  $\geq 15$  mm and contains at least 10 periportal areas; (7) hemoglobin  $> 90$  g/L, prothrombin time 11-15.1 s; (8) activated partial thromboplastin time and thrombin time were at a normal range; and (9) cardiac and renal functions were normal. Negative for the following: Human immunodeficiency virus, hepatitis A virus, hepatitis C virus (HCV), hepatitis D virus, hepatitis E virus super-infection or co-infection, auto-immune liver diseases, alcoholic steatosis, NAFLD, hepatocellular carcinoma (HCC), pregnancy, ascites, as well as jaundice. Of the 245 eligible CHB patients, 39 were excluded because of the following: NAFLD ( $n = 10$ ), received antiviral treatment before this study ( $n = 8$ ), jaundice ( $n = 5$ ), alcoholic steatosis ( $n = 6$ ), HCV infection ( $n = 2$ ), auto-immune liver disease ( $n = 1$ ), with age  $< 18$  ( $n = 4$ ), with age  $> 65$  ( $n = 1$ ), and declined to participate ( $n = 2$ ). Healthy group consisted of 40 volunteers, with 30 males and 10 females, aged range from 20-53 years old, with mean age of  $39.8 \pm 11.45$  years and no hepatitis B virus (HBV) or HCV infection, no hypertension, diabetes, fatty liver and other apparent diseases. The BMI of healthy subjects were between 18.5 and 31.0. Other parameters were similar to the CHB patients. All CHB patients were examined by ARFI one day before or on the day of liver biopsy. All the subjects had blood or sera drawn for the detection of platelet and fibrotic serological markers.

#### Liver biopsy and pathological staging

Liver biopsy tissue specimens were collected by needle puncture (MN1613, Bard Biopsy Systems, Tempe, AZ) under the Color Doppler Ultrasound guidance in a separate clinic setting for diagnostic purposes. The liver specimen was 15-20 mm in length, including at least 10 portal vein areas. Then it was embedded by paraffin and stained by Sirius Red (Sigma-Aldrich, St. Louis, MO). Liver fibrosis stage was assessed by the METAVIR scoring system (F0 = no fibrosis; F1 = portal fibrosis without septa; F2 = portal fibrosis and a few septa; F3 = numerous fibrosis without cirrhosis; and F4 = cirrhosis)<sup>[17]</sup>. The METAVIR scoring system was previously used in other reports on CHB<sup>[18,19]</sup>. Two independent pathologists were responsible for the

staging of all samples without additional information about the specimens they checked.

#### ARFI

The detection of ARFI in the liver was performed under fasting conditions using Siemens Acuson S2000 with probe detector 4C1, frequency 2.0-4.0 MHz (Siemens Healthcare, Erlangen, Germany) according to routine instructions. ARFI was mainly conducted by a radiologist (Dong CF) with assistant from another physician and a nurse. Dong CF has 11-year experience in clinical radiology and 4-year experience in ARFI diagnosis. Form of the liver capsule and the echogenicity of hepatic parenchyma were recorded. Detection of SWV (m/s) of hepatic segments s5, s6, s7 and s8 was repeated for 3 times and the mean values were calculated. Thus, 12 measurements of hepatic segments s5, s6, s7, s8 were recorded. Our pilot study in healthy volunteers showed that when compared with conventional ARFI protocol (mean value from 10 measurements), the current protocol exhibited similar results with smaller standard deviation ( $1.08 \pm 0.21$  m/s vs  $1.11 \pm 0.12$  m/s;  $t = 0.6794$ ,  $P > 0.05$ ). This is consistent with a report that showed the reproducibility of measurements in the right lobe was higher<sup>[20]</sup>. Images and data of ARFI were saved for analysis.

#### Blood markers for APRI and Forns index evaluations

AST was determined in the same laboratory prior to the liver biopsy using Siemens ADVIA 2400 Chemistry system (Siemens Healthcare). Enzymatic activity was measured at 37 °C, according to International Federation of Clinical Chemistry standards. Platelet count was assessed by an automatic blood cell analyzer (XE-5000 Automated Hematology System, Sysmex, Lincolnshire, IL). The ULN range of AST was considered as 40 U/L.

$APRI = AST(ULN)/PLT(10^9/L) \times 100$ .

$Forns\ index = 7.811 - 3.131 \times \ln(PLT) + 0.781 \times \ln(GGT) + 3.467 \times \ln(age) - 0.014 \times (cholesterol)$

#### Combined assessments of ARFI + APRI/ARFI + Forns index

A logistic regression analysis model for hepatic fibrosis  $\geq F2$  has been established by using the ENTER method.

#### Statistical analysis

Continuous normal distribution data were represented with means  $\pm$  SD. Categorical normal distribution data were represented with median  $\pm$  quartile ( $M \pm Q$ ). Kruskal-Wallis test was used to analyze the differences among these different groups. When there was a statistical significance ( $P < 0.05$ ), a post-hoc Bonferroni test was applied to analyze data between two groups.  $P < 0.05$  was considered to be statistically significant using a SPSS 13.0, IBM, Armonk, NY. The box plot was used to record the mean and degree of variation. MedCalc software (Ostend, Belgium) was used to draw receiver operating characteristic curve (ROC) and calculate cut-off value, sensitivity, specificity, positive predictive

For age and Forns index, data were represented in mean ± SD. For ARFI and APRI data, results were exhibited in median ± quartile. <sup>1</sup>Means significant change against the F0 group; <sup>2</sup>Means significant change against the F1 group; <sup>3</sup>Means significant change against the F2 group; <sup>4</sup>Means significant change against the F3 group. For gender, ARFI and APRI comparisons, size of test  $\alpha' = \alpha/n = 0.005$ ; for age and Forns index comparison, size of test  $\alpha = 0.05$ . ARFI: Acoustic radiation force impulse; APRI: Aspartate aminotransferase to platelet ratio index; BMI: Body mass index.

**Figure 1** Box plots show correlation between noninvasive tests and histological stages from liver biopsy. Top and bottom of boxes represent first and third quartiles, respectively. Length of box represents interquartile range within which 50% of values are located. Line through each box represents median. Error bars mark the minimum and maximum values (range). Small circles represent the outliers. Triangles represent the extreme value, which is  $> 3 \times$  interquartile range. ARFI: Acoustic radiation force impulse; APRI: Aspartate transaminase to platelet ratio index.

values, negative predictive values, AUROC of ARFI and APRI for every liver fibrotic stage. The ROC curve of two variables combination (ARFI + APRI and ARFI + Forns index) and three variables combination (ARFI + APRI + Forns index) for significant hepatic fibrosis ( $\geq F2$ ) was also analyzed. When AUROC  $> 0.5$ , the closer of AUROC to 1, the better diagnostic outcome it provided. Comparison of AUROC among these parameters and their combination was analyzed by the Delong test<sup>[21]</sup>.

## RESULTS

### Results of basic information, ARFI, APRI, and Forns index

Basic information (e.g., age and gender) and assess-

ment results of ARFI, APRI, and Forns index of all subjects were shown in Table 1. The average ages of subjects with significant or serious fibrosis (F2, F3 and F4) were significantly higher than subjects with mild fibrosis (F1) ( $P = 0.009$  for F2 vs F3,  $P < 0.001$  for F2 vs F4, and  $P < 0.001$  for F3 vs F4). Also, male patients showed higher incidence of hepatic fibrosis (from F1 to F4) than female patients. The differences of ARFI results among F0, F1, F2, F3 and F4 groups were significant ( $P < 0.05$ ). For Forns index, except for F0 and F1 group, the differences among other groups were significant ( $P < 0.05$ ). Results of APRI indicated that only F4 showed significant change from other groups (F0, F1, F2 and F3) (all  $P < 0.001$ ), while the F1, F2, and F3 groups showed significantly higher values than the F0 group (all  $P < 0.001$ ) (Table 1).

### Correlations between ARFI, APRI, Forns index and hepatic pathology

The median, quartile, minimum value, maximum value and outlier image (Figure 1). There was a high correlation between the staging of ARFI/APRI/Forns index and the hepatic histology, with correlation coefficient 0.845 ( $P < 0.001$ ), 0.641 ( $P < 0.001$ ) and 0.644 ( $P < 0.001$ ), respectively (Table 2). In ENTER model, Y axis was the result from liver biopsy and the X axis was the results from ARFI + APRI or ARFI + Forns Index combined assessments. The equation for ARFI + APRI was  $y = -13.27 + 9.11 \text{ ARFI} + 5.03 \text{ APRI}$ , while the equation for ARFI + Forns index was  $y = -15.08 + 8.67 \text{ ARFI} + 0.70 \text{ Forns index}$ .

### Determination of the cut-off values of hepatic fibrosis staging

There were significantly different interval ranges between different liver fibrotic stages and the corresponding ARFI and APRI results. In order to determine the cut-off value of each fibrotic stage, we applied ROC to analyze the data from both ARFI and APRI (Figure 2). From the result, it showed that the diagnostic performance of ARFI for predicting stages more than F2, F3 and F4 was 91% (95%CI: AUROC = 0.87-0.95,  $P < 0.05$ ), 94% (95%CI:

	Constant	-15.08	2.08	52.68	< 0.001	-	-

ARFI: Acoustic radiation force impulse; APRI: Aspartate aminotransferase to platelet ratio index; OR: Odds ratio; RC: Regression coefficient.

AUROC = 0.90-0.96,  $P < 0.05$ ), 96% (95%CI: AUROC = 0.93-0.98,  $P < 0.05$ ), and the best cut-off value of F2, F3 and F4 was 1.29, 1.43 and 1.62 m/s. However, APRI measurement showed decreased accuracy of diagnosing significant fibrosis when compared with ARFI (Table 3).

#### Combined assessment of ARFI + APRI/ARFI + Forns index/ARFI + APRI + Forns index for hepatic fibrosis ≥ F2

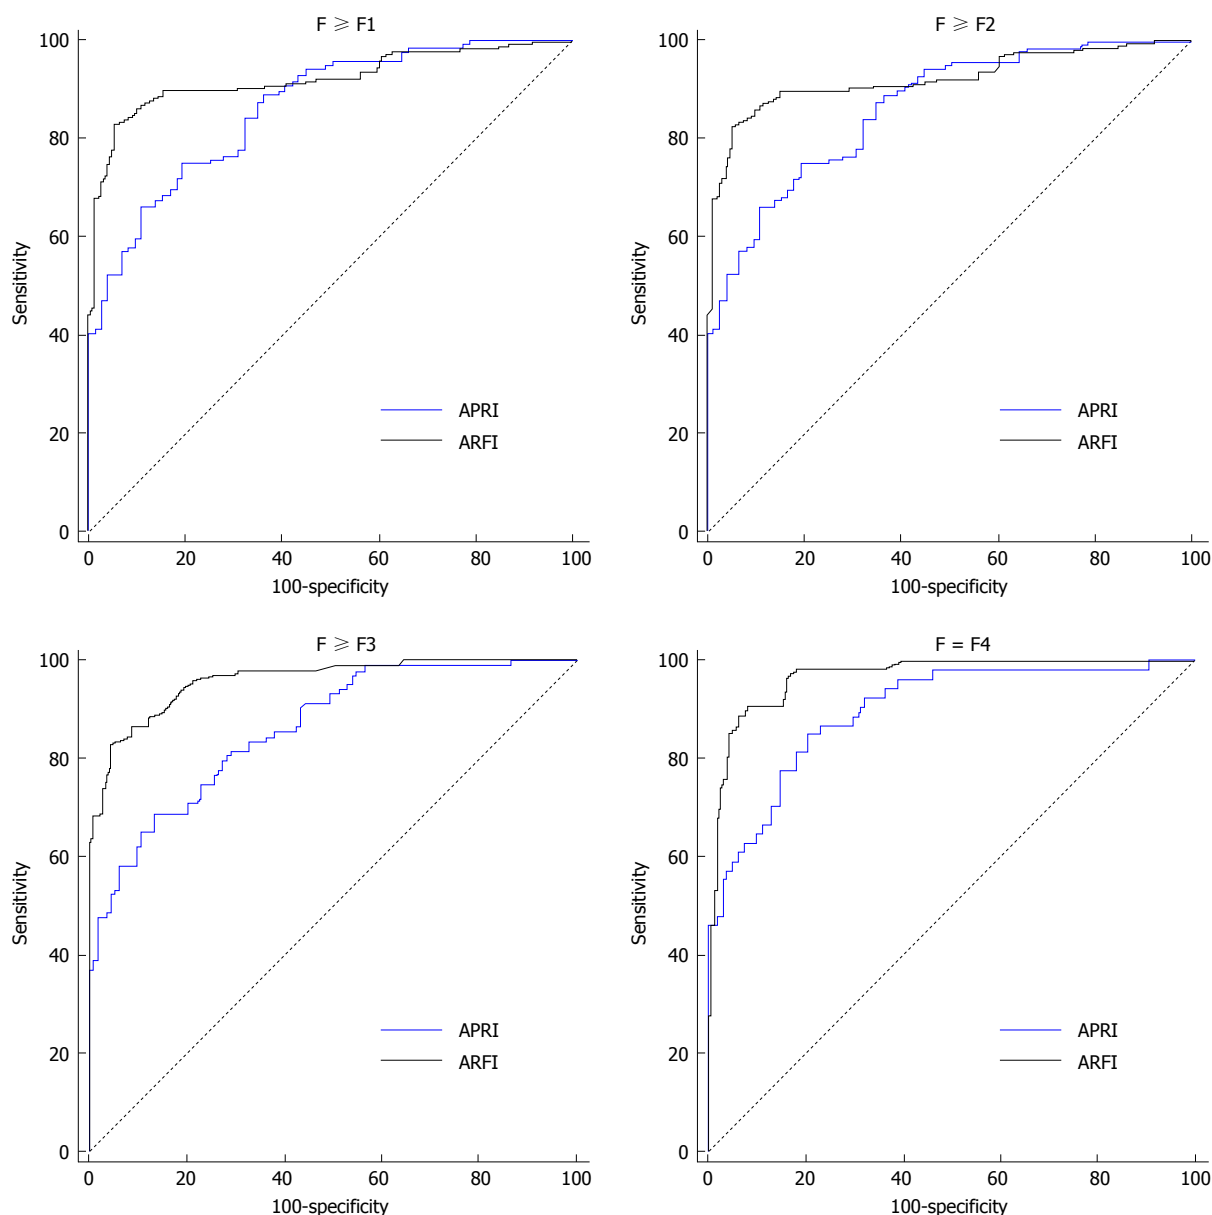

Firstly we established a logistic regression analysis model for hepatic fibrosis ≥ F2 in which the Y axis was the result from liver biopsy and the X axis was the results from combined ARFI + APRI/ARFI + Forns index assessment (Table 4). From the AUROC results of Table 5, when evaluating patients with hepatic fibrosis ≥ F2, there was a significant change between the AUROCs of ARFI + APRI and ARFI alone (0.940 and 0.913, respectively;  $Z = 2.77$ ,  $P = 0.006$ ), also

between ARFI + Forns index and ARFI alone (0.933 and 0.913, respectively;  $Z = 2.091$ ,  $P = 0.037$ ), ARFI + APRI + Forns index and ARFI alone (0.944 and 0.913, respectively;  $Z = 2.893$ ,  $P = 0.004$ ), indicating an enhanced screening ability of the combined assessment than ARFI alone. However, the change between ARFI + APRI and ARFI + APRI + Forns index was not significant (0.940 and 0.944, respectively;  $Z = 0.958$ ,  $P = 0.338$ ), suggesting that Forns index cannot further improve the diagnostic accuracy for staging hepatic fibrosis ≥ F2 when using a combined method of ARFI + APRI (Figure 3).

## DISCUSSION

To date, the gold standard for the diagnosis of liver fibrosis remains to be liver biopsy. In most circumstances, patients find it difficult to accept liver biopsy due

**Figure 2** Receiver operating characteristic curves for acoustic radiation force impulse and aspartate transaminase to platelet ratio index for diagnosis of hepatic fibrosis (F1-F4). ARFI: Acoustic radiation force impulse; APRI: Aspartate transaminase to platelet ratio index.

to its complications. From 2009, with the introduction of ARFI, the clinical research on non-invasive assessment of fibrosis rapidly progressed. As an advanced imaging technology, ARFI is capable of providing biomechanical information on the tissue stiffness and elasticity using conventional ultrasound scanning of anatomical location and structure<sup>[22,23]</sup>. However, its utility, particularly in combination with other non-invasive methods in hepatitis B, has not been adequately evaluated.

In the current study, CHB patients with different stages of liver fibrosis were diagnosed by ARFI, APRI, Forns index and their combined assessments. Our results demonstrated that the mean SWV value from ARFI was highly correlated with the staging of liver fibrosis classified by liver biopsy (METAVIR classification). This result indicated that biomechanical properties (e.g., hepatic elasticity and stiffness) had progressed

from liver fibrosis to cirrhosis during the development of CHB, which was consistent with the pathological progression of hepatocyte degeneration, necrosis, inflammation reaction, hepatocyte regeneration, formation of connective tissue fiber intervals, and liver lobule structural failure during the course of liver fibrosis of HBV infection<sup>[24]</sup>.

With the progression of liver fibrosis from F2 to F4, the effectiveness of ARFI on the diagnosis of liver fibrosis also increased. That is, when the value of SWV was lower than 1.29 m/s (clinically F0 and F1 patients), hepatic fibrosis could be unlikely significant. SWV higher than 1.43 m/s could be likely considered as an indication for serious liver fibrosis (F3, sensitivity 82.3% and specificity 89.5%), and SWV > 1.62 m/s could be diagnosed as early cirrhosis (F4, sensitivity 90.7% and specificity 92.2%). In addition, when they were used

AUROC: Area under the receiver operating characteristic curve; ARFI: Acoustic radiation force impulse; APRI: Aspartate aminotransferase to platelet ratio index.

**Figure 3** Receiver operating characteristic curves of acoustic radiation force impulse + aspartate transaminase to platelet ratio index/acoustic radiation force impulse + Forns index/ acoustic radiation force impulse + aspartate transaminase to platelet ratio index + Forns index assessment for the diagnosis of liver fibrosis  $\geq$  F2 in patient with chronic hepatitis B. ARFI: Acoustic radiation force impulse; APRI: Aspartate transaminase to platelet ratio index.

independently, ARFI was the best way for the diagnosis of fibrosis  $\geq$  F2; ARFI provides a dynamic technical support for non-invasive diagnosis of liver fibrosis. This result is in line with a report found that ARFI correlated well with liver biopsy and thus was a reliable ultrasound-based method for the assessment of advanced fibrosis induced by CHB<sup>[25]</sup>.

Currently it is difficult for non-invasive diagnostic methods to differentiate F0 and F1 fibrotic stages. However, in this study, we found that there was a significant change of ARFI readings between the F0 and F1 groups (Table 1). It is known that stage F2 posse-

sses significant diagnostic value in determining the progression of liver disease and anti-viral therapy choice. At this stage, patients have more risk in developing complications such as portal hypertension, cirrhosis, and HCC than patients without significant liver fibrosis<sup>[26]</sup>. If patients receive anti-viral therapy promptly during this period, it is possible to retard or even reverse the pathological progression of fibrosis<sup>[27]</sup>. Thus, early accurate diagnosis and appropriate therapy to patients at F2 fibrosis evidently decreases the morbidity and mortality of patients with CHB<sup>[28,29]</sup>.

Similar to the FibroScan method which is partially affected by obesity<sup>[30]</sup>, ARFI also has some disadvantages. For example, certain hepatic disorders (e.g., ascites and acute icteric hepatitis) may affect the ARFI results. However, in our study, all the enrolled subjects including obese patients with BMI of 30.81 successfully got SWV values. Thus, ARFI may have a wider application range than FibroScan. In general, ARFI overcome a spectrum of disadvantages of conventional ultrasound technologies, such as no manual operation of pressing, improved depth limitation (5 cm of the earlier machines and 8 cm of the newer machines) and location of imaging. Compared to other methods, ARFI has no pain, with good reproducibility of data and simple operation. Indeed, ARFI is potentially limited by patients with a BMI > 40 or after contrast-enhanced ultrasonography. Thus, its combination with other non-invasive methods is necessary to enhance the diagnostic accuracy<sup>[31]</sup>.

Currently, serological diagnostic assays for non-invasive assessment of liver fibrosis are available including direct and indirect methods. The main purpose of these methods is to identify the existence of fibrosis but not the grading or staging. In this study, APRI and Forns index were also used to stage liver fibrotic stage. Although the sensitivity and specificity of these methods for the diagnosis of liver fibrosis was lower than ARFI,

they partially reflected the pro-inflammatory response and hepatic compensation. The most important finding of this study was that combined measurement of ARFI and APRI exhibited better accuracy than ARFI or APRI alone when evaluating  $\geq$  F2 fibrosis stage. Combination of ARFI, APRI and Forns index did not further improve the diagnostic effect than the combination of ARFI and APRI.

In conclusion, ARFI, APRI and Forns index correlated well with the histological liver fibrosis stages in CHB patients. ARFI showed better accuracy than APRI when evaluating F2, F3 and F4 stages. Combined check with ARFI and APRI showed a significant enhancement of diagnostic accuracy than ARFI or APRI alone. ARFI + APRI exhibited similar enhancement of diagnostic accuracy of hepatic fibrosis with ARFI + APRI + Forns index when evaluating fibrotic stages more than F2 in CHB patients. This study provides an ideal and convenient non-invasive diagnostic method for the detection of hepatic fibrosis of CHB patients in clinical practice.

## COMMENTS

### Background

Hepatitis B virus (HBV) infection-mediated chronic injury of hepatocytes induces fibrosis, which may progress to end-stage liver diseases like cirrhosis and hepatocellular carcinoma. Thus, accurate grading of hepatic fibrosis is important for the application of appropriate intervening strategy to retard the progression. To date, the "golden standard" of fibrotic grading is still liver biopsy, which wide clinical application is hindered by its inherent drawbacks. In recent years, biomechanical-based ultrasonic elastography received mass attention. However, several clinical studies found that the sole application of ultrasonic elastography may bring evident errors in diagnosing hepatic fibrosis. It is suggested that a combination of ultrasonic elastography and serum liver functions tests holds the potential to overcome those disadvantages.

### Research frontiers

There are an increasing number of hospitals using non-invasive ultrasonic elastography techniques, such as acoustic radiation force impulse (ARFI) and Fibroscan to grade hepatic fibrosis of chronic hepatitis B (CHB) patients in China and chronic hepatitis C patients in Western countries. Combination of different ultrasonic elastography techniques has been reported by a number of reports. However, few studies investigate the accuracy of the combination of ultrasonic elastography and serum liver functions tests.

### Innovations and breakthroughs

This study evaluated the accuracy of one ultrasound elastography method (ARFI) and two serum biochemical tests [aspartate aminotransferase to platelet ratio index (APRI) and Forns index], as well as their combination in the assessment of liver fibrosis in CHB. The authors found that ARFI + APRI exhibited similar enhancement of diagnostic accuracy of hepatic fibrosis with ARFI + APRI + Forns index when evaluating fibrotic stages more than F2 in CHB patients.

### Applications

The data in this study suggest that doctor can yield favorable outcomes through the accumulation of technical experience. Furthermore, this study also provides readers with important information regarding an ideal and convenient non-invasive diagnostic method for the grading of hepatic fibrosis of CHB patients.

### Terminology

ARFI imaging involves mechanically exciting a localized region of interest in the tissue with acoustic radiation force to induce a shear wave in the tissue. The displacement of the shear wave is tracked using a pulse-echo mode ultrasound

at several lateral locations along the propagation path of the shear wave. By measuring the time to peak displacement at each location, the shear wave velocity was calculated, which is directly related to the elasticity of the tissue.  $APRI = AST(ULN)/PLT(109/L) \times 100$ . Forns index =  $7.811 - 3.131 \times \ln(PLT) + 0.781 \times \ln(GGT) + 3.467 \times \ln(\text{age}) - 0.014 \times (\text{cholesterol})$ .

### Peer-review

This is a good attempt by Dong *et al* to compare ARFI, APRI and Forns to determine fibrosis stage in chronic HBV patients. As these are not new techniques for fibrosis evaluation and they wanted to establish that combination of ARFI/APRI and ARFI/Forns as better non-invasive technique.

## Abstract

**AIM:** To investigate the efficacy of pegylated interferon alfa (PEG-IFN $\alpha$ ) therapy with and without entecavir in patients with chronic hepatitis D.

**METHODS:** Forty hepatitis D virus (HDV) RNA positive patients were randomized to receive either PEG-IFN $\alpha$ -2a 180  $\mu$ g weekly in combination with entecavir 0.5 mg daily ( $n = 21$ ) or PEG-IFN $\alpha$  alone ( $n = 19$ ). Patients who failed to show 2 log reduction in HDV RNA level at 24 wk of treatment, or had detectable HDV RNA at 48 wk of therapy were considered as treatment failure. Treatment was continued for 72 wk in the rest of the patients. All the patients were followed for 24 wk post treatment. Intention to treat analysis was performed.

**RESULTS:** The mean age of the patients was  $26.7 \pm 6.8$  years, 31 were male. Two log reduction in HDV RNA levels at 24 wk of therapy was achieved in 9 (43%) patients receiving combination therapy and 12 (63%) patients receiving PEG-IFN $\alpha$  alone ( $P = 0.199$ ). Decline in hepatitis B surface antigen (HBsAg) levels was insignificant. At the end of treatment, HDV RNA was negative in 8 patients (38%) receiving combination

therapy and 10 patients (53%) receiving PEG-IFN $\alpha$ -2a alone. Virological response persisted in 7 (33%) and 8 (42%) patients, respectively at the end of the 24 wk follow-up period. One responder patient in the combination arm lost HBsAg and became hepatitis B surface antibody positive. Six out of 14 baseline hepatitis B e antigen reactive patients seroconverted and four of these seroconverted patients had persistent HDV RNA clearance.

**CONCLUSION:** Administration of PEG-IFN $\alpha$ -2a with or without entecavir, resulted in persistent HDV RNA clearance in 37% of patients. The addition of entecavir did not improve the overall response.

**Key words:** Hepatitis D; Entecavir; Hepatitis B surface antigen; Pegylated interferon; Hepatitis D virus RNA; Treatment

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Chronic hepatitis D is a difficult to treat infection. Six months post treatment response is seen only in one quarter of the patients treated with pegylated interferon alfa (PEG-IFN $\alpha$ ). In an attempt to improve the response of PEG-IFN, we combined entecavir. This is the first study to evaluate the efficacy of PEG-IFN with entecavir compared to PEG-IFN alone for the treatment of hepatitis D infection. Our study showed that the combination treatment did not have any additional benefit in terms of hepatitis D virus RNA suppression and hepatitis B surface antigen reduction as compared to PEG-IFN alone.

Co-treatment with pegylated interferon alfa-2a and entecavir for hepatitis D: A randomized trial. *World J Hepatol* 2016; 8(14): 625-631 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i14/625.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i14.625>

## INTRODUCTION

The prevalence of hepatitis B surface antigen (HBsAg) positive individuals in Pakistan is 2.5%<sup>[1]</sup> and it is estimated that 5 million persons are HBsAg positive. In a large series, hepatitis D virus (HDV) antibodies in HBsAg positive individuals were found to be present in 16.6% cases<sup>[2]</sup>. So there is a large pool of patients exposed to hepatitis D in this country.

Chronic hepatitis D is a difficult to treat infection. Standard interferon-alfa is not an ideal treatment<sup>[3]</sup>. Recent few trials with pegylated interferon alfa (PEG-IFN $\alpha$ ) have shown a better response of 25%-30% six months post treatment<sup>[4,5]</sup>. In an attempt to improve the response of PEG-IFN $\alpha$ , the International Hepatitis Delta Network evaluated adefovir and later tenofovir in combination with PEG-IFN $\alpha$  in HIDIT-1 and HIDIT-2

studies<sup>[6,7]</sup>. It was expected that HIDIT-2 will yield better results due to use of potent nucleotide analogue in combination with PEG-IFN $\alpha$  for a longer duration of therapy.

Recently presented results of HITID-2 trial<sup>[7]</sup> showed that 96 wk of PEG-IFN $\alpha$ -2a and tenofovir therapy was associated with a high frequency of serious adverse events. Combination treatment had similar effects on HBsAg reduction as compared to PEG-IFN $\alpha$  alone. More than one third of the on-treatment responders experienced a posttreatment HDV RNA relapse despite prolonged therapy. The results of the long term post treatment follow-up are awaited. Combination therapy with tenofovir did not provide obvious benefits in hepatitis D patients with low baseline hepatitis B virus (HBV)-DNA levels and prolongation of treatment to 96 wk did not provide higher off-treatment HDV RNA responses (compared to 48 wk in the HIDIT-1 study).

The aim of this study is to evaluate the efficacy of PEG-IFN $\alpha$ -2a with entecavir for the treatment of chronic hepatitis D. The reason for choosing entecavir was that HIDIT-2 study using tenofovir was in progress with high hopes and no data was available for entecavir in combination with PEG-IFN $\alpha$ -2a in the chronic hepatitis D setting. This drug, particularly in combination with PEG-IFN $\alpha$ -2a, have shown good results in HBsAg decline<sup>[8]</sup>.

## MATERIALS AND METHODS

### Trial design

This randomized study compared the efficacy of PEG-IFN $\alpha$ -2a plus entecavir vs PEG-IFN $\alpha$ -2a alone for the treatment of chronic hepatitis D. Patients were randomized 1:1 into two groups. Duration of treatment was 72 wk with a post-treatment follow-up of 24 wk.

### Participants

Inclusion criteria were age 15-60 years, anti-HDV anti body positive and detectable serum HDV RNA at enrolment by real time polymerase chain reaction (PCR), elevated alanine aminotransferase (ALT) on two occasions in last 3 mo during screening phase, patients with compensated liver disease, *i.e.*, Child Pugh class A, hemoglobin > 12.0 g/dL for males and > 11.0 g/dL for females at screening, total leucocyte count > 3.000/mm<sup>3</sup>, and neutrophils > 1500/mm<sup>3</sup>, platelets > 80.000/mm<sup>3</sup>, serum creatinine level < 1.5 mg/dL and liver biopsy within 6 mo prior to randomization.

Exclusion criteria were patients who had received therapy for chronic hepatitis D, co-infection with hepatitis C or human immunodeficiency virus, serum total bilirubin greater than twice the upper limit of normal at screening, evidence of decompensated liver disease (Childs B-C), history or other evidence of a medical condition associated with chronic liver disease (*e.g.*, Wilson's disease, hemochromatosis, autoimmune hepatitis, alcoholic liver disease, alpha1 anti-trypsin deficiency, toxin exposures, thalassemia), women with ongoing pregnancy or who are breast feeding, evidence of drug

**Figure 1** Flow diagram of study patients. PEG-IFN: Pegylated interferon; ETR: End of treatment response.

and/or alcohol abuse, history of severe cardiac or pulmonary disease, inability or unwillingness to provide informed consent or abide by the requirements of the study.

### Settings

The study was conducted at the Orthopaedic and Medical Institute, Karachi, Liver Stomach Clinic, Karachi and Asian Institute of Medical Sciences, Hyderabad, Pakistan. The study was conducted in accordance with the guidelines of the Declaration of Helsinki and principles of Good Clinical Practice. Patients gave the informed consent and the ethics committee approved the study.

### Interventions

The dose of PEG-IFN $\alpha$ -2a in each arm was 180  $\mu$ g weekly (Pegasys<sup>®</sup>, F. Hoffmann-La Roche Ltd, Basel). Entecavir was given in a dose of 0.5 mg per oral daily in the combination arm.

### Outcomes

Virological response was defined as HDV RNA clearance at the end of treatment and at follow-up six months post treatment. Biochemical response was normalization of ALT at the end of treatment and at follow-up.

Treatment failure was defined as failure to show 2 log reduction in HDV RNA level at 24 wk of treatment, or presence of detectable HDV RNA at 48 wk of therapy or relapse at 24 wk post treatment follow-up. Development of decompensation (ascites or hepatic encephalopathy) during the treatment, drop outs, and lost to follow-up were also considered as treatment failure in an intention to treat analysis (Figure 1).

### Randomization

Randomization (1:1 allocation) was computer-generated. The investigators were not involved in sequence

generation or allocation concealment steps and were provided with sealed envelopes containing the treatment code to administer, in increasing numbers, according to chronological inclusion in the study.

### Viral nucleic acids and serologic testing

Viral nucleic acids were isolated from patients' serum samples by High Pure Viral Nucleic Acid Kit, according to the manufacturer's instructions (Roche Diagnostics, United States). Serum HBV DNA levels were measured using the Cobas TaqMan (Roche Diagnostics Systems, Basel, Switzerland) with a lower limit of quantification 20 IU/mL. For HDV RNA, qualitative test was based on the reverse transcription PCR of the target gene. Quantification of HDV RNA was done by real time PCR having a lower limit of detection of 500 IU/mL. Hepatitis B e antigen (HBeAg) and antibody against HBeAg (anti-HBe) status was determined using enzyme immunoassays. Serum HBsAg was quantified using the Architect HBsAg assay (Abbott Laboratories, Abbott Park, IL, United States). Grading of inflammation and the staging of fibrosis was performed according to the Batt's and Ludwig's classification<sup>[9]</sup>.

### On-treatment evaluation

The Patients were educated regarding administration of subcutaneous pegylated interferon and oral entecavir, expected adverse events, schedule for laboratory monitoring, and clinic appointment. Patients were evaluated as outpatients for safety, tolerance and efficacy every 4 wk during treatment until week 72 and then at 92 wk, *i.e.*, 24 wk post treatment during the follow-up period. At each visit complete blood count and biochemistry was assessed. HDV RNA levels were measured at baseline, 24, 48, 72 and 96 wk. HBsAg levels were measured at baseline and 24 wk. HBeAg and anti-HBe antibodies were checked at baseline. In case of HBeAg reactive, tests for HBeAg and anti-HBeAg

done were checked at 24, 48 and 72 wk to document seroconversion.

### Adverse events

Adverse events and clinical laboratory parameters were recorded. Serious adverse events were defined as those that were fatal, life-threatening, required inpatient hospitalization or discontinuation of treatment. These included decompensation of liver disease and mortality. Non-serious adverse events and laboratory abnormalities leading to dose modifications and premature withdrawal from therapy were noted.

### Statistical analysis

Data were expressed as the number of subjects with percentages for nominal variables. These variables were compared by  $\chi^2$  or Fisher exact test. Continuous variables were presented as mean (standard deviation), and compared using Mann-Whitney *U* test. The degree of the relationship between linear related variables was measured by the Pearson *r* correlation test. Statistical analyses were performed using SPSS 20.0 software (IBM SPSS Statistics, New York, NY, United States). All tests were 2-tailed and a two-tailed *P* value < 0.05 was required for statistical significance. Intention-to-treat analysis was done to include all randomized patients.

## RESULTS

A total of 40 patients with chronic hepatitis D was included during the study period of 2012-2014. Twenty-one patients were treated with PEG-IFN $\alpha$  plus entecavir (combination arm) and 19 with PEG-IFN $\alpha$  alone (mono-

therapy arm). The mean age of the patients was 26.7  $\pm$  6.8 years, 31 were male and 14 were HBeAg reactive; 7 in each arm.

Demographic and baseline clinical characteristics of the patients are shown in Table 1. Age, gender, body mass index, degree of fibrosis and inflammation on liver biopsy, ALT, HBeAg status, and HDV RNA levels were comparable to the combination and monotherapy arm patients. However, platelet count in monotherapy arm was lower than in the combination arm. Baseline HBsAg and HBV DNA levels were correlated (Pearson correlation = 0.625, *P* < 0.001). Liver biopsy was available in all cases as one of the inclusion criteria. Mild inflammation was seen in 6 and moderate to severe in 34 patients. Stage of the disease was 0-2 in 18 and 3-4 in 22 patients. Cirrhosis of the liver as evident from histology, ultrasound or clinical examination was present in 8 (20%) patients.

Two log reduction in HDV RNA levels at 24 wk of therapy was achieved in 9 (43%) patients receiving combination therapy and in 12 (63%) patients receiving PEG-IFN $\alpha$  alone (*P* = 0.199) (Figure 1). There was no significant difference in the HBsAg log10 levels after six months of therapy; 4.13  $\pm$  0.91 in the combination arm vs 4.01  $\pm$  0.51 in the monotherapy arm (*P* = 0.608), and a mean decline in HBsAg levels (*P* = 0.579). At the end of treatment, HDV RNA was negative in 8 patients (38%) receiving combination therapy and in 10 patients (53%) receiving PEG-IFN $\alpha$ -2a alone by intention to treat analysis (*P* = 0.356). ALT normalization was seen in 4 (19%) patients of the combination arm and 7 (37%) patients of the monotherapy arm (*P* = 0.293). One 29-year-old male patient in the combination arm

**Table 2** Factors associated with hepatitis D virus RNA negativity at 24 wk post-treatment *n* (%)

Variable	Responders ( <i>n</i> = 15)	Non-responders ( <i>n</i> = 25)	<i>P</i> value

Patients with decrease in HBsAg level at 24 wk from baseline	12 (80)	12 (48)	0.056
HBeAg reactive patients ( <i>n</i> = 14) who seroconverted	4/4 (100)	2/10 (20)	0.015 <sup>1</sup>

<sup>1</sup>Significant *P* value. ALT: Alanine aminotransferase; GGT: Gamma glutamyl transferase; HBeAg: Hepatitis B e antigen; HDV: Hepatitis D virus; PEG-IFN $\alpha$ : Pegylated interferon alfa; HBsAg: Hepatitis B surface antigen.

**Figure 2** Number of patients who became hepatitis D virus RNA negative. HDV: Hepatitis D virus; PEG-IFN: Pegylated interferon.

lost HBsAg and became anti-HBs antibody positive. His baseline parameters were HBsAg 2903 IU/mL (log<sub>10</sub> = 3.46), HBeAg negative with undetectable HBV DNA, and HDV RNA 158000 IU/mL (log<sub>10</sub> = 5.20). At 24 wk of treatment, his HBsAg level was 11.6 IU/mL, and HDV RNA negative. HBsAg became undetectable at 48 wk and he developed anti-HBs antibodies.

Two patients in the monotherapy arm relapsed during the 24 wk post-treatment period and one patient in the combination arm was lost to follow-up, decreasing the persistent virological clearance 24 wk post treatment to 7 (33%) in the combination arm and 8 (42%) in the monotherapy arm (*P* = 0.567) (Table 2 and Figure 2) in an intention to treat analysis. End of follow-up biochemical response was seen in only patients with the virologic response; 5/21 (24%) and 7/19 (37%)

patients of combination arm and monotherapy arm respectively (*P* = 0.369).

Though there were no statistical differences in log reduction of HBsAg levels at 24 wk of treatment between responders and non responders, there was a trend of decrease in HBsAg levels (*P* = 0.056). Out of 14 HBeAg reactive patients, HBeAg seroconversion was seen in 2 patients on combination arm and 4 patients of monotherapy arm. Both patients of the combination arm and 2 patients of the monotherapy arm achieved persistence HDV RNA clearance during the follow-up period while one patient relapsed and another had virological breakthrough during treatment. In contrast, 7 out of 8 patients, who did not seroconvert, were null responders and one patient could not complete treatment due to complications of treatment (combination arm).

One patient from the combination arm could achieve only one log reduction in the HDV RNA levels at 24 wk of treatment, and was considered as a non-responder according to the protocol. He was taken off the study and was considered a treatment failure in an intention to treat analysis. However, he continued to receive PEG-IFN $\alpha$  monotherapy for another 24 wk and became HDV RNA negative at the end of treatment and the response persisted 24 wk post treatment.

The side effects reported by these patients were usually of PEG-IFN and included nausea, weakness, fever, decreased appetite, bloating, body aches, headaches, weight loss. These side effects did not require a dose reduction. One patient developed transient

neutropenia and responded to subcutaneous filgrastim. Two patients discontinued treatment; one in each arm during the treatment before 24 wk of therapy. One patient in the monotherapy arm developed ascites while treatment was stopped in another patient in the combination arm due to severe depression.

## DISCUSSION

We used PEG-IFN $\alpha$  in combination with entecavir to treat HDV patients for the first time. The results of our study are in congruence with the previous studies that the combination treatment of nucleos(t)ides with PEG-IFN $\alpha$  does not have any edge over PEG-IFN monotherapy in terms of sustained clearance of HDV RNA<sup>[10]</sup>.

Some of the previous studies, including one of ours, have shown that response to the treatment can be predicted by the HDV RNA assessment at six months, and may give a clue whether to stop treatment<sup>[11,12]</sup>. Patients with negative HDV RNA at six months are more likely to have sustained virologic response<sup>[5]</sup> while non-responders could be identified by a less than 3 log decrease of HDV RNA at 6 mo of treatment<sup>[11]</sup>. We used two log reduction at 24 wk as a criterion to continue treatment in our protocol. One of our patients from the combination arm had one log reduction at 24 wk, was taken off the study as non-responder but he continued treatment and showed persistent virological clearance. As there are not many treatment options for chronic hepatitis D, we may suggest that the patients, even with one log reduction in the viral load at 24 wk of therapy, who continue to show steady decline in HDV RNA levels may remain on treatment.

We had a low relapse rate in this study compared to our previous experience<sup>[5]</sup> as according to the protocol only better responders continued treatment, *i.e.*, patients who had a 2 log reduction in HDV RNA levels at 24 wk of treatment. Moreover, treatment was extended to 72 wk instead of stopping at 48 wk. It may be beneficial to extend treatment duration beyond 48 wk in good responders to decrease the relapse rate, *i.e.*, patients who show a reduction in HDV RNA and HBsAg levels, and HBeAg reactive patients who seroconvert during the treatment. However, proper way to judge this dictum could be a randomized trial comparing 48 wk vs 72-96 wk of therapy. Extending duration of therapy may also be useful in patients with slow but steady decline of HDV RNA and HBsAg levels.

Heller *et al.*<sup>[13]</sup> studied prolonging therapy of chronic hepatitis D with PEG-IFN $\alpha$  for up to 5 years. Only three of 12 patients treated achieved a complete virologic response, endpoint defined as the combination of undetectable HDV RNA with loss of HBsAg and anti-HBsAg seroconversion in serum. Thus, given the poor response rates, and long-term risks of interferon-based therapies, we have to be selective in choosing our patients for a prolonged therapy. The long term results of HIDIT-1 study<sup>[6]</sup> where patients were treated for 48 wk

vs HIDIT-2 study<sup>[7]</sup> when the treatment was extended for 92 wk were not much different. Thus, given the poor response rates, and long-term risks of interferon-based therapies, we have to be selective in choosing our patients for a prolonged therapy and we cannot make it a rule. Optimized HBsAg titer monitoring and checking HDV RNA levels may improve the outcome<sup>[14,15]</sup>.

In our study, HBeAg reactive patients who seroconverted during the treatment had a less chance of relapse. One of our responder patients in the combination arm, who had a lower HBsAg level as compared to the average of the cohort, lost HBsAg during the treatment. Interferon based therapy is known to induce HBsAg seroconversion and it is usually associated with low pretreatment HBsAg levels<sup>[16]</sup>.

We did not check for genotypes of HBV and HDV for this study as it is already known that the genotype of hepatitis D is 1<sup>[17]</sup> and of hepatitis B is D in our region<sup>[18]</sup>. We followed our patients for six months post treatment. Late HDV RNA relapses may occur after PEG-IFN $\alpha$  therapy of hepatitis delta and thus the term "sustained virological response" should be used with caution in HDV infection<sup>[19]</sup>. There was a possibility of a higher relapse rate in our patients if we had followed up our patients for a longer period.

In conclusion, combination treatment did not show any additional benefit in terms of HDV RNA suppression and HBsAg reduction as compared to PEG-IFN $\alpha$  alone. Liver fibrosis and HBsAg levels did not predict HDV RNA response. HDV RNA response at 24 wk, HBeAg seroconversion and any reduction in HBsAg levels during treatment may predict the patients who are going to have a better outcome.

## ACKNOWLEDGMENTS

We are thankful to Dr. Syed Salman Ali and Dr. Muhammad Mustafa for their help as coordinator in the initial phases of study.

## COMMENTS

### Background

Chronic hepatitis D is a difficult to treat infection. Six months post treatment response is seen only in one quarter of the patients treated with pegylated interferon alfa (PEG-IFN $\alpha$ ).

### Research frontiers

In an attempt to improve the response of PEG-IFN, the authors combined entecavir which is a reverse transcriptase inhibitor.

### Innovations and breakthroughs

This is the first study to evaluate the efficacy of subcutaneous PEG-IFN with oral entecavir compared to PEG-IFN alone for the treatment of hepatitis D infection.

### Applications

This study showed that the combination treatment did not have any additional benefit in terms of hepatitis D virus (HDV) RNA suppression and hepatitis B surface antigen reduction as compared to PEG-IFN alone.

## Terminology

HDV is a small spherical enveloped RNA virus. It is considered to be a subviral satellite because it can propagate only in the presence of the hepatitis B virus. There is no satisfactory treatment available to treat this infection. However, PEG-IFN is often used.

## Peer-review

The paper indicates in a randomized trial that the addition of entecavir to PEG-IFN does not increase efficacy vs PEG-IFN monotherapy in the treatment of chronic hepatitis D. The data are valuable as they extend and confirm previous anecdotal reports.

### Abstract

Autoimmune phenomena are common in patients with chronic hepatitis C. Management of chronic hepatitis C/autoimmune hepatitis syndrome has until recently been problematic due to the adverse effects of interferon on autoimmune processes and immunosuppression on viral replication. In this report we describe 3 patients with chronic hepatitis C/autoimmune hepatitis overlap syndrome who responded rapidly to direct acting antiviral therapy. The resolution of the autoimmune process supports a direct viral role in its pathophysiology.

**Core tip:** Autoimmune phenomena are common in patients with chronic hepatitis C, and occasionally patients with chronic hepatitis C have concomitant features of autoimmune hepatitis (AIH). Management of these patients has until recently been problematic due to the adverse effects of interferon on autoimmune processes and immunosuppression on viral replication. In this report we describe 3 patients with chronic hepatitis C/AIH overlap syndrome who responded rapidly to direct acting anti-viral therapy with prompt normalization of liver tests and progressive decrease in the serologic

markers of AIH. The resolution of the autoimmune process supports a direct viral role in its pathophysiology.

Sahebjam F, Hajdu CH, Nortey E, Sigal SH. Direct acting antiviral therapy is curative for chronic hepatitis C/autoimmune hepatitis overlap syndrome. *World J Hepatol* 2016; 8(14): 632-636 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i14/632.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i14.632>

## INTRODUCTION

Chronic hepatitis C virus (HCV) infection has a worldwide prevalence of 2%-3% and is a leading cause of cirrhosis and hepatocellular carcinoma in Western countries<sup>[1]</sup>. In 40%-74% of patients, HCV is associated with autoimmune phenomena ranging from positive serologic markers to wide spread autoimmune diseases, including rheumatoid arthritis, mixed cryoglobulinemia, B-cell lymphoma, systemic lupus erythematosus, sicca syndrome, autoimmune thyroiditis, and autoimmune hepatitis (AIH).

AIH is a condition of unknown etiology characterized by a progressive inflammatory process with histopathologic changes that include interface hepatitis with a predominant lymphoplasmacytic infiltrate, elevated transaminases and immunoglobulin levels, and the presence of autoantibodies. To standardize diagnostic criteria, the International Autoimmune Hepatitis Group (IAHG) devised a scoring system to categorize patients as definite AIH, probable AIH and not AIH<sup>[2]</sup> in which points are distributed based on the presence of anti-nuclear antibody (ANA), anti smooth antibody (ASMA or F-Actin Antibody), anti-soluble liver/liver pancreas antigen, immunoglobulin G (IgG) level, liver histology and the absence of viral hepatitis.

In patients with chronic hepatitis C, markers of AIH are frequently present. Up to 40% of HCV patients may have positive ANA, SMA, and LKM-1 autoantibodies<sup>[3]</sup>. In most cases, titers are usually low, and cases with positive serologies are in general histologically indistinguishable from those without detectable antibodies. However, patients with an autoimmune overlap syndrome in whom liver biopsies reveal features of both chronic hepatitis C and inflammatory features characteristic of AIH are occasionally encountered<sup>[4]</sup>.

The treatment of patients with HCV/AIH overlap syndrome has until recently been challenging. Because interferon (IFN) therapy for chronic HCV can trigger latent AIH and lead to severe hepatic failure, there are significant concerns about its use in patients with preexisting autoimmune processes<sup>[5]</sup>. Immunosuppression, on the hand, has an adverse effect on viral replication<sup>[6]</sup>. In this report, we present three patients with AIH/hepatitis C overlap syndrome in whom both processes rapidly responded to interferon-free antiviral therapy.

## CASE REPORT

### Case report 1

A 22-year-old Caucasian man with chronic hepatitis C presented with mild generalized fatigue and anhedonia. Risk factors for infection included intravenous drug use and possible vertical transmission. Physical examination did not reveal stigmata of advanced liver disease. Initial laboratory evaluation was remarkable for markedly elevated aspartate aminotransferase (AST) 314 U/L (normal, 15-46) and alanine aminotransferase (ALT) 608 U/L (normal, 15-65) levels, total bilirubin 0.6 mg/dL (normal, 0-1), albumin 4.5 g/dL (normal, 3.5-5), international normalized ratio 1.1, platelet count of 156 K/uL (normal 150-400), HCV RNA viral load of 1410000 IU/mL (6.15 logs), HCV genotype 1. Serological markers of AIH were remarkable for elevated IgG at 2100 mg/dL (normal, 700-1600), positive ANA (1:80), and positive F-actin antibody of 37 units (normal, 0-19).

Liver biopsy showed established cirrhosis with mild to moderate activity. Inflammatory infiltrates composed of lymphocytes with lymphoid aggregate formation, polymorphonuclear cells and scattered plasma cells were present in the portal tracts, interface and fibrous septae. A brisk lobular lymphoplasmacytic infiltrate with rare acidophil bodies was also present. Due to the severity of the inflammatory activity, the overall histologic appearance was suggestive of an autoimmune process with a simplified IAHG, diagnostic score of 6 (probable AIH).

The patient was treated with budesonide 3 mg three times daily for two months with limited biochemical response (ALT, 343 U/L) and response in either the total protein level (8.2 g/dL, pre-; 7.6 g/dL, post-) or HCV viral load [1523252 IU/ML (6.18 logs)]. Budesonide was then discontinued, and a 12 wk interferon-free regimen of simeprevir and sofosbuvir started with prompt normalization of aminotransferase levels, normalization of the IgG level (1350 mg/dL), and achievement of a sustained response. F-Actin antibody titer did not change following treatment (37 U before, 36 U after) (Figure 1).

### Case report 2

A 62-year-old man with chronic hepatitis C presented with generalized fatigue. Risk factors for hepatitis C infection included a blood transfusion at birth. Past medical history was significant for epilepsy and depression. Physical examination did not reveal stigmata of chronic liver disease. Laboratory evaluation was remarkable for AST 447 U/L, ALT 480 U/L, total bilirubin of 0.8 mg/dL, albumin 3.9 g/dL, international normalized ratio 1.4, HCV genotype 1, platelet count of 115 K/uL, HCV RNA viral load 1660000 IU/mL. Serologic markers of AIH were remarkable for elevated IgG at 3030 mg/dL, ANA titer 1:80, and F-actin antibody titer of 24 U.

Liver biopsy revealed mild to moderate portal infiltration consisting of lymphocytes with lymphoid aggregate formation, plasma cells and eosinophils. Interface

**Figure 1** Aspartate aminotransferase and alanine aminotransferase levels in case 1 and case 2 prior and after immunosuppression and hepatitis C infection treatment. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

**Figure 2** Liver biopsy of case 3 demonstrating interface activity with abundant plasma cell infiltration (600 × H and E staining).

activity was moderate with plasma cells easily identified and lobular inflammation was mild to moderate with acidophil bodies readily found. Macrovesicular steatosis in 30% to 40% of the specimen with focal ballooning degeneration and focal bridging fibrosis (stage 3) was also present. The moderate interface activity with numerous plasma cells was consistent with an autoimmune process with a simplified IAHG diagnostic score of 6 (probable AIH)<sup>[7]</sup>.

The patient declined interferon therapy and was started on budesonide 3 mg twice daily without significant effect on ALT or IgG levels (Figure 1) and HCV viral load remain unchanged (1177912 IU/mL). After 6 mo, budesonide was tapered to 3 mg daily, and a repeat liver biopsy was performed which revealed persistent portal and lobular inflammation, worsening ballooning degeneration and progression to cirrhosis. Budesonide was discontinued, and interferon-free therapy with 12 wk of simeprevir and sofosbuvir initiated. Aminotransferase levels promptly normalized. HCV RNA was undetectable by treatment week 8, and a sustained virologic response was achieved. During and after completion of therapy, IgG and F-actin levels progressively decreased (2070 mg/dL, 15 units respectively), and ANA titer was negative one year after completion of antiviral therapy.

### Case report 3

A 62-year-old African American woman with a history

of alcoholism was referred for treatment of chronic hepatitis C. Risk factors included a history of intravenous drug abuse. Liver biopsy 3 years previously revealed stage IV fibrosis and moderate necroinflammatory activity with plasma cell component (Figure 2). Physical examination was significant for an enlarged left lobe of liver. Initial laboratory evaluation was remarkable for mildly elevated AST 68 U/L, ALT of 84 U/L levels, total bilirubin 0.8 mg/dL, albumin 3.6 g/dL, total protein 8.89 g/dL, international normalized ratio 1.2, platelet count of 85 K/uL, HCV RNA viral load of 285000 IU/mL (5.46 logs), HCV genotype 1a. Serological markers of AIH were remarkable for elevated IgG 3250 mg/dL, positive ANA, F-actin antibody titer of 37.

The patient was started on ledipasvir/sofosbuvir. Viral load became undetectable within 4 wk, and she achieved SVR with 12 wk of treatment. At the end of therapy, aminotransferase levels were normal (AST, 36; ALT, 27). ANA became negative, serum total protein decreased to normal level of 7.6 g/dL (normal, 6.3-8.2), and serum IgG decreased to 2300 mg/dL (normal, 700-1600). F-actin antibody titer also decreased to the normal range (17 U).

## DISCUSSION

In this report, we present the response of HCV/AIH overlap syndrome to direct acting antiviral (DAA) therapy. The diagnosis of overlap syndrome was established by the presence of active viremia and characteristic biochemical, serologic, and histopathologic features of AIH. Although only a simplified AIH score of 6 was present, it is important to note that only a maximum score of 6 is possible if viral hepatitis component is not included. There were no biochemical or immunologic responses, but rather worsening pathologic changes in the one case in which a repeat liver biopsy was performed. In contrast, there was a prompt normalization of liver biochemistries and resolution of serologic features of AIH in response to DAA therapy in all three cases.

Although the pathogenesis of AIH is incompletely understood, a frequently cited mechanism is a reaction to viral infections in genetically susceptible persons. Cross-reaction between viral particles and liver auto-

antigens has been proposed as a trigger mechanism of virus induced AIH. Activation of resting T cells by inducing the release of a variety of cytokines, and polyclonal activation of lymphocytes has also been proposed to play a role. An association with measles virus was first proposed in 1987 after identification of persistent measles virus genome in lymphocytes and high antibody titers in 12 of 18 patients with AIH<sup>[8]</sup>. Vento *et al*<sup>[9]</sup> reported the development of AIH in healthy relatives of patients with AIH that was associated with cases of infectious mononucleosis due to Epstein-Barr virus (EBV) infection. In these cases, the development and persistence of autoantibodies to the asialoglycoprotein receptor were documented, and it was proposed that cross reactivity between asialoglycoprotein and EBV antibodies caused an autoimmune reaction. Recently, high prevalence of hepatitis E antibody positivity was found in patients with AIH, compared to healthy, and individuals with HCV or HBV infection<sup>[10]</sup>. Other viral infections that have been associated with AIH include hepatitis B, varicella-zoster and rubella<sup>[11]</sup>.

There are several proposed mechanisms in the pathogenesis of autoimmunity in HCV. HCV facilitates lymphotropism in which clonal B-lymphocyte expansion leads to widespread autoantibody production. The HCV envelope protein E2 is able to bind to the CD81 molecule expressed on hepatocytes and B-lymphocytes, resulting in a dysregulation of cytokines with an enhanced Th1 immune response. This may cause self-reactive lymphocytes to induce autoimmunity in the chronic HCV patient. Recently, cross-reactivity between CYP2E1 and specific sequences in HCV-NS5b protein has been shown responsible for the production of auto-antibodies targeting self-proteins<sup>[12]</sup>.

There are no established treatment strategies for HCV/AIH overlap syndrome. IFN alone previously was avoided due to the concern about its potential to induce an autoimmune flare. Early reports of steroid therapy prior to the era in which HCV RNA testing was available frequently included RNA negative patients, making determination of efficacy difficult to assess. Several small series and case reports have advocated pre-treatment with corticosteroids with or without azathioprine followed by IFN-based therapy to prevent an IFN-induced flare<sup>[13-15]</sup>.

The development of interferon-free direct acting antiviral regimens has revolutionized the treatment of HCV. These new treatments are potent, safe, and achieve rapid normalization of aminotransferase levels and viral suppression within the first few weeks of therapy. This is the first description of DAA therapy for HCV/AIH overlap syndrome. The rapid normalization of aminotransferase level and suppression of viral RNA followed by a gradual disappearance of autoimmune markers without immunosuppression supports the hypothesis that the viral infection triggers the autoimmune response. Based on our cases, we propose DAA agents as an initial treatment for patients with HCV/AIH overlap syndrome and early reassessment of response.

Corticosteroids and immunosuppression should be reserved for those who are refractory to this approach.

## COMMENTS

### Case characteristics

Three patients presented for treatment of chronic hepatitis C.

### Clinical diagnosis

Severe hepatitis with markedly elevated aminotransferase levels.

### Differential diagnosis

Chronic hepatitis C with severe activity or superimposed second process such as autoimmune hepatitis (AIH).

### Laboratory diagnosis

Positive anti-nuclear antibody and anti-smooth muscle antibody, elevated immunoglobulin G (IgG) level.

### Pathologic diagnosis

Liver biopsy reveal in all three cases prominent numbers of plasma cells compatible with AIH.

### Treatment

Treatment with steroids in the form of budesonide was not effective. However, there was prompt resolution of both the chronic hepatitis C and AIH with direct acting anti-viral therapy.

### Related reports

Reports have suggested an infectious precipitant for AIH. Previous therapeutic approach for the treatment of chronic hepatitis C/AIH have usually involved steroid therapy followed by interferon-based therapy with variable success.

### Term explanation

In chronic hepatitis C/AIH overlap syndrome, hepatitis C viremia is present in patients with AIH as defined by the presence of anti-nuclear and anti-smooth muscle antibodies, elevated IgG levels, and lymphoplasmacytic infiltrates on liver biopsy.

### Experiences and lessons

Resolution of both the viral and AIH in response to direct acting antiviral therapy supports the hypothesis that the autoimmune process is caused by the viral infection.

### Peer-review

In the present manuscript, the authors described 3 case patients with chronic HCV/AIH syndrome who were treated with direct acting antiviral (DAA). DAA treatment promptly induced the normalization of liver biochemistries and the resolution of serological features of AIH. The present report is potentially easily understandable and very interesting.

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Kazuaki Inoue, MD, PhD, Associate Professor, Department of Internal Medicine, Division of Gastroenterology, Showa University Fujigaoka Hospital, Yokohama 227-8501, Japan

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

## Abstract

**AIM:** To examine the association between interferon (IFN) therapy and loss of hepatitis B surface antigen (HBsAg) in inactive HBsAg carriers.

**METHODS:** This was a retrospective cohort study in inactive HBsAg carriers, who were treatment-naïve, with a serum HBsAg level < 100 IU/mL and an undetectable hepatitis B virus (HBV) DNA level (< 100 IU/mL). All the 20 treated patients received subcutaneous PEG-IFN alfa-2a 180 µg/wk for 72 wk and were then followed for 24 wk. There were 40 untreated controls matched with 96 wk of observation. Serum HBsAg, HBV DNA, and alanine aminotransferases were monitored every 3 mo in the treatment group and every 3-6 mo in the control group.

**RESULTS:** Thirteen (65.0%) of 20 treated patients achieved HBsAg loss, 12 of whom achieved HBsAg seroconversion. Mean HBsAg level in treated patients decreased to  $6.69 \pm 13.04$  IU/mL after 24 wk of treatment from a baseline level of  $26.22 \pm 33.00$  IU/mL. Serum HBV DNA level remained undetectable (< 100 IU/mL) in all treated patients during the study. HBsAg level of the control group decreased from  $25.72 \pm 25.58$  IU/mL at baseline to  $17.11 \pm 21.62$  IU/mL at

week 96 ( $P = 0.108$ ). In the control group, no patient experienced HBsAg loss/seroconversion, and two (5.0%) developed HBV reactivation.

**CONCLUSION:** IFN treatment results in HBsAg loss and seroconversion in a considerable proportion of inactive HBsAg carriers with low HBsAg concentrations.

**Key words:** Chronic hepatitis B surface antigen carriers; Inactive hepatitis B surface antigen carriers; Interferon; Peginterferon alfa-2a; Hepatitis B surface antigen loss/seroconversion

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This study examined the association between interferon (IFN) therapy and loss of hepatitis B surface antigen (HBsAg) in inactive HBsAg carriers. This was a retrospective cohort study in inactive HBsAg carriers with a serum HBsAg level  $< 100$  IU/mL and a persistently undetectable hepatitis B virus (HBV) DNA level ( $< 100$  IU/mL). All the 20 treated patients received subcutaneous PEG-IFN alfa-2a 180  $\mu$ g/wk for 72 wk and were then followed for 24 wk. IFN treatment resulted in HBsAg loss (65.0%) and seroconversion in a considerable proportion of inactive HBsAg carriers with low HBsAg concentrations. In the control group, no patient experienced HBsAg loss/seroconversion, and 2 (5.0%) developed HBV reactivation.

Li MH, Xie Y, Zhang L, Lu Y, Shen G, Wu SL, Chang M, Mu CQ, Hu LP, Hua WH, Song SJ, Zhang SF, Cheng J, Xu DZ. Hepatitis B surface antigen clearance in inactive hepatitis B surface antigen carriers treated with peginterferon alfa-2a. *World J Hepatol* 2016; 8(15): 637-643 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i15/637.htm> DOI: <http://dx.doi.org/10.4254/wjh.v8.i15.637>

## INTRODUCTION

Chronic hepatitis B virus (HBV) infection is the leading cause of end-stage liver disease or hepatocellular carcinoma (HCC) throughout the world. In the nature history of chronic HBV infection, inactive hepatitis B surface antigen (HBsAg) carriers, defined as HBsAg positive, hepatitis B envelope antigen (HBeAg)-negative/antiHBe-positive, undetectable HBV DNA level and normal alanine aminotransferases (ALT) levels, frequently have good long-term clinical outcomes and thus are not recommended for antiviral treatment<sup>[1-3]</sup>. However, this inactive carrier status was not always sustained. Fourteen percent to 24% of inactive carriers have reactivation after years of quiescent disease, and 4.2% to 20% of them reverse back to HBeAg positivity<sup>[4-7]</sup>, with increased cumulative probabilities of reactivation of hepatitis B after years of follow-up<sup>[8]</sup>. Compared to a control subcohort (negative for HBsAg), inactive HBsAg

carriers have higher risks of hepatocellular carcinoma and liver-related death<sup>[9]</sup>, especially in countries with a high prevalence of HBV infection<sup>[8,9]</sup>. In contrast, 100% and 90% of patients had improvement and stable liver inflammation and liver fibrosis<sup>[10]</sup>, respectively, and no HCC occurred in patients with HBsAg clearance after interferon (IFN) treatment<sup>[11]</sup>. Nevertheless, spontaneous HBsAg loss occurred in inactive carriers only at rates from 1% to 1.5% per year observed in Caucasians<sup>[12]</sup> and Asians<sup>[13]</sup>. HBsAg clearance usually indicates recovery from HBV infection, and has been an aim of antiviral therapy<sup>[2]</sup>. In the real life, HBsAg positive people were restricted in many aspects such as work, diet, and cosmetic surgery, in China, and many of them hope to obtain HBsAg loss through effective methods.

IFN treatment exerts direct antiviral as well as immunoregulatory effects<sup>[14]</sup>, and can induce specific and nonhepatotoxic degradation of nuclear HBV covalently closed circular DNA (cccDNA)<sup>[15]</sup>, and increased HBV-specific T-cell responses in chronic HBV infected patients with undetectable levels of serum HBV DNA<sup>[16]</sup>. This retrospective cohort study was conducted to evaluate the efficacy of PEG-IFN alfa-2a treatment in chronic inactive carriers with a low HBsAg level.

## MATERIALS AND METHODS

### Selection of patients

A retrospective cohort study including inactive HBsAg carriers attending the department of hepatology, Beijing Ditan Hospital, Capital Medical University between May 2008 and August 2012 was conducted. We diagnosed inactive HBsAg carriers based on their history of HBV infection, HBV DNA level, serological markers, and liver function. Patients with cirrhosis, which was diagnosed as liver stiffness  $> 9$  kPa or presence of portal hypertension (spleen enlargement with a reduction in platelet count) by FibroScan and ultrasonic examinations, were excluded. Patients who were treatment-naïve, HBsAg positive, anti-HBs-negative and HBeAg negative for more than 6 mo, had a persistently undetectable HBV DNA level ( $< 100$  IU/mL) and normal ALT levels ( $< 19$  IU/mL for females and  $< 30$  IU/mL for males, measured every 3-6 mo) during the preceding 2 years, and serum HBsAg  $< 100$  IU/mL on two occasions during the month prior to enrollment were included in the study. Patients with other liver diseases or co-infection of hepatitis C virus, hepatitis D virus, and human immunodeficiency virus, as well as those who had a history of immunosuppressive or antiviral drug usage were excluded. HBV genotyping cannot be performed due to an undetectable HBV DNA level in the subjects; however, epidemiological studies showed the HBV genotypes in China were mainly genotypes B and C<sup>[17,18]</sup>.

Participants in the treatment group contained all the patients who were willing to receive IFN treatment for achieve HBsAg clearance and had completed 72 wk of treatment with PEG-IFN alfa-2a and 24 wk of follow-up after completing the treatment. There were

**Figure 1** Mean hepatitis B surface antigen level decreased in a time-dependent manner in treated patients and was significantly lower at week 24 than at baseline. HBsAg: Hepatitis B surface antigen.

40 controls matched for age, sex, and HBsAg level, and undetectable HBV DNA with persistently normal ALT levels, and they were selected from 284 untreated patients who attended the clinic and completed 96 wk of observation during the same period as treated patients.

#### Ethics approval

The study adhered to the Declaration of Helsinki and ethics approval was obtained from the Beijing Ditan Hospital of Capital Medical University Institutional Review Board. Written informed consent was obtained from all subjects before enrolment.

#### Treatment and follow-up

The treated cohort comprised 20 patients who had received subcutaneous PEG-IFN alfa-2a at a dose of 180 µg/wk for 72 wk and had been followed for 24 wk after completing the treatment, while the control cohort comprised 40 matched patients who had finished 96 wk of observation.

None of the participants received immunosuppressive or oral antiviral drugs during the study period. In the treated patients, serum HBsAg, anti-HBs and HBV DNA levels were measured once every 3 mo, and peripheral blood neutrophil and platelet counts, and liver and kidney function tests were performed once every 1-3 mo. These biomarkers were measured once every 3-6 mo in controls.

#### Safety and efficacy assessments

Kidney and liver function biomarkers, including serum creatinine, blood urea nitrogen, ALT, aspartate aminotransferase, albumin and total bilirubin (Tbil), were measured with an automated biochemical analyzer. Peripheral blood neutrophil and platelet counts were measured with an automatic blood cell analyzer.

HBV DNA was measured with a commercially available real-time fluorescence PCR kit with a detection limit of 100 IU/mL (Piji Company, Shenzhen City, China). HBsAg concentrations were quantified by an automated chemoluminescent microparticle immunoassay (Architect i2000 HBsAg quantitative assay, Abbott Laboratories,

Abbott Park, IL, United States, sensitivity < 0.05 IU/mL; dynamic range 0.05-250 IU/mL). HBsAg loss was defined as HBsAg concentration < 0.05 IU/mL. Anti-HBs was measured with an Architect i2000 kit (Abbott Laboratories, dynamic range of 0.00-1000 mIU/mL), with concentrations ≥ 10 mIU/L being considered positive. The primary efficacy endpoints were HBsAg loss and seroconversion.

#### Statistical analysis

Unless otherwise stated, clinical and biological outcomes before and after treatment are expressed as mean ± SD or median (range), and were compared using paired Student's *t*-tests, with a *P*-value less than 0.05 being considered statistically significant. Qualitative variables are presented as counts and percentages and were compared using Fisher's exact tests. All statistical analyses were performed using SPSS statistical software version 13.0 (Chicago, IL, United States).

## RESULTS

#### Patients and clinical characteristics

A total of 60 inactive chronic HBsAg carriers were included in the study, 20 of whom were in the treated group and 40 in the control group. There were no significant differences in the baseline characteristics between the treated and control groups (Table 1). However, in the treatment group, the patients who achieved HBsAg loss had a lower baseline HBsAg level of 8.09 (3.81-22.50) IU/mL and were younger (age of 31.46 ± 12.16 years) than patients without HBsAg loss after treatment [baseline HBsAg level of 18.95 (2.85-83.00) IU/mL and age of 38.24 ± 9.25 years], but there was no significant difference.

#### HBsAg kinetics and clinical outcomes

HBsAg levels decreased with increasing treatment period in the treated group (Figure 1). Among patients treated with PEG-IFN alfa-2a, the mean HBsAg level decreased by 55.98% from baseline to week 12 (from 26.22 ± 33.00 to 11.59 ± 20.83 IU/mL, *P* = 0.108), by 74.59% from baseline to week 24 (to 6.69 ± 13.04 IU/mL, *P* = 0.024 vs baseline), and was 0.045 IU/mL (range, 0.02-2.44 IU/mL) at the end of follow-up (week 96). Of the 20 treated patients, 13 achieved HBsAg loss, of whom 12 occurred during treatment and 1 at follow-up time, with a mean of 40.62 ± 22.74 mo after the initiation of treatment, in which 12 achieved HBsAg seroconversion (Table 1). Eighty percent (8/10) of patients with an HBsAg level < 10 IU/mL achieved HBsAg loss after treatment. In the remaining seven treated patients, the mean HBsAg level decreased by 66.93% from baseline to the end of follow-up (from 37.43 ± 38.69 to 8.20 ± 15.69 IU/mL, *P* = 0.049). Serum HBV DNA remained undetectable (< 100 IU/mL) in all treated patients during the treatment and follow-up periods, and no return to HBsAg positivity occurred in all patients during the study course. In contrast,

**Table 1** Baseline characteristics and outcomes at the end of treatment and follow-up

Characteristic	Treatment group	Control group	P-value
No.	20	40

HBsAg seroconversion, <i>n</i> (%)	12 (60.0)	0 (0)	0.000
HBV DNA reactivation, <i>n</i> (%)	0 (0)	2 (5.0)	0.309

ALT: Alanine aminotransferase; EOF: End of follow-up; EOT: End of treatment; HBsAg: Hepatitis B surface antigen; HBV: Hepatitis B virus.

the mean HBsAg level of the control group remained relatively stable over 96 wk and was 25.72  $\pm$  25.58 IU/mL at baseline and 17.11  $\pm$  21.62 IU/mL at week 96 ( $P$  = 0.108; Figure 1). No patients in the control group experienced HBsAg loss/seroconversion, and two (5.0%) experienced HBV reactivation, defined as return of serum HBV DNA to positivity from undetectable level (< 100 IU/mL) (Table 1).

### Safety

Among all patients in the treated group, peripheral blood neutrophil count decreased, which was lower than  $0.85 \times 10^9/L$  in 13 (65.0%) individuals. The platelet count also decreased, which was lower than  $6.0 \times 10^{12}/L$  in eight (40.0%) patients, and dose reductions were not required. Serum creatinine and blood urea nitrogen remained stable during treatment with PEG-IFN alfa-2a. Five patients had a loss of body weight and six patients had mild hair loss during treatment. There were no thyroid dysfunction and neuropsychiatric adverse effects, including depression, delirium, irritability and agitation. All adverse reactions disappeared 3-6 mo after the therapy was discontinued.

ALT levels increased during treatment in 18 of 20 (90.0%) treated patients, and 9 (45.0%) individuals experienced an ALT level > 80 IU/L. However, bilirubin levels remained within normal limits throughout the treatment and follow-up periods in all treated patients. Normalization of ALT levels coincided with HBsAg loss and/or the end of treatment, and was maintained during follow-up.

## DISCUSSION

HBsAg level reflects the transcriptional activity of the cccDNA and is used as a proxy measure of HBV

infection and for treatment guidance<sup>[19-21]</sup>. HBsAg declines during treatment and its level at the end of treatment can predict HBeAg seroconversion in HBeAg-positive patients<sup>[22-24]</sup> and sustained viral response in HBeAg-negative patients<sup>[25-27]</sup>. Thus, inactive HBsAg carriers were not recommended for antiviral therapy<sup>[1-3]</sup>. However, this inactive state was not always sustained. A long-term follow-up study showed cumulative probabilities of hepatitis relapse in inactive HBsAg carriers of 10.2%, 17.4%, 19.3%, 20.2% and 20.2% after 5, 10, 15, 20 and 25 years of follow-up, respectively, with an annual rate of 1.55%<sup>[28]</sup>. Another long-term longitudinal study (up to 23 years) showed that 1%-17% of inactive carriers reverted back to HBeAg-positive chronic hepatitis<sup>[4]</sup>. Cirrhosis and HCC may still develop in some inactive HBsAg carriers<sup>[28-30]</sup>. In contrast, no cirrhosis or HCC occurred in patients with HBsAg loss after IFN treatment, indicating that HBsAg clearance is currently the only parameter associated with an excellent long-term prognosis<sup>[10]</sup>, and the strongest factor predicting excellent long-term outcome in HBV infected individuals is HBsAg loss, spontaneously or after treatment<sup>[10]</sup>. Therefore, it could be speculated that inactive HBsAg carriers can get further improvement in outcomes if HBsAg loss could be achieved after IFN treatment.

This study contained all participants who were inactive carriers with HBsAg < 100 IU/mL and wished to achieve HBsAg clearance by PEG-IFN alfa-2a treatment during the study period. Despite the lack of liver pathology for diagnosis, the patients could be considered as inactive for having undetectable HBV DNA and persistent normal ALT for 2 years, serum HBV DNA < 100 IU/mL and HBsAg < 100 IU/mL at enrollment. It has been reported that HBsAg < 1000 IU/mL with HBV DNA < 2000 IU/mL can distinguish inactive from active carriers with a diagnostic accuracy of 94.3%, sensitivity

of 91.1%, specificity of 95.4%, positive predictive value of 87.9%, and negative predictive value of 96.7%<sup>[31]</sup>. Although the present study was not a randomized controlled study, all treated inactive carriers with HBsAg < 100 IU/mL and matched controls according to age, sex, and HBsAg and ALT levels were included for eliminating the bias.

Effects, including the probability of HBsAg clearance, can be enhanced by extended therapy with PEG-IFN alfa-2a<sup>[32]</sup>. In our study the patients were given 72 wk of treatment. After 12 wk of treatment with PEG-IFN alfa-2a, HBsAg levels decreased significantly compared with baseline levels. Furthermore, at the end of study, HBsAg loss occurred in most of treated patients, and HBsAg levels in the remaining seven treated carriers who did not achieve HBsAg loss decreased significantly. In contrast, mean HBsAg level of the control group remained constant during 96 wk of observation and no patients experienced HBsAg loss. These results suggest that inactive HBsAg carriers could benefit from PEG-IFN alfa-2a treatment.

In the present study, all participants had HBsAg < 100 IU/mL and they may have a good long-term clinical outcome, even HBsAg loss, after long-term follow-up. However, it was reported that spontaneous HBsAg loss in patients with HBsAg < 100 IU/mL occurred in a mean period of  $86.6 \pm 29$  mo (range, 26-115) after the baseline visit with an annual rate of 1.6%<sup>[33]</sup>, and in the present study after 72 wk treatment of PEG-IFN alfa-2a, HBsAg clearance occurred in 65% of treated objects. In a study by Tseng *et al.*<sup>[34]</sup>, HBsAg level < 10 IU/mL at baseline was the strongest predictor of HBsAg loss. However, the rate of HBsAg loss was only 7.4 per 100 persons per year and it occurred in a mean period of  $5.8 \pm 4.2$  years. Although half of the subjects included in this study had HBsAg < 10 IU/mL and undetectable HBV DNA, 80% (8/10) of them achieved HBsAg loss after 72 wk of IFN treatment, suggesting that PEG-IFN alfa-2a treatment can make inactive carriers achieve HBsAg clearance in a short-term period compared with spontaneous HBsAg loss occurring in the nature history. Although Chen *et al.*<sup>[35]</sup> reported in a case-control study that the positive predictive value of HBsAg level of 200 IU/mL in predicting HBsAg loss occurring within 1 year was 36%, their study design was different from ours. The aim of their study was to observe the difference in HBsAg decrease between 46 patients who underwent spontaneous HBsAg loss and 46 patients who had no HBsAg loss during the same observation course. The aim of our study was to compare the rate of HBsAg clearance in patients treated with PEG-IFN alfa-2a compared with untreated patients, and the result showed that the rate of HBsAg clearance was significantly higher in patients treated with PEG-IFN alfa-2a than in untreated patients. The results of our study suggested that inactive carriers can receive PEG-IFN alfa-2a therapy to increase the probability of HBsAg clearance and shorten the time compared with that occurring spontaneously.

In conclusion, our study demonstrated that treat-

ment with PEG-IFN alfa-2a produced a high rate of HBsAg loss/seroconversion in inactive carriers with low HBsAg levels. However, whether inactive carriers with HBsAg levels more than 100 IU/mL could benefit from PEG-IFN alfa-2a treatment needs further study.

We are grateful to staff for effectively facilitating the present project.

## COMMENTS

### Background

Although inactive hepatitis B surface antigen (HBsAg) carriers often have no liver inflammation and are not recommended to undergo treatment, they may develop hepatitis relapse or revert back to HBeAg-positive chronic hepatitis, and cirrhosis and hepatocellular carcinoma (HCC) may still develop in some inactive HBsAg carriers in a long-term follow-up period. In contrast, no cirrhosis or HCC occurred in patients with HBsAg loss after interferon (IFN) treatment. So, HBsAg loss is generally considered to be the ultimate goal of therapy, indicating a complete response to treatment and the resolution of the disease. It was suggested that inactive HBsAg carriers could get benefits from IFN treatment if HBsAg loss was achieved after treatment.

### Research frontiers

HBsAg loss is the goal and ideal end-point of treatment in chronic hepatitis B. The spontaneous rate of HBsAg loss in inactive carriers was only 0.5%-2.5% per year, and HBsAg clearance occurred in a mean period of  $86.6 \pm 29$  mo (range, 26-115) after the initial visit. Even in patients with an HBsAg level < 10 IU/mL, a mean period of  $5.8 \pm 4.2$  years is required to achieve HBsAg clearance.

### Innovations and breakthroughs

In contrast to chronic hepatitis B, in which a low rate of HBsAg loss is achieved after IFN treatment, inactive HBsAg carriers with HBsAg < 100 IU/mL could obtain a high rate of HBsAg loss after PEG-IFN treatment in a shorter period than that occurring spontaneously.

### Applications

Inactive HBsAg carriers will benefit from PEG-IFN treatment, if HBsAg loss can be achieved after a short period of PEG-IFN therapy.

### Terminology

Inactive HBsAg carriers are patients who were HBsAg-positive, with low hepatitis B virus (HBV) replication and no liver inflammation. HBsAg loss was defined as an HBsAg concentration < 0.05 IU/mL, and seroconversion defined as an HBsAg concentration < 0.05 IU/mL and an anti-HBs level  $\geq 10$  mIU/L. HBsAg loss often indicates recovery from HBV infection.

### Peer-review

The manuscript entitled "Hepatitis B surface antigen clearance in inactive hepatitis B surface antigen carriers treated with peginterferon alfa-2a" discusses a possible application of an IFN therapy in inactive HBsAg carriers with a very low HBsAg level. The authors report that in their study the HBsAg disappeared in 65% of treated patients. This result seems to be very good, taking into account that usually HBsAg clearance is rarely observed.

### Abstract

**AIM:** To review the outcomes of liver trauma in patients with hepatic injuries only and in patients with associated injuries outside the liver.

**METHODS:** Data of liver trauma patients presented to our center from January 2003 to October 2013 were reviewed. The patients were divided into two groups. Group 1 consisted of patients who had hepatic injuries only. Group 2 consisted of patients who also had associated injuries outside the liver.

**RESULTS:** Seven (30.4%) patients in group 1 and 10 (28.6%) patients in group 2 received non-operative management; the rest underwent operation. Blunt trauma occurred in 82.8% (48/58) of the patients and penetrative trauma in 17.2% (10/58). A higher injury severity score (ISS) was observed in group 2 (median 45 vs 25,  $P < 0.0001$ ). More patients in group 1 were hemodynamically stable (65.2% vs 37.1%,  $P = 0.036$ ). Other parameters were comparable between groups. Group 1 had better 30-d survival (91.3% vs 71.4%,  $P = 0.045$ ). On multivariate analysis using the logistic regression model, ISS was found to be associated with mortality ( $P = 0.004$ , hazard ratio = 1.035, 95%CI:

1.011-1.060).

**CONCLUSION:** Liver trauma patients with multiple injuries are relatively unstable on presentation. Despite a higher ISS in group 2, non-operative management was possible for selected patients. Associated injuries outside the liver usually account for morbidity and mortality.

**Key words:** Non-operative management; Liver trauma; Multiple injuries; Penetrative trauma; Liver laceration; Blunt trauma

© **The Author(s) 2016.** Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Liver trauma patients who have not only liver injury but also associated injury outside the liver usually have a high injury severity score (ISS) and a bigger chance of morbidity and death. Management of liver trauma features surgical and nonsurgical approaches. Choice of approach should depend on individual patients' overall clinical condition rather than just ISS or imaging findings. The applicability of nonsurgical approach has extended to penetrative injuries with success.

## INTRODUCTION

The liver is well known to be the most frequently injured internal organ in abdominal injury despite its relatively hidden location behind the subcostal region<sup>[1]</sup>. In liver trauma management, the widespread use of ultrasonography and computed tomography (CT) has facilitated decision-making, and non-operative management (NOM) has been shown to reduce mortality<sup>[2]</sup>. NOM is now the standard of care for blunt liver injury in hemodynamically stable patients<sup>[3-7]</sup>. A contrast CT scan of the abdomen can accurately identify the pathology, presence of complication and proper severity grade of injury in hemodynamically stable patients. For hemodynamically unstable patients, operative management (OM) may be necessary. Other considerations should also be taken into account as patients may suffer multiple injuries. Some injuries call for OM. In such cases, the liver injury can be dealt with in the laparotomy required by associated injuries. Treatment outcomes depend on the severity of injuries to organs. This study reviewed the management of liver trauma with or without associated injuries over 10 years at a level-1 trauma center in Hong Kong.

## MATERIALS AND METHODS

This is a retrospective study. The period for review is from January 2003 to October 2013. Patients at Department of Surgery, Queen Mary Hospital, the University of Hong Kong, who had liver trauma from blunt or penetrative injuries in the period were reviewed. Data of interest included demographic data, presentation, associated injury, mechanism of injury, grade of liver injury, injury severity score (ISS), and management outcome. The data were retrieved by a dedicated trauma nurse coordinator and then screened and reviewed by the authors.

The patients were divided into two groups. Group 1 consisted of patients who had hepatic injuries only. Group 2 was comprised of patients who also had associated injuries outside the liver. The presence of associated injuries was checked for either during the primary and the secondary surveys according to the Advanced Trauma Life Support principle and then by imaging (X-ray or CT scan) of various regions, or during operation. Patients (with or without initial fluid resuscitation) were regarded as hemodynamically stable if they had a patent airway, satisfactory oxygen saturation of > 95%, good volume pulse, heart rate of < 100 beats/min, and systolic blood pressure of > 90 mmHg.

The patients' grade of liver injury was determined according to the Organ Injury Scaling developed by the Organ Injury Scaling Committee of the American Association for the Surgery of Trauma<sup>[8]</sup>, with grade 1 being the least severe and Grade 6 being unsurvivable. For patients who received NOM, grade of liver injury was determined with a CT scan; for those who received OM, it was determined during operation.

The ISS is an anatomical scoring system that provides an overall score (0-75) for patients with multiple injuries. Calculation of each patient's ISS was based on signs shown upon physical examination, results of investigation, and findings in operation. Each injury in the six body regions (head, face, chest, abdomen, extremities and external) was assigned an Abbreviated Injury Score (AIS) according to the Abbreviated Injury Scale, and only the highest AIS in each body region were used. Each patient's three most severely injured body regions had their AIS squared and added together to produce an ISS for the patient. An AIS of 6 (unsurvivable injury) always entailed an ISS of 75 (fatality)<sup>[9]</sup>.

NOM was adopted for hemodynamically stable patients whose abdominal examination showed no peritoneal signs and whose imaging scans (X-ray, CT or ultrasonography) showed no intraperitoneal, retroperitoneal or extra-abdominal injuries requiring operative intervention. OM was indicated otherwise and when NOM failed.

All patients were closely monitored in the intensive care unit. Reassessment measures included physical examination, daily blood tests, and reassessment CT scan. Reassessment CT scan of the abdomen was performed 3 to 5 d after initial insult. CT scan for other

regions was performed if necessary.

### Statistical analysis

At the Department of Surgery, The University of Hong Kong, we have our own statistical staff. The biostatistics in this study was performed by our own statistical staff. The computer software SPSS, version 21.0, from IBM SPSS Statistics was used for statistical analyses. Continuous variables were compared by the Mann-Whitney *U* test and expressed as median with interquartile range. Student's *t*-test and Pearson's  $\chi^2$  test were employed. Thirty-day survival was measured. The Kaplan-Meier method was used for survival estimation

**Figure 1** Thirty-day survival in the two groups.

and the log-rank test was used for survival comparison. Multivariate analysis was performed to identify the risks for mortality. *P* values < 0.05 were considered statistically significant.

## RESULTS

Fifty-eight patients were included in the study, with 23 patients in group 1 and 35 patients in group 2. Seven (30.4%) patients in group 1 and 10 (28.6%) patients in group 2 received NOM. No change in management plan occurred. The median age was 32 years in patients receiving NOM and 39 years in patients receiving OM (*P* = 0.140). Comparison of group 1 and group 2 is shown in Table 1. The amounts of blood loss in patients who received OM were similar in the two groups (300 mL vs 1250 mL, *P* = 0.133); the amounts of blood transfused were also similar (2700 mL vs 2880 mL, *P* = 0.799). However, significantly more patients in Group 2 required transfusion (70.6% vs 39.1%, *P* = 0.018). In the 58 patients, 48 (82.8%) suffered blunt trauma and 10 (17.2%) suffered penetrative trauma. Both group 1 and group 2 had road traffic accident as the commonest cause of injury. ISS (*P* < 0.0001) and hemodynamic stability (*P* = 0.036) were significantly different between the two groups. Group 1 had significantly better 30-d survival (91.3% vs 71.4%, *P* = 0.045), as shown in Figure 1. Figure 2 shows 30-d survival stratified by grade of liver injury (*P* = 0.104). On multivariate analysis using the logistic regression model, ISS was found to be associated with mortality (*P* = 0.004, hazard ratio = 1.035, 95%CI: 1.011-1.060) (Table 2).

## DISCUSSION

The liver is the most commonly injured abdominal organ despite its well-protected position<sup>[1]</sup>. Management of liver injury depends on the patient's condition, diagnosis,

**Table 2 Multivariate analysis of risk factors for mortality**

Dependent factor

ISS: Injury severity score.

transfusion requirement and complications, as well as facilities for monitoring. NOM of liver injuries has gained wide support; it was adopted for approximately 60% of cases of liver injuries from low grades to high grades<sup>[8,10]</sup>. Its application has been extended to penetrative injuries<sup>[11]</sup>.

At our center, liver trauma patients (with blunt or penetrative injuries) are subjected to CT for diagnostic purpose if they are hemodynamically stable; otherwise they are resuscitated and stabilized in the Accident and Emergency department, with a brief examination by a Focused Assessment with Sonography for Trauma scan, and then sent to the operation theater. Severity of injuries and presence of associated injuries are checked with CT or during laparotomy.

CT scan of the abdomen is widely used to evaluate intra-abdominal injuries in patients with stable hemodynamics; it should not be used if a patient has unstable hemodynamics since the patient's condition may deteriorate rapidly during scanning. CT scan can present the precise grade of liver injury, thereby allowing formulation of a proper management plan. A high grade (Grade 3-5) represents relatively severe injury. Patients with a high grade of liver injury tend to be more unstable and require OM<sup>[12]</sup>. But NOM is becoming more applicable to these patients because of improvement in intensive clinical care and increased use of interventional radiology. If NOM is adopted, reassessment CT scan should be performed within 7 to 10 d after the initial CT scan to check if there are any delayed complications<sup>[5]</sup>.

Grade of liver injury can reflect the degree of hepatic parenchymal damage, but it is not indicative of complication development or need for OM<sup>[13]</sup>. Grade-6 injuries are by definition not salvageable. In our present study, morbidity and mortality tended to worsen with a higher grade of liver injury. However, the presence of associated injuries also mattered; patients in group 2 with a high ISS fared the worst. Our 30-d survival curves by grade of liver injury reflected worsening survival with rising grades in both groups. However, further subgroup analysis showed that grade of liver injury did not make difference in survival ( $P = 0.104$ ). In fact, if there are associated injuries outside the liver, grade of liver injury cannot reflect the overall severity of injuries.

Multiple injuries, which can be caused by more than one mechanism of injury, often lead to major trauma (or

Figure 2 Thirty-day survival by grade of liver injury (with 1 missing datum).

multi-trauma) and result in serious physical complications and physiological decompensation. Major trauma is defined as ISS > 15<sup>[14]</sup>. It is usually caused by a high impact of energy, and the commonest cause is road traffic accident<sup>[15]</sup>. The higher median ISS in group 2 was due to significant associated injuries outside the liver. And more patients in this group had transfusion need, a reflection of the severity of injury. It is not surprising that group 2 had a lower survival rate<sup>[16]</sup> as it has been reported that ISS could predict length of intensive care unit stay as well as mortality and survival<sup>[17]</sup>. Our multivariate analysis also found that patients with a higher ISS were more likely to have shorter survival.

Most of the patients who suffered blunt injuries in group 2 were unstable. At our center, the decision on management approach is based on individual patients' clinical condition rather than ISS. Although ISS is used as an index for quality assurance at most trauma centers, it is not an accurate indicator and it does not reflect multiple injuries in the same body region. Hence, a high ISS should not be an indicator for OM. OM is required if a patient's hemodynamics is unstable; it is also required in the presence of another operative indication (e.g., the need for thoracotomy, neurosurgery, orthopedic operation, repair of viscera, management of pelvic bleeding, etc). Decision on initial and subsequent management approaches should be based on clinical condition as well as mechanism and site of injury. Understanding the mechanism of the injury helps to identify potential life-threatening and limb-threatening conditions, which can maximize the chance of salvage and prevent functional deficit.

This study is not rid of the inherent limitations of a single-center retrospective study, and the patients were heterogeneous in terms of premorbid status, mechanism of injury and severity of injury. The use of ISS was to quantify severity of injuries for a more standardized representation.

In conclusion, liver trauma patients with multiple injuries are relatively unstable on presentation. Despite a significantly higher ISS in group 2, NOM was possible for selected patients. Associated injuries outside the liver usually account for morbidity and mortality.

## COMMENTS

### Background

In liver trauma management, the widespread use of ultrasonography and computed tomography (CT) has facilitated decision-making, and non-operative management (NOM) has been shown to reduce mortality. NOM is now the standard of care for blunt liver injury in hemodynamically stable patients.

### Research frontiers

This study reviewed the management of liver trauma with or without associated injuries over 10 years at a level-1 trauma center in Hong Kong.

### Innovations and breakthroughs

Liver trauma patients with multiple injuries are relatively unstable on presentation. Despite a significantly higher injury severity score in group 2, NOM was possible for selected patients. Associated injuries outside the liver usually account for morbidity and mortality.

### Peer-review

It is well written and documented and discussed paper, it has valuable points to stress the nonoperative management of liver trauma in addition to that on behalf of the scope of your journal this type of articles may increase the impact effect of it since the paper is discussed a huge number of cases even they collected them in 10 years but it is meaningful and it likes a review of liver trauma.

### Abstract

**AIM:** To estimate the progression of the hepatitis C virus (HCV) epidemic and measure the burden of HCV-related morbidity and mortality.

**METHODS:** Age- and gender-defined cohorts were used to follow the viremic population in Argentina and estimate HCV incidence, prevalence, hepatic complications, and mortality. The relative impact of two scenarios on HCV-related outcomes was assessed: (1) increased sustained virologic response (SVR); and (2) increased SVR and treatment.

**RESULTS:** Under scenario 1, SVR raised to 85%-95% in 2016. Compared to the base case scenario, there was a 0.3% reduction in prevalent cases and liver-related deaths by 2030. Given low treatment rates, cases of hepatocellular carcinoma and decompensated cirrhosis decreased < 1%, in contrast to the base case in 2030. Under scenario 2, the same increases in SVR were modeled, with gradual increases in the annual diagnosed and treated populations. This scenario decreased prevalent infections 45%, liver-related deaths 55%, liver cancer cases 60%, and decompensated cirrhosis 55%, as compared to the base case by 2030.

**CONCLUSION:** In Argentina, cases of end stage liver disease and liver-related deaths due to HCV are still growing, while its prevalence is decreasing. Increasing in SVR rates is not enough, and increasing in the number of patients diagnosed and candidates for treatment is needed to reduce the HCV disease burden. Based on this scenario, strategies to increase diagnosis and treatment uptake must be developed to reduce HCV burden in Argentina.

**Key words:** Diagnosis; Disease burden; Epidemiology; Incidence; Mortality; Prevalence; Treatment; Argentina; Hepatitis C

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** This is a study evaluating potential policies to diminish hepatitis C virus (HCV) disease burden. Increasing diagnoses and treated individuals with the high current sustained virologic response rates, will diminish HCV disease burden.

## INTRODUCTION

Chronic hepatitis C virus (HCV) liver disease is a global public health issue, with an estimated prevalence of 170 million infected people. Every year, 3000000 to 4000000 new HCV infections are diagnosed, and a mean global seroprevalence of nearly 3%<sup>[1]</sup>.

In many countries, while HCV prevalence is decreasing, its morbidity and mortality is increasing<sup>[2]</sup>. Population aging results in a rise in all-cause mortality. This leads to a reduction in the total of infected patients. Progression to advanced HCV related liver disease combined with populace aging, is associated with a rising in mortality due to advanced liver disease<sup>[2,3]</sup>.

In Argentina, the exact HCV prevalence is unknown. According to different studies it varies between 0.17%

to 5.6%; in some areas of high endemicity it may vary between 2.2% to 7.3%<sup>[4]</sup>. Nosocomial transmission appears to be the main route of infection, and genotype 1 is most prevalent in the infected population<sup>[5,6]</sup>. Precise data for incidence and prevalence estimates are lacking in Argentina. Also, there are no data about the burden of the disease and its impact on public health. Data on the percentage of HCV patients treated and their outcomes are also scarce. It has been estimated that only 0.15% of HCV patients have been treated in the last 15 years in Argentina<sup>[7]</sup>. These results are comparable to other countries in the region. Our aim was, using a modeling method, to describe HCV-related disease progression at the national level.

A model was also used to evaluate the influence of distinct actions aimed at diminishing the burden of HCV disease (*e.g.*, multiply the percentage of treated patients, improved cure rates and improved case identification). This model has been already validated and used in similar studies in different countries<sup>[8-11]</sup>.

## MATERIALS AND METHODS

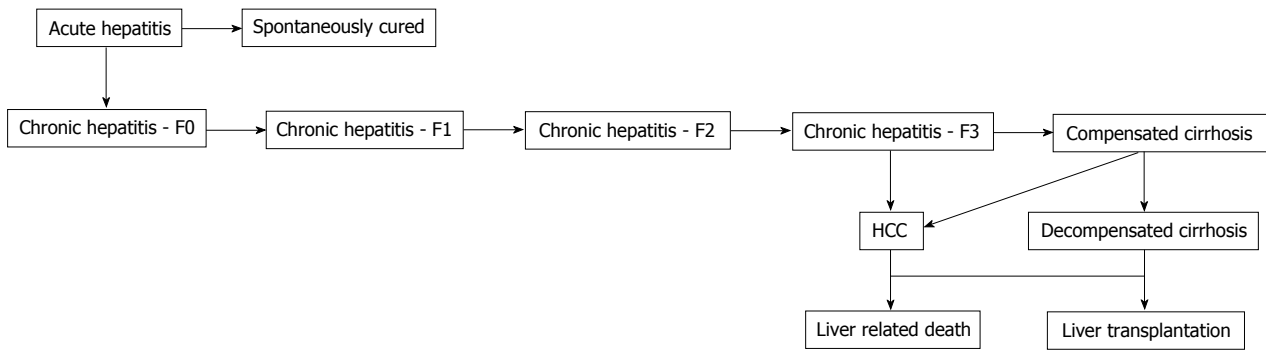

A systematic review of the literature was done to find studies addressing the proportion of HCV patients who had been diagnosed, received treatment and achieve sustained virologic response (SVR) in Argentina. The review included all studies published between January 1990 and July 2014.

PubMed and EMBASE databases were consulted looking for indexed articles. Non-indexed sources were identified by searching in the National Ministry of Health Website, proceedings of local medical meetings, unpublished data and data from large liver centers.

Also, an expert panel including epidemiologists, hepatologists, infectious disease specialists, public health professionals and virologists, gathered in a person to person meeting to analyze all the retrieved information.

Data from countries with similar healthcare practices and/or risk factors, or expert consensus were used there was no input data available. Some of these data were included in a previous global report<sup>[2,3]</sup>. To populate a disease progression model and to assess the magnitude of the HCV-infected populace according to liver fibrosis stages (METAVIR score F0-F4), country-specific inputs from 2013-2030 were loaded in Microsoft Excel® database (Microsoft Corp., Redmond, WA) (Figure 1). Crystal Ball, an Excel add-in by Oracle, was utilized for uncertainty and sensitivity analyses. For the uncertainty model, beta-PERT distributions were utilized associated with all inputs. To analyze the incertitudes that had the biggest repercussion on in 2030 HCV prevalence, a sensitivity analysis was utilized.

Populace information were arranged by sex, five-year age groups, and year (1950-2100) and obtained from the United Nations population database<sup>[12]</sup>. Based on expert inputs, in adults (persons aged ≥ 20 years) HCV viremia prevalence in Argentina in 2013, was estimated at 1.5%. The HCV viremic rate in Argentina is

**Figure 1** The flow of the hepatitis C virus disease progression model. HCC: Hepatocellular carcinoma.

80%, as previously reported<sup>[13]</sup>.

Using a 0.83% viremic prevalence, it was calculated that 342000 persons had HCV RNA detectable in 2013.

A hybrid distribution was constructed to calculate age and gender specific HCV diagnosis rates by five-year age group using notification inputs for HCV infection for persons aged 0 to 59 years<sup>[14]</sup>, and transplant inputs classified by age and gender for persons aged  $\geq 60$  years<sup>[15]</sup>. The notified and transplanted people were weighted to the national estimate for total prevalence and aged to the year 2013, accounting for mortality and cured patients.

To estimate HCV genotype distribution, data from over 200 treated patients was used<sup>[16]</sup>. Genotype 1 (G1) subtypes distribution was calculated using data from another study<sup>[5]</sup>. The genotype distribution applied in the model was G1/other = 63%, G2 = 25%, G3 = 11%, G4 = 1%.

As outlined in a previous work, annual patients progress through each disease state were include in the model using age and gender specific transition probabilities<sup>[2,3]</sup>.

Changes in historical HCV incidence were estimated according to expert opinion. Changes in historical HCV incidence were estimated according to expert opinion. After an estimated peak incidence in 1989, it has markedly decrease with the introduction of antiHCV screening in blood donors. In Argentina, it was estimated that 1850 new infections were diagnosed in 2013.

It was estimated that 350 and 200 patients receive treatment in 2014 and 2015, respectively, based on expert consensus and IMS data for pegylated-interferon (IFN) units sold in Argentina<sup>[17]</sup>. A multiplier was used to account for under-reporting in IMS data. The Argentinean genotype distribution was used to estimate the average number of weeks of treatment per patient with 85% compliance/persistence.

In 2013, 74 of 329 (22.4%) patients receiving a liver transplant were related to HCV end stage liver disease. Data from the national organ registry for the years 1999 to 2013 showed that the percentage of liver transplant in HCV patients was 22.0% before adoption of model for end stage liver disease (MELD) based allocation and 22.4% after MELD implementation<sup>[15,16]</sup>.

Database from the Pan American Health Organization

allow us to estimate the diagnosed population based upon data for HCV positive blood donors<sup>[7]</sup>. The annual number of confirmed cases was balanced to account for diagnosis in other settings. It was assumed that 118800 persons were previously diagnosed and 6560 new cases were confirmed in 2010. The Berkeley Human Mortality database was used to estimate mortality rate by year, age group and gender<sup>[18]</sup> (Table 1).

Using estimates of 65000 active injection drug users (IDU) and a 54.6% HCV prevalence in Argentina, it was calculated that in 2001, 9.3% of the HCV population were IDU<sup>[19,20]</sup>.

Using a standard mortality ratio (SMR) of 10.0 for persons between 15 and 44 years old, a raised mortality was estimated among active IDU<sup>[21-26]</sup>.

It was estimated that 20.8% of the HCV patients were related blood transfusions in 2005, according to data from a national study<sup>[6]</sup>. In this subgroup of patients, a SMR of 1.5 was applied for all age groups<sup>[27]</sup>.

## Scenarios

**Base scenario:** Patients aged 15-69 years were considered for treatment and 60% of potential patients in Argentina were considered candidates for antiHCV therapy. It was considered that median SVR rates were 60% (G1), 75% (G2/4), and 65% (G3). Treated populations of 350 patients in 2014 and 200 patients annually during 2015-2030 were modeled, was and were restricted to patients with fibrosis stages  $\geq F3$  (G1) and  $\geq F2$  (G2/3/4).

It was considered that until 2016 patients with severe liver disease such as decompensated cirrhosis or eligible for transplantation, or those with hepatocellular carcinoma (HCC), were not candidates for treatment.

**Scenario 1:** Increased efficacy: It was assumed that by 2016, treatment eligibility raised to 95% for all genotypes and SVR rates steadily raised to 90% (G1/4), 95% (G2), and 85% (G3). The number of patients treated and newly diagnosed every year remained constant, while treatment was extended to fibrosis stages  $\geq F2$  in all genotypes (Figure 2).

**Scenario 2:** Increased efficacy and treatment: SVR, treatment eligibility, and fibrosis restriction increases

**Table 1 Model inputs and 2013 estimates**

	Historical	Year	2013 (Est.)
HCV infected cases	427890 (132720-829480)	2013	428260
AntiHCV prevalence	1.0% (0.3%-2.0%)		1.0%
Total viremic cases	342310 (106170-663580)	2013	342310
Viremic prevalence	0.8% (0.3%-1.6%)		0.8%
Viremic rate	80.0%		80.0%
HCV diagnosed (viremic)	112270	2010	117250
Viremic diagnosis rate	32.8%		34.2%
Annual newly diagnosed	4920	2010	4920
New infections			1950
New infection rate (per 100K)			4.7
Treated			
Number treated			650
Annual treatment rate			0.2%
Risk factors			
Number of active IDU with HCV			31950
Percent active IDU			9.3%
Previous blood transfusion			48420
Percent previous blood transfusion			14.1%

were the same as in scenario 1. The number of patients newly diagnosed every year progressively escalated to 14770 in 2016, while the number of patients treated every year progressively escalated to 12000 by 2020 (Figure 3).

## RESULTS

### **Prevalence of chronic hepatitis C and complications**

According to the model, the HCV prevalence in Argentina peaked in 2002 at 376000 viremic individuals. In 2013, there were an estimated 342000 (95%CI: 146000-517000) infected individuals, a 10% decline from 2002. In the base scenario, viremic cases are estimated at 241000 in 2030, a decline of 30% from 2014 (Figure 4). The incidence of HCV in Argentina peaked in 1989 with an estimated 21340 new infections, and declined by 90% in 2013 with an estimated 1850 cases new infections.

There were 42910 compensated cirrhotic patients in 2013 and it was calculated that there will be 69600 by 2030. Also by 2030 there will be 2500 new cases of HCC 7830 patients will develop decompensated

cirrhosis. By 2030, 2890 patients will die from HCV related liver disease in contrast to 1520 patients who died in 2013. The proportion of viremic patients who have compensated cirrhosis or decompensated cirrhosis or HCC will increase to 34% in 2030, as compared with 14% in 2013 (Figures 5 and 6).

New HCV treatment strategies imply an increase in SVR rates. Based on recent results SVR rates will increase to at least 90% (G1/4), 95% (G2), and 85% (G3) by 2016. In the same period, treatment eligibility will increase to 95% for all genotypes. According to the model, increasing treatment efficacy but keeping the same low number of treated patients (scenario 1) will result in 660 fewer viremic patients in 2030, a 0.3% reduction as compared to the base case.

Compared with the base case, by 2030 it was estimated a 0.3% decrease in the number of HCC cases (2490 cases), a 0.3% decrease in liver related deaths (2880 cases), a 0.2% decrease in decompensated and 0.3% in compensated cirrhosis new cases (7800 and 69380 cases, respectively) (Figure 7).

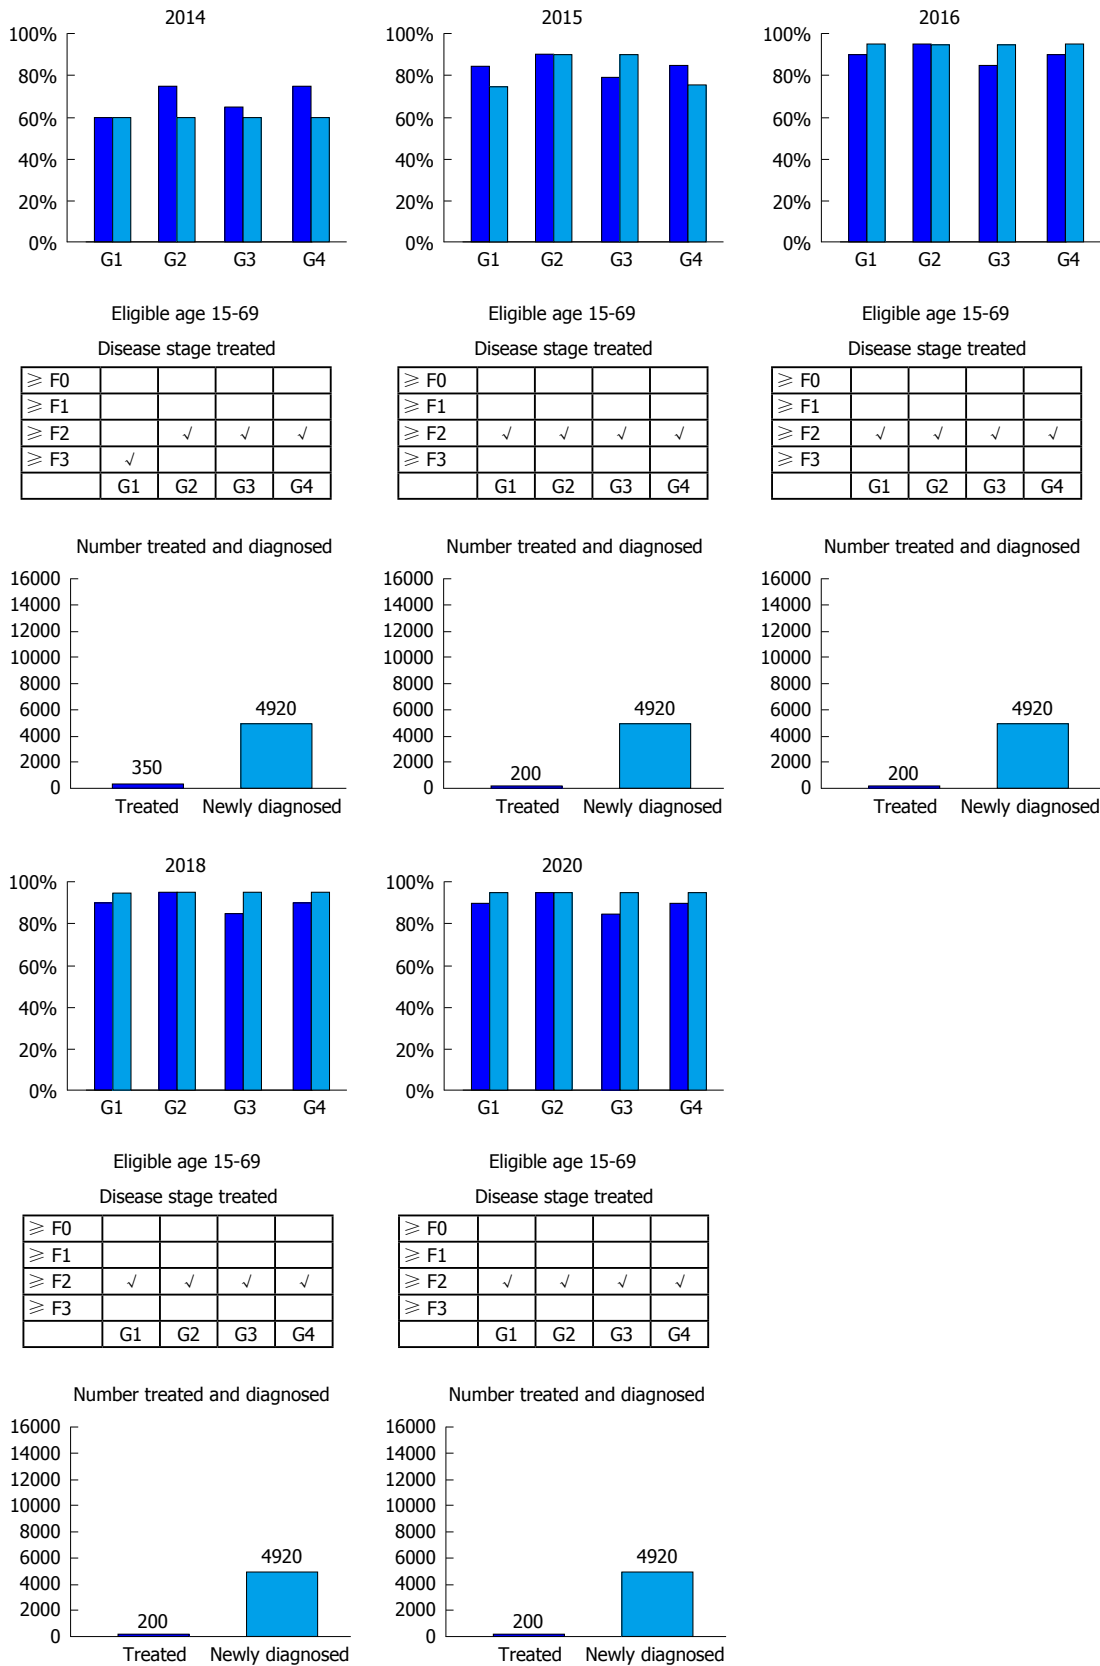

Increased treatment efficacy alone seems to have little impact in decreasing HCV burden, so another scenario was developed with the same SVR rates but increasing numbers of patients diagnosed and treated (scenario 2).

If the number of diagnosed and treated patients is markedly increased, a 45% reduction in the number of viremic patients can be obtained by 2030, meaning 107000 fewer infected patients. A 60% reduction in HCC cases is expected, with 1000 new HCC cases diagnosed by 2030. It is expected that the number of liver related deaths will also decrease with 1260 by 2030, meaning a 55% reduction when compared to the base case. New cirrhosis cases will decrease by 55% in decompensated and by 60% in compensated cases by 2030 (3390 and 29210, respectively) (Figure 7).

## DISCUSSION

Increasing access to HCV diagnosis and treatment are pending actions in Argentina and in Latin-America. It is estimated that less than 20%-30% of patients are diagnosed and only 1%-2% of those diagnosed have been treated<sup>[7]</sup>. Approval of new HCV treatments in the region is delayed compared with Europe or the United States. In the last months of 2015, three novel regimens were approved in Argentina. Upcoming IFN and ribavirin free regimens are safe and effective, offering SVR rates over 90%-95% for most genotypes. To impact the burden of disease, patients must be diagnosed and treatment availability must increase.

Our study shows important results for our country. The greatest burden of HCV-related advanced liver disease will come in the next 5 to 15 years. HCV burden will increase if no action is taken. Our model showed that the only way to significantly reduce HCV burden is to increase diagnosed and treated patients 10 times the current number of treated persons. Similar results have been reported in many countries around the world, including some in Latin-America, including Brazil and Mexico<sup>[2,3]</sup>.

The main challenge in the region is to develop strategies to increase diagnosis. Strategies must be country specific since epidemiology and risk factors for HCV infection vary between countries. For example, the United States Centers for Disease Control and Prevention has recommended a birth-year based screening strategy: Persons born during 1945-1965 in the United States have an increased rate of HCV infection and focused screening of this cohort is an efficient use of resources<sup>[28]</sup>. But this strategy might not be effective in Argentina, since in 2013 the majority of HCV patients are estimated to be 40 to 75 years old (Figure 2), meaning that they were born between 1938 and 1973. The same was shown in Brazil where most patients were born between 1950 and 1980<sup>[29]</sup>. Country specific screening campaigns must be developed to achieve this goal.

Another pending issue is adequate access to care and treatment. This means that all people involved in HCV management must make an effort to achieve this goal. Patients need greater access to new therapies, but the main restriction is treatment cost. In resource constrained countries, treating all patients with current drug costs is unaffordable. There must be strategies to reduce HCV treatment costs and at the beginning, prioritization of treatment may be necessary. For example, the sickest patients will be treated first with the safest and more effective drugs. Then earlier stage patients will be treated later to reduce the impact of the disease.

This is the first study evaluating HCV burden in Argentina. These results might help public health authorities take action to reduce its impact. But it has to be mentioned that our results have some limitations.

First, each input may have its limitations, but to our knowledge the best data from published and unpu-

blished studies available in Argentina were applied in our model. Second, some patients may have progressive liver disease despite achieving SVR; progression of cured patients was not evaluated in this model<sup>[30]</sup>. And finally, we did not include extrahepatic manifestations of HCV infection in the model, which may have contributed to all-cause mortality and may lead to underestimation in mortality among viremic patients<sup>[9]</sup>.

In conclusion, the present analysis, with the available data, showed that HCV prevalence is decreasing in Argentina, but advanced liver disease prevalence is expected to raise as HCV infected patients get older. There is an urgent need to enhance diagnosis and treatment rates to reduce the future disease burden and its impact on Argentina's public health.

## COMMENTS

### Background

Chronic hepatitis C virus (HCV) infection is one of the main causes of end stage liver disease, liver transplantation, hepatocellular carcinoma (HCC) and liver-related mortality in Argentina. Burden of HCV disease is unknown, and strategies to reduce it are not yet developed.

### Research frontiers

An epidemiological model has been developed to estimate HCV disease burden and to evaluate different diagnostic and therapeutic strategies that may impact in HCV natural history.

### Innovations and breakthroughs

This model allows them for the first time to evaluate HCV burden in Argentina. This estimated data can help health authorities to develop a national plan to manage HCV disease. Also, it permits the authors to estimate the number of persons needing treatment to reduce HCV burden in the next 15 years.

### Applications

This study shows that HCV treatment impacts in its disease burden and that a major work has to be done in improving its diagnosis and access to treatment.

### Terminology

HCV disease burden implies the development of liver related disease: Cirrhosis, HCC, liver failure, liver transplantation and death.

### Peer-review

In this study the authors have used a modeling approach to describe HCV-related disease progression in Argentina. The methods are well designed and are exposed very clearly for the reader. In general, it is a good manuscript.

### Abstract

Non-alcoholic fatty liver disease (NAFLD) is a recognized problem in patients after orthotopic liver transplantation and may lead to recurrent graft injury. As the increased demand for liver allografts fail to match the available supply of donor organs, split liver transplantation (SLT) has emerged as an important technique to increase the supply of liver grafts. SLT allows two transplants to occur from one donor organ, and provides a unique model for observing the pathogenesis of NAFLD with respect to the role of recipient environmental and genetic factors. Here we report on two recipients of a SLT from the same deceased donor where only one developed non-alcoholic steatohepatitis (NASH), suggesting that host factors are critical for the development of NASH.

**Key words:** Liver; Split graft; Steatohepatitis; Host factors; Transplant

© The Author(s) 2016. Published by Baishideng Publishing Group Inc. All rights reserved.

**Core tip:** Split liver transplantation provides a unique model of the pathogenesis of non-alcoholic fatty liver disease with respect to the role of recipient environmental risk factors and genetic background because the same donor graft is shared by two distinct recipients. Here we present two recipients of a split liver transplantation from same deceased donor, with one developing nonalcoholic steatohepatitis and the other without any evidence of hepatic steatosis three years after they were transplanted. These cases provide a unique natural experiment to explore host factors that contributed to the development of nonalcoholic steatohepatitis after liver transplantation.

Host factors are dominant in the development of post-liver transplant non-alcoholic steatohepatitis. *World J Hepatol* 2016; 8(15): 659-664 Available from: URL: <http://www.wjgnet.com/1948-5182/full/v8/i15/659.htm> DOI: <http://dx.doi.org/10.4254/wjgh.v8.i15.659>

## INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) affects around one third of the western population with an incidence that continues to grow in other parts of the world<sup>[1]</sup>. Histopathological findings of NAFLD in the liver range from simple steatosis to non-alcoholic steatohepatitis (NASH), and can eventually progress to cirrhosis and liver cancer<sup>[2]</sup>. NAFLD is recognized as a potential complication following LT and studies are being conducted to determine the prevalence and risk factors for development of NAFLD in LT recipients<sup>[3,4]</sup>.

Split liver transplantation (SLT) has emerged as an important strategy to increase the supply of liver grafts by allowing two transplants to occur from one donor organ, and provide a unique opportunity to observe the role of host factors in the development of NAFLD. The technique of SLT is continuously evolving with reduced ischemia times and reduced vascular and biliary complications, and when performed *in situ*, SLT has yielded excellent outcomes<sup>[5]</sup>. However, SLT still involves significant complexity and short and long term complications of the split grafts need to be continually analyzed. Here we present data on the clinical course and outcomes of two recipients of a SLT from the same deceased donor where only one developed NASH, suggesting that extrahepatic host factors are critical for the development of NASH.

## CASE REPORT

### Case 1

A female infant with a diagnosis of Crigler Najjar syn-

drome underwent a SLT at age 15 mo old, receiving a left lateral liver segment from a deceased donor who was exitus because of head trauma at age 16 years without any history of obesity, diabetes, hyperlipidemia or hypertension. The explanted liver did not reveal any significant histopathological abnormality and the donor pre-reperfusion biopsy was also negative for any significant pathologic findings, including inflammation, fibrosis, necrosis and steatosis (Figure 1). During the first year following transplantation, several episodes of liver test elevations were noted. Histology of the liver biopsy performed 19 mo post-SLT was not consistent with acute cellular rejection but showed minimal lobular inflammation, mild periportal edema and mild fibrosis (stage 1-2/4) without significant ductular reaction. No steatosis was present. A second biopsy performed 25 mo post-transplant due to continued liver test abnormalities revealed no histologic evidence of steatosis or progression of fibrosis (Figure 2). At this time the liver biopsy showed minimal portal fibrosis and no evidence of rejection, duct injury or duct loss. Subsequently magnetic resonance cholangiopancreatography was performed and an anatomic biliary stricture and dilated intrahepatic biliary ducts were identified. The patient underwent biliary reconstruction and a Roux-en-Y hepatojejunostomy and biliary stenting with internal-external drain placement at age 4 years. Three years following transplantation and two months after the biliary repair, liver tests improved [alanine aminotransferase (ALT): 29 U/L, aspartate aminotransferase (AST): 39 U/L, T/D Bil: 0.34/0.10 mg/dL, international normalized ratio (INR): 0.93]. Growth was in the normal range with a body mass index (BMI): 17.58 kg/m<sup>2</sup>. She was maintained on tacrolimus, mycophenolate mofetil and ursodeoxycholic acid treatment with routine biliary drain checks and close follow-up.

### Case 2

A 69-year-old male patient with a history of heterozygosity for genetic hemochromatosis (single copy of C282Y for the *HFE* gene) and alcoholic cirrhosis complicated by development of hepatocellular carcinoma (HCC) within Milan criteria (a 2.6 cm in segment III, and 1.5 and 1.1 cm lesions in segment VI). He was treated with chemoembolization and 8 mo later underwent an extended right lobe LT (segments I-IV-VIII) from the same deceased donor. The explanted liver revealed cirrhosis with residual viable nodules of moderately differentiated hepatocellular carcinoma without any vascular invasion, mild steatosis with steatohepatitis and increased hepatocellular siderosis. His past medical history was remarkable for hypertension, hyperlipidemia and diabetes mellitus. Initial immunosuppression was with steroid and tacrolimus, and he was changed to sirolimus and a lower dosage of tacrolimus at eight weeks post-transplant to try to reduce the risk of recurrent HCC. Although his postoperative course was uncomplicated but he remained on insulin for glycemic control. Twenty-four months after SLT, he had HCC

**Figure 1** Biopsy of the donor liver showing a lack of obvious pathologic changes. Specifically there is no steatosis, fibrosis or inflammation (H and E stain). A: Low magnification ( $\times 100$ ); B: Higher magnification ( $\times 200$ ) of the biopsy.

**Figure 2** Biopsy of liver graft from case 1 performed 25 mo later showing a lack of significant pathologic changes. Specifically, no steatosis is noted (H and E stain). A: Low magnification ( $\times 100$ ); B: Higher magnification ( $\times 200$ ) of the biopsy.

**Figure 3** Biopsy of the liver graft from case 2 about 3 years post split liver transplantation showing marked macrovesicular steatosis (H and E stain). A: Low magnification ( $\times 100$ ); B: Higher magnification showing rare Mallory-Denk bodies (arrow), ballooned hepatocytes and mild lobular inflammation ( $\times 200$ ). Trichrome stain revealed mild sinusoidal fibrosis (not shown here).

recurrence with a solitary 1.5 cm nodule in segment VIII found on surveillance imaging. The tumor was treated by selective chemoembolization and he is without recurrence on follow up magnetic resonance images; the most recent being 34 mo post-transplant. Three years after transplantation, his liver function tests were found to be elevated on routine testing, and increased cholesterol and triglyceride levels were noted (ALT: 154 U/L, AST: 125 U/L, T/D Bil: 0.85/0.20 mg/dL, INR:

1.1, total cholesterol: 218 mg/dL, HDL cholesterol: 34 mg/dL, triglyceride: 501 mg/dL). At the same time, his weight had increased by 12% (had BMI increased from 30.5 kg/m<sup>2</sup> to 34 kg/m<sup>2</sup>). He denied drinking alcohol. A liver biopsy was performed and showed no evidence of acute or chronic cellular rejection but was notable for marked macrovesicular steatosis involving about 70% of liver parenchyma, steatohepatitis and perisinusoidal fibrosis (grade 1 of 3, stage 1 of 4, Brunt system) (Figure

3).

## DISCUSSION

LT is the accepted treatment of end-stage liver disease. The establishment of standard transplantation techniques, development of better immunosuppressive medications and accumulated experience in their safe use, improvement of intensive care and anesthesia all have played a major role in improving current 1-year survival after LT to 90%. Long-term outcomes, however, are still compromised by recurrent liver disease, increased risk of cancer, adverse effects of immunosuppressive drugs and possible metabolic complications<sup>[6,7]</sup>. One of the possible metabolic complications is the development of NASH/NAFLD.

SLT has developed as an alternative to increase the donor pool of organ for LT. The concept of splitting a liver allograft between two recipients was reported almost simultaneously by Pichlmayr *et al.*<sup>[8]</sup> and Bismuth *et al.*<sup>[9]</sup>. Recipients of SLT in the mid 1990s<sup>[10,11]</sup> were primarily one child who received the left-lateral segments and one adult who received the extended right lobe. SLT provides a unique model of the pathogenesis of NAFLD with respect to the role of recipient environmental risk factors and genetic background because the same donor graft is shared by two distinct recipients. Here we present two recipients of a SLT from same deceased donor, with one developing NASH and the other without any evidence of hepatic steatosis three years after they were transplanted. These cases provide a unique natural experiment to explore host factors that contributed to the development of NASH after LT.

LT recipients have several risk factors that put them at risk for NAFLD. Age and rapid weight gain causing obesity and long-term exposure to immunosuppressive medications can in part be responsible for NAFLD. Hyperlipidemia occurs frequently following solid-organ transplantation. Between 16% and 43% of adult LT recipients can have increased plasma cholesterol levels<sup>[7,12,13]</sup>. Furthermore corticosteroids and calcineurin inhibitors promote hypertension and hypercholesterolemia, prednisone, tacrolimus, and cyclosporine A are diabetogenic, and sirolimus induces hyperlipidemia. Although both of our recipients were placed on tacrolimus, the older patient was also treated with sirolimus. In our adult recipient, use of tacrolimus and the aberrant gain in weight likely increased his already present insulin resistance and contributed to further deterioration of glucose regulation, causing an increase in hepatic fatty infiltration and inflammation that ended with steatohepatitis.

In the first few months after liver LT, weight gain may be regarded as one of the positive effects of transplantation, especially in patients with advanced liver disease and pre-transplant cachexia. However, within two years of transplantation, an excess body weight is recorded in up to 60% to 70% of patients and 20% of previously non-obese transplant recipients become

obese<sup>[14,15]</sup>. The recipient with steatohepatitis showed an increase in BMI from 30.5 kg/m<sup>2</sup> at time of transplant to 34 kg/m<sup>2</sup>, corresponding to a 12% increase in weight over 3 years time. NAFLD is strongly linked to obesity, (BMI > 30 kg/m<sup>2</sup>) with a reported prevalence as high as 80% in obese patients and only 16% in individuals with a normal BMI<sup>[16]</sup>. Although the exact mechanisms leading to excessive weight gain in post-LT patients are uncertain, a major role is attributed to the development of post-LT insulin resistance, diabetes mellitus, arterial hypertension, hyperlipidemia and the metabolic effects of immunosuppressive medications (corticosteroids, mTOR inhibitors and calcineurin inhibitors).

There are other factors in our steatohepatic recipient that may have increased hepatic fatty infiltration. The patient had a history of alcoholic cirrhosis, and some patients transplanted for alcoholic disease have a significantly higher risk of post-LT NAFLD even in the absence of recurrent alcoholic intoxication. Kim *et al.*<sup>[4]</sup>, reported that even though in 156 patients who had stopped drinking or had a limited amount of alcohol after LT, pre-LT alcoholic liver cirrhosis was a significant factor for their development of post-LT NAFLD. Similarly Dumortier *et al.*<sup>[17]</sup> suggested that many patients with post-LT NAFLD have an unrecognized combination of alcoholic and non-alcoholic steatohepatitis that put them at risk of secondary liver failure because of persistent metabolic abnormalities. Recently Hejlova *et al.*<sup>[18]</sup> examined 2360 post-transplant biopsies of 548 LT recipients to identify risk factors for the development of significant steatosis and found alcohol induced cirrhosis as a pre-transplant factor that is associated with significant post-transplant steatosis. It is likely patients with this combination of alcoholic and non-alcoholic steatohepatitis pre-transplant have an increased risk of persistence of metabolic abnormalities post-LT due to newly *de-novo* or aggravated insulin resistance.

Though the adult recipient had a pre-transplant diagnosis of iron overload disorder, genetic hemochromatosis is cured by liver transplantation<sup>[19]</sup>. There are instances where recipients received organs from patients with hemochromatosis and iron accumulation has occurred<sup>[20]</sup>. In the adult recipient, we did not find iron accumulation in his liver biopsy, suggesting iron did not play any additional role in the genesis of his steatohepatitis. Of the factors mentioned above; age, genetic background and even pretransplant history of alcoholic cirrhosis may be considered as unchangeable host factors where as post-transplant life style changes, diet, glycemic control by anti-diabetic medications, control of weight gain, hyperlipidemia therapy and immunosuppressive medications are changeable host factors that can affect the presence and progression of post-LT NASH.

In conclusion, this SLT provided a unique opportunity to observe the pathogenesis of NAFLD in the post-transplant setting. Although we can not exclude an interaction of donor and host factors, our data suggest host factors may be dominant for the development of

post-LT NASH.

Because we can not change the genetic background of the donor organ, careful attention to potentially alterable host factors or treatments like diet, life style changes, hyperlipidemia therapy and immunosuppressive medications can result in improved long term outcomes for recipients.

## COMMENTS

### Case characteristics

A female infant with a diagnosis of Crigler Najjar syndrome and a 69-year-old male patient with cirrhosis complicated by development of hepatocellular carcinoma (HCC) underwent split liver transplantation (SLT).

### Clinical diagnosis

Infant had jaundice and the elderly patient had signs of cirrhosis such as jaundice, ascites and spider angioma.

### Differential diagnosis

Inherited disorders of bilirubin metabolism for the first patient and primary and metastatic malignities of the liver for the second patient.

### Laboratory diagnosis

The first patient had elevated bilirubin levels (total bilirubin: 21 mg/dL, direct bilirubin: 0.25 mg/dL) and the second patient had an alpha fetoprotein of 109 ng/mL.

### Imaging diagnosis

The adult patient had a 2.6 cm HCC lesion in segment III, and 1.5 and 1.1 cm HCC lesions in segment VI on magnetic resonance scan.

### Pathological diagnosis

While the explanted liver did not reveal any significant histopathological abnormality in the first patient and revealed cirrhosis with residual viable nodules of HCC in the second patient; post-transplant liver biopsies showed minimal portal fibrosis and no histologic evidence of steatosis in the first patient and showed macrovesicular steatosis, steatohepatitis and perisinusoidal fibrosis in the second patient.

### Treatment

First patient underwent biliary reconstruction, a Roux-en-Y hepatojejunostomy and biliary stenting with internal-external drain placement and was maintained on tacrolimus, mycophenolate mofetil and ursodeoxycholic acid treatment and the second patient had an initial immunosuppression with steroid and tacrolimus, and then was changed to sirolimus and a lower dosage of tacrolimus at eight weeks post-transplant and had selective chemoembolization for recurrent HCC.

### Related reports

Even though emerging literature puts non-alcoholic fatty liver disease (NAFLD) forward as a potential complication following liver transplantation, SLT presented in this report provided a unique model of the pathogenesis of NAFLD with respect to the role of recipient environmental risk factors and genetic background because the same donor graft was shared by two distinct recipients.

### Term explanation

Crigler-Najjar syndrome is a rare hereditary disorder of bilirubin metabolism characterized by unconjugated hyperbilirubinemia due to deficiency of the enzymatic activity of glucuronosyltransferase.

### Experiences and lessons

This SLT provided a unique opportunity to observe the pathogenesis of

NAFLD in the post-transplant setting. The data suggest host factors may be dominant for the development of post-LT non-alcoholic steatohepatitis (NASH). The authors recommend paying careful attention to potentially alterable host factors or treatments like diet, life style changes, hyperlipidemia therapy and immunosuppressive medications to improve the long term outcomes for recipients.

### Peer-review

This is an interesting case report about post transplant NASH comparing two different scenarios (two different hosts) for a unique donor from a split liver transplant.

**MINIREVIEWS**

- 665 Mechanisms of adaptation of the hepatic vasculature to the deteriorating conditions of blood circulation in liver cirrhosis

*Garbuzenko DV, Arefyev NO, Belov DV*

**ORIGINAL ARTICLE****Basic Study**

- 673 Obese diet-induced mouse models of nonalcoholic steatohepatitis-tracking disease by liver biopsy

*Kristiansen MNB, Veidal SS, Rigbolt KTG, Tølbøl KS, Roth JD, Jelsing J, Vrang N, Feigh M*

**Retrospective Study**

- 685 Hepatocellular carcinoma after locoregional therapy: Magnetic resonance imaging findings in falsely negative exams

*Becker-Weidman D, Civan JM, Deshmukh SP, Roth CG, Herrine SK, Parker L, Mitchell DG*

**SYSTEMATIC REVIEWS**

- 691 Redefining Budd-Chiari syndrome: A systematic review

*Shin N, Kim YH, Xu H, Shi HB, Zhang QQ, Colon Pons JP, Kim D, Xu Y, Wu FY, Han S, Lee BB, Li LS*

**ABOUT COVER**

Editorial Board Member of *World Journal of Hepatology*, Bum-Joon Kim, PhD, Professor, Department of Microbiology and Immunology, and Liver Research Institute, Seoul National University, College of Medicine, Seoul 151-742, South Korea

**AIM AND SCOPE**

*World Journal of Hepatology* (*World J Hepatol*, *WJH*, online ISSN 1948-5182, DOI: 10.4254), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

*WJH* covers topics concerning liver biology/pathology, cirrhosis and its complications, liver fibrosis, liver failure, portal hypertension, hepatitis B and C and inflammatory disorders, steatohepatitis and metabolic liver disease, hepatocellular carcinoma, biliary tract disease, autoimmune disease, cholestatic and biliary disease, transplantation, genetics, epidemiology, microbiology, molecular and cell biology, nutrition, geriatric and pediatric hepatology, diagnosis and screening, endoscopy, imaging, and advanced technology. Priority publication will be given to articles concerning diagnosis and treatment of hepatology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJH*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

**INDEXING/  
ABSTRACTING**

*World Journal of Hepatology* is now indexed in PubMed, PubMed Central, and Scopus.

**FLYLEAF**

I-IV Editorial Board

**EDITORS FOR  
THIS ISSUE**

Responsible Assistant Editor: *Xiang Li*  
Responsible Electronic Editor: *Su-Qing Liu*  
Proofing Editor-in-Chief: *Lian-Sheng Ma*

Responsible Science Editor: *Fang-Fang Ji*  
Proofing Editorial Office Director: *Xiu-Xia Song*

NAME OF JOURNAL  
*World Journal of Hepatology*

ISSN  
ISSN 1948-5182 (online)

LAUNCH DATE  
October 31, 2009

FREQUENCY  
36 Issues/Year (8<sup>th</sup>, 18<sup>th</sup>, and 28<sup>th</sup> of each month)

EDITORS-IN-CHIEF  
**Clara Balsano, PhD, Professor**, Departement of Biomedicine, Institute of Molecular Biology and Pathology, Rome 00161, Italy

**Wan-Long Chuang, MD, PhD, Doctor, Professor**, Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung 807, Taiwan
